This chapter develops the finite-dimensional geometry which the path integral is expected to produce after localization. The identification of a Gromov–Witten integral with a continuum QFT is made at the level where the regulator, integration cycle, compactification, anomaly line, and gluing maps have been specified. Those data are part of the QFT problem surrounding the enumerative formula.

Hypothesis 107.1 (A-model cohomological sigma-model structure)**.** A closed A-model cohomological structure is a tuple

$$\mathfrak{A}_X = \big(\Sigma, j_\Sigma; X, \omega, J, g_X; [B + \mathrm{i}\omega]; \mathcal{F}_{\Sigma,X}, Q_A, \bar{\partial}_J, \mathfrak{V}_X, \Lambda_{\mathrm{Nov}}, \mathfrak{c}_A\big)$$

with the following entries.

(i) (Σ, j_Σ) is a compact marked Riemann surface, and (X, ω, J, g_X) is compact almost Kähler.

(ii) $\mathcal{F}_{\Sigma,X}$ is the locally super-ringed mapping field space whose bosonic body is $C^\infty(\Sigma, X)$ and whose odd directions are the twisted fermionic section spaces.

(iii) Q_A is an odd cohomological vector field whose scalar local observable complex is identified with $(\Omega^\bullet(X), d)$, and $\bar\partial_J \phi = 0$ is the localization equation for the bosonic zero modes.

(iv) The action splits into a Q_A-exact nonnegative term plus the complexified Kähler weight $Q^\beta = \exp(2\pi\mathrm{i} \int_\beta (B + \mathrm{i}\omega))$ on each curve class $\beta \in H_2(X; \mathbb{Z})$.

(v) $\mathfrak{V}_X$ is a virtual integration package for the stable-map compactifications $\overline{\mathcal{M}}_{g,n}(X, \beta)$, including evaluation maps, forgetful maps, deformation identifications, and gluing compatibility.

(vi) Λ_{Nov} is the Novikov completion in which the instanton sum is interpreted, and $\mathfrak{c}_A$ is the source, collision, and contact-term prescription used to define products of local insertions.

This is a hypothesis about the cohomological QFT layer. The finite-dimensional Gromov–Witten package $\mathfrak{V}_X$ is an output expected from localization once this structure is constructed. The continuum QFT construction itself is the separate problem recorded in Open Problem 107.11.

Hypothesis 107.2 (Closed B-model cohomological sigma-model structure)**.** A closed B-model cohomological structure is a tuple

$$\mathfrak{B}_X = \big(\Sigma, j_\Sigma; X, J_X, \Omega_X; \mathcal{F}_{\Sigma,X}, Q_B, \mathrm{PV}^{\bullet,\bullet}(X), \mathrm{Tr}_{\Omega_X}, \mathfrak{c}_B\big)$$

where X is a compact complex m-fold with trivial canonical bundle, Ω_X is a nowhere-vanishing holomorphic volume form, $\mathrm{PV}^{p,q}(X) = \Omega^{0,q}(X, \wedge^p T^{1,0}X)$, $Q_B = \bar\partial$ on scalar local observables, and

$$\mathrm{Tr}_{\Omega_X}(\mu) = \int_X \Omega_X \wedge \iota_\mu \Omega_X$$

is the trace pairing when the total polyvector and Dolbeault degrees make the integrand top degree. The structure also includes the anomaly-free axial twist, the regulated Q_B-invariant integration cycle, and the contact-term prescription $\mathfrak{c}_B$. Its first-order deformation complex is the Dolbeault polyvector differential graded Lie algebra

$$\big(\mathrm{PV}^{1,\bullet}(X), \bar\partial, [\cdot,\cdot]\big),$$

with Maurer–Cartan equation $\bar\partial\mu + \frac{1}{2}[\mu, \mu] = 0$.

107.1 The Mapping Field Space

Definition 107.3 (Mapping space and fermionic directions)**.** Let X be a smooth manifold. The smooth bosonic field space is the Fréchet manifold

$$\mathcal{F}^{\mathrm{bos}}_{\Sigma,X} = C^\infty(\Sigma, X).$$

At $\phi \in C^\infty(\Sigma, X)$, its tangent space is

$$T_\phi \mathcal{F}^{\mathrm{bos}}_{\Sigma,X} = \Gamma(\Sigma, \phi^* TX).$$

A fermionic field in a sigma model is a parity-reversed section of a vector bundle built functorially from $T\Sigma$, $T^*\Sigma$, and ϕ^*TX. Thus the full field space is a locally super-ringed Fréchet space over $C^\infty(\Sigma, X)$. Its structure sheaf is locally the completed exterior algebra on the continuous dual of the chosen fermionic section spaces.

The last sentence is part of the definition. Fermionic field variables are odd generators in a supercommutative algebra of functions on field space, rather than elements of the underlying bosonic mapping space. Fermionic field operators in Lorentzian QFT are linear operators on a Hilbert-space domain and are different objects.

For the A-model structure of Hypothesis 107.1, the target data are an almost Kähler manifold

$$(X, \omega, J, g_X),$$

where $J^2 = -1$,

$$\omega(u, v) = g_X(Ju, v), \qquad d\omega = 0,$$

and J is compatible with ω. For the B-model structure of Hypothesis 107.2, the target is a compact complex manifold X with trivial canonical bundle and a choice of nowhere-vanishing holomorphic volume form Ω_X; a Kähler metric is used to write a Lagrangian representative, but the cohomological observables depend on complex-structure data.

107.2 The A-Model Complex

The scalar A-model differential acts on local functions of ϕ as the de Rham differential on X. In local coordinates x^i on X, introduce an odd scalar field ψ^i transforming as dx^i. On zero-form observables,

$$Q_A\phi^i = \psi^i, \qquad Q_A\psi^i = 0.$$

For $\alpha \in \Omega^p(X)$, define

$$\mathcal{O}_\alpha(x) = \frac{1}{p!}\,\alpha_{i_1\cdots i_p}(\phi(x))\psi^{i_1}(x)\cdots\psi^{i_p}(x).$$

The Koszul sign rule gives

$$Q_A\mathcal{O}_\alpha = \mathcal{O}_{d\alpha}.$$

Therefore local scalar A-model observables are represented by

$$H^\bullet_{\mathrm{dR}}(X; \mathbb{C})$$

when contact terms are controlled by a specified source and collision prescription. The coordinate computation is part of the definition of this local complex: since $Q_A\phi^i = \psi^i$ and $Q_A\psi^i = 0$,

$$Q_A\mathcal{O}_\alpha = \frac{1}{p!}\,\partial_j\alpha_{i_1\cdots i_p}(\phi)\,\psi^j\psi^{i_1}\cdots\psi^{i_p}.$$

Antisymmetrizing the coefficient of the product of odd variables gives

$$\frac{1}{(p+1)!}(d\alpha)_{ji_1\cdots i_p}\psi^j\psi^{i_1}\cdots\psi^{i_p},$$

which is $\mathcal{O}_{d\alpha}$.

107.3 The Cauchy–Riemann Section and the Energy Identity

Let $J_\Sigma = j_\Sigma$. For a smooth map $\phi : \Sigma \to X$, define the $(0,1)$-part of its differential by

$$\bar{\partial}_J \phi = \frac{1}{2}\big(d\phi + J \circ d\phi \circ J_\Sigma\big) \in \Omega^{0,1}(\Sigma, \phi^* TX).$$

The A-model localization equation is

$$\bar{\partial}_J \phi = 0.$$

Its solutions are J-holomorphic maps.

Pointwise energy identity. Fix a conformal metric on Σ. Normalize the norm on the $(0,1)$-form bundle by

$$|\bar{\partial}_J \phi|^2 = \frac{1}{2}\big|d\phi(e) + J d\phi(J_\Sigma e)\big|^2$$

for any positively oriented unit vector e, one has the pointwise identity

$$\frac{1}{2}|d\phi|^2 \, d\mathrm{vol}_\Sigma = \phi^*\omega + |\bar{\partial}_J \phi|^2 \, d\mathrm{vol}_\Sigma.$$

Consequently

$$E(\phi) := \frac{1}{2}\int_\Sigma |d\phi|^2 \, d\mathrm{vol}_\Sigma = \int_\Sigma \phi^*\omega + \int_\Sigma |\bar{\partial}_J \phi|^2 \, d\mathrm{vol}_\Sigma.$$

Let $e_1 = e$ and $e_2 = J_\Sigma e$. Put $u = d\phi(e_1)$ and $v = d\phi(e_2)$. Compatibility of (ω, J, g_X) gives

$$\phi^*\omega(e_1, e_2) = \omega(u, v) = g_X(Ju, v).$$

Since J is g_X-orthogonal,

$$\frac{1}{2}|u + Jv|^2 = \frac{1}{2}|u|^2 + \frac{1}{2}|v|^2 + g_X(u, Jv) = \frac{1}{2}|u|^2 + \frac{1}{2}|v|^2 - \omega(u, v).$$

Multiplying by $d\mathrm{vol}_\Sigma$ gives the stated identity.

For a fixed homology class $\beta \in H_2(X; \mathbb{Z})$, the topological quantity $\int_\Sigma \phi^*\omega = \int_\beta \omega$ is constant on the component of maps with $\phi_*[\Sigma] = \beta$. Thus the positive part of the action is the squared norm of the section $\bar{\partial}_J$ plus a topological term. In a cohomological representative, the squared norm and its fermionic linearization arise as Q_A-variation of a gauge fermion, while the complexified Kähler weight is

$$Q^\beta := \exp\left(2\pi \mathrm{i} \int_\beta (B + \mathrm{i}\omega)\right) = \exp\left(2\pi \mathrm{i} \int_\beta B - 2\pi \int_\beta \omega\right),$$

for a closed real B-field. This fixes the convention used below for the Novikov weight Q^β.

107.4 The Linearized Equation and Virtual Dimension

Let $\phi : \Sigma \to X$ solve $\bar{\partial}_J \phi = 0$. If J is integrable and X is Kähler, the linearization is the Dolbeault operator

$$D_\phi = \bar{\partial}_{\phi^* T^{1,0} X} : \Gamma(\Sigma, \phi^* T^{1,0} X) \longrightarrow \Omega^{0,1}(\Sigma, \phi^* T^{1,0} X),$$

up to the standard connection expression which is complex-linear on the holomorphic locus. For an almost complex target, the linearization is a real Cauchy–Riemann type Fredholm operator with the same index.

Index of the fixed-domain deformation complex. Let $m = \dim_{\mathbb{C}} X$, g be the genus of Σ, and $\beta = \phi_*[\Sigma]$. The real Fredholm index calculation for the deformation complex

$$\Gamma(\Sigma, \phi^*TX) \xrightarrow{D_\phi} \Omega^{0,1}(\Sigma, \phi^*TX)$$

is

$$\operatorname{ind}_{\mathbb{R}}(D_\phi) = 2\left(m(1-g) + \int_\beta c_1(TX)\right).$$

For integrable J, the complex index of $\bar{\partial}_{\phi^*T^{1,0}X}$ is

$$\chi(\Sigma, \phi^*T^{1,0}X) = \operatorname{rank}_{\mathbb{C}}(T^{1,0}X)(1-g) + \deg(\phi^*T^{1,0}X)$$

by Riemann–Roch for holomorphic vector bundles on a compact Riemann surface. Here the rank is m, and

$$\deg(\phi^*T^{1,0}X) = \int_\Sigma \phi^* c_1(T^{1,0}X) = \int_\beta c_1(TX).$$

The real index is twice the complex index. For almost complex J, connect the operator through elliptic real Cauchy–Riemann type operators to a complex-linear representative; the Fredholm index is locally constant in such families.

When the complex structure of the domain and n marked points are also allowed to vary, the expected real dimension of the stable-map moduli space is

$$\operatorname{vdim}_{\mathbb{R}} \overline{\mathcal{M}}_{g,n}(X,\beta) = 2\left((1-g)(m-3) + n + \int_\beta c_1(TX)\right).$$

This is obtained by adding the real dimension $6g - 6 + 2n$ of the stable curve moduli space to the fixed-domain index above; the unstable cases are defined by quotienting by the automorphism group of the marked curve.

107.5 Stable Maps and the A-Model Correlator

Definition 107.4 (Stable maps)**.** Let X be compact almost Kähler. A genus-g, n-marked stable map to X in class β is a tuple

$$(C, p_1, \ldots, p_n, \phi)$$

where C is a connected nodal complex curve of arithmetic genus g, the p_a are distinct smooth marked points, $\phi : C \to X$ is continuous and J-holomorphic on every irreducible component after normalization, and $\phi_*[C] = \beta$. Stability means that every irreducible component on which ϕ is constant has finite automorphism group after retaining its marked and nodal special points.

The compact moduli space is denoted

$$\overline{\mathcal{M}}_{g,n}(X,\beta).$$

There are evaluation maps

$$\operatorname{ev}_a : \overline{\mathcal{M}}_{g,n}(X,\beta) \to X, \qquad \operatorname{ev}_a(C, p_1, \ldots, p_n, \phi) = \phi(p_a).$$

The rigorous finite-dimensional object used by the A-model is a virtual fundamental class

$$[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}} \in H_{\mathrm{vdim}_{\mathbb{R}}}\big(\overline{\mathcal{M}}_{g,n}(X,\beta);\mathbb{Q}\big),$$

or an equivalent virtual integration theory such as a Kuranishi atlas, polyfold Fredholm structure, or derived geometric perfect obstruction theory in the algebraic case. The present chapter records exactly which properties of this object enter the QFT formulas.

Virtual integration package used below. The virtual integration entry $\mathfrak{V}_X$ in Hypothesis 107.1 is the following package. The symbol $[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}}$ denotes more than a homology class attached to a space. The formulas below require the following finite-dimensional package.

$$\mathfrak{V}_X = \big([\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}}, \mathrm{ev}_a, \pi, \rho, \iota_\Gamma\big)_{g,n,\beta,\Gamma}.$$

Here ev_a are the evaluation maps, π denotes the forgetful maps that drop marked points and stabilize the curve, ρ denotes deformation identifications for smooth families of targets or almost complex structures, and ι_Γ denotes gluing maps associated to nodal boundary strata labelled by stable graphs Γ. The package is required to satisfy:

$$\dim_{\mathbb{R}}[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}} = 2\left((1-g)(m-3)+n+\int_\beta c_1(TX)\right),$$

compatibility with pullback of cohomology classes by the evaluation and forgetful maps, invariance under the deformation identifications ρ, and compatibility with gluing. In genus zero, the gluing compatibility used for associativity is the following boundary-stratum identity. For a four-point splitting S and a decomposition $\beta=\beta_1+\beta_2$, let

$$\mathcal{D}_S(\beta_1,\beta_2) = \overline{\mathcal{M}}_{0,3}(X,\beta_1)\times_X \overline{\mathcal{M}}_{0,3}(X,\beta_2),$$

where the fiber product uses the two evaluation maps at the node. The virtual class on this boundary stratum is required to be

$$[\mathcal{D}_S(\beta_1,\beta_2)]^{\mathrm{vir}} = \Delta_X^!\big([\overline{\mathcal{M}}_{0,3}(X,\beta_1)]^{\mathrm{vir}}\times[\overline{\mathcal{M}}_{0,3}(X,\beta_2)]^{\mathrm{vir}}\big)\,, \tag{107.1}$$

where $\Delta_X^!$ is the refined pullback along the diagonal $\Delta_X : X\to X\times X$. If $\iota_S : \mathcal{D}_S(\beta_1,\beta_2)\to \overline{\mathcal{M}}_{0,4}(X,\beta)$ is the gluing map, then

$$(\iota_S)_*\sum_{\beta_1+\beta_2=\beta}[\mathcal{D}_S(\beta_1,\beta_2)]^{\mathrm{vir}}$$

is the virtual class of the boundary fiber over the corresponding boundary point of $\overline{\mathcal{M}}_{0,4}\cong\mathbb{P}^1$. The two boundary points of $\overline{\mathcal{M}}_{0,4}$ used in the WDVV comparison are linearly equivalent divisors on $\mathbb{P}^1$. This is the nontrivial input from virtual geometry; it is not derived from the formal algebra of the QFT path integral in this chapter.

Definition 107.5 (Primary Gromov–Witten functional)**.** Given a virtual integration package $\mathfrak{V}_X$ with the properties specified above, the primary Gromov–Witten functional is the multilinear map defined for cohomology classes $\alpha_a\in H^\bullet(X;\mathbb{C})$ by

$$\langle\alpha_1,\ldots,\alpha_n\rangle^X_{g,n,\beta} = \int_{[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}}}\bigwedge_{a=1}^n \mathrm{ev}_a^*\alpha_a.$$

The A-model primary correlator at fixed genus is the Novikov series

$$\langle \alpha_1, \ldots, \alpha_n \rangle^A_{g,n} = \sum_{\beta \in H_2(X;\mathbb{Z})} Q^\beta \, \langle \alpha_1, \ldots, \alpha_n \rangle^X_{g,n,\beta}\,,$$

whenever the series is defined in the chosen Novikov completion.

Proposition 107.6 (Worldsheet-instanton sector as an amplitude datum)**.** *Fix the A-model datum of Hypothesis 107.1. For a curve class β, the finite-dimensional expression*

$$Q^\beta \int_{[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}}} \bigwedge_{a=1}^{n} \mathrm{ev}_a^* \alpha_a \tag{107.2}$$

is the localized amplitude assigned to the β worldsheet-instanton sector only after the determinant, orientation, compactification, and contact-term data in $\mathfrak{V}_X$ and $\mathfrak{c}_A$ have been fixed. The bare space of J-holomorphic maps is not by itself the QFT amplitude.

Proof. The topological term in the action is constant on the component $\phi_*[\Sigma] = \beta$, giving the factor Q^β. The remaining Q_A-exact positive term localizes the bosonic zero locus to $\bar{\partial}_J \phi = 0$. Its linearization is the Fredholm operator D_ϕ. Even and odd nonzero modes contribute a determinant-line factor for the virtual index of D_ϕ, not an automatic scalar. Choosing the orientation, obstruction, gluing, and compactification data in $\mathfrak{V}_X$ identifies this determinant-line datum with the virtual integration cycle. Local observables $\mathcal{O}_{\alpha_a}$ restrict to the evaluation pullbacks $\mathrm{ev}_a^* \alpha_a$. Finally, coincident marks, nodal boundary strata, and source collisions are interpreted using the contact prescription $\mathfrak{c}_A$. These steps produce (107.2). ☐

Proposition 107.7 (Zero-mode saturation and the A-model selection rule)**.** *Let*

$$v_{g,n,\beta} = \mathrm{vdim}_{\mathbb{R}} \, \overline{\mathcal{M}}_{g,n}(X,\beta).$$

After the nonzero modes have been paired by the cohomological regulator and the determinant line has been oriented by $\mathfrak{V}_X$, the fixed β primary amplitude is a top-degree extraction on the remaining zero-mode space. Therefore

$$\langle \alpha_1, \ldots, \alpha_n \rangle^X_{g,n,\beta} = 0 \quad \textit{unless} \quad \sum_{a=1}^{n} \deg_{\mathbb{R}} \alpha_a = v_{g,n,\beta}.$$

For gravitational descendants the same zero-mode extraction gives

$$\langle \tau_{k_1}(\alpha_1) \cdots \tau_{k_n}(\alpha_n) \rangle^X_{g,n,\beta} = 0 \quad \textit{unless} \quad \sum_{a=1}^{n} \big(\deg_{\mathbb{R}} \alpha_a + 2k_a \big) = v_{g,n,\beta}. \tag{107.3}$$

Equivalently, in complex degree $|\alpha|_{\mathbb{C}} = \deg_{\mathbb{R}} \alpha / 2$,

$$\sum_{a=1}^{n} \big(|\alpha_a|_{\mathbb{C}} + k_a \big) = (1-g)(m-3) + n + \int_\beta c_1(TX). \tag{107.4}$$

Proof. On a regular component of the holomorphic-map locus, the odd scalar zero modes are identified with differentials on the finite-dimensional zero-mode manifold. The insertion $\mathcal{O}_{\alpha_a}$

restricts to the form $\mathrm{ev}_a^*\alpha_a$. Berezin integration over the odd zero modes is therefore ordinary top-form extraction: a form of total real degree smaller than $v_{g,n,\beta}$ leaves unsaturated odd zero modes, while a form of larger degree has no component of the required top degree. On a nonregular component the same statement is imposed on the virtual tangent-obstruction complex by the orientation and obstruction data in $\mathfrak{V}_X$. The classes $\psi_a^{k_a}$ have real degree $2k_a$, so descendants simply add the terms $2k_a$ in (107.3). Substituting the virtual dimension formula gives (107.4). $\square$

Thus the selection rule is not a slogan about holomorphic maps. It is the zero-mode saturation condition for the regulated instanton sector after the nonzero-mode determinant and virtual orientation have supplied a scalar measure. In the primary case, Proposition 107.7 specializes to the familiar dimension rule: the integral vanishes unless

$$\sum_{a=1}^{n} \deg_{\mathbb{R}} \alpha_a = \mathrm{vdim}_{\mathbb{R}} \overline{\mathcal{M}}_{g,n}(X,\beta).$$

Equivalently, in complex degree $|\alpha|_{\mathbb{C}} = \deg_{\mathbb{R}} \alpha/2$,

$$\sum_{a=1}^{n} |\alpha_a|_{\mathbb{C}} = (1-g)(m-3) + n + \int_\beta c_1(TX).$$

107.6 Quantum Cohomology from Genus-Zero Gluing

Let $H = H^\bullet(X;\mathbb{C})$, and choose a homogeneous basis $\{T_a\}$. The Poincaré pairing is

$$\eta_{ab} = \int_X T_a \wedge T_b, \qquad \eta^{ab}\eta_{bc} = \delta^a_c.$$

Definition 107.8 (Small quantum product)**.** The genus-zero small quantum product is the Novikov-linear product on $H \otimes \Lambda_{\mathrm{Nov}}$ determined by

$$(T_a \star T_b, T_c) = \sum_\beta Q^\beta \langle T_a, T_b, T_c \rangle^X_{0,3,\beta},$$

where $(\cdot,\cdot)$ is the Poincaré pairing. Equivalently,

$$T_a \star T_b = \sum_{\beta,c,d} Q^\beta \langle T_a, T_b, T_d \rangle^X_{0,3,\beta} \eta^{dc} T_c.$$

Associativity from the splitting axiom. With the genus-zero splitting identity (107.1) as part of the virtual integration package, the product $\star$ is associative. This is a conditional consequence of the virtual package, not an independent construction of that package from continuum QFT.

It is enough to prove

$$((T_a \star T_b) \star T_c, T_d) = (T_a \star (T_b \star T_c), T_d)$$

for basis elements. Expanding the left side by the definition of $\star$ gives

$$\sum_{\beta_1+\beta_2=\beta} \sum_{e,f} Q^\beta \langle T_a, T_b, T_e \rangle_{0,3,\beta_1} \eta^{ef} \langle T_f, T_c, T_d \rangle_{0,3,\beta_2}.$$

Expanding the right side gives

$$\sum_{\beta_1+\beta_2=\beta} \sum_{e,f} Q^\beta \langle T_a, T_f, T_d \rangle_{0,3,\beta_1} \eta^{fe} \langle T_b, T_c, T_e \rangle_{0,3,\beta_2}.$$

The two expressions are equal because they are the virtual integrals of $\mathrm{ev}_1^* T_a \,\mathrm{ev}_2^* T_b \,\mathrm{ev}_3^* T_c \,\mathrm{ev}_4^* T_d$ over two linearly equivalent boundary divisors in $\overline{\mathcal{M}}_{0,4} \cong \mathbb{P}^1$, pulled back to $\overline{\mathcal{M}}_{0,4}(X, \beta)$. The splitting axiom identifies the restriction of the virtual class to the boundary with the fiber product of two three-point virtual classes over X; the diagonal class of X is

$$[\Delta_X] = \sum_{e,f} \eta^{ef} \, T_e \otimes T_f.$$

Substituting this diagonal decomposition gives exactly the two displayed factorizations. Hence the pairings with all T_d agree, and nondegeneracy of η gives associativity.

The calculation shows precisely where the geometry enters: compactness of the stable-map space, construction of virtual classes, and compatibility of those classes with the two boundary factorizations of a four-marked rational curve. The algebraic conclusion is then formal.

107.7 Example: Projective Space

Let $X = \mathbb{P}^m$, let $H \in H^2(\mathbb{P}^m; \mathbb{Z})$ be the hyperplane class, and normalize

$$\int_{\mathbb{P}^m} H^m = 1.$$

The classical cohomology is $\mathbb{C}[H]/(H^{m+1})$. The small quantum cohomology is

$$QH^\bullet(\mathbb{P}^m) \cong \mathbb{C}[H, Q]/(H^{m+1} - Q),$$

where Q is the Novikov variable for the positive line class.

Proposition 107.9 (Degree-one projective instanton and the quantum relation)**.** *In the Gromov–Witten normalization used above,*

$$\left\langle H^a, H^b, H^c \right\rangle_{0,3,1}^{\mathbb{P}^m} = \begin{cases} 1, & a+b+c = 2m+1, \\ 0, & a+b+c \neq 2m+1 \end{cases}$$

for $0 \le a, b, c \le m$*. Consequently*

$$H^{m+1} = Q$$

in $QH^\bullet(\mathbb{P}^m)$*.*

Proof. The expected complex dimension of $\overline{\mathcal{M}}_{0,3}(\mathbb{P}^m, d)$ is

$$m + (m+1)d.$$

Thus

$$\left\langle H^a, H^b, H^c \right\rangle_{0,3,d}$$

can be nonzero only when $a+b+c = m+(m+1)d$. For $d = 1$, the moduli space can be described on its open degree-one stratum as a line $\ell \subset \mathbb{P}^m$ together with three marked points on ℓ:

$$\dim_{\mathbb{C}} \mathrm{Gr}(2, m+1) + 3 = (2m-2) + 3 = 2m+1.$$

Equivalently, use the automorphism group of the domain to put the three marked points at $0, \infty, 1 \in \mathbb{P}^1$. A degree-one map is represented by two independent vectors $A, B \in \mathbb{C}^{m+1}$, up to common scale, through

$$[s : t] \longmapsto [sA + tB].$$

Generic representatives of H^a, H^b, H^c are linear subspaces $L_a, L_b, L_c \subset \mathbb{P}^m$ of codimensions a, b, c. The conditions $A \in \widehat{L}_a$, $B \in \widehat{L}_b$, and $A+B \in \widehat{L}_c$ impose $a+b+c$ independent linear equations on $(A, B) \in \mathbb{C}^{m+1} \oplus \mathbb{C}^{m+1}$. If $a+b+c = 2m+1$, the solution space is one-dimensional and therefore gives one projective degree-one map. If the codimensions do not sum to $2m+1$, the dimension rule gives zero. This proves the displayed degree-one invariant.

For $d = 0$, the invariant is the classical intersection number and gives $H^a \star H^b = H^{a+b}$ when $a+b \leq m$. If $a+b = m+1$, pairing $H^a \star H^b$ with 1 receives exactly the degree-one contribution above, so $H^a \star H^b = Q$. Taking $a = m$ and $b = 1$ gives $H^{m+1} = Q$. Associativity then determines all products. ☐

For $m = 1$, this gives

$$QH^{\bullet}(\mathbb{P}^1) = \mathbb{C}[H, Q]/(H^2 - Q).$$

The quantum correction is detected by

$$(H \star H, H) = Q \, \langle H, H, H \rangle_{0,3,1} = Q,$$

so $H \star H = Q \cdot 1$. This example is the smallest exact check that the quantum product differs from the classical cup product.

107.8 Descendants and the Universal Curve

Let

$$\pi : \mathcal{C}_{g,n}(X, \beta) \to \overline{\mathcal{M}}_{g,n}(X, \beta)$$

be the universal curve and s_a the section corresponding to the a-th marked point. The cotangent line at the marked point is

$$L_a = s_a^* \omega_\pi,$$

where ω_π is the relative dualizing sheaf. Its first Chern class

$$\psi_a = c_1(L_a) \in H^2(\overline{\mathcal{M}}_{g,n}(X, \beta))$$

is the gravitational descendant class. The descendant invariant is

$$\langle \tau_{k_1}(\alpha_1) \cdots \tau_{k_n}(\alpha_n) \rangle_{g,n,\beta}^X = \int_{[\overline{\mathcal{M}}_{g,n}(X,\beta)]^{\mathrm{vir}}} \prod_{a=1}^n \psi_a^{k_a} \, \mathrm{ev}_a^* \alpha_a.$$

In the fixed-source-surface cohomological field theory, descendants arise from the descent equations of Chapter 106. After coupling to topological gravity, the ψ_a-classes are the finite-dimensional remnants of the marked-point cotangent directions. These are related constructions occupying different layers: the latter requires integration over the moduli of domains.

107.9 The B-Model Complex

Let X be a compact complex m-fold with $K_X \simeq \mathcal{O}_X$, and choose a holomorphic volume form Ω_X. Define the polyvector Dolbeault complex

$$\mathrm{PV}^{p,q}(X) = \Omega^{0,q}(X, \wedge^p T^{1,0}X), \qquad Q_B = \bar{\partial}.$$

If

$$\mu = \mu^{i_1\cdots i_p}{}_{\bar{j}_1\cdots\bar{j}_q} d\bar{z}^{\bar{j}_1}\cdots d\bar{z}^{\bar{j}_q} \otimes \partial_{i_1}\wedge\cdots\wedge\partial_{i_p},$$

then the corresponding local observable is represented by

$$\mathcal{O}_\mu = \mu^{i_1\cdots i_p}{}_{\bar{j}_1\cdots\bar{j}_q}(\phi)\eta^{\bar{j}_1}\cdots\eta^{\bar{j}_q}\theta_{i_1}\cdots\theta_{i_p},$$

where $\eta^{\bar{j}}$ is the odd variable corresponding to $d\bar{z}^{\bar{j}}$ and θ_i is the odd variable dual to ∂_i. The scalar Q_B-cohomology of local observables is

$$H^q(X, \wedge^p T^{1,0}X).$$

The holomorphic volume form converts polyvectors into forms by contraction,

$$\iota_\mu \Omega_X \in \Omega^{m-p,q}(X).$$

For $\mu_1, \ldots, \mu_k$ with total polyvector degree m and total Dolbeault degree m, the genus-zero classical B-model pairing is

$$\langle \mu_1, \ldots, \mu_k\rangle_B = \int_X \Omega_X \wedge \iota_{\mu_1\wedge\cdots\wedge\mu_k}\Omega_X.$$

If either total degree condition fails, the integral is zero by form degree.

Remark 107.10 (B-model dependence on complex structure). Infinitesimal deformations of the complex structure are represented by

$$\mu \in \Omega^{0,1}(X, T^{1,0}X).$$

The integrability equation for a finite deformation is the Maurer–Cartan equation

$$\bar{\partial}\mu + \frac{1}{2}[\mu, \mu] = 0,$$

where $[\cdot,\cdot]$ is the Schouten–Nijenhuis bracket extended to Dolbeault forms. Thus the B-model deformation problem is controlled by the differential graded Lie algebra

$$\big(\mathrm{PV}^{1,\bullet}(X), \bar{\partial}, [\cdot,\cdot]\big).$$

Write the deformed $(0,1)$-operator on functions as

$$\bar{\partial}_\mu = \bar{\partial} + \mu \cdot \partial.$$

A complex structure is integrable exactly when $\bar{\partial}_\mu^2 = 0$. Expanding the square on local functions gives

$$\bar{\partial}\mu + \frac{1}{2}[\mu, \mu],$$

with the bracket equal to the Schouten–Nijenhuis bracket in the vector index and the wedge product in the Dolbeault indices. Hence integrability is the displayed Maurer–Cartan equation.

The B-twist uses the axial $U(1)$ R-symmetry of the parent $\mathcal{N} = (2, 2)$ sigma model. The anomaly of this symmetry is measured by $c_1(TX)$, so the closed B-model requires $c_1(TX) = 0$, equivalently triviality of K_X after choosing the holomorphic volume form needed for the trace pairing. Boundary conditions and open B-models require additional Chan–Paton and anomaly data.

107.10 A-Model and B-Model Parameter Dependence

The two models organize target geometry in complementary ways.

- The A-model local scalar complex is $H^\bullet_{\mathrm{dR}}(X)$. Its instanton weights depend on the complexified Kähler class $[B + \mathrm{i}\omega]$ through Q^β. A change of the target complex structure changes the representative of the Cauchy–Riemann section, but under a Q_A-preserving regulator and compactness hypotheses the induced variation of primary correlators is Q_A-exact.
- The B-model local scalar complex is $H^q(X, \wedge^p T^{1,0}X)$. Its deformation theory is controlled by the complex-structure Maurer–Cartan equation above. Kähler variations occur in Q_B-exact metric-response terms, again provided the regulator and integration cycle preserve the Q_B-Ward identity.

These statements are Ward-identity statements. They require the hypotheses listed in Chapter 106: a Q-invariant regulated cycle, control of boundary terms at noncompact ends, and a treatment of contact terms for colliding insertions.

107.11 Continuum QFT Status

The A-model has a mathematically rich finite-dimensional output in Gromov–Witten theory. The B-model has a finite-dimensional classical closed sector expressed through polyvector Dolbeault cohomology and, at higher genus, through the Kodaira–Spencer/BCOV effective theory. These outputs are indispensable, and the continuum sigma-model QFT still demands a field-theoretic construction.

Open Problem 107.11 (Topological sigma model as continuum QFT)*.* Construct A- and B-models as continuum cohomological QFTs with explicit regulated field spaces, Q-invariant integration cycles, anomaly lines, compactified zero-mode spaces, compatible virtual integration, and gluing maps for cutting and sewing source surfaces. The construction should recover the Gromov–Witten and B-model finite-dimensional formulas as theorems rather than as definitions of the path integral.

This open problem is the precise interface where enumerative geometry, supersymmetric sigma-model regularization, and functorial QFT meet.

Chapter 108

Twists of Supersymmetric Theories

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

A topological twist is a change of the rotation background of a supersymmetric QFT by an R-symmetry background. Its first output is representation-theoretic: fields and supercharges are reinterpreted as sections of different geometric bundles. Its second output, when the twisted theory has a scalar odd symmetry Q satisfying the hypotheses of Chapter 106, is a cohomological QFT. The two steps are logically distinct. The twist supplies a candidate cohomological differential; the Ward identity, stress-tensor relation, contact prescription, and regulator decide whether it defines a metric-independent continuum theory.

108.1 Twisting as a Background Construction

Let the flat-space Euclidean theory have rotation group $\mathrm{Spin}(d)$ and compact internal R-symmetry group G_R. The odd supersymmetry generators form a finite-dimensional $\mathbb{Z}_2$-odd representation

$$\mathsf{Q} \quad \text{of} \quad \mathrm{Spin}(d) \times G_R.$$

The fields form representations of the same group together with gauge and flavor representations.

Definition 108.1 (Twisting homomorphism)**.** A twisting homomorphism is a continuous homomorphism

$$\rho : \mathrm{Spin}(d) \longrightarrow G_R.$$

The corresponding twisted rotation group is the diagonal subgroup

$$\mathrm{Spin}(d)_\rho = \{(s, \rho(s)) \mid s \in \mathrm{Spin}(d)\} \subset \mathrm{Spin}(d) \times G_R.$$

Every flat-space representation V of $\mathrm{Spin}(d) \times G_R$ becomes a representation

$$V_\rho := \mathrm{Res}^{\mathrm{Spin}(d)\times G_R}_{\mathrm{Spin}(d)_\rho} V$$

of the twisted rotation group.

On a curved oriented Riemannian d-manifold M, this restriction has the following geometric meaning. Let $P_{\mathrm{Spin}}(M)$ be a spin frame bundle when M is spin. Turning on the R-symmetry background determined by the twist means choosing the principal G_R-bundle

$$P_R(M) = P_{\mathrm{Spin}}(M) \times_\rho G_R.$$

If V is a representation of $\mathrm{Spin}(d) \times G_R$, the twisted associated bundle is

$$E^\rho_V(M) = P_{\mathrm{Spin}}(M) \times_{\mathrm{Spin}(d)} V_\rho.$$

Thus a field which was a spinor in the untwisted flat theory can become a differential form, a tensor, or a section of another natural bundle after restriction to $\mathrm{Spin}(d)_\rho$.

Definition 108.2 (Scalar twisting supercharge)**.** A supercharge $Q \in \mathsf{Q}$ is a scalar for the twist ρ if

$$Q \in \mathsf{Q}^{\mathrm{Spin}(d)_\rho}.$$

It is a cohomological candidate if, in the twisted algebra of fields or observables,

$$Q^2 = \delta_{\mathrm{gauge}}(\lambda_Q) + \delta_{\mathrm{flavor}}(\alpha_Q) + \mathcal{L}_{v_Q} \tag{108.1}$$

with specified field-dependent or background-dependent parameters. On a chosen observable sector, Q is a differential exactly when the right side acts trivially there.

For a topological twist on a closed manifold, the intended sector in the examples below is gauge-invariant, flavor-invariant, and invariant under the bosonic symmetry generated by v_Q. In the Donaldson-Witten twist below, $v_Q = 0$ and Q^2 is a gauge transformation by the adjoint scalar. In many localization problems on curved manifolds, v_Q is an isometry; the theory is then equivariant with respect to that isometry rather than purely topological.

108.2 Anomaly and Global-Form Conditions

The homomorphism ρ is a representation-theoretic input. A QFT twist requires additional conditions.

Definition 108.3 (Regulator-level twist datum)**.** A regulator-level twist datum on M consists of:

rotation geometry	$P_{\mathrm{Spin}}(M)$ or the corresponding spin^c/oriented replacement,
R-background	$P_R(M)$ induced by ρ or by a specified refinement,
field/BV space	$\mathcal{F}^\rho_\Lambda$,
odd symmetry	Q_Λ,
closure relation	Q^2_Λ as in (108.1),
regulated action or state	S^ρ_Λ or ω^ρ_Λ,
integration cycle	Γ^ρ_Λ,
observable algebra	$\mathcal{A}^\rho_\Lambda$ including contact representatives.

The datum is admissible when the R-symmetry used in the twist is nonanomalous for the chosen backgrounds and when Q_Λ preserves S^ρ_Λ, Γ^ρ_Λ, and the source/contact prescription.

The global condition may be weaker than the original spin condition. For example, after twisting, every field in a particular multiplet may transform as a tensor field on an oriented four-manifold. This tensorial appearance is a conclusion about the associated bundles after the twist; possible anomaly-line and global-form constraints still come from fermion determinants, gauge bundles, discrete theta angles, and background R-symmetry bundles. Each theory requires its own determinant-line and anomaly check.

108.3 Metric Independence from a Twisted Supercharge

Let M be compact and let

$$Z^\rho_g(\mathcal{O}_1, \dots, \mathcal{O}_n)$$

be a regulated correlator of Q_Λ-closed insertions in the twisted theory. The general cohomological criterion was proved in Chapter 106. In a supersymmetric twist, the required metric-response statement is supplied by the supercurrent multiplet together with the chosen curved-background coupling.

Remark 108.4 (Regulator-level metric-independence criterion). Assume the regulator-level twist datum above satisfies:

(i) the Q_Λ-Ward identity has no boundary anomaly on Γ^ρ_Λ;

(ii) $Q_\Lambda \mathcal{O}_i = 0$ for all insertions;

(iii) the integrated metric response has the form

$$\delta_g S^\rho_\Lambda = Q_\Lambda \mathcal{V}_{\Lambda,\delta g} + \mathcal{C}_{\Lambda,\delta g}, \tag{108.2}$$

where $\mathcal{C}_{\Lambda,\delta g}$ is the declared contact and anomaly representative;

(iv) the insertion prescription makes

$$\left\langle \mathcal{C}_{\Lambda,\delta g} \prod_i \mathcal{O}_i \right\rangle_\Lambda = 0.$$

Then $Z^\rho_g(\mathcal{O}_1, \dots, \mathcal{O}_n)$ is locally constant in the metric g at the regulator scale. If the continuum limit exists and the hypotheses are stable under that limit, the limiting correlator is locally metric independent. Differentiating the regulated path integral gives

$$\delta_g Z^\rho_g = -\left\langle \delta_g S^\rho_\Lambda \prod_i \mathcal{O}_i \right\rangle_\Lambda + \delta_g^{\text{contact}} \left\langle \prod_i \mathcal{O}_i \right\rangle_\Lambda .$$

Insert (108.2). The term with $Q_\Lambda \mathcal{V}_{\Lambda,\delta g}$ is, up to the vanishing $Q_\Lambda \mathcal{O}_i$ terms, the Q_Λ-variation of $\mathcal{V}_{\Lambda,\delta g} \prod_i \mathcal{O}_i$. The Ward identity sets its expectation value to zero. The remaining contact representative is zero by hypothesis. Hence the first variation vanishes.

The criterion is deliberately stated at regulator level. A formal identity $\delta_g S = Q(\cdots)$ in a continuum Lagrangian is one ingredient; it becomes a theorem about a QFT only after the regulated Ward identity, contact terms, and boundary behavior are controlled.

108.4 Four-Dimensional $\mathcal{N} = 2$ Supercharges

In four Euclidean dimensions,

$$\mathrm{Spin}(4) = SU(2)_+ \times SU(2)_-.$$

The pure $\mathcal{N} = 2$ vector multiplet has R-symmetry

$$G_R = SU(2)_R \times U(1)_r$$

at the classical level; the subgroup used in the Donaldson twist is $SU(2)_R$. The supercharges transform as

$$Q_\alpha{}^A \in (2, 1; 2)_{+1}, \qquad \bar{Q}_{\dot{\alpha}A} \in (1, 2; 2)_{-1}, \tag{108.3}$$

where α is an $SU(2)_+$ spinor index, $\dot{\alpha}$ is an $SU(2)_-$ spinor index, A is an $SU(2)_R$ index, and the subscript denotes $U(1)_r$ charge in the normalization used in this chapter. The Donaldson twisting homomorphism uses the $SU(2)_R$ factor.

The Donaldson twisting homomorphism identifies $SU(2)_+$ with $SU(2)_R$:

$$\rho_{\mathrm{DW}} : SU(2)_+ \times SU(2)_- \longrightarrow SU(2)_R, \qquad \rho_{\mathrm{DW}}(s_+, s_-) = s_+.$$

The twisted rotation group is

$$\mathrm{Spin}(4)' = SU(2)'_+ \times SU(2)_-, \qquad SU(2)'_+ = \mathrm{diag}(SU(2)_+ \times SU(2)_R).$$

Under $SU(2)'_+ \times SU(2)_-$,

$$(2, 1; 2) \longmapsto (1, 1) \oplus (3, 1), \qquad (1, 2; 2) \longmapsto (2, 2).$$

Thus the twisted supercharges consist of a scalar Q, a self-dual two-form supercharge $Q^+_{\mu\nu}$, and a one-form supercharge Q_μ. The first representation has an $SU(2)_+$ doublet index and an $SU(2)_R$ doublet index. Restriction to the diagonal $SU(2)'_+$ gives

$$2 \otimes 2 = 1 \oplus 3.$$

The singlet is represented by contraction with the invariant tensor $\epsilon^{\alpha A}$, hence

$$Q = \epsilon^{\alpha A} Q_{\alpha A}$$

is a scalar. The triplet is the symmetric traceless part and is identified with self-dual two-forms because the adjoint representation of $SU(2)_+$ is $\Lambda^{2,+}$. The second representation has no $SU(2)_+$ spinor index; its $SU(2)_R$ doublet becomes an $SU(2)'_+$ doublet, while the $SU(2)_-$ doublet remains. Therefore it becomes $(2, 2)$, the vector representation T^*M.

108.5 Donaldson-Witten Field Decomposition

The untwisted vector multiplet contains a connection A_μ, complex adjoint scalars $\phi, \bar{\phi}$, gauginos $\lambda_\alpha{}^A$, $\bar{\lambda}_{\dot{\alpha}A}$, and auxiliary fields. After the twist, the gauginos decompose by the same representation calculation:

$$\lambda_\alpha{}^A \longmapsto \eta \oplus \chi^+_{\mu\nu}, \qquad \bar{\lambda}_{\dot{\alpha}A} \longmapsto \psi_\mu.$$

On a four-manifold M and a principal gauge bundle $P \to M$, the twisted fields are therefore

$$A \in \mathcal{A}(P), \qquad \phi, \bar{\phi}, \eta \in \Omega^0(M, \mathrm{ad}\, P),$$
$$\psi \in \Omega^1(M, \mathrm{ad}\, P), \qquad \chi^+, H^+ \in \Omega^{2,+}(M, \mathrm{ad}\, P).$$

The fields η, ψ, χ^+ are odd; $A, \phi, \bar{\phi}, H^+$ are even. The auxiliary field H^+ is included so that the scalar symmetry closes off shell.

Use the infinitesimal gauge convention

$$\delta_\epsilon A = d_A \epsilon, \qquad \delta_\epsilon X = -[\epsilon, X] \quad \text{for } X \in \Omega^\bullet(M, \mathrm{ad}\, P). \tag{108.4}$$

The Donaldson-Witten scalar supercharge acts by

$$\begin{aligned} &QA = \psi, && Q\psi = -d_A\phi, && Q\phi = 0, \\ &Q\bar{\phi} = \eta, && Q\eta = [\phi, \bar{\phi}], && \\ &Q\chi^+ = H^+, && QH^+ = [\phi, \chi^+]. && \end{aligned} \tag{108.5}$$

Off-shell closure. With the convention (108.4), the transformations (108.5) satisfy

$$Q^2 = \delta_{-\phi}$$

on all twisted vector-multiplet fields. Hence $Q^2 = 0$ on gauge-invariant observables.

For the connection,

$$Q^2 A = Q\psi = -d_A\phi = \delta_{-\phi} A.$$

For an adjoint field X, $\delta_{-\phi} X = [\phi, X]$. The transformations give

$$Q^2\bar{\phi} = Q\eta = [\phi, \bar{\phi}], \qquad Q^2\chi^+ = QH^+ = [\phi, \chi^+], \qquad Q^2\phi = 0 = [\phi, \phi].$$

It remains to check ψ and H^+. Since $QA = \psi$ and $Q\phi = 0$,

$$Q(d_A\phi) = [\psi, \phi],$$

where the bracket includes the wedge product of forms and the Lie bracket in $\mathrm{ad}\, P$. Hence

$$Q^2\psi = -[\psi, \phi] = [\phi, \psi] = \delta_{-\phi}\psi.$$

Finally,

$$Q^2 H^+ = Q[\phi, \chi^+] = [\phi, H^+] = \delta_{-\phi} H^+.$$

Thus the closure relation holds on each generator and therefore on the graded algebra they generate.

108.6 The Donaldson-Witten Gauge Fermion

Let the monograph gauge trace convention be $\mathrm{tr}(t^a t^b) = \delta^{ab}$. The Yang-Mills action is written with

$$\frac{1}{4g_{\mathrm{YM}}^2} \int_M d\mathrm{vol}_g \; \mathrm{tr}(F_{\mu\nu} F^{\mu\nu}) = \frac{1}{2g_{\mathrm{YM}}^2} \int_M \mathrm{tr}(F \wedge *F).$$

The topological term uses

$$k(P) = -\frac{1}{8\pi^2}\int_M \operatorname{tr}(F_A \wedge F_A).$$

A convenient cohomological representative of the Donaldson-Witten action has the form

$$S_{\mathrm{DW}} = \frac{1}{g_{\mathrm{YM}}^2} Q\Psi - \frac{i\theta}{8\pi^2}\int_M \operatorname{tr}(F_A \wedge F_A), \tag{108.6}$$

where the gauge fermion contains the Mathai-Quillen term

$$\Psi_{\mathrm{MQ}} = \int_M \operatorname{tr}\left[\chi^+ \wedge *\left(F_A^+ + \frac{1}{2}H^+\right)\right] + \text{terms fixing the scalar/gauge directions.} \tag{108.7}$$

Applying Q to the displayed term gives

$$Q\Psi_{\mathrm{MQ}} = \int_M \operatorname{tr}\left[H^+ \wedge *\left(F_A^+ + \frac{1}{2}H^+\right) - \chi^+ \wedge * d_A^+\psi\right],$$

up to the sign convention for moving the odd field χ^+ through Q. The algebraic equation of motion for H^+ is

$$H^+ = -F_A^+.$$

Substitution gives the bosonic square

$$\frac{1}{2}\int_M \operatorname{tr}(F_A^+ \wedge *F_A^+)$$

with the convention of (108.7). Rescaling Ψ_{MQ} rescales this square; the localization locus is the zero-set of the section

$$F_A^+ = 0.$$

The cohomological fields (ψ, χ^+, H^+) are precisely the gauge-equivariant Mathai-Quillen variables for the section

$$F^+ : \mathcal{A}(P) \longrightarrow \Omega^{2,+}(M, \operatorname{ad} P).$$

After quotienting by the gauge group, the virtual tangent-obstruction complex at an anti-self-dual connection is

$$\Omega^0(M, \operatorname{ad} P) \xrightarrow{d_A} \Omega^1(M, \operatorname{ad} P) \xrightarrow{d_A^+} \Omega^{2,+}(M, \operatorname{ad} P),$$

which is the complex used in the Witten-Donaldson chapter to compute the expected dimension.

108.7 Donaldson Observables from Descent

Let p be an invariant polynomial on $\mathfrak{g}$. For $\mathfrak{g} = \mathfrak{su}(2)$ the basic example in the monograph trace convention is

$$p(\phi) = \frac{1}{2}\operatorname{tr}(\phi^2).$$

Using the universal curvature combination

$$\mathcal{F}_Q = F_A + \psi + \phi$$

graded by form degree plus Q-degree, the Bianchi identity and (108.5) imply the equivariant closure

$$(Q + d_A)\mathcal{F}_Q = 0 \quad \text{modulo the gauge action.}$$

Consequently

$$(Q + d)\,\mathrm{tr}(\mathcal{F}_Q^2) = 0$$

on gauge-invariant expressions. Writing

$$\frac{1}{2}\,\mathrm{tr}(\mathcal{F}_Q^2) = \mathcal{O}^{(0)} + \mathcal{O}^{(1)} + \mathcal{O}^{(2)} + \mathcal{O}^{(3)} + \mathcal{O}^{(4)}$$

by form degree gives the descent equations

$$Q\mathcal{O}^{(0)} = 0, \qquad Q\mathcal{O}^{(r)} + d\mathcal{O}^{(r-1)} = 0 \quad (1 \le r \le 4).$$

For a closed r-cycle $\gamma \subset M$,

$$\mathcal{O}_\gamma = \int_\gamma \mathcal{O}^{(r)}$$

is Q-closed. If $\gamma - \gamma' = \partial C$, then

$$\mathcal{O}_\gamma - \mathcal{O}_{\gamma'} = -Q \int_C \mathcal{O}^{(r+1)}.$$

Thus Donaldson observables depend on homology classes in Q-cohomology, subject to the contact-term prescription for products of integrated descendants.

108.8 Two-Dimensional $\mathcal{N} = (2,2)$ A and B Twists

Let the Euclidean rotation group in two dimensions be $U(1)_{\mathrm{rot}}$. Use supercharges

$$Q_+, \quad Q_-, \quad \bar{Q}_+, \quad \bar{Q}_-,$$

with spins

$$s(Q_+) = s(\bar{Q}_+) = +\frac{1}{2}, \qquad s(Q_-) = s(\bar{Q}_-) = -\frac{1}{2}.$$

Assume both vector and axial R-symmetries exist as nonanomalous symmetries. Fix charges

	Q_+	Q_-	$\bar{Q}_+$	$\bar{Q}_-$
q_V	$+1$	$+1$	-1	-1
q_A	$+1$	-1	-1	$+1.$

With the convention

$$s_\rho = s + \frac{1}{2} q_R,$$

the A-twist uses $q_R = q_V$ and has scalar supercharges

$$\bar{Q}_+, \qquad Q_-.$$

The B-twist uses $q_R = q_A$ and has scalar supercharges

$$\bar{Q}_+, \qquad \bar{Q}_-.$$

The standard BRST choices are

$$Q_A = \bar{Q}_+ + Q_-, \qquad Q_B = \bar{Q}_+ + \bar{Q}_-.$$

The A-model and B-model complexes developed in Chapter 107 arise from these two scalar supercharges after twisting the $\mathcal{N} = (2, 2)$ sigma-model fields. The vector or axial R-symmetry used in the twist must be nonanomalous for the chosen target and background. In sigma models this condition becomes the familiar restriction: the A-twist is controlled by symplectic data, while the closed B-twist requires the Calabi-Yau condition for the axial R-symmetry and trace pairing.

108.9 What the Twist Does and What Remains to Construct

The twist provides a representation-theoretic and geometric conversion:

$$\text{spinors with } R\text{-indices} \longrightarrow \text{forms or tensors on } M.$$

It also identifies candidate scalar supercharges and candidate descent complexes. A theorem-level cohomological QFT requires the additional regulator-level closure statement (108.1) and Remark 108.4: Q-invariant regularization, anomaly cancellation, off-shell closure or BV closure, contact representatives, compactification of fixed loci, and gluing.

Open Problem 108.5 (Twisted continuum construction). Construct four-dimensional twisted supersymmetric gauge theories as continuum QFTs with Q-preserving regulator or BV regularization, off-shell or BV closure, determinant-line and global-form control, contact term prescriptions for descendant observables, compactified fixed loci, and a derivation of the Q-exact metric-response relation. For Donaldson-Witten theory this construction should recover the anti-self-dual-moduli-space description and the Donaldson observables from the regulated cohomological gauge theory.

Chapter 109

Witten-Donaldson Theory And The Seiberg-Witten Comparison

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops the four-dimensional cohomological gauge theory whose correlation functions are Donaldson invariants and explains the precise mathematical content of the comparison with Seiberg-Witten monopole theory. There are three logically distinct layers. The first layer is finite dimensional differential geometry: anti-self-dual connections, monopole equations, deformation complexes, orientations, compactifications, and intersection pairings. The second layer is cohomological field theory: twisted supersymmetry, descent, Q-exact metric variation, and contact terms. The third layer is the four-dimensional RG statement: the twisted non-Abelian ultraviolet theory has a Coulomb-branch Wilsonian description whose singular fibers are Abelian monopole theories. The chapter keeps these layers separate because they have different hypotheses and different mathematical status.

How the comparison argument is organized. The local mechanisms in this chapter should be read as a dependency ladder, not as interchangeable derivations of the final comparison formula. The Donaldson moduli-space layer defines the ASD invariants, the μ-classes, simple type, compactification faces, and wall links. The cohomological field-theory layer explains why these finite-dimensional objects are the localization targets of a twisted gauge theory, and why metric changes produce BV boundary terms rather than arbitrary chamber jumps. The Coulomb-branch layer supplies a different description of the same putative four-dimensional QFT: a regular u-plane integral, contact terms, electromagnetic-duality determinant lines, and singular-fiber monopole theories. The comparison statement at the end is the assertion that these three layers can be glued by one Q-compatible Wilsonian construction. Consequently a wall-link identity, a monopole dimension count, a u-plane boundary model, or a blow-up coefficient table is only a test of one arrow in the ladder; none of them alone is a proof of the Donaldson–Seiberg-Witten comparison.

109.1 Four-Manifold And Gauge Conventions

Let X be a closed connected oriented smooth four-manifold equipped with a Riemannian metric g. The Hodge star operator satisfies

$$*_g^2 = 1 \quad \text{on } \Omega^2(X),$$

and the bundle of two-forms decomposes as

$$\Lambda^2 T^*X = \Lambda^{2,+}T^*X \oplus \Lambda^{2,-}T^*X.$$

For a two-form ω, write

$$\omega^\pm = \frac{1}{2}(\omega \pm *_g\omega).$$

The integer $b_2^+(X)$ is the dimension of a maximal positive subspace of the intersection form on $H^2(X;\mathbb{R})$, equivalently the dimension of the space of harmonic self-dual two-forms for any metric g. The Euler characteristic and signature are

$$\chi(X) = 2 - 2b_1(X) + b_2^+(X) + b_2^-(X), \qquad \sigma(X) = b_2^+(X) - b_2^-(X).$$

Let $P \to X$ be a principal $SU(2)$ bundle and let $\operatorname{ad} P = P \times_{\mathrm{Ad}} \mathfrak{su}(2)$. The gauge group is

$$\mathcal{G}_P = \Gamma(X, P \times_{\mathrm{Ad}} SU(2)).$$

The monograph uses the gauge trace convention fixed in the gauge-theory volumes:

$$\operatorname{tr}(t^a t^b) = \delta^{ab}$$

for the fundamental $SU(N)$ generators. With this convention the Euclidean Yang–Mills action is written

$$S_{\mathrm{YM}}(A) = \frac{1}{4g_{\mathrm{YM}}^2}\int_X d\,\mathrm{vol}_g \ \operatorname{tr}(F_{A,\mu\nu}F_A^{\mu\nu}) - \frac{i\theta}{8\pi^2}\int_X \operatorname{tr}(F_A \wedge F_A).$$

Equivalently,

$$S_{\mathrm{YM}}(A) = \frac{1}{2g_{\mathrm{YM}}^2}\int_X \operatorname{tr}(F_A \wedge *_g F_A) - \frac{i\theta}{8\pi^2}\int_X \operatorname{tr}(F_A \wedge F_A).$$

The instanton number is

$$k(P) = -\frac{1}{8\pi^2}\int_X \operatorname{tr}(F_A \wedge F_A).$$

It is independent of the connection A. For $SU(2)$, this integer is the second Chern number $c_2(P)$ in the present trace convention.

The curvature decomposes as $F_A = F_A^+ + F_A^-$. Define

$$\|F_A^\pm\|^2 = \int_X \mathrm{tr}(F_A^\pm \wedge *_g F_A^\pm).$$

Then

$$\int_X \mathrm{tr}(F_A \wedge *_g F_A) = \|F_A^+\|^2 + \|F_A^-\|^2, \qquad \int_X \mathrm{tr}(F_A \wedge F_A) = \|F_A^+\|^2 - \|F_A^-\|^2.$$

Hence

$$\frac{1}{2g_{\mathrm{YM}}^2}\int_X \mathrm{tr}(F_A \wedge *_g F_A) = \frac{1}{g_{\mathrm{YM}}^2}\|F_A^+\|^2 + \frac{4\pi^2}{g_{\mathrm{YM}}^2}k(P).$$

The anti-self-dual equation

$$F_A^+ = 0$$

therefore saturates the topological bound in the sector $k(P) \geq 0$. The normalization $4\pi^2 k/g_{\mathrm{YM}}^2$ is the trace-delta version of the common half-trace expression $8\pi^2 k/g_{\mathrm{ht}}^2$, with $g_{\mathrm{ht}}^2 = 2g_{\mathrm{YM}}^2$.

109.2 Donaldson-Witten Cohomological Fields

The Donaldson twist of the pure four-dimensional $\mathcal{N} = 2$ vector multiplet was defined in Chapter 108. After twisting, the fields are organized as differential forms on X:

$$A \in \mathcal{A}(P), \qquad \phi, \bar\phi \in \Omega^0(X, \mathrm{ad}\, P), \qquad \psi \in \Omega^1(X, \mathrm{ad}\, P),$$
$$\chi^+ \in \Omega^{2,+}(X, \mathrm{ad}\, P), \qquad \eta \in \Omega^0(X, \mathrm{ad}\, P),$$

together with an auxiliary self-dual field

$$H^+ \in \Omega^{2,+}(X, \mathrm{ad}\, P).$$

The scalar odd symmetry Q acts by

$$\begin{aligned} &QA = \psi, && Q\psi = -d_A\phi, && Q\phi = 0, && \\ &Q\bar\phi = \eta, && Q\eta = [\phi, \bar\phi], && Q\chi^+ = H^+, && QH^+ = [\phi, \chi^+]. \end{aligned}$$

Thus Q^2 is the infinitesimal gauge transformation with parameter $-\phi$ on A and with the corresponding adjoint action on all adjoint fields. On gauge-invariant observables, $Q^2 = 0$.

The bosonic localization term may be chosen so that its H^+-dependent part has the form

$$\int_X \mathrm{tr}\left(\frac{1}{2}H^+ \wedge *_g H^+ + H^+ \wedge *_g F_A^+\right).$$

The algebraic equation of motion for H^+ gives $H^+ = -F_A^+$, and the corresponding bosonic square is proportional to

$$\|F_A^+\|^2.$$

Hence the weak-coupling localization locus in a fixed instanton sector is the anti-self-dual equation $F_A^+ = 0$. Metric independence of Q-closed correlators follows from the Ward identity of Remark 108.4 once a regulator, contact prescription, and compactification boundary prescription preserving the required Q-relations have been fixed.

109.3 The Anti-Self-Dual Moduli Space

The anti-self-dual moduli space in the sector P is

$$\mathcal{M}(P,g) = \{A \in \mathcal{A}(P) \mid F_A^+ = 0\}/\mathcal{G}_P.$$

A connection A is irreducible when its stabilizer in $\mathcal{G}_P$ is the center of $SU(2)$. At an irreducible anti-self-dual connection, the linearized equation and infinitesimal gauge transformations form the elliptic complex

$$0 \longrightarrow \Omega^0(X, \operatorname{ad} P) \xrightarrow{d_A} \Omega^1(X, \operatorname{ad} P) \xrightarrow{d_A^+} \Omega^{2,+}(X, \operatorname{ad} P) \longrightarrow 0.$$

Its cohomology groups are denoted

$$H_A^0, \qquad H_A^1, \qquad H_A^2.$$

Irreducibility gives $H_A^0 = 0$. The Zariski tangent space is H_A^1, and H_A^2 is the obstruction space. When $H_A^2 = 0$, the moduli space is a smooth manifold near $[A]$ of dimension $\dim H_A^1$.

The gauge-fixed elliptic operator is

$$D_A = d_A^* \oplus d_A^+ : \Omega^1(X, \operatorname{ad} P) \longrightarrow \Omega^0(X, \operatorname{ad} P) \oplus \Omega^{2,+}(X, \operatorname{ad} P).$$

Its index equals the virtual dimension

$$\dim_{\mathrm{vir}} \mathcal{M}(P,g) = \dim H_A^1 - \dim H_A^0 - \dim H_A^2.$$

Index of the anti-self-dual complex. For $P \to X$ a principal $SU(2)$ bundle with instanton number k, the virtual dimension of the anti-self-dual moduli space is

$$\dim_{\mathrm{vir}} \mathcal{M}(P,g) = 8k - 3(1 - b_1(X) + b_2^+(X)).$$

The Atiyah–Singer index theorem applied to

$$D_A = d_A^* \oplus d_A^+$$

gives

$$\operatorname{ind} D_A = -2p_1(\operatorname{ad} P) - \frac{\dim SU(2)}{2}\big(\chi(X) + \sigma(X)\big).$$

For a principal $SU(2)$ bundle,

$$p_1(\operatorname{ad} P) = -4c_2(P) = -4k.$$

Also

$$\frac{\chi(X) + \sigma(X)}{2} = 1 - b_1(X) + b_2^+(X).$$

Since $\dim SU(2) = 3$, substitution gives

$$\operatorname{ind} D_A = 8k - 3(1 - b_1(X) + b_2^+(X)).$$

This index is $\dim H^1_A - \dim H^0_A - \dim H^2_A$, the virtual dimension of the elliptic complex.

The determinant line of the complex is

$$\mathcal{L}_A = \det H^1_A \otimes (\det H^0_A)^{-1} \otimes (\det H^2_A)^{-1}.$$

An orientation of the instanton moduli problem is an orientation of this line over the irreducible moduli space. For simply connected X, such an orientation is fixed by an orientation of $H^2_+(X;\mathbb{R})$. For general X, the homology orientation is an orientation of

$$H^1(X;\mathbb{R}) \oplus H^2_+(X;\mathbb{R}).$$

The Uhlenbeck compactification $\overline{\mathcal{M}}(P,g)$ adds ideal instantons:

$$([A'], x_1, \dots, x_\ell), \qquad k(P') + \ell = k(P).$$

Geometrically, curvature concentration at finitely many points carries the missing second Chern number. Donaldson invariants are defined by extending the relevant cohomology classes to this compactification or to an equivalent smooth compactified model, with reducible strata and wall crossing treated separately when they occur.

109.4 Donaldson Series, Simple Type, And Uhlenbeck Boundary Terms

For the comparison formula it is useful to use the standard $SO(3)$ or $U(2)$ notation. Fix an integral lift $w \in H^2(X;\mathbb{Z})$ of the second Stiefel–Whitney class of the adjoint bundle; the earlier $SU(2)$ case is the special case $w = 0$. Let $x \in H_0(X;\mathbb{Z})$ denote the positive generator represented by a point and let $h \in H_2(X;\mathbb{R})$. The Donaldson generating function is the degree-selected formal series

$$D^w_X(p,h) = \sum_{r,n\geq 0} \frac{p^r}{r!\,n!} D^w_X(x^r h^n), \tag{109.1}$$

where terms whose total Donaldson degree does not equal the relevant virtual dimension are zero. The point class has Donaldson degree four and a surface class has Donaldson degree two.

Definition 109.1 (Donaldson simple type and Donaldson series)**.** Assume $b_1(X) = 0$ and $b_2^+(X) > 1$, so that the Donaldson invariants are independent of the metric chamber after the orientation convention has been fixed. The pair (X,w) has Donaldson simple type if

$$D^w_X\big((x^2 - 4)z\big) = 0 \tag{109.2}$$

for every homogeneous element z of the Donaldson homology algebra. In that case the reduced Donaldson series is

$$\mathbb{D}^w_X(h) = D^w_X\left(\left(1 + \frac{x}{2}\right)\exp(h)\right). \tag{109.3}$$

The normalization $x^2 = 4$ in (109.2) is part of the Donaldson-invariant convention used in this chapter; changing the normalization of the point observable rescales the numerical constant but not the structure of the comparison.

Quoted Theorem 109.2 (Donaldson simple-type structure theorem). *Let X be a closed connected oriented smooth four-manifold with $b_1(X) = 0$ and $b_2^+(X) > 1$. If (X, w) has Donaldson simple type, then there is a finite set*

$$\mathcal{B}_D(X, w) \subset H^2(X; \mathbb{Z})$$

and rational coefficients a_K^w such that

$$\mathbb{D}_X^w(h) = \exp\left(\frac{1}{2}Q_X(h, h)\right) \sum_{K \in \mathcal{B}_D(X,w)} a_K^w \, \exp\bigl(\langle K, h\rangle\bigr). \tag{109.4}$$

The classes K are characteristic:

$$K \equiv w_2(TX) \pmod 2. \tag{109.5}$$

They are called Donaldson basic classes. The theorem is a theorem of the finite-dimensional Donaldson-invariant construction, not a theorem that the four-dimensional twisted QFT has been constructed non-perturbatively.

What the structure theorem supplies. The theorem contains two different kinds of information, and they should not be confused. The first is geometric. Donaldson invariants define a linear functional on the graded algebra generated by the point class x and homology classes of X. The simple-type relation (109.2) says that the point operator has minimal polynomial $T^2 - 4$ on this functional. Passing to the reduced series (109.3) selects the $+2$-eigensummand in the normalization used here. The structure theorem then proves, using the finite-dimensional Donaldson moduli-space construction, gluing, blow-up, and compactification control, that the remaining surface-source dependence has only finitely many characteristic exponential weights after a universal quadratic factor is removed. The finiteness of the set $\mathcal{B}_D(X, w)$, the characteristic parity (109.5), and the fact that no polynomial prefactors multiply the exponentials are part of this deep theorem.

The second kind of information is algebraic and follows once the finite set is known. Put

$$F_X^w(h) = \exp\left(-\frac{1}{2}Q_X(h, h)\right) \mathbb{D}_X^w(h). \tag{109.6}$$

Then (109.4) is equivalent to saying that F_X^w is a finite exponential sum on the vector space $H_2(X; \mathbb{R})$. For every $v \in H_2(X; \mathbb{R})$, it obeys the constant-coefficient ordinary differential equation

$$\prod_{K \in \mathcal{B}_D(X,w)} \left(\frac{d}{dt} - \langle K, v\rangle\right) F_X^w(h + tv) = 0. \tag{109.7}$$

Conversely, a finite-dimensional space of translation derivatives with simultaneously diagonal characters K gives a sum of exponentials $\exp\langle K, h\rangle$. This converse is linear algebra over the commuting derivative operators; the hard Donaldson input is the geometric statement that the derivative representation is finite and semisimple with characteristic weights.

The exponential form in (109.4) is not a slogan. It says that all dependence on the ordinary intersection form is the universal Gaussian factor $\exp(Q_X/2)$, while all differentiable information in the simple-type sector is carried by finitely many characteristic linear functionals K. A coefficient a_K^w is defined only after the orientation, lift w, point-observable normalization, and compactification extension of the μ-classes have been fixed.

Definition 109.3 (Donaldson simple-type normalization convention)**.** The symbol a_K^w in (109.4) is used only after the following data have been declared.

homology orientation	an orientation of $H^1(X;\mathbb{R}) \oplus H^{2,+}(X;\mathbb{R})$,
lift	$w \in H^2(X;\mathbb{Z}), \quad w \equiv w_2(\mathrm{ad}\, P) \pmod 2$,
point class	$x \in H_0(X;\mathbb{Z})$ normalized by $D_X^w((x^2-4)z) = 0$,
surface source	$h \in H_2(X;\mathbb{R})$ paired with $K \in H^2(X;\mathbb{Z})$,
compactification	an extension of the relevant μ-classes to the boundary.

Changing any one of these data changes the numerical coefficients by a controlled convention: reversing the homology orientation reverses all oriented counts, changing w changes the chamber and phase convention of the $SO(3)$ or $U(2)$ invariant, and rescaling the point observable changes the constant 4 in (109.2).

Remark 109.4 (Coefficient extraction from the reduced series)*.* Assume the hypotheses and conventions of Theorem 109.2. Define

$$F_X^w(h) = \exp\left(-\frac{1}{2}Q_X(h,h)\right)\mathbb{D}_X^w(h).$$

Then

$$F_X^w(h) = \sum_{K \in \mathcal{B}_D(X,w)} a_K^w e^{\langle K,h\rangle}. \tag{109.8}$$

For any $v \in H_2(X;\mathbb{R})$ and $m \geq 0$,

$$\left.\frac{d^m}{dt^m}\right|_{t=0} F_X^w(tv) = \sum_{K \in \mathcal{B}_D(X,w)} a_K^w \,\langle K, v\rangle^m. \tag{109.9}$$

Consequently, after the finite set $\mathcal{B}_D(X,w)$ is known, the coefficients a_K^w are determined by finitely many Donaldson invariants: choose vectors $v_1,\ldots,v_N$ such that the numbers $\langle K, v_i\rangle$ separate the basic classes, and invert the resulting finite Vandermonde system.

Multiplying (109.4) by $\exp(-Q_X/2)$ gives (109.8). Differentiating the finite sum in the direction v gives (109.9). If the linear functionals K are separated by the chosen directions, the matrix of moments is a product of ordinary Vandermonde matrices. Its determinant is nonzero precisely because the exponential weights have distinct evaluations. Thus the a_K^w are not extra formal symbols: they are the finite Fourier coefficients of the reduced Donaldson series in the basis of characteristic exponentials.

Uhlenbeck boundary as BV boundary data. Let $\mathcal{M}_k^{\mathrm{sm}}$ be a smooth irreducible ASD stratum in instanton number k, and let

$$\overline{\mathcal{M}}_k^U = \mathcal{M}_k^{\mathrm{sm}} \sqcup \bigsqcup_{\ell \geq 1} \mathcal{M}_{k-\ell}^{\mathrm{sm}} \times \mathrm{Sym}^\ell(X) \sqcup \{\text{reducible and obstructed strata}\} \tag{109.10}$$

denote the relevant part of the Uhlenbeck compactification. If the Donaldson-Witten path integral is represented as a BV pushforward over $\mathcal{M}_k^{\mathrm{sm}}$, then the compactification strata contribute boundary functionals:

$$\Delta_{\mathrm{res}}(\pi_*^{\mathcal{M}_k^{\mathrm{sm}}}\rho) = -\sum_{\ell\geq 1} \mathcal{B}_{\mathcal{M}_{k-\ell}^{\mathrm{sm}} \times \mathrm{Sym}^\ell(X)}(\rho) - \mathcal{B}_{\mathrm{red/obs}}(\rho). \tag{109.11}$$

Consequently a Donaldson invariant obtained from the compactified moduli space is a QME-preserving cohomological correlator only after the boundary terms in (109.11) have been cancelled by codimension, by an extension of the insertion classes, by a chamber wall-crossing term, or by an explicitly supplied compactification datum.

This is the singular-stratum obstruction formula (111.12) applied to the finite-dimensional localization locus of Donaldson-Witten theory. The strata $\mathcal{M}^{\mathrm{sm}}_{k-\ell} \times \mathrm{Sym}^{\ell}(X)$ are the small-instanton boundary strata: ℓ units of second Chern number have left the smooth connection and are recorded as unordered points of X. Reducible and obstructed strata are additional singular strata of the same BV-boundary type. Removing collar neighborhoods of all these strata gives a manifold with boundary; BV Stokes produces exactly the right hand side of (109.11). If the sum vanishes or is cancelled, the residual semidensity satisfies the QME; otherwise the formal localization expression is not yet a cohomological invariant.

Remark 109.5 (Donaldson–Uhlenbeck versus Gieseker policy). The small-instanton charge bookkeeping in this paragraph is the compact four-manifold analogue of the local map from the Gieseker compactification to the Uhlenbeck one in Construction 101.7. In a holomorphic $\mathbb{C}^2$ chart, a torsion-free sheaf E has a double dual E^{**} and a zero-dimensional quotient Q of length ℓ, and the instanton number splits as

$$k(E) = k(E^{**}) + \ell.$$

The Donaldson–Uhlenbeck compactification keeps the lower-charge smooth connection together with the unordered support of the lost charge. The Gieseker/Nekrasov compactification instead keeps the punctual quotient data that resolve the same boundary stratum and then integrates its equivariant Euler class.

Thus the two compactifications are not interchangeable names for the same localized integral. A Donaldson invariant uses Uhlenbeck compactification, extensions of the μ-classes, and possible wall or reducible boundary terms. A Nekrasov factor uses the resolved Gieseker fixed-point cycle and therefore needs the regulator-selection datum of Definition 101.18 before it can be claimed as the output of a continuum S^4 gauge-theory path integral. In BV language the distinction is exactly the choice between cancelling the boundary functional $\mathcal{B}_{\mathcal{M}^{\mathrm{sm}}_{k-\ell} \times \mathrm{Sym}^{\ell}(X)}$ on the Uhlenbeck side and replacing it by a specified resolved pushforward on the Gieseker side.

109.5 Donaldson Observables And The μ-Map

The basic degree-four gauge-invariant polynomial in the twisted scalar is

$$\mathcal{O}^{(0)} = \frac{1}{8\pi^2} \operatorname{tr} \phi^2.$$

With the Q-rules above, the first descendants may be chosen as

$$\mathcal{O}^{(1)} = \frac{1}{4\pi^2} \operatorname{tr}(\phi\psi),$$

$$\mathcal{O}^{(2)} = \frac{1}{4\pi^2} \operatorname{tr}\left(\phi F_A + \frac{1}{2}\psi \wedge \psi\right),$$

and the sequence continues to four-forms. They obey the descent equations

$$d\mathcal{O}^{(j)} = \{Q, \mathcal{O}^{(j+1)}\}_{\mathrm{gr}}, \qquad j = 0, 1, 2, 3.$$

For a cycle $\gamma_j \in H_j(X;\mathbb{Z})$, define

$$I(\gamma_j) = \int_{\gamma_j} \mathcal{O}^{(j)}.$$

The Q-cohomological degree of $I(\gamma_j)$ is $4-j$. In the finite dimensional instanton description this insertion represents the Donaldson μ-class

$$\mu(\gamma_j) \in H^{4-j}(\mathcal{M}(P,g);\mathbb{Q}).$$

If $\mathbb{P} \to X \times \mathcal{M}(P,g)$ denotes a universal bundle over a smooth irreducible locus, then the class can be written as

$$\mu(\gamma_j) = -\frac{1}{4} p_1(\operatorname{ad}\mathbb{P})/\gamma_j,$$

where the slash denotes slant product with γ_j. This formula is a differential-geometric version of the descent construction. In particular, for a point $x \in X$, $\mu(x)$ has degree four, and for a surface $\Sigma \subset X$, $\mu(\Sigma)$ has degree two.

Given homology classes $\gamma_{j_1}, \ldots, \gamma_{j_r}$, the Donaldson correlator in the smooth compact case is the pairing

$$\langle I(\gamma_{j_1}) \cdots I(\gamma_{j_r}) \rangle_{P,g} = \int_{\overline{\mathcal{M}}(P,g)} \mu(\gamma_{j_1}) \smile \cdots \smile \mu(\gamma_{j_r})$$

when

$$\sum_{\alpha=1}^{r} (4 - j_\alpha) = \dim_{\mathrm{vir}} \mathcal{M}(P,g).$$

If the total degree differs, the correlator vanishes after the usual degree-selection rule, apart from contact-term and reducible-wall phenomena specified by the compactified theory.

109.6 Spin^c Structures And Monopole Equations

A Spin^c structure $\mathfrak{s}$ on X consists of rank-two Hermitian bundles $S^\pm_{\mathfrak{s}}$, a determinant line

$$L_{\mathfrak{s}} = \det S^+_{\mathfrak{s}} = \det S^-_{\mathfrak{s}},$$

and Clifford multiplication

$$\rho : T^*X \longrightarrow \operatorname{Hom}(S^+_{\mathfrak{s}}, S^-_{\mathfrak{s}})$$

compatible with the metric. The characteristic class

$$c_1(\mathfrak{s}) = c_1(L_{\mathfrak{s}}) \in H^2(X;\mathbb{Z})$$

is characteristic:

$$c_1(\mathfrak{s}) \equiv w_2(TX) \pmod 2.$$

Proposition 109.6 (Spin^c structures as characteristic lifts)**.** *On an oriented smooth four-manifold X, the set* Spin$^c(X)$ *of isomorphism classes of* Spin^c *structures is a torsor for $H^2(X;\mathbb{Z})$. Tensoring $\mathfrak{s}$ by a Hermitian line bundle $M \to X$ gives a new* Spin^c *structure $\mathfrak{s} \otimes M$ with*

$$c_1(\mathfrak{s} \otimes M) = c_1(\mathfrak{s}) + 2c_1(M). \tag{109.12}$$

The image of the map

$$c_1 : \mathrm{Spin}^c(X) \longrightarrow H^2(X;\mathbb{Z})$$

is the affine set of integral characteristic classes

$$\{c \in H^2(X;\mathbb{Z}) \mid c \equiv w_2(TX) \pmod 2\}. \tag{109.13}$$

If $H^2(X;\mathbb{Z})$ has two-torsion, distinct Spin^c *structures can have the same first Chern class; the structure, not only c_1, is then part of the data.*

Proof. Existence of Spin^c structures on oriented smooth four-manifolds is the topological fact $W_3(TX) = \beta(w_2(TX)) = 0$; this is equivalent to the existence of an integral characteristic lift of $w_2(TX)$. The group $\mathrm{Spin}^c(4)$ is

$$\mathrm{Spin}^c(4) = (\mathrm{Spin}(4) \times U(1))/\{\pm(1,1)\}.$$

A Spin^c structure lifting the oriented frame bundle can therefore be tensored by any principal $U(1)$-bundle, equivalently by a Hermitian line bundle M. This action is free and transitive because the difference between two lifts of the same oriented frame bundle is exactly a $U(1)$-bundle. The determinant representation squares the additional $U(1)$ factor, so tensoring by M changes the determinant line by

$$L_{\mathfrak{s}\otimes M} = L_{\mathfrak{s}} \otimes M^{\otimes 2},$$

which proves (109.12). The reduction of $c_1(L_{\mathfrak{s}})$ modulo two is the obstruction $w_2(TX)$ to a spin lift, so every $c_1(\mathfrak{s})$ is characteristic. Conversely, if c is another integral lift of $w_2(TX)$, then $c - c_1(\mathfrak{s})$ lies in the kernel of reduction modulo two. The exact sequence associated to

$$0 \longrightarrow \mathbb{Z} \xrightarrow{\times 2} \mathbb{Z} \longrightarrow \mathbb{Z}_2 \longrightarrow 0$$

identifies this kernel with $2H^2(X;\mathbb{Z})$, so $c = c_1(\mathfrak{s}) + 2c_1(M)$ for some line bundle M. If $2c_1(M) = 0$, tensoring by M leaves the first Chern class unchanged, which is the stated two-torsion caveat. $\square$

For a unitary connection B on $L_{\mathfrak{s}}$, the Dirac operator is

$$\not{D}_B : \Gamma(S^+_{\mathfrak{s}}) \longrightarrow \Gamma(S^-_{\mathfrak{s}}).$$

Let $q \in \Gamma(S^+_{\mathfrak{s}})$. The quadratic map

$$\sigma : S^+_{\mathfrak{s}} \longrightarrow \Lambda^{2,+}T^*X \otimes i\mathbb{R}$$

is defined by

$$\rho(\sigma(q)) = (qq^\dagger)_0,$$

where $(qq^\dagger)_0$ is the traceless Hermitian endomorphism of $S^+_{\mathfrak{s}}$ obtained from the rank-one endomorphism $v \mapsto q\,\langle q, v\rangle$. This equation fixes the normalization of σ used below.

The unperturbed Seiberg-Witten equations are

$$\not{D}_B q = 0, \qquad F^+_B = \sigma(q).$$

A perturbation by a self-dual imaginary two-form η^+ gives

$$\not{D}_B q = 0, \qquad F^+_B = \sigma(q) + \eta^+.$$

The gauge group is

$$\mathcal{G}_L = C^\infty(X, U(1)),$$

acting by

$$u \cdot (B, q) = (B - u^{-1}du,\, uq).$$

The moduli space is

$$\mathcal{M}_{\mathrm{SW}}(\mathfrak{s}, g, \eta^+) = \{(B, q) \mid \not{D}_B q = 0,\ F_B^+ = \sigma(q) + \eta^+\}/\mathcal{G}_L.$$

The linearized, gauge-fixed elliptic operator at a solution is

$$\mathcal{D}_{(B,q)} : \Omega^1(X; i\mathbb{R}) \oplus \Gamma(S_{\mathfrak{s}}^+) \longrightarrow \Omega^0(X; i\mathbb{R}) \oplus \Omega^{2,+}(X; i\mathbb{R}) \oplus \Gamma(S_{\mathfrak{s}}^-).$$

Its index is the expected dimension of the monopole moduli space.

Index of the monopole deformation problem. For a Spin^c structure $\mathfrak{s}$, the expected dimension of the Seiberg-Witten moduli space is

$$d_{\mathrm{SW}}(\mathfrak{s}) = \frac{c_1(\mathfrak{s})^2 - \big(2\chi(X) + 3\sigma(X)\big)}{4}.$$

The real index of the Dirac part is twice the complex index:

$$2 \operatorname{ind}_{\mathbb{C}} \not{D}_B = 2\int_X \widehat{A}(TX) e^{c_1(\mathfrak{s})/2} = \frac{c_1(\mathfrak{s})^2 - \sigma(X)}{4}.$$

The Abelian gauge-fixing and self-dual curvature operator

$$d^* \oplus d^+ : \Omega^1(X; i\mathbb{R}) \longrightarrow \Omega^0(X; i\mathbb{R}) \oplus \Omega^{2,+}(X; i\mathbb{R})$$

has index

$$-(1 - b_1(X) + b_2^+(X)).$$

Adding the two real indices gives

$$\frac{c_1(\mathfrak{s})^2 - \sigma(X)}{4} - (1 - b_1(X) + b_2^+(X)).$$

The identity

$$2\chi(X) + 3\sigma(X) = 4(1 - b_1(X) + b_2^+(X)) + \sigma(X)$$

converts this expression to

$$\frac{c_1(\mathfrak{s})^2 - \big(2\chi(X) + 3\sigma(X)\big)}{4}.$$

109.7 Compactness Input From The Weitzenbock Identity

The monopole equations have compactness properties stronger than the instanton equations because the spinor obeys a nonlinear elliptic equation with a quartic term. The Dirac Weitzenbock identity is

$$\not{D}_B^* \not{D}_B q = \nabla_B^* \nabla_B q + \frac{s_g}{4} q + \frac{1}{2}\rho(F_B^+)q,$$

where s_g is the scalar curvature. Pairing with q, integrating over X, and using $\not{D}_B q = 0$ gives

$$0 = \int_X \left(|\nabla_B q|^2 + \frac{s_g}{4}|q|^2 + \frac{1}{2}\langle \rho(F_B^+)q, q\rangle \right) d\,\mathrm{vol}_g\,.$$

With the normalization $\rho(\sigma(q)) = (qq^\dagger)_0$, the unperturbed curvature equation gives

$$\frac{1}{2}\langle \rho(F_B^+)q, q\rangle = \frac{1}{4}|q|^4.$$

Thus solutions obey

$$\int_X \left(|\nabla_B q|^2 + \frac{s_g}{4}|q|^2 + \frac{1}{4}|q|^4 \right) d\,\mathrm{vol}_g = 0$$

in the unperturbed case. With perturbation η^+, the right side is controlled by the L^2-norm of η^+ and the negative part of scalar curvature. Elliptic bootstrapping then bounds q and F_B^+, while the topological identity fixing $c_1(L_{\mathfrak{s}})$ controls the anti-self-dual component modulo gauge. This is the analytic source of compactness for the monopole moduli space after excluding reducible solutions by a generic perturbation when the usual chamber hypotheses allow it.

109.8 Seiberg-Witten Invariants And Basic Classes

Assume $b_2^+(X) > 1$, choose a homology orientation, and choose generic metric/perturbation data so that the monopole moduli spaces are cut out transversely and contain no reducible solutions in the relevant classes. If $\mathfrak{s}$ has expected dimension $d_{\mathrm{SW}}(\mathfrak{s}) = 0$, its Seiberg-Witten invariant is the signed count

$$\mathrm{SW}_X(\mathfrak{s}) = \#_{\mathrm{or}}\, \mathcal{M}_{\mathrm{SW}}(\mathfrak{s}, g, \eta^+). \tag{109.14}$$

For positive expected dimension, the invariant pairs the fundamental cycle of the compact oriented monopole moduli space with the standard cohomology classes obtained from the universal $U(1)$ bundle and, when $b_1(X) > 0$, from $H_1(X)$. In this chapter the zero-dimensional case is the main one because it is the simple-type sector appearing in Witten's comparison.

Definition 109.7 (Seiberg-Witten basic class and simple type)**.** An integral class $K \in H^2(X;\mathbb{Z})$ is a Seiberg-Witten basic class if $K = c_1(\mathfrak{s})$ for a Spin^c structure $\mathfrak{s}$ whose Seiberg-Witten invariant is nonzero. The four-manifold has Seiberg-Witten simple type if every basic class satisfies

$$d_{\mathrm{SW}}(\mathfrak{s}) = 0, \qquad \text{equivalently} \qquad K^2 = 2\chi(X) + 3\sigma(X). \tag{109.15}$$

The adjective "basic" is not a synonym for "allowed." Allowed Spin^c structures are the characteristic lifts of Proposition 109.6. Basic classes are the much smaller subset detected by a nonzero monopole count or by the higher-dimensional monopole pairings. The Weitzenbock estimate gives the compactness input for each fixed characteristic class; the finiteness of nonzero basic classes is a global theorem of the Seiberg-Witten invariant construction.

Example 109.8 (K3, elliptic surfaces, and blow-up bookkeeping)**.** For a K3 surface,

$$\chi = 24, \qquad \sigma = -16, \qquad 2\chi + 3\sigma = 0.$$

The only Seiberg-Witten basic class is $K = 0$, with invariant ± 1 after a homology-orientation choice. Hence the simple-type dimension condition is saturated exactly:

$$K^2 = 0 = 2\chi + 3\sigma.$$

For the relatively minimal simply connected elliptic surface $E(n)$ with no multiple fibers and $n \geq 2$,

$$\chi(E(n)) = 12n, \qquad \sigma(E(n)) = -8n, \qquad 2\chi + 3\sigma = 0.$$

Let F be the fiber class. Since $F^2 = 0$, the classes

$$K_j = (n - 2 - 2j)F, \qquad j = 0, \ldots, n-2, \tag{109.16}$$

all have square zero. With an orientation convention fixed, their Seiberg-Witten coefficients are encoded by

$$\sum_K \mathrm{SW}_{E(n)}(K)\, \mathrm{e}^K = \left(\mathrm{e}^F - \mathrm{e}^{-F}\right)^{n-2}. \tag{109.17}$$

The case $n = 2$ is K3. The formula records both the location of the basic classes and their binomial coefficients; changing the homology orientation multiplies all coefficients by a common sign.

If $\widetilde{X} = X \# \overline{\mathbb{CP}}^2$ and E is the exceptional class with $E^2 = -1$, then

$$\chi(\widetilde{X}) = \chi(X) + 1, \qquad \sigma(\widetilde{X}) = \sigma(X) - 1.$$

Thus $2\chi + 3\sigma$ decreases by one. If $K^2 = 2\chi(X) + 3\sigma(X)$, then

$$(K \pm E)^2 = K^2 - 1 = 2\chi(\widetilde{X}) + 3\sigma(\widetilde{X}). \tag{109.18}$$

The blow-up formula for Seiberg-Witten invariants gives

$$\mathrm{SW}_{\widetilde{X}}(K + E) = \mathrm{SW}_{\widetilde{X}}(K - E) = \mathrm{SW}_X(K) \tag{109.19}$$

up to the same global orientation convention. This example is a useful normalization check: the dimension formula, basic-class positions, and coefficient doubling are independent pieces of data.

109.9 Stable Cohomotopy Refinement And Furuta's Constraint

The ordinary Seiberg-Witten invariant is an integer obtained after choosing perturbations and counting or pairing with a finite-dimensional moduli space. There is a sharper object before this integer is extracted. After Sobolev completion and Coulomb-slice gauge fixing, the monopole equations define a Fredholm map with compact nonlinear part, called the monopole map. Its finite-dimensional approximations define a stable cohomotopy class. The ordinary Seiberg-Witten invariant is obtained from this stable cohomotopy class by applying the appropriate Hurewicz-type map and evaluating on the orientation class.

Monopole map before taking its degree. Fix a background connection B_0 on $L_{\mathfrak{s}}$, write $B = B_0 + b$, and impose the Coulomb condition $d^*b = 0$. After Sobolev completion, the Seiberg-Witten equations are encoded by a map

$$\mathcal{F} : L^2_k\big(i\Omega^1(X) \oplus \Gamma(S^+_{\mathfrak{s}})\big) \longrightarrow L^2_{k-1}\big(i\Omega^0(X) \oplus i\Omega^{2,+}(X) \oplus \Gamma(S^-_{\mathfrak{s}})\big) \tag{109.20}$$

of the form

$$\mathcal{F}(b,q) = \Big(d^*b,\ d^+b - \sigma(q) + F^+_{B_0} - \eta^+,\ \ \not{D}_{B_0} q + \rho(b)q\Big). \tag{109.21}$$

Thus

$$\mathcal{F} = L + C, \qquad L = d^* \oplus d^+ \oplus\ \not{D}_{B_0}, \tag{109.22}$$

where L is Fredholm and C is compact on bounded sets after Sobolev embedding and Rellich compactness. The Weitzenbock estimate in the previous section supplies the a priori bound needed to restrict to a large ball whose boundary contains no zeroes of $\mathcal{F}$, after the perturbation has been chosen away from reducible walls. Choose finite-dimensional subspaces

$$W_\Lambda \subset L^2_{k-1}\big(i\Omega^0 \oplus i\Omega^{2,+} \oplus \Gamma(S^-_{\mathfrak{s}})\big)$$

spanned by low eigenmodes of LL^*, and set

$$V_\Lambda = L^{-1}(W_\Lambda).$$

For sufficiently large Λ, the projected map

$$\mathcal{F}_\Lambda : V_\Lambda \longrightarrow W_\Lambda \tag{109.23}$$

has the same zero set as $\mathcal{F}$ in the chosen ball and gives a based map between one-point compactifications

$$S^{V_\Lambda} \longrightarrow S^{W_\Lambda}. \tag{109.24}$$

Increasing Λ suspends this map by finite-dimensional pieces of the Fredholm operator. The stable homotopy class of the resulting map is the object refined by Bauer and Furuta. The ordinary integer invariant is obtained only after applying a cohomological orientation map to this stable class; it is therefore a shadow, not the primary object.

Quoted Theorem 109.9 (Bauer-Furuta)**.** *For a closed oriented smooth four-manifold with a fixed* Spin^c *structure, the finite-dimensional approximation of the Seiberg-Witten monopole map defines a stable cohomotopy invariant*

$$\mathrm{BF}_X(\mathfrak{s}). \tag{109.25}$$

The ordinary Seiberg-Witten invariant is the image of $\mathrm{BF}_X(\mathfrak{s})$ *under the corresponding stable cohomotopy to cohomology map, with the usual orientation conventions.*

The theorem packages the independence of all auxiliary choices in the construction above: Sobolev index, background connection, radius of the isolating ball, spectral cutoff, and generic perturbation inside a chamber. The proof is not a formal consequence of the integer Seiberg-Witten invariant. It uses properness on the chosen bounded region, homotopy invariance of finite-dimensional approximations, and compatibility of the suspension coordinates with the Fredholm index. The monograph uses this theorem as a pure four-manifold input adjacent to QFT, while the displayed monopole-map construction records exactly what additional structure an eventual non-perturbative twisted-QFT construction would have to recover.

Quoted Theorem 109.10 (Furuta $10/8 + 2$ inequality)**.** *Let X be a closed smooth spin four-manifold with $b_2^+(X) > 0$. Then*

$$b_2(X) \geq \frac{10}{8}\,|\sigma(X)| + 2. \tag{109.26}$$

Why stable cohomotopy can imply a smooth constraint. When X is spin, the spinor bundles carry a quaternionic structure and the monopole map is equivariant for the group $\mathrm{Pin}(2) \subset \mathbb{H}^\times$ generated by $U(1)$ and an element j with $jzj^{-1} = \bar{z}$. The finite-dimensional approximation therefore produces a Pin(2)-equivariant stable map between representation spheres. The virtual difference of these representation spheres is fixed by the Dirac index and by $b_2^+(X)$; for a spin four-manifold the Dirac index is $-\sigma(X)/8$ as a quaternionic index. Furuta's theorem applies equivariant stable homotopy, in particular the Pin(2) representation-theoretic obstruction to such a stable map, to force (109.26). Thus the inequality is not derived from a numerical monopole count. It uses the extra equivariant information retained by the Bauer-Furuta refinement.

The relevance for the present chapter is conceptual and structural. The Donaldson-Witten path integral suggests that four-manifold invariants should arise from a cohomological field theory, but ordinary integer invariants can forget stable homotopy information in the monopole map. The Bauer-Furuta class records part of that information. Furuta's inequality is a theorem extracted from this stronger structure in the spin case; for K3,

$$b_2 = 22, \qquad |\sigma| = 16,$$

and (109.26) is saturated:

$$22 = \frac{10}{8} \cdot 16 + 2.$$

The monograph treats these as rigorous four-manifold theorems adjacent to the QFT comparison. A future theorem-level QFT construction should explain which refinement of the twisted path integral sees the stable cohomotopy class rather than only its integer shadow.

109.10 The Coulomb-Branch Description

The Donaldson-Witten theory is the twist of pure $\mathcal{N} = 2$ Yang–Mills theory. Its local supersymmetric Coulomb-branch data for gauge algebra $\mathfrak{su}(2)$ were developed in Chapter 91. The gauge-invariant coordinate is

$$u = \langle \operatorname{tr} \phi^2 \rangle,$$

and the special coordinates $(a_D(u), a(u))$ determine the Abelian coupling

$$\tau(u) = \frac{da_D/du}{da/du}.$$

The Coulomb branch has singular fibers where a BPS monopole or dyon becomes massless. Near such a fiber, the Wilsonian effective theory contains an Abelian vector multiplet together with the light charged hypermultiplet. The topological twist of this local Abelian theory has localization equations of Seiberg-Witten monopole type.

The cohomological path integral on a four-manifold receives three kinds of terms:

instanton description	intersection pairing on ASD moduli spaces,
Coulomb branch	integral over u with Abelian zero modes and contact terms,
singular fibers	monopole or dyon Seiberg-Witten invariants.

For $b_2^+(X) > 1$, the Coulomb-branch integral has no chamber-wall contribution in the generic situation used for the simple-type comparison. For $b_2^+(X) = 1$, the u-plane contribution and wall crossing are part of the invariant. The comparison requires the contact terms of the Abelian effective action because products of descent observables collide in the low-energy description.

109.11 Chambers, Reducibles, And Wall Crossing

When $b_2^+(X) = 1$, a metric g determines a ray

$$\mathbb{R}_{>0}\,\omega_g \subset \{v \in H^2(X;\mathbb{R}) \mid Q_X(v,v) > 0\} \tag{109.27}$$

by the self-dual harmonic line. A chamber is a connected component of the positive cone after removing the walls on which reducible connections can occur. To describe those walls without hiding the bundle data, take a rank-two Hermitian bundle $E \to X$ with fixed determinant and write

$$w = c_1(E), \qquad p = c_1(E)^2 - 4c_2(E) = p_1(\mathfrak{su}(E)).$$

A reducible splitting has the form

$$E = L \oplus (\det E \otimes L^{-1}),$$

and the associated characteristic wall class is

$$\lambda = 2c_1(L) - c_1(E). \tag{109.28}$$

It satisfies

$$\lambda \equiv w \pmod 2, \qquad \lambda^2 = p. \tag{109.29}$$

The reducible connection is anti-self-dual precisely when the self-dual harmonic projection of λ vanishes, equivalently

$$\langle \lambda, \omega_g \rangle = 0 \tag{109.30}$$

in the $b_2^+ = 1$ chamber picture.

Quoted Theorem 109.11 (Donaldson wall crossing in link form)**.** *Let a generic one-parameter path of metrics cross exactly one wall W_λ transversely and let z be a homogeneous Donaldson insertion whose degree matches the virtual dimension. The jump of Donaldson invariants is the oriented link pairing at the reducible stratum:*

$$D^w_{X,+}(z) - D^w_{X,-}(z) = \varepsilon(\lambda) \int_{\mathbb{L}_\lambda} \mu_\lambda(z). \tag{109.31}$$

Here $\mathbb{L}_\lambda$ is the link of the reducible in the parameterized compactified moduli space, $\mu_\lambda(z)$ is the restriction of the universal μ-class expression to this link, and $\varepsilon(\lambda)$ is the orientation sign determined by the direction in which the period point crosses $\langle \lambda, \omega \rangle = 0$. Equivalently, the right hand side is the Kotschick-Morgan wall-crossing polynomial

$$\mathrm{WC}^X_\lambda(z) = \varepsilon(\lambda) \int_{\mathbb{L}_\lambda} \mu_\lambda(z), \tag{109.32}$$

whose coefficients are universal functions of the intersection form, the class λ, the lift w, and the degree of z.

Mechanism of the link formula. Let

$$\mathcal{W} = \{(t, A) \mid F^+_{A,g_t} = 0\}/\mathcal{G}$$

be the parameterized moduli problem for the metric path g_t. Away from reducibles and compactification strata, $\mathcal{W}$ is the zero set of a Fredholm section whose index is one larger than the index of the fixed-metric ASD problem. Truncate small neighborhoods of the reducible stratum and of the other Uhlenbeck boundary strata. The resulting oriented space has boundary of the form

$$\partial\mathcal{W}^{\mathrm{tr}} = \mathcal{M}_+ \sqcup (-\mathcal{M}_-) \sqcup \mathbb{L}_\lambda \sqcup \{\text{other compactification faces}\}, \tag{109.33}$$

with the last faces absent or cancelled under the hypotheses of the theorem. The universal Donaldson class representing z extends over $\mathcal{W}^{\mathrm{tr}}$ and is closed there. Stokes' theorem therefore gives

$$0 = \int_{\partial\mathcal{W}^{\mathrm{tr}}} \mu(z) = D^w_{X,+}(z) - D^w_{X,-}(z) + \varepsilon_{\mathrm{link}} \int_{\mathbb{L}_\lambda} \mu_\lambda(z),$$

which is (109.31) after fixing the convention $\varepsilon(\lambda) = -\varepsilon_{\mathrm{link}}$. The sign is the orientation comparison between the outward normal of the deleted tubular neighborhood and the direction in which the period point crosses $\langle\lambda, \omega\rangle = 0$.

The local model of the deleted neighborhood is obtained by decomposing the bundle near a reducible splitting

$$E = L \oplus (\det E \otimes L^{-1}).$$

The diagonal part gives the Abelian stabilizer and the wall equation; the off-diagonal part gives the normal ASD complex. Its finite-dimensional kernel, cokernel, and stabilizer quotient determine the link $\mathbb{L}_\lambda$. Restricting the universal μ-classes to this normal model leaves only the intersection form, the wall class λ, the lift w, and the topological numbers entering the index. This is the geometric reason that the right hand side can be written as the universal Kotschick-Morgan polynomial rather than as a new invariant attached to each metric path.

This is the form of the wall-crossing theorem that is most useful for QFT. It identifies the jump with an actual boundary integral. In BV language, the two chamber invariants are the two sides of a one-parameter family of pushforwards, and the link $\mathbb{L}_\lambda$ is the boundary component where the pushforward fails to be closed. Thus wall crossing is not an exception to metric independence; it is the boundary term required by the Uhlenbeck BV-boundary calculation above.

Remark 109.12 (Kotschick-Morgan polynomial normal form). In the situation of Theorem 109.11, restrict for simplicity to insertions generated by a point class x and a surface source $h \in H_2(X;\mathbb{R})$. For each pair (r, n) with the correct Donaldson degree, the wall-crossing functional has the universal form

$$\mathrm{WC}^X_\lambda(x^r h^n) = \varepsilon(\lambda) \sum_{\substack{j,\ell\geq 0\\ j+2\ell\leq n}} c_{r,n;j,\ell}(p, w^2, \lambda^2, \chi, \sigma)\, \langle\lambda, h\rangle^{\,n-j-2\ell} Q_X(h,h)^\ell \langle w, h\rangle^j. \tag{109.34}$$

The coefficients are universal rational numbers after the Donaldson normalization and orientation convention have been fixed. The allowed monomials are exactly the scalar polynomials in h built from the link data (Q_X, λ, w) with total Donaldson surface degree $2n$.

The link of a reducible is constructed from the normal complex to the reducible stratum and the universal μ-classes restricted to it. After the determinant line and orientation of the crossing are fixed, the only homological tensors available on $H_2(X;\mathbb{R})$ are the intersection form Q_X, the wall class λ, and the fixed lift w. Therefore the restriction of a homogeneous insertion $x^r h^n$ to the link is an ordinary polynomial in the three scalar contractions

$$Q_X(h,h), \qquad \langle\lambda,h\rangle, \qquad \langle w,h\rangle.$$

The exponent of $Q_X(h,h)$ consumes two surface insertions, while each linear contraction consumes one. This gives the degree constraint $j+2\ell \le n$. Universality follows because the local model of the reducible link depends on the four-manifold only through the topological numbers $p, w^2, \lambda^2, \chi, \sigma$ and the intersection pairing. The theorem of Kotschick and Morgan computes these universal coefficients by evaluating the link integral; (109.34) is the coordinate form of that computation needed for comparison with the u-plane boundary.

Chamber jump as a BV boundary term. Let ρ_t be a regulated Donaldson-Witten BV semidensity along a generic metric path g_t, $t \in [-1,1]$, crossing a single reducible wall λ at $t=0$. Assume the parameterized moduli problem is smooth away from the reducible link and all insertion classes have been extended to the truncated compactification. Then

$$D^w_{X,+}(z) - D^w_{X,-}(z) = \mathcal{B}_{\mathbb{L}_\lambda}(\rho z), \tag{109.35}$$

with the sign convention of (109.31). If the path crosses several walls, the jump is the signed sum of the corresponding link functionals.

Under these hypotheses, Stokes' theorem applies to the parameterized compactified moduli space with small collar neighborhoods of reducibles removed. The ordinary boundary at $t=1$ gives $D^w_{X,+}(z)$, the ordinary boundary at $t=-1$ gives $-D^w_{X,-}(z)$, and the new boundary is the link $\mathbb{L}_\lambda$. In the finite-dimensional BV model, include the metric parameter among the residual variables and apply (111.12) to the residual cycle with the reducible collar removed. Its boundary functional is precisely the localized integral over $\mathbb{L}_\lambda$. The link orientation is exactly the sign $\varepsilon(\lambda)$ in the wall-crossing theorem.

109.12 Observable Map And Contact Terms

The Donaldson generating function is organized by a point variable p and a two-cycle source $S \in H_2(X;\mathbb{R})$:

$$Z_D(p,S) = \left\langle \exp\bigl(p\, I(x) + I(S)\bigr) \right\rangle.$$

Here $I(x)$ has degree four and $I(S)$ has degree two. In the Abelian Coulomb-branch description, the point observable maps to a function of the Coulomb coordinate,

$$I(x) \longmapsto u,$$

whereas the surface observable has a linear term in the Abelian field strength and a quadratic contact term:

$$I(S) \longmapsto \int_S \Omega_u + \frac{1}{2}(S,S)\, T(u).$$

The two-form Ω_u is the appropriate descent two-form in the Abelian effective theory, and $T(u)$ is fixed by compatibility of the low-energy Ward identities, duality transformations, and short-distance collision of two surface descendants. The symbol (S,S) denotes the intersection pairing on $H_2(X;\mathbb{R})$.

At a monopole singularity, the Abelian surface insertion evaluates on the monopole line bundle and gives an exponential weight

$$\exp\big((S,\lambda)\big)$$

for a characteristic class $\lambda = c_1(\mathfrak{s})$ associated with the corresponding Spin^c structure, multiplied by the contact factor coming from $T(u)$. The final comparison formula in simple-type chambers has the general form

$$Z_D(p,S) = e^{Q(S)/2} \sum_{\mathfrak{s}} C_{\mathfrak{s}}\ \mathrm{SW}(\mathfrak{s})\ \exp\big(p\,u_{\mathfrak{s}} + (S,\lambda_{\mathfrak{s}})\big),$$

where $Q(S) = (S,S)$. The constants $C_{\mathfrak{s}}$, the phases, and the choice of chamber depend on the global form of the gauge group, the orientation convention, and the contact-term normalization. In this monograph the displayed expression is treated as a target comparison statement: the rigorous QFT problem is to derive every term from a constructed twisted continuum theory and its Wilsonian flow, rather than to declare the formula from moduli-space geometry alone.

Hypothesis 109.13 (Witten simple-type comparison statement)**.** Let X be a closed connected oriented smooth four-manifold with $b_1(X) = 0$, $b_2^+(X) > 1$, and Seiberg-Witten simple type. Fix the lift w, homology orientation, point-observable convention (109.2), and the trace-delta gauge normalization used in this chapter. The Donaldson-Seiberg-Witten comparison predicts that the reduced Donaldson series has the form

$$\mathbb{D}_X^w(h) = \exp\left(\frac{1}{2}Q_X(h,h)\right) \sum_{K\in\mathcal{B}_{\mathrm{SW}}(X)} A_X^w(K)\,\mathrm{SW}_X(K)\ \exp\big(\langle K,h\rangle\big), \tag{109.36}$$

where $\mathcal{B}_{\mathrm{SW}}(X)$ is the set of Seiberg-Witten basic classes. The phase has the characteristic form

$$A_X^w(K) = C_X\,(-1)^{\frac{1}{2}(w^2+\langle w,K\rangle)} \tag{109.37}$$

when w is chosen so that the exponent is integral. The universal constant C_X depends only on the Euler characteristic, signature, and normalization of Donaldson observables; in the common Moore-Witten normalization it is written as

$$C_X = 2^{\,2+(7\chi(X)+11\sigma(X))/4}. \tag{109.38}$$

Equation (109.36) is a theorem in the mathematical Donaldson/SW comparison under the hypotheses of the relevant comparison theorems, but in this monograph it is also a QFT target: a non-perturbative construction of the twisted four-dimensional gauge theory should derive the same coefficient, phase, contact, and boundary data from Wilsonian flow.

The distinction between (109.4) and (109.36) is important. The first is the Donaldson simple-type structure: there are some Donaldson basic classes with some coefficients. The second identifies those classes and coefficients with Seiberg-Witten monopole invariants. The QFT explanation of that identification is the central RG statement.

Factor ledger for the simple-type comparison. Equation (109.36) contains several pieces with different origins. Keeping them separate prevents the comparison from being read as a single formal substitution:

1. The Donaldson simple-type theorem supplies only the finite exponential shape

$$\exp(Q_X/2)\sum_K a_K^w \exp\langle K,h\rangle$$

after the point-operator normalization is fixed. It does not identify the labels K with monopole basic classes or compute the coefficients a_K^w.

2. The Seiberg-Witten finite-dimensional theory supplies the candidate labels $K = c_1(\mathfrak{s})$, the oriented counts $\mathrm{SW}_X(K)$, and the simple-type vanishing of nonzero-dimensional monopole moduli spaces. It does not by itself produce the Donaldson contact Gaussian, the w-dependent phase, or the universal power of 2.

3. The Abelian low-energy observable map supplies the Gaussian $\exp(Q_X(h,h)/2)$ through the surface-contact term $T(u)$. This is a collision-of-descendants datum in the twisted Abelian theory, not a consequence of the finite monopole count.

4. Electromagnetic-duality determinant lines and the lift w supply the phase $(-1)^{(w^2+\langle w,K\rangle)/2}$. This phase must be matched with the orientation conventions for Donaldson and monopole determinant lines; changing the lift changes the exceptional-class parity as in Example 109.14.

5. The numerical constant C_X comes from the regularized Abelian measure factors, one-loop gravitational terms, and the normalization of Donaldson observables. Its dependence on $\chi(X)$ and $\sigma(X)$ is therefore a determinant-line and contact-normalization claim, not a topological fact following from simple type.

6. Chamber dependence is controlled separately. For $b_2^+ > 1$ the simple-type comparison uses the absence of a residual regular u-plane bulk contribution under the stated hypotheses. For $b_2^+ = 1$, the regularized u-plane boundary and the Donaldson link wall-crossing formula must be matched before a chamber-specific comparison is meaningful.

The open problem below is precisely to construct a single QFT framework in which all six entries arise from the same regulator, anomaly line, Wilsonian flow, and compactification boundary convention.

Proof obligations hidden by the comparison formula. A derivation of Hypothesis 109.13 from QFT would have to prove the following chain of constructions and identifications. First, one needs a non-perturbative construction of the twisted pure $\mathcal{N} = 2$ gauge theory on X, including a regulator or BV/lattice replacement for the gauge-fixed measure, the scalar charge Q, the descent observables $I(x)$ and $I(S)$, and compactification boundary data for the ASD localization locus. Second, the Wilsonian flow must be defined on this cohomological theory in a way compatible with Q and with the anomaly line, and must produce the Seiberg-Witten Coulomb-branch family away from singular fibers with the Abelian contact term $T(u)$. Third, the regular u-plane integral has to be shown to supply only the stated chamber-dependent boundary contribution, with no hidden bulk term for the $b_2^+ > 1$ simple-type situation. Fourth, a neighborhood of each singular fiber must be identified with the twisted Abelian monopole theory, including orientation lines, determinant phases, and the map from surface observables to the monopole determinant line. This is the step that turns the singular-fiber boundary contribution into $\mathrm{SW}_X(K)\exp\langle K,h\rangle$. Finally, the normalization of the point observable, the Gaussian surface contact term, the phase $(-1)^{(w^2+\langle w,K\rangle)/2}$, and the power of 2 in (109.38) must be derived from the same regularized determinant and contact-term conventions, rather than fitted after the fact.

Thus (109.36) is not used below as an unproved physical theorem. It is a precise target statement: each factor in the formula names a separate analytic, topological, or Wilsonian ingredient that a future theorem-level construction must supply.

Finite comparison residual budget. The proof obligations above are not only a list of words. On any finite set of Donaldson insertions they define a comparison budget: a partial construction is meaningful only to the extent that each arrow in the comparison ladder has a controlled residual.

Fix a finite-dimensional test space $\mathcal{T}_N$ generated by finitely many point and surface Donaldson insertions, with norm $\|\cdot\|_{\mathcal{T}}$. Let

$$\mathcal{D}_{\mathrm{UV}}, \quad \mathcal{D}_{\mathrm{ASD}}, \quad \mathcal{D}_{\mathrm{Coul}}, \quad \mathcal{D}_{\mathrm{split}}, \quad \mathcal{D}_{\mathrm{mon}}, \quad \mathcal{D}_{\mathrm{SW}} \in \mathcal{T}_N^{\vee}$$

be the finite linear functionals obtained, respectively, from a regulated twisted UV theory, its ASD localization formula, the regular Coulomb-branch description before singular neighborhoods are separated, the regular u-plane plus raw singular-fiber boundary split, the monopole replacement with raw determinant-line normalization, and the normalized Donaldson–Seiberg-Witten comparison formula. Define

$$R_Q = \mathcal{D}_{\mathrm{UV}} - \mathcal{D}_{\mathrm{ASD}}, \qquad R_{\mathrm{RG}} = \mathcal{D}_{\mathrm{ASD}} - \mathcal{D}_{\mathrm{Coul}}, \tag{109.39}$$

$$R_u = \mathcal{D}_{\mathrm{Coul}} - \mathcal{D}_{\mathrm{split}}, \qquad R_{\mathrm{sing}} = \mathcal{D}_{\mathrm{split}} - \mathcal{D}_{\mathrm{mon}}, \tag{109.40}$$

$$R_{\mathrm{norm}} = \mathcal{D}_{\mathrm{mon}} - \mathcal{D}_{\mathrm{SW}}. \tag{109.41}$$

Then for every $T \in \mathcal{T}_N$,

$$\mathcal{D}_{\mathrm{UV}}(T) - \mathcal{D}_{\mathrm{SW}}(T) = R_Q(T) + R_{\mathrm{RG}}(T) + R_u(T) + R_{\mathrm{sing}}(T) + R_{\mathrm{norm}}(T). \tag{109.42}$$

Consequently, if $|R_\bullet(T)| \le \varepsilon_\bullet \|T\|_{\mathcal{T}}$ for the five residuals above, then

$$|\mathcal{D}_{\mathrm{UV}}(T) - \mathcal{D}_{\mathrm{SW}}(T)| \le (\varepsilon_Q + \varepsilon_{\mathrm{RG}} + \varepsilon_u + \varepsilon_{\mathrm{sing}} + \varepsilon_{\mathrm{norm}})\|T\|_{\mathcal{T}}. \tag{109.43}$$

Indeed, subtract and add the intermediate functionals:

$$\begin{aligned}\mathcal{D}_{\mathrm{UV}} - \mathcal{D}_{\mathrm{SW}} = {} & (\mathcal{D}_{\mathrm{UV}} - \mathcal{D}_{\mathrm{ASD}}) + (\mathcal{D}_{\mathrm{ASD}} - \mathcal{D}_{\mathrm{Coul}}) + (\mathcal{D}_{\mathrm{Coul}} - \mathcal{D}_{\mathrm{split}}) \\ & + (\mathcal{D}_{\mathrm{split}} - \mathcal{D}_{\mathrm{mon}}) + (\mathcal{D}_{\mathrm{mon}} - \mathcal{D}_{\mathrm{SW}}).\end{aligned}$$

Evaluating on T gives (109.42). The bound follows from the triangle inequality and the five declared residual estimates.

The five residuals have separate meanings:

- R_Q measures nonperturbative construction and Q-localization error.
- R_{RG} measures Q-compatible Wilsonian-flow error.
- R_u measures regular u-plane compactification and chamber-boundary error.
- R_{sing} measures singular-fiber replacement by monopole neighborhoods.
- R_{norm} measures contact-term, determinant-phase, and universal-constant normalization error.

A theorem proving (109.36) is the special case in which these five residuals vanish on every finite test space and the finite estimates are compatible as N increases. A controlled physical approximation must state the five residuals rather than quoting the final comparison formula as a single black-box identity.

Example 109.14 (Donaldson-side tables from the comparison statement)**.** The following table is not an independent derivation of the Donaldson–Seiberg-Witten comparison. It is the explicit Donaldson-side output of Hypothesis 109.13 in examples where the Seiberg-Witten basic classes were fixed in Example 109.8. We take $w = 0$ when this is compatible with the displayed parity and choose the common Moore–Witten constant (109.38).

X	$\sum_K \mathrm{SW}_X(K)e^K$	$\mathbb{D}^0_X(h)$
$K3$	1	$\exp(Q_X(h,h)/2)$
$E(n)$	$(e^F - e^{-F})^{n-2}$	$2^{2-n}\exp(Q_X(h,h)/2)(e^{\langle F,h\rangle} - e^{-\langle F,h\rangle})^{n-2}$

For $E(2) = K3$, the second row reduces to the first. For $E(3)$, the Donaldson basic classes predicted by the comparison are $\pm F$ with opposite coefficients in this $w = 0$ convention:

$$\mathbb{D}^0_{E(3)}(h) = \frac{1}{2}\, e^{Q(h,h)/2}\big(e^{\langle F,h\rangle} - e^{-\langle F,h\rangle}\big). \tag{109.44}$$

If $\widetilde{X} = X\#\overline{\mathbb{CP}}^2$, let E be the exceptional cohomology class and choose $e \in H_2(\widetilde{X};\mathbb{R})$ with $Q_{\widetilde{X}}(e,e) = -1$ and $\langle E, e\rangle = 1$. With the lift chosen so that the two exceptional basic classes have the same phase, the comparison gives

$$\mathbb{D}^{\widetilde{w}}_{\widetilde{X}}(h + te) = e^{-t^2/2}\cosh(t)\,\mathbb{D}^w_X(h). \tag{109.45}$$

With the adjacent lift convention the two exceptional phases differ and the factor $\cosh(t)$ is replaced by $\sinh(t)$, up to the common orientation sign. In the exponential generating series this gives an explicit parity table:

$$[t^{2m}]\, e^{-t^2/2}\cosh t = \sum_{r=0}^{m} \frac{(-1)^r}{2^r r!(2m-2r)!}, \qquad [t^{2m+1}]\, e^{-t^2/2}\cosh t = 0, \tag{109.46}$$

$$[t^{2m+1}]\, e^{-t^2/2}\sinh t = \sum_{r=0}^{m} \frac{(-1)^r}{2^r r!(2m+1-2r)!}, \qquad [t^{2m}]\, e^{-t^2/2}\sinh t = 0. \tag{109.47}$$

Thus the even lift has coefficients $1, 0, -1/12, \ldots$ in degrees $0, 2, 4, \ldots$, while the adjacent lift has coefficients $1, -1/3, 1/20, \ldots$ in degrees $1, 3, 5, \ldots$. These numbers are not new invariants; they are the exact exceptional-insertion Taylor coefficients obtained by multiplying the contact Gaussian by the two exceptional basic-class phases. The point of writing the table is that the constants, phases, Gaussian factor, basic-class locations, and blow-up square shift are separate pieces of information; none is determined by the word "simple type" alone.

109.13 The u-Plane Integral And Boundary Contributions

For $b_2^+(X) = 1$, the Coulomb-branch contribution cannot be suppressed by the simple-type argument. The low-energy path integral over the regular part of the u-plane is written, after fixing the Donaldson observable normalization used in (109.36), as

$$Z^w_u(p, S; \omega) = \int_{\mathcal{B}^{\mathrm{reg}}_u} da \wedge d\bar{a}\, A(u)^{\chi(X)} B(u)^{\sigma(X)} \Psi_{\Gamma,w,\omega}(\tau,\bar{\tau}; S)\exp\big(2pu + S^2 T(u)\big)\,. \tag{109.48}$$

Here $\mathcal{B}_u^{\mathrm{reg}}$ is the Coulomb branch with the singular fibers removed, a is a local special coordinate,

$$\tau(u) = \frac{da_D/du}{da/du},$$

$\Gamma = H^2(X;\mathbb{Z})/\mathrm{torsion}$ with intersection pairing Q_X, and ω is the chamber period point in (109.27). The functions

$$A(u) = \alpha\left(\frac{du}{da}\right)^{1/2}, \qquad B(u) = \beta\,\Delta(u)^{1/8} \tag{109.49}$$

encode the gravitational measure factors of the Abelian twisted effective theory; $\Delta(u)$ is the discriminant of the Seiberg-Witten family and α, β are convention-dependent constants. The factor $\Psi_{\Gamma,w,\omega}$ is the Siegel-Narain theta kernel obtained by summing over Abelian fluxes shifted by $w/2$, with the positive and negative projections defined by ω. Its dependence on ω is the analytic source of wall crossing. The contact term $T(u)$ is the same surface-observable collision term that appears in the observable map above.

Definition 109.15 (Regularized u-plane integral)**.** Let $\Omega_u^w(p,S;\omega)$ denote the two-form integrand in (109.48). Choose small disjoint disks

$$D_\epsilon(u_\alpha)$$

around the singular fibers u_α of the Seiberg-Witten family and, in a coordinate $q = e^{2\pi i\tau}$ near the weak-coupling cusp, remove the region $|q| < \epsilon_\infty$. The regulated domain is

$$\mathcal{B}_{u,\epsilon}^{\mathrm{reg}} = \mathcal{B}_u \setminus \left(\bigcup_\alpha D_\epsilon(u_\alpha) \cup \{|q| < \epsilon_\infty\}\right).$$

The regulated Coulomb contribution is

$$Z_{u,\epsilon}^w(p,S;\omega) = \int_{\mathcal{B}_{u,\epsilon}^{\mathrm{reg}}} \Omega_u^w(p,S;\omega). \tag{109.50}$$

A renormalized u-plane contribution means a limit

$$Z_u^w = \lim_{\epsilon\to 0}\left[Z_{u,\epsilon}^w + \sum_\alpha C_{\alpha,\epsilon}^{\mathrm{sing}} + C_{\infty,\epsilon}^{\mathrm{cusp}}\right], \tag{109.51}$$

when the boundary counterterms $C_{\alpha,\epsilon}^{\mathrm{sing}}$ and $C_{\infty,\epsilon}^{\mathrm{cusp}}$ have been derived from the corresponding monopole/dyon and weak-coupling effective theories. They are not arbitrary subtractions; they are part of the declared low-energy regularization datum.

Wall-normal factor in the theta kernel. Only one elementary analytic mechanism is needed to understand why the u-plane wall crossing is localized on fluxes satisfying the wall equation. Fix a lattice flux

$$\lambda \in \Gamma + \frac{w}{2}$$

and write

$$x_\lambda(\omega) = \langle \lambda, \omega\rangle$$

for its component along the positive period ray. The complete Siegel-Narain kernel contains smooth factors in u, S, and a wall-normal factor whose local model is

$$E_t(x) = \mathrm{erf}(\sqrt{\pi t}\, x), \qquad t > 0. \tag{109.52}$$

The parameter t is proportional to the positive imaginary part of the Abelian coupling in the normal direction. This model records the only feature relevant for the wall jump: as $t \to \infty$,

$$E_t(x) \to \mathrm{sgn}(x) \qquad (x \neq 0),$$

while

$$\frac{dE_t}{dx} = 2\sqrt{t}\, \exp(-\pi t x^2) \tag{109.53}$$

is a delta sequence of total mass 2:

$$\int_{-\infty}^{\infty} 2\sqrt{t}\, \exp(-\pi t x^2)\, \mathrm{d}x = 2.$$

Thus changing the chamber by moving ω through $x_\lambda(\omega) = 0$ changes the corresponding completed sign factor by exactly 2. Flux sectors with $x_\lambda(\omega) \neq 0$ remain smooth in ω; the only singular chamber dependence comes from the codimension one locus $x_\lambda = 0$. This is the local analytic content behind the phrase that wall crossing is supported on reducible fluxes. The global statement still requires the remaining factors in the u-plane integrand, the singular-fiber counterterms, and the determinant-line orientation matching to be controlled.

Controlled Approximation 109.16 (Wall crossing from the u-plane boundary)**.** Assume that the Abelian low-energy description is valid on $\mathcal{B}_u^{\mathrm{reg}}$, that the singular-fiber contributions are computed by the corresponding monopole or dyon Seiberg-Witten theories, and that the theta kernel has the standard Gaussian decay away from walls. When ω crosses the wall $\langle \lambda, \omega \rangle = 0$, the discontinuity of Z_u^w is a boundary term supported by the flux sector λ, and equals the link wall-crossing functional WC_λ^X after the contact normalization and determinant-line phase are matched.

Only the positive/negative decomposition of the lattice vector in $\Psi_{\Gamma,w,\omega}$ changes discontinuously at a wall. The local model (109.52)–(109.53) shows that the chamber jump of a completed sign factor is a delta-supported normal contribution with total jump 2. Away from $\lambda_+ = 0$, the Gaussian factor in the theta kernel gives a smooth ω-dependent integral. Crossing the wall changes the prescription for the sector with $\lambda_+ = 0$; differentiating with respect to the period point produces a total $\bar{\partial}$-term on the u-plane. By Stokes' theorem the change is therefore a sum of boundary contributions from the cusps and singular fibers. The singular-fiber boundaries are precisely the monopole/dyon effective theories, while the cusp and reducible boundary combine into the Donaldson wall link. Matching determinant-line orientations and the contact term $T(u)$ identifies the result with (109.32). This proves the conditional statement: the analytic equality rests on the stated validity of the Abelian Wilsonian description and on the matching of its measure factors.

109.14 Comparison As A QFT Statement

The comparison can be formulated as a precise datum. Fix:

UV theory	twisted pure $\mathcal{N} = 2$ $SU(2)$ gauge theory on X,
observable algebra	Q-cohomology generated by Donaldson descent classes,
metric chamber	a chamber for $b_2^+(X) = 1$ or the $b_2^+ > 1$ regime,
Wilsonian coordinate	u and the Abelian special geometry near each singular fiber,
contact prescription	$T(u)$ and all collision counterterms for descent insertions,
IR localization	Spin^c monopole moduli spaces with orientations.

The QFT comparison asserts equality between the ultraviolet cohomological correlators and the sum of the Coulomb-branch integral plus monopole contributions computed from this datum. A theorem-level derivation would therefore contain the following ingredients:

construction	a four-dimensional twisted continuum gauge theory,
Ward identities	Q-invariance, descent, and metric variation including contacts,
RG control	flow from the UV description to the Abelian Coulomb chart,
singular fiber analysis	derivation of the monopole effective theory and its measure,
compactness	finite-dimensional compactified moduli spaces and boundary terms,
orientation and phases	matching of determinant lines and electromagnetic duality phases.

The finite-dimensional Donaldson and Seiberg-Witten invariants are rigorous objects once their compactifications, orientations, perturbations, and wall crossing conventions are fixed. The physical comparison supplies a deep explanation by RG, and the present formulation isolates the additional analytic QFT construction needed to turn that explanation into a theorem inside four-dimensional quantum field theory.

Open Problem 109.17 (Donaldson-SW QFT comparison). Construct the Donaldson-Witten theory and its Coulomb-branch Wilsonian flow with enough analytic control to derive the Seiberg-Witten comparison formula, including the ultraviolet twisted gauge theory, the Abelian monopole effective theories at singular fibers, the u-plane contribution, descent contact terms, determinant-line phases, chamber dependence, wall crossing, and compactification boundary contributions.

Chapter 110

Boundaries, Defects, And Categories In Topological QFT

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops boundary and defect data in topological QFT through finite-dimensional models where the algebra can be written explicitly. The central mechanism is that cutting a topological theory along strata produces state spaces, module categories, defect bimodules, junction spaces, and gluing pairings, and these structures must satisfy concrete associativity and nondegeneracy identities.

110.1 Boundary Conditions As Modules

Let Z be an extended n-dimensional topological theory with a chosen target (∞, n)-category. A boundary condition B for Z assigns compatible data to manifolds with boundary labelled by B. In a fully local formulation, if the value of Z on a point is an algebraic object $\mathcal{A}$, then a boundary condition is represented by a module object over $\mathcal{A}$, in the target appropriate to the codimension.

Definition 110.1 (Boundary category in dimension one)**.** Let Z be a one-dimensional topological theory with a set of boundary labels $\mathcal{B}$. For $B_0, B_1 \in \mathcal{B}$, let

$$\mathcal{H}(B_0, B_1).$$

be the state space assigned to an interval whose incoming endpoint is labelled by B_0 and outgoing endpoint by B_1. Gluing intervals gives linear maps

$$\mathcal{H}(B_0, B_1) \otimes \mathcal{H}(B_1, B_2) \longrightarrow \mathcal{H}(B_0, B_2).$$

If these maps are associative and if the interval of zero length gives identity elements in $\mathcal{H}(B, B)$, then the labels B are the objects of a category and $\mathcal{H}(B_0, B_1)$ are its morphism spaces.

Remark 110.2 (Associativity from one-dimensional gluing). The interval amplitudes of a one-dimensional topological theory with labelled endpoints satisfy the associativity condition in Definition 110.1.

Let $I = I_1 \cup I_2 \cup I_3$ be an interval decomposed into three subintervals with intermediate labels B_1, B_2. Topological invariance says that the linear map assigned to I depends only on the labelled bordism, not on the choice of cut positions. The two parenthesizations

$$(I_1 \cup I_2) \cup I_3, \qquad I_1 \cup (I_2 \cup I_3)$$

are the same labelled bordism. Functoriality therefore identifies the two composite multiplication maps from $\mathcal{H}(B_0, B_1) \otimes \mathcal{H}(B_1, B_2) \otimes \mathcal{H}(B_2, B_3)$ to $\mathcal{H}(B_0, B_3)$. The zero-length interval is the identity bordism, hence gives identity morphisms.

110.2 BF_2 and Finite Gauge Boundary States

The most concrete two-dimensional example is untwisted finite gauge theory, the finite counterpart of BF_2. Let G be a finite group. The closed state space on the circle is the center of the group algebra

$$\mathcal{H}(S^1) = Z(\mathbb{C}[G]).$$

The pair-of-pants product is multiplication in $Z(\mathbb{C}[G])$. For each irreducible complex representation ρ of G, with character χ_ρ and dimension d_ρ, define

$$e_\rho = \frac{d_\rho}{|G|} \sum_{g \in G} \chi_\rho(g^{-1})\, g \in Z(\mathbb{C}[G]). \tag{110.1}$$

The elements e_ρ, as ρ ranges over irreducible representations of G, are the primitive central idempotents of $\mathbb{C}[G]$:

$$e_\rho e_\sigma = \delta_{\rho\sigma} e_\rho, \qquad \sum_{\rho \in \mathrm{Irr}(G)} e_\rho = 1.$$

The elementary closed-channel topological boundary states of this semisimple model are therefore labelled by $\mathrm{Irr}(G)$. Equivalently, the elementary modules over the closed Frobenius algebra $Z(\mathbb{C}[G])$ are

$$M_\rho = e_\rho Z(\mathbb{C}[G]), \qquad \mathrm{Hom}_{Z(\mathbb{C}[G])}(M_\rho, M_\sigma) \cong \begin{cases} \mathbb{C}, & \rho = \sigma, \\ 0, & \rho \neq \sigma. \end{cases}$$

The regular representation decomposes as

$$\mathbb{C}[G] \cong \bigoplus_{\rho \in \mathrm{Irr}(G)} V_\rho \otimes V_\rho^*.$$

The center acts on the summand $V_\rho \otimes V_\rho^*$ by a scalar. Schur orthogonality gives the central projector onto that summand as (110.1). Projectors onto distinct summands are orthogonal and their sum is the identity. Since $Z(\mathbb{C}[G])$ is a finite direct product of copies of $\mathbb{C}$, its simple modules are exactly the one-dimensional summands $e_\rho Z(\mathbb{C}[G])$, with the displayed Hom spaces.

This calculation is deliberately a closed-sector statement. A fully extended finite-gauge theory has a richer boundary classification by module categories over $\mathrm{Rep}(G)$, and twisted theories replace $\mathrm{Rep}(G)$ by the corresponding cocycle-twisted tensor category. The idempotents above are the part of that story visible to the ordinary two-dimensional closed TQFT.

110.3 Defect Fusion and Junction Spaces

A codimension-one defect D_{12} from a theory Z_1 to a theory Z_2 is placed on a separating hypersurface. Fusion is defined by bringing two parallel defects together:

$$D_{12} \circ D_{23} = D_{13}.$$

For a topological defect, correlation functions are unchanged under deformations that keep the ordering of defects and avoid operator insertions. The fusion product is associative when the three-defect collision limit is independent of the relative distances used to take the limit. In a regulated QFT this independence is a theorem to be proved; in a bordism presentation it is part of the functorial data.

Example 110.3 (Finite gauge defects as bisets)**.** Let G and H be finite groups. A topological interface from two-dimensional finite G-gauge theory to finite H-gauge theory can be modelled by a finite (G, H)-biset X, namely a finite set with commuting left G- and right H-actions. If Y is an (H, K)-biset, the fused interface is the balanced product

$$X \otimes_H Y = (X \times Y)/\{(xh, y) \sim (x, hy) : h \in H\},$$

which is a (G, K)-biset. Junction fields between two (G, H)-bisets X and X' are the equivariant functions

$$\mathrm{Hom}_{G,H}(X, X') = \{f : X \to X' : f(gxh) = gf(x)h\}.$$

Associativity of finite defect fusion. For finite biset defects the balanced-product convention gives

$$(X \otimes_H Y) \otimes_K Z \cong X \otimes_H (Y \otimes_K Z)$$

canonically as (G, L)-bisets, whenever X, Y, Z are composable (G, H)-, (H, K)-, and (K, L)-bisets. Both sides are quotients of $X \times Y \times Z$ by the equivalence relation generated by

$$(xh, y, z) \sim (x, hy, z), \qquad (x, yk, z) \sim (x, y, kz), \qquad h \in H,\ k \in K.$$

The identity map on $X \times Y \times Z$ therefore descends to a bijection between the two iterated quotients. The left G- and right L-actions commute with the two generating equivalences, so the bijection is a (G, L)-biset isomorphism. This is quotient bookkeeping, not a theorem about the existence of defect fusion in an arbitrary continuum QFT; the latter requires the topological-defect sector and its fusion operation to have been constructed independently.

110.4 Line Defects and Modular Tensor Data

In a three-dimensional oriented TQFT, line defects form a monoidal category $\mathcal{C}$. The tensor product is parallel fusion:

$$X \otimes Y = \lim_{\epsilon \to 0} X(\epsilon) Y(0).$$

Braiding is obtained by exchanging two topological lines in $\mathbb{R}^3$:

$$c_{X,Y} : X \otimes Y \longrightarrow Y \otimes X.$$

The hexagon identities are equalities of isotopies of three braided lines. If every line has a dual line and the vacuum line has endomorphism ring $\mathbb{C}$, then $\mathcal{C}$ is rigid and has a distinguished unit object. Additional finiteness, semisimplicity, and nondegenerate braiding hypotheses give a modular tensor category; these hypotheses are part of the claimed three-dimensional theory, not consequences of topology alone.

Definition 110.4 (Modular tensor category data)**.** For the purposes of this volume, a semisimple modular tensor category $\mathcal{C}$ consists of a finite set I of simple objects, a tensor unit $0 \in I$, duals $a \mapsto a^*$, fusion multiplicities ${N_{ab}}^c$, associativity isomorphisms F, braiding isomorphisms R, twists θ_a, and a nondegenerate matrix

$$S_{ab} = \frac{1}{\mathcal{D}} \operatorname{tr}_{a \otimes b}(c_{b,a} c_{a,b}) \,, \qquad \mathcal{D}^2 = \sum_{a \in I} d_a^2,$$

subject to the pentagon, hexagon, ribbon, and nondegeneracy identities. The numbers d_a are categorical dimensions. A three-dimensional TQFT whose line category is $\mathcal{C}$ must produce these data from line fusion, line exchange, and framed line rotation.

Example 110.5 ($SU(2)_k$ line data)**.** For $SU(2)$ Chern–Simons theory at positive integer level k, the line labels are $a = 0, \ldots, k$, corresponding to spin $a/2$. The modular matrix is

$$S_{ab} = \sqrt{\frac{2}{k+2}} \sin\!\left(\frac{(a+1)(b+1)\pi}{k+2}\right),$$

and the fusion rule is

$${N_{ab}}^c = 1 \quad \Longleftrightarrow \quad |a-b| \le c \le \min(a+b, 2k-a-b), \quad a+b+c \in 2\mathbb{Z},$$

with ${N_{ab}}^c = 0$ otherwise. The derivation and the Hopf-link normalization are given in Chapter 105; here the same data are read as the input controlling boundaries, condensable algebras, and line-defect junctions.

110.5 Boundary Categories for Chern–Simons Theory

For compact G Chern–Simons theory at level k, a Wilson line labelled by a representation R is

$$W_R(\gamma) = \operatorname{tr}_R \mathcal{P} \exp\!\left(\int_\gamma A\right).$$

Quantum gauge invariance restricts the admissible line labels. For simply connected compact simple G, the expected finite label set is the set of integrable highest weights at level k. Fusion of line defects is then encoded by the corresponding representation category of the affine algebra or quantum group at a root of unity, depending on the construction chosen.

The boundary chiral algebra is not an extra decoration. It is the algebraic object that describes states on a surface with boundary and line endpoints. The equality between bulk Chern–Simons amplitudes and boundary conformal blocks is a gluing statement relating two constructions of the same surface-state spaces.

Definition 110.6 (Lagrangian subgroup of an abelian Chern–Simons theory)**.** Let K be a non-degenerate integral symmetric $r \times r$ matrix defining an abelian Chern–Simons theory. The finite group of line labels is

$$A_K = \mathbb{Z}^r / K\mathbb{Z}^r.$$

For charge representatives $\ell, \ell' \in \mathbb{Z}^r$, define

$$b(\ell, \ell') = \ell^T K^{-1} \ell' \mod \mathbb{Z}, \qquad q(\ell) = \frac{1}{2} \ell^T K^{-1} \ell \mod \mathbb{Z}.$$

A subgroup $L \subset A_K$ is Lagrangian if $q|_L = 0$ and

$$L = L^\perp, \qquad L^\perp = \{a \in A_K : b(a, \ell) = 0 \text{ for every } \ell \in L\}.$$

Abelian Chern–Simons boundary algebra. In the pointed modular category of an abelian Chern–Simons theory, a Lagrangian subgroup $L \subset A_K$ determines a commutative separable algebra object

$$A_L = \bigoplus_{\ell \in L} \ell.$$

The condition $q|_L = 0$ is exactly the condition that the summands have trivial topological spin, and $L = L^\perp$ is the condition that no nontrivial bulk line has trivial monodromy with every condensed line. This follows from the finite semisimple algebra of the pointed category: the simple objects form an abelian group under fusion, here A_K. The braiding monodromy of charges ℓ, ℓ' is $\exp(2\pi i b(\ell, \ell'))$, and the twist of ℓ is $\exp(2\pi i q(\ell))$. The direct sum over a subgroup carries multiplication induced by the group law $L \times L \to L$. Commutativity of this multiplication requires trivial mutual braiding among condensed summands; this follows from $q|_L = 0$ by the quadratic identity

$$b(\ell, \ell') = q(\ell + \ell') - q(\ell) - q(\ell').$$

Separability is the finite semisimple averaging idempotent for the finite group L. A line a can pass through the boundary condensate without monodromy precisely when $a \in L^\perp$. If $L = L^\perp$, the only such transparent bulk lines are the condensed ones, so the boundary is a boundary to the trivial bulk rather than to another residual topological order.

Example 110.7 (Toric-code boundary subgroups)**.** For

$$K = \begin{pmatrix} 0 & 2 \\ 2 & 0 \end{pmatrix},$$

the line group is $A_K \cong \mathbb{Z}_2 \oplus \mathbb{Z}_2$. Writing the generators as $e = (1, 0)$ and $m = (0, 1)$, one has

$$q(e) = q(m) = 0, \qquad b(e, m) = \frac{1}{2}.$$

Thus

$$L_e = \{0, e\}, \qquad L_m = \{0, m\}$$

are Lagrangian subgroups, while $\{0, e+m\}$ is not because $q(e+m) = 1/2$. The two Lagrangian subgroups are the two elementary gapped boundaries: one condenses the electric line and the other condenses the magnetic line.

110.6 BV-BFV Boundary Mechanism

For a gauge theory on a manifold M with boundary, the BV variation has the form

$$\delta S_{\mathrm{BV}} = \iota_{Q_{\mathrm{BV}}}\omega_{\mathrm{BV}} + \pi^*_{\partial M}\alpha_\partial.$$

The boundary one-form α_∂ has differential

$$\omega_\partial = \delta\alpha_\partial.$$

The pair $(\mathcal{F}_\partial, \omega_\partial)$ is the BFV phase space, and the bulk BV vector field induces a boundary cohomological vector field when the master equation is compatible with the boundary term. A boundary condition is a Lagrangian subspace or derived Lagrangian object

$$\mathcal{L}_\partial \subset \mathcal{F}_\partial$$

on which the boundary variation vanishes. This is the local mechanism behind boundary categories in gauge-theoretic TQFTs.

110.7 Crane–Yetter and Walker–Wang Boundaries

Four-dimensional state-sum and lattice-Hamiltonian constructions make the boundary role of braided tensor categories especially visible. The fully general Crane–Yetter state sum and Walker–Wang Hamiltonian construction belong to a broad categorical theorem package. The local mechanism needed for the present monograph can be proved directly in the pointed case, which is already rich enough to distinguish bulk deconfinement from boundary topological order.

Definition 110.8 (Pointed braided input and its radical)**.** Let A be a finite abelian group. A pointed braided input is a quadratic function

$$q : A \to \mathbb{Q}/\mathbb{Z}$$

whose polarization

$$b(a, x) = q(a+x) - q(a) - q(x) \tag{110.2}$$

is a symmetric biadditive pairing $A \times A \to \mathbb{Q}/\mathbb{Z}$. The topological spin of the simple line a is $\theta_a = \exp(2\pi \mathrm{i} q(a))$, and the double braiding of a around x is

$$M(a, x) = \exp(2\pi \mathrm{i} b(a, x)).$$

The radical, or transparent subgroup, is

$$\mathrm{Rad}(A, b) = \{a \in A : \ b(a, x) = 0 \text{ in } \mathbb{Q}/\mathbb{Z} \text{ for every } x \in A\}. \tag{110.3}$$

The pointed input is nondegenerate when $\mathrm{Rad}(A, b) = 0$.

Construction 110.9 (Pointed Walker–Wang boundary mechanism)**.** Fix the pointed braided finite input of Definition 110.8. The finite Walker–Wang mechanism used here is the following algebraic lattice model. Oriented edge labels take values in A. Vertex terms enforce the group-law fusion constraint, and a plaquette move inserts a closed loop of label $x \in A$ and recouples it through the existing labels. When a candidate line of label a crosses that loop, the local move multiplies the state by the double-braiding phase

$$M(a,x) = \exp(2\pi \mathrm{i} b(a,x)). \tag{110.4}$$

In this finite mechanism a bulk line label a is called deconfined when its line insertion commutes with every plaquette recoupling away from its endpoints; equivalently, translating a segment of the line through the bulk leaves no string of plaquette violations. The construction therefore gives the finite criterion

$$a \text{ is deconfined} \quad \Longleftrightarrow \quad M(a,x) = 1 \quad \text{for every } x \in A \quad \Longleftrightarrow \quad a \in \mathrm{Rad}(A,b). \tag{110.5}$$

If b is nondegenerate, this finite algebraic model has no nontrivial deconfined bulk line. On a boundary where strings are allowed to end, the endpoint labels still carry the pointed braided category (A,q): fusion is addition in A, spins are $\exp(2\pi \mathrm{i} q(a))$, and double braiding is $\exp(2\pi \mathrm{i} b(a,x))$.

Verification of the finite criterion. The vertex constraint only uses the group law of A, so a closed plaquette loop can be slid through a candidate line one elementary crossing at a time. Each crossing contributes the phase (110.4). If $M(a,x) \neq 1$ for some x, the plaquette term with loop label x detects the line segment; moving the segment changes the local plaquette eigenvalue along its path, which is the finite-lattice meaning of confinement in this mechanism. If $M(a,x) = 1$ for all x, all plaquette recouplings away from the endpoints commute with the line insertion, so the energy cost is localized at the endpoints and the line is deconfined. The equality $M(a,x) = 1$ for every x is precisely $b(a,x) = 0$ in $\mathbb{Q}/\mathbb{Z}$ for every x, hence (110.5). A boundary removes the plaquette relation that would continue the detection surface outside the material, so a string may terminate there; the same local crossing calculation records the boundary spin and double-braiding data. Thus the finite mechanism separates a radical bulk spectrum from a boundary pointed braided category.

Example 110.10 (Toric-code input as a modular boundary order)**.** For $A = \mathbb{Z}_2 e \oplus \mathbb{Z}_2 m$, set

$$q(e) = q(m) = 0, \qquad q(e+m) = \frac{1}{2}.$$

Then $b(e,m) = 1/2$, while $b(e,e) = b(m,m) = 0$. The radical is zero:

$$\mathrm{Rad}(A,b) = \{0\}.$$

The pointed Walker–Wang mechanism therefore has no nontrivial deconfined bulk line, but the boundary still supports the toric-code anyons $\{1, e, m, e+m\}$ with the displayed mutual semionic braiding.

Definition 110.11 (Müger center)**.** Let $\mathcal{C}$ be a finite semisimple braided tensor category over $\mathbb{C}$, with braiding

$$c_{a,x} : a \otimes x \longrightarrow x \otimes a.$$

For simple objects a, x, the monodromy is the natural automorphism

$$M_{a,x} = c_{x,a}c_{a,x} : a \otimes x \longrightarrow a \otimes x.$$

The Müger center $\mathcal{Z}_2(\mathcal{C})$ is the full fusion subcategory generated by the simple objects a such that

$$M_{a,x} = \mathrm{id}_{a\otimes x} \qquad \text{for every simple } x \in \mathcal{C}. \tag{110.6}$$

The braided category is nondegenerate when $\mathcal{Z}_2(\mathcal{C})$ is generated only by the tensor unit.

Operational Müger-center criterion. The categorical input supplied by the Walker–Wang plaquette test is the local crossing datum between plaquette-loop recouplings and transverse line insertions. Assume a local plaquette algebra whose simple string labels are the simple objects of $\mathcal{C}$, and assume that dragging a plaquette loop labelled by x through a transverse simple line a acts on $a \otimes x$ by the monodromy

$$M_{a,x} = c_{x,a}c_{a,x}.$$

Let P_x be the elementary plaquette recoupling in which a small loop labelled by x is created, slid across the candidate line a, and absorbed. The part of P_x detected by the crossing with a is exactly $M_{a,x}$. Therefore a commutes with every local plaquette-loop recoupling precisely when

$$M_{a,x} = \mathrm{id}_{a\otimes x} \qquad \text{for every simple } x,$$

which is the defining condition (110.6) for

$$a \in \mathcal{Z}_2(\mathcal{C}).$$

Equivalently, the categorical candidates for bulk deconfined lines are the simple objects in the Müger center. If $\mathcal{C}$ is nondegenerate, this local plaquette-commutation test leaves only the tensor unit as a bulk deconfined line. Thus the criterion isolates the local algebraic datum that any concrete non-pointed Hamiltonian realization must implement before the global excitation-sector statement can be made.

Example 110.12 (Non-pointed check: the Ising braided category)**.** The Ising modular category has simple labels

$$1, \qquad \psi, \qquad \sigma,$$

with quantum dimensions $1, 1, \sqrt{2}$ and total dimension $\mathcal{D} = 2$. In the ordered basis $(1, \psi, \sigma)$, its modular matrix is

$$S = \frac{1}{2}\begin{pmatrix} 1 & 1 & \sqrt{2} \\ 1 & 1 & -\sqrt{2} \\ \sqrt{2} & -\sqrt{2} & 0 \end{pmatrix}.$$

For a transparent simple object a in a modular category, the Hopf-link amplitude factorizes as

$$S_{ax} = \frac{d_a d_x}{\mathcal{D}} \qquad \text{for every simple } x. \tag{110.7}$$

The unit row satisfies this identity. The ψ row fails at $x = \sigma$, because

$$S_{\psi\sigma} = -\frac{\sqrt{2}}{2} \neq \frac{d_\psi d_\sigma}{\mathcal{D}} = \frac{\sqrt{2}}{2}.$$

The σ row fails already at $x = \psi$. Hence the Müger center is trivial. The Ising input is non-pointed and nondegenerate, so the local Walker–Wang plaquette criterion leaves no nontrivial bulk deconfined line, while the non-pointed Ising anyons may still appear as boundary line data when the boundary construction is supplied.

Remark 110.13 (General categorical status). For a general spherical, ribbon, or modular fusion category $\mathcal{C}$, the Crane–Yetter and Walker–Wang constructions require the full categorical state-sum or lattice-Hamiltonian theorem: pentagon and hexagon identities, Pachner-move invariance, spherical trace normalization, and the analysis of bulk excitation sectors. The monograph uses the general theorem as external mathematics until those categorical proofs are developed in full. The pointed theorem above proves the mechanism that is used conceptually here: bulk deconfined lines are controlled by the Müger center, and a nondegenerate braided input leaves its nontrivial anyons as boundary, not bulk, topological order.

110.8 Extended Assignment

An extended n-dimensional TQFT assigns:

$$Z(M^n) \in \mathbb{C}, \qquad Z(\Sigma^{n-1}) \in \mathrm{Vect},$$

$$Z(Y^{n-2}) \in \mathrm{Cat},$$

and higher categorical objects to lower-dimensional strata, in a target (∞, n)-category chosen before the assignment is made. Dualizability conditions ensure that gluing along all strata is represented by composition and evaluation maps. In a QFT realization, the target objects must be constructed from regulated state spaces, boundary operator algebras, and defect junction spaces.

Open Problem 110.14 (Gauge-theoretic extended construction). Construct the extended boundary and defect categories of four-dimensional cohomological gauge theories directly from regulated BV-BFV data, including instanton and monopole boundary strata, line and surface defects, gluing maps, orientations, and anomaly lines.

Chapter 111

BV Integration And Finite-Dimensional Localization

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Topological and cohomological field theories use two related operations. The first is BV integration: a semidensity on an odd symplectic space is restricted to a Lagrangian cycle and integrated. The second is cohomological localization: an integral of a closed density is deformed by an exact term and evaluated from the zero locus of the deformation. This chapter proves the finite-dimensional identities with all cycle, boundary, and determinant data visible. Infinite-dimensional gauge-theoretic applications in later chapters must supply a regulator, a replacement for compactness, determinant-line orientations, and control of singular strata.

111.1 Odd Symplectic BV Data

Let $\mathcal{F}$ be a finite-dimensional smooth graded manifold. Its fermionic coordinates are coordinates of the structure sheaf; they are not points of an underlying ordinary set. An odd symplectic form of cohomological degree -1 is a closed nondegenerate two-form

$$\omega \in \Omega^2(\mathcal{F}), \qquad |\omega| = -1.$$

For a homogeneous function $F \in C^\infty(\mathcal{F})$, the Hamiltonian vector field X_F is defined by

$$\iota_{X_F}\omega = \delta F.$$

The BV bracket is the odd Poisson bracket

$$\{F,G\} = X_F(G).$$

It has cohomological degree 1, satisfies the graded Jacobi identity, and obeys the graded Leibniz rule in each argument. If S is an even function of degree zero, the vector field

$$Q_S = \{S,-\}$$

has degree 1. The classical master equation is

$$\{S,S\} = 0. \tag{111.1}$$

The Jacobi identity gives

$$Q_S^2 F = \frac{1}{2}\{\{S,S\},F\},$$

so (111.1) is equivalent to $Q_S^2 = 0$ on functions.

In local Darboux coordinates (x^i,ξ_i), where

$$|x^i| + |\xi_i| = 1, \qquad \omega = \sum_i \delta x^i\,\delta\xi_i,$$

the bracket is the coordinate expression determined by the preceding Hamiltonian convention. A choice of Berezinian density μ compatible with these coordinates gives a BV Laplacian on functions,

$$\Delta_\mu = \sum_i (-1)^{|x^i|}\frac{\partial^2}{\partial x^i\,\partial\xi_i}. \tag{111.2}$$

Intrinsic BV integration is most cleanly stated for semidensities. In a coordinate chart a semidensity is written $f\,\mu^{1/2}$; the canonical odd-symplectic operator on semidensities is denoted Δ. After the choice of μ, it is represented by Δ_μ on the coefficient function f. The price of working with functions is that a change of μ changes the displayed operator.

111.2 Quantum Master Equation And Observables

Let ρ be a semidensity on $\mathcal{F}$. The finite-dimensional quantum master equation is

$$\Delta\rho = 0. \tag{111.3}$$

If $\rho = \exp(S/\hbar)\mu^{1/2}$ in a chosen compatible Berezinian trivialization, then (111.3) becomes

$$\frac{1}{2}\{S,S\} + \hbar\Delta_\mu S = 0. \tag{111.4}$$

Indeed, applying the second-order operator Δ_μ to $\exp(S/\hbar)$ gives

$$\Delta_\mu\left(\mathrm{e}^{S/\hbar}\right) = \hbar^{-1}\left(\Delta_\mu S + \frac{1}{2\hbar}\{S,S\}\right)\mathrm{e}^{S/\hbar},$$

which is equivalent to (111.4).

An observable is a function $\mathcal{O}$ for which

$$\Delta(\mathcal{O}\rho) = 0.$$

In the same trivialization, if S obeys (111.4), this condition reads

$$\Delta_\mu \mathcal{O} + \hbar^{-1}\{S, \mathcal{O}\} = 0. \tag{111.5}$$

The classical limit of (111.5) is $\{S, \mathcal{O}\} = 0$, the Q_S-closedness condition.

Remark 111.1 (BV product identity). For a homogeneous function F and an action S satisfying (111.4),

$$\Delta_\mu(F e^{S/\hbar}) = \left(\Delta_\mu F + \hbar^{-1}\{S, F\}\right) e^{S/\hbar}.$$

The defining second-order identity for Δ_μ is

$$\Delta_\mu(FG) = (\Delta_\mu F)G + (-1)^{|F|} F \Delta_\mu G + (-1)^{|F|}\{F, G\}.$$

Take $G = e^{S/\hbar}$. Since S is even,

$$\{F, e^{S/\hbar}\} = \hbar^{-1}\{F, S\} e^{S/\hbar}.$$

The graded antisymmetry of the odd bracket converts the last term to $\hbar^{-1}\{S, F\}e^{S/\hbar}$ with the displayed convention. The term containing $\Delta_\mu G$ vanishes by the quantum master equation for $e^{S/\hbar}\mu^{1/2}$. This proves the identity.

111.3 Lagrangian Cycles And BV Stokes

A Lagrangian submanifold $\mathcal{L} \subset \mathcal{F}$ is a graded submanifold for which the pullback of ω vanishes and whose dimension is half the dimension of $\mathcal{F}$ in the graded sense. The restriction of a semidensity ρ to $\mathcal{L}$ is an ordinary Berezinian density on $\mathcal{L}$, denoted $\rho|_{\mathcal{L}}$. The BV expectation of an observable is

$$\langle \mathcal{O} \rangle_{\mathcal{L}} = \int_{\mathcal{L}} (\mathcal{O}\rho)|_{\mathcal{L}}.$$

The Lagrangian $\mathcal{L}$ is the gauge-fixing cycle.

Theorem 111.2 (Finite-dimensional BV Stokes theorem)**.** *Let σ be a compactly supported semidensity on an odd symplectic finite-dimensional graded manifold $\mathcal{F}$, and let $\mathcal{L} \subset \mathcal{F}$ be an oriented Lagrangian submanifold without boundary. Then*

$$\int_{\mathcal{L}} (\Delta\sigma)|_{\mathcal{L}} = 0.$$

If $\mathcal{L}$ has boundary, the same calculation gives the induced boundary integral on $\partial\mathcal{L}$.

Proof. Cover the compact support of $\sigma|_{\mathcal{L}}$ by Darboux–Weinstein charts adapted to $\mathcal{L}$. In such a chart the coordinates are (x^i, ξ_i), the odd symplectic form is $\sum_i dx^i\, d\xi_i$, and $\mathcal{L}$ is given by $\xi_i = 0$. Write the semidensity as

$$\sigma = f(x, \xi)\, \mu^{1/2}.$$

In this chart the canonical BV operator on semidensities is

$$\Delta\sigma = \left(\sum_i (-1)^{|x^i|} \frac{\partial^2 f}{\partial x^i\, \partial \xi_i}\right) \mu^{1/2}.$$

After restriction to $\mathcal{L}$, this is the ordinary divergence of the vector density

$$V = \sum_i (-1)^{|x^i|} \left.\frac{\partial f}{\partial \xi_i}\right|_{\xi=0} \iota_{\partial/\partial x^i}\, \mathrm{d}x,$$

because

$$\mathrm{d}_{\mathcal{L}} V = \sum_i (-1)^{|x^i|} \left.\frac{\partial^2 f}{\partial x^i\, \partial \xi_i}\right|_{\xi=0} \mathrm{d}x.$$

Choose a partition of unity on $\mathcal{L}$ subordinate to the adapted charts. Applying the preceding calculation to each partitioned semidensity gives an ordinary divergence on each chart. The local boundary contributions on chart overlaps cancel because the canonical BV operator on semidensities and the restricted density are invariant under adapted canonical coordinate changes. Hence the only remaining boundary term is the geometric boundary of $\mathcal{L}$. If $\partial\mathcal{L} = \varnothing$ the integral vanishes. If $\partial\mathcal{L}$ is present, the same calculation gives the induced ordinary Stokes integral $\int_{\partial\mathcal{L}} V$. □

Remark 111.3 (Gauge-fixing independence). Let ρ satisfy $\Delta\rho = 0$, and let $\mathcal{O}$ satisfy $\Delta(\mathcal{O}\rho) = 0$. Let $\mathcal{L}_s$, $s \in [0,1]$, be a smooth family of compact Lagrangian cycles such that the swept chain has no boundary except $\mathcal{L}_1 - \mathcal{L}_0$. Then

$$\int_{\mathcal{L}_1} (\mathcal{O}\rho)|_{\mathcal{L}_1} = \int_{\mathcal{L}_0} (\mathcal{O}\rho)|_{\mathcal{L}_0}.$$

The family $\mathcal{L}_s$ sweeps a Lagrangian cobordism, so this is the direct finite-dimensional consequence of Theorem 111.2 applied to the closed semidensity $\mathcal{O}\rho$. The hypotheses $\Delta\rho = 0$ and $\Delta(\mathcal{O}\rho) = 0$ are the finite-dimensional BV analogues of the quantum master equation and the observable Ward identity; they are exactly what makes the integrand closed for the Stokes argument.

111.4 BV Pushforward

Let the odd symplectic space split as

$$\mathcal{F} = \mathcal{F}_{\mathrm{res}} \times \mathcal{F}_{\mathrm{fluc}}, \qquad \omega = \omega_{\mathrm{res}} + \omega_{\mathrm{fluc}}.$$

The first factor contains residual fields and the second factor contains fluctuation fields to be integrated out. Let $\mathcal{L}_{\mathrm{fluc}} \subset \mathcal{F}_{\mathrm{fluc}}$ be a Lagrangian cycle. For a semidensity ρ on $\mathcal{F}$, define the BV pushforward

$$(\pi_*\rho)(\phi_{\mathrm{res}}) = \int_{\mathcal{L}_{\mathrm{fluc}}} \rho(\phi_{\mathrm{res}}, \phi_{\mathrm{fluc}})\big|_{\mathcal{L}_{\mathrm{fluc}}}.$$

The result is a semidensity on $\mathcal{F}_{\mathrm{res}}$.

Theorem 111.4 (QME preservation by BV pushforward)**.** *Assume that ρ has compact support in the fluctuation directions, or that the chosen fluctuation cycle has decay strong enough to eliminate the boundary term in Theorem 111.2. If*

$$\Delta_{\mathcal{F}}\rho = 0,$$

then

$$\Delta_{\mathrm{res}}(\pi_*\rho) = 0.$$

The same statement holds for observables:

$$\Delta_{\mathcal{F}}(\mathcal{O}\rho) = 0 \quad \Longrightarrow \quad \Delta_{\mathrm{res}}\pi_*(\mathcal{O}\rho) = 0.$$

Proof. Work in product Darboux coordinates

$$(x^i, \xi_i; y^a, \eta_a)$$

adapted to $\mathcal{F}_{\mathrm{res}} \times \mathcal{F}_{\mathrm{fluc}}$, with (x^i, ξ_i) residual and (y^a, η_a) fluctuation coordinates. The canonical BV semidensity Laplacian is local in these coordinates, and the product Berezinian contains no mixed residual-fluctuation term. Hence

$$\Delta_{\mathcal{F}} = \Delta_{\mathrm{res}} + \Delta_{\mathrm{fluc}}.$$

The residual Laplacian differentiates only (x, ξ), so, under the compact support or decay hypothesis, it may be moved through the fluctuation integral. In a local trivialization of the semidensity line this is ordinary differentiation under the integral sign; coordinate independence follows from the transformation law of the BV Laplacian on semidensities. Therefore

$$\Delta_{\mathrm{res}}\pi_*\rho = \int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{res}}\rho)|_{\mathcal{L}_{\mathrm{fluc}}} = -\int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{fluc}}\rho)|_{\mathcal{L}_{\mathrm{fluc}}}.$$

The last integral is zero by Theorem 111.2 applied to the fluctuation BV manifold and the cycle $\mathcal{L}_{\mathrm{fluc}}$. The hypotheses in the statement are exactly the conditions needed for this Stokes step: either there is no boundary contribution because the fluctuation support is compact, or the chosen noncompact cycle has decay strong enough for the boundary functional to vanish.

If $\Delta_{\mathcal{F}}(\mathcal{O}\rho) = 0$, the same argument is applied to the semidensity $\mathcal{O}\rho$. No new algebraic input is used: $\mathcal{O}\rho$ is simply the semidensity being pushed forward, and the product decomposition gives

$$\Delta_{\mathrm{res}}\pi_*(\mathcal{O}\rho) = -\int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{fluc}}(\mathcal{O}\rho))|_{\mathcal{L}_{\mathrm{fluc}}},$$

and the fluctuation BV Stokes theorem again makes the right hand side vanish. □

Definition 111.5 (Boundary functional of a fluctuation cycle)**.** Let $\mathcal{L}_{\mathrm{fluc}}$ be a fluctuation Lagrangian cycle with boundary. For a semidensity $\sigma = f\,\mu^{1/2}$ on $\mathcal{F}_{\mathrm{fluc}}$, define $\mathcal{B}_{\partial\mathcal{L}_{\mathrm{fluc}}}(\sigma)$ by

$$\int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{fluc}}\sigma)|_{\mathcal{L}_{\mathrm{fluc}}} = \mathcal{B}_{\partial\mathcal{L}_{\mathrm{fluc}}}(\sigma). \tag{111.6}$$

In a Darboux chart in which $\mathcal{L}_{\mathrm{fluc}} = \{\xi_i = 0\}$, this boundary functional is the ordinary Stokes boundary integral of the vector density with components

$$(-1)^{|x^i|} \left.\frac{\partial f}{\partial \xi_i}\right|_{\xi=0}. \tag{111.7}$$

The coordinate-independence is precisely the boundary version of Theorem 111.2.

Proposition 111.6 (BV pushforward with fluctuation boundary)**.** *Let $\mathcal{F} = \mathcal{F}_{\mathrm{res}} \times \mathcal{F}_{\mathrm{fluc}}$ and let $\mathcal{L}_{\mathrm{fluc}} \subset \mathcal{F}_{\mathrm{fluc}}$ be a fluctuation Lagrangian cycle with boundary. Assume that all integrations converge and that ρ obeys the full finite-dimensional QME $\Delta_{\mathcal{F}}\rho = 0$. Then the pushed semidensity satisfies*

$$\Delta_{\mathrm{res}}(\pi_*\rho) = -\mathcal{B}_{\partial\mathcal{L}_{\mathrm{fluc}}}(\rho). \tag{111.8}$$

Thus BV pushforward preserves the QME if and only if the displayed boundary functional vanishes or is cancelled by an additional boundary, residue, or regulator contribution. If $\mathcal{O}$ is a quantum observable in the finite-dimensional sense that $\Delta_{\mathcal{F}}(\mathcal{O}\rho) = 0$, the same formula holds with ρ replaced by $\mathcal{O}\rho$.

Proof. As in Theorem 111.4, the product Darboux/Berezinian convention gives

$$\Delta_{\mathcal{F}} = \Delta_{\mathrm{res}} + \Delta_{\mathrm{fluc}}.$$

The residual BV Laplacian differentiates only the residual variables, so the convergence hypothesis permits it to pass through the fluctuation integral:

$$\Delta_{\mathrm{res}}\pi_*\rho = \int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{res}}\rho)|_{\mathcal{L}_{\mathrm{fluc}}} = -\int_{\mathcal{L}_{\mathrm{fluc}}} (\Delta_{\mathrm{fluc}}\rho)|_{\mathcal{L}_{\mathrm{fluc}}}. \tag{111.9}$$

The second equality uses the full QME to replace $\Delta_{\mathrm{res}}\rho$ by $-\Delta_{\mathrm{fluc}}\rho$. Definition 111.5 identifies the last integral with the fluctuation-boundary functional, including its Darboux-coordinate Stokes expression and its coordinate-independent semidensity meaning. This proves (111.8). The observable statement is identical after replacing ρ by $\mathcal{O}\rho$ and using $\Delta_{\mathcal{F}}(\mathcal{O}\rho) = 0$. □

In field theory this theorem is the finite-dimensional model for Wilsonian integration of BV fields. A regulator must provide a finite-dimensional replacement or a trace-class analogue of the split above. If $\Delta\rho = \mathcal{A}\rho$, the semidensity $\mathcal{A}\rho$ is the finite-dimensional anomaly insertion; the pushforward preserves the anomaly class rather than producing a solution of the quantum master equation.

111.5 Singular Strata As BV Boundary Data

Gauge-theoretic localization often integrates over a smooth moduli stratum whose natural compactification has additional strata. Let $\mathcal{M}^{\mathrm{sm}}$ denote the smooth locus and let

$$\overline{\mathcal{M}} = \mathcal{M}^{\mathrm{sm}} \sqcup \bigsqcup_{\alpha} S_\alpha \tag{111.10}$$

be a stratified compactification. In applications S_α may be a reducible-connection stratum, a singular-monopole stratum, or the small-instanton stratum of an Uhlenbeck compactification. A BV localization argument over $\mathcal{M}^{\mathrm{sm}}$ is not complete until it states the boundary functional produced by the strata S_α.

Definition 111.7 (Boundary-cancellation data)**.** For a regulated BV localization problem with smooth fixed locus $\mathcal{M}^{\mathrm{sm}}$ and compactification (111.10), boundary-cancellation data consists of one of the following:

1. vanishing of every stratum functional, $\mathcal{B}_{S_\alpha}(\rho) = 0$;
2. a relative integration cycle whose boundary cancels $\sum_\alpha \mathcal{B}_{S_\alpha}(\rho)$;
3. a resolved regulated fixed locus $\widetilde{\mathcal{M}} \to \overline{\mathcal{M}}$ with an induced semidensity $\widetilde{\rho}$;
4. a finite-dimensional contour or residue rule whose Stokes boundary equals $-\sum_\alpha \mathcal{B}_{S_\alpha}(\rho)$.

In the resolution case the necessary equality is the identity of pushed residual semidensities

$$\pi_*^{\widetilde{\mathcal{M}}}\widetilde{\rho} = \pi_*^{\mathcal{M}^{\mathrm{sm}}}\rho + \sum_\alpha C_\alpha, \qquad \Delta_{\mathrm{res}} C_\alpha = \mathcal{B}_{S_\alpha}(\rho), \tag{111.11}$$

where C_α is the contribution supported over the exceptional or relative piece replacing S_α. Equation (111.11) is data to be proved from the regulator; it is not implied by writing a compactification symbol.

Singular-stratum obstruction to the localized QME. Assume that a regulated gauge-theoretic BV integral has been localized to a smooth finite-dimensional fixed locus $\mathcal{M}^{\mathrm{sm}}$ and that the full regulated semidensity obeys the QME before the limiting compactification is taken. If the compactification of $\mathcal{M}^{\mathrm{sm}}$ contains strata S_α, then the residual localized semidensity obeys

$$\Delta_{\mathrm{res}}(\pi_*^{\mathcal{M}^{\mathrm{sm}}}\rho) = -\sum_\alpha \mathcal{B}_{S_\alpha}(\rho). \tag{111.12}$$

Therefore the localized expression is a BV pushforward satisfying the QME only after boundary-cancellation data in the sense of Definition 111.7 have been supplied and verified.

Choose a collar neighborhood of each singular stratum in the compactified moduli problem and remove a tubular neighborhood of radius ϵ. The resulting truncated fixed locus $\mathcal{M}_\epsilon^{\mathrm{sm}}$ is a manifold with boundary. Applying Proposition 111.6 gives

$$\Delta_{\mathrm{res}}(\pi_*^{\mathcal{M}_\epsilon^{\mathrm{sm}}}\rho) = -\sum_\alpha \mathcal{B}_{\partial_\alpha \mathcal{M}_\epsilon^{\mathrm{sm}}}(\rho). \tag{111.13}$$

If the limit $\epsilon \to 0$ exists as a distributional or semidensity limit, the boundary functionals converge to the stratum functionals $\mathcal{B}_{S_\alpha}(\rho)$, giving (111.12). If the limit does not exist, the localization formula itself is not yet defined. A vanishing, relative-cycle, resolution, or residue input is exactly the additional input that makes the right hand side vanish or cancel in the residual QME.

Collar form of the stratum functional. The preceding obstruction is useful only when the stratum functional is a specified object. A collar description supplies such an object. Assume that, near a stratum S_α, the compactified fixed locus is equipped with a defining function $r \geq 0$, a link fibration

$$L_\alpha \longrightarrow S_\alpha,$$

and boundary faces

$$L_{\alpha,\epsilon} = \{r = \epsilon\} \subset \mathcal{M}^{\mathrm{sm}}$$

with the boundary orientation inherited from the truncated space $\mathcal{M}_\epsilon^{\mathrm{sm}} = \{r \geq \epsilon\}$. Let V_ρ^{bdry} be the ordinary boundary density obtained from Definition 111.5. The stratum functional is then the residual semidensity limit

$$\mathcal{B}_{S_\alpha}(\rho) = \lim_{\epsilon \downarrow 0} \int_{L_{\alpha,\epsilon}} V_\rho^{\mathrm{bdry}}, \tag{111.14}$$

whenever this limit exists in the topology used for residual semidensities. Thus the words "compactification", "resolution", and "residue prescription" acquire content only after the collar, orientation, boundary density, and limiting topology have been stated.

The collar also gives a practical vanishing/residue test. Suppose, in a norm on residual semidensities, that the boundary integral has an asymptotic expansion

$$\int_{L_{\alpha,\epsilon}} V_\rho^{\mathrm{bdry}} = \epsilon^{\eta_\alpha} B_{\alpha,0} + O(\epsilon^{\eta_\alpha+\delta}), \qquad \delta > 0. \tag{111.15}$$

If $\eta_\alpha > 0$, the stratum contributes zero to the residual QME. If $\eta_\alpha = 0$, the coefficient $B_{\alpha,0}$ is the finite boundary residue that must vanish, cancel against other strata, or be represented by a relative/resolved contribution C_α. If $\eta_\alpha < 0$, the localized expression has a divergent boundary term; the proposed localization formula is then undefined until the regulator or integration cycle is changed. Logarithmic terms are treated by the same rule: every coefficient of $\epsilon^0(\log\epsilon)^k$ is boundary data, and powers with negative η_α signal divergent boundary data.

For the S^4 instanton factors of Chapter 101, the Uhlenbeck small-instanton strata are precisely such S_α, with the instanton scale playing the role of the collar coordinate r. Replacing the Uhlenbeck compactification by the Gieseker/Nekrasov resolution supplies a candidate C_α in (111.11). The statement that the original four-dimensional path integral selects those resolved data is therefore a regulator theorem or a hypothesis, as stated in Hypothesis 101.17, rather than a consequence of formal Q-exact deformation alone.

111.6 Cohomological Localization

Let M be an oriented finite-dimensional manifold and let $\mathcal{A}$ be a finite-dimensional graded-commutative algebra. An integration functional

$$\int_M : \Omega^\bullet(M) \otimes \mathcal{A} \longrightarrow \mathbb{C}$$

is obtained by taking the top ordinary form degree and the chosen Berezin coefficient in $\mathcal{A}$. Let Q be an odd derivation of $\Omega^\bullet(M) \otimes \mathcal{A}$ such that $Q^2 = 0$. Assume that the cycle and boundary conditions give

$$\int_M Q\beta = 0 \tag{111.16}$$

for every integrand β in the class being integrated.

Let S and $\mathcal{O}$ be even Q-closed elements and let V be odd. Define

$$I(t) = \int_M \mathcal{O}\, \mathrm{e}^{-S-tQV}.$$

Remark 111.8 (Q-exact deformation identity). Under the hypotheses above,

$$\frac{dI}{dt} = 0.$$

Differentiate under the integral:

$$\frac{dI}{dt} = -\int_M \mathcal{O}\,(QV)\,\mathrm{e}^{-S-tQV}.$$

Since $Q\mathcal{O} = QS = Q^2V = 0$, the graded Leibniz rule gives

$$Q\big(V\mathcal{O}\,\mathrm{e}^{-S-tQV}\big) = (QV)\mathcal{O}\,\mathrm{e}^{-S-tQV}.$$

Thus dI/dt is minus the integral of a Q-exact term, and (111.16) gives the result.

The identity has content only after (111.16) has been verified. For compact M and $Q = \mathrm{d}$, it is Stokes' theorem. For noncompact cycles it is a decay estimate. For contour prescriptions it is a statement about the chosen relative homology class.

111.7 One-Loop Normal Form

Assume the real part of QV is nonnegative and its zero locus is a compact submanifold $F \subset M$. Let N_F be the normal bundle of F. In a tubular neighborhood write y for even normal coordinates and χ for their odd partners. Suppose the quadratic normal part is

$$QV = \frac{1}{2}\,y^T Ay + \frac{1}{2}\,\chi^T B\chi + O(3), \tag{111.17}$$

where A is a positive definite symmetric operator on the even normal bundle and B is a nondegenerate antisymmetric operator on the odd normal bundle. The orientation of the normal integration cycle fixes the branch of $\sqrt{\det A}$ and the sign of $\mathrm{Pf}(B)$.

Normal Gaussian factor. If the limit $t \to \infty$ may be exchanged with the integral after the standard rescaling $y = t^{-1/2}u$, then the normal variables contribute

$$\frac{\mathrm{Pf}(B)}{\sqrt{\det A}}.$$

Consequently the localized integral has the finite-dimensional form

$$I = \int_F \frac{\iota_F^*(\mathcal{O}\,\mathrm{e}^{-S})}{e_Q(N_F)},$$

where $e_Q(N_F)$ is the equivariant Euler class represented by the normal complex.

The even normal integral is

$$\int_{\mathbb{R}^r} \exp\!\Big(-\frac{t}{2}y^T Ay\Big)\,\mathrm{d}^r y = (2\pi)^{r/2} t^{-r/2} (\det A)^{-1/2}.$$

The odd normal integral is

$$\int \mathrm{d}\chi_1 \cdots \mathrm{d}\chi_{2s}\, \exp\!\Big(-\frac{t}{2}\chi^T B\chi\Big) = t^s\,\mathrm{Pf}(B)$$

with the Berezin orientation fixed by the ordering of the χ's. In a cohomological normal complex the odd rank equals the even rank after pairing by Q, so the powers of t cancel once the ordinary normalization of the Thom density is included. The remaining determinant is $\mathrm{Pf}(B)/\sqrt{\det A}$. The higher-order terms in (111.17) vanish in the rescaled limit under the stated dominated-convergence hypothesis. Gluing these local normal factors over F gives the inverse equivariant Euler class of N_F.

111.8 Mathai–Quillen Rank-One Model

The following model fixes the normalization used in localization. Let

$$s_a : \mathbb{R} \longrightarrow \mathbb{R}, \qquad s_a(x) = ax, \qquad a \neq 0,$$

be a section of the oriented trivial real line bundle over $\mathbb{R}$. For $t > 0$, define the one-form

$$\Theta_{t,a} = \left(\frac{t}{2\pi}\right)^{1/2} a \exp\left(-\frac{ta^2x^2}{2}\right) \mathrm{d}x.$$

It is the rank-one Mathai–Quillen Thom density pulled back by s_a. Its integral is

$$\int_{\mathbb{R}} \Theta_{t,a} = \operatorname{sign}(a). \tag{111.18}$$

Indeed, setting $u = \sqrt{t}\,|a|x$ gives

$$\left(\frac{t}{2\pi}\right)^{1/2} a\,\mathrm{d}x = \operatorname{sign}(a)\frac{\mathrm{d}u}{\sqrt{2\pi}},$$

and

$$\int_{\mathbb{R}} \frac{1}{\sqrt{2\pi}} \mathrm{e}^{-u^2/2} \mathrm{d}u = 1.$$

This proves (111.18). The sign is the local degree of the section at its zero $x = 0$, namely the orientation sign of the derivative $\mathrm{d}s_a = a\,\mathrm{d}x$.

For a rank-r oriented Euclidean vector bundle $E \to M$ with connection ∇, section s, and curvature R_∇, the Mathai–Quillen representative is obtained by replacing the single odd variable above by odd fiber variables χ^a and using the exponent

$$-\frac{t}{2}\|s\|^2 + \mathrm{i}\sqrt{t}\,\chi_a(\nabla s)^a + \frac{1}{2}\,\chi_a(R_\nabla)^{ab}\chi_b.$$

The Berezin integral over the χ's gives a closed differential form whose cohomology class is independent of t. When the zero locus of s is transverse, the $t \to \infty$ limit is the signed integration current on $s^{-1}(0)$. The rank-one calculation above is the local normal calculation at a transverse zero.

111.9 Atiyah–Bott Fixed-Point Model on the Two-Sphere

The preceding normal determinant has a visible fixed-point form in the two-sphere model. Write S^2 with coordinates

$$x \in [-1, 1], \qquad \varphi \in \mathbb{R}/2\pi\mathbb{Z}$$

away from the two poles, and orient it by

$$\omega = \mathrm{d}\varphi \wedge \mathrm{d}x.$$

Then $\int_{S^2} \omega = 4\pi$. Let the circle act by $\varphi \mapsto \varphi + \alpha$, and let $V = \partial_\varphi$ be its generating vector field. With equivariant parameter λ, define

$$\mathrm{d}_\lambda := \mathrm{d} - \lambda\, \iota_V, \qquad H = x.$$

Since $\iota_V \omega = \mathrm{d}x$, the equivariant two-form

$$\Omega_\lambda := \omega + \lambda H$$

is closed:

$$\mathrm{d}_\lambda \Omega_\lambda = \lambda\, \mathrm{d}x - \lambda\, \iota_V \omega = 0.$$

Fixed-point formula in the S^2 model. For $\lambda \neq 0$,

$$\int_{S^2} \mathrm{e}^{\Omega_\lambda} = 2\pi\, \frac{\mathrm{e}^{\lambda} - \mathrm{e}^{-\lambda}}{\lambda}. \tag{111.19}$$

The same value is obtained from the two fixed points of the circle action:

$$2\pi \left(\frac{\mathrm{e}^{\lambda H(N)}}{\lambda w_N} + \frac{\mathrm{e}^{\lambda H(S)}}{\lambda w_S} \right), \qquad H(N) = 1, \quad H(S) = -1, \quad w_N = 1, \quad w_S = -1.$$

Only the top ordinary form degree contributes to the integral:

$$\mathrm{e}^{\Omega_\lambda} = \mathrm{e}^{\lambda x}(1 + \omega), \qquad [\mathrm{e}^{\Omega_\lambda}]_{\mathrm{top}} = \mathrm{e}^{\lambda x} \omega.$$

Therefore

$$\int_{S^2} \mathrm{e}^{\Omega_\lambda} = \int_0^{2\pi} \mathrm{d}\varphi \int_{-1}^{1} \mathrm{e}^{\lambda x} \mathrm{d}x = 2\pi\, \frac{\mathrm{e}^{\lambda} - \mathrm{e}^{-\lambda}}{\lambda}.$$

Near the north pole, use a complex coordinate z in which the circle acts by $z \mapsto \mathrm{e}^{\mathrm{i}\alpha} z$. The tangent weight is $w_N = 1$, and $H(N) = 1$. Near the south pole the coordinate z^{-1} has tangent weight $w_S = -1$, and $H(S) = -1$. The one-dimensional normal Gaussian factor is the inverse equivariant Euler factor $(\lambda w_p)^{-1}$ at each fixed point p, multiplied by the angular normalization 2π. Summing the two contributions gives exactly (111.19).

This model is finite-dimensional and compact, so no boundary term is hidden. In gauge-theory localization the fixed set is replaced by a moduli space of solutions to field equations, the weights become determinant lines of elliptic complexes, and compactness or a relative-cycle prescription must be proved before the fixed-point formula has the status of a field-theoretic identity.

111.10 Boundary And Noncompact Terms

If the integration cycle has boundary or noncompact ends, the derivative in Remark 111.8 is the corresponding boundary integral:

$$\frac{dI}{dt} = -\int_{\partial M_{\mathrm{eff}}} \text{the boundary value of } V\mathcal{O}\, \mathrm{e}^{-S - tQV}.$$

A localization statement must therefore state one of the following pieces of data:

a compact integration cycle,	a decay estimate at every noncompact end,
a boundary condition cancelling the term,	a specified relative cycle or residue prescription.

In gauge-theoretic localization, Coulomb-branch ends, reducible connections, small instantons, singular monopole strata, and boundaries of moduli spaces are exactly the loci where this analysis enters. A residue prescription such as a Jeffrey–Kirwan rule is part of the integration-cycle data; it is a finite-dimensional replacement for a boundary analysis, and its validity in a field-theoretic construction must be proved from the chosen regulator and cycle.

Open Problem 111.9 (Infinite-dimensional BV localization)*.* Give theorem-level localization statements for cohomological gauge theories from a regulated BV-BFV functional integral, including integration cycles, compactness or boundary estimates, zero modes, determinant lines, singular strata, and gluing compatibility.

Chapter 112

Finite Gauge Theory and State-Sum TQFT

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Finite gauge theory is the cleanest nonperturbative laboratory for topological path integrals. The field spaces are finite groupoids, the "measure" is groupoid cardinality, the state spaces are finite-dimensional vector spaces of functions or sections over boundary groupoids, and gluing is Fubini's theorem for finite homotopy fibers. This chapter develops the untwisted theory and its Dijkgraaf–Witten cocycle twists with enough detail that later references to finite topological gauge theory have a precise meaning.

Throughout this chapter G is a finite group. A principal G-bundle means a right principal bundle. All manifolds are compact, smooth, oriented when orientation is needed, and equipped with collars at boundary components. If X is a finite groupoid, $\pi_0 X$ denotes the set of isomorphism classes of objects and $\mathrm{Aut}_X(x)$ denotes the automorphism group of an object x.

Definition 112.1 (Finite gauge state-sum datum)**.** Fix a dimension D. A finite G-gauge state-sum datum is a tuple

$$\mathfrak{Z}^{(D)}_{G,\omega} = \big(G, [\omega], M \mapsto \mathrm{Bun}_G(M), \mathcal{L}_\omega, \mathcal{H}_{G,\omega}, Z_{G,\omega}, K \mapsto \mathrm{Flat}_G(K)\big)$$

with the following entries.

(i) G is a finite group, and $[\omega] \in H^D(BG, U(1))$ is the Dijkgraaf–Witten twist. The untwisted theory is the case $[\omega] = 0$.

(ii) For every compact collared D-manifold M and closed $(D-1)$-manifold Σ, $\mathrm{Bun}_G(M)$ and $\mathrm{Bun}_G(\Sigma)$ are the finite groupoids of right principal G-bundles and bundle isomorphisms.

(iii) $\mathcal{L}_\omega(\Sigma)$ is the transgressed boundary line over $\mathrm{Bun}_G(\Sigma)$. In the untwisted theory this line is canonically trivial.

(iv) The boundary state space is

$$\mathcal{H}_{G,\omega}(\Sigma) = \Gamma\big(\mathrm{Bun}_G(\Sigma), \mathcal{L}_\omega(\Sigma)\big),$$

with the groupoid-cardinality pairing. In the untwisted case this is the vector space of functions on $\pi_0 \mathrm{Bun}_G(\Sigma)$.

(v) A bordism $M : \Sigma_0 \to \Sigma_1$ defines the restriction span

$$\mathrm{Bun}_G(\Sigma_0) \xleftarrow{r_0} \mathrm{Bun}_G(M) \xrightarrow{r_1} \mathrm{Bun}_G(\Sigma_1),$$

and $Z_{G,\omega}(M)$ is the corresponding push-pull operator, weighted by the cocycle phase and by automorphism denominators.

(vi) For a branched triangulation K of M, $\mathrm{Flat}_G(K)$ is the finite set of flat edge labelings whose action groupoid $\mathrm{Flat}_G(K)//G^{K_0}$ presents $\mathrm{Bun}_G(M)$. The simplicial state sum is a representative of the intrinsic groupoid integral.

The gluing theorem below proves that these entries define a symmetric monoidal TQFT on the corresponding collared bordism category.

112.1 Finite Groupoids and the Gauge Volume

Definition 112.2 (Finite groupoid cardinality)**.** A finite groupoid is a groupoid with finitely many isomorphism classes and finite automorphism groups. Its cardinality is

$$|X| = \sum_{[x]\in\pi_0 X} \frac{1}{|\operatorname{Aut}_X(x)|}. \tag{112.1}$$

If $F : X \to \mathbb{C}$ is a function constant on isomorphism classes, its integral over X is

$$\int_X F = \sum_{[x]\in\pi_0 X} \frac{F(x)}{|\operatorname{Aut}_X(x)|}. \tag{112.2}$$

The factor $1/|\operatorname{Aut}(x)|$ is the finite gauge-volume factor. It is forced by gluing. Omitting it gives the wrong cylinder and the wrong answer for a quotient with stabilizers.

Action groupoid cardinality. Let a finite group H act on a finite set X. The action groupoid $X//H$ has objects X and morphisms $x \to hx$ labeled by $h \in H$. Its groupoid cardinality is

$$|X//H| = \frac{|X|}{|H|}. \tag{112.3}$$

The isomorphism classes are the orbits $\mathcal{O} \subset X$. For $x \in \mathcal{O}$, the automorphism group is the stabilizer H_x. Thus

$$|X//H| = \sum_{\mathcal{O}} \frac{1}{|H_x|} = \sum_{\mathcal{O}} \frac{|\mathcal{O}|}{|H|} = \frac{|X|}{|H|},$$

where the orbit-stabilizer theorem was used in the second equality. This calculation is the finite model for dividing by gauge volume: summing one over each object and then weighting by automorphisms gives the same result as averaging over the acting group before passing to orbits.

112.2 Fields as Principal-Bundle Groupoids

For the datum $\mathfrak{Z}^{(D)}_{G,\omega}$, and in particular for the untwisted theory used first, define for a compact manifold M

$$\mathrm{Bun}_G(M)$$

to be the groupoid of principal G-bundles $P \to M$ and bundle isomorphisms. Equivalently, $\mathrm{Bun}_G(M)$ is the mapping groupoid from M to the classifying stack BG. In this chapter this phrase has the concrete meaning supplied by principal bundles and their isomorphisms; no analytic mapping-space structure is being assumed.

Definition 112.3 (Untwisted finite gauge partition function)**.** For a closed D-manifold M, the untwisted finite G-gauge theory partition function is

$$Z_G(M) = |\operatorname{Bun}_G(M)| = \sum_{[P] \in \pi_0 \operatorname{Bun}_G(M)} \frac{1}{|\operatorname{Aut}(P)|}. \tag{112.4}$$

If M is connected and $m \in M$ is a basepoint, a principal G-bundle is classified by a monodromy homomorphism

$$\rho : \pi_1(M, m) \to G$$

up to conjugation by G. The automorphism group of the corresponding bundle is

$$C_G(\rho) = \{h \in G : h\rho(\gamma)h^{-1} = \rho(\gamma) \text{ for all } \gamma \in \pi_1(M, m)\}.$$

For connected closed M,

$$Z_G(M) = \frac{|\operatorname{Hom}(\pi_1(M), G)|}{|G|}. \tag{112.5}$$

The groupoid $\mathrm{Bun}_G(M)$ is equivalent to the action groupoid

$$\operatorname{Hom}(\pi_1(M), G)//G,$$

where G acts by conjugation. The stabilizer of ρ is $C_G(\rho)$, which is the automorphism group of the corresponding bundle. The action-groupoid cardinality calculation gives (112.5). This argument uses connectedness to choose one basepoint and identify every flat finite G-bundle with a homomorphism $\pi_1(M, m) \to G$ modulo change of trivialization at the basepoint, namely conjugation by G.

For a disconnected $M = \bigsqcup_{\alpha=1}^{c} M_\alpha$, groupoid cardinality is multiplicative under disjoint union:

$$Z_G(M) = \prod_{\alpha=1}^{c} Z_G(M_\alpha).$$

The empty manifold has value 1, as required for a symmetric monoidal field theory.

112.3 State Spaces and Push-Pull Along Spans

Let Σ be a closed $(D-1)$-manifold. The boundary field groupoid in Definition 112.1 is

$$\mathcal{B}_\Sigma = \mathrm{Bun}_G(\Sigma).$$

In the untwisted theory the state space is

$$\mathcal{H}_G(\Sigma) = \mathrm{Fun}(\pi_0\mathcal{B}_\Sigma, \mathbb{C}), \tag{112.6}$$

the vector space of complex-valued functions on isomorphism classes of boundary bundles. Its canonical bilinear pairing is the groupoid integral

$$\langle f_1, f_2\rangle_\Sigma = \int_{\mathcal{B}_\Sigma} f_1(Q)f_2(Q) = \sum_{[Q]} \frac{f_1(Q)f_2(Q)}{|\operatorname{Aut}(Q)|}. \tag{112.7}$$

The pairing identifies $\mathcal{H}_G(\bar{\Sigma})$ with the dual of $\mathcal{H}_G(\Sigma)$, in agreement with Proposition 103.5.

If

$$M : \Sigma_0 \to \Sigma_1$$

is a collared bordism, restriction to the boundary gives a span of finite groupoids

$$\mathcal{B}_{\Sigma_0} \xleftarrow{r_0} \mathrm{Bun}_G(M) \xrightarrow{r_1} \mathcal{B}_{\Sigma_1}. \tag{112.8}$$

The bordism operator is the push-pull map

$$Z_G(M) = (r_1)_!\, r_0^* : \mathcal{H}_G(\Sigma_0) \to \mathcal{H}_G(\Sigma_1). \tag{112.9}$$

Here r_0^* is pullback of functions, and $(r_1)_!$ is integration over the finite homotopy fiber of r_1.

Concretely, if $Q_1 \in \mathcal{B}_{\Sigma_1}$, then

$$\big(Z_G(M)f\big)(Q_1) = \int_{P\in \mathrm{Bun}_G(M)_{Q_1}} f(r_0P), \tag{112.10}$$

where $\mathrm{Bun}_G(M)_{Q_1}$ is the groupoid of pairs (P,α) with $P \in \mathrm{Bun}_G(M)$ and an isomorphism $\alpha : r_1P \simeq Q_1$.

Lemma 112.4 (Finite groupoid Fubini with automorphism weights)**.** *Let*

$$p : E \to B$$

be a functor between finite groupoids, and let $F : E \to \mathbb{C}$ be constant on isomorphism classes. For $b \in B$, let E_b be the homotopy fiber groupoid whose objects are pairs (e, ϕ), with $e \in E$ and $\phi : p(e) \simeq b$ in B. Then

$$\int_E F = \int_{b\in B}\int_{E_b} F. \tag{112.11}$$

Consequently, if $X \xrightarrow{f} Y \xrightarrow{g} Z$ are finite groupoids, then

$$(g\circ f)_!F = g_!f_!F. \tag{112.12}$$

Proof. Choose representatives b for the isomorphism classes of B. The right hand side of (112.11) is

$$\sum_{[b]\in\pi_0 B}\frac{1}{|\operatorname{Aut}_B(b)|}\sum_{[(e,\phi)]\in\pi_0 E_b}\frac{F(e)}{|\operatorname{Aut}_{E_b}(e,\phi)|}.$$

We compare the contribution of one isomorphism class $[e]\in\pi_0 E$. After replacing b by an isomorphic representative, assume

$$b=p(e).$$

Let

$$I_e=\operatorname{im}\bigl(\operatorname{Aut}_E(e)\to\operatorname{Aut}_B(p(e))\bigr),\qquad K_e=\ker\bigl(\operatorname{Aut}_E(e)\to\operatorname{Aut}_B(p(e))\bigr).$$

The possible identifications $\phi : p(e)\simeq b$ form a torsor for $\operatorname{Aut}_B(b)$. Passing to the homotopy fiber divides this torsor by the image I_e. Hence the class $[e]$ gives

$$\frac{|\operatorname{Aut}_B(b)|}{|I_e|}$$

isomorphism classes in E_b, and the automorphism group of each such fiber object is K_e. Its total contribution to the iterated integral is

$$\frac{1}{|\operatorname{Aut}_B(b)|}\frac{|\operatorname{Aut}_B(b)|}{|I_e|}\frac{F(e)}{|K_e|}=\frac{F(e)}{|I_e|\,|K_e|}=\frac{F(e)}{|\operatorname{Aut}_E(e)|}.$$

This is exactly the contribution of $[e]$ to $\int_E F$. Summing over $\pi_0 E$ proves (112.11).

For pushforwards, the homotopy fiber of $g\circ f$ over $z\in Z$ is equivalent to the homotopy fiber product

$$X\times_Y Y_z.$$

Applying (112.11) to the projection

$$X\times_Y Y_z\to Y_z$$

gives the equality between integration over this single homotopy fiber and the iterated integration first over X_y and then over Y_z. This is (112.12). ☐

Theorem 112.5 (Finite groupoid gluing)**.** *Let $M_{01}:\Sigma_0\to\Sigma_1$ and $M_{12}:\Sigma_1\to\Sigma_2$ be collared bordisms. The natural restriction functor gives an equivalence of finite groupoids*

$$\operatorname{Bun}_G(M_{12}\circ M_{01})\simeq\operatorname{Bun}_G(M_{01})\times_{\operatorname{Bun}_G(\Sigma_1)}\operatorname{Bun}_G(M_{12}),\tag{112.13}$$

where the fiber product is the homotopy fiber product of groupoids. With the push-pull definition (112.9),

$$Z_G(M_{12}\circ M_{01})=Z_G(M_{12})\,Z_G(M_{01}).\tag{112.14}$$

Proof. The equivalence (112.13) is descent for principal bundles over the collar cover

$$M_{12}\circ M_{01}=M_{01}\cup_{\Sigma_1}M_{12}.$$

An object on the right is a bundle $P_{01}\to M_{01}$, a bundle $P_{12}\to M_{12}$, and an isomorphism

$$P_{01}|_{\Sigma_1}\simeq P_{12}|_{\Sigma_1}.$$

Gluing the total spaces along this isomorphism gives a principal bundle on the glued manifold. Conversely, restricting a bundle on the glued manifold gives such data. A bundle isomorphism on the glued manifold restricts to a pair of isomorphisms on M_{01} and M_{12} compatible with the chosen boundary identification; conversely, any compatible pair glues uniquely to an isomorphism of the glued bundles. Thus the equivalence includes the morphism groupoids, not only the object sets.

The bordism operator is the linear map associated to the restriction span. Composition of such span operators is composition of finite-groupoid pullbacks and pushforwards. By Lemma 112.4, the pushforward along a composite finite-groupoid map is the iterated pushforward, with the automorphism denominators matching by the image-kernel calculation in the lemma. Combining this Fubini identity with the descent equivalence (112.13) gives

$$Z_G(M_{12} \circ M_{01}) = Z_G(M_{12})\, Z_G(M_{01}),$$

as an equality of linear maps $\mathcal{H}_G(\Sigma_0) \to \mathcal{H}_G(\Sigma_2)$. □

Figure 112.1 records the span-level gluing proof: restriction from bulk G-bundles to boundary G-bundles composes by homotopy pullback, and groupoid cardinality supplies the Fubini identity.

$$\begin{tikzcd}
 & & \mathrm{Bun}_G(M_{01}) \times_{\mathrm{Bun}_G(\Sigma_1)} \mathrm{Bun}_G(M_{12}) \arrow[dl, dashed] \arrow[dr, dashed] & & \\
 & \mathrm{Bun}_G(M_{01}) \arrow[dl] \arrow[dr] & & \mathrm{Bun}_G(M_{12}) \arrow[dl] \arrow[dr] & \\
\mathrm{Bun}_G(\Sigma_0) & & \mathrm{Bun}_G(\Sigma_1) & & \mathrm{Bun}_G(\Sigma_2)
\end{tikzcd}$$

Figure 112.1: Gluing finite gauge theory is composition of spans of finite groupoids. The middle groupoid is retained as a homotopy fiber product, so automorphisms of the intermediate boundary bundle are divided out exactly once.

112.4 Triangulated State Sums

Let K be a finite triangulation of a closed oriented D-manifold M, equipped with a branching, meaning an ordering of vertices on every simplex compatible on faces. A lattice G-connection assigns an element

$$g_{ij} \in G$$

to every oriented edge $i \to j$, with $g_{ji} = g_{ij}^{-1}$. It is flat when

$$g_{ij} g_{jk} = g_{ik} \tag{112.15}$$

on every oriented triangle. Gauge transformations are vertex labels

$$h_i \in G,$$

acting by

$$g_{ij} \longmapsto h_i g_{ij} h_j^{-1}. \tag{112.16}$$

Let $\mathrm{Flat}_G(K)$ be the finite set of flat edge labelings. The action groupoid

$$\mathrm{Flat}_G(K)//G^{K_0}$$

is equivalent to $\mathrm{Bun}_G(M)$. Therefore

$$Z_G(M) = \frac{|\,\mathrm{Flat}_G(K)|}{|G|^{|K_0|}}. \tag{112.17}$$

For connected K, choose a spanning tree T in the one-skeleton. Every flat connection is gauge equivalent to a unique flat connection with

$$g_{ij} = 1 \qquad \text{for every edge } (ij) \in T,$$

up to the remaining constant conjugation by G. This gauge fixing gives the equality between (112.17) and (112.5).

112.5 Dijkgraaf–Witten Twists

The Dijkgraaf–Witten entry $[\omega]$ in Definition 112.1 is represented by

$$\omega \in Z^D(BG, U(1))$$

normalized as a group cocycle. In an inhomogeneous cochain convention this means a function

$$\omega : G^D \to U(1)$$

which is 1 when any argument is the identity and satisfies

$$(\delta\omega)(g_1, \ldots, g_{D+1}) = 1. \tag{112.18}$$

For example, for $D = 2$,

$$\omega(g_2, g_3)\,\omega(g_1 g_2, g_3)^{-1}\,\omega(g_1, g_2 g_3)\,\omega(g_1, g_2)^{-1} = 1. \tag{112.19}$$

For a branched oriented D-simplex $\sigma = [i_0 \cdots i_D]$, define

$$\omega_\sigma(g) = \omega(g_{i_0 i_1}, g_{i_1 i_2}, \ldots, g_{i_{D-1} i_D})^{\varepsilon(\sigma)}, \tag{112.20}$$

where $\varepsilon(\sigma) = +1$ if the branching order agrees with the orientation of M on σ, and -1 otherwise. The twisted state-sum is

$$Z_{G,\omega}(M; K) = \frac{1}{|G|^{|K_0|}} \sum_{g \in \mathrm{Flat}_G(K)} \prod_{\sigma^D \in K_D} \omega_\sigma(g). \tag{112.21}$$

Proposition 112.6 (Triangulation independence of the cocycle weight)**.** *For closed M, the quantity (112.21) is invariant under branching-preserving Pachner moves and changes by the expected boundary coboundary factor if ω is replaced by $\omega\,\delta\lambda$. Hence on closed manifolds it depends only on the cohomology class*

$$[\omega] \in H^D(BG, U(1)).$$

Proof. A flat edge labeling of a branched triangulation is equivalently a simplicial map from the triangulation to the nerve model of BG: the ordered edge labels on a simplex are composable group elements, and flatness says that the label on a longer edge is their product. The factor $\omega_\sigma(g)$ is therefore the pullback of the normalized D-cochain ω evaluated on the oriented D-simplex σ.

A branching-preserving Pachner move replaces a collection of oriented D-faces in the boundary of one branched $(D+1)$-simplex by the complementary collection of D-faces. For a fixed flat labeling, all boundary labels are restrictions of one $(D+1)$-simplex label $(g_1, \dots, g_{D+1})$. The ratio between the two products of ω-weights is the alternating product over the D-faces of this $(D+1)$-simplex, namely

$$(\delta\omega)(g_1, \dots, g_{D+1}),$$

where the exponent sign records whether the face orientation agrees with the boundary orientation. The cocycle condition (112.18) makes this ratio equal to 1. Since a Pachner move is local and gives a bijection between flat labelings that agree outside the moved ball, the whole state-sum is unchanged.

Now replace ω by $\omega\,\delta\lambda$, with λ a $(D-1)$-cochain on G. On each D-simplex the extra factor is the alternating product of the λ-weights on its $(D-1)$-faces. When one multiplies over all D-simplices, every interior $(D-1)$-face appears twice with opposite induced orientations and cancels. The surviving product is supported on ∂M. Thus a closed M has no residual factor, while a manifold with boundary changes by exactly the boundary coboundary term. The closed state-sum therefore depends only on $[\omega] \in H^D(BG, U(1))$. $\square$

The intrinsic form of the same definition is the following. A bundle $P \to M$ has a classifying map

$$f_P : M \to BG$$

well-defined up to homotopy. The cocycle supplies a phase

$$\exp\left(2\pi \mathrm{i} \int_M f_P^* \omega\right).$$

Then

$$Z_{G,\omega}(M) = \sum_{[P] \in \pi_0 \operatorname{Bun}_G(M)} \frac{1}{|\operatorname{Aut}(P)|} \exp\left(2\pi \mathrm{i} \int_M f_P^* \omega\right). \tag{112.22}$$

Equation (112.21) is the simplicial representative of (112.22).

On a manifold with boundary, the same transgression produces a line over $\operatorname{Bun}_G(\partial M)$. The state space is therefore not ordinary functions but sections of that line:

$$\mathcal{H}_{G,\omega}(\Sigma) = \Gamma\big(\operatorname{Bun}_G(\Sigma), \mathcal{L}_\omega(\Sigma)\big). \tag{112.23}$$

The gluing theorem continues to hold because the two transgressed boundary lines on a cut hypersurface are dual and contract under gluing.

112.6 Explicit Closed-Surface Partition Functions

Let Σ_g be a closed connected oriented surface of genus g. Its fundamental group has presentation

$$\pi_1(\Sigma_g) = \left\langle a_1, b_1, \dots, a_g, b_g \;\middle|\; \prod_{r=1}^{g} [a_r, b_r] = 1 \right\rangle.$$

Thus

$$Z_G(\Sigma_g) = \frac{1}{|G|}\#\left\{(A_r, B_r)_{r=1}^g \in G^{2g} : \prod_{r=1}^{g}[A_r, B_r] = 1\right\}. \tag{112.24}$$

Proposition 112.7 (Character formula for the $2D$ untwisted theory)**.** *Let* $\mathrm{Irr}(G)$ *be the set of irreducible complex representations of* G*, and let* $d_R = \dim R$*. Then*

$$Z_G(\Sigma_g) = |G|^{2g-2} \sum_{R\in\mathrm{Irr}(G)} d_R^{2-2g} = \sum_{R\in\mathrm{Irr}(G)} \left(\frac{d_R}{|G|}\right)^{2-2g}. \tag{112.25}$$

Proof. Let

$$\delta_e(x) = \begin{cases} 1, & x = e, \\ 0, & x \neq e \end{cases}$$

be the delta function at the identity. The character expansion of the central delta function is

$$\delta_e(x) = \frac{1}{|G|} \sum_{R\in\mathrm{Irr}(G)} d_R\, \chi_R(x), \tag{112.26}$$

which follows from the orthogonality of irreducible characters. Define the commutator-sum operator on class functions by

$$(Tf)(x) = \sum_{a,b\in G} f(x[a,b]).$$

Since T commutes with conjugation and convolution by central functions, Schur orthogonality gives

$$T\chi_R = \frac{|G|^2}{d_R^2}\,\chi_R. \tag{112.27}$$

To see this, write the representation matrix also as $R(\cdot)$. Schur averaging says that for every endomorphism A of R,

$$\sum_{b\in G} R(b)AR(b)^{-1} = \frac{|G|\ \mathrm{tr}_R\, A}{d_R}\,\mathbf{1}_R. \tag{112.28}$$

With $A = R(a)^{-1}$,

$$\sum_{b\in G} R([a,b]) = R(a)\sum_{b\in G} R(b)R(a)^{-1}R(b)^{-1} = \frac{|G|\chi_R(a^{-1})}{d_R}R(a).$$

The central-idempotent form of character orthogonality gives

$$\sum_{a\in G} \chi_R(a^{-1})R(a) = \frac{|G|}{d_R}\,\mathbf{1}_R.$$

Therefore

$$\sum_{a,b\in G} R([a,b]) = \frac{|G|^2}{d_R^2}\,\mathbf{1}_R,$$

and multiplying by $R(x)$ and taking the trace proves (112.27).

The number of solutions of $\prod_{r=1}^{g}[A_r, B_r] = 1$ is $T^g\delta_e(e)$. Applying (112.26) and (112.27) gives

$$\#\,\mathrm{Hom}(\pi_1(\Sigma_g), G) = |G|^{2g-1}\sum_R d_R^{2-2g}.$$

Dividing by the residual global gauge volume $|G|$ gives (112.25). □

For $g = 0$, the formula gives

$$Z_G(S^2) = \frac{1}{|G|}$$

because $\sum_R d_R^2 = |G|$. For $g = 1$,

$$Z_G(T^2) = |\,\mathrm{Irr}(G)|,$$

which is also the number of conjugacy classes of G. If $G = A$ is finite abelian, all irreducible representations are one-dimensional, so

$$Z_A(\Sigma_g) = |A|^{2g-1}. \tag{112.29}$$

112.7 Circle State Space and the Two-Dimensional Algebra

For the circle,

$$\mathrm{Bun}_G(S^1) \simeq G//G,$$

where G acts on itself by conjugation. Therefore

$$\mathcal{H}_G(S^1) = \{\text{class functions } G \to \mathbb{C}\}. \tag{112.30}$$

The pairing (112.7) becomes

$$\langle f_1, f_2\rangle_{S^1} = \frac{1}{|G|}\sum_{g\in G} f_1(g)f_2(g). \tag{112.31}$$

The pair of pants defines a commutative Frobenius algebra on class functions. In the orientation convention where the outgoing holonomy is the product of the incoming holonomies, the product is convolution

$$(f_1 * f_2)(k) = \sum_{\substack{a,b\in G\\ ab=k}} f_1(a)f_2(b). \tag{112.32}$$

Associativity is associativity of group multiplication plus finite Fubini. Commutativity on class functions follows by the change of variables

$$(a, b) \mapsto (aba^{-1}, a),$$

which preserves the product ab up to conjugacy; class functions cannot distinguish conjugate outgoing holonomies. The counit is the disk amplitude, and the nondegenerate pairing is (112.31). This identifies the ordinary $2D$ finite gauge theory with the Frobenius algebra construction of Theorem 103.7.

112.8 Three-Dimensional Finite Gauge Theory

For a closed connected 3-manifold M, the untwisted partition function is again

$$Z_G(M) = \frac{|\operatorname{Hom}(\pi_1(M), G)|}{|G|}.$$

In particular,

$$Z_G(T^3) = \frac{1}{|G|}\#\{(a,b,c) \in G^3 : ab = ba,\ ac = ca,\ bc = cb\}. \tag{112.33}$$

The state space on T^2 is the vector space of functions on commuting pairs (a, b) modulo simultaneous conjugation. The extended three-dimensional theory assigns to the circle a category. In the untwisted case this category is equivalent to representations of the Drinfeld double

$$D(G),$$

and in the ω-twisted case to representations of the twisted quantum double. Equivalently, the line operators form the Drinfeld center

$$Z(\mathrm{Vect}_G^\omega).$$

The simple objects are labeled by a conjugacy class $\mathcal{C} \subset G$ and an irreducible projective representation of the centralizer $C_G(c)$, with the projective 2-cocycle obtained by transgressing ω to the flux $c \in \mathcal{C}$. Fusion and braiding are finite tensor-category operations. This is a theorem of finite tensor categories, but the path-integral origin is already visible: a line insertion fixes magnetic monodromy around a small linking circle, while electric labels are representations of the residual stabilizer of that monodromy.

112.9 Finite Abelian Boundaries and Line Condensation

The preceding construction gives a finite bulk theory. To test boundary and defect statements without hiding behind categorical terminology, it is useful to write one family of boundaries entirely in finite algebra. Let A be a finite abelian gauge group in the untwisted three-dimensional theory. Its simple bulk line labels form the finite abelian group

$$\mathcal{C}_A = A \oplus \widehat{A}, \qquad \widehat{A} = \operatorname{Hom}(A, U(1)).$$

An element

$$c = (a, \chi) \in \mathcal{C}_A$$

has magnetic flux $a \in A$ and electric character $\chi \in \widehat{A}$. The fusion law is addition in $\mathcal{C}_A$. The nondegenerate braiding pairing is

$$B\big((a,\chi),(b,\psi)\big) = \chi(b)\psi(a), \tag{112.34}$$

and the topological spin is

$$\theta(a,\chi) = \chi(a). \tag{112.35}$$

These formulas are the Abelian specialization of the Drinfeld-double line description above: a charge line $(0,\chi)$ evaluates the flux linked by the line, and a flux line $(a,1)$ is detected by linked electric characters.

For a subgroup $L \subset \mathcal{C}_A$, define its braiding orthogonal by

$$L^{\perp} = \{c \in \mathcal{C}_A \mid B(c,\ell) = 1 \text{ for every } \ell \in L\}. \tag{112.36}$$

The subgroup L is Lagrangian if

$$L = L^{\perp} \qquad \text{and} \qquad \theta(\ell) = 1 \quad \text{for every } \ell \in L.$$

Equivalently, the spin is trivial on L, the pairing B is trivial on $L \times L$, and

$$|L| = |A|.$$

Indeed, nondegeneracy of B identifies $\mathcal{C}_A/L^{\perp}$ with $\widehat{L}$, hence

$$|L|\,|L^{\perp}| = |\mathcal{C}_A| = |A|^2.$$

Thus an isotropic subgroup with $|L| = |A|$ has $|L^{\perp}| = |L|$ and $L \subset L^{\perp}$, so equality follows. The spin condition is the locality condition for endpoint operators: trivial-spin lines supply bosonic local boundary endpoints, while a line with nontrivial topological spin carries intrinsic boundary statistics even when its mutual braiding with the other condensed lines is trivial.

Definition 112.8 (Finite Abelian line-condensation boundary datum)**.** For the untwisted three-dimensional finite A-gauge theory, a finite Abelian line-condensation boundary datum is a Lagrangian subgroup

$$L \subset \mathcal{C}_A = A \oplus \widehat{A}.$$

The boundary B_L is the finite topological boundary model in which a bulk line $c \in \mathcal{C}_A$ has a topological endpoint on the boundary exactly when $c \in L$. Lines in L are called condensed at B_L. Lines not in L terminate only after adjoining an additional boundary excitation external to this datum.

The Lagrangian condition is the finite algebraic form of mutual locality for condensed endpoints. If $\ell_1, \ell_2 \in L$, moving one endpoint around the other at the boundary produces the bulk braiding phase $B(\ell_1, \ell_2)$. A boundary vacuum containing both endpoints as local topological operators requires this phase to be 1. Maximality, $L = L^{\perp}$, says that every line mutually local with the condensed endpoint algebra has already been declared condensable; otherwise the boundary datum was not complete.

Theorem 112.9 (Cylinder sectors for finite Abelian boundaries)**.** *Let B_{L_0} and B_{L_1} be two finite Abelian line-condensation boundaries of the untwisted three-dimensional finite A-gauge theory. The topological line sectors on an interval with left boundary L_0 and right boundary L_1 are canonically labeled by*

$$\mathcal{C}_A/(L_0 + L_1). \tag{112.37}$$

Consequently the cylinder ground-sector vector space in this finite topological model is

$$\mathcal{H}_{\mathrm{cyl}}(L_0, L_1) = \mathbb{C}[\mathcal{C}_A/(L_0 + L_1)], \qquad \dim \mathcal{H}_{\mathrm{cyl}}(L_0, L_1) = |\mathcal{C}_A/(L_0 + L_1)| = |L_0 \cap L_1|. \tag{112.38}$$

Proof. Place a representative bulk line $c \in \mathcal{C}_A$ along the interval. If $\ell_0 \in L_0$, then ℓ_0 may end on the left boundary. Fusing ℓ_0 to the interval line therefore changes the representative

$$c \longmapsto c + \ell_0$$

without changing the topological sector. Similarly, every $\ell_1 \in L_1$ can be absorbed at the right boundary, so

$$c \longmapsto c + \ell_1$$

is the same sector. Hence the sector label depends only on the coset of c in $\mathcal{C}_A/(L_0 + L_1)$.

Conversely, if two interval lines c and c' define the same sector in the finite line-condensation model, their difference can be removed by endpoint operations at the two boundaries. The available endpoint operations are precisely fusion with elements of L_0 and L_1, by Definition 112.8. Therefore

$$c' - c \in L_0 + L_1,$$

and the quotient above is neither too coarse nor too fine.

The vector space statement is the finite state-space assignment for this topological sector set: one basis vector for each simple sector. For the dimension, use

$$|\mathcal{C}_A/(L_0 + L_1)| = \frac{|\mathcal{C}_A|}{|L_0 + L_1|} = \frac{|A|^2}{|L_0||L_1|/|L_0 \cap L_1|} = |L_0 \cap L_1|,$$

because L_0 and L_1 are Lagrangian and therefore both have cardinality $|A|$. □

For $A = \mathbb{Z}_N$, write line labels as

$$(m, e) \in \mathbb{Z}_N^{\mathrm{m}} \oplus \mathbb{Z}_N^{\mathrm{e}}, \qquad B((m, e), (m', e')) = \exp\left(\frac{2\pi \mathrm{i}}{N}(em' + e'm)\right).$$

The electric and magnetic boundaries are

$$L_{\mathrm{e}} = \{(0, e) : e \in \mathbb{Z}_N\}, \qquad L_{\mathrm{m}} = \{(m, 0) : m \in \mathbb{Z}_N\}.$$

They are Lagrangian. Therefore

$$\dim \mathcal{H}_{\mathrm{cyl}}(L_{\mathrm{e}}, L_{\mathrm{e}}) = \dim \mathcal{H}_{\mathrm{cyl}}(L_{\mathrm{m}}, L_{\mathrm{m}}) = N, \qquad \dim \mathcal{H}_{\mathrm{cyl}}(L_{\mathrm{e}}, L_{\mathrm{m}}) = 1.$$

The first two cases have one nontrivial topological line label running along the cylinder, while in the mixed case every line can be absorbed by one of the two boundaries. This is the finite algebraic version of the rough/smooth boundary distinction in the $\mathbb{Z}_N$ gauge-code laboratory. It supplies an exact finite calibration for claims about line endpoints and boundary topological sectors; continuum boundary theorems require their own regulator, locality, and limiting hypotheses.

112.10 Subgroup Boundaries and Relative Dijkgraaf–Witten Cocycles

For a nonabelian finite group the most direct boundary condition is a reduction of the gauge group at the boundary. Let $H \subset G$ be a subgroup. If $P \to M$ is a principal G-bundle and $N \subset \partial M$ is a boundary component, an H-reduction of P along N is a principal H-bundle $Q \to N$ together with an isomorphism of principal G-bundles

$$Q \times_H G \cong P|_N.$$

The subgroup boundary B_H is the boundary theory whose boundary fields are such reductions. In a triangulated representative, after choosing a boundary trivialization, this says that boundary edge labels lie in H, while bulk edge labels lie in G. Boundary gauge transformations are H-valued and bulk gauge transformations are G-valued.

This definition is phrased as a condition on bundles. The boundary datum is the restriction functor

$$\mathrm{Bun}_H(N) \longrightarrow \mathrm{Bun}_G(N), \qquad Q \longmapsto Q \times_H G,$$

and all stabilizers are the automorphism groups of these finite groupoids.

Interval sector groupoid for subgroup boundaries. Consider the untwisted finite G-gauge theory on an interval with left boundary subgroup $H_0 \subset G$ and right boundary subgroup $H_1 \subset G$. Choose a trivialization of the G-bundle at one point of the interval. Flatness identifies the bundle with a single parallel-transport element $g \in G$. Changing the left boundary H_0-trivialization by $h_0 \in H_0$ multiplies g on the left, while changing the right boundary H_1-trivialization by $h_1 \in H_1$ multiplies g on the right by h_1^{-1}, because parallel transport is read from the left endpoint to the right endpoint. Thus the boundary field groupoid is the action groupoid

$$G//(H_0 \times H_1), \qquad (h_0, h_1) : g \longmapsto h_0 g h_1^{-1}.$$

Its isomorphism classes, hence the simple topological sectors, are the double cosets

$$H_0 \backslash G / H_1, \tag{112.39}$$

and the finite action-groupoid cardinality formula (112.3) gives

$$\big|G//(H_0 \times H_1)\big| = \frac{|G|}{|H_0|\,|H_1|}. \tag{112.40}$$

For a representative $g \in G$, the automorphism group of the corresponding sector is the stabilizer of g:

$$\mathrm{Aut}(g) = \{(h_0, h_1) \in H_0 \times H_1 : h_0 g = g h_1\} \cong H_0 \cap g H_1 g^{-1}. \tag{112.41}$$

Projection to the first factor identifies this stabilizer with

$$H_0 \cap g H_1 g^{-1},$$

and projection to the second factor identifies it with

$$g^{-1} H_0 g \cap H_1.$$

The vector space assigned to an interval in this boundary sector is therefore

$$\mathrm{Fun}(H_0 \backslash G / H_1, \mathbb{C}),$$

with the groupoid pairing weighted by the stabilizers in (112.41). For example, $H_0 = H_1 = G$ has one sector, while $H_0 = H_1 = \{1\}$ has sectors indexed by all elements of G. If $G = S_3$ and $H = \langle(12)\rangle$, then

$$H\backslash S_3/H$$

has two sectors, represented by the identity and by a three-cycle; the stabilizer weights distinguish the sector containing H from the sector with trivial stabilizer.

Proposition 112.10 (Subgroup-boundary junction convolution)**.** *Let $H_0, H_1, H_2 \subset G$ be subgroup boundary data in the untwisted finite G-gauge theory. Put*

$$\mathcal{V}(H_i, H_j) = \mathrm{Fun}(G, \mathbb{C})^{H_i \times H_j}, \qquad f(h_i g h_j^{-1}) = f(g).$$

The finite pair-of-intervals junction

$$(B_{H_0}, B_{H_1}) \times (B_{H_1}, B_{H_2}) \longrightarrow (B_{H_0}, B_{H_2})$$

defines the bilinear product

$$(f \star_{H_1} k)(g) = \frac{1}{|H_1|} \sum_{\substack{x,y\in G\\ xy=g}} f(x)k(y), \qquad f \in \mathcal{V}(H_0, H_1), \quad k \in \mathcal{V}(H_1, H_2). \tag{112.42}$$

This product lands in $\mathcal{V}(H_0, H_2)$, is associative under successive junction composition, and has unit

$$\mathbf{1}_H(g) = \begin{cases} 1, & g \in H, \\ 0, & g \notin H, \end{cases} \qquad \mathbf{1}_H \in \mathcal{V}(H, H).$$

If $A = H_0 a H_1$, $B = H_1 b H_2$, and $C = H_0 c H_2$, then the double-coset basis structure constants are

$$\mathbf{1}_A \star_{H_1} \mathbf{1}_B = \sum_C N_{AB}^C \mathbf{1}_C, \qquad N_{AB}^C = \frac{1}{|H_1|} \#\{(x,y) \in A \times B : xy = c\}, \tag{112.43}$$

where the integer N_{AB}^C is independent of the representative $c \in C$.

Proof. The junction field groupoid is the finite action groupoid

$$G^2//(H_0 \times H_1 \times H_2),$$

where

$$(h_0, h_1, h_2) : (x, y) \longmapsto (h_0 x h_1^{-1}, h_1 y h_2^{-1}).$$

The incoming restriction remembers x and y, while the outgoing restriction remembers the composite parallel transport

$$g = xy.$$

Thus the junction is the span

$$G//(H_0 \times H_1) \times G//(H_1 \times H_2) \leftarrow G^2//(H_0 \times H_1 \times H_2) \xrightarrow{xy} G//(H_0 \times H_2).$$

Push-pull along this finite span gives (112.42). The factor $|H_1|^{-1}$ is the groupoid-volume factor for the intermediate boundary gauge transformation h_1; it is the same automorphism denominator that appears in the finite gluing theorem.

The result is H_0-left and H_2-right invariant. For instance,

$$(f \star_{H_1} k)(h_0 g h_2^{-1}) = \frac{1}{|H_1|} \sum_{xy=g} f(h_0 x) k(y h_2^{-1}) = (f \star_{H_1} k)(g),$$

using the bi-invariance of f and k. Associativity follows from finite Fubini and associativity in G:

$$((f \star_{H_1} k) \star_{H_2} \ell)(t) = \frac{1}{|H_1|\,|H_2|} \sum_{\substack{x,y,z \in G \\ xyz=t}} f(x)k(y)\ell(z) = (f \star_{H_1} (k \star_{H_2} \ell))(t).$$

The unit statement follows because, for $f \in \mathcal{V}(H, K)$,

$$(\mathbf{1}_H \star_H f)(g) = \frac{1}{|H|} \sum_{h \in H} f(h^{-1} g) = f(g),$$

and similarly $f \star_K \mathbf{1}_K = f$.

For the structure constants, first note that $\mathbf{1}_A \star_{H_1} \mathbf{1}_B$ is (H_0, H_2)-bi-invariant, so it is constant on every output double coset C. If $c' \in C$, say $c' = h_0 c h_2^{-1}$, multiplication by (h_0, h_2) gives a bijection between the factorization sets with product c and c'. Finally, H_1 acts freely on

$$\{(x, y) \in A \times B : xy = c\}$$

by

$$h : (x, y) \longmapsto (xh^{-1}, hy).$$

The quotient by this free action is exactly the intermediate boundary gauge identification in the span, so the cardinality is divisible by $|H_1|$ and N_{AB}^{C} is a nonnegative integer. $\square$

For $G = S_3$ and $H = \langle (12) \rangle$, the H-H double cosets are

$$A_0 = H, \qquad A_1 = H(123)H.$$

The characteristic function of A_0 is the unit, and the nontrivial sector $X = \mathbf{1}_{A_1}$ obeys

$$X \star_H X = 2\,\mathbf{1}_{A_0} + X.$$

This small example shows why the stabilizer and intermediate gauge-volume factors cannot be dropped: the finite path integral produces the Hecke-type integer algebra with the normalization fixed by gluing, not by a later choice of basis.

Now include a three-dimensional Dijkgraaf–Witten twist. Let

$$\omega \in Z^3(G, U(1))$$

be the normalized inhomogeneous cocycle used above. A subgroup boundary supports a local finite boundary counterterm exactly when the pulled-back bulk cocycle is a coboundary on H.

Definition 112.11 (Relative Dijkgraaf–Witten boundary datum)**.** Let $i : H \hookrightarrow G$ be a subgroup inclusion and let $\omega \in Z^3(G, U(1))$ be normalized. A relative Dijkgraaf–Witten boundary datum for B_H is a normalized 2-cochain

$$\beta : H \times H \to U(1)$$

such that

$$(\delta\beta)(h_1,h_2,h_3)=\beta(h_2,h_3)\,\beta(h_1h_2,h_3)^{-1}\,\beta(h_1,h_2h_3)\,\beta(h_1,h_2)^{-1}=\omega(h_1,h_2,h_3) \qquad (112.44)$$

for every $h_1,h_2,h_3\in H$. Equivalently,

$$(\omega,\beta)\in C^3(G,U(1))\oplus C^2(H,U(1))$$

is a relative cocycle for the pair (BG,BH) with relative differential

$$d_{\mathrm{rel}}(\omega,\beta)=\big(\delta\omega,\ i^*\omega\,(\delta\beta)^{-1}\big).$$

In the triangulated state sum, write the bulk 3-simplex weight as before and multiply by the inverse boundary 2-cochain weight

$$W_{\omega,\beta}(K,g)=\prod_{\sigma^3\subset K}\omega(g_\sigma)^{\varepsilon(\sigma)}\prod_{\tau^2\subset\partial K}\beta(h_\tau)^{-\varepsilon_\partial(\tau)}. \qquad (112.45)$$

Here $h_\tau=(h_{i_0i_1},h_{i_1i_2})$ for an oriented boundary triangle $\tau=[i_0i_1i_2]$, and $\varepsilon_\partial(\tau)$ is computed using the induced boundary orientation. The inverse sign is part of the convention; with this convention the condition (112.44) is the cancellation equation.

Boundary cocycle cancellation. Let G be finite, $H\subset G$, and let (ω,β) be a relative Dijkgraaf–Witten boundary datum in the sense of Definition 112.11. The weight (112.45) is invariant under elementary triangulation changes that preserve the boundary H-reduction. Interior Pachner moves use $\delta\omega=1$. Boundary Pachner moves use exactly the identity $\delta\beta=i^*\omega$.

The verification is local in the moved simplex. Interior Pachner moves are the closed-manifold argument in Proposition 112.6; the ratio of the two bulk products is $(\delta\omega)(g_1,g_2,g_3,g_4)$, hence 1.

It remains to check the boundary elementary move. A boundary 2-2 or 1-3 move is represented, after adding the collar direction, by the boundary of a single oriented 3-simplex whose edge labels lie in H. For a branched simplex with ordered edge labels (h_1,h_2,h_3), the ratio of the boundary β^{-1}-weights on the two sides of the move is

$$(\delta\beta)(h_1,h_2,h_3)^{-\varepsilon},$$

where ε is the sign of the corresponding oriented 3-simplex. The missing bulk collar contribution would be

$$\omega(h_1,h_2,h_3)^{\varepsilon}.$$

Multiplying the two ratios gives

$$\omega(h_1,h_2,h_3)^{\varepsilon}(\delta\beta)(h_1,h_2,h_3)^{-\varepsilon}=1$$

by (112.44). The argument is local and the set of flat labelings outside the moved ball is unchanged, so the whole finite state-sum weight is unchanged.

The obstruction to such a boundary is therefore the restriction class

$$i^*[\omega]\in H^3(BH,U(1)).$$

If this class vanishes, choices of β form a torsor for

$$H^2(BH, U(1)).$$

In the untwisted case $\omega = 1$, the condition says that β is a normalized 2-cocycle on H; it supplies a projective boundary counterterm, and different cohomology classes give different finite boundary theories. Thus the subgroup boundary data in the twisted finite theory are the finite path-integral counterparts of the module-category labels $(H, [\beta])$, but the present formulation is only the concrete state-sum construction needed here: boundary fields are H-reductions and the equality $\delta\beta = i^*\omega$ is the local gauge-invariance and triangulation-invariance equation.

Relative gluing and the boundary line. The preceding local check proves invariance of one relative state-sum weight. The gluing statement uses a second, independent sign fact: a boundary component that is outgoing for one bordism is incoming for the other, so the same β-trivialization appears with reciprocal exponent. Let

$$M_L : \Sigma_{\text{in}} \to \Sigma \qquad \text{and} \qquad M_R : \Sigma \to \Sigma_{\text{out}}$$

be collared triangulated three-dimensional finite G-gauge bordisms, with an H-reduction on the common boundary Σ. Choose compatible branched triangulations whose restrictions to Σ agree. For a fixed flat boundary H-labeling h on Σ, let $\varepsilon_\Sigma(\tau)$ be the orientation sign of a boundary triangle τ as seen from M_L. The same triangle has sign $-\varepsilon_\Sigma(\tau)$ as seen from M_R. Hence the interface part of the product of the two relative weights is

$$\prod_{\tau \subset \Sigma} \beta(h_\tau)^{-\varepsilon_\Sigma(\tau)} \prod_{\tau \subset \Sigma} \beta(h_\tau)^{+\varepsilon_\Sigma(\tau)} = 1. \tag{112.46}$$

All remaining factors are exactly the bulk ω-weights and the external-boundary β-weights of the glued triangulation. Thus, before any summation over fields,

$$W_{\omega,\beta}(K_L, g_L)\, W_{\omega,\beta}(K_R, g_R) = W_{\omega,\beta}(K_L \cup_\Sigma K_R, g_L \cup_h g_R), \tag{112.47}$$

for every pair of bulk labelings whose H-boundary restrictions are the chosen h. The subsequent sum over h, with the automorphism denominator of the boundary H-bundle, is precisely finite groupoid Fubini:

$$Z_{G,\omega,\beta}(M_R \circ M_L) = \int_{Q \in \mathrm{Bun}_H(\Sigma)} Z_{G,\omega,\beta}(M_R; Q)\, Z_{G,\omega,\beta}(M_L; Q). \tag{112.48}$$

Equation (112.48) is the concrete finite version of pairing a section of the transgressed boundary line with a section of the dual line over the oppositely oriented boundary. If β is changed by a coboundary $\delta\lambda$, each open boundary state is multiplied by the corresponding transgressed 1-cochain factor. The two factors on a glued interface are reciprocal by the same orientation argument as (112.46). Thus β is a choice of boundary-line trivialization; the obstruction to making such a choice remains the relative class $i^*[\omega]$.

112.11 Defects, Boundaries, and Anomaly Inflow

Finite gauge theories also provide exact models of defects. A codimension-one defect between G- and H-gauge theories is described, in the finite path-integral language, by a finite correspondence of boundary field groupoids

$$\mathrm{Bun}_G(\Sigma) \leftarrow \mathcal{D}(\Sigma) \rightarrow \mathrm{Bun}_H(\Sigma), \tag{112.49}$$

possibly decorated by a cocycle line. A concrete subgroup defect is obtained from

$$K \subset G \times H,$$

by requiring the two gauge fields to reduce on the wall to a common principal K-bundle. Composition of such defects is again a homotopy fiber product of finite groupoids.

In a D-dimensional theory with finite global symmetry G, an anomaly is represented by a class

$$[\alpha] \in H^{D+1}(BG, U(1)).$$

For a background G-bundle A on a closed D-manifold M, the would-be anomalous partition function is not a number canonically attached to A. It is a vector in the transgressed line determined by α. Keeping a $(D+1)$-dimensional bulk with action α makes the combined bulk-boundary amplitude gauge invariant. Gauging the boundary symmetry alone requires a trivialization of this anomaly line. This is the finite model of the relative field theory language in Definition 103.4.

Open Problem 112.12 (Extended finite models). Construct extended finite-gauge TQFTs with boundaries, defects, junctions, twists, and anomaly inflow as functors on a chosen bordism (∞, D)-category, including a direct comparison between the higher-categorical functor and the finite groupoid state-sum formulas in this chapter.

Global Structure, Phases, and Extended Operators

Chapter 113

Global Forms and Higher-Form Symmetry

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The local Lie algebra of gauge transformations does not by itself define a quantum gauge theory. A continuum gauge theory also contains global bundle data, a spectrum of genuine line and surface operators, and topological defects that act on those extended operators. This chapter gives the finite-dimensional algebra that controls these data for compact connected semisimple gauge groups. The analytic definition of a renormalized 't Hooft line is given in Chapter 115; here the purpose is to define the electric and magnetic charge lattices on which that construction depends.

113.1 Character and Cocharacter Lattices

Let $\mathfrak{g}$ be a compact semisimple Lie algebra and let G_{sc} be the connected simply connected compact Lie group with Lie algebra $\mathfrak{g}$. Fix a maximal torus $T_{\mathrm{sc}} \subset G_{\mathrm{sc}}$, with Lie algebra $\mathfrak{t}$. The character and cocharacter groups of a compact torus T are

$$X^*(T) = \mathrm{Hom}_{\mathrm{Lie\,grp}}(T, U(1)), \qquad X_*(T) = \mathrm{Hom}_{\mathrm{Lie\,grp}}(U(1), T).$$

They are free abelian groups of rank $\dim T$. A character $\lambda \in X^*(T)$ and a cocharacter $m \in X_*(T)$ have an integer pairing

$$\lambda \circ m : U(1) \longrightarrow U(1), \qquad z \longmapsto z^{\langle \lambda, m\rangle}, \qquad \langle \lambda, m\rangle \in \mathbb{Z}.$$

This pairing is part of the definition of $X^*(T)$ and $X_*(T)$; no metric on $\mathfrak{t}$ is needed.

For T_{sc}, write

$$\Lambda_{\mathrm{wt}} = X^*(T_{\mathrm{sc}}), \qquad \Lambda_{\mathrm{crt}} = X_*(T_{\mathrm{sc}}).$$

These are the weight lattice and the coroot lattice. The root lattice $\Lambda_{\mathrm{rt}} \subset \Lambda_{\mathrm{wt}}$ is generated by the roots of $(G_{\mathrm{sc}}, T_{\mathrm{sc}})$. The coweight lattice is

$$\Lambda_{\mathrm{cwt}} = X_*(T_{\mathrm{ad}}), \qquad T_{\mathrm{ad}} = T_{\mathrm{sc}}/Z(G_{\mathrm{sc}}),$$

and contains Λ_{crt}. The finite quotients

$$\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}}, \qquad \Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}}$$

are naturally dual finite abelian groups. The first quotient records central characters of representations of G_{sc}; the second records cocharacters modulo ordinary coroot magnetic charges.

Definition 113.1 (Global form)**.** A global form of the compact gauge group with Lie algebra $\mathfrak{g}$ is a connected compact group

$$G = G_{\mathrm{sc}}/\Gamma, \qquad \Gamma \subset Z(G_{\mathrm{sc}}).$$

The maximal torus of G is $T_G = T_{\mathrm{sc}}/\Gamma$. Its character and cocharacter lattices are

$$X^*(T_G) = \{\lambda \in \Lambda_{\mathrm{wt}} \mid \lambda(\gamma) = 1 \text{ for every } \gamma \in \Gamma\}, \tag{113.1}$$

and

$$X_*(T_G) = \{m \in \Lambda_{\mathrm{cwt}} \mid \exp_{G_{\mathrm{sc}}}(2\pi \mathrm{i} m) \in \Gamma\}. \tag{113.2}$$

The exponential in the second formula uses the identification of a cocharacter with an element of $\mathfrak{t}$ whose exponential closes in the adjoint torus. It closes in $G = G_{\mathrm{sc}}/\Gamma$ precisely when its endpoint in G_{sc} lies in Γ.

The local curvature term in the Yang–Mills Lagrangian depends only on $\mathfrak{g}$ and on the normalization of the invariant quadratic form. The global form changes the allowed bundles and the admissible line operators. These changes are invisible in ordinary perturbation theory around a trivial bundle unless extended operators or background fields for higher-form symmetries are included.

Let V_λ be an irreducible representation of G_{sc} with highest weight $\lambda \in \Lambda_{\mathrm{wt}}$. It defines a representation of $G = G_{\mathrm{sc}}/\Gamma$ if and only if $\lambda \in X^*(T_G)$, equivalently if and only if every element of Γ acts trivially on V_λ. The representation V_λ factors through the quotient map $G_{\mathrm{sc}} \to G_{\mathrm{sc}}/\Gamma$ exactly when Γ is contained in the kernel of the representation. Since Γ is central, Schur's lemma says that every $\gamma \in \Gamma$ acts on the irreducible module V_λ by a scalar. That scalar is the central character determined by λ, namely the restriction of λ to $Z(G_{\mathrm{sc}}) \subset T_{\mathrm{sc}}$. Hence the action of every $\gamma \in \Gamma$ is trivial exactly when $\lambda(\gamma) = 1$ for all γ, which is (113.1).

Example 113.2 ($SU(N)/\mathbb{Z}_k$)**.** Let k divide N, let $z = \exp(2\pi \mathrm{i}/N)\mathbf{1}_N$, and let $\mathbb{Z}_k \subset Z(SU(N))$ be the subgroup generated by $z^{N/k}$. An irreducible $SU(N)$-representation has an N-ality

$$e \in \mathbb{Z}_N = \mathbb{Z}/N\mathbb{Z},$$

defined as the number of boxes of its Young diagram modulo N, or equivalently as its central character $z \mapsto \exp(2\pi \mathrm{i} e/N)$. The representation descends to $SU(N)/\mathbb{Z}_k$ if and only if

$$\exp(2\pi \mathrm{i} e/k) = 1, \qquad \text{that is} \qquad e \in k\mathbb{Z}_N.$$

Thus the quotient removes Wilson lines whose N-ality is not divisible by k. Dually, the cocharacter lattice is enlarged: modulo the coroot lattice, the allowed magnetic classes are

$$m \in (N/k)\mathbb{Z}_N.$$

Indeed, after choosing the first fundamental coweight as the generator of $\Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}} \cong \mathbb{Z}_N$, the cocharacter represented by m times this generator closes in $SU(N)/\mathbb{Z}_k$ precisely when its endpoint z^m lies in $\mathbb{Z}_k$, i.e. precisely when m is a multiple of N/k modulo N.

113.2 Genuine Lines and the Dirac Pairing

Definition 113.3 (Genuine line operator)**.** A line operator $L(C)$ supported on an embedded oriented curve C is genuine if its definition does not require a choice of an auxiliary surface ending on C. If a surface S with $\partial S = C$ is part of the definition, then the insertion is a boundary of a higher-dimensional defect rather than an autonomous line operator. In gauge theory, being genuine is a property of the chosen global form, discrete theta data, and spectrum of allowed charged defects; it is not a property of the local gauge algebra alone.

Before dividing by screening, a dyonic line in a gauge theory with local algebra $\mathfrak{g}$ has an electric weight and a magnetic cocharacter. For the finite center-sensitive part of the discussion one may record only the classes

$$\overline{\lambda} \in \Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}}, \qquad \overline{m} \in \Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}}.$$

The root and coroot quotients remove charges that can be screened by adjoint gluonic fields or shifted by ordinary smooth monopole cores. The remaining finite data are precisely the charges detected by center and magnetic one-form symmetries.

For two dyonic labels

$$\gamma = (\lambda, m), \qquad \gamma' = (\lambda', m'),$$

define the Dirac pairing

$$B(\gamma, \gamma') = \lambda(m') - \lambda'(m) \quad \in \mathbb{Q}. \tag{113.3}$$

The value may be fractional when λ is a weight and m' is a coweight of the universal center-sensitive lattice. Its class in $\mathbb{Q}/\mathbb{Z}$ is independent of representatives modulo $\Lambda_{\mathrm{rt}} \oplus \Lambda_{\mathrm{crt}}$. Two lines can be simultaneously genuine in the same theory only if

$$B(\gamma, \gamma') \in \mathbb{Z}. \tag{113.4}$$

Equivalently, the finite Aharonov–Bohm phase $\exp(2\pi \mathrm{i} B(\gamma, \gamma'))$ must be trivial.

Definition 113.4 (Finite line-spectrum datum)**.** For a fixed local gauge algebra, the finite line-spectrum datum is a subgroup

$$L \subset \big(\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}}\big) \oplus \big(\Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}}\big)$$

on which the Dirac pairing (113.3) vanishes modulo $\mathbb{Z}$. It is maximal if it equals its orthogonal complement with respect to that finite pairing. Maximality is the finite-charge statement that no further center-sensitive Wilson–'t Hooft charge can be added while preserving mutual locality.

The definition is deliberately finite and algebraic. A complete continuum definition of the corresponding line operator also requires singular boundary conditions, renormalization of the defect, and a regulator or constructive framework; these analytic data are separated in Definition 115.2.

Proposition 113.5 ($\mathfrak{su}(N)$ finite line lattices)**.** *For local algebra $\mathfrak{su}(N)$, identify*

$$\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}} \cong \Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}} \cong \mathbb{Z}_N.$$

Write a finite dyonic charge as $(e, m) \in \mathbb{Z}_N \oplus \mathbb{Z}_N$. The finite Dirac pairing is

$$\overline{B}\big((e, m), (e', m')\big) = \frac{em' - e'm}{N} \quad \in \mathbb{Q}/\mathbb{Z}. \tag{113.5}$$

Let $k \mid N$ and let $p \in \mathbb{Z}_k$. The subgroup

$$L_{N,k,p} = \big\langle (k, 0), (p, N/k) \big\rangle \subset \mathbb{Z}_N \oplus \mathbb{Z}_N \tag{113.6}$$

is maximal isotropic. In the Yang–Mills convention used in Chapter 117, it is the finite Wilson–'t Hooft line lattice of the $SU(N)/\mathbb{Z}_k$ theory with discrete theta parameter p, before adding matter that could screen center charges.

Proof. The quotient $\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}} \cong \mathbb{Z}_N$ is generated by the fundamental Wilson N-ality. The dual quotient $\Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}} \cong \mathbb{Z}_N$ is generated by the fundamental coweight magnetic class. The generator pair has pairing $1/N$, which gives (113.5) by bilinearity and antisymmetry.

The two generators in (113.6) pair as

$$\overline{B}((k, 0), (p, N/k)) = 1 = 0 \quad \text{in } \mathbb{Q}/\mathbb{Z},$$

and each generator pairs trivially with itself by antisymmetry. Hence $L_{N,k,p}$ is isotropic. Its first generator gives N/k distinct electric classes. Modulo this subgroup, the second generator has magnetic component N/k, which has order k. Thus $|L_{N,k,p}| = N$.

It remains to see that no larger isotropic subgroup exists. If $(x, y) \in (\mathbb{Z}_N)^2$ pairs trivially with $(k, 0)$, then $-ky/N \in \mathbb{Z}$, so $y = (N/k)b$ modulo N. Trivial pairing with $(p, N/k)$ then gives

$$\frac{x(N/k) - py}{N} = \frac{x - pb}{k} \in \mathbb{Z},$$

so $x = pb + ka$ modulo N. Therefore

$$(x, y) = a(k, 0) + b(p, N/k),$$

and the orthogonal complement of $L_{N,k,p}$ is $L_{N,k,p}$ itself. This proves maximality. The identification with the global form follows from Example 113.2: Wilson charges are multiples of k, magnetic charges are multiples of N/k, and the discrete theta coordinate shifts the minimal magnetic line by electric charge p. □

Figure 113.1 displays the finite line-charge lattice in the $SU(5)$-type example and marks the maximal mutually local sublattice selected by the global form and discrete theta coordinate.

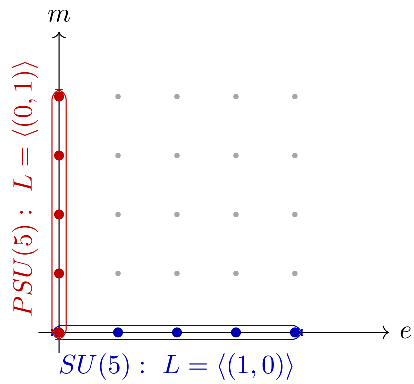

Figure 113.1: The finite $\mathfrak{su}(5)$ charge group $\mathbb{Z}_5^{\mathrm{e}} \oplus \mathbb{Z}_5^{\mathrm{m}}$. A line spectrum is not the whole grid but a maximal isotropic subgroup for (113.5). The $SU(5)$ and $PSU(5)$ choices shown here are the two coordinate axes; discrete theta choices tilt the magnetic axis as in (113.6).

113.3 Abelian Group-Like Higher-Form Symmetry

Definition 113.6 (Abelian group-like p-form global symmetry)**.** Let D be the spacetime dimension and let $0 \leq p \leq D-2$. A group-like abelian p-form global symmetry with finite or compact abelian group A assigns to every closed oriented codimension-$(p+1)$ submanifold M^{D-p-1} and every $a \in A$ an invertible topological defect

$$U_a(M).$$

The defects obey

$$U_a(M)U_b(M) = U_{a+b}(M), \qquad U_0(M) = 1,$$

inside correlation functions, and their correlation functions are invariant under smooth deformations of M that avoid charged insertions, boundaries, and singularities. A charged p-dimensional operator $W_\chi(\Sigma^p)$ has charge $\chi \in A^\vee = \mathrm{Hom}_{\mathrm{cont}}(A, U(1))$ if

$$U_a(M)W_\chi(\Sigma) = \chi(a)^{\mathrm{Link}(M,\Sigma)}W_\chi(\Sigma) \tag{113.7}$$

inside correlation functions whenever M and Σ are disjoint and their linking number is defined.

Here is the chain-level content of the linking phase. Work in an oriented region where the closed codimension-$(p+1)$ submanifold M bounds an oriented $(D-p)$-chain B, and assume that B meets the closed p-dimensional support Σ transversely. The linking number is the oriented intersection number

$$\mathrm{Link}(M,\Sigma) = B \cdot \Sigma = \sum_{x \in B \cap \Sigma} \mathrm{sgn}_x(B,\Sigma). \tag{113.8}$$

Let M' be obtained from M by a smooth deformation, and let C be the oriented $(D-p)$-dimensional sweep, so

$$\partial C = M' - M.$$

Choose bounding chains B and B' with $\partial B = M$ and $\partial B' = M'$. In a local ball, or more generally after fixing the homology class of the bounding chain in the complement of Σ, the change in linking is the intersection of the sweep with the charged support,

$$\mathrm{Link}(M', \Sigma) - \mathrm{Link}(M, \Sigma) = C \cdot \Sigma.$$

Thus a topological defect can be moved without changing its action as long as the sweep does not cross the charged insertion. If the sweep crosses Σ once with sign $\varepsilon = \pm 1$, the linking number changes by ε, and the correlator is multiplied by $\chi(a)^\varepsilon$. Iterating this local crossing rule gives (113.7). This is the topological part of the statement only: the existence of the defect $U_a(M)$ as a renormalized QFT operator and the allowed set of charged $W_\chi(\Sigma)$ remain part of the theory data.

For $p = 0$, this definition covers the abelian part of ordinary internal symmetry. Nonabelian zero-form symmetry requires topological defects labelled by group elements with noncommutative fusion; the one-form symmetries used below are abelian in precisely the sense of Definition 113.6.

For a continuous $U(1)$ p-form symmetry, a charge is an integer $q \in \mathbb{Z}$, the character is $\chi_q(e^{\mathrm{i}\alpha}) = e^{\mathrm{i}q\alpha}$, and (113.7) becomes

$$U_\alpha(M) W_q(\Sigma) = \exp\bigl(\mathrm{i}\alpha q \ \mathrm{Link}(M, \Sigma)\bigr) W_q(\Sigma).$$

The linking formula is not an analogy: it is the operator definition of the symmetry action on extended charged objects.

113.4 Electric-Magnetic One-Form Symmetries

Let G be a compact connected gauge group and assume for the moment that there is no dynamical matter carrying nontrivial center charge and no dynamical magnetic object that allows 't Hooft lines to end. The group of electric one-form symmetry defects is

$$Z(G).$$

Its characters act on Wilson lines. A Wilson line in representation R has electric one-form charge given by the central character

$$Z(G) \longrightarrow U(1), \qquad z \longmapsto R(z).$$

If $G = SU(N)$, this is the usual N-ality. If matter of nonzero N-ality is present, the corresponding Wilson line can end on a dynamical field and the electric one-form symmetry is explicitly reduced or broken.

For a non-simply connected G, there is also a magnetic one-form symmetry whose background fields measure the obstruction class of G-bundles. The topological magnetic surface defects are labelled by

$$\pi_1(G)^\vee = \mathrm{Hom}(\pi_1(G), U(1)).$$

Equivalently, a background two-form field for this symmetry is valued in $\pi_1(G)$. The distinction between $\pi_1(G)$ and its Pontryagin dual is only invisible after choosing a noncanonical perfect pairing; the definition keeps them separate. For $G = SU(N)/\mathbb{Z}_k$,

$$Z(G) \cong \mathbb{Z}_{N/k}, \qquad \pi_1(G) \cong \mathbb{Z}_k.$$

The line lattice $L_{N,k,p}$ in Proposition 113.5 is the finite algebraic record of which Wilson–'t Hooft probes are genuine for the chosen global form and discrete theta parameter.

Screening and confinement are therefore statements about the behavior of renormalized extended operators with charges in a specified line spectrum. They are developed in Chapter 116. Gauging a finite one-form symmetry and tracking its anomaly require cochain-level background fields and are developed in Chapters 117 and 123.

Open Problem 113.7 (Global structure from continuum local data). Determine, for a continuum QFT specified by local fields and local correlators, what additional data recover the full lattice of genuine line, surface, and defect operators. A Wightman field presentation determines local correlators and charged local sectors under stated hypotheses; global form, higher-form symmetries, and extended-operator completeness require further information about bundles, boundary conditions around defects, screening, and topological defect fusion.

Chapter 114

Extended Operators and Topological Defects

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Extended operators are QFT data supported on submanifolds. Their definition fixes allowed singularities, endpoint conditions, defect degrees of freedom, counterterms along the support, and the correlation functionals obtained after the regulator is removed. Local operator algebras control the behavior near points. A full theory also contains a completion by line, surface, wall, and higher-codimension objects, together with rules for their collision, crossing, and fusion.

114.1 Submanifold Support And Tubular Neighborhood Data

Let M be a smooth D-dimensional spacetime manifold, Euclidean or Lorentzian according to the context. Let

$$i : \Sigma^p \hookrightarrow M$$

be a properly embedded oriented p-manifold. Its normal bundle is

$$N_{\Sigma/M} = i^*TM/T\Sigma, \qquad \mathrm{rank}\, N_{\Sigma/M} = D - p.$$

When a framing, spin structure, orientation of the normal bundle, or background gauge field is required, that structure is part of the support datum. For sufficiently small $\varepsilon > 0$, a tubular neighborhood is a disk bundle

$$T_\varepsilon(\Sigma) \subset N_{\Sigma/M}$$

embedded in M. The punctured neighborhood

$$T_\varepsilon(\Sigma) \setminus \Sigma$$

records how bulk fields approach the support.

Definition 114.1 (Extended operator datum)**.** An extended operator $D(\Sigma)$ supported on $\Sigma \subset M$ is a renormalized correlation-functional datum consisting of:

support data	$(\Sigma, N_{\Sigma/M})$ with the declared auxiliary structures,
bulk condition	allowed fields on $M \setminus T_\varepsilon(\Sigma)$,
normal model	singular or boundary behavior on $\partial T_\varepsilon(\Sigma)$,
defect fields	degrees of freedom living on Σ when present,
coupling	local terms coupling bulk and defect variables,
counterterms	local functionals on Σ used in the limit $\varepsilon \to 0$,
correlators	distributions with insertions away from Σ.

Two representatives define the same extended operator when all renormalized correlation distributions with external insertions away from the support agree.

For local fields $\mathcal{O}_j(x_j)$ inserted at points

$$x_j \in M \setminus \Sigma,$$

the defining distributions are

$$\langle D(\Sigma)\, \mathcal{O}_1(x_1) \cdots \mathcal{O}_n(x_n) \rangle\,.$$

They are defined on the configuration space where the x_j are pairwise distinct and avoid Σ, and they are extended to collision loci by a chosen bulk and defect renormalization prescription. The bulk-to-defect operator product expansion is the local expansion, in a normal coordinate

$$x = \exp_y(r\hat{n}), \qquad y \in \Sigma, \quad \hat{n} \in S(N_{\Sigma/M,y}),$$

of a bulk operator near the defect:

$$\mathcal{O}(x)\, D(\Sigma) \sim \sum_\alpha C_{\mathcal{O}\alpha}(r, \hat{n}; \partial_y)\, \widehat{\mathcal{O}}_\alpha(y)\, D(\Sigma).$$

The operators $\widehat{\mathcal{O}}_\alpha$ are local operators of the defect theory on Σ. The coefficients are distributions in the normal variables and differential operators along Σ. This expansion is part of the defect's short-distance data, just as the ordinary OPE is part of the local operator algebra.

Figure 114.1 records the basic operations on extended defects used in this chapter: tubular neighborhoods, defect-local operators, fusion, and deformation through topological regions.

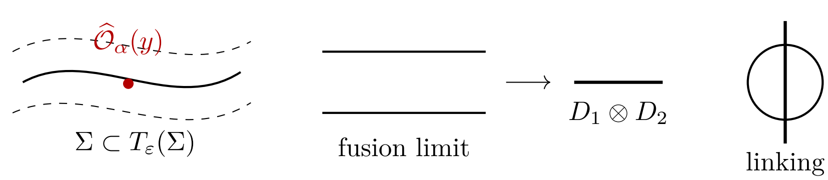

Figure 114.1: Tubular-neighborhood data for a defect Σ, including a defect-local insertion $\widehat{\mathcal{O}}_\alpha(y)$, fusion of parallel defects, and a topological linking configuration.

114.2 Genuine Defects, Boundaries, And Junctions

Let $D(\Sigma)$ have codimension $c = D - p$. A defect is genuine when its definition uses only data on an arbitrarily small tubular neighborhood of Σ and the complement $M \setminus \Sigma$. If an additional $(p+1)$-dimensional submanifold B with

$$\partial B = \Sigma$$

is required, then the insertion is a boundary of a higher defect rather than an autonomous p-dimensional defect. This distinction is part of the operator spectrum of the theory.

If two p-dimensional defects D_a and D_b meet along a $(p-1)$-dimensional submanifold J, the junction is a lower-dimensional defect operator

$$\Psi_{ab}(J) \in \mathrm{Hom}(D_a, D_b)$$

in the defect category appropriate to the theory. For a line operator, a point endpoint is a local operator in such a Hom space. In gauge theory, a Wilson line in representation R ending at a point requires an endpoint operator transforming in $R^\vee$ or an equivalent charged state. The existence of such an endpoint is the operator statement of screening.

114.3 The Displacement Operator

Let $D(\Sigma)$ be a renormalized defect in a QFT with stress tensor $T_{\mu\nu}$. Near a point of Σ, choose coordinates

$$(y^a, n^i), \qquad a = 1, \ldots, p, \quad i = 1, \ldots, D - p,$$

where y^a are tangent to Σ and n^i are normal coordinates. Translation perpendicular to the defect is broken by the insertion. The corresponding Ward identity has the form

$$\nabla_\mu T^{\mu i}(y, n) = \delta_\Sigma(n)\, \mathcal{D}^i(y)$$

inside correlation functions with the defect inserted, up to contact terms with other insertions. The defect local operator

$$\mathcal{D}^i(y)$$

is the displacement operator. Its index is a section of

$$N_{\Sigma/M}.$$

The identity is a definition of the normalization of $\mathcal{D}^i$.

Proposition 114.2 (Shape variation and displacement). *Let Σ_t be a smooth one-parameter family of embedded supports with $\Sigma_0 = \Sigma$. Let*

$$v^i(y) = \left.\frac{d\Sigma_t}{dt}\right|_{t=0}$$

be the normal deformation vector. Assume the external insertions are kept away from the swept tubular neighborhood and that no boundary term is produced at infinity or at $\partial\Sigma$. Then

$$\left.\frac{d}{dt}\right|_{t=0} \langle D(\Sigma_t)\, \mathcal{X} \rangle = - \int_\Sigma d^p y\, \sqrt{h}\, v_i(y) \left\langle \mathcal{D}^i(y)\, D(\Sigma)\, \mathcal{X} \right\rangle,$$

where h is the induced metric on Σ and $\mathcal{X}$ is the product of external insertions.

Proof. Represent the deformation by a diffeomorphism generated by a vector field v^μ supported in the tubular neighborhood and normal to Σ on the support. The variation of a correlation functional under this diffeomorphism is the Ward variation generated by the stress tensor:

$$\delta_v\langle D(\Sigma)\mathcal{X}\rangle = -\int_M d^D x\,\sqrt{g}\,\nabla_\mu v_\nu \langle T^{\mu\nu}(x) D(\Sigma)\mathcal{X}\rangle.$$

Integrating by parts gives

$$\delta_v\langle D(\Sigma)\mathcal{X}\rangle = \int_M d^D x\,\sqrt{g}\,v_\nu \langle \nabla_\mu T^{\mu\nu}(x) D(\Sigma)\mathcal{X}\rangle,$$

with no boundary contribution by hypothesis. Tangential components generate reparametrizations of the support, so only the normal components contribute to the shape. Inserting the defect Ward identity

$$\nabla_\mu T^{\mu i} = \delta_\Sigma \mathcal{D}^i$$

and using

$$\int_M d^D x\,\sqrt{g}\,\delta_\Sigma(n) f(x) = \int_\Sigma d^p y\,\sqrt{h}\,f(y,0)$$

gives the stated formula, with the sign fixed by the convention that moving the support rather than the coordinates gives the opposite diffeomorphism. □

Definition 114.3 (Topological defect)**.** A defect $D(\Sigma)$ is topological relative to a declared class of background structures when its renormalized correlation functionals are invariant under every isotopy of Σ that preserves those background structures and avoids the other insertions.

Displacement criterion. Under the hypotheses of Proposition 114.2, if the displacement operator vanishes inside the physical correlation functionals, then $D(\Sigma)$ is topological. In a cohomological theory with odd differential Q, the same conclusion holds for Q-closed external insertions when

$$\mathcal{D}^i = \{Q, \mathcal{V}^i\}_{\mathrm{gr}}$$

and the Q-Ward identity has no boundary contribution.

The shape derivative is the integral of the displacement insertion. If the displacement insertion vanishes in all relevant correlators, the derivative along every isotopy path is zero. If $\mathcal{D}^i = \{Q, \mathcal{V}^i\}_{\mathrm{gr}}$, the integrand is a Q-variation after moving Q through the Q-closed external insertions. The Ward identity sets the expectation value of this Q-variation to zero. Hence the correlation functional is constant along the isotopy.

114.4 Fusion

Let $D_1(\Sigma)$ and $D_2(\Sigma)$ be topological defects of the same dimension and compatible normal structures. Choose two nearby parallel copies $\Sigma_0, \Sigma_\varepsilon$ inside a tubular neighborhood. Their fusion is defined by the correlation-function limit

$$(D_1 \otimes D_2)(\Sigma) = \lim_{\varepsilon \downarrow 0} D_1(\Sigma_\varepsilon) D_2(\Sigma_0),$$

with external insertions kept outside the tubular neighborhood. The limit is taken after subtracting local defect counterterms supported on Σ. The result can be a single defect, a finite direct sum, an integral over continuous labels, or a distributional kernel. The precise target depends on the analytic category in which the QFT and its defects are defined.

Fusion is associative when the triple-collision limits are compatible:

$$(D_1 \otimes D_2) \otimes D_3 \cong D_1 \otimes (D_2 \otimes D_3).$$

The isomorphism is part of the defect data. In a fully extended topological theory these associators, unit defects, adjoints, and higher junctions form a higher category. In a non-topological QFT, the same language applies only to the topological subsector of defects or to protected cohomological defects for which the required collision limits exist.

Example 114.4 (Group-like topological defects)**.** Let A be a finite abelian group. A set of invertible topological defects

$$\{U_a\}_{a \in A}$$

is group-like when

$$U_a \otimes U_b = U_{a+b}, \qquad U_0 = \mathbf{1}, \qquad U_a^{-1} = U_{-a}.$$

For $A = \mathbb{Z}_N$, this says

$$U_r \otimes U_s = U_{r+s \bmod N}.$$

The associator may be trivial or may carry a cocycle. A nontrivial cocycle is part of the anomaly data of the symmetry-defect system.

114.5 Higher-Form Ward Defects

Let A be an abelian p-form symmetry group in a D-dimensional QFT. For

$$a \in A$$

there is a topological symmetry defect

$$U_a(N)$$

supported on an oriented closed $(D-p-1)$-manifold

$$N^{D-p-1} \subset M.$$

A charged p-dimensional operator

$$W_q(\Sigma^p)$$

has charge

$$q \in \widehat{A} = \mathrm{Hom}(A, U(1)).$$

When N and Σ are disjoint, their linking number is the integer

$$\mathrm{Link}(N, \Sigma) \in \mathbb{Z}$$

defined as follows. If $N = \partial B$ for an oriented $(D-p)$-chain B transverse to Σ, then

$$\mathrm{Link}(N, \Sigma) = B \cdot \Sigma,$$

the signed intersection number. In general the same integer is the Alexander-duality pairing between the homology class of N in

$$H_{D-p-1}(M \setminus \Sigma; \mathbb{Z})$$

and the class of Σ.

Higher-form Ward action. For an abelian p-form symmetry defect $U_a(N)$ and a charged p-operator $W_q(\Sigma)$, the Ward action inside correlation functions whose other insertions are outside the isotopy region is

$$U_a(N)\, W_q(\Sigma) = q(a)^{\mathrm{Link}(N,\Sigma)} W_q(\Sigma)$$

inside correlation functions whose other insertions are outside the isotopy region. For $A = \mathbb{Z}_N$, with $a = r$ and $q = s$ represented by integers modulo N,

$$q(a) = \exp\left(\frac{2\pi i\, rs}{N}\right).$$

This is the topological definition of the action written in linking-number form. Because U_a is topological, move N through the complement of Σ without changing the correlator. The only change occurs when the swept chain crosses Σ. A single positive crossing implements the symmetry action on W_q, which is multiplication by the character

$$q(a) \in U(1).$$

A negative crossing contributes $q(a)^{-1}$. Summing the signed crossings gives the intersection number $B \cdot \Sigma$ for a bounding chain $\partial B = N$. This is the linking number. Homological invariance of the intersection pairing extends the formula to the Alexander-duality definition of linking. For $\mathbb{Z}_N$, the character group is canonically $\mathbb{Z}_N$ after choosing the generator

$$s(r) = \exp(2\pi i\, rs/N),$$

which gives the displayed phase.

The dimensions satisfy

$$\dim N + \dim \Sigma = (D - p - 1) + p = D - 1,$$

which is the dimension condition for linking in D dimensions. If N crosses an endpoint or junction of W_q, the Ward identity includes the action on that endpoint or junction operator as well. Charge conservation at a junction is the statement that the product of all character factors associated with a small linking symmetry defect around the junction is one.

114.6 Locality And Braiding

In Lorentzian signature, two extended operators with spacelike separated supports admit an exchange operation. For ordinary bosonic local operators this exchange is commutation. For line, surface, and defect operators the exchange can carry a braiding determined by topology, spin, and gauge charge. The braiding is measured by transporting one support around another in the configuration space of disjoint submanifolds.

For abelian Wilson–'t Hooft line charges

$$\gamma = (\lambda, m), \qquad \gamma' = (\lambda', m'),$$

the center-sensitive part of the braiding phase is

$$\exp\bigl(2\pi i\, B(\gamma,\gamma')\bigr), \qquad B(\gamma,\gamma') = \lambda(m') - \lambda'(m),$$

with the pairing defined in Chapter 113. A line spectrum in a four-dimensional gauge theory is mutually local when this phase is one for every pair of genuine lines in the declared spectrum. The analytic construction of the corresponding magnetic and dyonic lines is developed in Chapter 115.

114.7 Defect Completeness Data

The local observable net or Wightman field content determines many constraints on defects: covariance, locality, stress-tensor Ward identities, superselection sectors, and possible endpoint charges. A QFT also contains additional completion data specifying which extended operators are genuine, which higher defects they may bound, which junctions exist, and which fusion limits are part of the theory. Distinct global forms of a gauge theory have the same local Lie algebra and perturbative local vertices but different line spectra and higher-form symmetry defects. This is the basic reason that extended operators must be included as primary QFT data in any complete nonperturbative definition.

Open Problem 114.5 (Extended operators from local reconstruction)*.* Develop reconstruction theorems that recover the extended-operator completion of a QFT from local observables, phase-space or split-property data, superselection sectors, and specified global-form input. The target is a theorem that identifies the genuine line, surface, wall, endpoint, junction, and fusion data determined by locality and duality, and separates that determined part from additional global completion choices.

Chapter 115

Line, Surface, and Domain-Wall Operators

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.

- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Extended operators are QFT data supported on submanifolds. They are not determined by local operators alone. This chapter defines the basic objects needed for later discussions of confinement, screening, duality, and anomaly inflow.

115.1 Defect Data

Let X be a spacetime manifold and let $Y \subset X$ be an embedded submanifold. A defect supported on Y is specified by:

(i) a choice of fields or boundary conditions on the complement $X \setminus Y$;

(ii) singular behavior or extra degrees of freedom along Y;

(iii) a coupling between bulk and defect variables;

(iv) a renormalization prescription for correlation functions with the defect inserted;

(v) an equivalence relation identifying defect representatives with the same correlation functionals.

The codimension of Y determines whether the object is a local operator, line, surface, domain wall, boundary condition, or higher defect.

115.2 Wilson Lines

Let G be a compact gauge group and R a finite-dimensional representation. For an oriented curve γ, the Wilson line is the parallel-transport functional

$$W_R(\gamma) = \mathrm{Tr}_R \ \mathrm{Pexp} \int_\gamma A.$$

In a regulated quantum gauge theory this expression is a coordinate for a renormalized line operator. Its definition requires the global form of G, the representation R, framing or endpoint data when needed, and a renormalization scheme for the short-distance singularity along the line. If γ is open, the endpoints must carry charged states or additional operators so that the full insertion is gauge invariant.

For a closed curve, choose a base point $p \in \gamma$ and write $\mathrm{Hol}_\gamma(A) \in G$ for parallel transport from p back to p. Under a gauge transformation $u : X \to G$,

$$\mathrm{Hol}_\gamma(A^u) = u(p)^{-1} \, \mathrm{Hol}_\gamma(A) u(p),$$

so $\mathrm{Tr}_R \, \mathrm{Hol}_\gamma(A)$ is gauge invariant. For an interval $\gamma = [p_-, p_+]$, parallel transport is a map

$$U_\gamma(A) : R_{p_-} \longrightarrow R_{p_+}, \qquad U_\gamma(A^u) = R(u(p_+))^{-1} U_\gamma(A) R(u(p_-)).$$

Gauge invariance is then obtained after contracting the endpoint indices with charged endpoint vectors or endpoint local operators in the dual representations. This endpoint bookkeeping is part of the line definition because it determines whether the line is genuine, a boundary of a surface operator, or an operator that changes the charged sector of the Hilbert space.

115.3 Magnetic and Dyonic Lines

A magnetic line in four-dimensional gauge theory is defined by a prescribed singularity of the gauge field near a curve. Around a small sphere linking the line, the magnetic flux is labelled by a cocharacter

$$m : U(1) \longrightarrow G$$

modulo conjugation, or equivalently by an element of the magnetic cocharacter lattice modulo the Weyl group. A dyonic line carries both the magnetic label m and an electric representation of the stabilizer of m. The allowed electric and magnetic labels obey the Dirac pairing condition: the phase obtained by moving one line around another must be trivial for mutually local operators in the chosen theory.

The global form of the gauge group changes the allowed labels. For example, the electric lattice of $SU(N)$ differs from that of $PSU(N)$, and the dual magnetic lattice changes accordingly. Therefore the line-operator spectrum is part of the definition of a gauge theory: it is fixed by the global gauge group, the allowed bundles, and the chosen mutually local electric-magnetic charge lattice.

115.3.1 The Local Monopole Model

Let $m : U(1) \to T \subset G$ be a cocharacter and let

$$m_* : \mathrm{i}\mathbb{R} \longrightarrow \mathfrak{t}$$

be its differential. We identify m_* with the element of $\mathfrak{t}$ obtained by evaluating the differential on i. On a small oriented two-sphere linking the candidate line, use spherical coordinates (ϑ, φ). Cover the sphere by the northern and southern patches $U_N = \{\vartheta \neq \pi\}$ and $U_S = \{\vartheta \neq 0\}$. The embedded Dirac monopole connection is

$$A_N = \frac{m_*}{2}(1 - \cos\vartheta)\,\mathrm{d}\varphi, \qquad A_S = -\frac{m_*}{2}(1 + \cos\vartheta)\,\mathrm{d}\varphi. \tag{115.1}$$

On the overlap,

$$A_N - A_S = m_*\,\mathrm{d}\varphi.$$

The transition function

$$g_{NS}(\varphi) = m(e^{\mathrm{i}\varphi})$$

satisfies

$$A_N = g_{NS}^{-1} A_S g_{NS} + g_{NS}^{-1} \mathrm{d} g_{NS}$$

in the abelianized T-valued model, and in a nonabelian theory after the choice of local reduction to T. Its curvature is

$$F_m = \frac{m_*}{2} \sin\vartheta\,\mathrm{d}\vartheta \wedge \mathrm{d}\varphi, \qquad \int_{S^2} \frac{F_m}{2\pi} = m_*. \tag{115.2}$$

The equality in the second formula means equality in the cocharacter lattice after pairing with characters of T.

Lemma 115.1 (Cocharacter criterion for the monopole singularity)**.** *The local model* (115.1) *defines a G-connection on the punctured ball modulo the chosen singularity exactly when $m \in X_*(T) = \mathrm{Hom}(U(1), T)$. For every character $\lambda \in X^*(T)$, a charge-λ Wilson probe transported across the Dirac ray changes by the phase*

$$\exp\bigl(2\pi\mathrm{i}\langle\lambda, m\rangle\bigr),$$

which is one by the definition of the character-cocharacter pairing.

Proof. The northern and southern gauge potentials define a single connection on the punctured sphere precisely when the transition map on the equatorial overlap is a single-valued smooth map $S^1 \to T$. Such maps are exactly cocharacters $m : U(1) \to T$. The relation $g_{NS}^{-1}\mathrm{d}g_{NS} = m_*\,\mathrm{d}\varphi$ gives the patching equation above.

Let a Wilson probe have T-weight λ. In the one-dimensional weight space, $g_{NS}(\varphi)$ acts by

$$\lambda(g_{NS}(\varphi)) = \lambda(m(e^{\mathrm{i}\varphi})) = e^{\mathrm{i}\langle\lambda, m\rangle\varphi}.$$

Taking φ once around the equator gives $\exp(2\pi\mathrm{i}\langle\lambda, m\rangle)$. Since $\lambda \circ m : U(1) \to U(1)$ is a group homomorphism, it has integer degree $\langle\lambda, m\rangle$. Hence the phase is trivial. Conversely, a T-valued transition map with this single-valuedness property for all characters is an element of $X_*(T)$, because characters separate points of the compact torus. $\square$

Two cocharacters related by the Weyl group determine gauge-equivalent local singularities: a gauge transformation whose value on the linking sphere implements the Weyl representative conjugates one Cartan reduction to the other. The underlying topological class of the G-bundle on the linking two-sphere records only the image of m in $\pi_1(G)$. The full cocharacter class is finer data: it fixes an asymptotic reduction of the connection and thereby determines the stabilizer group and electric labels of a dyonic refinement.

Definition 115.2 (Renormalized 't Hooft line)**.** Let X be an oriented four-manifold, let $\gamma \subset X$ be an oriented embedded curve, and let G be a compact connected gauge group with maximal torus T and Weyl group W. A bare magnetic line of magnetic charge

$$m \in \mathrm{Hom}(U(1), T)/W$$

is defined by removing a tubular neighborhood $N_\epsilon(\gamma)$ and integrating over G-connections on $X \setminus N_\epsilon(\gamma)$ whose restriction to each small linking sphere S^2_p lies in the topological class determined by m. In a local trivialization over $\gamma \times (S^2_p \setminus \{\text{Dirac ray}\})$, this means that the connection is gauge-equivalent near the boundary to the embedded Dirac monopole

$$F \sim \frac{m_*}{2} \sin\theta \, \mathrm{d}\theta \wedge \mathrm{d}\varphi, \qquad \int_{S^2_p} \frac{F}{2\pi} = m_*,$$

where $m_* \in \mathfrak{t}$ is the differential of the cocharacter in the chosen normalization. Gauge transformations are required to preserve the cocharacter class on the boundary. Let $\mathcal{A}_m$ denote the resulting space of regulated connections and let $\mathcal{G}_m$ denote the corresponding boundary-preserving gauge group. The renormalized 't Hooft line $H_m(\gamma)$ is the limit

$$H_m(\gamma) = \lim_{\epsilon \to 0} Z_{\text{line}}(\epsilon) \int_{\mathcal{A}_m(X \setminus N_\epsilon(\gamma))/\mathcal{G}_m} \mathcal{D}A \, \exp(-S[A])$$

as a correlation functional with the same additional insertions, after multiplication by local line counterterms $Z_{\text{line}}(\epsilon)$. The definition exists only in a specified regulator or constructive framework in which the limit and the allowed counterterms are part of the line-operator data.

115.3.2 Dyonic Refinement and the Stabilizer

The magnetic singularity m breaks the gauge transformations along the line to the centralizer

$$G_m = Z_G(m(U(1))).$$

Equivalently, G_m is the compact subgroup whose Lie algebra is the sum of $\mathfrak{t}$ and the root spaces with roots α satisfying $\langle \alpha, m \rangle = 0$. The tangential component of the connection along γ, restricted to the boundary condition above, is a G_m-connection up to terms fixed by the singular normal model. A dyonic Wilson–'t Hooft line is therefore specified by

$$(m, \rho), \qquad m \in X_*(T)/W, \quad \rho \in \mathrm{Rep}(G_m),$$

with the convention that ρ is replaced by its Weyl-conjugate representation when m is Weyl-conjugated. The insertion is the magnetic boundary condition together with the Wilson parallel transport in ρ for the residual G_m-connection along γ, followed by the same line-counterterm renormalization appearing in Definition 115.2. If γ has endpoints, the endpoint states must be modules for the corresponding residual stabilizer groups.

For center-sensitive questions it is often enough to abelianize the label to

$$(\lambda, m) \in \big(\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}}\big) \oplus \big(\Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}}\big),$$

as in Chapter 113. This quotient records the charge detected by electric and magnetic one-form symmetries. The full operator also contains the stabilizer representation, defect counterterms, and the choice of regularization.

Linking phase and mutual locality. Let $L_{\lambda,m}$ and $L_{\lambda',m'}$ be two abelianized dyonic labels in the universal center-sensitive lattice. In a configuration where the first line links once with the second, the finite topological phase obtained by moving the first line around the second is

$$\exp\big[2\pi\mathrm{i}\big(\lambda(m') - \lambda'(m)\big)\big]\,.$$

Consequently two line labels can belong to the same mutually local genuine line spectrum only if

$$\lambda(m') - \lambda'(m) \in \mathbb{Z}. \tag{115.3}$$

Choose disjoint tubular neighborhoods of the two curves. Near $L_{\lambda',m'}$, the first line's Wilson factor of weight λ sees the transition function $m'(e^{\mathrm{i}\varphi})$ when its path crosses the Dirac ray of the second magnetic singularity. By the computation in Lemma 115.1, the phase is $\exp(2\pi\mathrm{i}\lambda(m'))$. Interchanging the roles of the two lines gives $\exp(2\pi\mathrm{i}\lambda'(m))$. The orientation convention for linking assigns the second contribution with the opposite sign, because dragging the first line around the second is inverse to dragging the second around the first. Multiplying the two contributions gives the displayed phase. The line operators are mutually local precisely when the phase is one for all allowed linking moves, which is (115.3).

Screening equivalence of center-sensitive charges. Adjoint dynamical particles shift the electric weight of a line by an element of the root lattice Λ_{rt}. Smooth monopole cores shift the magnetic cocharacter by an element of the coroot lattice Λ_{crt}. Therefore the finite charge of a genuine Wilson–'t Hooft line is a class in

$$\big(\Lambda_{\mathrm{wt}}/\Lambda_{\mathrm{rt}}\big) \oplus \big(\Lambda_{\mathrm{cwt}}/\Lambda_{\mathrm{crt}}\big),$$

subject to the mutual-locality condition imposed by the chosen theory.

An adjoint field transforms with weights in the root lattice together with zero weights. Attaching a massive adjoint particle worldline to a Wilson line changes the line's electric weight by one of these roots. The endpoint of the adjoint worldline is a local charged insertion in the screened sector, so the two Wilson lines differ by a locally creatable charge and have the same finite one-form charge.

For the magnetic statement, a smooth finite-energy monopole embedded in the $\mathfrak{su}(2)$ subalgebra of a root α has magnetic charge the coroot $\alpha^\vee$. Bringing such a monopole worldline to the 't Hooft line changes the singular cocharacter by $\alpha^\vee$ while leaving the asymptotic bundle class modulo smooth monopole creation unchanged. The coroots generate Λ_{crt}, so magnetic charges are screened modulo this lattice.

115.3.3 Theta Angle and the Witten Effect

In an abelian sector with curvature normalized by $\int_\Sigma F/(2\pi) \in \mathbb{Z}$, the theta term changes the electric charge measured at infinity in a magnetic background. With the convention

$$S_\theta = \frac{\mathrm{i}\theta}{8\pi^2} \int_X F \wedge F$$

in Euclidean signature, varying the action with respect to the boundary value of A shows that the electric displacement receives the magnetic contribution $(\theta/2\pi)m$. Thus a line whose integral electric label is λ and magnetic label is m has theta-dependent electric charge

$$q_\theta = \lambda + \frac{\theta}{2\pi} m$$

after pairing with any probe character. Under $\theta \mapsto \theta + 2\pi$, the integral label changes by the lattice automorphism

$$T : (\lambda, m) \longmapsto (\lambda + m, m). \tag{115.4}$$

For a nonabelian gauge theory the theta term contains a chosen invariant integral quadratic form. Its polarization gives a symmetric homomorphism

$$I : X_*(T) \longrightarrow X^*(T), \qquad I(m)(m') = I(m, m').$$

The Witten-effect automorphism is then

$$T_I : (\lambda, m) \longmapsto (\lambda + I(m), m).$$

The abelian formula (115.4) is the special case in which I is the identity under the chosen electric-magnetic identification. The automorphism T_I preserves the Dirac pairing:

$$(\lambda + I(m))(m') - (\lambda' + I(m'))(m) = \lambda(m') - \lambda'(m),$$

because $I(m, m') = I(m', m)$. Hence theta periodicity maps mutually local line spectra to mutually local line spectra.

For $G = U(1)$, the cocharacter lattice is $\mathbb{Z}$. The minimal 't Hooft line $H(\gamma)$ has magnetic charge 1, so the boundary condition is

$$\int_{S^2_p} \frac{F}{2\pi} = 1$$

for every small linking sphere. If the line also carries electric charge q, one multiplies the magnetic boundary condition by a Wilson factor for the unbroken gauge group along γ; this gives a dyonic line. A dynamical monopole operator is an endpoint for such a magnetic line. Hence a theory containing dynamical monopoles does not have the magnetic one-form symmetry under which closed 't Hooft lines are charged.

115.4 Surface Operators

A surface operator supported on a two-dimensional submanifold Σ may be defined by singular behavior of the gauge field, by coupling a two- dimensional QFT on Σ to the bulk, or by inserting a higher-form charged object. In four-dimensional gauge theory an abelianized surface singularity has local model

$$A \sim \alpha\, d\varphi$$

near the normal plane to Σ, where α is valued in a Cartan subalgebra modulo the cocharacter lattice and Weyl group. Additional parameters can couple to the magnetic flux through Σ. A complete definition must state the singularity, defect counterterms, gauge equivalence, and how local operators approaching the surface are renormalized.

Here is the corresponding local definition. Let N_Σ be the oriented real rank-two normal bundle of Σ, and on each punctured normal disk write polar coordinates (r, φ). A Cartan-type surface singularity is a reduction of the gauge field near Σ to a maximal torus T with

$$A = \alpha\, \mathrm{d}\varphi + A_{\mathrm{reg}}, \qquad \alpha \in \mathfrak{t}, \tag{115.5}$$

where A_{reg} has a finite limit as $r \to 0$ in the chosen regulator. The holonomy around a small positively oriented normal circle is

$$\exp(2\pi\alpha) \in T$$

after the convention that $\mathfrak{t}$ is the compact real Lie algebra. If $u \in X_*(T)$, the gauge transformation

$$g_u(\varphi) = u(e^{\mathrm{i}\varphi})$$

shifts α by u_*. Thus the singular holonomy parameter is

$$\alpha \in \mathfrak{t}/X_*(T)$$

modulo the Weyl group. In distributional notation the singular part of the curvature is

$$F_{\mathrm{sing}} = 2\pi\alpha\, \delta_\Sigma,$$

where δ_Σ is the two-form current Poincare dual to Σ; the formula is an instruction for the regulated boundary condition and for the boundary values of correlation functions with the surface insertion.

An abelianized surface operator may also contain a two-dimensional theta parameter

$$\eta \in X^*(T) \otimes_{\mathbb{Z}} \mathbb{R}/X^*(T),$$

paired with magnetic flux through Σ. If F_T denotes the regularized T-curvature on Σ, the phase is

$$\exp\left(2\pi\mathrm{i}\,\eta\left(\int_\Sigma \frac{F_T}{2\pi}\right)\right),$$

with the flux interpreted in the cocharacter lattice. The pair (α, η), modulo cocharacter shifts and Weyl transformations, is the center-sensitive datum of the abelianized surface singularity. Coupling a genuine two-dimensional QFT on Σ refines this datum by adding a defect Hilbert space, a defect stress tensor, and defect counterterms.

Gauge equivalence of Cartan surface singularities. Two Cartan surface singularities with parameters $\alpha, \alpha' \in \mathfrak{t}$ have the same normal-circle holonomy datum exactly when

$$\alpha' = w(\alpha) + u_* \qquad \text{for some } w \in W,\ u \in X_*(T).$$

A boundary-preserving gauge transformation may conjugate the chosen Cartan reduction by an element of the normalizer $N_G(T)$; modulo T, this is the Weyl action $W = N_G(T)/T$. A gauge transformation on the punctured normal disk whose restriction to the normal circle is a map $S^1 \to T$ is a cocharacter u, and its logarithmic derivative is $u_* \, \mathrm{d}\varphi$. It shifts the coefficient of $\mathrm{d}\varphi$ by u_*. These two operations generate the displayed equivalence.

Conversely, equal holonomies in the compact torus mean $\exp(2\pi\alpha') = \exp(2\pi w(\alpha))$ for some Weyl representative after matching Cartan reductions. The kernel of the exponential map $\mathfrak{t} \to T$ is the cocharacter lattice, so $\alpha' - w(\alpha) = u_*$ for some $u \in X_*(T)$.

115.5 Domain Walls and Interfaces

A domain wall between theories T_- and T_+ is a codimension-one defect whose correlation functional takes bulk fields of T_- on one side and bulk fields of T_+ on the other. A topological wall is one whose correlators are invariant under deformations of the wall that avoid other insertions. Such a wall acts on local and extended operators by bringing an operator to the wall and moving it through, provided the required limits exist.

Definition 115.3 (Fusion of topological defects)**.** Let D_1 and D_2 be parallel topological defects of the same codimension. Their fusion $D_1 \otimes D_2$, when it exists, is the defect defined by the limit in which the separation between D_1 and D_2 goes to zero, after subtracting or renormalizing local defect counterterms.

Fusion is an operation only after the limiting procedure and equivalence relation have been supplied. In favorable topological sectors the resulting objects form a category or higher category; in a general QFT the short-distance limit can produce new defect degrees of freedom or fail to exist.

Open Problem 115.4 (Extended-operator reconstruction). Given the local operator algebra and symmetry data of a QFT, determine what additional input is required to reconstruct its extended operators. The answer must include global forms, higher-form symmetries, singular boundary conditions, defect renormalization, and the topology in which defect fusion limits are taken.

Chapter 116

Confinement, Screening, and Oblique Confinement

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Confinement is a property of gauge-invariant extended-observable data in a specified infinite-volume or continuum limit. Its basic inputs are external probes, endpoint maps for dynamical charged objects, renormalized large-distance asymptotics of line insertions, and the Hilbert-space sectors generated by those probes. This chapter develops the finite charge-lattice and line-operator part of that structure. Chapter 119 then embeds it in the broader definition of a phase of a gauge theory.

116.1 Line-Charge Data

Let G be the global form of the compact gauge group and let $\mathfrak{g}$ be its Lie algebra. Fix a maximal torus $T \subset G$. Electric Wilson charges are integral weights of T that exponentiate to representations of G. Magnetic 't Hooft charges are cocharacters

$$U(1) \longrightarrow T$$

allowed by the same global form, modulo the Weyl group. We write the electric and magnetic charge groups as

$$\Gamma_{\mathrm{e}} \subset X^*(T), \qquad \Gamma_{\mathrm{m}} \subset X_*(T),$$

and a dyonic line label as

$$\gamma = (\lambda_{\mathrm{e}}, \lambda_{\mathrm{m}}) \in \Gamma_{\mathrm{e}} \oplus \Gamma_{\mathrm{m}}.$$

The unscreened center-sensitive part is often finite; for an $\mathfrak{su}(N)$ theory it is

$$\mathcal{C} = \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}.$$

The full charge lattice and the finite center-sensitive quotient should not be confused. The former remembers weights, cocharacters, and masses of dynamical states; the latter remembers precisely the data detected by center-linked topological surfaces and by the global form.

The Dirac pairing of two line labels is

$$\langle \gamma, \gamma' \rangle_D = \lambda_{\mathrm{e}}(\lambda'_{\mathrm{m}}) - \lambda'_{\mathrm{e}}(\lambda_{\mathrm{m}}) \in \mathbb{Z} \tag{116.1}$$

for simultaneously genuine lines. On the finite $\mathfrak{su}(N)$ charge group this becomes the alternating pairing

$$B((e,m),(e',m')) = \frac{em' - e'm}{N} \in \mathbb{Q}/\mathbb{Z}. \tag{116.2}$$

The phase acquired by moving one line once around the other is $\exp(2\pi \mathrm{i} B)$. Thus a set of line operators can be simultaneously genuine only when the relevant pairings vanish modulo integers.

Definition 116.1 (External charge system)**.** For the purposes of confinement diagnostics, an external charge system is a triple

$$(\mathcal{C}, B, S),$$

where $\mathcal{C}$ is a finite abelian group of center-sensitive line charges, $B : \mathcal{C} \times \mathcal{C} \to \mathbb{Q}/\mathbb{Z}$ is a nondegenerate alternating pairing, and $S \subset \mathcal{C}$ is the subgroup of charges screened by finite-energy dynamical objects. The quotient

$$\mathcal{C}_{\mathrm{ext}} = \mathcal{C}/S$$

is the group of static external charges modulo screening. If S is isotropic, the residual topological charge group is

$$\mathcal{C}_{\mathrm{top}} = S^{\perp}/S, \qquad S^{\perp} = \{\gamma \in \mathcal{C} \mid B(\gamma, s) = 0 \text{ for every } s \in S\}.$$

The distinction between $\mathcal{C}_{\mathrm{ext}}$ and $\mathcal{C}_{\mathrm{top}}$ is important. $\mathcal{C}_{\mathrm{ext}}$ classifies external sources after allowing dynamical endpoints. $\mathcal{C}_{\mathrm{top}}$ classifies charges with well-defined finite braiding after quotienting by screening.

Pairing on the screened topological quotient. If $S \subset \mathcal{C}$ is isotropic, then B descends to a nondegenerate alternating pairing on $S^{\perp}/S$. The verification is the linear algebra of orthogonal quotients. Let $\gamma, \eta \in S^{\perp}$ and change representatives by

$$\gamma \mapsto \gamma + s, \qquad \eta \mapsto \eta + t, \qquad s, t \in S.$$

Then

$$B(\gamma + s, \eta + t) - B(\gamma, \eta) = B(s, \eta) + B(\gamma, t) + B(s, t).$$

The first two terms vanish because $\gamma, \eta \in S^{\perp}$, and the last vanishes because S is isotropic. Hence the value of B is independent of representatives. The descended pairing is alternating because B is. For nondegeneracy, suppose $\bar{\gamma} \in S^{\perp}/S$ pairs trivially with all of $S^{\perp}/S$. Then γ pairs trivially with all of $S^{\perp}$, so $\gamma \in (S^{\perp})^{\perp}$. Nondegeneracy of B on $\mathcal{C}$ gives $(S^{\perp})^{\perp} = S$. Therefore $\bar{\gamma} = 0$.

116.2 Renormalized Line Laws

Let $L_\gamma(C)$ be a Euclidean line operator with charge $\gamma \in \mathcal{C}$ supported on a closed contour C. A regulator is part of the definition: on a lattice, C is a lattice path; in a continuum scheme, C is a smooth embedded loop together with a short-distance definition of the singular line insertion. A line has self-energy and possible curvature/contact counterterms. We therefore write

$$L_\gamma^{\mathrm{ren}}(C) = Z_\gamma(C,a)\, L_\gamma^{(a)}(C),$$

where a is the cutoff and $Z_\gamma(C,a)$ is local along the line in the chosen scheme. Statements about area or perimeter laws are statements about the renormalized object and about an order of limits.

Definition 116.2 (Area, perimeter, and zero-tension laws)**.** Let $\{C_R\}_{R\geq 1}$ be a family of planar loops whose linear size is R, with minimal spanning area A_R and length ℓ_R. Assume

$$A_R \to \infty, \qquad \ell_R \to \infty, \qquad A_R/\ell_R \to \infty.$$

For a renormalized line L_γ^{ren}:

1. an area law with string tension $\sigma_\gamma > 0$ means
$$-\log |\langle L_\gamma^{\mathrm{ren}}(C_R)\rangle| = \sigma_\gamma A_R + o(A_R);$$
2. a perimeter law means
$$-\log |\langle L_\gamma^{\mathrm{ren}}(C_R)\rangle| = \mu_\gamma \ell_R + o(\ell_R)$$
for some scheme-dependent μ_γ;
3. a zero-tension law means
$$\lim_{R\to\infty} \frac{-\log |\langle L_\gamma^{\mathrm{ren}}(C_R)\rangle|}{A_R} = 0.$$

The perimeter coefficient is not universal because it changes under local line counterterms. The statement $\sigma_\gamma > 0$, when defined by the area coefficient after perimeter renormalization, is the robust asymptotic claim. In a gapless Coulomb regime neither the area/perimeter dichotomy nor the word "string tension" is by itself a complete asymptotic description.

Definition 116.3 (Static potential from rectangular lines)**.** For a rectangular Euclidean loop $C_{T,L}$ of time length T and spatial separation L, define

$$V_\gamma(L) = -\lim_{T\to\infty} \frac{1}{T} \log\langle L_\gamma^{\mathrm{ren}}(C_{T,L})\rangle$$

when the limit exists after line renormalization. Linear confinement of the external charge γ means

$$V_\gamma(L) = \sigma_\gamma L + o(L), \qquad \sigma_\gamma > 0.$$

Screening means that $V_\gamma(L)$ remains bounded as $L \to \infty$.

Transfer-matrix extraction of the static potential. Assume a reflection-positive regulator with a transfer matrix, and assume the rectangular line creates a nonzero vector $\Psi_{\gamma,L}$ in the Hilbert space with static external sources separated by L. If

$$\langle L_\gamma^{\mathrm{ren}}(C_{T,L})\rangle = \langle \Psi_{\gamma,L}, e^{-T(H_{\gamma,L}-E_0)}\Psi_{\gamma,L}\rangle$$

and the spectral measure of $\Psi_{\gamma,L}$ has bottom $E_\gamma(L)$, then $V_\gamma(L) = E_\gamma(L)$.

Let $\rho_{\gamma,L}$ be the positive finite spectral measure of $H_{\gamma,L} - E_0$ in the vector $\Psi_{\gamma,L}$. The loop expectation is

$$\int e^{-TE}\, d\rho_{\gamma,L}(E).$$

If $E_\gamma(L)$ is the bottom of the support of this measure, then every interval $[E_\gamma(L), E_\gamma(L)+\varepsilon]$ has positive measure. The elementary Laplace principle for a finite positive measure gives

$$-\lim_{T\to\infty}\frac{1}{T}\log\int e^{-TE}\, d\rho_{\gamma,L}(E) = E_\gamma(L).$$

Indeed, the upper and lower bounds follow respectively from $E \geq E_\gamma(L)$ and from restricting the integral to $[E_\gamma(L), E_\gamma(L)+\varepsilon]$, then letting $\varepsilon \downarrow 0$.

116.3 Screening and String Breaking

Screening is a statement about endpoint maps. If a dynamical finite-energy operator or state carries line charge $s \in S$, then a line of charge $\gamma + s$ and a line of charge γ differ by an endpoint that can be supplied from the Hilbert space. The static probe cannot distinguish the two charges at arbitrarily long distance.

Endpoint screening bound on the static energy. Assume a charge γ can be screened by a pair of dynamical particles of finite mass M_{scr}, in the sense that the external-source sector at separation L contains a trial state equal outside bounded neighborhoods of the two sources to the vacuum, with energy at most $2M_{\mathrm{scr}} + o(1)$ above the vacuum. Then

$$\limsup_{L\to\infty} V_\gamma(L) \leq 2M_{\mathrm{scr}}.$$

In particular this external charge cannot have a positive linear static potential. This is a variational consequence of the trial-state hypothesis. In the transfer-matrix construction, $V_\gamma(L)$ is the infimum of the static-source Hamiltonian spectrum in the sector with external charge γ at separation L. For any normalized trial state Ψ_L in that sector,

$$V_\gamma(L) \leq \langle \Psi_L, H_{\gamma,L}\Psi_L\rangle - E_{\mathrm{vac}}.$$

The assumed screened trial state has the right charge at the endpoints and has energy $2M_{\mathrm{scr}}+o(1)$ above the vacuum. Taking the limsup gives the displayed bound. A function bounded along large L cannot satisfy $V_\gamma(L) = \sigma L + o(L)$ with $\sigma > 0$. The nontrivial physical input is not the inequality but the construction of the screened endpoint state in the regulated theory and its control under the large-volume and large-L limits.

This bound gives the precise endpoint-screening content needed to interpret Wilson loops in theories with dynamical fundamental matter. The closed loop may display a large intermediate string regime, while the asymptotic static energy is bounded once the string can break by pair creation. Fredenhagen–Marcu type ratios, defined in Chapter 119, measure a different overlap after dividing out the universal flux cost.

116.4 Strong-Coupling Lattice Area Law

Consider a hypercubic Euclidean lattice gauge theory with compact group G. Let each plaquette Boltzmann weight be a central function with character expansion

$$w(U_p) = \sum_R c_R \chi_R(U_p), \qquad c_{\mathbf{1}} > 0.$$

Write

$$q_R = \frac{c_R}{c_{\mathbf{1}}}.$$

At strong coupling the nontrivial q_R are small. The Wilson loop in an irreducible representation R_0 is

$$W_{R_0}(C) = \operatorname{tr}_{R_0} \prod_{\ell \in C} U_\ell.$$

The key algebraic fact is Haar projection: an integral over a link vanishes unless the tensor product of all representation matrices incident on that link contains the trivial representation.

Surface selection by Haar projection. In the character expansion of a Wilson-loop expectation, every nonzero term contains a collection of plaquettes whose oriented boundary carries the representation flux inserted by the Wilson loop. In particular a Wilson loop with nonscreened charge cannot be saturated by plaquettes supported away from a spanning surface.

Expand each plaquette weight in characters and integrate link by link. A link on the Wilson contour carries one matrix factor in R_0 or R_0^*. Haar integration over that link is the projection onto the invariant subspace of the tensor product of all representation factors incident on the link. Unless adjacent plaquette characters supply flux whose oriented boundary cancels the Wilson factor, the tensor product has no invariant vector in the center-sensitive sector and the integral is zero. Repeating this for every link on the contour forces a two-chain of plaquettes whose boundary is C, up to screened charges. If the charge is nonscreened, the boundary cannot be removed by local endpoints.

Controlled Approximation 116.4 (Area mechanism)**.**

Let R_0 have nonscreened center-sensitive charge. For a family of planar loops C_R, let $A_{\min}(C_R)$ be the minimal lattice area of a plaquette surface spanning C_R. A strong-coupling proof of an area mechanism consists of the following uniform polymer-expansion estimates. First, the Haar-projection selection rule permits no center-sensitive contribution of area $< A_{\min}(C_R)$. Second, the sum of all minimal-area contributions is nonzero and has magnitude at least

$$m_0 \exp[-\sigma_+ A_{\min}(C_R)]$$

for some $m_0 > 0$ and finite σ_+. Third, the total contribution of all larger decorated surfaces is bounded by

$$M_0 \exp[-(\sigma_+ + \delta)A_{\min}(C_R)]$$

for some $M_0 > 0$ and $\delta > 0$, after possibly restricting to a sufficiently small strong-coupling neighborhood. Once these estimates have actually been proved for the chosen lattice action, there are constants $a, b > 0$ such that

$$e^{-bA_{\min}(C_R)} \leq |\langle W_{R_0}(C_R)\rangle| \leq e^{-aA_{\min}(C_R)}$$

for all sufficiently large loops in the family, up to subexponential factors. Consequently every subsequential exponential rate $-A_{\min}(C_R)^{-1} \log |\langle W_{R_0}(C_R)\rangle|$ is strictly positive and finite.

The first hypothesis is the kinematic selection part: link integration forces the center-sensitive flux to be carried by a plaquette two-chain with boundary C_R, so no term of smaller area can occur. The third hypothesis gives the upper bound after choosing $a < \sigma_+$ and absorbing the subexponential number of local decorations into the prefactor. For the lower bound, write the expectation as $M_R + E_R$, where M_R is the minimal-area sum and $|E_R| \leq M_0 e^{-(\sigma_+ + \delta)A_{\min}}$. The lower estimate on $|M_R|$ gives

$$|M_R + E_R| \geq m_0 e^{-\sigma_+ A_{\min}} \left(1 - \frac{M_0}{m_0} e^{-\delta A_{\min}}\right),$$

which is at least $\frac{1}{2} m_0 e^{-\sigma_+ A_{\min}}$ for sufficiently large loops. This gives the lower exponential bound with any $b > \sigma_+$, after absorbing constants into the allowed subexponential factors. The logarithmic rate statement follows immediately. The exact string tension is not obtained from these estimates alone; it depends on the complete convergent polymer sum and on the lattice action.

This becomes a theorem about a controlled lattice regime only when the displayed area estimates are proved for the chosen action. Its continuum analogue requires a continuum limit, a mass gap or other infrared control, and renormalized line operators whose asymptotics survive the limit.

116.5 Three-Dimensional Monopole Gas Area Mechanism

There is one important continuum semiclassical setting where magnetic topological events do produce a Wilson-loop area law by a direct calculation: compact $U(1)$ gauge theory in three Euclidean dimensions, or the long-distance $U(1)$ sector of the three-dimensional Georgi–Glashow model after $SU(2)$ is Higgsed to $U(1)$. The magnetic events are monopole-instantons, not four-dimensional BPST instantons. Their physical effect is not a theta-vacuum cumulant; it is a mass for the dual photon and a domain-wall cost for an electric Wilson loop.

Controlled Approximation 116.5 (3D monopole gas area law)**.** Assume a three-dimensional compact Abelian infrared window in which the heavy charged fields are separated from the monopole scale, primitive monopoles and anti-monopoles have a finite fugacity ζ_{M}, and the dilute Coulomb-gas expansion is controlled on distances large compared with the monopole core. Let $\varphi \sim \varphi + 2\pi$ be the dual photon and choose the local normalization

$$S_{\mathrm{dual}}[\varphi] = \int_{\mathbb{R}^3} \left[\frac{\kappa_{\mathrm{d}}}{2}(\partial\varphi)^2 + 2\zeta_{\mathrm{M}}(1 - \cos\varphi)\right] \mathrm{d}^3x. \tag{116.3}$$

This is the sine–Gordon representative of the monopole and anti-monopole grand canonical sum in this normalization. Expanding at a vacuum $\varphi = 2\pi n$ gives the dual-photon mass

$$m_\gamma^2 = \frac{2\zeta_{\mathrm{M}}}{\kappa_{\mathrm{d}}}. \tag{116.4}$$

For a primitive electric Wilson loop $W(C)$ which is not screened by dynamical endpoints in the declared low-energy theory, the dual description imposes a 2π discontinuity of φ across an oriented spanning surface Σ with $\partial\Sigma = C$. For a large nearly planar loop, the leading saddle is a one-dimensional sine–Gordon wall normal to Σ. It satisfies

$$\kappa_{\mathrm{d}}\varphi'' = 2\zeta_{\mathrm{M}} \sin\varphi, \qquad \varphi(-\infty) = 0, \quad \varphi(+\infty) = 2\pi,$$

or, equivalently, the first-order equation

$$\varphi' = 2m_\gamma \sin\frac{\varphi}{2}. \tag{116.5}$$

The wall tension is therefore

$$\sigma_{\mathrm{P}} = \int_0^{2\pi} \sqrt{2\kappa_{\mathrm{d}}\, 2\zeta_{\mathrm{M}}(1-\cos\varphi)}\,\mathrm{d}\varphi = 8\sqrt{2\kappa_{\mathrm{d}}\zeta_{\mathrm{M}}} = 8\kappa_{\mathrm{d}} m_\gamma. \tag{116.6}$$

After local line counterterms have removed the perimeter self-energy, the Wilson loop has the semiclassical large-area form

$$-\log|\langle W(C)\rangle| = \sigma_{\mathrm{P}}\,\mathrm{Area}(\Sigma_{\min}) + o(\mathrm{Area}) \tag{116.7}$$

for loop families whose curvature radii and linear sizes are large compared with m_γ^{-1}, provided no lower-energy screened endpoint channel is available.

The derivation is the following finite chain of physical inputs. The monopole fugacity inserts $\mathrm{e}^{\mathrm{i}\varphi}$, the anti-monopole fugacity inserts $\mathrm{e}^{-\mathrm{i}\varphi}$, and the dilute grand canonical sum gives the cosine potential in (116.3). The cosine pins the dual photon and opens the mass gap (116.4). The Wilson loop is not evaluated by a monopole moduli-space volume; it changes the dual-photon boundary condition across Σ. The minimum action configuration with that discontinuity is the sine–Gordon wall, and its action per unit area is (116.6).

The scope of this mechanism is the three-dimensional compact-Abelian semiclassical window. Here the semiclassical objects live in three Euclidean dimensions, the dual photon is a local scalar in the infrared effective theory, and the Wilson loop is converted into a calculable wall problem. The dilute BPST instanton gas of Chapter 51 supplies theta-dependent amplitude data in four dimensions rather than this dual-photon wall mechanism.

116.6 Condensation and Oblique Confinement

The finite part of a gapped line-operator response can often be organized by an isotropic subgroup

$$K \subset \mathcal{C}$$

of condensed charges. The isotropy condition

$$B(k,k') = 0, \qquad k, k' \in K,$$

is mutual locality of the condensed objects. It is a consistency condition, not a dynamical proof that such objects actually condense.

Definition 116.6 (Finite confinement diagnostic from a condensate)**.** Given a finite charge system $(\mathcal{C}, B)$ and an isotropic subgroup $K \subset \mathcal{C}$, define

$$K^{\perp} = \{\gamma \in \mathcal{C} \mid B(\gamma, k) = 0 \text{ for every } k \in K\}.$$

The finite condensate diagnostic declares γ unconfined only if $\gamma \in K^{\perp}$. Charges outside $K^{\perp}$ have nontrivial finite braiding with the condensate and are confined in this diagnostic.

Assume a gapped regime in which perimeter-law lines must braid trivially with all condensed charges in an isotropic subgroup $K \subset \mathcal{C}$. Then only charges in $K^{\perp}$ can have perimeter behavior. If K is maximal isotropic, then $K^{\perp} = K$. Moving a test line of charge γ once around a condensed object of charge k multiplies the state by

$$\exp(2\pi \mathrm{i} B(\gamma, k)).$$

A perimeter-law line compatible with the condensate background must be single-valued under this operation for every $k \in K$. This is exactly the condition $\gamma \in K^{\perp}$.

If $K \subsetneq K^{\perp}$, choose $\eta \in K^{\perp} \setminus K$. Since the pairing is alternating, $B(\eta, \eta) = 0$, and by definition $B(\eta, K) = 0$. Therefore the subgroup generated by K and η is isotropic and strictly larger than K, contradicting maximal isotropy. Hence a maximal isotropic K satisfies $K = K^{\perp}$.

Example 116.7 ($\mathfrak{su}(N)$ finite charges)**.** For

$$\mathcal{C} = \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}, \qquad B((e, m), (e', m')) = \frac{em' - e'm}{N},$$

magnetic condensation is $K = \langle (0, 1) \rangle$. A charge (e, m) lies in $K^{\perp}$ exactly when

$$B((e, m), (0, 1)) = \frac{e}{N} = 0 \quad \text{in } \mathbb{Q}/\mathbb{Z},$$

so only $e = 0$ survives the finite diagnostic. Pure electric probes with nonzero N-ality are confined. Electric condensation $K = \langle (1, 0) \rangle$ gives the dual statement: purely magnetic probes with nonzero magnetic center charge are confined.

For a dyonic condensate

$$K_p = \langle (p, 1) \rangle,$$

the unconfined finite charges obey

$$B((e, m), (p, 1)) = \frac{e - pm}{N} = 0, \qquad \text{so} \qquad e \equiv pm \pmod{N}.$$

Thus the perimeter-law direction is the dyonic line generated by the condensate. Pure electric probes with $e \neq 0$ are confined, and pure magnetic probes are confined unless $pm \equiv 0 \pmod{N}$. This is oblique confinement: the unconfined direction is neither the electric nor the magnetic axis.

Figure 116.1 displays the finite charge lattice for this oblique-confinement example: the dyonic condensate selects the perimeter-law direction $e \equiv pm \pmod{N}$.

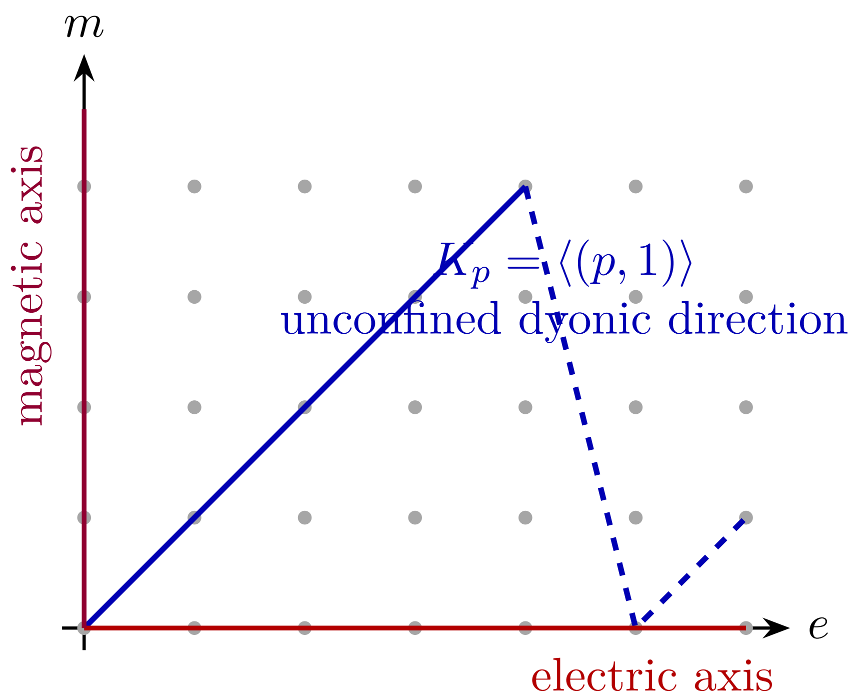

Figure 116.1: Finite charge-lattice picture of oblique confinement. The unconfined finite direction is the dyonic condensate line; charges with nontrivial finite Dirac pairing against it are confined in the condensate diagnostic.

116.7 Logical Status of the Diagnostic

The finite charge-lattice criterion is kinematic plus an explicit dynamical input. The kinematic part is the nondegenerate Dirac pairing and the screening quotient. The dynamical input is the assertion that a particular subgroup K is condensed and that nontrivial braiding with K forces an area law. In a lattice strong-coupling domain the dynamical input can be verified by a convergent expansion, as in the controlled strong-coupling estimate 116.4. In a continuum four-dimensional Yang–Mills theory it is a major theorem-level target rather than a definition.

The following implication is therefore the correct logical form:

$$\begin{array}{c}\text{regulator and continuum limit}\\ \text{renormalized line operators}\\ \text{mass gap or controlled infrared behavior}\\ \text{screening and condensate hypotheses}\end{array} \Longrightarrow \begin{array}{c}\text{area/perimeter laws}\\ \text{electric, magnetic, or oblique}\\ \text{confinement diagnostics.}\end{array}$$

The converse is not automatic. Observing an area law for one family of Wilson loops does not by itself reconstruct the infrared topological sector, the complete screening subgroup, or the full spectrum of stable flux tubes.

Open Problem 116.8 (Continuum confinement criterion). Formulate and prove a continuum QFT confinement criterion that uses renormalized line operators, screening quotients, cluster properties, a mass gap or another controlled infrared spectral hypothesis, and a precise endpoint/condensate structure. The criterion should reproduce the lattice strong-coupling area mechanism where a lattice regulator is available, and it should distinguish electric, magnetic, and oblique confinement through the full line-charge lattice rather than through a single Wilson-loop diagnostic.

Chapter 117

Discrete Theta Terms

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Discrete theta terms are topological phases depending on global bundle data and finite higher-form gauge fields. They are part of the definition of a gauge theory with a specified global form: the same local gauge algebra and the same curvature Lagrangian can have distinct sums over bundles, distinct topological weights, and distinct spectra of genuine line operators. This chapter gives the cochain-level definitions needed for the four-dimensional gauge-theory applications in Volume IX.

Definition 117.1 (Discrete theta structure)**.** Fix a spacetime category $\mathcal{C}_D$, for example closed oriented triangulated D-manifolds or closed spin D-manifolds with compatible triangulations. A finite-cochain discrete theta structure is a tuple

$$\mathfrak{d}_{\mathrm{fin}} = (\mathcal{C}_D, A, q, [\omega], \omega_{\mathrm{loc}})$$

where A is a finite abelian coefficient group for a q-form background, $[\omega]$ is a class in the appropriate group of local topological actions on $B^{q+1}A$, and $\omega_{\mathrm{loc}}(B) \in C^D(M, \mathbb{R}/\mathbb{Z})$ is a natural cocycle representative for each flat background

$$B \in Z^{q+1}(M, A), \qquad B \sim B + \delta\Lambda.$$

The exponentiated phase is

$$S_{\mathfrak{d}_{\mathrm{fin}}}[M, B] = \exp\left(2\pi\mathrm{i}\int_M \omega_{\mathrm{loc}}(B)\right),$$

and changing ω_{loc} by a natural coboundary gives the same closed-manifold phase.

For a four-dimensional Yang–Mills theory with a fixed local Lie algebra, a global-form discrete theta structure additionally specifies

$$\mathfrak{d}_{\mathrm{YM}} = \big(\mathfrak{g}, G, \mathcal{B}_G(M), w_2^\Gamma, \theta, \tau_{\mathrm{disc}}, L_{\mathrm{line}}\big).$$

Here $G = \widetilde{G}/\Gamma$ is the chosen global form of the compact gauge group, $\mathcal{B}_G(M)$ is the groupoid of principal G-bundles, w_2^Γ is the obstruction to lifting a G-bundle to a $\widetilde{G}$-bundle, θ is the continuous theta coordinate, τ_{disc} is the finite topological weight assigned to the obstruction and any higher-form backgrounds, and L_{line} is the maximal mutually local lattice of genuine Wilson–'t Hooft line charges. For $G = SU(N)/\mathbb{Z}_k$ this last entry is denoted

$$L_{\mathrm{line}} = L_{N,k,p} = \langle (k,0), (p, N/k)\rangle \subset \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}, \qquad p \in \mathbb{Z}_k.$$

Thus a discrete theta coordinate is part of the global definition of the theory: it is not visible in perturbation theory around the trivial bundle, but it changes the bundle weights and the genuine line spectrum.

117.1 Finite Cochains And Topological Actions

Let M be a closed oriented triangulated D-manifold. For an abelian group A, write

$$C^r(M,A), \qquad Z^r(M,A), \qquad B^r(M,A), \qquad H^r(M,A)$$

for r-cochains, cocycles, coboundaries, and cohomology classes. The coboundary is denoted δ. A finite A-valued zero-form gauge field is a one-cocycle

$$a \in Z^1(M,A),$$

with gauge equivalence

$$a \sim a + \delta\lambda, \qquad \lambda \in C^0(M,A).$$

For a finite p-form symmetry or gauge field, the background is instead a $(p+1)$-cocycle

$$B \in Z^{p+1}(M,A), \qquad B \sim B + \delta\Lambda, \quad \Lambda \in C^p(M,A).$$

The finite-cochain part of Definition 117.1 is implemented by an exponentiated finite topological action, namely a function

$$S_{\mathrm{top}} : Z^{p+1}(M,A) \longrightarrow U(1)$$

that is invariant under subdivision and gauge transformation, and is local in the sense that it is obtained by evaluating a D-cocycle built from cochains on the fundamental class of M. For a zero-form finite gauge field this structure is equivalently represented by a class

$$[\omega] \in H^D(BA, U(1)).$$

For a p-form field it is represented by a class on $B^{p+1}A$. Explicitly, if $\omega(a) \in C^D(M, \mathbb{R}/\mathbb{Z})$ is a cocycle depending naturally on a, then

$$S_{\mathrm{top}}[a] = \exp\left(2\pi \mathrm{i} \int_M \omega(a)\right).$$

Here

$$\int_M : C^D(M, \mathbb{R}/\mathbb{Z}) \longrightarrow \mathbb{R}/\mathbb{Z}$$

is evaluation on the fundamental cycle.

Remark 117.2 (Coboundary invariance on closed manifolds). If two finite topological Lagrangians differ by a coboundary,

$$\omega'(a) - \omega(a) = \delta\alpha(a),$$

then their exponentiated actions agree on every closed D-manifold for every flat finite background field a.

Let c_M be a fundamental D-cycle of M. Since M is closed,

$$\partial c_M = 0.$$

The evaluation pairing satisfies

$$\langle \delta\alpha(a), c_M \rangle = \langle \alpha(a), \partial c_M \rangle = 0 \quad \text{in } \mathbb{R}/\mathbb{Z}.$$

Therefore

$$\exp\left(2\pi \mathrm{i} \int_M \omega'(a)\right) = \exp\left(2\pi \mathrm{i} \int_M \omega(a)\right).$$

For a manifold with boundary, $\partial c_M = c_{\partial M}$, so the coboundary contribution is

$$\langle \delta\alpha(a), c_M \rangle = \langle \alpha(a), c_{\partial M} \rangle = \int_{\partial M} \alpha(a).$$

This boundary evaluation is the boundary term used in anomaly inflow.

117.2 Two-Form $\mathbb{Z}_N$ Fields

The four-dimensional examples use a two-form finite field

$$B \in Z^2(M, \mathbb{Z}_N).$$

Choose an integral lift

$$\widetilde{B} \in C^2(M, \mathbb{Z})$$

whose reduction modulo N is B. Since B is closed modulo N, there is an integral three-cochain C such that

$$\delta\widetilde{B} = NC.$$

The Pontryagin square is the cohomology operation

$$\mathcal{P} : H^2(M, \mathbb{Z}_N) \longrightarrow H^4(M, \mathbb{Z}_{2N})$$

characterized by

$$\mathcal{P}(B) \equiv B \smile B \pmod{N}$$

and by the quadratic-refinement identity

$$\mathcal{P}(B + B') = \mathcal{P}(B) + \mathcal{P}(B') + 2\, B \smile B' \quad \text{in } H^4(M, \mathbb{Z}_{2N}).$$

A cochain representative is

$$\mathcal{P}(B) = \widetilde{B} \smile \widetilde{B} - N\,\widetilde{B} \smile_1 C \mod 2N,$$

where $\smile_1$ is Steenrod's first cup product. The second term is what makes the expression independent of the chosen lift and invariant under $B \mapsto B + \delta\Lambda$. When N is odd, 2 is invertible modulo N, and the same information can be represented by the ordinary square

$$B \smile B \in H^4(M, \mathbb{Z}_N).$$

When N is even, the lift to $\mathbb{Z}_{2N}$ is essential.

The corresponding four-dimensional local counterterms for a background $\mathbb{Z}_N$ one-form symmetry have the form

$$S_p[B] = \exp\left(\frac{2\pi \mathrm{i} p}{2N} \int_M \mathcal{P}(B)\right).$$

On oriented manifolds the coefficient is valued in

$$p \in \begin{cases} \mathbb{Z}_N, & N \text{ odd}, \\ \mathbb{Z}_{2N}, & N \text{ even}, \end{cases}$$

using the identifications of $H^4(B^2\mathbb{Z}_N, U(1))$. On spin manifolds some terms that differ on a general oriented manifold can coincide, because the Wu-class relations constrain the integral of the Pontryagin square. For odd N, the displayed formula is read as

$$\frac{p}{2N}\mathcal{P}(B) = \frac{p}{N}\,\frac{1}{2} B \smile B \quad \text{in } \mathbb{R}/\mathbb{Z},$$

where $1/2$ denotes the inverse of 2 in $\mathbb{Z}_N$. Thus the spacetime category is part of the definition of the available counterterm group.

Remark 117.3 (Quadratic refinement phase). Let $B, B' \in H^2(M, \mathbb{Z}_N)$. The ratio of counterterms obeys

$$\frac{S_p[B + B']}{S_p[B] S_p[B']} = \exp\left(\frac{2\pi \mathrm{i} p}{N} \int_M B \smile B'\right).$$

Use the defining identity of the Pontryagin square:

$$\mathcal{P}(B + B') - \mathcal{P}(B) - \mathcal{P}(B') = 2B \smile B' \mod 2N.$$

Substituting this into the exponent gives

$$\frac{2\pi \mathrm{i} p}{2N} \int_M 2B \smile B' = \frac{2\pi \mathrm{i} p}{N} \int_M B \smile B'.$$

Exponentiation gives the stated ratio. Thus S_p is a quadratic refinement of the bilinear pairing $(B, B') \mapsto \exp[(2\pi \mathrm{i} p/N) \int_M B \smile B']$. The formula is independent of the chosen cochain representatives because the Pontryagin square identity is a cohomological identity modulo $2N$.

117.3 Global Form And Obstruction Classes

Let

$$G = SU(N)/\mathbb{Z}_k, \qquad k \mid N,$$

where $\mathbb{Z}_k \subset Z(SU(N))$ is generated by

$$\exp(2\pi\mathrm{i}/k)\mathbf{1}_N = \exp(2\pi\mathrm{i}\, N/kN)\mathbf{1}_N.$$

A principal G-bundle $P_G \to M$ has an obstruction class

$$w_2^{(k)}(P_G) \in H^2(M, \mathbb{Z}_k)$$

to lifting P_G to an $SU(N)$-bundle. This class is obtained from the central extension

$$1 \longrightarrow \mathbb{Z}_k \longrightarrow SU(N) \longrightarrow SU(N)/\mathbb{Z}_k \longrightarrow 1$$

by the connecting homomorphism in nonabelian cohomology. Concretely, choose local lifts of the G-transition functions to $SU(N)$. On triple overlaps the lifted transition functions multiply to a $\mathbb{Z}_k$-valued two-cocycle. Its cohomology class is $w_2^{(k)}(P_G)$. Changing the local lifts changes this two-cocycle by a coboundary.

For $k = N$, $G = PSU(N)$ and the obstruction class is usually written

$$w_2(P_{PSU(N)}) \in H^2(M, \mathbb{Z}_N).$$

Proposition 117.4 (Fractional $PSU(N)$ instanton number)**.** *With the instanton-number convention compatible with*

$$k = c_2(E)$$

for an $SU(N)$-bundle E, the fractional part of the instanton number of a $PSU(N)$-bundle is fixed by its obstruction class:

$$\nu(P_{PSU(N)}) = -\frac{N-1}{2N}\int_M \mathcal{P}(w_2) \quad \mathit{mod}\ 1.$$

Proof. A projective $PSU(N)$-bundle can be described locally by $SU(N)$ transition functions that close on triple overlaps up to a central $\mathbb{Z}_N$-valued two-cocycle representing w_2. Equivalently, for the purpose of computing the fractional characteristic class, choose local $U(N)$ lifts and write x for the integral Cech two-cocycle that reduces to w_2 modulo N. If the projective bundle is represented by an ordinary $U(N)$-bundle E, then $x = c_1(E)$; the local Cech computation gives the same expression in general.

The projective second Chern coordinate is

$$\nu(E) = c_2(E) - \frac{N-1}{2N}c_1(E)^2 \quad \in \mathbb{Q}.$$

This combination is invariant under tensoring E by a line bundle. Indeed, if $\ell = c_1(L)$, then

$$c_1(E \otimes L) = c_1(E) + N\ell$$

and

$$c_2(E \otimes L) = c_2(E) + (N-1)c_1(E)\ell + \frac{N(N-1)}{2}\ell^2.$$

Substitution gives

$$\begin{aligned} c_2(E \otimes L) - \frac{N-1}{2N}c_1(E \otimes L)^2 \\ = c_2(E) - \frac{N-1}{2N}c_1(E)^2. \end{aligned}$$

Thus ν is a characteristic class of the projective bundle. Since $c_2(E)$ is integral, its fractional part is

$$-\frac{N-1}{2N}c_1(E)^2 \mod 1.$$

The Pontryagin square is the lift of w_2^2 modulo $2N$; hence

$$c_1(E)^2 \equiv \mathcal{P}(w_2) \pmod{2N}.$$

The displayed formula follows. □

This characteristic-class formula is the global reason that shifting the ordinary continuous theta angle by 2π changes the discrete theta coordinate in a theory whose bundles fail to lift to $SU(N)$.

117.4 Discrete Theta Coordinate For $SU(N)/\mathbb{Z}_k$

The pure $SU(N)/\mathbb{Z}_k$ Yang–Mills theories have a discrete theta coordinate

$$p \in \mathbb{Z}_k$$

in addition to the continuous theta angle. This coordinate can be detected without writing a continuum path integral: it is the electric tilt of the minimal magnetic line. With the finite charge notation of Chapter 113, write a dyonic line label as

$$(e, m) \in \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}.$$

The genuine line lattice is

$$L_{N,k,p} = \langle (k, 0), (p, N/k) \rangle.$$

The generator $(k, 0)$ records the Wilson lines that descend to $SU(N)/\mathbb{Z}_k$. The generator $(p, N/k)$ records the minimal magnetic line, whose magnetic charge is N/k and whose electric charge is shifted by the discrete theta coordinate p. The identification

$$p \sim p + k$$

holds because

$$(p + k, N/k) = (p, N/k) + (k, 0).$$

Thus p is naturally a class in $\mathbb{Z}_k$.

Remark 117.5 (Discrete theta tilt and maximal locality). For each $p \in \mathbb{Z}_k$, the line lattice

$$L_{N,k,p} = \langle (k,0), (p, N/k) \rangle \subset \mathbb{Z}_N \oplus \mathbb{Z}_N$$

is maximal isotropic for the finite Dirac pairing

$$\overline{B}((e,m),(e',m')) = \frac{em' - e'm}{N} \quad \in \mathbb{Q}/\mathbb{Z}.$$

Changing p changes the electric charge of the minimal magnetic line by a Witten-effect shift.

The isotropy and maximality are proved in Proposition 113.5. The new point is the interpretation of p. The minimal magnetic generator has magnetic component N/k, the generator of the magnetic subgroup allowed by the global form. Its electric component is p. Replacing p by $p+k$ adds the Wilson generator $(k,0)$, so the subgroup is unchanged. Therefore the inequivalent tilts are indexed by $p \in \mathbb{Z}_k$. A shift of the continuous theta angle by 2π changes the electric charge of a magnetic line by its magnetic charge in the finite pairing convention; in these coordinates this sends

$$p \longmapsto p+1 \quad \text{in } \mathbb{Z}_k.$$

For $N = 2$ this gives the familiar three finite line spectra:

$$SU(2): \ \langle (1,0) \rangle, \qquad SO(3)_+: \ \langle (0,1) \rangle, \qquad SO(3)_-: \ \langle (1,1) \rangle.$$

The last two have the same local Lie algebra and the same quotient gauge group $SO(3) = SU(2)/\mathbb{Z}_2$, but different discrete theta coordinate and different dyonic line spectrum.

117.5 Gauging One-Form Symmetry And Counterterms

Start with the $SU(N)$ theory and its electric $\mathbb{Z}_N$ one-form symmetry. Coupling this symmetry to a background two-form field

$$B \in Z^2(M, \mathbb{Z}_N)$$

modifies the allowed bundles by allowing transition functions to close only up to the center. Gauging a subgroup $\mathbb{Z}_k \subset \mathbb{Z}_N$ means summing over the corresponding two-form gauge field, with a choice of Pontryagin-square counterterm. The result is an $SU(N)/\mathbb{Z}_k$ theory, and the counterterm choice is the discrete theta coordinate p seen by the line lattice above.

The counterterm also controls anomalies. If the generating functional in background B transforms under a one-form gauge transformation by a phase

$$Z[B + \delta\Lambda] = \exp\left(2\pi \mathrm{i} \int_M \alpha(B,\Lambda)\right) Z[B],$$

then the phase is removed by a local counterterm exactly when α is the gauge variation of a D-dimensional local cochain. If the phase is the boundary variation of a $(D+1)$-dimensional invertible theory, it is an anomaly. Discrete theta terms and anomaly inflow are therefore the same cohomological mechanism viewed in neighboring dimensions: in D dimensions the cochain changes the definition of the theory, and in $D+1$ dimensions its variation supplies an inflow phase for a boundary.

117.6 Continuum Gauge-Theory Status

A continuum Yang–Mills theory with nontrivial global form is specified by the global-form discrete theta datum of Definition 117.1. For the $SU(N)/\mathbb{Z}_k$ family the entries are:

local data	$\mathfrak{su}(N)$ fields and curvature action,
global form	$SU(N)/\mathbb{Z}_k$,
bundle sum	principal $SU(N)/\mathbb{Z}_k$ bundles on M,
topological weights	θ and $p \in \mathbb{Z}_k$,
line spectrum	$L_{N,k,p} \subset \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}$,
background fields	two-form backgrounds for remaining one-form symmetries.

A lattice regulator implements the same data by plaquette variables and finite cochains for higher-form backgrounds. Matching a lattice construction to the continuum description requires matching the obstruction class $w_2^{(k)}$, the Pontryagin-square phase, the continuous theta coordinate, and the genuine line spectrum. Perturbation theory around the trivial bundle sees only the local Lie algebra and curvature vertices; the discrete theta data are detected by global bundle sectors and extended operators.

Open Problem 117.6 (Discrete theta terms in interacting continuum QFT)*.* Give a nonperturbative construction of four-dimensional gauge theories with all global forms and discrete theta terms in which bundles, one-form backgrounds, line operators, anomalies, and continuum limits are treated in a single framework, and prove the equivalence between continuum characteristic classes, lattice finite-cochain definitions, and the operator line spectra.

Chapter 118

Anomaly Inflow and Invertible Field Theories

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

An anomaly is a precise failure of background-field covariance. The partition function of an anomalous D-dimensional theory is not an ordinary function on the moduli groupoid of background fields; it is a vector in a one-dimensional complex vector space depending on the background. An invertible $(D+1)$-dimensional theory packages these lines and their gluing laws. Inflow is the statement that the anomalous D-dimensional theory is a boundary condition, or relative theory, for this invertible bulk.

Definition 118.1 (Anomaly-inflow structure)**.** Fix a spacetime dimension D. An anomaly-inflow structure is a tuple

$$\mathfrak{A} = \left(\mathcal{B}, \mathrm{Bord}^{\mathcal{B}}_{D+1}, \mathcal{Z}_{\mathrm{bulk}}, \mathcal{L}, Z_\partial\right)$$

with the following entries.

1. $\mathcal{B}$ assigns to each closed D-manifold M, with the declared spacetime structure, a groupoid $\mathcal{B}(M)$ of background fields and background isomorphisms.
2. $\mathrm{Bord}^{\mathcal{B}}_{D+1}$ is the corresponding background bordism category. Its objects are pairs (M, A), $A \in \mathcal{B}(M)$; its morphisms are $(D+1)$-dimensional bordisms $X : M_0 \to M_1$ equipped with background fields restricting to the prescribed boundary backgrounds.
3. $\mathcal{Z}_{\mathrm{bulk}}$ is an invertible $(D+1)$-dimensional field theory,

$$\mathcal{Z}_{\mathrm{bulk}} : \mathrm{Bord}^{\mathcal{B}}_{D+1} \longrightarrow \mathrm{Lines}_{\mathbb{C}},$$

namely a symmetric monoidal functor to one-dimensional complex vector spaces and nonzero linear maps. On a closed $(D+1)$-manifold X it gives a nonzero complex number.

4. $\mathcal{L}$ is the boundary line functor induced by $\mathcal{Z}_{\mathrm{bulk}}$. For each closed M it is a functor

$$\mathcal{L}_M : \mathcal{B}(M) \longrightarrow \mathrm{Lines}_{\mathbb{C}},$$

with the orientation convention that a boundary partition vector $Z_{\partial,M}(A)$ lies in $\mathcal{L}_M(A)$. When fillings exist, $\mathcal{L}_M(A)$ may be constructed by the filling quotient described in Section 118.2; otherwise the functor $\mathcal{L}$ is taken as the boundary value of the invertible bulk.

5. Z_∂ is a relative D-dimensional QFT partition assignment: for each closed (M, A),

$$Z_{\partial,M}(A) \in \mathcal{L}_M(A),$$

with covariance under background isomorphisms and with the usual gluing law after pairing with compatible bulk states.

A trivialization of the anomaly is a monoidal natural isomorphism $\mathcal{L} \simeq \mathbf{1}$, possibly after tensoring with a local counterterm invertible theory or with an inverse anomalous sector. A coordinate anomaly formula, such as a descent form or a finite cochain cocycle, is a representative of this structure after choices of local frames and local representatives have been made.

This definition is the object controlled throughout the chapter. The connected Chern–Weil descent, the finite higher-form cochain models, the Weyl-fermion index representative, and the noninvertible wall examples below are different coordinate presentations of the same kind of background-line and invertible-bulk structure.

Coordinate comparison. The anomaly line has three coordinate shadows used in different volumes. In a finite-regulator chart such as the one used in Chapter 51, a background transformation $g : A \to A^g$ is represented by the additive cochain

$$C_\Lambda(g; A) = W_\Lambda[A^g] - W_\Lambda[A] \quad \in \mathbb{R}/\mathbb{Z}, \qquad C_\Lambda(gh; A) = C_\Lambda(g; A) + C_\Lambda(h; A^g). \tag{118.1}$$

After a local frame s_A for the anomaly line is chosen, the same information is the multiplicative line cocycle

$$\alpha_\Lambda(A, g) = \exp\bigl(2\pi\mathrm{i} C_\Lambda(g; A)\bigr), \qquad \mathcal{L}(g) s_A = \alpha_\Lambda(A, g) s_{A^g}. \tag{118.2}$$

Adding a local finite-regulator counterterm $B_\Lambda(A)$ shifts the effective-action representative by

$$C_\Lambda(g; A) \longmapsto C_\Lambda(g; A) + B_\Lambda(A^g) - B_\Lambda(A). \tag{118.3}$$

Equivalently, moving that counterterm from the scalar coordinate into the line frame uses the inverse frame change $s_A \mapsto \exp(-2\pi\mathrm{i} B_\Lambda(A)) s_A$, giving the same transformed α_Λ.

The inflow bulk carries the inverse coordinate. If a cylinder or mapping cylinder realizes the transformation g, then the bulk transition phase on that bordism is

$$\mathcal{Z}_{\mathrm{bulk}}([0, 1] \times_g M) = \alpha_\Lambda(A, g)^{-1} = \exp\bigl(-2\pi\mathrm{i} C_\Lambda(g; A)\bigr), \tag{118.4}$$

so that the boundary vector and the bulk state pair to a background-invariant number. In the free-fermion global-anomaly chapter the same line cocycle is computed analytically by determinant-line transport,

$$\alpha_{\det}(A, g) = \mathrm{Hol}_g(\mathrm{Det}\, D) = \exp\bigl(-2\pi\mathrm{i}\, \xi(B_{Y_g})\bigr)\,,$$

or by the corresponding Pfaffian sign in the real case. Thus the finite cochain, the inflow boundary line, and the determinant/Pfaffian holonomy are not separate anomaly notions; they are regulator, invertible-bulk, and global-analysis coordinates on the same obstruction to descent. The analytic theorems quoted in Chapter 153 compute this coordinate for Dirac families, while the algebra above is the QFT-facing descent and cancellation bookkeeping.

118.1 Background Fields and Relative Partition Functions

Let M be a closed D-manifold with the spacetime structure required by the theory: orientation, spin structure, metric, conformal class, or another declared structure. Let

$$\mathcal{B}(M)$$

be the background-field groupoid in the anomaly-inflow structure $\mathfrak{A}$ of Definition 118.1. An object $A \in \mathcal{B}(M)$ may contain ordinary gauge fields, higher-form gauge fields, metric data, spin connections, and background defect data. A morphism

$$u : A \longrightarrow A'$$

is a background-field isomorphism, for example a gauge transformation, higher-form gauge transformation, or diffeomorphism preserving the declared spacetime structure.

For a nonanomalous theory the partition function is a function on isomorphism classes:

$$Z_M(A') = Z_M(A) \quad \text{whenever } A \simeq A'.$$

For an anomalous theory the correct object is a complex line over each background. Write

$$\mathcal{L}_M : \mathcal{B}(M) \longrightarrow \mathrm{Lines}_{\mathbb{C}}$$

for a functor from the background groupoid to the groupoid of one-dimensional complex vector spaces and nonzero linear maps. The anomalous partition function is a section

$$Z_M(A) \in \mathcal{L}_M(A).$$

For a morphism $u : A \to A'$, covariance means

$$Z_M(A') = \mathcal{L}_M(u) Z_M(A),$$

not equality of complex numbers. The functor $\mathcal{L}_M$ is the anomaly line.

Choosing a nonzero vector $s_A \in \mathcal{L}_M(A)$ for every object A trivializes the line as a collection of vector spaces, but generally not as a functor. In such a trivialization,

$$Z_M(A) = z_M(A) s_A, \qquad z_M(A) \in \mathbb{C},$$

and every morphism $u : A \to A'$ acts by a nonzero phase or scalar

$$\mathcal{L}_M(u) s_A = \alpha_M(u; A) s_{A'}.$$

Thus

$$z_M(A') = \alpha_M(u; A) z_M(A).$$

The scalar α_M is not itself the anomaly; it is the anomaly written in a chosen local trivialization.

Remark 118.2 (Functorial cocycle condition). Let $u : A \to A'$ and $v : A' \to A''$ be composable morphisms in $\mathcal{B}(M)$. In any choice of nonzero local frame s_A for the anomaly line,

$$\alpha_M(vu; A) = \alpha_M(v; A')\alpha_M(u; A).$$

If the frame is changed by

$$s'_A = c(A)s_A, \qquad c(A) \in \mathbb{C}^\times,$$

then

$$\alpha'_M(u; A) = c(A')^{-1}\alpha_M(u; A)c(A).$$

Functoriality gives

$$\mathcal{L}_M(vu) = \mathcal{L}_M(v)\mathcal{L}_M(u).$$

Applying both sides to s_A gives

$$\alpha_M(vu; A)s_{A''} = \alpha_M(u; A)\alpha_M(v; A')s_{A''},$$

which is the stated cocycle identity. If $s'_A = c(A)s_A$, then

$$\mathcal{L}_M(u)s'_A = c(A)\alpha_M(u; A)s_{A'} = c(A)\alpha_M(u; A)c(A')^{-1}s'_{A'}.$$

This is exactly the displayed transformation law.

A local counterterm is a choice of local functional $K_M(A)$ whose exponential changes the frame:

$$s_A \longmapsto \exp(2\pi \mathrm{i} K_M(A))s_A.$$

It changes the representative cocycle by a coboundary. Therefore an anomaly class is not a particular variation formula; it is the isomorphism class of the line functor together with its locality and gluing structure.

118.2 Invertible Bulk Theory and Boundary Lines

For the same structure $\mathfrak{A}$, the category $\mathrm{Bord}^{\mathcal{B}}_{D+1}$ has closed D-manifolds with background fields as objects and $(D+1)$-dimensional bordisms with compatible background fields as morphisms. Its invertible bulk entry is a symmetric monoidal functor

$$\mathcal{Z}_{\mathrm{bulk}} : \mathrm{Bord}^{\mathcal{B}}_{D+1} \longrightarrow \mathrm{Lines}_{\mathbb{C}}$$

such that every closed $(D+1)$-manifold X is assigned a nonzero complex number and every D-manifold M is assigned a line. If

$$X = X_1 \cup_M X_2,$$

then the value on X is obtained by pairing the line assigned to M from X_1 with the dual line assigned from X_2. This gluing axiom is the mathematical content behind the word “inflow”.

It is useful to name the two line variances separately. For a boundary background $A \in \mathcal{B}(M)$, write

$$\mathcal{B}^{\mathrm{bulk}}_M(A) := \mathcal{Z}_{\mathrm{bulk}}(M, A)$$

for the bulk state line assigned to the closed D-manifold M. With the convention of Definition 118.1, the boundary anomaly line is the dual line

$$\mathcal{L}_M(A) = \big(\mathcal{B}_M^{\mathrm{bulk}}(A)\big)^{\vee}. \tag{118.5}$$

Thus a relative boundary partition vector is a covector on the bulk state line, while a filling of M supplies a vector in the bulk state line. For a background isomorphism $u : A \to A'$, the bulk line map

$$\mathcal{B}_M^{\mathrm{bulk}}(u) : \mathcal{B}_M^{\mathrm{bulk}}(A) \longrightarrow \mathcal{B}_M^{\mathrm{bulk}}(A')$$

induces the anomaly-line map by inverse duality,

$$\mathcal{L}_M(u) = \big(\mathcal{B}_M^{\mathrm{bulk}}(u)^{-1}\big)^{\vee} : \mathcal{L}_M(A) \longrightarrow \mathcal{L}_M(A').$$

Orientation reversal dualizes these lines:

$$\mathcal{B}_{-M}^{\mathrm{bulk}}(A) \simeq \big(\mathcal{B}_M^{\mathrm{bulk}}(A)\big)^{\vee}, \qquad \mathcal{L}_{-M}(A) \simeq \mathcal{L}_M(A)^{\vee}.$$

This is the same variance used in the Dai–Freed construction of Chapter 153: the boundary fermion determinant is a vector in the anomaly line, and the filling supplies the inverse-line vector with which it is evaluated.

When the bulk is represented locally by a $(D+1)$-cocycle

$$I_{D+1}(\widetilde{A}) \in C^{D+1}(X, \mathbb{R}/\mathbb{Z})$$

or by a differential-cocycle representative, its closed-manifold value is

$$\mathcal{Z}_{\mathrm{bulk}}(X, \widetilde{A}) = \exp\left(2\pi \mathrm{i} \int_X I_{D+1}(\widetilde{A})\right).$$

The periods are integral in the normalization used, so changing a local representative by a globally defined coboundary leaves the closed value unchanged.

There is a concrete construction of the boundary anomaly line from the bulk. Fix $A \in \mathcal{B}(M)$. A filling

$$(X, \widetilde{A}), \qquad \partial X = M, \quad \widetilde{A}|_M = A,$$

is a bordism $\emptyset \to (M, A)$, so the bulk functor supplies a state

$$b_X(\widetilde{A}) := \mathcal{Z}_{\mathrm{bulk}}(X, \widetilde{A})(1) \in \mathcal{B}_M^{\mathrm{bulk}}(A),$$

not a number. Since the bulk is invertible this state is nonzero, hence it determines a dual frame

$$b_X(\widetilde{A})^{-1} \in \big(\mathcal{B}_M^{\mathrm{bulk}}(A)\big)^{\vee} = \mathcal{L}_M(A), \qquad b_X(\widetilde{A})^{-1}\big(b_X(\widetilde{A})\big) = 1.$$

A vector in the anomaly line may therefore be represented as

$$z\, b_X(\widetilde{A})^{-1}, \qquad z \in \mathbb{C}.$$

Two representatives $(X, \widetilde{A}, z)$ and $(X', \widetilde{A}', z')$ are identified if

$$z' = z\, \mathcal{Z}_{\mathrm{bulk}}\big((-X) \cup_M X',\, (-\widetilde{A}) \cup_A \widetilde{A}'\big).$$

Equivalently, the closed phase relates the two bulk states by

$$b_{X'}(\widetilde{A}') = \mathcal{Z}_{\mathrm{bulk}}\big((-X) \cup_M X',\, (-\widetilde{A}) \cup_A \widetilde{A}'\big)\, b_X(\widetilde{A}),$$

so the dual frames in $\mathcal{L}_M(A)$ transform by the inverse phase and the coordinate z transforms by the displayed phase. The quotient is therefore the coordinate law for dual frames, not a declaration that the filling itself is a scalar. This quotient is one-dimensional whenever the background admits the relevant extensions and the usual bordism-locality assumptions hold. A relative boundary theory assigns a vector in this line. The scalar attached to a chosen compatible filling is the evaluation pairing

$$Z_{\mathrm{glued}}(X; A) = \mathrm{ev}_{\mathcal{B}^{\mathrm{bulk}}_M(A)}\big(Z_{\partial,M}(A) \otimes b_X(\widetilde{A})\big) \in \mathbb{C}. \tag{118.6}$$

Thus the filling supplies the bulk state that is evaluated by the boundary covector; a filling with nonempty boundary is not itself a numerical bulk partition function.

Bulk gluing and the anomaly line. The construction above defines a line functor over the background groupoid of M. If the bulk invertible theory is trivializable, the line functor is trivializable; if a boundary theory has partition vectors in this line, then the combined bulk-boundary partition function on a closed glued manifold is an ordinary complex number invariant under background isomorphisms. The mathematical content rests on the functorial gluing law of the bulk invertible theory, the existence of the allowed fillings or the corresponding colimit over fillings, and the lifting of background isomorphisms to the filling data. Under these inputs, transitivity of the equivalence relation follows from the closed-manifold gluing axiom:

$$\mathcal{Z}((-X) \cup_M X'') = \mathcal{Z}((-X) \cup_M X')\, \mathcal{Z}((-X') \cup_M X'')$$

with the common boundary X' paired with its orientation reverse. A background isomorphism $u : A \to A'$ maps a filling of A to the same filling with boundary background identified by u, hence gives a linear map between the corresponding quotient lines. Functoriality of these maps is again the gluing axiom. A trivialization of the bulk functor supplies canonical nonzero vectors in all bulk state lines, hence dual frames in all boundary anomaly lines, and therefore trivializes the line functor. In the absence of such a trivialization, the boundary partition function is a vector in the anomaly line, and evaluation on the compatible bulk filling state produces a number. Gauge covariance of the number follows because the bulk state and boundary covector transform by dual line maps under this pairing. Scalar phase checks after gluing can verify the resulting number, but by themselves they cannot detect a mistaken global dualization of $\mathcal{B}^{\mathrm{bulk}}_M(A)$ and $\mathcal{L}_M(A)$; the line variance in (118.5) is part of the datum.

Figure 118.1 records the gluing statement for anomaly inflow: a boundary partition vector evaluates on a compatible bulk filling state to give a gauge-covariant number.

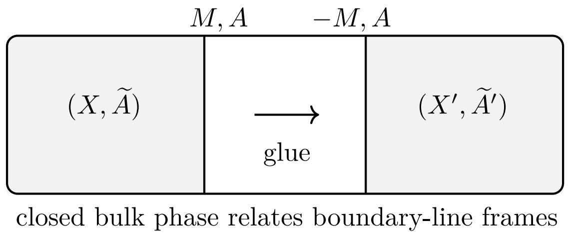

Figure 118.1: A boundary anomaly line is obtained by comparing the dual frames defined by fillings. Gluing two fillings along their common boundary produces the closed invertible-bulk phase that changes the frame.

118.3 Descent for Connected Symmetries

Let A be a connection for a connected Lie symmetry and let

$$F = dA + A \wedge A$$

be its curvature. Let $P_{D+2}(F)$ be a closed invariant polynomial of degree $D+2$, normalized so that its integral on every closed $(D+2)$-manifold with the corresponding bundle is integral. Locally one can choose a Chern–Simons form $I^{(0)}_{D+1}(A)$ satisfying

$$dI^{(0)}_{D+1}(A) = P_{D+2}(F).$$

For the common case $D = 2n$ and

$$P_{2n+2}(F) = \langle F^{n+1} \rangle,$$

where $\langle \cdots \rangle$ is an invariant symmetric $(n+1)$-linear form on the Lie algebra, this local primitive is constructed by a path of connections. Put

$$A_t = tA, \qquad F_t = dA_t + A_t \wedge A_t = t\, dA + t^2 A \wedge A.$$

Define

$$I^{(0)}_{2n+1}(A) = (n+1) \int_0^1 dt\, \langle A\, F_t^n \rangle. \tag{118.7}$$

Chern–Weil transgression. The form (118.7) satisfies

$$dI^{(0)}_{2n+1}(A) = \langle F^{n+1} \rangle.$$

Let $D_t = d + [A_t, \cdot]$ be the covariant exterior derivative for A_t. Since $\dot{A}_t = A$, the curvature variation is

$$\dot{F}_t = D_t \dot{A}_t = D_t A.$$

Using invariance of $\langle \cdots \rangle$ and the Bianchi identity $D_t F_t = 0$,

$$\frac{d}{dt} \langle F_t^{n+1} \rangle = (n+1) \langle D_t A\, F_t^n \rangle = (n+1) d\langle A\, F_t^n \rangle.$$

Integrating this identity from $t = 0$ to $t = 1$ gives

$$\langle F^{n+1} \rangle - \langle F_0^{n+1} \rangle = d\left((n+1) \int_0^1 dt \, \langle A \, F_t^n \rangle \right).$$

Because $F_0 = 0$, the left side is $\langle F^{n+1} \rangle$, proving the claim.

In the Abelian case $F = dA$ and (118.7) reduces to

$$I_{2n+1}^{(0)}(A) = A \wedge F^n.$$

For a gauge variation $\delta_\lambda A = d\lambda$,

$$\delta_\lambda I_{2n+1}^{(0)} = d\lambda \wedge F^n = d(\lambda F^n), \qquad dF = 0,$$

so $I_{2n}^{(1)}(\lambda, A) = \lambda F^n$ is an explicit descent representative in this normalization. For an infinitesimal gauge parameter α,

$$\delta_\alpha A = D_A \alpha = d\alpha + [A, \alpha].$$

Since $P_{D+2}(F)$ is gauge invariant,

$$d \, \delta_\alpha I_{D+1}^{(0)}(A) = 0.$$

Locally, and globally after passing to the descent complex, this gives a D-form $I_D^{(1)}(\alpha, A)$ such that

$$\delta_\alpha I_{D+1}^{(0)}(A) = dI_D^{(1)}(\alpha, A).$$

Therefore, for X^{D+1} with boundary M,

$$\delta_\alpha 2\pi\mathrm{i} \int_X I_{D+1}^{(0)} = 2\pi\mathrm{i} \int_M I_D^{(1)}(\alpha, A).$$

The boundary generating functional must transform by the negative of this phase for the combined bulk-boundary object to be gauge invariant.

Proposition 118.3 (Wess–Zumino consistency from descent)**.** *Let M be a closed D-manifold and let*

$$\delta_\alpha W_M[A] = 2\pi\mathrm{i} \int_M I_D^{(1)}(\alpha, A)$$

be obtained from a gauge-invariant polynomial by descent. Then

$$\delta_\alpha \delta_\beta W_M - \delta_\beta \delta_\alpha W_M = \delta_{[\alpha,\beta]} W_M.$$

Proof. Introduce a ghost c valued in the Lie algebra and the BRST differential $\mathsf{s}A = D_A c$, $\mathsf{s}c = -\frac{1}{2}[c, c]$. Gauge invariance of $P(F)$ and the Chern–Weil transgression give a local descent tower

$$\mathsf{s}I_{D+1}^{(0)} + dI_D^{(1)} = 0, \qquad \mathsf{s}I_D^{(1)} + dI_{D-1}^{(2)} = 0,$$

with the sign convention chosen so that the component of the first equation linear in a ghost value α is

$$\delta_\alpha I_{D+1}^{(0)}(A) = dI_D^{(1)}(\alpha, A).$$

We now extract the ghost-number-two coefficient explicitly. Introduce two odd scalar tags ε, η, put

$$c = \varepsilon\alpha + \eta\beta, \qquad \varepsilon\eta = -\eta\varepsilon, \qquad \varepsilon^2 = \eta^2 = 0.$$

The BRST rule gives

$$[c, c] = 2\varepsilon\eta[\alpha, \beta], \qquad \mathsf{s}c = -\varepsilon\eta[\alpha, \beta],$$

while

$$\mathsf{s}A = \varepsilon D_A\alpha + \eta D_A\beta.$$

Since $I_D^{(1)}(c, A)$ is linear in c, the coefficient of $\varepsilon\eta$ in $\mathsf{s}I_D^{(1)}(c, A)$ is

$$\delta_\alpha I_D^{(1)}(\beta, A) - \delta_\beta I_D^{(1)}(\alpha, A) - I_D^{(1)}([\alpha, \beta], A). \tag{118.8}$$

The first two terms come from the variation of A; the relative minus sign is the Koszul sign obtained when the odd tag of the varied parameter crosses the odd BRST differential. The last term comes from $\mathsf{s}c = -\varepsilon\eta[\alpha, \beta]$. Thus the second descent equation gives

$$\delta_\alpha I_D^{(1)}(\beta, A) - \delta_\beta I_D^{(1)}(\alpha, A) - I_D^{(1)}([\alpha, \beta], A) = -d\, I_{D-1}^{(2)}(\alpha, \beta, A), \tag{118.9}$$

where $I_{D-1}^{(2)}(\alpha, \beta, A)$ denotes the $\varepsilon\eta$-coefficient of $I_{D-1}^{(2)}(c, A)$.

Integrating (118.9) over closed M annihilates the right side. Multiplication by $2\pi\mathrm{i}$ gives

$$\delta_\alpha\delta_\beta W_M - \delta_\beta\delta_\alpha W_M - \delta_{[\alpha,\beta]}W_M = 0.$$

This is the Chevalley–Eilenberg cocycle condition for the local anomaly one-cochain

$$\mathcal{A}_M(\alpha; A) = 2\pi\mathrm{i}\int_M I_D^{(1)}(\alpha, A).$$

A change of descent representative by a local counterterm adds a Chevalley–Eilenberg coboundary, so the identity survives the representative change. If M has a boundary, the right side of (118.9) is the boundary descent term that must be included in the corresponding relative anomaly-line structure. □

Remark 118.4 (Cocycle ambiguity and local counterterms). Changing $I_{D+1}^{(0)}$ by

$$I_{D+1}^{(0)} \longmapsto I_{D+1}^{(0)} + dK_D(A)$$

changes the boundary anomaly by the variation of the local D-dimensional functional

$$2\pi\mathrm{i}\int_M K_D(A).$$

Thus the anomaly invariant is the cohomology class of the bulk invertible theory, while a representative anomaly current depends on a boundary counterterm coordinate.

On a manifold with boundary,

$$\int_X dK_D = \int_M K_D.$$

Under a background gauge transformation, the additional boundary variation is exactly the variation of this D-dimensional local functional. Hence two bulk cocycles differing by a coboundary define anomaly representatives that are related by a local counterterm. The same statement in the anomaly-line language is the frame change in Remark 118.2.

118.4 Finite Higher-Form Inflow

The connected descent formalism is not the whole theory of anomalies. Finite symmetries and higher-form symmetries are naturally described by cochains. Let A be a finite abelian group and let a p-form background on a $(D+1)$-manifold X be

$$B \in Z^{p+1}(X, A), \qquad B \sim B + \delta\Lambda.$$

An invertible finite response is represented by a cocycle

$$\omega(B) \in Z^{D+1}(X, \mathbb{R}/\mathbb{Z})$$

natural under subdivision and pullback. Its value is

$$\exp\left(2\pi \mathrm{i} \int_X \omega(B)\right).$$

If X is closed and ω is a cocycle on the classifying space $B^{p+1}A$, gauge invariance follows by the same evaluation-on-cycles argument as Remark 117.2. If X has boundary, gauge variation leaves a boundary cochain. The boundary QFT is then a section of the corresponding finite anomaly line.

For one-form symmetries in four dimensions the bulk is five-dimensional. A particularly useful local model is the finite Heisenberg response with

$$b, c \in C^2(X, \mathbb{Z}_N)$$

and

$$S_H[X; b, c] = \exp\left(\frac{2\pi \mathrm{i}}{N} \int_X b \smile \delta c\right).$$

Here b and c are the two finite two-form fields paired by the $\mathbb{Z}_N$ Pontryagin duality. On a closed X the action is invariant under

$$b \mapsto b + \delta\lambda, \qquad c \mapsto c + \delta\kappa, \qquad \lambda, \kappa \in C^1(X, \mathbb{Z}_N).$$

On a manifold with boundary M, the first transformation changes the exponent by

$$\frac{2\pi \mathrm{i}}{N} \int_M \lambda \smile \delta c.$$

This is an anomaly for a boundary condition that keeps $c|_M$ as a background. Different boundary conditions correspond to different choices of which finite field is fixed, which is summed, and which boundary counterterm has been attached. This is the cochain model behind one-form gauging, duality interfaces, and the symmetry-TQFT discussion in Chapter 123.

Remark 118.5 (Finite bulk variation). For the five-dimensional action

$$\frac{2\pi \mathrm{i}}{N} \int_X b \smile \delta c,$$

the variation under $b \mapsto b + \delta\lambda$ is trivial on closed X and equals

$$\frac{2\pi \mathrm{i}}{N} \int_{\partial X} \lambda \smile \delta c$$

when X has boundary. The variation under $c \mapsto c + \delta\kappa$ is zero.

Since $\delta^2 = 0$, changing c by $\delta\kappa$ does not change δc. Under $b \mapsto b + \delta\lambda$, the exponent changes by

$$\frac{2\pi\mathrm{i}}{N}\int_X \delta\lambda \smile \delta c.$$

The cup-product differential satisfies

$$\delta(\lambda \smile \delta c) = \delta\lambda \smile \delta c - \lambda \smile \delta^2 c = \delta\lambda \smile \delta c,$$

because $\deg\lambda = 1$. Evaluation of a coboundary on a closed fundamental cycle is zero. On a manifold with boundary, the cochain Stokes formula gives the displayed boundary term.

118.5 Weyl-Fermion Inflow

The local descent formalism of Chapter 51 becomes an invertible five-dimensional theory after the anomaly polynomial is placed in its index normalization. Let X be an oriented five-manifold with boundary

$$M = \partial X.$$

Let A_X be a background connection on X, and let R_X be the curvature of a Riemannian connection on TX. For one left-handed four-dimensional Weyl fermion in a representation R, the index-normalized six-form is

$$\mathcal{I}_6(R) = \left[\widehat{A}(TX)\,\mathrm{ch}_R(F_X)\right]_6, \tag{118.10}$$

with the notation of Section 51.9. Choose locally a five-form $\mathcal{I}_5^{(0)}$ satisfying

$$d\mathcal{I}_5^{(0)} = \mathcal{I}_6, \qquad \delta_\lambda \mathcal{I}_5^{(0)} = d\mathcal{I}_4^{(1)}(\lambda).$$

The five-dimensional response

$$W_X^{\mathrm{inv}}[A_X, g_X] = -2\pi\mathrm{i}\int_X \mathcal{I}_5^{(0)} \tag{118.11}$$

has boundary variation

$$\delta_\lambda W_X^{\mathrm{inv}} = -2\pi\mathrm{i}\int_M \mathcal{I}_4^{(1)}(\lambda).$$

It cancels a boundary left-handed determinant with

$$\delta_\lambda W_M = +2\pi\mathrm{i}\int_M \mathcal{I}_4^{(1)}(\lambda).$$

The sign in (118.11) is a boundary-condition choice: reversing the orientation of X, or using a right-handed boundary fermion, reverses the phase.

Coefficient of abelian inflow. Let the boundary field be one left-handed Weyl fermion of integer $U(1)$ charge q. Let $F = dA$, and normalize the first Pontryagin form by

$$p_1(TX) = -\frac{1}{8\pi^2}\,\mathrm{tr}_{TX}(\mathsf{R}^2).$$

Then a local representative of the inflow action is

$$W_X^{\mathrm{inv}} = -2\pi\mathrm{i}\int_X \left[\frac{q^3}{6(2\pi)^3}AF^2 - \frac{q}{24(2\pi)}A\,p_1(TX)\right], \tag{118.12}$$

and under $A \mapsto A + d\lambda$,

$$\delta_\lambda W_X^{\mathrm{inv}} = -2\pi\mathrm{i}\int_M \lambda\left[\frac{q^3}{6(2\pi)^3}F^2 - \frac{q}{24(2\pi)}p_1(TM)\right]. \tag{118.13}$$

For $U(1)$, the index-normalized polynomial is

$$\mathcal{I}_6(q) = \frac{q^3}{6(2\pi)^3}F^3 - \frac{q}{24(2\pi)}p_1(TX)F.$$

Because $dF = 0$ and $dp_1 = 0$ for the Chern–Weil representative, a primitive is the bracketed five-form in (118.12). Varying A gives

$$\delta_\lambda\left[\frac{q^3}{6(2\pi)^3}AF^2 - \frac{q}{24(2\pi)}A\,p_1\right] = d\lambda\left[\frac{q^3}{6(2\pi)^3}F^2 - \frac{q}{24(2\pi)}p_1\right].$$

The expression in square brackets is closed, hence this variation is the exterior derivative of

$$\lambda\left[\frac{q^3}{6(2\pi)^3}F^2 - \frac{q}{24(2\pi)}p_1\right].$$

Stokes' theorem gives (118.13) with the boundary orientation $M = \partial X$.

For several left-handed Weyl fermions, the local $U(1)^3$ and mixed gravitational-$U(1)$ anomaly coefficients are

$$\sum_i q_i^3, \qquad \sum_i q_i.$$

If the $U(1)$ symmetry is dynamical, the anomaly line for the dynamical gauge group must be canonically trivial. In the absence of a four-dimensional local counterterm that shifts these representatives, the local conditions are

$$\sum_i q_i^3 = 0, \qquad \sum_i q_i = 0,$$

together with the mixed nonabelian-$U(1)$ conditions when other gauge factors are present. If the $U(1)$ symmetry is a background global symmetry, the same polynomial is retained as the response that must be matched by any infrared description. Local cancellation does not by itself settle possible global anomalies; those are statements about the full invertible theory on the relevant bordism category.

118.6 From Inflow to Noninvertible Chiral Defects

Inflow also defines certain noninvertible codimension-one operators. Start with a transformation g of a D-dimensional QFT. Suppose that, in the presence of background fields A, implementing g across a hypersurface

$$\Sigma \subset M$$

leaves an anomaly line described by an invertible $(D+1)$-dimensional response $\mathcal{Z}_{\mathrm{anom}}(g; A)$. The bare wall for g is then not an ordinary topological symmetry wall. It is a relative theory for the restriction of the anomaly to a small tubular neighborhood of Σ.

Let $\mathcal{D}_g$ be the transformation wall. A wall theory $\mathcal{T}_\Sigma$ produces a genuine defect precisely when there is a trivialization

$$\mathcal{L}_{\mathcal{D}_g} \otimes \mathcal{L}_{\mathcal{T}_\Sigma} \simeq \mathbf{1}$$

of anomaly lines over the wall-background groupoid. The honest defect is

$$D_g = \mathcal{D}_g \otimes \mathcal{T}_\Sigma.$$

If $\mathcal{T}_\Sigma$ is obtained by gauging a finite higher-form symmetry on the wall, fusion of D_g with its orientation reverse contains a sum over the gauged sectors. That fusion is not a single copy of the identity defect, and D_g is noninvertible.

Remark 118.6 (Wall trivialization criterion). Assume the transformation wall $\mathcal{D}_g$ and the auxiliary wall theory $\mathcal{T}_\Sigma$ are topological away from their anomaly lines. The tensor product $D_g = \mathcal{D}_g \otimes \mathcal{T}_\Sigma$ is a genuine topological defect exactly when the tensor product of their anomaly-line functors is trivializable. If the trivializing wall theory contains a nontrivial finite gauge sum, then $D_g \otimes D_g^\vee$ contains the corresponding condensation projector and need not be the identity defect.

Topological invariance of a defect means that its correlation functional is a number invariant under isotopy, with no uncancelled dependence on a choice of background-field frame. The product wall has anomaly line $\mathcal{L}_{\mathcal{D}_g} \otimes \mathcal{L}_{\mathcal{T}_\Sigma}$. A trivialization of this line converts its partition vector into an ordinary number and removes the frame dependence, so the wall is genuine. Conversely, if the product line is nontrivial, changing the background by a morphism in the wall groupoid changes the wall vector by a nontrivial line map; no ordinary topological defect has this transformation law. When $\mathcal{T}_\Sigma$ is a finite gauge theory, fusing with the orientation reverse performs the finite gauge sum on the wall twice with the dual orientation. The result is the projector onto invariant wall sectors, not necessarily the invisible wall. This is the categorical source of noninvertibility.

Example 118.7 (Axial defects in compact QED)**.** Consider compact four-dimensional QED with a unit-charge massless Dirac fermion and with no dynamical monopoles. The axial rotation by angle α changes the effective action by the abelian anomaly

$$\delta_\alpha W = \mathrm{i}\alpha \, \frac{1}{4\pi^2} \int_M F \wedge F$$

in the convention of (51.6). For $\alpha = 2\pi/N$, the phase is sensitive to the magnetic one-form background when the theory is placed in sectors with fractional $F/2\pi$ induced by that background. The codimension-one axial wall therefore carries a mixed anomaly with the magnetic one-form symmetry. Attaching a three-dimensional finite gauge theory whose Pontryagin-square variation cancels this mixed phase gives the defects $D_{N,p}$ constructed in Chapter 123. The role of the three-dimensional theory is fixed by the inflow equation above: it is the boundary trivialization of the anomaly line of the axial wall, not an additional optional decoration.

118.7 One-Form Symmetry Example

Let a four-dimensional theory have a finite abelian one-form symmetry A. A background is a two-cocycle

$$B \in Z^2(M, A).$$

An anomaly involving this symmetry is represented by a five-dimensional cohomology class

$$\omega \in H^5(B^2A, U(1))$$

or, with spacetime structure included, by the corresponding generalized cohomology or bordism invariant. For $A = \mathbb{Z}_N$, expressions built from cup products and the Pontryagin square give concrete representatives after the manifold orientation and spin structure have been specified. The boundary theory then has line operators whose fusion and braiding with surface defects are acted on by the anomaly line; changing a four-dimensional discrete theta term shifts the representative but not the inflow class unless the bulk cohomology class changes.

The finite one-form anomaly is detected operationally as follows. Couple the theory to B. If a one-form gauge transformation

$$B \mapsto B + \delta\Lambda$$

changes the generating functional by

$$Z_M[B + \delta\Lambda] = \exp\left(2\pi \mathrm{i} \int_M \eta(B, \Lambda)\right) Z_M[B],$$

then η is a representative of the anomaly-line functor. If there is a local four-dimensional cochain $K(B)$ such that

$$\eta(B, \Lambda) = K(B + \delta\Lambda) - K(B) \mod \mathbb{Z},$$

the anomaly is removed by the counterterm $\exp(-2\pi\mathrm{i} \int_M K(B))$. If no such local cochain exists in the chosen background-field theory, gauging the one-form symmetry is obstructed unless another sector supplies the inverse anomaly.

118.8 Gauging Criterion

To gauge a global symmetry, one must sum or integrate over its backgrounds. For a finite symmetry this means a groupoid cardinality weighted sum; for a continuous symmetry it means a regularized path integral over connections and gauge transformations. In either case the integrand must be an ordinary number on the background groupoid. If the partition function is a section of a nontrivial anomaly line, there is no canonical summand to add.

In the invertible-language formulation the criterion is

$$\mathscr{Z}_{\text{bulk}} \otimes \mathscr{Z}_{\text{counter}} \simeq 1$$

as an invertible theory over the background-field bordism category. A local counterterm supplies such a trivialization exactly when the anomaly class is a coboundary in the chosen background-field cohomology theory. A second QFT sector can also supply the inverse line; this is anomaly cancellation by tensor product.

Remark 118.8 (Gauging requires a trivialized anomaly line). Let a finite global symmetry have background groupoid $\mathcal{B}(M)$. The gauged partition function

$$Z_{\mathrm{gauged}}(M) = \sum_{[A]\in\pi_0\mathcal{B}(M)} \frac{1}{|\operatorname{Aut}(A)|} Z_M(A)$$

is canonically defined only after the anomaly line $\mathcal{L}_M$ has been trivialized compatibly with morphisms in $\mathcal{B}(M)$. If two trivializations differ by a local counterterm, the two gauged theories differ by that counterterm before summation.

The summation formula adds complex numbers. If $Z_M(A)$ lies in $\mathcal{L}_M(A)$, then terms belonging to different isomorphism classes live in unrelated one-dimensional vector spaces. A trivialization identifies all these vectors with complex numbers. Compatibility with morphisms is required because the factor $1/|\operatorname{Aut}(A)|$ divides by automorphisms; if an automorphism acts nontrivially on the line, the would-be summand is frame dependent. A second trivialization differs from the first by a nowhere-zero function on the background groupoid. If this function is the exponential of a local cochain, it is exactly a local counterterm, and it weights each background sector before the groupoid sum is performed.

Open Problem 118.9 (Operator-level inflow)*.* Develop a reconstruction theorem that starts from an anomalous local QFT, constructs its anomaly line over background fields, and derives the action of the inflow theory on extended operators, defect junctions, and Hilbert spaces on manifolds with boundary.

Chapter 119

Phases Of Gauge Theories

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

A phase of a gauge theory is a statement about infinite-volume gauge-invariant QFT data. Gauge-variant fields, gauge-fixed expectation values, and coordinates on a weakly coupled Lagrangian chart are not phase invariants by themselves. The invariant data are states on observable algebras, spectra, local correlators, line and surface asymptotics, background-field responses, and the realization of ordinary and higher-form symmetries.

119.1 Observable Systems And Thermodynamic Limits

Fix a regulator class. On a finite spatial region Λ, let

$$\mathcal{A}_\Lambda$$

be the algebra generated by the declared gauge-invariant observables in that region. The word "declared" matters: one may study only local operators, or one may enlarge the observable system by including line operators, surface operators, boundary-condition sectors, and background-field responses. If $\Lambda \subset \Lambda'$, there is an inclusion

$$\iota_{\Lambda\Lambda'} : \mathcal{A}_\Lambda \hookrightarrow \mathcal{A}_{\Lambda'}.$$

The quasi-local observable algebra is the norm completion, or the analogous Euclidean distributional completion, of the directed union

$$\mathcal{A}_{\mathrm{obs}} = \overline{\bigcup_{\Lambda} \mathcal{A}_{\Lambda}}.$$

A thermodynamic-limit state is a positive normalized linear functional

$$\omega : \mathcal{A}_{\mathrm{obs}} \longrightarrow \mathbb{C}$$

obtained as a limit of finite-volume states along a specified boundary condition and regulator trajectory. In a Euclidean formulation the same data are encoded by compatible Schwinger distributions for all operators in the declared observable system, together with OS positivity when a Hilbert space reconstruction is intended.

Definition 119.1 (Declared phase problem)**.** A phase problem consists of:

regulator class	lattice, continuum cutoff, constructive scheme, or another regulator,
parameter domain	$\mathcal{P}$ of couplings, masses, theta angles, and counterterm data,
observable system	$\mathcal{A}_{\mathrm{obs}}$ including the chosen extended probes,
limit prescription	thermodynamic and continuum limits with boundary conditions,
comparison topology	the topology in which states, spectra, and operator data are compared.

A phase is always a phase of such a declared problem, not an absolute label attached to a Lagrangian density.

Definition 119.2 (Phase)**.** Let $\mathcal{U} \subset \mathcal{P}$ be a connected region where the declared limits exist. The points of $\mathcal{U}$ belong to one phase if the following data extend continuously over $\mathcal{U}$ in the declared comparison topology:

states	ω_p on $\mathcal{A}_{\mathrm{obs}}$,
local spectrum	mass gap, isolated particles, or specified gapless spectral type,
local correlators	renormalized distributions of local gauge-invariant operators,
extended operators	line/surface/wall fusion, endpoint maps, and asymptotic laws,
symmetry realization	ordinary, higher-form, higher-group, and anomalous responses,
topological sector	Hilbert spaces on spatial manifolds and topological operator maps.

A phase boundary is a locus where at least one declared datum fails to extend continuously or where the declared limit ceases to exist.

This definition is intentionally conditional. It does not assert that all gauge theories have a known complete phase invariant. It specifies what must be held fixed before statements such as "the Higgs and confinement regions are analytically connected" or "two regions are distinct" can be evaluated.

119.2 Finite-Regulator Locality Machinery For Phase Stability

The phase definition above uses continuity of local and extended data along a declared parameter region. In a regulated Hamiltonian system this continuity has mathematical content only after locality and spectral stability are named. This section records the finite machinery used later when a gapped lattice regularization is treated as a proof laboratory for gauge-theory phase data.

Let Λ be a finite metric lattice and let

$$\mathcal{A}_\Lambda = \bigotimes_{x\in\Lambda} \mathcal{B}(\mathcal{H}_x)$$

with $\dim \mathcal{H}_x < \infty$. For $X \subset \Lambda$, write $\mathcal{A}_X \subset \mathcal{A}_\Lambda$ for the subalgebra supported in X. A finite interaction is a map

$$\Phi : \{Z \subset \Lambda\} \longrightarrow \mathcal{A}_Z, \qquad \Phi(Z) = \Phi(Z)^*,$$

with Hamiltonian

$$H_\Lambda = \sum_{Z\subset\Lambda} \Phi(Z).$$

Let

$$\mathcal{I}_\Lambda = \{Z \subset \Lambda \mid \Phi(Z) \neq 0\}.$$

The finite overlap constants used below are

$$J_* = \sup_{Z\in\mathcal{I}_\Lambda} \|\Phi(Z)\|, \qquad N_* = \sup_{Z\in\mathcal{I}_\Lambda} \#\{Z' \in \mathcal{I}_\Lambda \mid Z' \cap Z \neq \varnothing\}.$$

For regions $X, Y \subset \Lambda$, define $d_\Phi(X, Y)$ to be the smallest integer $n \geq 1$ for which there are $Z_1, \ldots, Z_n \in \mathcal{I}_\Lambda$ with

$$Z_1 \cap X \neq \varnothing, \qquad Z_i \cap Z_{i+1} \neq \varnothing, \qquad Z_n \cap Y \neq \varnothing.$$

If no such chain exists, set $d_\Phi(X, Y) = \infty$. Also write

$$\partial_\Phi X = \{Z \in \mathcal{I}_\Lambda \mid Z \cap X \neq \varnothing\}.$$

Theorem 119.3 (Finite path-count Lieb–Robinson bound)**.** *Let*

$$\tau_t(A) = e^{\mathrm{i}tH_\Lambda} A e^{-\mathrm{i}tH_\Lambda}.$$

For $A_X \in \mathcal{A}_X$, $B_Y \in \mathcal{A}_Y$, and $X \cap Y = \varnothing$,

$$\|[\tau_t(A_X), B_Y]\| \leq 2\|A_X\| \, \|B_Y\| \, |\partial_\Phi X| \sum_{n\geq d_\Phi(X,Y)} \frac{(2J_*N_*|t|)^n}{n!}. \tag{119.1}$$

Consequently, for every $\mu > 0$,

$$\|[\tau_t(A_X), B_Y]\| \leq 2\|A_X\| \, \|B_Y\| \, |\partial_\Phi X| \, \exp\{-\mu d_\Phi(X, Y) + 2J_*N_*e^\mu|t|\}. \tag{119.2}$$

If the finite systems form an exhausting bounded-degree finite-range family, with J_*, N_*, and the conversion from d_Φ to the metric distance bounded uniformly, this gives a uniform light cone for local observables in the thermodynamic sequence.

Proof. For a finite region $S \subset \Lambda$, set

$$C_B(t, S) = \sup_{\substack{A\in\mathcal{A}_S \\ A\neq 0}} \frac{\|[\tau_t(A), B_Y]\|}{\|A\|}.$$

If $S \cap Y \neq \varnothing$, then

$$C_B(t,S) \le 2\|B_Y\|$$

by $\|[A, B_Y]\| \le 2\|A\|\,\|B_Y\|$. Suppose now that $S \cap Y = \varnothing$. Decompose the Hamiltonian as

$$H_\Lambda = H_{S^c}^{\mathrm{far}} + \sum_{Z \cap S \neq \varnothing} \Phi(Z),$$

where $H_{S^c}^{\mathrm{far}}$ is the sum of terms whose supports are disjoint from S. The terms in $H_{S^c}^{\mathrm{far}}$ commute with the initial observable $A \in \mathcal{A}_S$. Applying Duhamel's formula to the perturbation by the remaining terms and using the unitary invariance of the operator norm gives

$$C_B(t,S) \le 2 \sum_{Z \cap S \neq \varnothing} \|\Phi(Z)\| \int_0^{|t|} C_B(s, S \cup Z)\,\mathrm{d}s.$$

The factor 2 is the elementary commutator estimate $\|[\Phi(Z), A]\| \le 2\|\Phi(Z)\|\,\|A\|$. Iterating the inequality generates chains $Z_1, \ldots, Z_n$ of overlapping interaction supports. A chain can reach Y only when $n \ge d_\Phi(X,Y)$. The first step has at most $|\partial_\Phi X|$ choices, and each later step has at most N_* choices. The interaction norms contribute at most J_*^n, the commutator estimates contribute 2^n, and the ordered time simplex contributes $|t|^n/n!$. The final contact with Y contributes $2\|B_Y\|$, yielding (119.1), with N_*^n used as a harmless uniform upper bound for the chain count. Finally,

$$\sum_{n \ge d} \frac{a^n}{n!} \le e^{-\mu d} \sum_{n \ge 0} \frac{(ae^\mu)^n}{n!} = \exp(-\mu d + ae^\mu),$$

with $a = 2J_* N_* |t|$. This proves (119.2). □

The estimate is finite and quantitative. Its thermodynamic use requires the constants in the last sentence of the theorem. A volume-dependent interaction norm or an interaction graph with growing overlap degree can erase the uniform light cone.

Spectral transport before locality. Let $s \mapsto H_\Lambda(s)$ be a C^1 finite-volume Hamiltonian path and let $P_\Lambda(s)$ be the spectral projection onto an isolated band. The projection identity

$$P_\Lambda(s)^2 = P_\Lambda(s)$$

implies, after differentiating and multiplying by P_Λ on both sides, that

$$P_\Lambda(\partial_s P_\Lambda) P_\Lambda = 0.$$

Define the anti-self-adjoint finite spectral generator

$$K_\Lambda(s) = [\partial_s P_\Lambda(s), P_\Lambda(s)].$$

Then

$$\partial_s P_\Lambda(s) = [K_\Lambda(s), P_\Lambda(s)]. \tag{119.3}$$

Indeed,

$$[K_\Lambda, P_\Lambda] = (\partial_s P_\Lambda) P_\Lambda + P_\Lambda(\partial_s P_\Lambda) = \partial_s P_\Lambda.$$

Thus the finite ODE

$$\partial_s U_\Lambda(s) = K_\Lambda(s) U_\Lambda(s), \qquad U_\Lambda(0) = 1,$$

transports the band:

$$P_\Lambda(s) = U_\Lambda(s) P_\Lambda(0) U_\Lambda(s)^*.$$

This is exact spectral algebra, but the operator $K_\Lambda(s)$ is built from the global projection $P_\Lambda(s)$. It carries no locality estimate by itself.

Quasi-adiabatic continuation is the locality replacement for this projection generator. Suppose the chosen band is separated from the rest of the finite spectrum by a gap $\gamma > 0$. Choose a real odd filter

$$F_\gamma : \mathbb{R} \longrightarrow \mathbb{R}$$

whose Fourier transform, with convention

$$\widehat{F}_\gamma(\omega) = \int_{\mathbb{R}} e^{\mathrm{i}\omega t} F_\gamma(t)\,\mathrm{d}t,$$

satisfies

$$\widehat{F}_\gamma(\omega) = \frac{\mathrm{i}}{\omega}, \qquad |\omega| \geq \gamma,$$

and whose decay is fast enough for the integrals below. Let

$$V_\Lambda(s) = \partial_s H_\Lambda(s)$$

and define the self-adjoint finite quasi-adiabatic generator

$$D_\Lambda(s) = \int_{\mathbb{R}} F_\gamma(t)\, e^{\mathrm{i}tH_\Lambda(s)} V_\Lambda(s) e^{-\mathrm{i}tH_\Lambda(s)}\,\mathrm{d}t. \tag{119.4}$$

In an eigenbasis of $H_\Lambda(s)$, with a in the band and b outside the band,

$$\langle b|\partial_s P_\Lambda|a\rangle = -\frac{\langle b|V_\Lambda|a\rangle}{E_b - E_a}.$$

On the other hand,

$$\langle b|D_\Lambda|a\rangle = \widehat{F}_\gamma(E_b - E_a)\langle b|V_\Lambda|a\rangle = \frac{\mathrm{i}\,\langle b|V_\Lambda|a\rangle}{E_b - E_a}.$$

Therefore

$$\langle b|\mathrm{i}[D_\Lambda, P_\Lambda]|a\rangle = -\frac{\langle b|V_\Lambda|a\rangle}{E_b - E_a},$$

and the same calculation in the opposite off-diagonal block gives

$$\partial_s P_\Lambda(s) = \mathrm{i}[D_\Lambda(s), P_\Lambda(s)]. \tag{119.5}$$

The diagonal blocks are zero on both sides. Thus the quasi-adiabatic generator transports the isolated band exactly at finite volume.

Now assume the Hamiltonian path is local:

$$V_\Lambda(s) = \sum_{X \subset \Lambda} V_X(s), \qquad V_X(s) \in \mathcal{A}_X,$$

with a uniform interaction norm. Let X_R be the R-neighborhood of X, and let $\mathbb{E}_{X_R}$ be the conditional expectation from $\mathcal{A}_\Lambda$ onto $\mathcal{A}_{X_R}$ obtained by normalized partial trace over the complement. In finite dimension this conditional expectation can be written as Haar averaging over unitaries U supported in $\Lambda \setminus X_R$:

$$\mathbb{E}_{X_R}(A) = \int UAU^* \, \mathrm{d}U.$$

Therefore

$$A - \mathbb{E}_{X_R}(A) = \int (A - UAU^*) \, \mathrm{d}U, \qquad \|A - \mathbb{E}_{X_R}(A)\| \leq \sup_U \|[A, U]\|.$$

Apply this with $A = e^{\mathrm{i}tH_\Lambda} V_X e^{-\mathrm{i}tH_\Lambda}$. The unitaries U in the last supremum are supported at distance at least R from X, and the Lieb–Robinson estimate gives

$$\left\| e^{\mathrm{i}tH_\Lambda} V_X e^{-\mathrm{i}tH_\Lambda} - \mathbb{E}_{X_R}\left(e^{\mathrm{i}tH_\Lambda} V_X e^{-\mathrm{i}tH_\Lambda}\right) \right\| \leq C_X \|V_X\| \, e^{-\mu(R - v|t|)}$$

for $R \geq v|t|$, with constants inherited from (119.2). Inserting this estimate into (119.4) gives a quasi-local tail bound:

$$\|D_{\Lambda,X}(s) - D^{(R)}_{\Lambda,X}(s)\| \leq C_X \|V_X(s)\| \left(e^{-\mu R/2} \int_{|t| \leq R/(2v)} |F_\gamma(t)| \, \mathrm{d}t + 2 \int_{|t| > R/(2v)} |F_\gamma(t)| \, \mathrm{d}t \right),$$

where $D^{(R)}_{\Lambda,X}(s) \in \mathcal{A}_{X_R}$. The first term is the Lieb–Robinson leakage inside the time window, and the second term is the filter tail outside that window. This is the mechanism behind quasi-local spectral flow: the gap fixes the filter in frequency space, the filter tail controls long times, and the Lieb–Robinson estimate controls the spatial spread during the retained times.

Consequently, a uniformly gapped local path supplies a quasi-local automorphism of the quasi-local observable algebra in the thermodynamic limit, provided the interaction norms, gap, boundary convention, filter tail, and volume exhaustion are all uniform. This automorphism is the regulated mathematical object that transports local phase data. It is distinct from both physical time evolution and from an arbitrary finite-dimensional unitary interpolation of ground spaces.

119.3 Finite Flux-Torus Hall Response

Hall response in an interacting system is not a single-particle Chern number unless the theory has first been reduced to a free one-particle problem. The finite many-body object is a family of Hamiltonians over a flux torus. This formulation is the appropriate finite-regulator laboratory for quantized topological response, and it is also the place where the order of statements must be kept straight: curvature over the finite flux torus is exact; thermodynamic Hall conductance is obtained only after a separate locality, gap, and limit argument.

Let Λ be a finite two-dimensional torus with a conserved $U(1)$ charge. Choose two oriented cuts, one dual to each primitive cycle, and introduce dimensionless fluxes

$$\phi = (\phi_x, \phi_y) \in \mathbb{T}^2 = (\mathbb{R}/2\pi\mathbb{Z})^2.$$

The finite flux Hamiltonian

$$H_\Lambda(\phi)$$

is obtained by coupling charged terms crossing the a-cut to the flat background holonomy $e^{\mathrm{i}\mathfrak{q}\phi_a}$, with $\mathfrak{q}$ the $U(1)$ charge of the term crossing the cut. Equivalently, $H_\Lambda(\phi)$ is a C^2 family of self-adjoint matrices which is periodic in ϕ, or periodic up to a large background-gauge transformation. In the latter case the formulas below are read as formulas for the spectral vector bundle over $\mathbb{T}^2$ with the corresponding transition functions. The flux-current operators in this normalization are

$$I_a(\phi) = \partial_{\phi_a} H_\Lambda(\phi), \qquad a = x, y.$$

If a physical electric field is produced by a time-dependent flux, its sign relative to I_a is fixed by the convention used for $\phi_a(t)$; the finite curvature formula below is independent of that conversion convention.

Definition 119.4 (Finite flux-torus response structure)**.** A finite flux-torus response structure consists of:

finite Hilbert space	$\mathcal{H}_\Lambda$,
flux Hamiltonian	$H_\Lambda : \mathbb{T}^2 \to \mathrm{End}(\mathcal{H}_\Lambda)_{\mathrm{sa}}$,
isolated band	$P_\Lambda(\phi)$ of constant rank r_Λ,
uniform finite gap	$\mathrm{dist}\big(\mathrm{Spec}\, H_\Lambda\vert_{P_\Lambda}, \mathrm{Spec}\, H_\Lambda\vert_{1-P_\Lambda}\big) \geq \gamma_\Lambda > 0.$

The band curvature is the two-form

$$\mathcal{F}_{xy,\Lambda}(\phi)\, \mathrm{d}\phi_x \wedge \mathrm{d}\phi_y = \mathrm{i}\, \mathrm{Tr}_{\mathcal{H}_\Lambda}\big(P_\Lambda[\partial_{\phi_x} P_\Lambda, \partial_{\phi_y} P_\Lambda]\big) \mathrm{d}\phi_x \wedge \mathrm{d}\phi_y. \tag{119.6}$$

The flux-averaged dimensionless Hall coefficient of this finite structure is

$$\overline{\kappa}_{xy,\Lambda} = \frac{1}{r_\Lambda (2\pi)^2} \int_{\mathbb{T}^2} \mathcal{F}_{xy,\Lambda}(\phi)\, \mathrm{d}\phi_x\, \mathrm{d}\phi_y. \tag{119.7}$$

In units $e = \hbar = 1$, the corresponding physical Hall conductivity uses the same number when the flux/electric-field convention is the one stated above; restoring units multiplies by $e^2/\hbar$ and the conventional 2π normalization is already contained in (119.7).

Theorem 119.5 (Finite Hall curvature theorem)**.** *Let $H_\Lambda(\phi)$ and $P_\Lambda(\phi)$ be a finite flux-torus response structure. Then*

$$C_\Lambda = \frac{1}{2\pi} \int_{\mathbb{T}^2} \mathcal{F}_{xy,\Lambda}(\phi)\, \mathrm{d}\phi_x\, \mathrm{d}\phi_y \tag{119.8}$$

is an integer depending only on the spectral vector bundle $\mathrm{Ran}\, P_\Lambda \to \mathbb{T}^2$. It is unchanged under every C^1 deformation of the finite structure for which the rank of P_Λ and the spectral gap remain fixed.

If, in addition, the isolated band is an exact r_Λ-fold degenerate eigenvalue,

$$H_\Lambda(\phi) P_\Lambda(\phi) = E_0(\phi) P_\Lambda(\phi),$$

and

$$Q_\Lambda = 1 - P_\Lambda, \qquad R_\Lambda(\phi) = Q_\Lambda(\phi)\big(H_\Lambda(\phi) - E_0(\phi)\big)^{-1} Q_\Lambda(\phi),$$

then the same curvature has the finite Kubo form

$$\mathcal{F}_{xy,\Lambda} = \mathrm{i}\, \mathrm{Tr}\big(P_\Lambda I_x R_\Lambda^2 I_y P_\Lambda - P_\Lambda I_y R_\Lambda^2 I_x P_\Lambda\big)\,. \tag{119.9}$$

Thus

$$\overline{\kappa}_{xy,\Lambda} = \frac{C_\Lambda}{2\pi r_\Lambda}.$$

Proof. The integrality statement is the Chern-Weil formula for the determinant line of the finite-rank bundle $\operatorname{Ran} P_\Lambda$, and in this finite setting the proof can be written explicitly. On a coordinate patch $U_\alpha \subset \mathbb{T}^2$, choose a smooth orthonormal frame

$$\Psi_\alpha = (\psi_{\alpha,1}, \ldots, \psi_{\alpha,r_\Lambda})$$

for $\operatorname{Ran} P_\Lambda$. The trace Berry connection in this frame is

$$A_\alpha = \mathrm{i}\,\mathrm{Tr}\big(\Psi_\alpha^* \mathrm{d}\Psi_\alpha\big).$$

Using $P_\Lambda = \Psi_\alpha \Psi_\alpha^*$ and $\Psi_\alpha^* \Psi_\alpha = 1_q$, one obtains

$$\mathrm{d}A_\alpha = \mathrm{i}\,\mathrm{Tr}\big(P_\Lambda\, \mathrm{d}P_\Lambda \wedge \mathrm{d}P_\Lambda\big),$$

whose xy-component is (119.6). On an overlap $U_\alpha \cap U_\beta$, the two frames obey

$$\Psi_\beta = \Psi_\alpha g_{\alpha\beta}, \qquad g_{\alpha\beta} : U_\alpha \cap U_\beta \to U(r_\Lambda).$$

Therefore

$$A_\beta - A_\alpha = \mathrm{i}\,\mathrm{Tr}(g_{\alpha\beta}^{-1} \mathrm{d}g_{\alpha\beta}) = \mathrm{i}\,\mathrm{d}\log\det g_{\alpha\beta}.$$

Integrating $\mathrm{d}A_\alpha$ over a fundamental polygon for the torus and using Stokes' theorem reduces the integral to the winding of the transition function $\det g_{\alpha\beta} : S^1 \to U(1)$. Hence

$$\frac{1}{2\pi} \int_{\mathbb{T}^2} \mathrm{i}\,\mathrm{Tr}(P_\Lambda\, \mathrm{d}P_\Lambda \wedge \mathrm{d}P_\Lambda) \in \mathbb{Z}.$$

The same argument applies when the flux family is only covariantly periodic: the large-gauge transition unitaries are precisely the transition functions of the bundle. Constancy under a gapped deformation follows because the integer $C_\Lambda(s)$ depends continuously on s while the projection bundle is defined throughout the deformation.

It remains to prove the Kubo expression. Differentiate

$$H_\Lambda P_\Lambda = E_0 P_\Lambda$$

and multiply by Q_Λ on the left and P_Λ on the right. Since $Q_\Lambda P_\Lambda = 0$, this gives

$$Q_\Lambda (\partial_a P_\Lambda) P_\Lambda = -R_\Lambda Q_\Lambda I_a P_\Lambda, \qquad a = x, y.$$

Taking adjoints gives

$$P_\Lambda (\partial_a P_\Lambda) Q_\Lambda = -P_\Lambda I_a Q_\Lambda R_\Lambda.$$

The diagonal identities $P_\Lambda (\partial_a P_\Lambda) P_\Lambda = 0$, obtained from $P_\Lambda^2 = P_\Lambda$, imply

$$\mathrm{Tr}\big(P_\Lambda [\partial_x P_\Lambda, \partial_y P_\Lambda]\big) = \mathrm{Tr}\big(P_\Lambda (\partial_x P_\Lambda) Q_\Lambda (\partial_y P_\Lambda) P_\Lambda - P_\Lambda (\partial_y P_\Lambda) Q_\Lambda (\partial_x P_\Lambda) P_\Lambda\big).$$

Substituting the two off-diagonal formulas above gives (119.9). The final displayed equality follows by inserting (119.8) into (119.7). □

For a finite interacting system the coefficient at a fixed flux value need not be quantized. The quantized object in Theorem 119.5 is the flux average of the band curvature. A thermodynamic Hall theorem requires additional hypotheses: the flux family must be local in the sense that $I_a = \partial_{\phi_a} H$ is supported near the corresponding cut up to uniformly local tails; the gap above the relevant band must remain uniform over ϕ and over the volume sequence; the quasi-adiabatic flow from Section 119.2 must control the change of local current response under moving the cuts; and the thermodynamic limit of the response must exist. Under such hypotheses the fixed-flux response becomes independent of ϕ up to errors vanishing in the thermodynamic limit, and the finite integer C_Λ becomes the phase-stable Hall datum. Without these hypotheses, writing a continuum integer Hall conductance directly from a finite Kubo formula hides the substance of the theorem.

119.4 Gauge Invariance And Elitzur Averaging

Gauge-variant local fields cannot be order parameters for a gauge theory unless a gauge has been fixed and the residual meaning of the statement has been specified. The finite-regulator reason is elementary.

Finite-volume gauge averaging. Let a finite lattice gauge theory have compact gauge group G, gauge invariant action, and gauge invariant measure. Let O be an observable which transforms nontrivially under the gauge transformation at one site x. Then

$$\langle O\rangle_\Lambda = 0$$

in finite volume with gauge-invariant boundary conditions.

Average over gauge transformations supported at x. Gauge invariance of the measure and action gives

$$\langle O\rangle_\Lambda = \int_G dh\, \langle h\cdot O\rangle_\Lambda .$$

If O transforms in a representation ρ with no invariant vector in the component being averaged, Haar orthogonality gives

$$\int_G dh\, \rho(h) = 0$$

on that component. Therefore the group average of O is zero, and so is its expectation value. For a finite collection of gauge-variant insertions, perform the Haar average independently at each site touched by the product. The integral at a given site projects the tensor product of the local representation factors onto its invariant subspace. The expectation can survive only if this projection is nonzero at every site. The load-bearing input here is the finite-regulator Haar projection with gauge-invariant boundary conditions; the calculation is the local averaging step used in Elitzur-type statements. Continuum phase statements require the separate limiting data specified in Definition 119.1.

Consequently a Higgs regime must be described by gauge-invariant data: screening of external charges, massive vector states in gauge-invariant channels, boundary-condition response, or nonlocal diagnostics. A gauge-fixed scalar expectation value may be a useful coordinate in a weakly coupled chart, but it is not the invariant phase datum.

119.5 Static Potentials From Transfer Matrices

Let $W_R(C)$ be a renormalized Wilson loop in representation R. For a rectangle $C_{T,L}$ with temporal length T and spatial separation L, define the static potential by

$$V_R(L) = -\lim_{T\to\infty} \frac{1}{T} \log \langle W_R(C_{T,L})\rangle_{\text{ren}}\,, \tag{119.10}$$

when the limit exists. The subscript indicates that the line self-energy has been subtracted or divided out in a specified line-renormalization scheme.

Reflection positivity gives a Hilbert-space interpretation. In a finite spatial box, a pair of static external sources separated by L defines a sector Hilbert space $\mathcal{H}_{R,\bar{R};L}$ or, equivalently, a state $\Psi_{R,L}$ in the transfer-matrix construction with a Wilson transporter between the two sources. If $H_{R,L}$ is the Hamiltonian in this sector and E_0 is the vacuum energy, then

$$\langle W_R(C_{T,L})\rangle_{\text{ren}} = \langle \Psi_{R,L}, e^{-T(H_{R,L}-E_0)}\Psi_{R,L}\rangle.$$

By the spectral theorem this has the form

$$\int_0^\infty e^{-TE}\, d\rho_{R,L}(E)$$

for a positive finite spectral measure $\rho_{R,L}$.

Large-time spectral extraction. The static-potential limit uses the elementary Laplace principle for a positive spectral measure. Let ρ be a nonzero finite positive measure on $[E_*,\infty)$, and assume every interval $[E_*, E_*+\varepsilon]$ has positive ρ-measure. Then

$$-\lim_{T\to\infty}\frac{1}{T}\log\int e^{-TE}\, d\rho(E) = E_*.$$

Since $E \geq E_*$,

$$\int e^{-TE}\, d\rho(E) \leq \rho([E_*,\infty))e^{-TE_*}.$$

Thus the liminf of the left side is at least E_*. For every $\varepsilon > 0$,

$$\int e^{-TE}\, d\rho(E) \geq \rho([E_*, E_*+\varepsilon])e^{-T(E_*+\varepsilon)}.$$

The measure factor is positive and independent of T, so the limsup is at most $E_*+\varepsilon$. Letting $\varepsilon \to 0$ proves the claim. This calculation supplies only the last step after a reflection-positive transfer-matrix sector and a renormalized Wilson-loop spectral measure have already been constructed.

Thus $V_R(L)$ is the bottom of the static-source spectrum in the chosen sector. Its large-L behavior gives several distinct responses:

confining	$V_R(L) = \sigma_R L + o(L), \quad \sigma_R > 0,$
screened	$V_R(L)$ is bounded as $L \to \infty$,
Coulombic in four spacetime dimensions	$V_R(L) = V_\infty - \kappa_R/L + o(L^{-1}).$

These are responses of the chosen external probe. A theory with dynamical fundamental matter can screen the fundamental Wilson charge even when other probes or boundary conditions still diagnose nontrivial long-distance structure.

119.6 Loop Laws And Higher-Form Symmetry

For a closed contour C, let $L_\gamma(C)$ be a renormalized line operator with finite charge γ. For a sequence of large planar loops, an area law means

$$-\log\langle L_\gamma(C)\rangle = \sigma_\gamma\ \mathrm{Area}_{\min}(C) + o(\mathrm{Area}_{\min}(C)), \qquad \sigma_\gamma > 0,$$

after perimeter renormalization. A perimeter law means

$$-\log\langle L_\gamma(C)\rangle = \mu_\gamma\ \mathrm{Length}(C) + o(\mathrm{Length}(C)).$$

In a gapless Coulomb regime, logarithmic and power corrections can replace both pure laws; the phase datum is then the full asymptotic class, not a binary area/perimeter label.

Let A be a finite one-form symmetry and let

$$U_a(\Sigma), \qquad a \in A,$$

be its topological symmetry surface on a closed codimension-two surface Σ. If a line $L_\chi(C)$ carries character

$$\chi \in \widehat{A} = \mathrm{Hom}(A, U(1)),$$

then linking gives

$$U_a(\Sigma)L_\chi(C) = \chi(a)^{\mathrm{Link}(\Sigma,C)}L_\chi(C).$$

In a gapped phase with a homogeneous vacuum and no boundary contribution, the unbroken realization of a finite electric one-form symmetry is diagnosed by area laws for charged Wilson lines. A perimeter law for a charged line is the characteristic response of a broken one-form symmetry or a deconfined topological sector. This statement requires the line to be genuine and charged under an actual one-form symmetry; if dynamical matter lets the line end, the one-form symmetry is explicitly absent or reduced.

119.7 Screening, Condensation, And Oblique Confinement

Let $\mathcal{C}$ be the finite abelian group of center-sensitive dyonic line charges, with nondegenerate alternating pairing

$$B : \mathcal{C} \times \mathcal{C} \longrightarrow \mathbb{Q}/\mathbb{Z}.$$

For $\mathfrak{su}(N)$ this is

$$\mathcal{C} = \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}}, \qquad B((e,m),(e',m')) = \frac{em' - e'm}{N}.$$

Let $S \subset \mathcal{C}$ be the subgroup screened by dynamical finite-energy excitations: a line whose charge lies in S can end on a dynamical operator or state. The asymptotic external-probe labels are then identified modulo screened charges,

$$\mathcal{C}_{\mathrm{ext}} = \mathcal{C}/S$$

for questions about static sources. The finite braiding form does not, in general, descend to all of this quotient. If the screened subgroup is isotropic, then the genuine residual finite topological charges are

$$\mathcal{C}_{\mathrm{top}} = S^\perp/S, \qquad S^\perp = \{\gamma \in \mathcal{C} \mid B(\gamma, s) = 0 \text{ for every } s \in S\},$$

and the pairing descends to $\mathcal{C}_{\mathrm{top}}$ because changing a representative by $s \in S$ shifts $B(\gamma, \gamma')$ by $B(s, \gamma') = 0$ whenever $\gamma' \in S^{\perp}$.

A condensate of line or particle charges is encoded, at the finite center-sensitive level, by an isotropic subgroup

$$K \subset \mathcal{C}, \qquad B|_{K \times K} = 0.$$

The isotropy condition is mutual locality of condensed charges. The charges with trivial finite braiding against the condensate form

$$K^{\perp} = \{\gamma \in \mathcal{C} \mid B(\gamma, k) = 0 \text{ for every } k \in K\}.$$

Assume a gapped regime in which the long-distance condensate is described by an isotropic finite subgroup $K \subset \mathcal{C}$, and assume a line of charge γ has perimeter behavior only if it has trivial braiding with every condensed charge. Then the unconfined finite charges lie in

$$K^{\perp},$$

and every $\gamma \notin K^{\perp}$ is confined in this finite-charge diagnostic. If K is maximal isotropic, then $K^{\perp} = K$. Moving a test line of charge γ around a condensed object of charge k multiplies the state by

$$\exp(2\pi \mathrm{i} B(\gamma, k)).$$

A perimeter-law line in a condensate background must have a nonzero overlap with the condensate sector without introducing a branch-dependent phase. By the hypothesis this requires the displayed phase to be one for every $k \in K$, which is exactly $\gamma \in K^{\perp}$. If $K \subsetneq K^{\perp}$, an element $\eta \in K^{\perp} \setminus K$ would generate with K a strictly larger isotropic subgroup, because $B(\eta, K) = 0$ and $B(\eta, \eta) = 0$. Hence a maximal isotropic subgroup obeys $K = K^{\perp}$.

Electric confinement corresponds to magnetic condensation: purely electric charges pair nontrivially with the magnetic condensate and acquire area law. A Higgs response from electric condensation screens electric probes and confines appropriate magnetic probes. Oblique confinement is the same criterion with a dyonic condensate

$$K = \langle (e_c, m_c) \rangle$$

whose generator has both electric and magnetic components. The word "oblique" is therefore not a new mechanism; it is the finite Dirac pairing applied to a dyonic condensate.

119.8 Gauge-Higgs Analytic Connectivity

Consider a lattice gauge theory with compact gauge group and matter in a representation that screens the fundamental Wilson charge. At finite lattice volume the partition function is an analytic function of the couplings because it is an integral of an analytic bounded integrand over a compact domain. A cluster expansion gives open regions in the strong-gauge and large-Higgs coupling domains where connected correlations of local gauge-invariant operators decay exponentially and are analytic in the couplings.

Gauge-Higgs analytic corridor. Assume the cluster expansions in the strong-gauge and large-Higgs domains converge in a common connected corridor of lattice couplings, uniformly in volume for local gauge-invariant observables. Then those local observables have a single analytic infinite-volume continuation throughout the corridor.

Uniform convergence of the cluster expansion gives an absolutely convergent series for each connected local correlator with coefficients analytic in the couplings. The thermodynamic limit may therefore be taken term by term in the corridor. Analytic continuation along any path inside the connected corridor gives the same value because the local correlator is represented by one convergent analytic series on overlapping neighborhoods. Hence the two coordinate descriptions belong to one local-observable phase in the declared observable set.

This analytic-corridor argument concerns the declared local observable system. It does not say that every possible extended-probe datum is identical. Boundary conditions, heavy external charges, remnant higher-form backgrounds, and topological sectors can refine the phase problem. This is why the observable system in Definition 119.1 must be specified before claiming analytic connectivity or separation.

119.9 Fredenhagen–Marcu Type Ratios

When dynamical matter screens a Wilson charge, the Wilson loop itself need not distinguish a confinement-like region from a Higgs-like region. A more refined gauge-invariant probe uses an open transporter with charged matter fields at its endpoints. Let ϕ be a matter field in representation R, let γ_{xy} be a path from x to y, and define the gauge-invariant open-line correlator

$$G_R(\gamma_{xy}) = \left\langle \phi^\dagger(x)\, U_R(\gamma_{xy})\, \phi(y) \right\rangle .$$

Let C_γ be a closed contour built from γ_{xy} and a reference return path of comparable size. A Fredenhagen–Marcu type ratio is

$$\rho_R(\gamma) = \frac{G_R(\gamma)}{\sqrt{\langle W_R(C_\gamma)\rangle_{\rm ren}}},$$

with the regulator, endpoint renormalization, and order of limits specified. The denominator removes the bulk string contribution associated with the closed flux sheet. The resulting ratio asks whether the open charged configuration has nonzero overlap with the vacuum or with a charged superselection sector after the universal flux cost has been divided out.

Exponential scaling of the ratio. Suppose a family of paths has size R, and suppose

$$-\log|G_R(\gamma_R)| = aR + o(R), \qquad -\log\langle W_R(C_{\gamma_R})\rangle_{\rm ren} = bR + o(R)$$

with $b \geq 0$. Then

$$-\log|\rho_R(\gamma_R)| = \left(a - \frac{b}{2}\right) R + o(R).$$

In particular the ratio has a nonzero exponential limit only when the endpoint-open-line decay matches one half of the closed-loop decay at leading order. This is the logarithm of the definition:

$$-\log|\rho_R| = -\log|G_R| + \frac{1}{2}\log\langle W_R\rangle_{\rm ren}.$$

Substituting the two assumed asymptotic formulas gives

$$aR + o(R) - \frac{b}{2}R + o(R),$$

which is the displayed expression.

The ratio is therefore not a slogan for "Higgs" or "confinement" without the accompanying limit definition. Its interpretation depends on the matter representation, the boundary conditions, the renormalization of the endpoints, and the sector whose overlap is being measured. Its virtue is that all of these choices are gauge-invariant and can be stated at finite regulator.

119.10 Topological Order And Deconfined Gauge Theory

A gapped gauge theory can have a finite-dimensional Hilbert space on spatial manifolds with nontrivial topology, nontrivial line-operator braiding, and surface operators whose correlation functions depend on homology classes. These data form the long-distance topological sector. In continuum language they are encoded by an infrared TQFT together with a map

$$\Phi_{\mathrm{IR}} : \begin{matrix}\{\text{microscopic topological} \\ \text{extended operators}\}\end{matrix} \longrightarrow \begin{matrix}\{\text{topological operators} \\ \text{of the IR TQFT}\}\end{matrix} .$$

The map is part of the phase definition. Two microscopic theories may have the same emergent TQFT but differ in massive local spectra, symmetry fractionalization, anomaly inflow, or the embedding of microscopic line operators into the topological category.

119.11 Finite One-Form Laboratory: The $\mathbb{Z}_2$ Gauge Code

The preceding paragraph is abstract because a continuum gapped phase rarely comes with an exactly known Hilbert space on every spatial manifold. A finite commuting-projector gauge code supplies a useful laboratory, provided its logical status is kept clear. It is not a definition of continuum QFT and it does not replace the infinite-volume phase problem. It gives an exact operator algebra in which one-form charge, topological line operators, local indistinguishability, and energy-barrier limitations can be checked without asymptotic or semiclassical language.

Let Λ be an $L_x \times L_y$ square cellulation of the spatial torus, with $L_x, L_y \geq 3$. Let V, E, P be its vertices, edges, and plaquettes, and put a two-dimensional Hilbert space

$$\mathcal{H}_\Lambda = \bigotimes_{e\in E} \mathbb{C}^2_e$$

on the edges. Write X_e, Z_e for Pauli operators on the edge e. The star and plaquette stabilizers are

$$A_v = \prod_{e\ni v} X_e, \qquad B_p = \prod_{e\subset\partial p} Z_e. \tag{119.11}$$

The orientation of ∂p is irrelevant because all coefficients are in $\mathbb{Z}_2$. Each A_v and B_p squares to one, and all stabilizers commute: a star and a plaquette share either no edge or two edges, so the two $XZ = -ZX$ signs cancel. The Hamiltonian

$$H_\Lambda = -J \sum_{v \in V} A_v - J \sum_{p \in P} B_p, \qquad J > 0, \tag{119.12}$$

has ground projector

$$P_0 = \prod_{v \in V} \frac{1 + A_v}{2} \prod_{p \in P} \frac{1 + B_p}{2}. \tag{119.13}$$

The two products of all stars and all plaquettes are identities,

$$\prod_{v \in V} A_v = 1, \qquad \prod_{p \in P} B_p = 1,$$

and these are the only stabilizer relations on the connected torus. Hence the number of independent stabilizer constraints is

$$(|V| - 1) + (|P| - 1).$$

Since $|E| - |V| - |P| = 0$ for the square torus, the ground space has dimension

$$2^{|E| - (|V|-1) - (|P|-1)} = 4.$$

Equivalently, the two encoded qubits are the two $\mathbb{Z}_2$-homology cycles of the torus.

It is useful to express the logical algebra in chain-complex notation. For a $\mathbb{Z}_2$ edge chain $c \in C_1(\Lambda; \mathbb{Z}_2)$ and an edge cochain $\eta \in C^1(\Lambda; \mathbb{Z}_2)$, define

$$Z(c) = \prod_{e : c_e = 1} Z_e, \qquad X(\eta) = \prod_{e : \eta(e) = 1} X_e. \tag{119.14}$$

Their commutation relation is the finite intersection pairing

$$X(\eta) Z(c) = (-1)^{\langle \eta, c \rangle} Z(c) X(\eta), \qquad \langle \eta, c \rangle = \sum_{e \in E} \eta(e) c_e \pmod 2. \tag{119.15}$$

The operator $Z(c)$ commutes with every star iff $\partial c = 0$. If $c = \partial s$ is the boundary of a plaquette two-chain s, then

$$Z(c) = \prod_{p : s_p = 1} B_p$$

and $Z(c)$ acts as the identity on $P_0 \mathcal{H}_\Lambda$. Thus nontrivial Z-type logical lines are represented by

$$[c] \in H_1(T^2; \mathbb{Z}_2).$$

Dually, $X(\eta)$ commutes with every plaquette iff $\delta \eta = 0$; if $\eta = \delta f$ is exact, then $X(\eta)$ is a product of star stabilizers and is trivial on the ground space. The nontrivial X-type logical lines are represented by

$$[\eta] \in H^1(T^2; \mathbb{Z}_2).$$

Equation (119.15) is then the exact finite version of the one-form linking phase: a primal Z-loop and a dual X-loop anticommute precisely when their mod-two intersection number is one.

Local indistinguishability. Let $R \subset E$ be an edge set contained in a contractible disk of the cellulation, and let O_R be any operator supported on $\bigotimes_{e\in R} \mathbb{C}_e^2$. Expanding O_R in the Pauli basis, it is enough to consider a monomial

$$W = i^\ell X(\eta)Z(c), \qquad \mathrm{supp}(\eta, c) \subset R.$$

If $\partial c \neq 0$, then $Z(c)$ anticommutes with at least one star stabilizer; if $\delta\eta \neq 0$, then $X(\eta)$ anticommutes with at least one plaquette stabilizer. In either case

$$P_0 W P_0 = 0,$$

because the anticommuting stabilizer S obeys

$$P_0 W P_0 = P_0 S W P_0 = -P_0 W S P_0 = -P_0 W P_0.$$

If $\partial c = 0$ and $\delta\eta = 0$, contractibility of R implies that c is a plaquette boundary and η is a star coboundary inside the same disk. Therefore W is a phase times a product of stabilizers, and

$$P_0 W P_0 = \lambda(W) P_0, \qquad \lambda(W) \in \{0, \pm 1, \pm \mathrm{i}\}.$$

By linearity,

$$P_0 O_R P_0 = c(O_R) P_0 \tag{119.16}$$

for every operator supported in a contractible region R. This is the finite local-indistinguishability mechanism. It is stronger than saying that particular expectation values agree: the full local operator algebra acts projectively as scalars after projection to the ground sector. It is also weaker than a continuum phase theorem: stability under perturbations and passage to an infinite-volume gapped phase require separate locality and gap input, such as Lieb–Robinson and quasi-adiabatic-continuation estimates.

Open strings and the finite energy barrier. For an open chain c, the boundary ∂c is the set of star violations created by $Z(c)$. More precisely, for a ground vector ψ,

$$\langle Z(c)\psi, H_\Lambda Z(c)\psi\rangle - \langle \psi, H_\Lambda \psi\rangle = 2J\,|\partial c|. \tag{119.17}$$

A simple partial string has two endpoints, so the energy cost is $4J$, independent of its length. When the string closes into a noncontractible cycle, the endpoints disappear and the operator becomes a logical line inside the ground sector. The same statement holds for dual X-strings with plaquette violations. Thus this exact laboratory simultaneously exhibits topological logical lines and fixes the two-dimensional $\mathbb{Z}_2$ gauge-code barrier scale at order J, independent of system size. Any finite-temperature memory statement must additionally specify the bath, rates, decoder or absence of decoder, and the limiting notion of lifetime.

The lesson for gauge theory is the logical separation. The finite stabilizer model makes the microscopic line algebra and the one-form intersection phase completely explicit. A continuum deconfined gauge theory may have the same long-distance topological sector when a regulator family, phase classification, and infrared limit connect the microscopic model to that sector.

Open Problem 119.6 (Complete phase invariant for gauge theories). Define a tractable invariant of gauge-theory phases that includes local correlators, extended-operator categories, higher-form symmetry realization, background responses, boundary-condition sectors, and massive spectra, and prove its stability under finite local deformations inside a gapped phase.

Chapter 120

Boundaries And Defects

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Boundaries and defects are QFT data supported on submanifolds. They modify operator algebras, symmetry realization, anomaly inflow, and phase structure. This chapter formulates them as local data rather than as afterthoughts added to a bulk theory. The examples below are elementary enough that their fusion and anomaly data can be checked directly.

120.1 Boundary QFT Datum

Definition 120.1 (Boundary QFT datum)**.** Let M be a spacetime manifold with boundary ∂M. A boundary condition for a local QFT assigns the following data:

$$\begin{array}{ll} \text{bulk observables} & \mathcal{A}(U), \quad U \subset M^\circ, \\ \text{boundary observables} & \mathcal{B}(V), \quad V \subset \partial M, \\ \text{bulk-to-boundary maps} & \mathcal{A}(U) \to \mathcal{B}(V) \text{ for } U \to V, \\ \text{state or functional} & \omega_\partial \text{ on the combined algebra.} \end{array}$$

Locality requires that observables with spacelike separated supports commute or graded-commute after their supports are interpreted in the manifold with boundary.

The bulk-to-boundary maps in Definition 120.1 are not optional. They specify what happens when a bulk operator is brought to the boundary and therefore determine boundary operator expansions, boundary Ward identities, and the possible endpoints of bulk extended operators.

120.2 Boundary Operator Expansion

Definition 120.2 (Boundary operator expansion)**.** For a scalar bulk local operator $\mathcal{O}(x_\perp, y)$, with $x_\perp \geq 0$ the distance to the boundary and $y \in \partial M$, the boundary expansion has the form

$$\mathcal{O}(x_\perp, y) \sim \sum_\alpha c_{\mathcal{O}}^\alpha(x_\perp)\, \widehat{\mathcal{O}}_\alpha(y),$$

where $\widehat{\mathcal{O}}_\alpha$ are boundary local operators. The symbol means convergence inside the declared correlation-function topology after smearing away from coincident boundary insertions. Boundary critical exponents and boundary anomalies are properties of this expansion and of the boundary stress tensor.

Example 120.3 (Free scalar half-space boundary expansion)**.** Let ϕ be a free massless scalar field on the Euclidean half-space $\mathbb{R}_{\geq 0} \times \mathbb{R}^{D-1}$, with coordinates $(x_\perp, y)$. For Neumann boundary condition $\partial_\perp \phi|_{x_\perp=0} = 0$, the method of images gives

$$\langle \phi(x_\perp, y)\phi(x'_\perp, y')\rangle_N = G_D(x_\perp - x'_\perp, y - y') + G_D(x_\perp + x'_\perp, y - y').$$

For Dirichlet boundary condition $\phi|_{x_\perp=0} = 0$, the sign of the image term is reversed. Consequently the leading boundary operator in the Neumann case is $\widehat{\phi}(y) = \phi(0, y)$, whereas in the Dirichlet case the leading nonzero boundary operator is $\widehat{\partial_\perp \phi}(y) = \partial_\perp \phi(0, y)$. This example shows that the boundary operator expansion is a statement about a boundary condition together with the corresponding boundary field content.

120.3 Interfaces And Domain Walls

Definition 120.4 (Interface and domain wall)**.** An interface between two QFTs $\mathcal{T}_-$ and $\mathcal{T}_+$ is a codimension-one defect whose local neighborhoods have $\mathcal{T}_-$ on one side and $\mathcal{T}_+$ on the other. A domain wall is an interface between two phases or vacua of the same microscopic theory. Topological interfaces can be moved without changing separated correlation functions, up to contact terms specified on the wall. Non-topological interfaces carry ordinary localized excitations and have their own stress-tensor Ward identities.

Example 120.5 (Chern–Simons boundary and chiral WZW currents)**.** For Chern–Simons theory on a three-manifold with boundary, the variation of the bulk action contains the boundary one-form

$$\frac{k}{4\pi} \int_{\partial M} \mathrm{tr}(A \wedge \delta A).$$

After choosing the holomorphic polarization on the boundary surface Σ, the boundary field $g : \Sigma \to G$ has the chiral Wess–Zumino–Witten action displayed in Chapter 105. The boundary current

$$J(z) = -\frac{k}{2\pi} \partial_z g\, g^{-1}$$

obeys the affine current algebra at level k. Thus the boundary condition does not simply remove a boundary term; it creates a boundary operator algebra whose representation theory is the state-space input for Wilson-line endpoints and boundary conformal blocks.

120.4 Fusion

Definition 120.6 (Renormalized defect fusion)**.** Let D_1 and D_2 be parallel defects separated by distance ℓ. Fusion asks for the limit

$$D_2 \circ_\ell D_1 \quad \text{as} \quad \ell \to 0.$$

The limit is a defect $D_2 \star D_1$ only if correlation functions with separated external insertions converge after renormalizing defect-local operators. In a topological sector, fusion gives a monoidal category of defects. In a general QFT, fusion is a renormalization problem for codimension-one local data.

Example 120.7 (Ising topological defect fusion)**.** At the critical two-dimensional Ising point, the basic topological defects are

$$\mathbf{1}, \qquad \eta, \qquad \mathcal{N},$$

where η is the invertible spin-flip defect and $\mathcal{N}$ is the Kramers–Wannier duality defect. Their fusion rules are

$$\eta \otimes \eta \simeq \mathbf{1}, \qquad \eta \otimes \mathcal{N} \simeq \mathcal{N} \otimes \eta \simeq \mathcal{N}, \qquad \mathcal{N} \otimes \mathcal{N} \simeq \mathbf{1} \oplus \eta.$$

The last equation is the first test that the word "duality" is being used as a defect statement rather than as a slogan: $\mathcal{N}$ has no inverse, because its square is a direct sum. Chapter 121 derives the corresponding action on primary sectors from the Ising modular S-matrix.

Remark 120.8 (Fusion detects noninvertibility). In the fusion algebra of Example 120.7, the defect $\mathcal{N}$ is not invertible and has Frobenius–Perron dimension $\sqrt{2}$.

If $\mathcal{N}$ had an inverse X, then $\mathcal{N} \otimes X \simeq \mathbf{1}$ would be simple. But fusing $\mathcal{N} \otimes \mathcal{N} \simeq \mathbf{1} \oplus \eta$ with X gives

$$\mathcal{N} \simeq X \oplus (\eta \otimes X),$$

which expresses the simple defect $\mathcal{N}$ as a direct sum of two nonzero summands, a contradiction in the semisimple defect category. The positive dimension homomorphism satisfies

$$d_{\mathcal{N}}^2 = d_{\mathbf{1}} + d_\eta = 2,$$

because $d_{\mathbf{1}} = d_\eta = 1$. Hence $d_{\mathcal{N}} = \sqrt{2}$.

Example 120.9 (Electric-magnetic duality surface in three-dimensional BF)**.** The $\mathbb{Z}_N$ topological gauge theory can be written in continuum notation as the $U(1) \times U(1)$ BF action

$$S_{\mathrm{BF}} = \frac{N}{2\pi} \int B \wedge dA,$$

with compact one-form gauge fields A and B. Its simple line labels are pairs $(e, m) \in \mathbb{Z}_N \oplus \mathbb{Z}_N$, represented by

$$W_{e,m}(\gamma) = \exp\!\left(\mathrm{i}e \int_\gamma A + \mathrm{i}m \int_\gamma B \right).$$

The codimension-one surface defect S that exchanges A and B acts by

$$S:\ (e, m) \longmapsto (m, e).$$

It is topological because it preserves the BF action and the braiding pairing

$$\langle (e,m),(e',m')\rangle = \exp\left(\frac{2\pi \mathrm{i}}{N}(em'+me')\right).$$

Fusion satisfies $S \otimes S \simeq \mathbf{1}$. This is an invertible surface defect; unlike the Ising $\mathcal{N}$ defect, it is an ordinary duality wall because the induced map on the finite line-label group is an automorphism.

120.5 Anomalies And Inflow

Definition 120.10 (Anomaly line of a boundary or defect)**.** A boundary or defect can carry an anomaly line for background fields restricted to its support. If A_D denotes those restricted background fields, then a defect partition function with anomaly is a section

$$Z_D(A_D) \in \Gamma(\mathcal{L}_D),$$

where $\mathcal{L}_D$ is a complex line over the background-field space.

An invertible bulk theory with boundary D supplies a section of $\mathcal{L}_D^{-1}$. The product is then a complex number. If a boundary condition preserves a global symmetry, its boundary anomaly must match the restriction of the bulk inflow. If it breaks the symmetry, the broken background fields are not part of the boundary datum.

Remark 120.11 (Inflow cancellation as line trivialization). The combined bulk-defect amplitude is an ordinary complex-valued functional of background fields if and only if the tensor product of the defect anomaly line and the bulk inflow line is canonically trivialized.

If $Z_D(A_D)$ is a section of $\mathcal{L}_D$ and the bulk inflow amplitude $Z_{\mathrm{bulk}}(A)$ is a section of $\mathcal{L}_{\mathrm{bulk}}$, then their product is a section of $\mathcal{L}_D \otimes \mathcal{L}_{\mathrm{bulk}}$. It is a number precisely after choosing a natural isomorphism

$$\mathcal{L}_D \otimes \mathcal{L}_{\mathrm{bulk}} \cong \underline{\mathbb{C}}.$$

Conversely, if the product is a complex-valued functional for all background fields and is compatible with gluing of backgrounds, it defines exactly such a trivialization of the tensor product line.

120.6 Gauge-Theory Boundaries

For gauge theories, a boundary condition must specify which gauge transformations are redundancies at the boundary and which become global symmetries acting on boundary operators. Electric boundary conditions fix the tangential connection or electric flux according to the chosen Hamiltonian polarization. Magnetic boundary conditions fix the dual data. Line operators may end on the boundary precisely when boundary degrees of freedom carry the corresponding charge and cancel the endpoint gauge variation.

Example 120.12 (Endpoint gauge variation of a Wilson line)**.** Let γ be an oriented path from p to q, and let

$$U_\gamma(A) = \mathrm{Pexp}\int_\gamma A$$

be parallel transport in a representation R. Under a gauge transformation g,

$$U_\gamma(A^g) = R(g(p))\, U_\gamma(A)\, R(g(q))^{-1}.$$

Thus an open Wilson line is not gauge invariant by itself. It can end on a boundary only if boundary operators at p and q transform in the dual representations needed to contract these endpoint factors, or if the boundary condition converts the relevant gauge transformations into fixed global symmetry transformations and the line is interpreted as a charged operator under that boundary symmetry.

120.7 Defects And Phase Data

Boundary and defect categories refine the phase invariant of Chapter 119. A gapped phase includes the fusion category of topological line defects, higher-codimension defect operators, boundary conditions, and their anomaly responses. Two theories with the same local massive spectrum can be distinguished by these extended data.

Open Problem 120.13 (Defect-complete phase classification)*.* Construct a phase invariant that includes boundary conditions, defect fusion, endpoint maps for line and surface operators, anomaly inflow, and local operator data, and prove stability of this invariant under finite gapped deformations.

Chapter 121

Categorical Symmetry And Defect Fusion

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter formulates categorical symmetry through topological defects and their fusion. The object replacing a group is a category or higher category of topological operators, and the action on local or extended observables is defined by surrounding, ending, or fusing defects.

121.1 Topological Defect Category

Let $\mathcal{Q}$ be a D-dimensional local QFT. A codimension-one topological defect D is an operator supported on a hypersurface such that correlation functions are invariant under compactly supported deformations of the hypersurface avoiding insertions. Defects form a category $\mathcal{D}_{\mathcal{Q}}$ whose objects are boundary labels on small transverse intervals and whose morphisms are junction operators. Fusion is a monoidal product

$$\otimes : \mathcal{D}_{\mathcal{Q}} \times \mathcal{D}_{\mathcal{Q}} \longrightarrow \mathcal{D}_{\mathcal{Q}}.$$

If $D_g \otimes D_h \simeq D_{gh}$ and every D_g is invertible, the data reduce to an ordinary group symmetry. Categorical symmetry keeps the same fusion operation but allows noninvertible simple objects and nontrivial junction spaces.

Definition 121.1 (Topological defect datum in correlation functions)**.** Fix the class of Euclidean backgrounds and insertions on which $\mathcal{Q}$ is defined. A codimension-one defect label a assigns to every oriented framed hypersurface Σ, together with a tubular neighborhood disjoint from the other insertions, multilinear distributions

$$Z_{\Sigma,a}(\mathfrak{A}_1, \dots, \mathfrak{A}_n) = \big\langle D_a(\Sigma)\, \mathfrak{A}_1 \cdots \mathfrak{A}_n \big\rangle \tag{121.1}$$

on separated smeared local and extended insertions. The assignment is called topological if, for every smooth isotopy Σ_t fixed near the boundary of the chosen coordinate patch and avoiding the supports of $\mathfrak{A}_i$,

$$\frac{d}{dt} Z_{\Sigma_t,a}(\mathfrak{A}_1, \dots, \mathfrak{A}_n) = 0 \tag{121.2}$$

as a distribution in the insertion variables. The datum is local if it is compatible with restriction to sub-balls and gluing along collars. It is renormalized if the limit defining (121.1) is independent of auxiliary cutoff choices up to the declared finite defect counterterms.

When the response to a normal displacement is represented by a local defect operator $\mathfrak{D}_{\perp,a}$, called the displacement operator, the infinitesimal Ward identity has the form

$$\frac{d}{dt} \big\langle D_a(\Sigma_t)\, \mathfrak{A}_1 \cdots \mathfrak{A}_n \big\rangle = \left\langle D_a(\Sigma_t) \int_{\Sigma_t} \nu_t\, \mathfrak{D}_{\perp,a}\, \mathfrak{A}_1 \cdots \mathfrak{A}_n \right\rangle, \tag{121.3}$$

where ν_t is the scalar normal velocity of the deformation.

Remark 121.2 (Displacement criterion for topological defects). Assume the displacement Ward identity (121.3) holds for a renormalized defect label a. The defect is topological in the sense of Definition 121.1 if $\mathfrak{D}_{\perp,a} = 0$ as a defect local operator. Conversely, if (121.2) holds for all compactly supported normal variations and separated test insertions, then $\mathfrak{D}_{\perp,a}$ is zero in the defect-operator quotient by correlation functions. If $\mathfrak{D}_{\perp,a}$ is zero in all defect correlation functions, the right hand side of (121.3) vanishes for every normal velocity ν_t, hence every correlation functional is constant along the isotopy. This is exactly (121.2).

Conversely, suppose (121.2) holds. Choose ν_t supported in an arbitrarily small coordinate patch of Σ_t. The left hand side of (121.3) is then zero for every such ν_t and every separated test configuration. Since test functions ν_t separate distributions on the defect worldvolume, the distribution defined by inserting $\mathfrak{D}_{\perp,a}$ has zero pairing with every test function and every exterior insertion. Therefore $\mathfrak{D}_{\perp,a}$ lies in the null subspace of defect local operators, which is the asserted quotient statement.

Definition 121.3 (Physical defect category)**.** For a finite ordered list $X = (D_{a_1}, \dots, D_{a_m})$ of defect sheets entering a small ball and a finite ordered list Y exiting it, let $\mathcal{J}(X,Y)$ be the vector space spanned by renormalized junction insertions in the ball with those boundary defect labels. Let $\mathcal{N}(X,Y) \subset \mathcal{J}(X,Y)$ be the subspace of junctions whose ball correlation functions vanish after gluing to every compatible exterior defect network and every separated bulk insertion. The physical junction space is

$$\mathrm{Hom}_{\mathcal{D}_{\mathcal{Q}}}(X,Y) = \mathcal{J}(X,Y)/\mathcal{N}(X,Y). \tag{121.4}$$

Vertical composition is gluing of balls; tensor product is juxtaposition of defect sheets in a collar; fusion of parallel topological sheets is the correlation-function limit in which the collar thickness tends to zero. Whenever these operations exist and are associative up to specified junction isomorphisms, the quotient spaces form the physical defect category $\mathcal{D}_{\mathcal{Q}}$.

This definition is deliberately not a declaration that every local QFT has a finite semisimple defect category. Semisimplicity, rigidity, and finite-dimensionality of junction spaces are additional hypotheses. They hold in many rational examples and in finite topological models, but in a general continuum QFT the null quotient, the fusion limit, and the topology of the junction spaces are part of the mathematical problem. In the reflection-positive finite-dimensional case the quotient is made explicit by the Gram-radical construction in Proposition 121.9; that construction is the algebraic bridge between the correlation-function definition above and the dagger formulas for junctions below.

121.2 Action On Local Operators

The phrase "action on local operators" hides a limiting operation. It is not enough to draw a small sphere around an insertion; one must specify the topology in which the limit of the defect-surrounded insertion is taken.

Definition 121.4 (Correlation topology on local operators)**.** Let $\mathcal{V}_{\mathrm{loc}}(0)$ be the vector space of renormalized local operators at the origin, modulo the relation that an operator is zero if all its Euclidean correlation functions with separated test insertions vanish. For a finite list of smeared local or extended insertions $\mathfrak{A}_1, \ldots, \mathfrak{A}_n$ supported in the complement of a ball around the origin, define the seminorm

$$p_{\mathfrak{A}_1,\ldots,\mathfrak{A}_n}(\mathcal{O}) = \left|\langle \mathfrak{A}_1 \cdots \mathfrak{A}_n \, \mathcal{O}(0)\rangle\right| . \tag{121.5}$$

The correlation topology is the locally convex topology generated by these seminorms as the separated insertions vary. In a unitary conformal theory with radial quantization, the state-operator map $\mathcal{O} \mapsto \mathcal{O}(0)\Omega$ gives a stronger Hilbert topology on the image in $\mathcal{H}(S^{D-1})$; convergence in that Hilbert topology implies convergence of all seminorms (121.5) for bounded separated insertions.

Definition 121.5 (Defect action on local operators)**.** Let D be a topological codimension-one defect in Euclidean space. For $r > 0$, let S_r^{D-1} be the sphere of radius r centered at the origin, carrying D with the outward normal convention. The defect action on $\mathcal{O} \in \mathcal{V}_{\mathrm{loc}}(0)$ is defined if the limit

$$\rho_D(\mathcal{O}) = \lim_{r \downarrow 0} \left[D(S_r^{D-1}) \, \mathcal{O}(0) \right] \tag{121.6}$$

exists in the correlation topology, or in the radial Hilbert topology when that stronger structure is available. The local-operator space acted on by the defect category is the common domain on which these limits exist for the defects under discussion.

Remark 121.6 (Fusion acts by composition)*.* Assume D_1, D_2 and $D_1 \otimes D_2$ have shrinking limits on a common local-operator domain in the sense of Definition 121.5. Then

$$\rho_{D_1 \otimes D_2} = \rho_{D_1} \rho_{D_2} \tag{121.7}$$

on that domain. Choose radii $0 < r_1 < r_2$, put D_2 on $S_{r_1}^{D-1}$ and D_1 on $S_{r_2}^{D-1}$. Because the defects are topological, any deformation of the two spheres through configurations avoiding separated insertions leaves all seminorms (121.5) unchanged. First take $r_1 \downarrow 0$; by definition this gives $\rho_{D_2}(\mathcal{O})$. Then take $r_2 \downarrow 0$, giving $\rho_{D_1}\rho_{D_2}(\mathcal{O})$. Alternatively, keep the two spheres at fixed small separation and collapse the annular slab between them to the fused defect $D_1 \otimes D_2$, then take the common shrinking limit. The two procedures give the same correlation seminorms with every separated test configuration, hence the same element of $\mathcal{V}_{\mathrm{loc}}(0)$.

Proposition 121.7 (Reflection adjoint of a topological-defect action)**.** *Assume radial quantization is available and let $\mathcal{H}_{\mathrm{loc}}$ be the Hilbert completion of local states obtained from the reflection-positive BPZ inner product. Suppose D and its reflection-reversed defect $D^\dagger$ have shrinking actions on a common dense local-operator domain $\mathcal{D}_{\mathrm{loc}} \subset \mathcal{H}_{\mathrm{loc}}$, and suppose these actions extend to bounded operators on $\mathcal{H}_{\mathrm{loc}}$. Then*

$$\langle \rho_D v, w\rangle_{\mathrm{BPZ}} = \langle v, \rho_{D^\dagger} w\rangle_{\mathrm{BPZ}}, \qquad v, w \in \mathcal{H}_{\mathrm{loc}}. \tag{121.8}$$

Thus $\rho_{D^\dagger} = \rho_D^*$. In particular, a reflection-invariant defect acts by a self-adjoint bounded operator, but it need not act by a unitary operator unless the defect is invertible.

Proof. It is enough first to prove the identity on $\mathcal{D}_{\mathrm{loc}}$. Choose local-operator representatives $\mathcal{O}_v, \mathcal{O}_w$ of v, w, with all insertions placed in the unit ball and with the BPZ inner product written as the reflection-positive pairing

$$\langle v, w\rangle_{\mathrm{BPZ}} = \lim_{R\to\infty} \langle \Theta_R \mathcal{O}_w(R)\, \mathcal{O}_v(0)\rangle\,,$$

where Θ_R denotes radial reflection together with the anti-linear adjunction on operator labels. For $\epsilon > 0$ small, let $\rho_{D,\epsilon}$ be the operation of inserting D on the sphere S_ϵ^{D-1} around the origin. By the definition of the shrinking action,

$$\rho_{D,\epsilon} v \longrightarrow \rho_D v \quad \text{and} \quad \rho_{D^\dagger,\epsilon} w \longrightarrow \rho_{D^\dagger} w$$

in the Hilbert topology on the common domain. Hence

$$\langle \rho_D v, w\rangle_{\mathrm{BPZ}} = \lim_{\epsilon\downarrow 0} \langle \rho_{D,\epsilon} v, w\rangle_{\mathrm{BPZ}}.$$

The finite-ϵ inner product is the ball correlator with D on S_ϵ^{D-1}, $\mathcal{O}_v$ inside it, and the reflected insertion representing w outside it. Radial reflection reverses the coorientation of the defect sheet, so the reflected defect label is $D^\dagger$. The reflected sphere surrounds the reflected w-insertion and no other operator. Because the defect is topological, this sphere may be isotoped, inside the complement of all operator insertions, to the standard small sphere used in Definition 121.5 for the action of $D^\dagger$ on w. Therefore, at fixed ϵ,

$$\langle \rho_{D,\epsilon} v, w\rangle_{\mathrm{BPZ}} = \langle v, \rho_{D^\dagger,\epsilon} w\rangle_{\mathrm{BPZ}},$$

with the same orientation convention as in the definition of $D^\dagger$. Taking $\epsilon \downarrow 0$ gives

$$\langle \rho_D v, w\rangle_{\mathrm{BPZ}} = \langle v, \rho_{D^\dagger} w\rangle_{\mathrm{BPZ}}$$

for $v, w \in \mathcal{D}_{\mathrm{loc}}$. Since $\mathcal{D}_{\mathrm{loc}}$ is dense and both ρ_D and $\rho_{D^\dagger}$ are bounded by hypothesis, the identity extends uniquely to all of $\mathcal{H}_{\mathrm{loc}}$, which is precisely $\rho_{D^\dagger} = \rho_D^*$.

If $D \simeq D^\dagger$ through the chosen reflection structure, the operator is self-adjoint. Unitarity is stronger: it would require

$$\rho_D^* \rho_D = \rho_{D^\dagger} \rho_D = \rho_{D^\dagger \otimes D} = \mathbf{1}$$

on the Hilbert space, where the middle equality is the fusion-action identity (121.7). Thus unitarity follows from an invertible defect with $D^\dagger \otimes D \simeq \mathbf{1}$. Reflection symmetry by itself gives self-adjointness; invertibility supplies the inverse required for unitarity. $\square$

When D is not invertible, ρ_D may be a projection, a sum of endomorphisms, or a map with a nontrivial kernel. Selection rules follow from eigenvectors and images of these maps, not from characters of a group alone.

121.3 Fusion Coefficients And Junctions

Assume the defect category is semisimple with simple objects D_a. Fusion has coefficients

$$D_a \otimes D_b \simeq \bigoplus_c N_{ab}{}^c D_c, \qquad N_{ab}{}^c \in \mathbb{Z}_{\geq 0}.$$

A choice of basis in the junction spaces

$$\mathrm{Hom}(D_a \otimes D_b, D_c)$$

gives associator matrices F. The equality of the two ways of fusing four defects is the pentagon equation. This equation is obtained by comparing two isotopic networks of topological junctions in a ball.

Definition 121.8 (Adjoint junction and reflection pairing)**.** Assume the QFT is reflection positive. Let Θ denote reflection through an equatorial hyperplane in a small Euclidean ball, together with the anti-linear operation on operator labels induced by Hilbert-space adjunction after radial quantization. If

$$\psi \in \mathrm{Hom}(D_a \otimes D_b, D_c)$$

is a junction operator inserted at the center of the ball, its reflected adjoint is

$$\psi^\dagger \in \mathrm{Hom}(D_c, D_a \otimes D_b), \tag{121.9}$$

with orientations reversed as dictated by the reflected defect sheets. For two junctions ψ, χ with the same boundary defect labels, define

$$\langle \psi, \chi \rangle_{\mathrm{jun}} = Z\big(B^D; \Theta(\psi) \text{ in the reflected half-ball}, \chi \text{ in the original half-ball}\big), \tag{121.10}$$

where the boundary defect labels are connected by straight topological sheets. The notation means the ball correlation function obtained after gluing the two half-balls along the reflection plane.

Proposition 121.9 (Gram radical model for the physical null quotient)**.** *Fix boundary defect labels X, Y, and suppose the renormalized junction space*

$$J(X,Y) = \mathcal{J}(X,Y)$$

is finite dimensional. Assume reflection positivity gives the half-ball pairing $\langle -, - \rangle_{X,Y}$ of (121.10). Let

$$R(X,Y) = \{\psi \in J(X,Y) : \langle \psi, \psi \rangle_{X,Y} = 0\}. \tag{121.11}$$

Then $R(X,Y)$ is the radical

$$R(X,Y) = \{\psi \in J(X,Y) : \langle \psi, \chi \rangle_{X,Y} = 0 \textit{ for every } \chi \in J(X,Y)\},$$

and the quotient $J(X,Y)/R(X,Y)$ has a positive definite Hermitian pairing. If vertical composition and tensor product of junctions have reflected adjoints on these finite spaces, then both operations preserve the radicals and therefore descend to the quotients. When reflected half-ball states generated by compatible exterior defect networks separate correlation functionals, this Gram-radical quotient agrees with the correlation-null quotient of Definition 121.3.

Proof. The half-ball construction assigns to each junction ψ a vector $|\psi\rangle$ in the pre-Hilbert space obtained by radial quantization of the ball, with

$$\langle \psi, \chi \rangle_{X,Y} = \langle |\psi\rangle, |\chi\rangle \rangle.$$

Reflection positivity says this form is positive semidefinite. If $\langle \psi, \psi \rangle_{X,Y} = 0$, then $|\psi\rangle$ is zero in the Hilbert quotient, so $\langle \psi, \chi \rangle_{X,Y} = 0$ for every χ. Thus the zero-norm subspace is exactly the radical. Modding out by it removes precisely the vectors with zero pairing against all states, and the induced Hermitian form is positive definite.

Let $C_\phi : J(X,Y) \to J(X,Z)$ be postcomposition with a fixed junction $\phi : Y \to Z$. Its reflected adjoint is precomposition with $\phi^\dagger$ in the reflected ball, so

$$\langle C_\phi \psi, \eta \rangle_{X,Z} = \langle \psi, C_\phi^\dagger \eta \rangle_{X,Y}.$$

If $\psi \in R(X,Y)$, the right hand side vanishes for every η, hence $C_\phi \psi \in R(X,Z)$. The same argument applies to precomposition and to tensoring with a fixed junction, using the reflected adjoint of the corresponding gluing map. Therefore changing a representative by a radical element does not change the composite or tensor product in the quotient.

Finally, a junction lies in the correlation-null subspace of Definition 121.3 exactly when all gluings to compatible exterior networks vanish. Under the stated separation hypothesis, those exterior networks span the same test states as the reflected half-ball vectors. Vanishing against all exterior networks is then the same condition as orthogonality to every $\chi \in J(X,Y)$, which is the radical condition above. ☐

Proposition 121.10 (Reflection positivity gives a dagger category)**.** *After replacing raw junction spaces by the Gram-radical quotients of Proposition 121.9, suppose the reflected gluing maps are defined on the junction spaces under consideration. Then reflection defines an anti-linear contravariant involution on junctions,*

$$(\chi \circ \psi)^\dagger = \psi^\dagger \circ \chi^\dagger, \qquad (\psi^\dagger)^\dagger = \psi, \tag{121.12}$$

and the pairings are positive:

$$\langle \psi, \psi \rangle_{\mathrm{jun}} \geq 0, \qquad \langle \psi, \psi \rangle_{\mathrm{jun}} = 0 \implies \psi = 0$$

on the quotient. In orthonormal bases for these pairings, isotopy maps between two bases of the same junction network are unitary matrices.

Proof. Place the junction network in a ball cut by the reflection hyperplane into incoming and outgoing half-balls. Vertical composition of junctions is gluing of such half-balls in the radial time direction. Reflection exchanges the two halves and reverses that gluing order; hence the reflected adjoint of $\chi \circ \psi$ is $\psi^\dagger \circ \chi^\dagger$. Applying the same reflection a second time restores the original oriented ball and the original defect-sheet orientations, which gives $(\psi^\dagger)^\dagger = \psi$.

For positivity, let $|\psi\rangle$ denote the state on the equatorial boundary Hilbert space produced by the lower half-ball with junction ψ. The pairing (121.10) is exactly $\langle \psi | \psi \rangle$ in the reflection-positive Hilbert space obtained from the ball. Reflection positivity gives $\langle \psi, \psi \rangle_{\mathrm{jun}} \geq 0$. By Proposition 121.9, the zero-norm junctions form the radical of this pairing, and quotienting by them gives a positive definite Hermitian pairing.

Finally, an isotopy of a topological junction network inside the ball changes the chosen basis vector but not the ball correlation function with reflected adjoint boundary conditions. Therefore the linear isotopy map preserves the Hermitian form (121.10). In bases orthonormal for that form, preservation of the Hermitian form is exactly the matrix identity $U^\dagger U = 1$. □

121.4 Gauging A Categorical Symmetry

For a finite group symmetry, gauging sums over flat bundles. For a finite categorical symmetry, the analogous operation is a condensation of a commutative separable algebra object

$$A \in \mathcal{D}_{\mathcal{Q}}.$$

The algebra maps are

$$m : A \otimes A \to A, \qquad \eta : \mathbf{1} \to A,$$

and the Frobenius and separability identities encode the local moves of the defect network. The gauged theory has topological defects given by A-modules or A-bimodules, depending on the codimension and the placement. This construction is a QFT operation only when the defect-network sum or condensation is defined as a regulated insertion in correlation functions.

121.5 Finite Regular Algebra And Self-Dual Gauging

The finite-group case is the minimal example in which the abstract word "condensation" becomes an explicit algebra object. Let H be a finite group acting by distinct invertible topological defects

$$\{D_h : h \in H\}, \qquad D_g \otimes D_h \simeq D_{gh}.$$

Assume for the moment that the associator phases in the pointed defect subcategory have been trivialized. A nontrivial 3-cocycle associator is an anomaly or discrete-torsion datum; it modifies the junction maps below and must be carried explicitly.

Definition 121.11 (Regular algebra of a finite symmetry)**.** The regular algebra object of the untwisted pointed defect subcategory generated by H is

$$A_H = \bigoplus_{h \in H} D_h.$$

Its multiplication is the direct sum of the group-law junctions

$$m_{g,h} : D_g \otimes D_h \longrightarrow D_{gh},$$

and its unit is the inclusion $\eta_A : \mathbf{1} = D_e \hookrightarrow A_H$. Choose the normalized comultiplication

$$\Delta(D_k) = \frac{1}{|H|} \sum_{\substack{g,h \in H \\ gh = k}} D_g \otimes D_h, \tag{121.13}$$

where the displayed formula means the corresponding sum of dual junction maps in the chosen bases.

Regular algebra identities. In the untwisted pointed defect category generated by H, the regular algebra object satisfies

$$A_H \otimes A_H \simeq |H|\, A_H, \qquad m \circ \Delta = \mathrm{id}_{A_H}, \tag{121.14}$$

and the Frobenius identity

$$\Delta \circ m = (m \otimes \mathrm{id}) \circ (\mathrm{id} \otimes \Delta) = (\mathrm{id} \otimes m) \circ (\Delta \otimes \mathrm{id}) \tag{121.15}$$

holds on every simple summand $D_g \otimes D_h$. These are the finite group-algebra identities encoded by the multiplication and normalized comultiplication, not a separate structural theorem. The object identity follows from

$$A_H \otimes A_H \simeq \bigoplus_{g,h\in H} D_{gh}.$$

For fixed $k \in H$, the equation $gh = k$ has exactly $|H|$ solutions: choose g freely and set $h = g^{-1}k$. Hence each D_k occurs $|H|$ times.

For separability, apply $m \circ \Delta$ to D_k. The summands in (121.13) all multiply back to D_k, and there are $|H|$ of them, so the normalized coefficient gives one copy of D_k.

For the Frobenius identity, evaluate on $D_g \otimes D_h$. The left side is

$$\Delta(D_{gh}) = \frac{1}{|H|} \sum_{\substack{c,d\in H \\ cd=gh}} D_c \otimes D_d.$$

The middle expression gives

$$\frac{1}{|H|} \sum_{\substack{a,b\in H \\ ab=h}} D_{ga} \otimes D_b.$$

The map $(a, b) \mapsto (c, d) = (ga, b)$ is a bijection from the set $\{(a, b) : ab = h\}$ to the set $\{(c, d) : cd = gh\}$. Thus the two sums agree. The right expression is identical by the bijection $(a, b) \mapsto (c, d) = (a, bh)$ from $\{(a, b) : ab = g\}$ to $\{(c, d) : cd = gh\}$.

Self-dual finite gauging fusion algebra. Suppose anomaly-free H-gauging of $\mathcal{Q}$ admits an equivalence $\Phi : \mathcal{Q}/H \to \mathcal{Q}$. Let $I_H : \mathcal{Q} \to \mathcal{Q}/H$ be the gauging interface, and let $\mathcal{N}_H = \Phi \circ I_H$ be the resulting gauging defect. The nontrivial inputs are the existence of this gauging interface, the equivalence Φ, and a choice of equivalence for which $\mathcal{N}_H^\dagger \simeq \mathcal{N}_H$ and the H-defects are absorbed on both sides of the gauging interface:

$$D_h \otimes \mathcal{N}_H \simeq \mathcal{N}_H \otimes D_h \simeq \mathcal{N}_H.$$

After these assumptions have been supplied, the object-level fusion algebra generated by D_h and $\mathcal{N}_H$ is

$$D_g D_h = D_{gh}, \qquad D_h \mathcal{N}_H = \mathcal{N}_H D_h = \mathcal{N}_H, \qquad \mathcal{N}_H^2 = \bigoplus_{h\in H} D_h. \tag{121.16}$$

The first rule is the ordinary symmetry-defect fusion. The second is the absorption property at an H-gauging interface. The third is the self-adjoint version of the slab fusion

$$\mathcal{N}_H^\dagger \otimes \mathcal{N}_H \simeq A_H$$

from the finite groupoid sum over the slab between the interface and its reverse. Thus the formula is not a construction of the self-duality; it is the object-level algebra forced by that self-duality once the categorical data have been chosen.

Associativity is then an object-level check. If only D_h's occur, it is associativity of the group H. If exactly one $\mathcal{N}_H$ occurs, both bracketings reduce to $\mathcal{N}_H$. If two $\mathcal{N}_H$'s occur, for example

$$(\mathcal{N}_H^2)D_g = \bigoplus_{h\in H} D_{hg} = \bigoplus_{k\in H} D_k = \mathcal{N}_H(\mathcal{N}_H D_g),$$

where right multiplication by g permutes H; the other placements are the same. If three $\mathcal{N}_H$'s occur, then

$$(\mathcal{N}_H^2)\mathcal{N}_H = \bigoplus_{h\in H} D_h\mathcal{N}_H = |H|\,\mathcal{N}_H = \mathcal{N}_H\big(\mathcal{N}_H^2\big).$$

Frobenius–Perron dimension is additive on direct sums and multiplicative on fusion products. Thus $d(D_h) = 1$, and the last fusion rule gives

$$d(\mathcal{N}_H)^2 = \sum_{h\in H} d(D_h) = |H|.$$

The positive solution is $\sqrt{|H|}$. If $\mathcal{N}_H$ were invertible, its square would be a single simple invertible object rather than a direct sum of $|H| > 1$ distinct simple defects. Therefore

$$d(D_h) = 1, \qquad d(\mathcal{N}_H) = \sqrt{|H|}.$$

For $|H| > 1$, $\mathcal{N}_H$ is not invertible.

Example 121.12 (Cyclic self-dual gauging fusion rings)**.** For $H = \mathbb{Z}_N = \langle a : a^N = e\rangle$, the finite self-dual gauging fusion ring has simple invertible objects D_{a^j} and one noninvertible object $\mathcal{N}_N$ obeying

$$D_{a^i}D_{a^j} = D_{a^{i+j}}, \qquad D_{a^j}\mathcal{N}_N = \mathcal{N}_N D_{a^j} = \mathcal{N}_N, \qquad \mathcal{N}_N^2 = \bigoplus_{j=0}^{N-1} D_{a^j}.$$

The $N = 2$ case is the Ising Kramers–Wannier fusion rule. For $N > 2$ the same equations are only the fusion-ring part of a possible defect category: associators, junction pairings, and the existence of a local QFT realizing the required self-duality are additional data, not consequences of the fusion ring alone.

121.6 The Ising/Kramers–Wannier Defect

The simplest noninvertible example is the defect category of the critical two-dimensional Ising model. We describe the categorical data abstractly, because these data are what survive as the symmetry object. Let the simple codimension-one topological defects be

$$\mathbf{1}, \qquad \eta, \qquad \mathcal{N}.$$

Here $\mathbf{1}$ is the invisible defect, η is the invertible $\mathbb{Z}_2$ spin-flip defect, and $\mathcal{N}$ is the Kramers–Wannier duality defect. Their fusion rules are

$$\begin{gathered} \eta\otimes\eta \simeq \mathbf{1}, \qquad \eta\otimes\mathcal{N} \simeq \mathcal{N}\otimes\eta \simeq \mathcal{N}, \\ \mathcal{N}\otimes\mathcal{N} \simeq \mathbf{1}\oplus\eta. \end{gathered} \tag{121.17}$$

The last line is the decisive one: $\mathcal{N}$ has no inverse, because fusing it with itself gives two simple summands rather than the identity.

Remark 121.13 (Quantum dimensions of the Ising defects)*.* The Frobenius–Perron dimensions of $\mathbf{1}, \eta, \mathcal{N}$ are

$$d_{\mathbf{1}} = 1, \qquad d_\eta = 1, \qquad d_{\mathcal{N}} = \sqrt{2}.$$

Frobenius–Perron dimension is the positive homomorphism from the fusion semiring to $\mathbb{R}_{>0}$. Thus $d_{\mathbf{1}} = 1$, and $\eta^2 = \mathbf{1}$ with positivity gives $d_\eta = 1$. The last fusion rule in (121.17) gives

$$d_{\mathcal{N}}^2 = d_{\mathbf{1}} + d_\eta = 2,$$

hence $d_{\mathcal{N}} = \sqrt{2}$. The negative square root is excluded by the defining positivity of the Frobenius–Perron dimension. These dimensions also solve the eigenvector equation for fusion by $\mathcal{N}$, whose matrix has Perron eigenvalue $\sqrt{2}$.

The defect is therefore noninvertible in a quantitative sense: surrounding an insertion by $\mathcal{N}$ is not an automorphism of the local-operator space. At the critical point the diagonal rational CFT has three primary families, which we denote

$$\mathbf{1}, \qquad \varepsilon, \qquad \sigma.$$

The topological line action on these primary sectors is diagonalized by the Ising modular S-matrix

$$S_{\text{Ising}} = \frac{1}{2}\begin{pmatrix} 1 & 1 & \sqrt{2} \\ 1 & 1 & -\sqrt{2} \\ \sqrt{2} & -\sqrt{2} & 0 \end{pmatrix}_{\mathbf{1},\varepsilon,\sigma}. \tag{121.18}$$

Here the row label ε is the same invertible topological line as the spin-flip defect η, and the row label σ is the same topological line as the Kramers–Wannier defect $\mathcal{N}$. We keep the notations distinct because ε, σ are also conventional names for primary sectors, whereas $\eta, \mathcal{N}$ emphasize the defect interpretation. The line D_a acts on the primary sector i by the scalar

$$\lambda_a(i) = \frac{S_{ai}}{S_{\mathbf{1}i}}. \tag{121.19}$$

For $a = \mathcal{N}$, this gives

$$\lambda_{\mathcal{N}}(\mathbf{1}) = \sqrt{2}, \qquad \lambda_{\mathcal{N}}(\varepsilon) = -\sqrt{2}, \qquad \lambda_{\mathcal{N}}(\sigma) = 0.$$

The zero on the spin sector is not a paradox: a noninvertible defect need not act as a bijection on local fields.

Remark 121.14 (Fusion action on Ising local sectors)*.* The eigenvalues (121.19) furnish a representation of the fusion algebra:

$$\lambda_a(i)\lambda_b(i) = \sum_c N_{ab}{}^c \lambda_c(i)$$

for every defect label a, b and every primary sector i.

For η the eigenvalues are

$$\lambda_\eta(\mathbf{1}) = 1, \qquad \lambda_\eta(\varepsilon) = 1, \qquad \lambda_\eta(\sigma) = -1,$$

so $\lambda_\eta^2 = 1$, matching $\eta \otimes \eta \simeq \mathbf{1}$. Multiplication by η leaves the $\mathcal{N}$-eigenvalues unchanged, because $\mathcal{N}$ has zero eigenvalue on σ, where η differs from $\mathbf{1}$. Finally,

$$\lambda_{\mathcal{N}}(i)^2 = \begin{cases} 2, & i = \mathbf{1}, \varepsilon, \\ 0, & i = \sigma, \end{cases} = 1 + \lambda_\eta(i),$$

which is exactly the action of $\mathbf{1} \oplus \eta$. These identities are the three fusion rules (121.17) evaluated on local sectors.

Remark 121.15 (Duality defect from gauging interface). Let $\mathcal{N}_{\mathbb{Z}_2}$ be the interface that gauges the spin-flip $\mathbb{Z}_2$ symmetry. At the self-dual critical Ising point the gauged theory is equivalent to the original theory after choosing the duality identification. Composing the gauging interface with this identification gives the Kramers–Wannier defect $\mathcal{N}$. The general interface identity of Chapter 122 then gives

$$\mathcal{N}^\dagger \otimes \mathcal{N} \simeq \mathbf{1} \oplus \eta,$$

which is the noninvertible fusion rule above. Thus the noninvertibility is the algebraic memory of summing over $\mathbb{Z}_2$-bundles in the gauging interface.

121.7 SymTFT Interpretation In The Rational Example

For a rational two-dimensional CFT, the categorical symmetry can be packaged by a three-dimensional topological theory whose bulk line category contains the defect category and whose boundary condition is the CFT. In the Ising case the relevant bulk topological line category has simple lines $\mathbf{1}, \eta, \mathcal{N}$ with the same fusion rules (121.17). A topological defect in the CFT is obtained by ending the corresponding bulk line on the boundary. Fusion of defects is then inherited from fusion of bulk lines before they end.

This statement is deliberately precise but limited. It does not assert that an arbitrary continuum QFT with a categorical symmetry has already been constructed from a fully extended topological bulk and boundary condition. Rather, in rational examples it supplies a concrete comparison map:

$$\text{bulk topological lines} \longrightarrow \text{boundary topological defects} \longrightarrow \mathrm{End}(\mathcal{V}_{\mathrm{loc}}).$$

The first arrow is the boundary endpoint operation, and the second is the surrounding action on local operators. The Ising computation above verifies the last map explicitly on the three primary sectors.

Semisimple modular-category mechanism. Here is the precise finite mechanism behind the rational examples. Let $\mathcal{C}$ be a semisimple modular tensor category with finite set $\mathcal{I}$ of simple labels, vacuum label $\mathbf{1}$, fusion coefficients $N_{ab}{}^c$, and modular matrix S_{ai}. When a Cardy diagonal full CFT with chiral category $\mathcal{C}$ has been constructed, the topological defects preserving the chosen chiral algebra are labelled by the same simple objects $a \in \mathcal{I}$. The defect D_a acts diagonally on the bulk sector labelled by $i \in \mathcal{I}$ by

$$\lambda_a(i) = \frac{S_{ai}}{S_{\mathbf{1}i}}. \tag{121.20}$$

The content of this formula is not that every categorical symmetry must be modular. It is the finite semisimple mechanism by which the rational SymTFT comparison map becomes a computable operator on local sectors.

The compatibility with fusion is the Verlinde diagonalization. For each simple label a, let N_a be the matrix

$$(N_a)_b{}^c = N_{ab}{}^c.$$

The Verlinde formula says

$$N_{ab}{}^c = \sum_{x\in\mathcal{I}} \frac{S_{ax}S_{bx}S_{c^\vee x}}{S_{\mathbf{1}x}}, \tag{121.21}$$

where $c^\vee$ is the dual label and the displayed convention assumes the standard unitary normalization of S, so $S_{c^\vee x} = S^*_{cx}$. Multiplying (121.21) by S_{ci} and summing over c, unitarity of S gives

$$\sum_c N_{ab}{}^c S_{ci} = \frac{S_{ai}}{S_{\mathbf{1}i}}\, S_{bi}. \tag{121.22}$$

Thus the i-th column of S is an eigenvector of N_a with eigenvalue $\lambda_a(i)$. Equivalently,

$$\lambda_a(i)\lambda_b(i) = \sum_c N_{ab}{}^c \lambda_c(i). \tag{121.23}$$

This is the general version of the Ising calculation (121.19): the surrounding action is a representation of the fusion algebra because the modular S-matrix diagonalizes fusion.

The boundary endpoint step is separate. A three-dimensional Reshetikhin– Turaev theory built from $\mathcal{C}$ supplies bulk topological lines labelled by $\mathcal{I}$. A choice of rational boundary condition supplies endpoint data turning those bulk lines into CFT defects. The formula (121.20) describes the Cardy diagonal case after this endpoint functor has been chosen. A non-diagonal modular invariant, a logarithmic theory, or an interacting continuum QFT without a known semisimple modular category requires different boundary and defect data; its defect category must be constructed from those data directly.

121.8 Anomaly As Obstruction To Condensation

An anomaly of a categorical symmetry is an obstruction to defining the defect networks independently of choices of triangulation, ordering, framing, or extension to one higher dimension. Algebraically it appears as failure of the pentagon, braiding, or trace identities in the proposed physical category. Geometrically it is encoded by an invertible theory in one higher dimension whose boundary is the original QFT with its defect category.

If the anomaly is cancelled by coupling to an invertible bulk, a defect network on the boundary is evaluated together with a bulk topological term. If the anomaly is trivialized by a local counterterm, the defect category can be modified by an equivalent associator or braiding datum.

Pointed finite mechanism. For ordinary finite invertible defects this obstruction is completely visible. Let G be a finite group and let D_g be invertible defects with

$$D_g \otimes D_h \simeq D_{gh}.$$

Choose junction isomorphisms

$$\mu_{g,h} : D_g \otimes D_h \to D_{gh}.$$

The two ways of identifying $((D_g \otimes D_h) \otimes D_k) \otimes D_l$ with D_{ghkl} can differ by a phase. Equivalently, the associator is a function

$$\alpha(g,h,k) \in U(1)$$

defined by

$$\mu_{gh,k} \circ (\mu_{g,h} \otimes \mathrm{id}_{D_k}) = \alpha(g,h,k)\, \mu_{g,hk} \circ (\mathrm{id}_{D_g} \otimes \mu_{h,k}). \tag{121.24}$$

Coherent evaluation of a four-fold junction requires the pentagon identity. Substituting (121.24) into the pentagon gives

$$\alpha(h,k,l)\, \alpha(g,hk,l)\, \alpha(g,h,k) = \alpha(gh,k,l)\, \alpha(g,h,kl). \tag{121.25}$$

This is precisely the inhomogeneous 3-cocycle condition $\delta\alpha = 1$. Thus the anomaly class of the pointed defect symmetry is

$$[\alpha] \in H^3(G, U(1))$$

for a two-dimensional QFT, or more generally the corresponding degree $D+1$ class for a D-dimensional finite symmetry defect network.

The dependence on the choice of junction basis is also explicit. Replacing

$$\mu_{g,h} \longmapsto \beta(g,h)\, \mu_{g,h}, \qquad \beta(g,h) \in U(1),$$

changes the associator by

$$\alpha(g,h,k) \longmapsto \alpha(g,h,k)\, \frac{\beta(g,h)\beta(gh,k)}{\beta(h,k)\beta(g,hk)}. \tag{121.26}$$

Hence only the cohomology class is invariant. A local counterterm or redefinition of junction normalization can remove the anomaly exactly when $[\alpha] = 0$. If the class is nonzero, the same local formulas define a relative defect theory: the missing phase is supplied by an invertible bulk whose boundary variation is the cocycle α. This finite pointed calculation is the model for the higher categorical obstruction, but it does not prove that a general interacting continuum QFT has finite junction spaces or a finite cohomological anomaly representative.

121.9 Beyond The Rational Example

The Ising example is a controlled rational model. The general interacting problem requires additional construction. Chapter 122 develops two further finite or algebraic examples: noninvertible defects obtained from gauging a finite normal subgroup at a self-dual point, and duality walls acting on electric-magnetic line-operator lattices. These examples still leave the genuinely hard continuum problem open: construct the defect category, junction operators, fusion rules, and anomaly or condensation data directly in interacting QFTs rather than importing them from a topological or rational model.

The next chapter continues this development for finite one-form symmetries. It writes the five-dimensional $\mathbb{Z}_N$ symmetry TQFT as an explicit cochain theory, and evaluates the finite higher-gauging condensation defect by an actual cochain sum. The point of separating the chapters is logical: this chapter defines the categorical action and its simplest rational example, while Chapter 123 constructs the higher-gauging mechanism that produces four-dimensional noninvertible condensation defects when the necessary continuum surface operators are available.

Open Problem 121.16 (Interacting categorical symmetries). Construct categorical-symmetry defect categories in interacting continuum QFTs with local algebras, reflection-positive state spaces, fusion of extended operators, and anomaly inflow, beyond finite topological models and rational two-dimensional examples.

Chapter 122

Duality Defects, Gauging, And Orbifold Data

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Gauging a finite symmetry is a finite path integral over background fields. A duality defect is an interface obtained from such a gauging operation, possibly followed by an equivalence between the gauged theory and another theory. The definitions in this chapter are formulated in terms of background-field groupoids, topological symmetry defects, and line-charge lattices. This keeps separate three pieces of data which are often compressed in the literature: the finite sum over bundles, the anomaly or counterterm choice, and the identification of the resulting theory with a theory already under study.

Hypothesis 122.1 (Finite gauging and duality-defect structure)**.** A finite gauging and duality-defect structure in dimension D is a tuple

$$\mathfrak{D}_{\mathcal{Q},G} = \big(\mathcal{Q}, G, \mathrm{Bun}_G, \alpha, \tau, \{D_g\}_{g\in G}, \mathcal{N}_G, \mathcal{N}_G^\dagger, \Phi, \Gamma_{\mathrm{line}}\big)$$

with the following entries.

(i) $\mathcal{Q}$ is a D-dimensional local QFT admitting a finite internal symmetry G, and $M \mapsto \mathrm{Bun}_G(M)$ is the finite groupoid of background G-bundles on collared spacetimes.

(ii) For every background $P \to M$, the background partition function $Z_{\mathcal{Q}}[M; P]$ and the corresponding correlators are defined as vectors in the anomaly line determined by the cohomology class

$$\alpha \in H^{D+1}(BG, U(1)).$$

(iii) τ is a chosen anomaly trivialization and degree-D Dijkgraaf–Witten counterterm. After τ is fixed, the finite groupoid sum over $\mathrm{Bun}_G(M)$ is an ordinary complex amplitude with a specified normalization.

(iv) D_g is the topological symmetry defect associated to $g \in G$, with junctions implementing $D_g \otimes D_h \simeq D_{gh}$ and with the orientation convention used below.

(v) $\mathcal{N}_G : \mathcal{Q} \to \mathcal{Q}/G$ and $\mathcal{N}_G^\dagger : \mathcal{Q}/G \to \mathcal{Q}$ are the gauging interface and its reverse, defined with the same groupoid normalization and anomaly trivialization τ.

(vi) $\Phi : \mathcal{Q}/G \to \mathcal{Q}'$ is optional equivalence data. When $\mathcal{Q}' = \mathcal{Q}$, the composite $\Phi \circ \mathcal{N}_G$ is the self-dual-gauging defect studied below.

(vii) In gauge-theory applications, Γ_{line} is the lattice or finite discriminant group of genuine line charges, equipped with its Dirac pairing and with the action induced by any proposed duality wall.

The finite algebraic conclusions in this chapter are consequences of this structure. The continuum construction of the interfaces and junctions is the problem isolated in Open Problem 122.10.

122.1 Finite Symmetry Backgrounds

Let G be the finite internal symmetry in Hypothesis 122.1. A background G-field on a spacetime M is a principal G-bundle

$$P \to M.$$

On a good cover $\{U_i\}$ it may be represented by locally constant transition functions

$$g_{ij} : U_i \cap U_j \longrightarrow G$$

obeying

$$g_{ij} g_{jk} = g_{ik} \quad \text{on } U_i \cap U_j \cap U_k.$$

Two representatives related by functions $u_i : U_i \to G$,

$$g_{ij} \mapsto u_i g_{ij} u_j^{-1},$$

define isomorphic bundles. Equivalently, after choosing a triangulation, a background is a flat G-valued one-cocycle on edges, modulo vertex gauge transformations.

The QFT with background P has partition function

$$Z_{\mathcal{Q}}[M; P],$$

and correlation functions with insertions carry the same background field. The collection of bundles and their isomorphisms is the finite groupoid

$$\mathrm{Bun}_G(M).$$

For a representative P, the automorphism group

$$\mathrm{Aut}(P)$$

is the group of gauge transformations preserving P. On connected M and for the trivial bundle it is G, while for a general flat bundle it is the centralizer of the holonomy representation.

Definition 122.2 (Finite gauging groupoid sum)**.** Assume the anomaly-trivialization and counterterm entry τ in Hypothesis 122.1 has been fixed. The gauged partition function is the groupoid cardinality sum

$$Z_{\mathcal{Q}/G}(M) = \sum_{[P]\in\pi_0 \operatorname{Bun}_G(M)} \frac{Z_{\mathcal{Q}}[M;P]}{|\operatorname{Aut}(P)|}. \tag{122.1}$$

Different choices of an invertible finite gauge theory multiplying (122.1) are different normalization conventions. Once a convention is fixed, the same convention must be used for closed manifolds, manifolds with boundary, interfaces, and operator insertions.

The groupoid factor is part of the finite path integral. It is the finite analogue of dividing by the gauge group volume in a continuous gauge theory.

Remark 122.3 (Disjoint-union multiplicativity). With the groupoid convention (122.1), finite gauging is multiplicative under disjoint union:

$$Z_{\mathcal{Q}/G}(M_1 \sqcup M_2) = Z_{\mathcal{Q}/G}(M_1)Z_{\mathcal{Q}/G}(M_2),$$

provided the original background partition functions are multiplicative.

A principal G-bundle on $M_1 \sqcup M_2$ is a pair (P_1, P_2) with $P_i \to M_i$. Its automorphism group is the product

$$\operatorname{Aut}(P_1, P_2) = \operatorname{Aut}(P_1) \times \operatorname{Aut}(P_2).$$

Thus the groupoid sum factorizes:

$$\begin{aligned} Z_{\mathcal{Q}/G}(M_1 \sqcup M_2) &= \sum_{[P_1],[P_2]} \frac{Z_{\mathcal{Q}}[M_1;P_1]Z_{\mathcal{Q}}[M_2;P_2]}{|\operatorname{Aut}(P_1)|\,|\operatorname{Aut}(P_2)|} \\ &= Z_{\mathcal{Q}/G}(M_1)Z_{\mathcal{Q}/G}(M_2). \end{aligned}$$

122.2 Dijkgraaf–Witten Twists And Anomaly Data

A class

$$\omega \in H^D(BG, U(1))$$

defines an invertible topological action for a G-bundle $P \to M$. If Ω is a cocycle representative, the exponentiated action is

$$\exp(\mathrm{i}S_\omega(P)) = \exp\left(2\pi\mathrm{i}\int_M f_P^*\Omega\right),$$

where $f_P : M \to BG$ classifies P. On a triangulated manifold this is the evaluation of the finite group cocycle on the flat edge labels of P. The twisted gauging is

$$Z_{\mathcal{Q}/G,\omega}(M) = \sum_{[P]} \frac{Z_{\mathcal{Q}}[M;P]\exp(\mathrm{i}S_\omega(P))}{|\operatorname{Aut}(P)|}. \tag{122.2}$$

If $\mathcal{Q}$ has a G-anomaly

$$\alpha \in H^{D+1}(BG, U(1)),$$

then $Z_{\mathcal{Q}}[M;P]$ is naturally a vector in a one-dimensional anomaly line rather than an ordinary complex number. Gauging requires a trivialization of this anomaly line over the groupoid of G-bundles, or a $(D+1)$-dimensional invertible bulk whose boundary is $\mathcal{Q}$. A Dijkgraaf–Witten twist in degree D changes the gauged theory; it cancels an anomaly only through its coboundary when a cochain-level trivialization of the degree $D+1$ anomaly has been chosen.

122.3 The Gauging Interface

The interface entry of Hypothesis 122.1 is a codimension-one interface

$$\mathcal{N}_G : \mathcal{Q} \longrightarrow \mathcal{Q}/G$$

obtained by gauging G on one side of the interface. More concretely, if a spacetime is cut along a hypersurface Y, then on the gauged side one sums over G-bundles whose restriction to Y is allowed to vary, while on the ungauged side the boundary value is interpreted as a background for $\mathcal{Q}$. The reverse interface is denoted

$$\mathcal{N}_G^\dagger : \mathcal{Q}/G \longrightarrow \mathcal{Q}.$$

For every $g \in G$ let D_g be the invertible symmetry defect of $\mathcal{Q}$. It is supported on Y and imposes G-holonomy g across a small transverse interval. The orientation convention is

$$D_g \otimes D_h \simeq D_{gh}.$$

Slab fusion calculation. Assume the anomaly of the G-symmetry has been trivialized, so that the gauging interface is an honest defect rather than a section of an anomaly line, and use the groupoid normalization of Definition 122.2 for both interfaces. Then the fused defect on the ungauged side is

$$\mathcal{N}_G^\dagger \circ \mathcal{N}_G \simeq \bigoplus_{g\in G} D_g \tag{122.3}$$

as defects of $\mathcal{Q}$.

Fuse $\mathcal{N}_G$ with $\mathcal{N}_G^\dagger$ and separate the two interfaces by a thin slab $Y \times [0,\epsilon]$. Inside the slab the G-field is flat. Choose trivializations on the two boundary components of the slab. A flat bundle on an interval with these endpoint trivializations is classified by a single holonomy $g \in G$. In the sector with holonomy g, transporting an operator across the slab inserts the symmetry defect D_g on Y. Summing over the finite gauge field in the slab therefore produces the direct sum over all holonomies.

The only normalization issue is the volume of gauge transformations in the slab that are identity on the two boundary components. With the interface normalization induced from Definition 122.2, these factors cancel between the two sides of the cut, leaving one copy of each holonomy sector. Hence the fused interface is $\oplus_{g\in G} D_g$. Its scope is the finite groupoid-sum calculation after the gauging construction and normalization have been chosen; existence of the interface is part of the gauging construction itself.

The opposite fusion

$$\mathcal{N}_G \circ \mathcal{N}_G^\dagger$$

is a defect of the gauged theory. It is the algebra object generated by the quantum symmetry defects acting on twisted sectors.

Definition 122.4 (Regular algebra defect of a finite symmetry)**.** The regular algebra object associated to a finite anomaly-free symmetry G is

$$A_G = \bigoplus_{g \in G} D_g$$

with multiplication induced by the defect junctions

$$D_g \otimes D_h \longrightarrow D_{gh}$$

and unit $\mathbf{1} = D_e \hookrightarrow A_G$. As an object in the fusion category generated by the symmetry defects,

$$A_G \otimes A_G \simeq |G|\, A_G. \tag{122.4}$$

The displayed square follows directly from $D_g \otimes D_h \simeq D_{gh}$:

$$A_G \otimes A_G \simeq \bigoplus_{g,h \in G} D_{gh}.$$

For each fixed $k \in G$, the equation $gh = k$ has exactly $|G|$ solutions, one for each choice of g, with $h = g^{-1}k$. Therefore every simple summand D_k appears with multiplicity $|G|$, which gives $|G| A_G$.

122.4 Mechanism Map For Finite Gauging

The same finite gauging operation appears in four coordinate systems in this chapter. In the background-field coordinate it is the groupoid-cardinality sum (122.1). In the interface coordinate it is the wall $\mathcal{N}_G$ and its reverse, whose slab fusion gives the regular algebra A_G. In the local-operator coordinate it is the passage from punctured-disk holonomy g to conjugacy classes and centralizer invariants. In the symmetry-TFT coordinate it is a boundary-changing operation: the ungauged boundary remembers G-backgrounds, while the gauged boundary condenses the finite symmetry algebra and exposes the quantum symmetry of the gauged theory. These are not four independent principles; they are four readings of the same finite sum, after the anomaly trivialization and normalization have been chosen.

For a finite Abelian subgroup H, the comparison can be written without any continuum input. Let $V_H = \mathbb{C}[H]$ have basis e_h, interpreted as a finite slab holonomy state, and let the original symmetry defect D_a act by translation,

$$D_a e_h = e_{a+h}.$$

Then the regular algebra

$$A_H = \sum_{a \in H} D_a$$

satisfies

$$A_H e_h = \sum_{k \in H} e_k, \qquad A_H^2 = |H| A_H, \qquad \Pi_H := |H|^{-1} A_H, \qquad \Pi_H^2 = \Pi_H. \tag{122.5}$$

Thus the normalized slab sum is the orbit-sum projector onto the H-invariant part. This is the finite linear-algebra shadow of $\mathcal{N}_H^\dagger \mathcal{N}_H = A_H$: fusing the two interfaces on the ungauged side projects by summing over the original symmetry line.

The gauged side has the Fourier-dual description. Its ordinary quantum symmetry is the character group $\widehat{H}$. On a holonomy sector e_h, the character defect $\widehat{D}_\chi$ acts by multiplication by $\chi(h)$. The dual regular algebra therefore acts by

$$\widehat{A}_H e_h = \sum_{\chi \in \widehat{H}} \chi(h) e_h = \begin{cases} |H| e_0, & h = 0, \\ 0, & h \neq 0. \end{cases} \tag{122.6}$$

Equations (122.5) and (122.6) are the two boundary coordinates of the same interface pair. The first condenses the original H-symmetry defects; the second resolves the holonomy sectors by the dual character symmetry. A self-duality equivalence $\Phi : \mathcal{Q}/H \to \mathcal{Q}$, when it exists, identifies these two boundary descriptions as defects of one QFT. The noninvertibility conclusion then follows from the regular algebra. The existence of Φ, topological invariance of the interface, and reflection-positive state spaces are separate QFT inputs, not consequences of the finite Fourier calculation.

122.5 Orbifold Local Operators In Two Dimensions

For a two-dimensional QFT with finite internal symmetry G, a local operator of the gauged theory is described by a punctured disk carrying a flat G-bundle. Choose a small positively oriented circle around the insertion. Its holonomy is an element

$$g \in G.$$

Changing the trivialization at the base point conjugates g, so the topological sector is a conjugacy class $[g]$. Let

$$\mathcal{V}_g$$

be the local operator space in the g-twisted sector. Gauge transformations preserving the chosen holonomy form the centralizer

$$C_G(g) = \{h \in G \mid hg = gh\}.$$

Thus the local operator space of the gauged theory is

$$\mathcal{V}_{\mathcal{Q}/G} = \bigoplus_{[g] \subset G} \mathcal{V}_g^{C_G(g)}. \tag{122.7}$$

In a two-dimensional orbifold by a finite group G, an OPE coefficient between twisted sectors can receive a contribution from a flat bundle on a pair of pants only if, after choosing compatible base paths,

$$g_1 g_2 g_3^{-1} = e. \tag{122.8}$$

Equivalently, the outgoing holonomy is the product $g_3 = g_1 g_2$, up to simultaneous conjugation. The fundamental group of a pair of pants has generators represented by the three boundary circles with the relation

$$\gamma_1 \gamma_2 \gamma_3^{-1} = 1$$

for the convention in which γ_3 is the outgoing boundary. A flat G-bundle is a homomorphism from this fundamental group to G, modulo conjugation. Therefore the boundary holonomies

$$g_i = \mathrm{Hol}(\gamma_i)$$

must satisfy $g_1 g_2 g_3^{-1} = e$. Conversely any triple satisfying this relation defines a flat bundle on the pair of pants after choosing a trivialization at the base point. Changing the base trivialization conjugates all three holonomies simultaneously.

Formula (122.7) and the pair-of-pants monodromy condition (122.8) give the finite topological part of the orbifold OPE. The analytic OPE coefficients inside each allowed twisted sector are still QFT data; they are not determined by the group G alone.

122.6 Duality Defects From Self-Dual Gauging

A duality defect is a topological interface whose fusion with its reverse is the regular algebra defect A_G rather than a single copy of the invisible defect. The construction is especially transparent when a gauged theory is equivalent to the original theory.

Self-dual gauging and the resulting defect. The substantial input in this construction is the existence of a fully specified self-duality of the gauged theory. Let H be finite, assume that H acts internally on a QFT $\mathcal{Q}$ and can be gauged without an anomaly. Suppose there is an equivalence

$$\Phi : \mathcal{Q}/H \longrightarrow \mathcal{Q}$$

after all background choices, discrete torsion choices, and local counterterms have been fixed. Then the composite

$$D_H := \Phi \circ \mathcal{N}_H$$

is a topological defect of $\mathcal{Q}$ satisfying

$$D_H^\dagger \otimes D_H \simeq A_H = \bigoplus_{h \in H} D_h. \tag{122.9}$$

If H is nontrivial and the D_h are distinct simple invertible defects, then D_H is noninvertible and has quantum dimension $\sqrt{|H|}$.

This last conclusion is finite defect algebra once the self-duality equivalence has been supplied. The equivalence Φ is invertible as an interface, so

$$\Phi^\dagger \circ \Phi \simeq \mathbf{1}_{\mathcal{Q}/H}.$$

Therefore

$$D_H^\dagger \otimes D_H = \mathcal{N}_H^\dagger \circ \Phi^\dagger \circ \Phi \circ \mathcal{N}_H \simeq \mathcal{N}_H^\dagger \circ \mathcal{N}_H.$$

The slab fusion calculation (122.3) identifies the last defect with $\oplus_{h\in H} D_h = A_H$, proving (122.9).

If D_H were invertible, $D_H^\dagger \otimes D_H$ would be a single copy of the invisible defect. For nontrivial H with distinct simple D_h, the right hand side of (122.9) has $|H|$ simple summands, so D_H is not invertible.

Quantum dimension is multiplicative under fusion and additive under direct sum. Since each D_h is invertible, $d(D_h) = 1$. Hence

$$d(D_H)^2 = d(D_H^\dagger \otimes D_H) = \sum_{h \in H} d(D_h) = |H|.$$

Positivity gives $d(D_H) = \sqrt{|H|}$.

Example 122.5 (The Ising Kramers–Wannier defect)**.** At the critical Ising point the anomaly-free spin-flip symmetry is $H = \mathbb{Z}_2 = \{e, \eta\}$. The gauged theory is equivalent to the original critical Ising CFT after the Kramers–Wannier self-duality identification is chosen. The construction above gives

$$\mathcal{N}^\dagger \otimes \mathcal{N} \simeq \mathbf{1} \oplus \eta, \qquad d(\mathcal{N}) = \sqrt{2},$$

which is the categorical fusion rule used in Chapter 121. The statement is conditional on the self-duality equivalence, while the fusion calculation itself is the finite slab calculation above.

122.7 Normal-Subgroup Gauging

Let G be a finite internal symmetry of $\mathcal{Q}$, and let

$$H \triangleleft G$$

be a normal subgroup. Assume the H-symmetry is anomaly-free after the restriction of all anomaly and counterterm data has been fixed. Gauging H produces $\mathcal{Q}/H$.

If the G-action on $\mathcal{Q}$ is anomaly-compatible with the chosen H-gauging, then $\mathcal{Q}/H$ has a residual ordinary symmetry

$$G/H.$$

For $g \in G$, conjugation maps an H-bundle P to another H-bundle

$$P^g := P \times_{H,c_g} H, \qquad c_g(h) = ghg^{-1}.$$

This is well-defined because H is normal. The original G-symmetry identifies the H-background partition functions for P and P^g, up to the specified anomaly-compatible counterterm. Therefore g acts on the groupoid sum defining $\mathcal{Q}/H$. If $g \in H$, this action is a gauge transformation of the summed H-field and hence acts trivially on gauge-invariant observables of the gauged theory. The action therefore factors through G/H. Compatibility of the anomaly and counterterm choices ensures that the factorized action is associative rather than projective.

Example 122.6 (Normal-subgroup interface and a finite test case)**.** Let $G = S_3$ and let

$$H = A_3 = \{e, r, r^2\} \triangleleft S_3.$$

After anomaly-free H-gauging, the residual ordinary symmetry is

$$S_3/A_3 \simeq \mathbb{Z}_2.$$

The gauging interface obeys

$$D_h \otimes \mathcal{N}_H \simeq \mathcal{N}_H, \qquad h \in H,$$

because an H-defect ending on the gauged side can be absorbed into the summed H-bundle. At a self-dual point with an equivalence $\Phi : \mathcal{Q}/H \to \mathcal{Q}$, the defect

$$D_H = \Phi \circ \mathcal{N}_H$$

satisfies

$$D_H^\dagger \otimes D_H \simeq \mathbf{1} \oplus D_r \oplus D_{r^2}, \qquad d(D_H) = \sqrt{3}.$$

This example separates the finite algebra from the dynamical question of whether a particular QFT possesses the required self-duality equivalence.

122.8 Gauge-Theory Duality Walls

In gauge theories, duality walls can act on electric-magnetic line-charge lattices. Let

$$\Gamma$$

be a free abelian group of line charges equipped with an integral antisymmetric Dirac pairing

$$\langle\ ,\ \rangle : \Gamma \times \Gamma \to \mathbb{Z}.$$

A line-lattice duality wall is a topological wall whose induced map

$$M : \Gamma \longrightarrow \Gamma$$

is an automorphism preserving this pairing:

$$\langle Mx, My \rangle = \langle x, y \rangle \qquad x, y \in \Gamma. \tag{122.10}$$

If the global form of the gauge group or a discrete theta angle selects a proper set of genuine lines, the wall is a wall between the corresponding theories only when M maps the genuine line data on one side to the genuine line data on the other side. Boundary degrees of freedom may be required to cancel an anomaly mismatch.

Example 122.7 (Four-dimensional abelian line-lattice duality walls)**.** For four-dimensional $U(1)$ gauge theory with electric and magnetic line charges

$$\Gamma = \mathbb{Z}^2, \qquad x = (q_e, q_m),$$

take the Dirac pairing

$$\langle x, y \rangle = q_e q_m' - q_m q_e'.$$

The two line-lattice generators used here act on column vectors by

$$S(q_e, q_m) = (q_m, -q_e), \qquad T(q_e, q_m) = (q_e + q_m, q_m). \tag{122.11}$$

The S-wall exchanges Wilson and 't Hooft charges with the orientation shown in (122.11). The T-wall implements the Witten-effect shift of electric charge by magnetic charge.

Remark 122.8 (Pairing preservation for the S and T walls). The transformations in Example 122.7 preserve the Dirac pairing on Γ.

For $Sx = (q_m, -q_e)$ and $Sy = (q'_m, -q'_e)$,

$$\langle Sx, Sy\rangle = q_m(-q'_e) - (-q_e)q'_m = q_e q'_m - q_m q'_e = \langle x, y\rangle.$$

For $Tx = (q_e + q_m, q_m)$ and $Ty = (q'_e + q'_m, q'_m)$,

$$\langle Tx, Ty\rangle = (q_e + q_m)q'_m - q_m(q'_e + q'_m) = q_e q'_m - q_m q'_e = \langle x, y\rangle.$$

Thus both maps are automorphisms of the charge lattice with its antisymmetric Dirac pairing.

Example 122.9 (Finite center-sensitive line lattice)**.** For a theory whose center-sensitive electric and magnetic charges reduce to

$$\mathcal{C}_N = \mathbb{Z}_N^{\mathrm{e}} \oplus \mathbb{Z}_N^{\mathrm{m}},$$

the finite pairing is

$$B((e,m),(e',m')) = \frac{em' - me'}{N} \in \mathbb{Q}/\mathbb{Z}.$$

The reductions of S and T modulo N,

$$S(e,m) = (m, -e), \qquad T(e,m) = (e+m, m),$$

preserve B. More generally

$$T^p(e,m) = (e + pm, m)$$

preserves B and maps a magnetic condensate direction to the dyonic direction used in oblique confinement:

$$(0,1) \mapsto (p,1).$$

Thus the finite line-lattice action gives a precise algebraic bridge between duality walls and the oblique-confinement diagnostic of Chapter 116.

122.9 Logical Scope

The finite statements above are theorem-level statements about groupoids of finite bundles, topological symmetry defects, and line-charge lattices. To apply them to an interacting continuum QFT one must supply the QFT input: existence of the symmetry defects as genuine topological extended operators, reflection-positive state spaces with the required defect sectors, anomaly trivializations, and any claimed equivalence $\Phi : \mathcal{Q}/H \to \mathcal{Q}$. Once those data are supplied, the slab fusion $\mathcal{N}_H^\dagger \mathcal{N}_H = A_H$, the orbifold twisted-sector decomposition, and the line-lattice pairing preservation are finite consequences.

Open Problem 122.10 (Continuum gauging interfaces). Construct gauging interfaces and duality defects in interacting continuum QFTs from background-field sums, local operator sectors, defect junctions, anomaly trivializations, and reflection-positive state spaces. The construction should prove topological invariance of the interface, the existence and composition law of junction operators, and compatibility with the Hilbert spaces obtained by cutting spacetime along the defect.

Chapter 123

Higher-Group Symmetry And Symmetry TQFT

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Higher-form symmetries and ordinary symmetries may combine into a single background-field structure. Its gauge transformations and anomalies may be linked by Postnikov classes, so the combined object carries more structure than a direct product of groups. This chapter defines higher-group backgrounds and then explains the symmetry-TQFT organization of boundary conditions and gauging operations.

Hypothesis 123.1 (Higher-group symmetry presentation)**.** A D-dimensional QFT with finite two-group symmetry and symmetry-TQFT presentation is specified, for the purposes of this chapter, by the tuple

$$\mathfrak{S}_{\mathcal{Q},\mathbb{G}} = \big(\mathcal{Q}, \mathbb{G}, \mathcal{B}_{\mathbb{G}}, \mathcal{L}_{\mathrm{anom}}, \mathfrak{T}_{\mathrm{sym}}, \mathfrak{B}_{\mathcal{Q}}, \mathcal{D}_{\mathrm{top}}, \tau\big).$$

The entries are as follows.

(i) $\mathcal{Q}$ is a D-dimensional local QFT in the sense used in the earlier foundational volumes.

(ii) $\mathbb{G} = (G_0, A, \rho, \beta)$ is a finite two-group: G_0 is a finite zero-form symmetry group, A is a finite abelian one-form symmetry group, $\rho : G_0 \to \mathrm{Aut}(A)$ is the action on one-form charges, and $\beta \in H^3(BG_0, A_\rho)$ is the Postnikov class.

(iii) $\mathcal{B}_{\mathbb{G}}(M)$ is the finite higher groupoid of backgrounds on a collared D-manifold M. In a triangulated chart its objects are pairs (g, B) satisfying the twisted cocycle equation $\delta_g B = \beta(g)$, and its higher morphisms are the zero-form, one-form, and gauge-for-gauge transformations preserving this equation.

(iv) $\mathcal{L}_{\mathrm{anom}}$ is the anomaly-line functor over $\mathcal{B}_{\mathbb{G}}$, equivalently the boundary value of an invertible $(D+1)$-dimensional theory for the same background fields.

(v) $\mathfrak{T}_{\mathrm{sym}}$ is the $(D+1)$-dimensional symmetry TQFT whose bulk fields are the $\mathbb{G}$-backgrounds and whose boundary conditions include background-fixing and summing/gauging boundaries.

(vi) $\mathfrak{B}_{\mathcal{Q}}$ is the boundary condition of $\mathfrak{T}_{\mathrm{sym}}$ representing the QFT $\mathcal{Q}$. Coupling $\mathcal{Q}$ to a background means placing $\mathfrak{B}_{\mathcal{Q}}$ opposite a background boundary of $\mathfrak{T}_{\mathrm{sym}}$.

(vii) $\mathcal{D}_{\mathrm{top}}$ is the corresponding topological defect system in $\mathcal{Q}$: symmetry surfaces, walls, junction lines, endpoint operators, and their isotopy and Pachner-move identifications.

(viii) τ is any chosen anomaly trivialization or discrete counterterm needed to turn a proposed gauging or condensation operation into an ordinary complex-valued path integral.

All finite cochain calculations below are consequences of such a presentation after a triangulated model for $\mathcal{B}_{\mathbb{G}}$ has been chosen. The existence of $\mathfrak{T}_{\mathrm{sym}}$, $\mathfrak{B}_{\mathcal{Q}}$, and $\mathcal{D}_{\mathrm{top}}$ for an interacting continuum theory is a separate QFT construction problem; see Open Problem 123.7.

123.1 Two-Group Backgrounds

Let $\mathfrak{S}_{\mathcal{Q},\mathbb{G}}$ be a presentation as in Hypothesis 123.1. The two-group entry $\mathbb{G} = (G_0, A, \rho, \beta)$ consists of an ordinary finite internal symmetry G_0, an abelian one-form symmetry A, an action of G_0 on A, and a Postnikov class

$$\beta \in H^3(BG_0, A_\rho).$$

On a triangulated spacetime M, a background consists of a G_0-valued one-cocycle g and an A-valued two-cochain B obeying

$$\delta_g B = \beta(g).$$

Here δ_g is the coboundary twisted by the G_0-action on A. Thus B is not closed when the ordinary background g has nontrivial Postnikov obstruction.

123.2 Gauge Transformations

A G_0 gauge transformation changes g by a coboundary. The two-form background B must transform at the same time so that $\delta_g B = \beta(g)$ remains valid. A one-form gauge transformation with A-valued one-cochain λ acts by

$$B \mapsto B + \delta_g \lambda.$$

If $\beta \neq 0$, the ordinary and one-form transformations do not commute as independent operations on the background fields. The physical statement is that charged line operators and local operators transform in a single higher-group representation problem.

123.3 Anomaly Functionals

An anomaly of a two-group symmetry in D dimensions is an invertible $(D+1)$-dimensional action for (g, B). A basic term is

$$S_{\mathrm{anom}}[g, B] = 2\pi i \int_X \langle B \smile \gamma(g)\rangle,$$

where $\gamma(g)$ is a G_0-dependent cochain with values in the Pontryagin dual of A. Gauge invariance on closed X imposes a cocycle condition using $\delta_g B = \beta(g)$. If X has boundary, the boundary QFT partition function is a section of the anomaly line over background fields.

123.4 Symmetry TQFT

For the presentation in Hypothesis 123.1, the object $\mathfrak{T}_{\mathrm{sym}}$ packages background fields, gauging, and duality defects in a $(D+1)$-dimensional topological theory. The physical QFT $\mathcal{Q}$ is represented by the boundary condition

$$\mathfrak{B}_{\mathcal{Q}}$$

for the symmetry TQFT. Coupling to a background corresponds to ending the topological theory on a background boundary. Gauging corresponds to replacing that boundary condition by a summing boundary condition.

For an ordinary finite group G, the symmetry TQFT is finite G-gauge theory in one higher dimension. For higher groups, the bulk field space is the groupoid of pairs (g, B) satisfying the Postnikov constraint. The fusion of topological defects in the QFT is inherited from the fusion of topological boundary-changing operators in the bulk.

123.5 $\mathbb{Z}_N$ One-Form Symmetry TQFT

We now write the finite cochain model that will be used as the local model for one-form gauging and condensation defects. Let X be an oriented triangulated five-manifold. Let

$$b, c \in C^2(X, \mathbb{Z}_N)$$

be two $\mathbb{Z}_N$-valued two-cochains. Their gauge transformations are

$$b \mapsto b + \delta\lambda, \qquad c \mapsto c + \delta\kappa, \qquad \lambda, \kappa \in C^1(X, \mathbb{Z}_N).$$

The finite Heisenberg, or BF, symmetry TQFT has exponentiated action

$$Z_H(X; b, c) = \exp\left(\frac{2\pi i}{N}\int_X b \smile \delta c\right). \tag{123.1}$$

The integral means evaluation of the resulting $\mathbb{Z}_N$-valued five-cochain on the fundamental class and then embedding $\mathbb{Z}_N \hookrightarrow \mathbb{R}/\mathbb{Z}$. Equivalently one chooses integer lifts and keeps the result modulo N; changing the lift changes the exponent by an integral multiple of $2\pi i$.

Remark 123.2 (Closed-manifold gauge invariance). If X is closed, (123.1) is invariant under the gauge transformations above.

The transformation $c \mapsto c + \delta\kappa$ does not change δc, because $\delta^2 = 0$. Under $b \mapsto b + \delta\lambda$, the exponent changes by

$$\frac{2\pi i}{N} \int_X \delta\lambda \smile \delta c.$$

Since $\deg \lambda = 1$,

$$\delta(\lambda \smile \delta c) = \delta\lambda \smile \delta c - \lambda \smile \delta^2 c = \delta\lambda \smile \delta c.$$

Thus the change is the integral of a coboundary. Evaluation of a coboundary on the fundamental cycle of a closed triangulated manifold is zero modulo N. The exponent is therefore unchanged.

If X has boundary $M = \partial X$, the last computation leaves the boundary term

$$\frac{2\pi i}{N} \int_M \lambda \smile \delta c.$$

A boundary condition must therefore specify which combination of b and c is fixed as a background and which is summed as a dynamical higher gauge field. A four-dimensional QFT $\mathcal{Q}$ with a $\mathbb{Z}_N$ one-form symmetry is a boundary condition for this five-dimensional theory after the choice of background boundary has been made. Gauging the one-form symmetry is the operation of replacing the boundary condition that fixes b by the boundary condition that sums over b and fixes the dual background c.

Example 123.3 (Four-dimensional $\mathbb{Z}_N$ line data)**.** In a four-dimensional theory whose electric and magnetic one-form backgrounds are both finite $\mathbb{Z}_N$ backgrounds, a line charge may be labelled abstractly by

$$(e, m) \in \mathbb{Z}_N \oplus \mathbb{Z}_N.$$

The pairing controlling mutual locality is the finite Dirac pairing

$$\langle (e, m), (e', m') \rangle = em' - me' \quad \in \mathbb{Z}_N.$$

A set of simultaneously genuine line operators is a subgroup on which this pairing vanishes. The five-dimensional action (123.1) packages the two one-form backgrounds and their finite symplectic pairing. The wall that exchanges b and c acts on line charges by

$$(e, m) \mapsto (m, -e),$$

the finite analogue of the S-wall discussed in Chapter 122. This statement is about the line-charge lattice and its mutual-locality pairing; it is not an assertion that arbitrary closed loops in four Euclidean dimensions have a topological pairwise braiding invariant.

123.6 Condensation And Gauging

Let $\mathcal{C}$ be the category or higher category of topological defects describing a finite symmetry. Gauging a sub-symmetry is condensation of a commutative algebra object

$$A_{\text{cond}} \in \mathcal{C}.$$

The gauged theory has boundary condition obtained by allowing endpoints of the condensed defects. If the algebra object is obstructed by an anomaly, the condensation exists only after coupling to an appropriate bulk or after choosing a trivialization of the anomaly.

Definition 123.4 (Triangulated higher-gauging defect)**.** Let $\mathcal{Q}$ be a four-dimensional QFT with an anomaly-free finite $\mathbb{Z}_N$ one-form symmetry. Assume that for every closed oriented surface Σ there are topological symmetry surfaces

$$U_n(\Sigma), \qquad n \in \mathbb{Z}_N,$$

with junctions implementing $U_nU_m \simeq U_{n+m}$, and assume these surface networks are invariant under triangulation moves. For a triangulated oriented three-manifold Y supporting a codimension-one defect, define the groupoid-normalized condensation insertion

$$\mathfrak{C}(Y) = \frac{|C^0(Y,\mathbb{Z}_N)|}{|C^1(Y,\mathbb{Z}_N)|} \sum_{b\in Z^2(Y,\mathbb{Z}_N)} \mathsf{U}_b(Y). \tag{123.2}$$

Here b is a closed two-cochain on Y. The symbol $\mathsf{U}_b(Y)$ denotes the topological wall network obtained from the Poincare-dual one-cycle of b: locally one thickens each dual edge in a small normal collar of Y and inserts the corresponding one-form symmetry surface segment. The condition $\delta b = 0$ is the conservation law at the vertices of the dual one-cycle, equivalently the absence of an uncancelled endpoint for the wall network. The factor $|C^0|/|C^1|$ is the finite groupoid volume of the two-form gauge parameter $C^1(Y,\mathbb{Z}_N)$ together with its degree-zero gauge-for-gauge redundancy. Omitting the $|C^0|$ factor gives a cellularly dependent representative; changing to a reduced convention divides by the constant factor $|H^0(Y,\mathbb{Z}_N)|$ on each connected component and changes the defect by an invertible normalization convention rather than by a dynamical QFT operation.

Finite two-form gauge groupoid behind the normalization. The coefficient in (123.2) is the homotopy cardinality of the finite two-form gauge groupoid, written before quotienting the field variables. Let $\mathcal{Z}^2_N(Y)$ be the finite 2-groupoid whose objects are closed two-cochains

$$b \in Z^2(Y,\mathbb{Z}_N),$$

whose 1-morphisms are one-cochains $\lambda \in C^1(Y,\mathbb{Z}_N)$ acting by

$$b \longmapsto b + \delta\lambda,$$

and whose 2-morphisms are zero-cochains $\xi \in C^0(Y,\mathbb{Z}_N)$ acting on gauge parameters by

$$\lambda \longmapsto \lambda + \delta\xi.$$

For a closed connected component this is the finite model of a $\mathbb{Z}_N$ two-form gauge field on Y. The homotopy cardinality of a finite 2-groupoid is

$$\sum_{[b]\in\pi_0} \frac{|\pi_2(\mathcal{Z}^2_N(Y),b)|}{|\pi_1(\mathcal{Z}^2_N(Y),b)|}.$$

Here

$$\pi_0 \simeq H^2(Y,\mathbb{Z}_N), \qquad \pi_1 \simeq H^1(Y,\mathbb{Z}_N), \qquad \pi_2 \simeq H^0(Y,\mathbb{Z}_N),$$

so

$$|\mathcal{Z}^2_N(Y)| = \frac{|H^0(Y,\mathbb{Z}_N)|\,|H^2(Y,\mathbb{Z}_N)|}{|H^1(Y,\mathbb{Z}_N)|}. \tag{123.3}$$

Equivalently, if one sums over the unquotiented set of closed cochains, the same cardinality is

$$|\mathcal{Z}^2_N(Y)| = \frac{|C^0(Y,\mathbb{Z}_N)|\,|Z^2(Y,\mathbb{Z}_N)|}{|C^1(Y,\mathbb{Z}_N)|}. \tag{123.4}$$

This is exactly the normalization used in (123.2): the summand $\mathsf{U}_b(Y)$ is written for every closed cochain b, while the factor $|C^0|/|C^1|$ divides by one-form gauge redundancy and restores the zero-form gauge-for-gauge volume. Thus the normalization is not an optional cellular convention; it is the finite path-integral measure for the two-form gauge field.

Theorem 123.5 (Finite higher gauging and condensation fusion)**.** *Under the hypotheses of Definition 123.4, the insertion $\mathfrak{C}(Y)$ is a topological codimension-one defect implementing finite $\mathbb{Z}_N$ one-form gauging on the hypersurface Y. The fusion of two parallel copies is*

$$\mathfrak{C}(Y)\circ\mathfrak{C}(Y) = Z^{(2)}_{\mathbb{Z}_N}(Y)\,\mathfrak{C}(Y), \qquad Z^{(2)}_{\mathbb{Z}_N}(Y) = \frac{|C^0(Y,\mathbb{Z}_N)|\,|Z^2(Y,\mathbb{Z}_N)|}{|C^1(Y,\mathbb{Z}_N)|}. \tag{123.5}$$

Equivalently,

$$Z^{(2)}_{\mathbb{Z}_N}(Y) = \frac{|H^0(Y,\mathbb{Z}_N)|\,|H^2(Y,\mathbb{Z}_N)|}{|H^1(Y,\mathbb{Z}_N)|}, \tag{123.6}$$

so the coefficient is the closed-three-manifold partition value of the finite three-dimensional $\mathbb{Z}_N$ two-form gauge theory in this normalization. With corners or boundaries the same state sum assigns the corresponding Hilbert spaces and operators; hence the fusion coefficient of condensation defects is, in general, a three-dimensional topological theory rather than an integer.

If the half-space gauged theory is identified with $\mathcal{Q}$ after all discrete theta terms and background boundary conditions are fixed, the half-space gauging interface is a duality defect of $\mathcal{Q}$. For $N>1$ it is noninvertible whenever the associated two-form gauge theory has non-one-dimensional state spaces, for example on a connected closed spatial surface where the flux label in $H^2(\Sigma,\mathbb{Z}_N)$ survives.

Proof. Topological invariance of $\mathfrak{C}(Y)$ has two logically distinct inputs. The QFT input is that the surface networks $U_n(\Sigma)$, their junctions, and their Pachner-move identifications have already been constructed as anomaly-free topological operators. The finite gauge-theory input is the groupoid measure (123.4). The cochain condition $\delta b = 0$ is exactly the junction conservation law for the Poincare-dual network, so a closed b produces a network without residual endpoints. A change $b \mapsto b+\delta\lambda$ inserts the boundary of a one-cochain of symmetry surfaces; by the assumed topological junction relations this is a gauge-equivalent representative of the same condensed configuration. A change $\lambda \mapsto \lambda + \delta\xi$ is the gauge-for-gauge redundancy of that boundary filling. Therefore the sum in (123.2) is precisely the unquotiented expression for the finite path integral over $\mathcal{Z}^2_N(Y)$. In a collar $(-\epsilon,\epsilon)\times Y$, replacing the fixed one-form background by this groupoid sum is the finite gauging operation on the hypersurface. This proves the gauging interpretation after the QFT surface-operator input has been supplied.

Place two copies of the defect on nearby parallel copies of Y. Their product is

$$\left(\frac{|C^0(Y,\mathbb{Z}_N)|}{|C^1(Y,\mathbb{Z}_N)|}\right)^2 \sum_{b,b'\in Z^2(Y,\mathbb{Z}_N)} \mathsf{U}_b(Y)\,\mathsf{U}_{b'}(Y).$$

Using the junction isomorphism $U_n U_m \simeq U_{n+m}$, change variables to

$$s = b + b', \qquad t = b.$$

For each closed s, the variable t runs freely over $Z^2(Y, \mathbb{Z}_N)$. The product therefore becomes

$$\frac{|C^0|\,|Z^2|}{|C^1|}\left(\frac{|C^0|}{|C^1|}\sum_{s\in Z^2(Y,\mathbb{Z}_N)} \mathsf{U}_s(Y)\right),$$

where all cochain groups are on Y. The second parenthesis is $\mathfrak{C}(Y)$, and the first factor is (123.5). It remains to see that this factor is topological. From the short exact sequences

$$0 \to Z^1 \to C^1 \to B^2 \to 0, \qquad 0 \to B^1 \to Z^1 \to H^1 \to 0, \qquad 0 \to H^0 \to C^0 \to B^1 \to 0,$$

and

$$0 \to B^2 \to Z^2 \to H^2 \to 0,$$

finite cardinalities multiply, giving

$$\frac{|C^0|\,|Z^2|}{|C^1|} = \frac{|H^0|\,|H^2|}{|H^1|}.$$

This proves (123.6). The extension to manifolds with boundary is the same finite gauge-theory state sum with boundary cochains left unsummed or summed according to the chosen boundary condition; it assigns vector spaces and linear maps, with closed three-manifold numbers as the special case. If half-space gauging lands back on $\mathcal{Q}$, the interface has the same theory on both sides and is therefore an internal duality defect. Its product with the opposite interface contains the nontrivial two-form gauge-theory summation just computed, so it is invertible only when that finite topological theory is the trivial invertible one. $\square$

Relative state space of the finite factor. The last sentence of the theorem has concrete content. Let Σ be a closed oriented triangulated surface obtained by cutting the three-dimensional defect worldvolume. A boundary value of the finite two-form gauge field is a closed two-cochain

$$z \in Z^2(\Sigma, \mathbb{Z}_N).$$

Since $\dim \Sigma = 2$, this is the same set as $C^2(\Sigma, \mathbb{Z}_N)$. The boundary one-form gauge transformations identify

$$z \sim z + \delta\lambda, \qquad \lambda \in C^1(\Sigma, \mathbb{Z}_N).$$

Thus the flux sectors on the cut surface are

$$[z] \in H^2(\Sigma, \mathbb{Z}_N), \qquad \mathcal{H}_N^{(2)}(\Sigma) = \mathbb{C}\big[H^2(\Sigma, \mathbb{Z}_N)\big], \tag{123.7}$$

with the automorphism groups H^0 and H^1 entering the gluing pairing through the same homotopy cardinality weights as in (123.3). More explicitly, a cobordism $W : \Sigma_0 \to \Sigma_1$ gives a matrix whose $([z_1], [z_0])$-entry is the homotopy cardinality of the finite groupoid of closed two-cochains $b \in Z^2(W, \mathbb{Z}_N)$ restricting to the prescribed boundary classes, with one-cochain gauge transformations and zero-cochain gauge-for-gauge transformations fixed on the boundary. For the cylinder $\Sigma \times$

$[0,1]$, restriction to the two ends forces $[z_0]=[z_1]$, so the operator is diagonal on the basis (123.7) up to the conventional automorphism scalar fixed by the gluing normalization.

This relative description is what the closed-manifold number $Z^{(2)}_{\mathbb{Z}_N}(Y)$ becomes when a cut is present. On a connected closed oriented surface,

$$H^2(\Sigma,\mathbb{Z}_N)\simeq\mathbb{Z}_N,$$

so the finite factor has an N-dimensional flux-sector space for $N>1$. Consequently fusion with the reverse gauging interface contains actual finite topological degrees of freedom. It is an invertible scalar line only when the relevant finite state spaces are all one-dimensional.

For Yang–Mills theories this construction becomes a QFT statement only after the $\mathbb{Z}_N$ one-form symmetry surfaces, their junctions, their correlation topology, and their anomaly trivialization have been constructed inside the theory or by a regulator such as the lattice. Once that input is available, the cochain calculation above is the local algebraic mechanism behind higher gauging and the resulting noninvertible condensation defects.

123.7 Chiral Defects In Abelian Gauge Theory

We now give the explicit abelian construction. Work on an oriented spin four-manifold and take compact unit-charge massless QED with gauge field A, curvature $F=\mathrm{d}A$, and flux normalization

$$\int_\Sigma \frac{F}{2\pi}\in\mathbb{Z}$$

for every closed two-cycle Σ. Let j_5 be the axial current in the normalization of Chapter 51: the axial rotation by angle α acts on the Dirac field by

$$\psi\mapsto\exp(\mathrm{i}\alpha\gamma_5/2)\psi,$$

and, in the massless theory,

$$\mathrm{d}\star j_5=\frac{1}{4\pi^2}F\wedge F. \tag{123.8}$$

This is the differential-form version of (51.6) with $e=q=1$. The magnetic one-form symmetry has current

$$j_m=\frac{1}{2\pi}\star F,\qquad \mathrm{d}\star j_m=\frac{1}{2\pi}\mathrm{d}F=0.$$

It is part of the QFT definition only when no dynamical monopole operator has been included; an inserted or dynamical monopole is an endpoint for the charged ’t Hooft line and explicitly breaks this symmetry.

For a closed oriented three-manifold M supporting a defect, the naive axial wall

$$U_\alpha(M)=\exp\left(\frac{\mathrm{i}\alpha}{2}\int_M\star j_5\right)$$

is not topological. If M is moved across a four-chain W, (123.8) changes it by

$$\exp\left(\frac{\mathrm{i}\alpha}{8\pi^2}\int_W F\wedge F\right).$$

It is also not a well-defined compact-gauge-field operator after replacing $\star j_5$ by the formally conserved Chern–Simons-improved current, because the required fractional Chern–Simons level is not invariant under large gauge transformations on a general compact M.

123.7.1 The Fractional Hall Dressing

Let $N > 0$, let $p \in \mathbb{Z}$ with $\gcd(p, N) = 1$, and put

$$\alpha = \frac{2\pi p}{N}.$$

Let $\mathcal{A}_{N,p}$ denote the minimal abelian three-dimensional TQFT with a $\mathbb{Z}_N$ one-form symmetry whose generating line ℓ has spins

$$h(\ell^s) = \frac{ps^2}{2N} \quad \mathrm{mod}\ 1.$$

The spin refinement of $\mathcal{A}_{N,p}$ is included when the pair (N, p) requires it; the spin structure on M is inherited from the ambient spin four-manifold. Equivalently, coupling this one-form symmetry to a $\mathbb{Z}_N$-valued two-cocycle B has four-dimensional inflow

$$\exp\left(-\frac{2\pi \mathrm{i} p}{2N}\int_Y P(B)\right),$$

on a four-manifold Y extending the background; P is the Pontryagin-square cohomology operation. When the integral curvature class of $A|_M$ is reduced modulo N, it defines

$$B_A = \left[\frac{F}{2\pi}\right] \mathrm{mod}\ N \in H^2(M, \mathbb{Z}_N).$$

The dressed chiral defect is

$$D_{N,p}(M) = \exp\left(\frac{\pi \mathrm{i} p}{N}\int_M \star j_5\right) Z_{\mathcal{A}_{N,p}}(M; B_A). \tag{123.9}$$

For $p = 1$, the minimal theory is the $U(1)_N$ Chern–Simons theory, and (123.9) becomes the more concrete path integral

$$D_{N,1}(M) = \int \mathcal{D}a \, \exp\left[\frac{\pi \mathrm{i}}{N}\int_M \star j_5 + \mathrm{i}\int_M \left(\frac{N}{4\pi} a \wedge \mathrm{d}a + \frac{1}{2\pi} a \wedge \mathrm{d}A\right)\right], \tag{123.10}$$

where a is a compact $U(1)$ gauge field living only on the defect worldvolume. The field a is not a new bulk particle; it is part of the operator insertion.

Topological cancellation for $D_{N,1}$. In the massless compact QED path integral without dynamical monopoles, the operator (123.10) is invariant under smooth deformations of M that avoid charged insertions.

Let M_0 and M_1 be two homologous placements of the defect and let W be the oriented four-chain swept out by the deformation. The axial factor in (123.10) changes by

$$\exp\left(\frac{\pi \mathrm{i}}{N}\int_W \mathrm{d} \star j_5\right) = \exp\left(\frac{\mathrm{i}}{4\pi N}\int_W F \wedge F\right).$$

The $U(1)_N$ defect theory is gauge invariant as a compact Chern–Simons theory. To compute its local dependence on the ambient field A, one may integrate out a at the level of the response action: the equation of motion is $N\mathrm{d}a + \mathrm{d}A = 0$, so locally

$$\frac{N}{4\pi} a \wedge \mathrm{d}a + \frac{1}{2\pi} a \wedge \mathrm{d}A \quad \rightsquigarrow \quad -\frac{1}{4\pi N} A \wedge \mathrm{d}A.$$

Therefore the change of the Hall response under the same deformation is

$$\exp\left(-\frac{\mathrm{i}}{4\pi N}\int_W F\wedge F\right),$$

which cancels the axial-anomaly phase. The argument uses only the local response to a deformation; the compact a-path integral in (123.10) is what makes the operator globally well-defined under large gauge transformations.

For general p/N, the same cancellation is expressed by the one-form anomaly of $\mathcal{A}_{N,p}$. The Pontryagin-square response of $\mathcal{A}_{N,p}(B_A)$ is the compact, gauge-invariant replacement for the fractional Chern–Simons counterterm whose differential-form shadow is

$$-\frac{\mathrm{i}p}{4\pi N}\int A\wedge \mathrm{d}A.$$

Its deformation phase cancels the axial phase from (123.8). Thus (123.9) is the compact topological defect associated with the rational axial angle $2\pi p/N$.

123.7.2 Half-Space Gauging Proof

There is a second construction that explains why the defect is tied to the magnetic one-form symmetry. Let $X_+ = \{x \geq 0\}$ and let $M = \partial X_+$. To gauge the $\mathbb{Z}_N$ subgroup of the magnetic $U(1)^{(1)}$ symmetry in X_+, introduce a compact two-form gauge field b and a compact one-form gauge field c on X_+. For $k\in\mathbb{Z}$ satisfying

$$pk \equiv 1 \pmod N,$$

add

$$S_{\mathrm{mag},N,k} = \mathrm{i}\int_{X_+}\left(\frac{1}{2\pi}b\wedge F + \frac{N}{2\pi}b\wedge \mathrm{d}c + \frac{Nk}{4\pi}b\wedge b\right). \tag{123.11}$$

The c-equation imposes the flatness condition that makes b a $\mathbb{Z}_N$ two-form gauge field after the finite gauge quotient. The last term is the discrete-torsion choice. In the smooth sector, completing the square gives the theta-angle shift

$$\Delta S_\theta = -\frac{\mathrm{i}p}{4\pi N}\int_{X_+} F\wedge F,$$

with the integral quantization fixed by the compact b, c path integral. The massless axial change of variables with

$$\alpha(x) = \frac{2\pi p}{N}\Theta(x)$$

contributes the inverse phase and a boundary insertion

$$\exp\left(\frac{\pi \mathrm{i}p}{N}\int_M \star j_5\right).$$

After imposing the topological boundary condition $b|_M = 0$, the remaining boundary theory produced by the b, c path integral is precisely $\mathcal{A}_{N,p}(B_A)$. The interface between the ungauged side and the half-space-gauged side is therefore (123.9). Since the operation is gauging on a half-space followed by a change of variables, the interface is topological as long as the magnetic one-form symmetry is unbroken.

123.7.3 Fusion And Action On Operators

The defect acts on local fermion operators by the axial rotation

$$\psi \mapsto \exp(\pi \mathrm{i} p \gamma_5 / N)\psi.$$

Wilson lines are not charged under the magnetic one-form symmetry, so the half-space gauging part leaves them unchanged. A minimal 't Hooft line $H(\gamma)$, in the sense of Definition 115.2, is charged. If $\gamma = \partial\Sigma$ while the defect is swept past the line, gauge invariance attaches the surface factor

$$H(\gamma) \longmapsto H(\gamma)\, \exp\left(\frac{\mathrm{i}p}{N}\int_\Sigma F\right), \tag{123.12}$$

with Σ stretching between the line and the displaced defect. This is the operational reason the defect is not an ordinary axial symmetry operator: its action on extended operators remembers the magnetic one-form symmetry.

The orientation-reverse fusion already shows noninvertibility. For $p = 1$,

$$D_{N,1}(M)D^\dagger_{N,1}(M) = \int \mathcal{D}a\, \mathcal{D}\bar{a}\, \exp\left[\mathrm{i}\int_M \left(\frac{N}{4\pi} a \wedge \mathrm{d}a - \frac{N}{4\pi}\bar{a} \wedge \mathrm{d}\bar{a} + \frac{1}{2\pi}(a - \bar{a}) \wedge \mathrm{d}A\right)\right]. \tag{123.13}$$

The axial factors cancel, but the Hall theories do not cancel to the trivial three-dimensional theory. Equation (123.13) is the magnetic $\mathbb{Z}_N$ condensation operator. In the finite cochain language used above, its general p analogue is a sum over $\mathbb{Z}_N$-valued two-cocycles on M, weighted by the Pontryagin-square phase and by the corresponding magnetic one-form symmetry surface network. Thus the fusion coefficient is a three-dimensional TQFT or finite state sum, not a number.

Controlled Approximation 123.6 (QED noninvertible chiral defects)**.** In compact unit-charge massless QED on oriented spin four-manifolds, with no dynamical monopoles and with the magnetic one-form symmetry retained in the QFT definition, every rational axial angle $2\pi p/N$ with $\gcd(p, N) = 1$ defines the topological defect $D_{N,p}$ in (123.9). The defect acts on local fermions by the corresponding axial rotation, acts on 't Hooft lines by (123.12), and is noninvertible because $D_{N,p}D^\dagger_{N,p}$ is a magnetic condensation defect rather than the invisible defect.

This statement is the compact path-integral construction just given. A fully axiomatic theorem would still require constructing compact QED, its charged line sectors, and the defect Hilbert spaces in a nonperturbative reconstruction framework. If dynamical monopoles are added, the magnetic one-form symmetry has endpoints and the half-space gauging step is no longer topological; the defect then fails to define an exact symmetry.

Let a more general four-dimensional abelian gauge theory contain massless fermions with a classical chiral transformation R_α. Suppose the ABJ anomaly changes the action by

$$\Delta S_\alpha = \frac{i\alpha q}{8\pi^2}\int_M F \wedge F,$$

where F is the $U(1)$ field strength and $q \in \mathbb{Z}$ is the anomaly coefficient in the chosen charge normalization. The codimension-one defect implementing R_α is topological only if this phase is cancelled or trivialized as the defect crosses insertions. In the absence of dynamical monopoles, the theory also has a magnetic one-form symmetry, and the anomaly phase can be represented by coupling the defect worldvolume to a three-dimensional topological theory whose anyons attach to magnetic background flux sectors. The resulting dressed defect is generally noninvertible: fusing it with its orientation reverse leaves a sum or a three-dimensional topological factor rather than the invisible defect alone.

123.8 Higher Fusion Categories And Truncations

The categorical level depends on which defects are retained. In a four-dimensional QFT, the full wall-junction system includes walls, junction surfaces, junction lines, and point junctions. It is therefore at least a three-categorical defect object. A fusion two-category appears only after a controlled truncation, for example by focusing on topological surfaces and their line and point junctions, or by studying the three-dimensional theory living on a wall. A finite semisimple fusion two-category has objects, one-morphisms, and two-morphisms, a monoidal product, duals, and finite semisimple Hom categories. Condensation is then formulated by separable algebra objects and their module two-categories.

This distinction matters in four-dimensional generalized symmetry. A one-form symmetry generated by topological surfaces is not fully described by a one-category of simple surfaces if its line junctions carry nontrivial operator spaces. The symmetry TQFT keeps this extra information because bulk boundary-changing defects, their junctions, and their endpoint operators live one categorical level higher than the ordinary group law. When a chapter later uses only a fusion ring of surfaces, the omission is a truncation and not a definition of the full symmetry object.

123.9 Example: Mixed Zero- And One-Form Data

Consider a four-dimensional gauge theory with gauge group $SU(N)$ and a charge conjugation symmetry acting on the center one-form symmetry

$$A = \mathbb{Z}_N$$

by inversion. A background for the ordinary symmetry changes the local system in which the A-valued two-form background lives. If a theta-angle or discrete theta term changes under charge conjugation, the anomaly is a five-dimensional functional of the combined background. The line-operator lattice then transforms as a module over the two-group rather than as a separate representation of each symmetry.

Comparison Summary

The symmetry-TQFT description is not a replacement for constructing the QFT. It records:

$$\begin{array}{rl} \text{allowed background fields,} & \text{anomaly lines,} \\ \text{gauging and condensation operations,} & \text{topological defect fusion.} \end{array}$$

Local correlators, Hilbert space, stress tensor, and dynamical phase structure must still be supplied by the QFT itself.

Open Problem 123.7 (Higher-group examples). Construct interacting continuum QFT examples whose higher-group backgrounds, symmetry TQFT, defect fusion, anomaly inflow, and local-operator action are all derived from a single regulator or reconstruction framework.

Part X

Thermal Quantum Field Theory, Hydrodynamics, and Nonequilibrium Dynamics

Chapter 124

KMS States and Thermal Correlators

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Thermal equilibrium is a property of a state together with a chosen time evolution. The KMS condition expresses this property as an analytic boundary condition on correlation functions. It agrees with the Gibbs trace in a finite system, but it does not require the trace formula to exist. This is why it is the correct starting point for infinite-volume thermal QFT, where the partition function per se is not an observable.

Statistical mechanics as a QFT absorption route. The statistical-mechanics material in Volumes X and XI is used as input for QFT only after it has been translated into observables, regulators, limits, and framework data. The finite Gibbs trace below is therefore the first rung of a route, not the template for every later thermal field theory. The route has five gates.

First, equilibrium data enter through a C^*-dynamical system and a KMS state. A finite Hamiltonian calculation may verify the strip boundary condition, detailed balance, and fluctuation–dissipation signs, but the QFT statement is the existence of a state on an infinite-volume observable algebra with a declared time evolution. This is the layer developed in the present chapter and used by the Kubo analysis of Chapter 127.

Second, transport and hydrodynamics use equilibrium correlation functions only after the order of limits and the retained slow variables are declared. Kubo formulae, the Ward-identity hydrodynamic family of Chapter 128, the Schwinger–Keldysh hydrodynamic effective theory of Chapter 129, and the long-time-tail analysis of Chapter 134 are linked by this datum: conserved densities and sources define the observable map, while the low-frequency and long-wavelength limits remain extra hypotheses or theorems in a specified model.

Third, nonequilibrium statistical mechanics contributes finite probability identities and representation changes before it contributes continuum QFT. The proof architecture of Chapter 133 separates path-measure fluctuation relations, MSRJD and Doi–Peliti rewritings, tilted generators, empirical-flow costs, GKSL limits, and Schwinger–Keldysh influence kernels from the later scaling claim that produces a stochastic or open-system field theory. Dynamic-critical labels such as Models A–H live at that scaling layer until a model-specific renormalization and observable limit have been supplied.

Fourth, finite-locality and topological laboratories test mechanisms without settling continuum existence. Lieb–Robinson bounds, quasi-adiabatic continuation, flux-torus Hall responses, toric-code sectors, and finite gauge or TQFT boundary models give controlled finite-regulator identities for locality, stability, and generalized-symmetry claims. Their role in the QFT spine is to expose which hypotheses a continuum theorem must retain, as in the lattice and local-QFT routes of Chapters 138, 140, and 143.

Fifth, the constructive and numerical material of Volume XI asks whether the regulated families actually produce QFT data. Cluster expansions, rigorous RG, stochastic quantization, continuum scaling windows, Monte Carlo evidence, transfer matrices, Hamiltonian truncation, tensor networks, and neural variational states are admissible coordinates only when accompanied by regulator families, renormalized observables, error budgets, and an OS/Wightman/AQFT reconstruction or comparison target, as organized in Chapters 136, 139, 142, 144, and 145.

This route prevents a common compression. A finite lattice identity, a stochastic action, a transfer-matrix spectrum, or a tensor-network fit is not yet a continuum QFT theorem. To be used at that level it must name the observable map, the thermodynamic or infinite-volume limit, the scaling window and topology, the positivity and locality conditions, and the framework in which the limiting object is reconstructed or compared.

124.1 Dynamical Algebras and Analytic Elements

Definition 124.1 (C^*-dynamical system)**.** A C^*-dynamical system is a pair $(\mathcal{A}, \alpha)$, where $\mathcal{A}$ is a C^*-algebra and

$$\alpha : \mathbb{R} \longrightarrow \mathrm{Aut}(\mathcal{A}), \qquad t \longmapsto \alpha_t,$$

is a strongly continuous one-parameter group of $*$-automorphisms. Thus $\alpha_{t+s} = \alpha_t \alpha_s$, $\alpha_0 = \mathrm{id}$, and for each $A \in \mathcal{A}$ the function $t \mapsto \alpha_t(A)$ is norm-continuous.

The algebra $\mathcal{A}$ is the algebra of bounded observables. Unbounded local fields, stress tensors, and currents are used later through smeared operators, affiliated operators, or distributional limits. The KMS condition is first stated on bounded observables because products and analytic continuation are then unambiguous.

Definition 124.2 (Analytic element)**.** An element $A \in \mathcal{A}$ is entire analytic for α if the map $t \mapsto \alpha_t(A)$ extends to an entire $\mathcal{A}$-valued function

$$z \longmapsto \alpha_z(A)$$

whose restriction to the real axis is the original orbit. If $w \in \mathbb{R}$, then $\alpha_w(A)$ is again entire analytic and its continuation is

$$z \longmapsto \alpha_{z+w}(A).$$

A subalgebra $\mathcal{A}_{\mathrm{an}} \subset \mathcal{A}$ is an analytic core if it is norm dense, α_t-invariant, and consists of entire analytic elements.

Lemma 124.3 (Existence of analytic elements by Gaussian smearing)**.** *Let $(\mathcal{A}, \alpha)$ be a C^*-dynamical system. For $A \in \mathcal{A}$ and $n > 0$, define*

$$A_n = \sqrt{\frac{n}{\pi}} \int_{\mathbb{R}} \mathrm{d}t \, \mathrm{e}^{-nt^2} \alpha_t(A), \tag{124.1}$$

where the integral is the Bochner integral in the norm of $\mathcal{A}$. Then A_n is entire analytic and $A_n \to A$ in norm as $n \to \infty$. Hence entire analytic elements form a norm-dense $*$-subalgebra.

Proof. Strong continuity implies that the integral in (124.1) exists and that

$$\|A_n - A\| \le \sqrt{\frac{n}{\pi}} \int_{\mathbb{R}} \mathrm{d}t \, \mathrm{e}^{-nt^2} \|\alpha_t(A) - A\|.$$

After the change of variables $u = \sqrt{n}\, t$, the integrand is bounded by $\pi^{-1/2}\mathrm{e}^{-u^2} 2\|A\|$ and converges to zero for each fixed u; dominated convergence gives $A_n \to A$. For complex z, define

$$\alpha_z(A_n) = \sqrt{\frac{n}{\pi}} \int_{\mathbb{R}} \mathrm{d}t \, \mathrm{e}^{-n(t-z)^2} \alpha_t(A).$$

On every compact subset of the z-plane, the norm of the integrand is bounded by $\|A\| \exp[-nt^2 + C(1 + |t|)]$, which is integrable in t. Differentiation under the integral is therefore justified by dominated convergence, so $z \mapsto \alpha_z(A_n)$ is entire. If A and B are entire analytic, the functions

$$z \longmapsto \alpha_z(A)\alpha_z(B), \qquad z \longmapsto \alpha_{\bar{z}}(A)^*$$

are respectively holomorphic and holomorphic as Banach-space-valued maps; on the real axis they equal $\alpha_t(AB)$ and $\alpha_t(A^*)$. The identity theorem gives the analytic continuations of AB and A^*. For the adjoint statement, if ℓ is any continuous linear functional on $\mathcal{A}$ and $\ell^{\#}(X) = \overline{\ell(X^*)}$, then $\ell(\alpha_{\bar{z}}(A)^*) = \overline{\ell^{\#}(\alpha_{\bar{z}}(A))}$; this is holomorphic in z because $w \mapsto \ell^{\#}(\alpha_w(A))$ is entire. Finite linear combinations then give a dense $*$-subalgebra. ∎

124.2 The KMS Boundary Condition

Definition 124.4 (KMS state)**.** Let $\beta > 0$. A state $\omega : \mathcal{A} \to \mathbb{C}$ is a β-KMS state for α if, for every $A, B \in \mathcal{A}_{\mathrm{an}}$, the function

$$t \longmapsto \omega(A\alpha_t(B))$$

is the lower boundary value of a function $F_{A,B}(z)$ that is holomorphic on the open strip

$$S_\beta = \{z \in \mathbb{C} : 0 < \operatorname{Im} z < \beta\},$$

continuous and bounded on the closed strip, and satisfies

$$F_{A,B}(t) = \omega(A\alpha_t(B))\,, \qquad F_{A,B}(t+\mathrm{i}\beta) = \omega(\alpha_t(B)A) \tag{124.2}$$

for all $t \in \mathbb{R}$. The analytic core may be replaced by any norm-dense analytic core; the resulting condition extends by continuity to the usual KMS condition on $\mathcal{A}$.

The inverse temperature β has dimensions of time when $\hbar = 1$. The time evolution α_t is part of the datum. Changing the time evolution, for example by adding a chemical-potential generator, changes the KMS condition.

Figure 124.1 displays the analytic strip in the KMS condition: the two boundary values differ by the time evolution through imaginary time $\mathrm{i}\beta$.

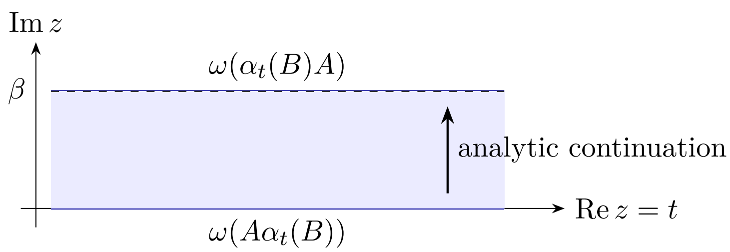

Figure 124.1: The KMS condition is a strip-analytic boundary condition. The lower edge is the ordered correlator $A\alpha_t(B)$; the upper edge is obtained by moving B past the thermal state.

Finite Gibbs traces as KMS states. Let $\mathcal{H}$ be finite dimensional, let $H = H^*$, and let $\alpha_t(A) = \mathrm{e}^{\mathrm{i}Ht}A\mathrm{e}^{-\mathrm{i}Ht}$ on $\mathcal{A} = \mathrm{End}(\mathcal{H})$. For

$$\omega_\beta(A) = \frac{\mathrm{Tr}(\mathrm{e}^{-\beta H}A)}{\mathrm{Tr}(\mathrm{e}^{-\beta H})}, \tag{124.3}$$

ω_β is a β-KMS state. To see the strip function explicitly, choose an orthonormal eigenbasis $H|m\rangle = E_m|m\rangle$, and write $A_{mn} = \langle m|A|n\rangle$, $B_{mn} = \langle m|B|n\rangle$. Then

$$F_{A,B}(z) = \frac{1}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_m} A_{mn}B_{nm}\,\mathrm{e}^{\mathrm{i}(E_n-E_m)z}, \qquad Z_\beta = \sum_m \mathrm{e}^{-\beta E_m}, \tag{124.4}$$

is entire because the sum is finite. At $z = t$ it equals $\omega_\beta(A\alpha_t(B))$. At $z = t + \mathrm{i}\beta$,

$$F_{A,B}(t+\mathrm{i}\beta) = \frac{1}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_n} A_{mn}B_{nm}\,\mathrm{e}^{\mathrm{i}(E_n-E_m)t}.$$

Relabeling $m \leftrightarrow n$ gives

$$F_{A,B}(t+\mathrm{i}\beta) = \frac{1}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_m} B_{mn}A_{nm}\,\mathrm{e}^{\mathrm{i}(E_m-E_n)t} = \omega_\beta(\alpha_t(B)A),$$

which is the boundary condition (124.2). This finite-dimensional calculation is the model for the general KMS definition. Infinite-volume thermal states require the strip analyticity and boundary condition to be verified in the chosen operator-algebraic or distributional framework.

Remark 124.5 (Chemical potentials). If Q_A are commuting conserved charges and μ_A are chemical potentials, the finite trace

$$Z^{-1}\,\mathrm{Tr}\exp[-\beta(H-\mu_A Q_A)]\,(\cdot)$$

is KMS for the automorphism generated by $H-\mu_A Q_A$. Equivalently, it is KMS for the original Hamiltonian time evolution together with a simultaneous imaginary-time internal-symmetry twist. The two descriptions must not be mixed without declaring which automorphism defines equilibrium.

124.3 Spectral Form of Detailed Balance

In this section the Fourier transform of a tempered distribution $G(t)$ is

$$\widetilde{G}(\omega) = \int_{\mathbb{R}} \mathrm{d}t\, \mathrm{e}^{\mathrm{i}\omega t} G(t). \tag{124.5}$$

With this convention, positive ω is the energy absorbed by the operator insertion in the finite-volume spectral formulas below.

Let A, B be observables whose time-dependent correlation functions have tempered boundary values. Define

$$G^{>}_{AB}(t) = \omega(A(t)B), \qquad G^{<}_{AB}(t) = \omega(BA(t)), \qquad A(t) = \alpha_t(A). \tag{124.6}$$

The KMS condition implies, in the distributional boundary-value sense,

$$G^{>}_{AB}(t-\mathrm{i}\beta) = G^{<}_{AB}(t), \tag{124.7}$$

or equivalently the frequency-space detailed-balance relation

$$\widetilde{G}^{<}_{AB}(\omega) = \mathrm{e}^{-\beta\omega}\widetilde{G}^{>}_{AB}(\omega). \tag{124.8}$$

Finite-volume spectral detailed balance. In the same finite-dimensional setting, the distributions $\widetilde{G}^{>}_{AB}$ and $\widetilde{G}^{<}_{AB}$ are finite sums of delta functions and obey (124.8). Using the eigenbasis above,

$$G^{>}_{AB}(t) = \frac{1}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_m} A_{mn} B_{nm} \mathrm{e}^{\mathrm{i}(E_m-E_n)t}.$$

Therefore

$$\widetilde{G}^{>}_{AB}(\omega) = \frac{2\pi}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_m} A_{mn} B_{nm} \delta(\omega - E_n + E_m). \tag{124.9}$$

Similarly,

$$\widetilde{G}^{<}_{AB}(\omega) = \frac{2\pi}{Z_\beta}\sum_{m,n} \mathrm{e}^{-\beta E_n} A_{mn} B_{nm} \delta(\omega - E_n + E_m), \tag{124.10}$$

where the second formula follows by relabeling the indices in $\omega(BA(t))$. On the support of the displayed delta function, $\mathrm{e}^{-\beta E_n} = \mathrm{e}^{-\beta\omega}\mathrm{e}^{-\beta E_m}$, proving (124.8).

Define the thermal spectral distribution

$$\rho_{AB}(\omega) = \widetilde{G}^{>}_{AB}(\omega) - \widetilde{G}^{<}_{AB}(\omega). \tag{124.11}$$

When $1-\mathrm{e}^{-\beta\omega}$ is invertible as a multiplier on the relevant test-function class, detailed balance gives

$$\widetilde{G}^{>}_{AB}(\omega)=\frac{\rho_{AB}(\omega)}{1-\mathrm{e}^{-\beta\omega}},\qquad \widetilde{G}^{<}_{AB}(\omega)=\frac{\mathrm{e}^{-\beta\omega}\rho_{AB}(\omega)}{1-\mathrm{e}^{-\beta\omega}}. \tag{124.12}$$

For conserved densities, the $\omega=0$ sector may contain delta functions or derivatives of delta functions. Those pieces have to be separated before dividing by $1-\mathrm{e}^{-\beta\omega}$. This is the same mathematical issue that later appears as susceptibilities, hydrodynamic poles, and contact terms.

Remark 124.6 (Bosonic fluctuation–dissipation identity). Assume $A=A^*$, $B=B^*$, and no singular zero-frequency term in the frequency window under consideration. Define the symmetrized spectrum

$$\widetilde{G}^{\mathrm{sym}}_{AB}(\omega)=\frac{1}{2}\left(\widetilde{G}^{>}_{AB}(\omega)+\widetilde{G}^{<}_{AB}(\omega)\right).$$

Then

$$\widetilde{G}^{\mathrm{sym}}_{AB}(\omega)=\frac{1}{2}\coth\left(\frac{\beta\omega}{2}\right)\rho_{AB}(\omega). \tag{124.13}$$

This identity follows directly from detailed balance. Insert (124.12) into the definition of $\widetilde{G}^{\mathrm{sym}}_{AB}$:

$$\widetilde{G}^{\mathrm{sym}}_{AB}=\frac{1}{2}\,\frac{1+\mathrm{e}^{-\beta\omega}}{1-\mathrm{e}^{-\beta\omega}}\rho_{AB}=\frac{1}{2}\coth\left(\frac{\beta\omega}{2}\right)\rho_{AB}.$$

The stated zero-frequency hypothesis is precisely the condition that this division is an ordinary distributional operation in the chosen window.

For odd operators in a $\mathbb{Z}_2$-graded theory, the KMS boundary condition includes the parity sign obtained by moving an odd operator around the thermal circle. The same proof gives

$$\widetilde{G}^{<}_{AB}(\omega)=-\mathrm{e}^{-\beta\omega}\widetilde{G}^{>}_{AB}(\omega)$$

for two odd operators in the convention where $G^{<}$ is not itself graded by an additional sign. Equivalently, one may absorb the sign into the definition of the fermionic lesser function. The convention must be declared before writing Fermi factors.

124.4 Linear Response and Retarded Correlators

Let $B(t)$ be coupled to a compactly supported real source $f(t)$ by

$$H_f(t)=H-f(t)B(t) \tag{124.14}$$

in a finite system, or by the corresponding time-dependent derivation on an analytic algebra. In the interaction picture,

$$U_f(t,-\infty)=1+\mathrm{i}\int_{-\infty}^{t}\mathrm{d}s\,f(s)B(s)+O(f^2). \tag{124.15}$$

Thus

$$U_f(t,-\infty)^{-1}A(t)U_f(t,-\infty)=A(t)+\mathrm{i}\int_{-\infty}^{t}\mathrm{d}s\,f(s)[A(t),B(s)]+O(f^2).$$

Stationarity of ω gives

$$\delta\omega(A(t)) = \int_{-\infty}^{t} \mathrm{d}s\, f(s)\, G^R_{AB}(t-s), \qquad G^R_{AB}(t) = -\mathrm{i}\,\theta(t)\,\omega([A(t),B(0)]). \tag{124.16}$$

The retarded distribution is causal: its support in the time variable lies in $t \geq 0$. Consequently, under the usual polynomial-growth hypotheses for tempered distributions, its Fourier transform is the boundary value from the upper half ω-plane.

Figure 124.2 records the causal support property of the retarded response function, which is the input for its upper-half-plane analytic Fourier transform.

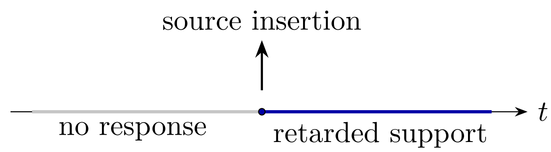

Figure 124.2: The retarded kernel is supported only after the source insertion. This causal support, not Euclidean periodicity alone, is what gives the upper-half-plane analyticity of $G^R(\omega)$.

For translation-invariant thermal QFT, the retarded two-point function of local densities is

$$G^R_{AB}(\omega,\mathbf{k}) = -\mathrm{i}\int_0^\infty \mathrm{d}t \int \mathrm{d}^{D-1}x\, \mathrm{e}^{\mathrm{i}\omega t - \mathrm{i}\mathbf{k}\cdot\mathbf{x}}\omega([A(t,\mathbf{x}),B(0,\mathbf{0})]). \tag{124.17}$$

With the Fourier convention (124.5), the spectral function associated to G^R is

$$\rho_{AB}(\omega,\mathbf{k}) = -2\,\operatorname{Im} G^R_{AB}(\omega+\mathrm{i}0,\mathbf{k}). \tag{124.18}$$

For Hermitian $A=B$, positivity of the finite-volume spectral weights gives $\rho_{AA}(\omega,\mathbf{k}) \geq 0$ for $\omega > 0$ before the thermodynamic limit. The infinite-volume statement is obtained by distributional limits, provided the local algebra and state have been constructed.

124.5 Conserved Densities and Hydrodynamic Variables

Hydrodynamics begins with conserved local currents in the microscopic theory. Let $T^{\mu\nu}$ be the stress tensor and let J^μ_A be conserved currents for ordinary internal symmetries:

$$\partial_\mu T^{\mu\nu} = 0, \qquad \partial_\mu J^\mu_A = 0. \tag{124.19}$$

In a homogeneous isotropic thermal state with unit future-timelike vector u^μ, temperature $T = \beta^{-1}$, and chemical potentials μ_A, the one-point functions define thermodynamic densities by

$$\omega(T^{\mu\nu}) = \varepsilon u^\mu u^\nu + p\Delta^{\mu\nu}, \qquad \omega(J^\mu_A) = n_A u^\mu, \qquad \Delta^{\mu\nu} = \eta^{\mu\nu} + u^\mu u^\nu. \tag{124.20}$$

Here ε is the energy density, p the pressure, and n_A the charge densities. These are numbers attached to a homogeneous equilibrium state. They become hydrodynamic fields only after one assumes a family of near-equilibrium states whose long-wavelength connected correlators are controlled by slowly varying local values of

$$T(x), \qquad \mu_A(x), \qquad u^\mu(x).$$

The derivative expansion is a statement about constitutive relations:

$$T^{\mu\nu} = T^{\mu\nu}_{(0)} + T^{\mu\nu}_{(1)} + T^{\mu\nu}_{(2)} + \cdots, \qquad J^\mu_A = J^\mu_{A,(0)} + J^\mu_{A,(1)} + J^\mu_{A,(2)} + \cdots, \tag{124.21}$$

where the subscript records the number of derivatives acting on T, μ_A, u^μ and on background sources. Existence of such an expansion requires hypotheses beyond the KMS boundary condition: it is a long-time, long-distance property of the QFT state.

First hydrodynamic poles from conservation. Let a homogeneous parity-even thermal state in $D = d_s + 1$ spacetime dimensions have enthalpy $w = \varepsilon + p > 0$, speed of sound

$$c_s^2 = \left(\frac{\partial p}{\partial \varepsilon}\right)_{n_A/s},$$

shear viscosity $\eta_{\rm sh}$, bulk viscosity ζ, and a decoupled charge-diffusion channel with conductivity σ and susceptibility $\chi > 0$. Linearizing the first-order constitutive relations around the homogeneous state gives the following small-$|\mathbf{k}|$ hydrodynamic denominators, and therefore the corresponding retarded poles in every conserved-current correlator whose residue on the mode is nonzero:

$$\omega_{\rm shear}(\mathbf{k}) = -\,\mathrm{i}\,\frac{\eta_{\rm sh}}{w}\,\mathbf{k}^2 + O(|\mathbf{k}|^4), \tag{124.22}$$

$$\omega_{\rm charge}(\mathbf{k}) = -\,\mathrm{i}\,\frac{\sigma}{\chi}\,\mathbf{k}^2 + O(|\mathbf{k}|^4), \tag{124.23}$$

and

$$\omega^{\pm}_{\rm sound}(\mathbf{k}) = \pm c_s|\mathbf{k}| - \frac{\mathrm{i}}{2w}\left(\zeta + \frac{2(d_s-1)}{d_s}\eta_{\rm sh}\right)\mathbf{k}^2 + O(|\mathbf{k}|^3). \tag{124.24}$$

Take $\mathbf{k}$ in the x-direction and use the Fourier convention $\mathrm{e}^{-\mathrm{i}\omega t + \mathrm{i}kx}$. In the shear channel a transverse velocity perturbation v_y obeys

$$-\mathrm{i}\omega\, w\, v_y + \eta_{\rm sh} k^2 v_y = 0,$$

which gives (124.22). In a decoupled charge channel, Fick's law $J^x_A = -\sigma\,\partial_x(\delta\mu_A)$ and $\delta n_A = \chi\,\delta\mu_A$ give

$$-\mathrm{i}\omega\,\delta n_A + \frac{\sigma}{\chi}k^2\delta n_A = 0,$$

which gives (124.23). For longitudinal sound, the linearized conservation equations are

$$-\mathrm{i}\omega\,\delta\varepsilon + \mathrm{i}k\,w\,v_x = 0,$$

$$-\mathrm{i}\omega\,w\,v_x + \mathrm{i}k\,c_s^2\delta\varepsilon + \left(\zeta + \frac{2(d_s-1)}{d_s}\eta_{\rm sh}\right)k^2 v_x = 0.$$

Eliminating v_x gives

$$\omega^2 - c_s^2k^2 + \frac{\mathrm{i}}{w}\left(\zeta + \frac{2(d_s-1)}{d_s}\eta_{\rm sh}\right)\omega k^2 = 0.$$

Solving this quadratic at small k gives (124.24). This calculation identifies the hydrodynamic poles of the retarded functions once the linearized constitutive relations, the long-distance derivative expansion, and the existence of the corresponding retarded correlators have been established.

Figure 124.3 depicts this analytic content of the hydrodynamic limit. The hydrodynamic variables are not new microscopic operators; they are the coordinates whose linearized equations describe the poles of retarded conserved-current correlators that approach the origin as $|\mathbf{k}| \to 0$.

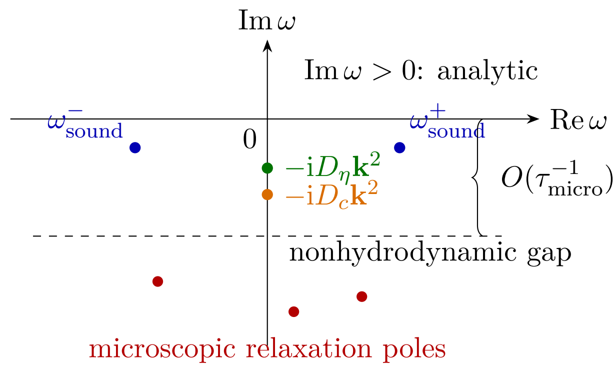

Figure 124.3: At fixed small $|\mathbf{k}|$, hydrodynamics appears in retarded thermal correlators as poles that approach the origin: two sound poles, a shear-diffusion pole with $D_\eta = \eta_{\text{sh}}/w$, and charge-diffusion poles with $D_c = \sigma/\chi$ in a decoupled channel. Nonhydrodynamic relaxation poles remain separated by a microscopic gap in a regime where the derivative expansion is controlled.

At first order, parity-even relativistic hydrodynamics in flat spacetime contains shear viscosity η_{sh}, bulk viscosity ζ, and charge-conductivity data. In the shear channel, couple a metric perturbation $h_{xy}(t)$ to T^{xy}. The linear-response formula gives

$$\delta\omega(T^{xy}(\omega)) = -\frac{1}{2} G^R_{T^{xy}T^{xy}}(\omega, \mathbf{0}) h_{xy}(\omega)$$

with the factor $1/2$ inherited from the metric coupling $\frac{1}{2}\int T^{ij} h_{ij}$. Comparing with the constitutive relation fixes

$$\eta_{\text{sh}} = \lim_{\omega \downarrow 0} \frac{\rho_{T^{xy}T^{xy}}(\omega, \mathbf{0})}{2\omega} = -\lim_{\omega \downarrow 0} \frac{\operatorname{Im} G^R_{T^{xy}T^{xy}}(\omega, \mathbf{0})}{\omega}. \tag{124.25}$$

This is a definition of the transport coefficient in terms of QFT correlators once the zero-frequency limit exists. Later chapters derive the constitutive relations, entropy-current constraints, Schwinger–Keldysh effective action, anomaly-induced transport, and kinetic limits from these correlator-level objects.

Open Problem 124.7 (Thermal real-time reconstruction). Give constructive hypotheses under which Euclidean finite-temperature Schwinger functions on $S^1_\beta \times \mathbb{R}^{D-1}$ reconstruct a real-time KMS QFT with local observables, spectral functions, and transport coefficients. The required analytic continuation is more delicate than the vacuum OS reconstruction because thermal correlators have periodic Euclidean time and no vacuum spectrum condition.

Chapter 125

Finite-Temperature Path Integrals

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter derives the Euclidean thermal path integral from the operator definition of equilibrium correlation functions. The derivation is first a finite-dimensional statement about a trace-class Gibbs operator. A field theory path integral on $S^1_\beta \times \mathbb{R}^{D-1}$ is obtained only after a spatial regulator, an operator-domain convention, and a limiting procedure have been specified. The circle, spin structure, Matsubara frequencies, and chemical-potential twists all follow from the trace formula.

125.1 Regulated Meaning of the Thermal Path Integral

The notation

$$\int [D\Phi]\, \mathrm{e}^{-S_E[\Phi]}$$

has a precise meaning only after one has specified the class of variables Φ, the algebra in which they take values, and the limiting operation. In this chapter it is used in the following restricted sense. One begins with a regulated quantum system with Hilbert space $\mathcal{H}_{\mathrm{reg}}$, a self-adjoint Hamiltonian H_{reg}, and a trace-class Gibbs operator $\mathrm{e}^{-\beta H_{\mathrm{reg}}}$. The thermal path integral is the finite time-sliced expression obtained by inserting resolutions of the identity in

$$\mathrm{Tr}_{\mathcal{H}_{\mathrm{reg}}}\, \mathrm{e}^{-\beta H_{\mathrm{reg}}}, \tag{125.1}$$

or in trace insertions with operators. Removing the regulator is a separate problem. It may be a lattice thermodynamic limit, a constructive continuum limit, a Hamiltonian limit, or a perturbative renormalized limit; the symbol $[D\Phi]$ alone does not specify which one is intended.

There are two algebraically different kinds of variables. Bosonic variables are ordinary commuting coordinates or fields at the regulator scale. Fermionic variables in a coherent-state path integral are generators of a finite Grassmann algebra at the regulator scale. Their "integration" is a Berezin linear functional. It is not a Borel measure on a set of fermionic field configurations. The continuum notation for fermionic fields therefore denotes the limit of a sequence of finite Grassmann-algebra calculations, not an ordinary measure space of anticommuting points.

125.2 Gibbs Traces and Euclidean Correlators

Let $\mathcal{H}$ be a Hilbert space and let H be a self-adjoint Hamiltonian bounded below. Fix $\beta > 0$ and assume, in this finite-volume discussion, that

$$Z(\beta) = \mathrm{Tr}_{\mathcal{H}}\, \mathrm{e}^{-\beta H} < \infty.$$

The Gibbs state is the positive normalized functional

$$\omega_\beta(A) = Z(\beta)^{-1}\, \mathrm{Tr}_{\mathcal{H}}(\mathrm{e}^{-\beta H} A)$$

on bounded operators A, and on suitable unbounded operators after a common trace-class domain has been declared. For Heisenberg operators

$$A(t) = \mathrm{e}^{\mathrm{i}Ht} A \mathrm{e}^{-\mathrm{i}Ht},$$

their Euclidean-time translates are

$$A_E(\tau) = \mathrm{e}^{\tau H} A \mathrm{e}^{-\tau H}, \qquad 0 \le \tau \le \beta,$$

whenever the displayed expression is defined as a quadratic form or as a trace insertion. If

$$0 < \tau_1 < \tau_2 < \cdots < \tau_n < \beta,$$

the Euclidean thermal correlator is

$$G_E(\tau_1, \ldots, \tau_n) = Z(\beta)^{-1}\, \mathrm{Tr}\Big(\mathrm{e}^{-\beta H} A_{n,E}(\tau_n) \cdots A_{1,E}(\tau_1)\Big)\,. \tag{125.2}$$

Moving the factor $\mathrm{e}^{-\beta H}$ cyclically through the trace shifts one operator by β in imaginary time. This is the finite-volume operator origin of the KMS boundary condition in Chapter 124.

Remark 125.1 (Trace cyclicity gives the thermal circle). Let A and B be bounded operators such that the traces below exist. For $0 < \tau < \beta$,

$$\omega_\beta(A_E(\tau)B) = \omega_\beta(B A_E(\tau - \beta)).$$

Equivalently, after analytic continuation $t = -\mathrm{i}\tau$, the two boundary values of the strip correlator differ by a cyclic permutation of the operators.

Using $A_E(\tau) = \mathrm{e}^{\tau H} A \mathrm{e}^{-\tau H}$,

$$\begin{aligned}
\mathrm{Tr}(\mathrm{e}^{-\beta H} A_E(\tau) B) &= \mathrm{Tr}(\mathrm{e}^{-(\beta-\tau)H} A \mathrm{e}^{-\tau H} B) \\
&= \mathrm{Tr}(B \mathrm{e}^{-(\beta-\tau)H} A \mathrm{e}^{-\tau H}) \\
&= \mathrm{Tr}(\mathrm{e}^{-\beta H} B\, \mathrm{e}^{(\tau-\beta)H} A \mathrm{e}^{-(\tau-\beta)H}).
\end{aligned}$$

Dividing by $Z(\beta)$ gives the stated identity.

125.3 Time Slicing and Bosonic Boundary Conditions

Let $q = (q^1, \dots, q^r)$ be a configuration coordinate for a regulated bosonic quantum system. Let $\{|q\rangle\}$ be a generalized coordinate resolution of the identity. For

$$\beta = N\epsilon,$$

the partition function is

$$Z(\beta) = \int \prod_{j=1}^{N} dq_j \prod_{j=1}^{N} K_\epsilon(q_{j+1}, q_j), \qquad q_{N+1} = q_1, \tag{125.3}$$

where

$$K_\epsilon(q', q) = \langle q'|\mathrm{e}^{-\epsilon H}|q\rangle.$$

The equality is the trace written as

$$\int dq_1 \, \langle q_1|(\mathrm{e}^{-\epsilon H})^N|q_1\rangle$$

with $N-1$ intermediate identity insertions. The condition $q_{N+1} = q_1$ is therefore exact at finite N.

For a local bosonic field with a spatial regulator, the same formula has one coordinate q_j for every spatial lattice degree of freedom at Euclidean time slice j. A formal continuum notation for the result is

$$Z(\beta) = \int_{\phi(\tau+\beta,\mathbf{x})=\phi(\tau,\mathbf{x})} [D\phi]_{\mathrm{reg}} \, \mathrm{e}^{-S_E[\phi]}.$$

The subscript reg is part of the formula: it denotes the particular lattice, constructive, Hamiltonian, or perturbative regulator from which the expression is obtained. The Euclidean time direction is a circle because the trace identifies the final and initial bosonic coordinates.

125.4 Fermionic Coherent States and Spin Structure

Let $c_i, c_i^\dagger$, $i = 1, \dots, r$, be fermionic annihilation and creation operators with

$$\{c_i, c_j^\dagger\} = \delta_{ij}, \qquad \{c_i, c_j\} = \{c_i^\dagger, c_j^\dagger\} = 0.$$

Let $\eta_i, \bar\eta_i$ be independent Grassmann variables. The coherent state

$$|\eta\rangle = \mathrm{e}^{-\sum_i \eta_i c_i^\dagger}|0\rangle$$

satisfies

$$c_i|\eta\rangle = \eta_i|\eta\rangle,$$

where the sign comes from moving the odd operator c_i through the odd coefficient η_i. The resolution of identity has the form

$$\mathbf{1} = \int \prod_i d\bar\eta_i \, d\eta_i \, \mathrm{e}^{-\bar\eta\eta} \, |\eta\rangle\langle\eta|, \qquad \bar\eta\eta = \sum_i \bar\eta_i \eta_i.$$

Definition 125.2 (Berezin integral at finite regulator)**.** Let Λ be the Grassmann algebra generated by $\eta_1, \dots, \eta_r, \bar\eta_1, \dots, \bar\eta_r$. The ordered Berezin integral

$$\int \prod_{i=1}^{r} d\bar\eta_i \, d\eta_i : \Lambda \longrightarrow \mathbb{C}$$

is the linear functional fixed by

$$\int \prod_{i=1}^{r} d\bar\eta_i \, d\eta_i \prod_{i=1}^{r} \bar\eta_i \eta_i = (-1)^r \tag{125.4}$$

and by the requirement that every monomial missing at least one generator integrates to zero. Equivalently,

$$\int \prod_{i=1}^{r} d\bar\eta_i \, d\eta_i \, \exp\left(- \sum_i \bar\eta_i \eta_i \right) = 1. \tag{125.5}$$

The variables $\eta_i, \bar\eta_i$ are algebra generators, not complex numbers. The integral is a linear functional on Λ, not a positive measure.

Fermionic trace identity. For every operator O on the finite fermionic Fock space,

$$\operatorname{Tr} O = \int d\bar\eta \, d\eta \, \mathrm{e}^{-\bar\eta\eta} \, \langle -\eta | O | \eta \rangle,$$

whereas

$$\operatorname{Tr}((-1)^F O) = \int d\bar\eta \, d\eta \, \mathrm{e}^{-\bar\eta\eta} \, \langle \eta | O | \eta \rangle.$$

It is enough to check one fermionic mode, since the r-mode formula is the ordered tensor product of one-mode identities with the ordering in Definition 125.2. In the basis $|0\rangle, |1\rangle = c^\dagger |0\rangle$, expand O as a 2×2 matrix and use

$$|\eta\rangle = |0\rangle - \eta |1\rangle, \qquad \langle \eta | = \langle 0 | - \langle 1 | \bar\eta.$$

Write $O_{ab} = \langle a | O | b \rangle$. Since $\langle -\eta | = \langle 0 | + \langle 1 | \bar\eta$,

$$\mathrm{e}^{-\bar\eta\eta} \langle -\eta | O | \eta \rangle = O_{00} - O_{01}\eta + \bar\eta O_{10} - (O_{00} + O_{11}) \bar\eta\eta.$$

With the convention $\int d\bar\eta \, d\eta \, \bar\eta\eta = -1$, the integral is $O_{00} + O_{11} = \operatorname{Tr} O$. Similarly,

$$\mathrm{e}^{-\bar\eta\eta} \langle \eta | O | \eta \rangle = O_{00} - O_{01}\eta - \bar\eta O_{10} - (O_{00} - O_{11}) \bar\eta\eta,$$

whose integral is $O_{00} - O_{11} = \operatorname{Tr}((-1)^F O)$.

Applying this finite coherent-state trace identity to $(\mathrm{e}^{-\epsilon H})^N$ gives the thermal Grassmann time-sliced integral. The first and last coherent-state labels obey

$$\eta_{N+1} = -\eta_1, \qquad \bar\eta_{N+1} = -\bar\eta_1$$

for the ordinary thermal partition function. Thus fermionic variables in the thermal trace are antiperiodic on S^1_β:

$$\psi(\tau + \beta, \mathbf{x}) = -\psi(\tau, \mathbf{x}), \qquad \bar\psi(\tau + \beta, \mathbf{x}) = -\bar\psi(\tau, \mathbf{x}).$$

The graded trace $\mathrm{Tr}((-1)^F e^{-\beta H}\cdots)$ uses the periodic spin structure. This is the operator origin of the distinction between a thermal partition function and a supersymmetric index.

Figure 125.1 records the trace-gluing convention: bosons are periodic on S^1_β, fermions are antiperiodic for the thermal trace, and the graded trace uses the periodic spin structure.

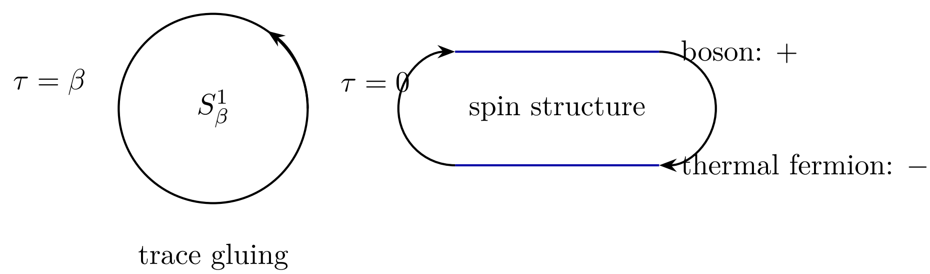

Figure 125.1: The thermal trace glues the end of the Euclidean time interval to its beginning. Coordinate variables are periodic, while ordinary thermal fermionic coherent-state variables are antiperiodic because the trace identity contains $\langle -\eta|$.

125.5 Matsubara Modes as Circle Eigenfunctions

Let $f(\tau)$ be a field component on the Euclidean thermal circle obeying

$$f(\tau+\beta) = s f(\tau), \qquad s = \pm 1.$$

An eigenfunction of $-i\partial_\tau$ has the form $e^{i\omega\tau}$. The boundary condition requires

$$e^{i\omega\beta} = s.$$

Hence

$$\omega_n^{\mathrm{B}} = \frac{2\pi n}{\beta}, \qquad n \in \mathbb{Z},$$

for periodic bosonic variables, and

$$\omega_n^{\mathrm{F}} = \frac{(2n+1)\pi}{\beta}, \qquad n \in \mathbb{Z},$$

for antiperiodic fermionic variables.

Let

$$K = -\partial_\tau^2 - \Delta_{\mathbf{x}} + m^2$$

on periodic functions on $S^1_\beta \times \mathbb{R}^{D-1}$. The translation invariant inverse of K, as a distribution, is

$$G_E(\tau,\mathbf{x}) = \frac{1}{\beta}\sum_{n\in\mathbb{Z}} \int \frac{d^{D-1}k}{(2\pi)^{D-1}} \frac{e^{i\omega_n^{\mathrm{B}}\tau + i\mathbf{k}\cdot\mathbf{x}}}{(\omega_n^{\mathrm{B}})^2 + \mathbf{k}^2 + m^2}.$$

The functions

$$\beta^{-1/2} e^{i\omega_n^{\mathrm{B}}\tau}$$

form the Fourier basis of $L^2(S^1_\beta)$, and plane waves form the Fourier basis in the spatial directions. Acting with K on one mode multiplies it by

$$(\omega_n^{\mathrm{B}})^2 + \mathbf{k}^2 + m^2.$$

The displayed kernel is therefore the spectral inverse of K on each Fourier mode. Applying K to it gives the periodic delta distribution on S^1_β times $\delta^{D-1}(\mathbf{x})$.

For fermions, the same diagonalization applies to the chosen Euclidean Dirac operator, but the frequency set is shifted to ω_n^{F}. The shift is a spin-structure effect, not a perturbative convention.

125.6 Thermal Spectral Representation and Analytic Continuation

The Euclidean circle values determine real-time response only after the analytic continuation problem has been specified. The finite-volume spectral formula makes the required data explicit. Let A and B be bosonic operators, and let $|n\rangle$ be an eigenbasis of H with

$$H|n\rangle = E_n|n\rangle.$$

For $0 < \tau < \beta$,

$$G_E^{AB}(\tau) = Z(\beta)^{-1} \sum_{m,n} \mathrm{e}^{-\beta E_n} \mathrm{e}^{-\tau(E_m - E_n)} A_{nm} B_{mn}.$$

The terms with $E_m = E_n$ are independent of τ. Denote this zero-frequency contribution by

$$G_0^{AB} = Z(\beta)^{-1} \sum_{m,n:E_m=E_n} \mathrm{e}^{-\beta E_n} A_{nm} B_{mn}.$$

For the remaining transitions define the thermal spectral distribution

$$\rho_{AB}(\omega) = Z(\beta)^{-1} \sum_{m,n:E_m \neq E_n} \left(\mathrm{e}^{-\beta E_n} - \mathrm{e}^{-\beta E_m}\right) A_{nm} B_{mn}\, \delta(\omega - (E_m - E_n)). \tag{125.6}$$

Then

$$G_E^{AB}(\tau) = G_0^{AB} + \int_{\mathbb{R}} \frac{\mathrm{e}^{-\omega\tau}}{1 - \mathrm{e}^{-\beta\omega}}\, \rho_{AB}(\omega)\, d\omega, \qquad 0 < \tau < \beta. \tag{125.7}$$

Indeed, on the support $\omega = E_m - E_n$,

$$\frac{\mathrm{e}^{-\beta E_n} - \mathrm{e}^{-\beta E_m}}{1 - \mathrm{e}^{-\beta\omega}} = \mathrm{e}^{-\beta E_n}.$$

The explicit G_0^{AB} term is necessary: it is invisible in the commutator spectral density because the numerator in (125.6) vanishes at $\omega = 0$.

The bosonic Matsubara transform is

$$G_E^{AB}(\mathrm{i}\omega_\ell^{\mathrm{B}}) = \int_0^\beta d\tau\, \mathrm{e}^{\mathrm{i}\omega_\ell^{\mathrm{B}}\tau} G_E^{AB}(\tau).$$

Using $\mathrm{e}^{\mathrm{i}\omega_\ell^{\mathrm{B}}\beta} = 1$ in (125.7) gives

$$G_E^{AB}(\mathrm{i}\omega_\ell^{\mathrm{B}}) = \beta G_0^{AB}\delta_{\ell 0} + \int_{\mathbb{R}} \frac{\rho_{AB}(\omega)}{\omega - \mathrm{i}\omega_\ell^{\mathrm{B}}}\, d\omega. \tag{125.8}$$

For fermionic operators the graded spectral density and the denominator $1 + \mathrm{e}^{-\beta\omega}$ replace the bosonic ones; the antiperiodic identity $\mathrm{e}^{\mathrm{i}\omega_\ell^{\mathrm{F}}\beta} = -1$ gives the same Cauchy-transform form with ω_ℓ^{F}.

The retarded correlator is the boundary value of a function obtained from the same spectral density,

$$G_R^{AB}(z) = \int_{\mathbb{R}} \frac{\rho_{AB}(\omega)}{\omega - z}\, d\omega, \qquad \operatorname{Im} z > 0,$$

under the growth and distributional hypotheses required for the integral. Thus the rule

$$\mathrm{i}\omega_n \mapsto \omega + \mathrm{i}0$$

is a shorthand for a spectral reconstruction problem. It is justified when the Euclidean data determine a spectral distribution with the stated analytic control; the discrete Matsubara values alone do not constitute such a proof.

125.7 Chemical Potentials, Twists, and Holonomies

Let Q be the self-adjoint generator of a global $U(1)$ symmetry and assume $[H, Q] = 0$. The grand-canonical Gibbs operator is

$$\mathrm{e}^{-\beta(H-\mu Q)}.$$

If an operator Φ_q has charge q,

$$[Q, \Phi_q] = q\Phi_q,$$

then moving $\mathrm{e}^{\beta\mu Q}$ through Φ_q gives

$$\mathrm{e}^{\beta\mu Q}\Phi_q \mathrm{e}^{-\beta\mu Q} = \mathrm{e}^{\beta\mu q}\Phi_q.$$

Consequently the Euclidean coordinate representation may be written in two equivalent ways:

$$D_\tau \longmapsto D_\tau - \mu q$$

with the original thermal boundary condition, or as a twisted boundary condition

$$\Phi_q(\tau + \beta, \mathbf{x}) = s\, \mathrm{e}^{\beta\mu q}\Phi_q(\tau, \mathbf{x}), \qquad s = +1 \text{ for bosons}, \quad s = -1 \text{ for fermions}.$$

For imaginary chemical potential $\mu = \mathrm{i}\nu$, the twist is a unitary background holonomy

$$\exp(\mathrm{i}\beta\nu q)$$

around S^1_β. If the $U(1)$ is compact and the charges are integers in the chosen normalization, large background gauge transformations identify

$$\nu \sim \nu + \frac{2\pi}{\beta}.$$

For real μ, the Euclidean action of a relativistic theory is generally complex in common field coordinates; this is the operator origin of the finite-density sign problem discussed later in this volume.

125.8 Gauge Fields on the Thermal Circle

For a gauge theory, the Euclidean thermal path integral integrates over connections on $S^1_\beta \times \Sigma$ modulo gauge transformations whose periodicity is compatible with the chosen bundle and matter boundary conditions. The component A_τ has a gauge-invariant zero-mode datum: the thermal holonomy

$$\mathcal{P}(\mathbf{x}) = \mathrm{Pexp}\left(\int_0^\beta A_\tau(\tau, \mathbf{x})\, d\tau\right),$$

defined up to conjugation. In a compact lattice regulator this holonomy is the Polyakov loop variable developed in Chapter 46. In a continuum gauge-fixed coordinate chart it should not be discarded as a pure-gauge variable: a gauge transformation that removes a constant A_τ may fail to be periodic around the thermal circle.

The gauge-theory thermal trace is over the physical Hilbert space, or equivalently over gauge-invariant states after imposing Gauss constraints. In the Euclidean path integral this appears as integration over gauge holonomies rather than fixing a chemical potential for a local gauge charge. External background holonomies may be fixed for global symmetries. Dynamical gauge holonomies are integrated, and their center transformations encode the thermal one-form symmetry data discussed in the gauge-theory volumes.

Open Problem 125.3 (Euclidean thermal reconstruction). Give constructive hypotheses under which Schwinger functions on $S^1_\beta \times \mathbb{R}^{D-1}$, with the appropriate spin structure and background holonomies, reconstruct a real-time KMS state with local observables, spectral functions, and transport correlators. The hypotheses must replace the vacuum spectrum condition by precise thermal analyticity and growth bounds and must specify the operator topology in which the infinite-volume limit is taken.

Chapter 126

Real-Time Schwinger–Keldysh Formalism

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The Schwinger–Keldysh formalism is the real-time generating functional for correlation and response functions in a specified initial state. It is an operator identity before it is a path integral. The doubled fields and sources are a bookkeeping device for the two sides of a trace, and the fundamental constraints come from unitarity, positivity of the density operator, and, in thermal equilibrium, the KMS condition.

126.1 Finite-System Definition

Let $\mathcal{H}$ be a Hilbert space, let H be a self-adjoint Hamiltonian, and let ρ_0 be a positive trace-class density operator with

$$\operatorname{Tr} \rho_0 = 1.$$

Let O_α, $\alpha \in \mathcal{I}$, be a finite or regulated family of Hermitian operators. For real compactly supported sources $J^\alpha(t)$, define the source-dependent Hamiltonian

$$H_J(t) = H - \sum_{\alpha \in \mathcal{I}} J^\alpha(t) O_\alpha.$$

The evolution operator $U_J(t,t_i)$ is the solution of

$$\mathrm{i}\frac{d}{dt}U_J(t,t_i) = H_J(t)U_J(t,t_i), \qquad U_J(t_i,t_i) = \mathbf{1},$$

equivalently

$$U_J(t_f,t_i) = \mathrm{T}\exp\left[-\mathrm{i}\int_{t_i}^{t_f} dt\,\left(H - \sum_\alpha J^\alpha(t)O_\alpha\right)\right].$$

The closed-time-path generating functional is

$$Z[J_+,J_-] = \mathrm{Tr}\Big(U_{J_+}(t_f,t_i)\rho_0 U_{J_-}(t_f,t_i)^\dagger\Big)\,. \tag{126.1}$$

The $+$ and $-$ labels record whether a source acts on the forward or backward side of the trace. The physical source is obtained on the diagonal $J_+ = J_-$.

126.2 Closed Contour Notation as a Trace Identity

It is often convenient to replace (126.1) by a single contour-ordered expression. This notation is shorthand for an operator identity, not an additional axiom. Let $\mathcal{C}$ be the oriented contour that runs from t_i to t_f on the $+$ branch and then from t_f back to t_i on the $-$ branch. Define

$$\int_{\mathcal{C}} dt_{\mathcal{C}}\, J^\alpha_{\mathcal{C}} O_\alpha = \int_{t_i}^{t_f} dt\, J^\alpha_+(t)O_\alpha(t) - \int_{t_i}^{t_f} dt\, J^\alpha_-(t)O_\alpha(t). \tag{126.2}$$

The minus sign is the orientation of the backward branch. The contour ordering operator $\mathrm{T}_{\mathcal{C}}$ orders later contour points to the left. With the interaction-picture convention determined by the unperturbed Hamiltonian,

$$Z[J_+,J_-] = \mathrm{Tr}\left(\rho_0\ \mathrm{T}_{\mathcal{C}}\exp\left[\mathrm{i}\int_{\mathcal{C}} dt_{\mathcal{C}}\, J^\alpha_{\mathcal{C}}(t_{\mathcal{C}})O_\alpha(t_{\mathcal{C}})\right]\right). \tag{126.3}$$

Expanding the contour exponential reproduces the four derivative rules below because insertions on the backward branch are anti-time ordered and carry the orientation sign in (126.2).

Figure 126.1 fixes the closed-time-path orientation used in the Schwinger–Keldysh generating functional: the forward branch is time-ordered, the backward branch is anti-time-ordered, and the source integral carries the contour orientation.

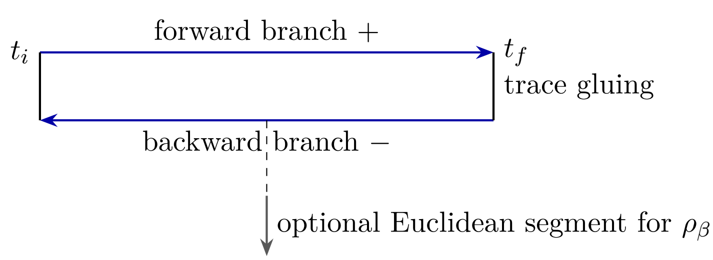

Figure 126.1: The closed time path is a compact notation for $\mathrm{Tr}(U_{J_+}\rho_0 U^\dagger_{J_-})$. The backward branch has the opposite orientation. For a thermal initial state, the density matrix may itself be represented by a Euclidean segment of length β, but that segment is the representation of ρ_β, not part of the real-time evolution.

Definition 126.1 (Closed-time-path correlators)**.** The Schwinger–Keldysh correlators of the regulated system are the functional derivatives of $Z[J_+, J_-]$ at $J_+ = J_- = 0$. Differentiation with respect to J_+ inserts operators on the forward branch with time ordering; differentiation with respect to J_- inserts operators on the backward branch with anti-time ordering and an opposite sign from the adjoint evolution.

For example, in the unperturbed Heisenberg convention

$$O_\alpha(t) = \mathrm{e}^{\mathrm{i}H(t-t_i)} O_\alpha \mathrm{e}^{-\mathrm{i}H(t-t_i)},$$

one has

$$\left.\frac{\delta Z}{\delta J_+^\alpha(t)}\right|_0 = \mathrm{i}\ \mathrm{Tr}(\rho_0 O_\alpha(t)), \qquad \left.\frac{\delta Z}{\delta J_-^\alpha(t)}\right|_0 = -\mathrm{i}\ \mathrm{Tr}(\rho_0 O_\alpha(t)).$$

Higher derivatives give the four contour orderings. With two insertions,

$$\frac{1}{\mathrm{i}^2} \left.\frac{\delta^2 Z}{\delta J_+^\alpha(t) \delta J_+^\beta(t')}\right|_0 = \mathrm{Tr}\big(\rho_0\ \mathrm{T}\, O_\alpha(t) O_\beta(t')\big)\,, \tag{126.4}$$

$$\frac{1}{(-\mathrm{i})^2} \left.\frac{\delta^2 Z}{\delta J_-^\alpha(t) \delta J_-^\beta(t')}\right|_0 = \mathrm{Tr}\Big(\rho_0\ \widetilde{\mathrm{T}} O_\alpha(t) O_\beta(t')\Big)\,, \tag{126.5}$$

$$\frac{1}{\mathrm{i}(-\mathrm{i})} \left.\frac{\delta^2 Z}{\delta J_+^\alpha(t) \delta J_-^\beta(t')}\right|_0 = \mathrm{Tr}\big(\rho_0\, O_\beta(t') O_\alpha(t)\big)\,, \tag{126.6}$$

$$\frac{1}{(-\mathrm{i})\mathrm{i}} \left.\frac{\delta^2 Z}{\delta J_-^\alpha(t) \delta J_+^\beta(t')}\right|_0 = \mathrm{Tr}\big(\rho_0\, O_\alpha(t) O_\beta(t')\big)\,. \tag{126.7}$$

These formulae are finite trace identities. In a continuum QFT the same symbols require a regulator, an operator topology, and a limiting procedure.

126.3 Unitarity, Reality, and Positivity Constraints

Setting the two sources equal gives

$$Z[J, J] = \mathrm{Tr}(U_J \rho_0 U_J^\dagger) = \mathrm{Tr}\,\rho_0 = 1. \tag{126.8}$$

This is the closed-time-path normalization constraint.

Basic Schwinger–Keldysh constraints. For real sources in the finite system above, unitarity and positivity give

$$Z[J, J] = 1, \tag{126.9}$$

$$Z[J_+, J_-]^* = Z[J_-, J_+], \tag{126.10}$$

$$|Z[J_+, J_-]| \leq 1. \tag{126.11}$$

If $Z = \exp(\mathrm{i}W)$ is defined by the branch with $W[0,0] = 0$, then near the origin

$$W[J, J] = 0, \qquad W[J_+, J_-]^* = -W[J_-, J_+], \qquad \mathrm{Im}\, W[J_+, J_-] \geq 0.$$

The first identity is (126.8). For real sources U_J is unitary, and complex conjugation of the trace gives

$$Z[J_+, J_-]^* = \mathrm{Tr}(U_{J_-}\rho_0 U_{J_+}^\dagger) = Z[J_-, J_+].$$

For the bound, write

$$Z[J_+, J_-] = \mathrm{Tr}\Big(\rho_0\, U_{J_-}^\dagger\, U_{J_+}\Big)\,.$$

The operator $V = U_{J_-}^\dagger\, U_{J_+}$ is unitary. Since ρ_0 is a positive normalized density matrix, $Z = \omega_{\rho_0}(V)$ is an expectation value of a unitary in a state. Cauchy–Schwarz for the positive inner product

$$(A, B)_{\rho_0} = \mathrm{Tr}(\rho_0 A^\dagger B)$$

gives

$$|Z|^2 \le \mathrm{Tr}(\rho_0 \mathbf{1})\,\mathrm{Tr}(\rho_0 V^\dagger V) = 1.$$

The statements about W follow from $Z = \exp(\mathrm{i}W)$ on the branch connected to $Z = 1$.

Equation (126.8) implies that all derivatives of Z or W with respect only to a common physical source vanish on the diagonal. This is the origin of the rule that every local term in a Schwinger–Keldysh effective action contains at least one difference field.

Largest-time cancellation. Let $T \in (t_i, t_f)$. If $J_+(t) = J_-(t) = J(t)$ for $T \le t \le t_f$, then $Z[J_+, J_-]$ is independent of the common future source J on that interval. Consequently every contour correlator in which the latest-time insertion is generated by variation of the common physical source cancels after summing over the two branches.

Factor the two evolution operators at T:

$$U_{J_\pm}(t_f, t_i) = U_J(t_f, T) U_{J_\pm}(T, t_i),$$

because the two sources agree on $[T, t_f]$. Substitution in (126.1) gives

$$Z[J_+, J_-] = \mathrm{Tr}\Big(U_J(t_f, T) U_{J_+}(T, t_i)\rho_0 U_{J_-}(T, t_i)^\dagger U_J(t_f, T)^\dagger\Big)\,.$$

Cyclicity of the trace and $U_J(t_f, T)^\dagger U_J(t_f, T) = \mathbf{1}$ give

$$Z[J_+, J_-] = \mathrm{Tr}\Big(U_{J_+}(T, t_i)\rho_0 U_{J_-}(T, t_i)^\dagger\Big)\,,$$

which contains no source on $[T, t_f]$. Functional differentiation with respect to such a common future source therefore gives zero. Taking T just below the latest insertion gives the stated largest-time identity. This is the finite trace form of the largest-time cancellation rule; the continuum use of the rule inherits the regulator and limiting assumptions of the closed-time-path functional.

126.4 The r/a Basis and Retarded Response

Introduce average and difference sources

$$J_{\mathrm{r}}^\alpha = \frac{1}{2}(J_+^\alpha + J_-^\alpha), \qquad J_{\mathrm{a}}^\alpha = J_+^\alpha - J_-^\alpha.$$

Equivalently,

$$J_+^\alpha = J_\mathrm{r}^\alpha + \frac{1}{2}J_\mathrm{a}^\alpha, \qquad J_-^\alpha = J_\mathrm{r}^\alpha - \frac{1}{2}J_\mathrm{a}^\alpha.$$

The connected generating functional is

$$W[J_\mathrm{r}, J_\mathrm{a}] = -\mathrm{i}\log Z[J_\mathrm{r}, J_\mathrm{a}], \qquad W[0,0] = 0.$$

The expectation value in the physical source J_r is

$$\langle O_\alpha(t)\rangle_{J_\mathrm{r}} = \left.\frac{\delta W}{\delta J_\mathrm{a}^\alpha(t)}\right|_{J_\mathrm{a}=0}. \tag{126.12}$$

At zero source this follows from the one-point identities above:

$$\left.\frac{\delta Z}{\delta J_\mathrm{a}^\alpha(t)}\right|_0 = \frac{1}{2}\left(\mathrm{i}\langle O_\alpha(t)\rangle + \mathrm{i}\langle O_\alpha(t)\rangle\right) = \mathrm{i}\langle O_\alpha(t)\rangle.$$

Source-response kernel from r/a differentiation. With the source convention $H_J = H - J^\alpha O_\alpha$,

$$\frac{\delta}{\delta J_\mathrm{r}^\beta(t')}\left.\frac{\delta W}{\delta J_\mathrm{a}^\alpha(t)}\right|_{J_\mathrm{r}=J_\mathrm{a}=0} = K_{\alpha\beta}^R(t,t'), \tag{126.13}$$

where

$$K_{\alpha\beta}^R(t,t') = \mathrm{i}\,\theta(t-t')\ \mathrm{Tr}\big(\rho_0[O_\alpha(t), O_\beta(t')]\big). \tag{126.14}$$

If the commutator-retarded convention is

$$G_{\alpha\beta}^{R,\mathrm{comm}}(t,t') = -\mathrm{i}\,\theta(t-t')\ \mathrm{Tr}\big(\rho_0[O_\alpha(t), O_\beta(t')]\big),$$

then $K_{\alpha\beta}^R = -G_{\alpha\beta}^{R,\mathrm{comm}}$. The sign is fixed by the source coupling $H_J = H - J^\gamma O_\gamma$, with summation over $\gamma \in \mathcal{I}$.

Let J_r be the same physical source on both branches. To first order in the source, the interaction-picture evolution gives

$$U_J(t,t_i) = U_0(t,t_i)\left[1 + \mathrm{i}\int_{t_i}^t ds\, J_\mathrm{r}^\beta(s) O_\beta(s) + O(J_\mathrm{r}^2)\right].$$

Inserting this in the Heisenberg expectation of $O_\alpha(t)$ gives

$$\begin{aligned}\delta\langle O_\alpha(t)\rangle &= \mathrm{i}\int_{t_i}^t ds\, J_\mathrm{r}^\beta(s)\ \mathrm{Tr}(\rho_0[O_\alpha(t), O_\beta(s)]) \\ &= \int ds\, J_\mathrm{r}^\beta(s)\ \big[\mathrm{i}\theta(t-s)\,\mathrm{Tr}(\rho_0[O_\alpha(t), O_\beta(s)])\big].\end{aligned}$$

Combining this linear-response identity with (126.12) gives the displayed derivative of W. The derivation is a finite-system sign check for the source convention. Its continuum counterpart is the regulated linear-response identity for the renormalized source and operator pair.

The same statement can be read directly from contour ordering. The derivative with respect to J_a inserts the physical operator whose expectation value is measured; the derivative with respect to J_r inserts the perturbation. The cancellation between the two contour branches removes all terms in which the perturbation is later than the measured operator, leaving the causal source-response commutator $\mathrm{i}\theta(t-t')\,\mathrm{Tr}(\rho_0[O_\alpha(t), O_\beta(t')])$.

126.5 Two-Point Matrix

For a bosonic Hermitian operator O, define

$$G^{>}(t,t') = \mathrm{Tr}(\rho_0 O(t) O(t')), \qquad G^{<}(t,t') = \mathrm{Tr}(\rho_0 O(t') O(t)).$$

The contour-ordered functions are

$$G_{++}(t,t') = \theta(t-t')G^{>}(t,t') + \theta(t'-t)G^{<}(t,t'), \tag{126.15}$$
$$G_{--}(t,t') = \theta(t'-t)G^{>}(t,t') + \theta(t-t')G^{<}(t,t'), \tag{126.16}$$
$$G_{-+}(t,t') = G^{>}(t,t'), \tag{126.17}$$
$$G_{+-}(t,t') = G^{<}(t,t'). \tag{126.18}$$

In the r/a basis the independent linear-response and fluctuation data are

$$G^{R,\mathrm{comm}}(t,t') = -\mathrm{i}\theta(t-t')\big(G^{>}(t,t') - G^{<}(t,t')\big),$$

$$G^{A,\mathrm{comm}}(t,t') = \mathrm{i}\theta(t'-t)\big(G^{>}(t,t') - G^{<}(t,t')\big),$$

$$G^{K}(t,t') = G^{>}(t,t') + G^{<}(t,t').$$

The component with two difference-type operator insertions vanishes:

$$G^{\mathrm{aa}}(t,t') = 0.$$

This is another form of $Z[J_\mathrm{r}, J_\mathrm{a} = 0] = 1$. The rr component is the symmetrized fluctuation, while ra and ar contain the causal response kernels. With the source convention $H - J^\alpha O_\alpha$, the physical source-response kernel is the negative of $G^{R,\mathrm{comm}}$.

126.6 Thermal KMS Constraint on the Contour

Let

$$\rho_\beta = Z(\beta)^{-1}\mathrm{e}^{-\beta H}.$$

For operators whose thermal strip analytic continuation is controlled, cyclicity of the trace gives

$$\mathrm{Tr}(\rho_\beta A(t) B(0)) = \mathrm{Tr}(\rho_\beta B(0) A(t+\mathrm{i}\beta)).$$

In frequency space this becomes detailed balance:

$$G^{<}(\omega) = \mathrm{e}^{-\beta\omega} G^{>}(\omega)$$

for bosonic operators in the convention of Chapter 124. Therefore

$$G^{K}(\omega) = \coth\!\left(\frac{\beta\omega}{2}\right)\big(G^{>}(\omega) - G^{<}(\omega)\big).$$

Since

$$G^{R,\mathrm{comm}}(\omega) - G^{A,\mathrm{comm}}(\omega) = -\mathrm{i}\big(G^{>}(\omega) - G^{<}(\omega)\big)$$

with the commutator-retarded convention above, the fluctuation-dissipation relation is

$$G^K(\omega) = \mathrm{i}\coth\left(\frac{\beta\omega}{2}\right)\left(G^{R,\mathrm{comm}}(\omega) - G^{A,\mathrm{comm}}(\omega)\right).$$

For fermionic operators the graded KMS condition replaces the hyperbolic cotangent by the hyperbolic tangent in the corresponding anticommutator fluctuation function.

Thermal Schwinger–Keldysh path integrals often implement this condition by adding an imaginary Euclidean segment of length β to the contour or, in effective theory, by imposing a dynamical KMS symmetry. Both formulations express the same operator statement: the initial density matrix is the Gibbs operator and the required strip analyticity exists.

126.7 Coordinate Path Integrals

A Schwinger–Keldysh path integral is a coordinate representation of (126.1). For a regulated bosonic configuration variable q, inserting coordinate resolutions of identity on both sides of the trace gives two histories

$$q_+(t), \qquad q_-(t),$$

with a final-time gluing condition implementing the trace:

$$q_+(t_f) = q_-(t_f).$$

The initial density matrix contributes its coordinate kernel

$$\rho_0(q_+(t_i), q_-(t_i)).$$

In formal continuum notation,

$$Z[J_+, J_-] = \int_{\mathrm{SK}} Dq_+ Dq_-\ \rho_0(q_+(t_i), q_-(t_i))\ \exp\left\{\mathrm{i}S[q_+] - \mathrm{i}S[q_-] + \mathrm{i}\int J_+ O[q_+] - \mathrm{i}\int J_- O[q_-]\right\}.$$

This formula has the same logical status as every path integral in the monograph: its meaning is supplied by the finite regulator or constructive definition from which it is obtained. For thermal initial data, the kernel ρ_β may be represented by the Euclidean thermal path integral of Chapter 125, producing the familiar contour with an imaginary thermal segment.

126.8 Gauge Theories and BV Data on the Closed Time Path

For a gauge theory, branch doubling must be applied to the full gauge-fixed or BV field space. A perturbative BV representation has two copies

$$\Phi_+, \Phi_+^*, \qquad \Phi_-, \Phi_-^*,$$

and a regulated exponent whose local part has the form

$$\mathrm{i}S_{\mathrm{BV}}[\Phi_+, \Phi_+^*] - \mathrm{i}S_{\mathrm{BV}}[\Phi_-, \Phi_-^*] + \mathrm{i}J_+ \cdot O[\Phi_+] - \mathrm{i}J_- \cdot O[\Phi_-]$$

plus the initial density matrix and the final gluing of physical variables. Gauge consistency is the statement that the doubled measure, action, sources, and boundary conditions satisfy the appropriate quantum BV master equation and preserve the diagonal identity $Z[J, J] = 1$. In a lattice gauge regulator the same physical constraints are expressed without gauge fixing by two copies of link variables on the closed time path, projection to gauge-invariant states or Gauss-law sectors, and final gluing inside the trace.

The real-time continuum construction is therefore stronger than writing a formal doubled action. It must define the initial state, operator domains, source space, contour gluing, gauge constraints, and limiting topology in which unitarity, positivity, KMS relations, and retarded support survive.

Open Problem 126.2 (Real-time continuum construction)*.* Construct Schwinger–Keldysh generating functionals for interacting continuum QFTs in a topology strong enough to derive retarded correlators, KMS relations, and transport limits. The construction must state the initial state, operator domains, regulator, contour matching, gauge or BV data when present, and the sense in which unitarity and positivity survive the continuum limit.

Chapter 127

Spectral Functions, Kubo Formulae, and Transport

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Transport coefficients are low-frequency limits of real-time response functions. The definitions use a thermal state, a conserved current or stress tensor, and a source coupled to the corresponding operator. The derivation is linear response from the Schwinger–Keldysh generating functional of Chapter 126. This chapter keeps separate three pieces that are often conflated: the commutator spectral density, possible local contact terms in the source response, and the order of limits needed to define a transport coefficient.

127.1 Retarded Functions and Spectral Densities

Let ρ_β be a KMS state at inverse temperature β. For bosonic Hermitian operators $A(t, \mathbf{x})$ and $B(t, \mathbf{x})$, define the retarded function

$$G^R_{AB}(t, \mathbf{x}) = -\mathrm{i}\,\Theta(t)\,\langle [A(t, \mathbf{x}), B(0, \mathbf{0})]\rangle_\beta \tag{127.1}$$

and the commutator spectral density

$$\rho_{AB}(t, \mathbf{x}) = \langle [A(t, \mathbf{x}), B(0, \mathbf{0})]\rangle_\beta. \tag{127.2}$$

Fourier transforms are defined distributionally by

$$G^R_{AB}(\omega,\mathbf{k}) = \int dt\, d^{D-1}x\, e^{\mathrm{i}\omega t - \mathrm{i}\mathbf{k}\cdot\mathbf{x}} G^R_{AB}(t,\mathbf{x}). \tag{127.3}$$

With this convention, a retarded distribution that obeys the required tempered-growth hypothesis is the boundary value of a function holomorphic for $\operatorname{Im}\omega > 0$.

Finite-volume Lehmann representation. Work in a finite spatial volume. Let $H|n\rangle = E_n|n\rangle$, let $Z = \sum_n e^{-\beta E_n} < \infty$, and let $A_{\mathbf{k}}$ obey $A^\dagger_{\mathbf{k}} = A_{-\mathbf{k}}$. Then

$$G^>_{AA}(\omega,\mathbf{k}) = \frac{2\pi}{Z}\sum_{m,n} e^{-\beta E_m} |\langle m|A_{\mathbf{k}}|n\rangle|^2 \delta(\omega - E_n + E_m), \tag{127.4}$$

and

$$\rho_{AA}(\omega,\mathbf{k}) = \frac{2\pi}{Z}\sum_{m,n} e^{-\beta E_m}\left(1 - e^{-\beta\omega}\right)|\langle m|A_{\mathbf{k}}|n\rangle|^2 \delta(\omega - E_n + E_m). \tag{127.5}$$

Consequently $\omega\,\rho_{AA}(\omega,\mathbf{k}) \geq 0$ as a distributional positivity statement. Indeed, inserting a complete set of energy eigenstates into

$$G^>_{AA}(t,\mathbf{k}) = Z^{-1}\operatorname{Tr}\left(e^{-\beta H} A_{\mathbf{k}}(t) A_{-\mathbf{k}}(0)\right).$$

Since

$$A_{\mathbf{k}}(t) = e^{\mathrm{i}Ht} A_{\mathbf{k}} e^{-\mathrm{i}Ht},$$

the matrix element carries the phase

$$e^{\mathrm{i}(E_m - E_n)t}\langle m|A_{\mathbf{k}}|n\rangle\langle n|A_{-\mathbf{k}}|m\rangle.$$

The adjoint relation makes the product the squared modulus displayed in (127.4), and the Fourier integral gives the delta function $\delta(\omega - E_n + E_m)$.

The lesser function has the same delta support with the Boltzmann weight $e^{-\beta E_n}$ after relabelling $m \leftrightarrow n$. On the support of the delta function,

$$E_n - E_m = \omega, \qquad e^{-\beta E_n} = e^{-\beta\omega} e^{-\beta E_m}.$$

Subtracting $G^<$ from $G^>$ gives (127.5). For $\omega > 0$ every coefficient in (127.5) is nonnegative; for $\omega < 0$ it is nonpositive. This is exactly $\omega\rho_{AA} \geq 0$.

Retarded boundary value and sign convention. Assume the finite-volume spectral measure above has a thermodynamic limit for which the displayed integrals remain meaningful as tempered boundary values. With the retarded convention (127.1), the nonlocal part of the retarded function is

$$G^R_{AA}(z,\mathbf{k}) = \int_{\mathbb{R}} \frac{d\omega'}{2\pi}\,\frac{\rho_{AA}(\omega',\mathbf{k})}{z - \omega'}, \qquad \operatorname{Im} z > 0, \tag{127.6}$$

up to real polynomial contact terms. The corresponding boundary-value convention is

$$\rho_{AA}(\omega,\mathbf{k}) = -2\,\operatorname{Im} G^R_{AA}(\omega + \mathrm{i}0,\mathbf{k}) \tag{127.7}$$

for the nonlocal part of the response. This sign is fixed by writing the inverse Fourier representation of ρ in (127.1): for $\operatorname{Im} z > 0$,

$$-\mathrm{i}\int_0^\infty dt\, e^{\mathrm{i}zt} e^{-\mathrm{i}\omega' t} = \frac{1}{z-\omega'}.$$

This gives (127.6). Taking $z = \omega + \mathrm{i}0$ and using

$$\frac{1}{\omega + \mathrm{i}0 - \omega'} = \mathrm{PV}\,\frac{1}{\omega-\omega'} - \mathrm{i}\pi\delta(\omega-\omega')$$

gives (127.7). Local source counterterms add real polynomials in ω and $\mathbf{k}$ to the real-time kernel in the absence of dissipation; they are not part of the commutator spectral measure.

127.2 KMS and Fluctuation–Dissipation

Define the Wightman functions

$$G^>_{AB}(t) = \langle A(t)B(0)\rangle_\beta, \qquad G^<_{AB}(t) = \langle B(0)A(t)\rangle_\beta.$$

The KMS condition gives

$$G^>_{AB}(t-\mathrm{i}\beta) = G^<_{AB}(t)$$

for operators in the analytic domain of the thermal state. In frequency space this implies detailed balance. For $A = B^\dagger$, the finite-volume formula above gives

$$G^<_{AA}(\omega,\mathbf{k}) = e^{-\beta\omega} G^>_{AA}(\omega,\mathbf{k}), \qquad \rho_{AA} = G^>_{AA} - G^<_{AA}. \tag{127.8}$$

Therefore the symmetrized correlator

$$G^{\mathrm{sym}}_{AA}(\omega,\mathbf{k}) = \frac{1}{2}\big(G^>_{AA}(\omega,\mathbf{k}) + G^<_{AA}(\omega,\mathbf{k})\big)$$

satisfies

$$G^{\mathrm{sym}}_{AA}(\omega,\mathbf{k}) = \frac{1}{2}\coth\!\left(\frac{\beta\omega}{2}\right)\rho_{AA}(\omega,\mathbf{k}). \tag{127.9}$$

The apparent singularity at $\omega = 0$ is interpreted distributionally: the product is meaningful when the small-ω behavior of ρ_{AA} is specified. In a diffusive or viscous channel, $\rho_{AA}(\omega) = O(\omega)$, so the symmetrized noise has a finite zero-frequency limit. If a ballistic channel produces a Drude delta function, this limit is a different observable and the dc transport coefficient is infinite rather than a finite number.

127.3 Linear Response from the Closed Time Path

Perturb the Hamiltonian by a source $h_B(t,\mathbf{x})$ coupled to B:

$$H(t) = H_0 - \int d^{D-1}x\, h_B(t,\mathbf{x})B(t,\mathbf{x}). \tag{127.10}$$

To first order in h_B, the interaction-picture evolution operator is

$$U_h(t,-\infty) = 1 + \mathrm{i}\int_{-\infty}^{t} dt' \int d^{D-1}x'\, h_B(t',\mathbf{x}')B(t',\mathbf{x}') + O(h_B^2).$$

Consequently

$$U_h(t,-\infty)^{-1}A(t,\mathbf{x})U_h(t,-\infty) = A(t,\mathbf{x}) + \mathrm{i}\int_{-\infty}^{t} dt'\, d^{D-1}x'\, h_B(t',\mathbf{x}')[A(t,\mathbf{x}),B(t',\mathbf{x}')] + O(h_B^2).$$

Taking the thermal expectation value gives

$$\delta\langle A(t,\mathbf{x})\rangle = -\int dt' d^{D-1}x'\, G^R_{AB}(t-t',\mathbf{x}-\mathbf{x}')h_B(t',\mathbf{x}'). \tag{127.11}$$

Equivalently, the source-response kernel for the convention $H = H_0 - h_B B$ is

$$K^R_{AB} = \mathrm{i}\Theta(t)\langle[A(t),B(0)]\rangle_\beta = -G^R_{AB}.$$

This is the branch-difference identity obtained from the Schwinger–Keldysh functional in Chapter 126: differentiating with respect to the a-type source and then setting $J_a = 0$ leaves the causal source-response commutator. Transport formulae below are stated in terms of the commutator spectral density ρ_{AB}, which is independent of this source-sign convention.

127.4 Contact Terms and Response Kernels

The commutator retarded function is not always the full response kernel to a background source. If the operator itself depends on the source, or if the regulated generating functional contains local source counterterms, then

$$\delta\langle A\rangle = (K^R_{AB} + C_{AB})\, h_B$$

in Fourier space, where $C_{AB}(\omega,\mathbf{k})$ is local in spacetime and therefore polynomial, or a distributional limit of polynomials, in $\omega,\mathbf{k}$. For gauge and metric sources these terms are not optional: they are fixed by Ward identities, equilibrium thermodynamics, and the chosen operator scheme.

The dissipative transport coefficient is extracted from the spectral slope of the nonlocal commutator part. Real local contact terms can change static susceptibilities and Euclidean zero-mode correlators, but they do not change the positive spectral measure ρ_{AA} at nonzero frequency. This is why Kubo formulae below are stated using ρ, with a separate warning about Drude weights and conserved-density projections.

127.5 Transport Limits and Zero-Frequency Singular Terms

Transport is a statement about an infinite system. In finite spatial volume the spectrum of the Hamiltonian is discrete, so real-time correlators are almost periodic sums of phases rather than decaying functions. The thermodynamic limit is therefore part of the definition of a finite dissipative coefficient.

Definition 127.1 (Transport limit datum)**.** A transport limit datum for a pair of local operators A, B consists of

$$(\Sigma_L, \rho_{\beta,L}, A_L, B_L, \mathcal{R}, \mathcal{O}),$$

where Σ_L is a sequence of spatial regions or lattices of volume V_L, $\rho_{\beta,L}$ is a KMS or finite Gibbs state on the regulated system, A_L, B_L are regulated extensive or density operators with their normalization declared, $\mathcal{R}$ is the prescription for subtracting local contact terms and conserved-density projections, and $\mathcal{O}$ is the order of limits. For ordinary dc transport the order is

$$L \to \infty, \qquad \mathbf{k} \to \mathbf{0} \text{ in the channel specified by symmetry}, \qquad \omega \downarrow 0. \tag{127.12}$$

Changing $\mathcal{O}$ can change the answer; for example static susceptibilities and dc conductivities use different zero-frequency limits.

The most elementary obstruction to a finite dc coefficient is an exactly conserved operator that has nonzero overlap with the current. Let I_i be the total current in direction i in finite volume V, and let $\bar{I}_i = I_i - \langle I_i \rangle_\beta$. Suppose $\{Q_a\}_{a=1}^N$ are Hermitian conserved operators with zero thermal expectation and positive covariance matrix

$$C_{ab} = \frac{1}{2V} \langle Q_a Q_b + Q_b Q_a \rangle_\beta. \tag{127.13}$$

Define the current–charge overlap vector

$$v_{ia} = \frac{1}{2V} \langle \bar{I}_i Q_a + Q_a \bar{I}_i \rangle_\beta. \tag{127.14}$$

The projection of $\bar{I}_i$ onto the span of conserved charges is

$$P\bar{I}_i = Q_a (C^{-1})^{ab} v_{ib}. \tag{127.15}$$

Lemma 127.2 (Finite-volume Mazur projection)**.** *In the finite-dimensional Gibbs setting above, for every real vector u_i, the infinite-time averaged connected symmetrized current autocorrelation satisfies*

$$\lim_{T\to\infty} \frac{1}{T} \int_0^T dt \, \frac{1}{2V} \left\langle \{u_i \bar{I}_i(t), u_j \bar{I}_j(0)\} \right\rangle_\beta \geq u_i v_{ia} (C^{-1})^{ab} v_{jb} u_j. \tag{127.16}$$

If the right hand side has a nonzero thermodynamic limit, the conductivity has a zero-frequency singular contribution and the ordinary dc limit is not a finite dissipative number.

Proof. Use the real Hilbert-space inner product on Hermitian operators

$$(X, Y)_{\beta,\mathrm{sym}} = \frac{1}{2V} \langle XY + YX \rangle_\beta.$$

Time evolution is orthogonal for this inner product because ρ_β commutes with H. For $X = u_i \bar{I}_i$, let

$$X_\parallel = Q_a (C^{-1})^{ab} (Q_b, X)_{\beta,\mathrm{sym}}.$$

Then $X_\parallel$ is conserved and is the orthogonal projection of X onto the conserved subspace spanned by the Q_a. The time average of the symmetrized correlation is the squared norm of the component of X in the zero-frequency subspace of the Liouville operator $L = [H, \cdot]$. This zero-frequency subspace contains $X_\parallel$, hence the time average is at least

$$(X_\parallel, X_\parallel)_{\beta,\mathrm{sym}} = u_i v_{ia} (C^{-1})^{ab} v_{jb} u_j.$$

If this quantity survives per unit volume as $V \to \infty$, the symmetrized current spectrum contains a term

$$\frac{2\pi}{\beta} D_{ij} \delta(\omega), \qquad D_{ij} = \beta \lim_{t\to\infty} \lim_{V\to\infty} \frac{1}{2V} \langle \{\bar{I}_i(t), \bar{I}_j(0)\} \rangle_\beta, \tag{127.17}$$

in the convention of (127.9). Equivalently $\operatorname{Re}\sigma_{ij}$ contains $\pi D_{ij}\delta(\omega)$. This is a singular transport sector, not the regular slope appearing in the finite dc Kubo formula. □

After the thermodynamic limit has been taken, the low-frequency real conductivity in a fixed tensor channel must be regarded as a distribution. The separation used below is

$$\operatorname{Re}\sigma_{ij}(\omega) = \pi D_{ij}\delta(\omega) + \sigma^{\mathrm{reg}}_{ij}(\omega), \qquad \sigma^{\mathrm{reg}}_{ij}(\omega) = \frac{1}{2\omega} \rho^{\mathrm{reg}}_{J_i J_j}(\omega, \mathbf{0}) \quad (\omega \neq 0), \tag{127.18}$$

where D_{ij} is the Drude matrix produced by conserved projections and $\sigma^{\mathrm{reg}}_{ij}$ is locally integrable near $\omega = 0$. The ordinary dissipative dc coefficient is

$$\sigma^{\mathrm{dc}}_{ij} = \lim_{\omega\downarrow 0} \sigma^{\mathrm{reg}}_{ij}(\omega) = \lim_{\omega\downarrow 0} \frac{1}{2\omega} \rho^{\mathrm{reg}}_{J_i J_j}(\omega, \mathbf{0}), \tag{127.19}$$

when this limit exists. The singular term is a separate distributional summand, while σ^{reg} is the locally integrable part used in the finite dc limit. Figure 127.1 records this order-of-limits prescription.

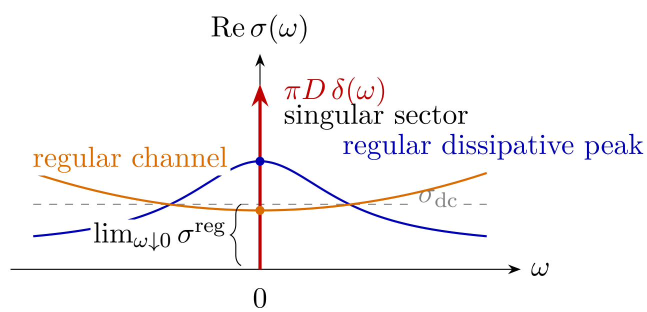

Figure 127.1: Distributional low-frequency content of a conductivity after the thermodynamic limit. The finite dc coefficient is the zero-frequency limit of the regular part σ^{reg}, equivalently the slope of $\rho^{\mathrm{reg}}_{JJ}(\omega, \mathbf{0})$ divided by 2ω. A Drude or superfluid weight is represented by the separate $\delta(\omega)$ summand.

127.6 Projection Identities and Memory Kernels

Kubo formulae identify transport coefficients as low-frequency response data. A second finite-regulator identity explains where hydrodynamic closures enter. Work in finite volume and let

$\mathcal{A}_L$ be the finite-dimensional operator space generated by the regulated degrees of freedom in the channel under study. Time evolution acts on this space by

$$X(t) = e^{t\mathcal{L}} X, \qquad \mathcal{L}X = \mathrm{i}[H_L, X],$$

so that $dX(t)/dt = \mathcal{L}X(t)$. For linearly independent Hermitian operators A_a with zero thermal expectation define the Kubo–Mori inner product

$$(X, Y)_\beta = \frac{1}{\beta} \int_0^\beta d\lambda \left\langle X^\dagger(-\mathrm{i}\lambda) Y \right\rangle_\beta, \qquad X(-\mathrm{i}\lambda) = e^{\lambda H_L} X e^{-\lambda H_L}. \tag{127.20}$$

Let

$$\chi_{ab} = (A_a, A_b)_\beta$$

and assume that χ is positive definite on the chosen slow subspace. The orthogonal projection onto this subspace is

$$PX = A_a (\chi^{-1})^{ab} (A_b, X)_\beta, \qquad Q = 1 - P. \tag{127.21}$$

The projection depends on the regulated state and on the declared slow operators. In hydrodynamic applications A_a are Fourier modes of conserved densities; in a transport calculation they may also include exactly conserved charges whose overlap creates the Drude sector isolated in Lemma 127.2.

Exact finite-regulator block identity. Let $X(t) = e^{t\mathcal{L}} X_0$. On the finite operator space above,

$$\begin{aligned} \frac{d}{dt} PX(t) = P\mathcal{L}P\, PX(t) + P\mathcal{L}e^{tQ\mathcal{L}Q} QX_0 \\ + \int_0^t ds\, P\mathcal{L}e^{(t-s)Q\mathcal{L}Q} Q\mathcal{L}P\, PX(s). \end{aligned} \tag{127.22}$$

Consequently, if X_0 lies in the range of P, its slow coordinates

$$\alpha^a(t) = (\chi^{-1})^{ab} (A_b, PX(t))_\beta$$

obey

$$\dot{\alpha}^b(t) = \Omega_a{}^b\, \alpha^a(t) - \int_0^t ds\, M_a{}^b(t-s) \alpha^a(s), \tag{127.23}$$

where

$$\Omega_a{}^b = (\chi^{-1})^{bc} (A_c, \mathcal{L}A_a)_\beta, \tag{127.24}$$

$$M_a{}^b(t) = -(\chi^{-1})^{bc} \left(A_c, \mathcal{L}e^{tQ\mathcal{L}Q} Q\mathcal{L}A_a\right)_\beta. \tag{127.25}$$

For a general X_0, the additional term

$$f_X^b(t) = (\chi^{-1})^{bc} \left(A_c, \mathcal{L}e^{tQ\mathcal{L}Q} QX_0\right)_\beta$$

must be added to the right hand side of (127.23).

To obtain the identity, write $x(t) = PX(t)$ and $y(t) = QX(t)$. Applying P and Q to $\dot{X} = \mathcal{L}X$ gives the exact block system

$$\dot{x} = P\mathcal{L}P\, x + P\mathcal{L}Q\, y, \qquad \dot{y} = Q\mathcal{L}P\, x + Q\mathcal{L}Q\, y.$$

The second equation is a finite-dimensional inhomogeneous linear equation. Duhamel's formula gives

$$y(t) = e^{tQ\mathcal{L}Q}QX_0 + \int_0^t ds\, e^{(t-s)Q\mathcal{L}Q}Q\mathcal{L}P\, x(s).$$

Substitution into the first block equation gives (127.22). If $X_0 = A_a\alpha^a(0)$, then $QX_0 = 0$ and

$$P\mathcal{L}P\, PX(t) = A_b\Omega_a{}^b\alpha^a(t).$$

The integral term is written in the same A_b basis by applying $(\chi^{-1})^{bc}(A_c,\cdot)_\beta$, which gives (127.23) with the definition (127.25). For a general initial operator the Duhamel term involving QX_0 is projected in the same way and produces $f_X^b(t)$.

The identity is algebraic at finite regulator. It has no decay statement in it: the unresolved evolution $e^{tQ\mathcal{L}Q}$ can be almost periodic in finite volume, and the memory kernel can fail to have a long-time integral before the thermodynamic limit is taken. A hydrodynamic closure is therefore an additional scaling statement about the kernel $M(t)$. In a conserved density channel the Ward identity gives

$$\partial_t n_A(t,\mathbf{k}) = -\mathrm{i}k_i J_A^i(t,\mathbf{k}).$$

If the slow variables are the densities $n_A(\mathbf{k})$, then $Q\mathcal{L}n_A(\mathbf{k})$ is proportional to k_i times the part of the current orthogonal to the density subspace. Hence the memory term begins at order k^2:

$$\partial_t n_A(t,\mathbf{k}) = -k^2\int_0^t ds\, \mathsf{D}_{AB}(t-s,\mathbf{k})n_B(s,\mathbf{k}) + \text{reactive terms and higher-gradient corrections.} \tag{127.26}$$

Replacing the kernel by a local diffusion matrix,

$$\int_0^t ds\, \mathsf{D}_{AB}(t-s,\mathbf{k})n_B(s,\mathbf{k}) \rightsquigarrow D_{AB}n_B(t,\mathbf{k}), \qquad D_{AB} = \int_0^\infty dt\, \mathsf{D}_{AB}(t,\mathbf{0}),$$

requires a thermodynamic limit, decay of the projected current kernel, control of the $k \to 0$ limit, and prior separation of Drude sectors. When these hypotheses hold, the resulting matrix D is the diffusion matrix that appears in the hydrodynamic pole $\omega = -\mathrm{i}\lambda k^2 + \cdots$ and in the Einstein relation $D = \Sigma\chi^{-1}$ derived in Chapter 128. If the projected kernel has a persistent component or a nonintegrable long-time tail, the local first-order constitutive relation is replaced by a singular or scale-dependent low-frequency response. Chapter 134 develops the hydrodynamic version of this infrared phenomenon.

127.6.1 The Closure Datum Behind a Diffusion Pole

The finite-regulator identity (127.22) becomes a transport statement only after a limiting datum is supplied. Let Λ_L be a sequence of spatial volumes tending to $\mathbb{R}^{d-1}$, let $n_A^L(\mathbf{k})$ be the regulated Fourier modes of conserved densities at momenta compatible with Λ_L, and let $\mathsf{D}_{AB}^L(t,\mathbf{k})$ denote the projected kernel obtained from (127.25) after the Drude sector and exact zero modes have been removed. A local diffusive closure consists of the following data.

Hypothesis 127.3 (Projected-current hydrodynamic closure datum)**.** For $\mathbf{k}$ in a neighborhood of 0 there is a matrix-valued locally integrable function $\mathsf{D}_{AB}(t,\mathbf{k})$ such that:

(i) for every compact time interval $[0,T]$ and every test matrix $u^{AB}(t,\mathbf{k})$ smooth in t and $\mathbf{k}$,

$$\lim_{L\to\infty}\int_0^T dt\,u^{AB}(t,\mathbf{k})\mathsf{D}^L_{AB}(t,\mathbf{k})=\int_0^T dt\,u^{AB}(t,\mathbf{k})\mathsf{D}_{AB}(t,\mathbf{k});$$

(ii) the Laplace transform

$$\widehat{\mathsf{D}}_{AB}(z,\mathbf{k})=\int_0^\infty e^{-zt}\mathsf{D}_{AB}(t,\mathbf{k})\,dt,\qquad \operatorname{Re}z>0,\tag{127.27}$$

has a finite limit at $(z,\mathbf{k})=(0,\mathbf{0})$ after the prescribed subtraction of singular conserved pieces, and admits a holomorphic continuation to a neighborhood of this point in the z-plane with

$$\widehat{\mathsf{D}}(z,\mathbf{k})=\widehat{\mathsf{D}}(0,\mathbf{0})+O(|z|+|\mathbf{k}|)$$

in the finite-dimensional charge-coordinate norm;

(iii) the finite-volume initial-force term $P\mathcal{L}e^{tQ\mathcal{L}Q}QX_0$ has no contribution to the hydrodynamic pole under the same thermodynamic and small-$\mathbf{k}$ limit, either because the initial perturbation lies in the slow subspace or because the projected force term decays in the limiting topology;

(iv) the susceptibility matrix $\chi_{AB}(\mathbf{k})=(n_A(\mathbf{k}),n_B(-\mathbf{k}))_\beta$ has a nonsingular limit $\chi_{AB}=\chi_{AB}(\mathbf{0})$ on the declared hydrodynamic charge sector.

These conditions are the theorem boundary for transport: in a concrete QFT one must prove them, or else keep them as hypotheses. Under Hypothesis 127.3, the memory equation has a precise small-momentum meaning. For simplicity suppress reactive terms and write the density equation in the form

$$\partial_t n_A(t,\mathbf{k})=-k^2\int_0^t ds\,\mathsf{D}_{AB}(t-s,\mathbf{k})n_B(s,\mathbf{k})+O(k^3)\tag{127.28}$$

in the thermodynamic limit.

In the following displays A,B are charge-coordinate labels. The position of an index marks row or column placement in a matrix product and is not a metric raising operation. The Laplace transform of the density memory equation is

$$\Big[z\delta_A{}^B+k^2\widehat{\mathsf{D}}_A{}^B(z,\mathbf{k})\Big]\,\widetilde{n}_B(z,\mathbf{k})=n_A(0,\mathbf{k})+O(k^3),\qquad \operatorname{Re}z>0.\tag{127.29}$$

If $D_A{}^B=\widehat{\mathsf{D}}_A{}^B(0,\mathbf{0})$ is diagonalizable on the charge sector and λ_r is one of its eigenvalues, analytic perturbation of the finite matrix

$$z\mathbf{1}+k^2\widehat{\mathsf{D}}(z,\mathbf{k})$$

gives a pole of the density response at

$$z_r(\mathbf{k})=-k^2\lambda_r+o(k^2).\tag{127.30}$$

With the real-time Fourier convention of (127.3), $z=-\mathrm{i}\omega$, this is the hydrodynamic pole

$$\omega_r(\mathbf{k})=-\mathrm{i}\lambda_r k^2+o(k^2).\tag{127.31}$$

The construction of the diffusion pole therefore has three distinct steps: construct the thermodynamic projected-current kernel, prove the zero-frequency regularity of its Laplace transform, and then expand the resolvent of the closed slow-coordinate equation.

The conductivity matrix entering the Einstein relation is the same datum expressed in current variables. Let Σ_{AB} denote the regular zero-frequency limit of the current response after subtracting the Drude sector and contact terms. In a purely diffusive charge channel,

$$\Sigma_{AB} = D_A{}^C \chi_{CB}. \tag{127.32}$$

This relation follows from the continuity equation: an external static source changes the equilibrium charge density by $\delta n_A = \chi_{AB}\delta\mu^B$, while the hydrodynamic constitutive response to the slowly varying source is

$$J^i_A = -D_A{}^B \partial_i \delta n_B = -\Sigma_{AB}\partial_i\delta\mu^B.$$

Equation (127.32) is therefore a statement about the same limiting kernel seen in two coordinate systems, not an independent postulate.

127.7 Conductivity

For a conserved current J^μ coupled to a background gauge field $A^{\rm ext}_\mu$, the electric field in the Fourier convention (127.3) is

$$E_i(\omega,\mathbf{k}) = \mathrm{i}\omega A^{\rm ext}_i(\omega,\mathbf{k}) - \mathrm{i}k_i A^{\rm ext}_0(\omega,\mathbf{k}).$$

At zero spatial momentum and in a gauge with $A^{\rm ext}_0 = 0$, define the full transverse response kernel K_{ij} by the conventional background-gauge-field sign

$$\langle J_i(\omega)\rangle = -K_{ij}(\omega,\mathbf{0})A^{\rm ext}_j(\omega) = \sigma_{ij}(\omega)E_j(\omega).$$

Thus

$$\sigma_{ij}(\omega) = -\frac{1}{\mathrm{i}\omega}K_{ij}(\omega,\mathbf{0}), \qquad K_{ij} = G^R_{J_iJ_j} + C_{ij}.$$

For $\omega \neq 0$, the dissipative real part is determined by the spectral density:

$$\operatorname{Re}\sigma_{ij}(\omega) = \frac{1}{2\omega}\,\rho_{J_iJ_j}(\omega,\mathbf{0}) \quad \text{in a transverse channel after contact terms are separated.} \tag{127.33}$$

The dc conductivity, when finite, is therefore

$$\sigma^{\rm dc}_{ij} = \lim_{\omega\downarrow 0}\frac{1}{2\omega}\rho_{J_iJ_j}(\omega,\mathbf{0}),$$

with the thermodynamic limit taken before the $\omega\to 0$ limit. If momentum conservation or another exactly conserved quantity overlaps with the current, a $\delta(\omega)$ Drude contribution is present and the dc conductivity is infinite unless the conserved contribution is relaxed or projected out.

127.8 Shear and Bulk Viscosity

Couple the theory to a spatial metric perturbation

$$g_{ij}(t, \mathbf{x}) = \delta_{ij} + h_{ij}(t, \mathbf{x}).$$

The stress tensor is defined by the first variation of the regulated generating functional with respect to the metric source. In an isotropic thermal state, take a shear perturbation $h_{xy}(t)$ at zero spatial momentum. The dissipative part of the stress response is characterized by the shear viscosity η. With the retarded sign convention (127.1) and the spectral convention (127.7),

$$\eta = \lim_{\omega \downarrow 0} \frac{1}{2\omega}\, \rho_{T_{xy}T_{xy}}(\omega, \mathbf{0}) = -\lim_{\omega \downarrow 0} \frac{1}{\omega}\, \operatorname{Im} G^R_{T_{xy}T_{xy}}(\omega, \mathbf{0}). \tag{127.34}$$

The equality between the two expressions is exactly (127.7). Positivity of $\omega \rho_{T_{xy}T_{xy}}$ gives $\eta \geq 0$ when the limit exists and no singular zero-frequency contribution is present.

The bulk channel requires a projection. For a neutral relativistic fluid in $d = D - 1$ spatial dimensions, define

$$\mathcal{P} = \frac{1}{d} T^i{}_i - c_s^2 T^{00}, \qquad c_s^2 = \left(\frac{\partial p}{\partial \varepsilon}\right)_{\mathrm{eq}}.$$

The subtraction removes the overlap of the pressure fluctuation with the conserved energy density. In charged fluids one must project out all conserved densities using the susceptibility matrix. After this projection, the bulk viscosity is

$$\zeta = \lim_{\omega \downarrow 0} \frac{1}{2\omega} \rho_{\mathcal{P}\mathcal{P}}(\omega, \mathbf{0}),$$

again with the thermodynamic and zero-momentum limits taken before the zero-frequency limit.

127.9 Dispersion Relations and Sum-Rule Boundaries

Retardedness gives analyticity in the upper half ω-plane. If the response kernel is sufficiently bounded after subtracting its local polynomial terms, then Cauchy's theorem gives a subtracted dispersion relation. A typical once-subtracted form is

$$G^R(\omega) - G^R(0) = \omega \int_{\mathbb{R}} \frac{d\omega'}{2\pi}\, \frac{\rho(\omega')}{\omega'(\omega - \omega' + \mathrm{i}0)}. \tag{127.35}$$

This formula is not a definition. It follows only after the large semicircle is controlled and after all contact terms have been declared. Sum rules for conductivity or viscosity compare the small-ω transport slope with Euclidean or equal-time data only under these additional analytic and ultraviolet assumptions.

127.10 Hydrodynamic Pole Boundary

Kubo formulae define transport coefficients when the indicated limits exist and commute with the thermodynamic and zero-momentum limits in the stated order. Hydrodynamics begins after these coefficients are inserted into the long-wavelength Ward identities for conserved densities. The microscopic Kubo formula by itself does not prove local equilibration, the derivative expansion, or the dominance of hydrodynamic poles; those are additional dynamical statements developed in the following chapters.

Open Problem 127.4 (Rigorous Kubo-to-hydrodynamics bridge). Give sufficient QFT hypotheses under which retarded stress-tensor and current correlators have the analyticity, spectral positivity, clustering, and low-frequency limits required by the Kubo formulae, and prove that the same coefficients control the long-time hydrodynamic effective theory.

Chapter 128

Hydrodynamics from Ward Identities

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Hydrodynamics is the long-wavelength effective theory of conserved densities. Its variables are local thermodynamic parameters attached to a family of states whose correlators are controlled, at long distances and long times, by Ward identities and by an expansion in gradients. This chapter develops the deterministic first-order theory in flat spacetime and fixes the sign and normalization conventions that connect it to the Kubo formulae of Chapter 127.

Let $D = d + 1$, where d is the number of spatial dimensions. The Minkowski metric is mostly plus, $\eta_{\mu\nu} = (-, +, \dots, +)$. Repeated ordinary charge labels A, B are summed. All formulas in this chapter are written for parity-even fluids without anomalies; anomalous transport is developed separately in Chapter 132.

128.1 Background Sources and Ward Identities

The conserved operators that enter hydrodynamics are defined by their response to background sources. Let $g_{\mu\nu}$ be a Lorentzian metric and let A_μ^A be background gauge fields for ordinary Abelian internal symmetries. For the regulated Schwinger–Keldysh generating functional

$$W[g_+, A_+; g_-, A_-],$$

the physical one-point functions are obtained by differentiating with respect to the difference sources and then setting the two branches equal, as in Chapter 126. On the diagonal source

$g_+ = g_- = g$, $A_+ = A_- = A$, we use the convention

$$\delta W_{\mathrm{phys}} = \frac{1}{2}\int d^D x\,\sqrt{-g}\,\langle T^{\mu\nu}\rangle\,\delta g_{\mu\nu} + \int d^D x\,\sqrt{-g}\,\langle J^\mu_A\rangle\,\delta A^A_\mu. \tag{128.1}$$

Equation (128.1) is a definition of the stress-tensor and current normalization in this chapter. Local contact terms may change the local polynomial part of the response kernels, but they do not change the operator Ward identities derived from gauge and diffeomorphism invariance.

Gauge invariance under $\delta_\lambda A^A_\mu = \partial_\mu \lambda^A$ gives

$$\nabla_\mu J^\mu_A = 0 \tag{128.2}$$

when the corresponding symmetry is not anomalous. Diffeomorphism invariance under the infinitesimal vector field ξ^μ gives

$$\delta_\xi g_{\mu\nu} = \nabla_\mu \xi_\nu + \nabla_\nu \xi_\mu, \qquad \delta_\xi A^A_\mu = \xi^\lambda F^A_{\lambda\mu} + \partial_\mu(\xi^\lambda A^A_\lambda),$$

where $F^A_{\mu\nu} = \partial_\mu A^A_\nu - \partial_\nu A^A_\mu$. Combining this variation with (128.2) and integrating by parts gives

$$\nabla_\mu T^\mu{}_\nu = F^A_{\nu\lambda} J^\lambda_A. \tag{128.3}$$

Thus the flat, source-free conservation laws are the specialization of the QFT Ward identities to $g_{\mu\nu} = \eta_{\mu\nu}$ and $A^A_\mu = 0$.

The same source formulation fixes the thermodynamic forces used below. For a fluid velocity u^μ, define the electric covector measured in the local rest frame by

$$\mathcal{E}^A_\mu = F^A_{\mu\nu} u^\nu, \qquad u^\mu \mathcal{E}^A_\mu = 0.$$

The source-free formulas in most of this chapter are recovered by setting $\mathcal{E}^A_\mu = 0$.

128.2 Hydrodynamic Scaling Families

The hydrodynamic expansion is an asymptotic statement about a family of states and sources whose variation scale is taken large compared with all microscopic relaxation scales except the modes protected by exact conservation laws. The following definition records the data that are being approximated.

Definition 128.1 (Hydrodynamic scaling family)**.** A hydrodynamic scaling family near a homogeneous KMS state consists of regulated real-time states ρ_λ, background sources $(g_{\lambda\mu\nu}, A^A_{\lambda\mu})$, and local fields $(T_\lambda, \mu_{\lambda A}, u^\mu_\lambda)$, indexed by $\lambda > 0$, such that in local inertial coordinates

$$\partial_{\alpha_1}\cdots\partial_{\alpha_m} T_\lambda, \quad \partial_{\alpha_1}\cdots\partial_{\alpha_m}\mu_{\lambda A}, \quad \partial_{\alpha_1}\cdots\partial_{\alpha_m} u^\mu_\lambda, \quad \partial_{\alpha_1}\cdots\partial_{\alpha_{m-1}} F^A_{\lambda\alpha_m\alpha_{m+1}} = O(\lambda^m) \qquad (m \geq 1),$$

while the zeroth-order fields remain in a fixed compact subset of the equilibrium state manifold with $T > 0$. A constitutive relation through order N is an asymptotic expansion of the one-point functions $\langle T^{\mu\nu}\rangle_{\rho_\lambda}$ and $\langle J^\mu_A\rangle_{\rho_\lambda}$ whose error is $O(\lambda^{N+1})$ after the thermodynamic limit and after subtraction of declared local contact terms.

This definition separates the kinematic part of hydrodynamics from the microscopic QFT assertion. The kinematic part is the classification of all local tensor structures compatible with the Ward identities and the chosen state variables. The microscopic assertion is that nonconserved excitations produce analytic terms in the scaling region, so that the nonanalytic long-distance response is exhausted by the conservation laws.

Definition 128.2 (First-order hydrodynamic constitutive structure)**.** A parity-even first-order hydrodynamic constitutive structure for ordinary Abelian charges is a tuple

$$\mathfrak{D}_{\rm hydro} = \big(W[g_+, A_+; g_-, A_-], T^{\mu\nu}, J^\mu_A, \mathcal{M}_{\rm eq}, T, \mu_A, u^\mu, \mathsf{f}, \mathsf{C}^{(0)}, \mathsf{C}^{(1)}, \mathsf{E}\big)$$

with the following entries.

(i) $W[g_+, A_+; g_-, A_-]$ is the regulated Schwinger–Keldysh generating functional of the microscopic QFT with background metric $g_{\mu\nu}$ and Abelian background gauge fields A^A_μ. The operators $T^{\mu\nu}$ and J^μ_A use the source normalization of (128.1).

(ii) The exact QFT input is the Ward-identity pair

$$\nabla_\mu J^\mu_A = 0, \qquad \nabla_\mu T^\mu{}_\nu = F^A_{\nu\lambda} J^\lambda_A,$$

with $F^A_{\mu\nu} = \partial_\mu A^A_\nu - \partial_\nu A^A_\mu$.

(iii) $\mathcal{M}_{\rm eq}$ is the thermodynamic manifold of homogeneous KMS states in the thermodynamic limit. Its local coordinates are temperature $T > 0$, chemical potentials μ_A, and a future-timelike unit vector u^μ satisfying $u^\mu u_\mu = -1$.

(iv) f is the hydrodynamic frame, namely the prescription for extending (T, μ_A, u^μ) away from exact equilibrium. This chapter uses Landau matching:

$$u_\mu T^{\mu\nu} = -\varepsilon u^\nu, \qquad n_A = -u_\mu J^\mu_A.$$

(v) $\mathsf{C}^{(0)}$ is the ideal constitutive map

$$T^{\mu\nu}_{(0)} = \varepsilon u^\mu u^\nu + p\Delta^{\mu\nu}, \qquad J^\mu_{A(0)} = n_A u^\mu, \qquad \Delta^{\mu\nu} = \eta^{\mu\nu} + u^\mu u^\nu.$$

The thermodynamic functions obey $dp = s\,dT + n_A\,d\mu_A$ and $\varepsilon + p = Ts + \mu_A n_A$.

(vi) $\mathsf{C}^{(1)}$ is the first-gradient constitutive map in the declared frame. In the source-free parity-even sector treated here its independent transport data are shear viscosity η, bulk viscosity ζ, and conductivity matrix Σ_{AB}, appearing as

$$\pi^{\mu\nu}_{(1)} = -\eta\sigma^{\mu\nu} - \zeta\Delta^{\mu\nu}\partial_\lambda u^\lambda, \qquad \nu^\mu_{A(1)} = -T\Sigma_{AB}\Delta^{\mu\nu}\partial_\nu(\mu_B/T).$$

(vii) E is the entropy-current and positivity condition. It consists of $S^\mu = su^\mu + O(\partial)$ and the requirement that the quadratic entropy-production form be nonnegative for all first gradients. In this sector the condition is

$$\eta \geq 0, \qquad \zeta \geq 0, \qquad \Sigma_{(AB)} v^A v^B \geq 0 \quad \text{for all } v^A \in \mathbb{R}.$$

Here $\Sigma_{(AB)} = (\Sigma_{AB} + \Sigma_{BA})/2$.

The structure $\mathfrak{D}_{\rm hydro}$ is evaluated on a hydrodynamic scaling family in the sense of Definition 128.1. The sections below derive the ideal equations, frame transformations, first-order entropy production, and hydrodynamic poles from this structure.

128.3 Conserved Densities and Local State Variables

Let $T^{\mu\nu}$ be the stress tensor and let J_A^μ be conserved currents for ordinary internal symmetries. In flat space without external sources,

$$\partial_\mu T^{\mu\nu} = 0, \qquad \partial_\mu J_A^\mu = 0. \tag{128.4}$$

A local equilibrium state is parametrized by a future-timelike velocity field $u^\mu(x)$, temperature $T(x) > 0$, and chemical potentials $\mu_A(x)$, with

$$u^\mu u_\mu = -1.$$

The spatial projector in the local rest frame is

$$\Delta^{\mu\nu} = \eta^{\mu\nu} + u^\mu u^\nu, \qquad \Delta^{\mu\nu} u_\nu = 0.$$

The ideal constitutive relations are

$$T_{(0)}^{\mu\nu} = \varepsilon u^\mu u^\nu + p\,\Delta^{\mu\nu}, \qquad J_{A(0)}^\mu = n_A u^\mu. \tag{128.5}$$

Here $\varepsilon(T,\mu)$, $p(T,\mu)$, and $n_A(T,\mu)$ are local thermodynamic functions of the underlying QFT. The frame used below is the Landau frame:

$$u_\mu T^{\mu\nu} = -\varepsilon u^\nu, \tag{128.6}$$

so the nonideal stress tensor carries no energy flux in the local rest frame. Charge diffusion is allowed to have components orthogonal to u^μ.

128.4 Hydrodynamic Frames

Hydrodynamic variables are local coordinates on the manifold of equilibrium states and its derivative expansion. They are not uniquely defined away from strict equilibrium. For any chosen u^μ, decompose the one-point functions as

$$T^{\mu\nu} = \varepsilon u^\mu u^\nu + p\Delta^{\mu\nu} + u^\mu q^\nu + u^\nu q^\mu + \pi^{\mu\nu}, \tag{128.7}$$
$$J_A^\mu = n_A u^\mu + \nu_A^\mu, \tag{128.8}$$

with

$$u_\mu q^\mu = u_\mu \nu_A^\mu = 0, \qquad u_\mu \pi^{\mu\nu} = 0.$$

The scalar quantities ε, p, n_A, the velocity u^μ, and the transverse tensors $q^\mu, \nu_A^\mu, \pi^{\mu\nu}$ depend on the chosen frame. Under a first-derivative redefinition

$$u^\mu \mapsto u^\mu + \delta u^\mu, \qquad T \mapsto T + \delta T, \qquad \mu_A \mapsto \mu_A + \delta\mu_A, \qquad u_\mu \delta u^\mu = 0,$$

while the physical one-point functions are held fixed, the transverse vectors change at first derivative order as

$$q^\mu \mapsto q^\mu - (\varepsilon + p)\delta u^\mu, \qquad \nu_A^\mu \mapsto \nu_A^\mu - n_A \delta u^\mu. \tag{128.9}$$

The scalar redefinitions change the separation between ideal scalar data and first-order scalar corrections. Landau matching is the choice

$$\varepsilon = u_\mu u_\nu T^{\mu\nu}, \qquad n_A = -u_\mu J_A^\mu,$$

so that no first-order correction is hidden inside the definitions of ε and n_A. To derive (128.9), keep $T^{\mu\nu}$ and J_A^μ fixed and vary only the ideal pieces. Since $\delta\Delta^{\mu\nu} = u^\mu\delta u^\nu + \delta u^\mu u^\nu$, the ideal stress changes by

$$\delta T_{(0)}^{\mu\nu} = (\varepsilon + p)(u^\mu \delta u^\nu + \delta u^\mu u^\nu) + \text{scalar variations}.$$

Its transverse energy-flux part is therefore $(\varepsilon+p)\delta u^\mu$. The ideal current changes by $\delta J_{A(0)}^\mu = n_A \delta u^\mu$ in the transverse sector. The nonideal vectors must shift by the negatives of these transverse changes. The Landau frame condition (128.6) is the choice $q^\mu = 0$. If $\varepsilon + p \neq 0$, it is reached by $\delta u^\mu = q^\mu/(\varepsilon + p)$ to the order considered here. This coordinate choice changes the displayed form of charge diffusion but cannot change pole locations, Kubo coefficients, or source-response functions.

128.5 Thermodynamic Closure

The equation of state supplies a function $p = p(T, \mu_A)$. In a finite spatial volume, before the thermodynamic limit, it is obtained from the grand-canonical partition function

$$Z_{\beta,\mu} = \operatorname{Tr} \exp[-\beta(H - \mu_A Q_A)], \qquad p_{\beta,\mu,V} = \frac{T}{V} \log Z_{\beta,\mu}.$$

The pressure $p(T, \mu)$ used in hydrodynamics is the thermodynamic limit of $p_{\beta,\mu,V}$, assuming this limit exists and is differentiable in the state under consideration. Differentiating the finite-volume expression gives

$$\left(\frac{\partial p}{\partial \mu_A}\right)_T = \frac{\langle Q_A \rangle}{V} \equiv n_A,$$

and

$$\left(\frac{\partial p}{\partial T}\right)_\mu = \frac{p + \varepsilon - \mu_A n_A}{T} \equiv s,$$

where $\varepsilon = \langle H \rangle / V$. Thus

$$p = p(T, \mu_A), \qquad s = \left(\frac{\partial p}{\partial T}\right)_\mu, \qquad n_A = \left(\frac{\partial p}{\partial \mu_A}\right)_T$$

are not independent definitions: they are the differentiability data of the equilibrium KMS state. Consequently,

$$s = \left(\frac{\partial p}{\partial T}\right)_\mu, \qquad n_A = \left(\frac{\partial p}{\partial \mu_A}\right)_{T,\mu_{B\neq A}},$$

and

$$\varepsilon + p = Ts + \mu_A n_A. \tag{128.10}$$

Then

$$dp = s\,dT + n_A\,d\mu_A, \qquad d\varepsilon = T\,ds + \mu_A\,dn_A. \tag{128.11}$$

In the rest frame of a homogeneous equilibrium state, spatial rotations give

$$\langle T^{00}\rangle = \varepsilon, \qquad \langle T^{0i}\rangle = 0, \qquad \langle T^{ij}\rangle = p\,\delta^{ij}, \qquad \langle J_A^0\rangle = n_A, \qquad \langle J_A^i\rangle = 0.$$

Lorentz covariance then gives the ideal tensors (128.5) in a state whose local rest frame velocity is u^μ. This derivation is local in the sense of the gradient expansion: it assumes that, on each hydrodynamic cell, the state is approximated by a homogeneous KMS state with the displayed values of T, μ_A, u^μ. These identities are the local thermodynamic closure of the ideal Ward system. They are imposed pointwise on the slowly varying local state variables; the microscopic QFT input is the equilibrium equation of state and the assumption that the hydrodynamic scaling limit probes only this local state manifold.

128.6 Ideal Equations and Entropy Conservation

Remark 128.3 (Ideal hydrodynamic equations). Substituting (128.5) into the Ward identities gives

$$u^\mu\partial_\mu\varepsilon + (\varepsilon+p)\partial_\mu u^\mu = 0, \tag{128.12}$$
$$(\varepsilon+p)u^\mu\partial_\mu u^\alpha + \Delta^{\alpha\mu}\partial_\mu p = 0, \tag{128.13}$$
$$u^\mu\partial_\mu n_A + n_A\partial_\mu u^\mu = 0. \tag{128.14}$$

Contract $\partial_\mu T^{\mu\nu}_{(0)} = 0$ with u_ν. Since

$$u_\nu\partial_\mu(\varepsilon u^\mu u^\nu) = -\partial_\mu(\varepsilon u^\mu), \qquad u_\nu\partial_\mu(p\Delta^{\mu\nu}) = -p\,\partial_\mu u^\mu,$$

using $u_\nu\partial_\mu u^\nu = \frac{1}{2}\partial_\mu(u_\nu u^\nu) = 0$, one obtains (128.12). Projecting the same Ward identity with $\Delta^\alpha{}_\nu$ gives

$$\Delta^\alpha{}_\nu\partial_\mu(\varepsilon u^\mu u^\nu) = \varepsilon u^\mu\partial_\mu u^\alpha, \qquad \Delta^\alpha{}_\nu\partial_\mu(p\Delta^{\mu\nu}) = p\,u^\mu\partial_\mu u^\alpha + \Delta^{\alpha\mu}\partial_\mu p,$$

which is (128.13). Current conservation gives (128.14) directly.

Remark 128.4 (Ideal entropy current). The ideal entropy current

$$S^\mu_{(0)} = su^\mu$$

is conserved on ideal hydrodynamic solutions:

$$\partial_\mu S^\mu_{(0)} = 0.$$

Using the first law,

$$Tu^\mu\partial_\mu s = u^\mu\partial_\mu\varepsilon - \mu_A u^\mu\partial_\mu n_A.$$

Substitute the ideal energy equation (128.12) and the ideal charge equations (128.14). This gives

$$Tu^\mu\partial_\mu s = -(\varepsilon+p)\partial_\mu u^\mu + \mu_A n_A\partial_\mu u^\mu = -Ts\,\partial_\mu u^\mu,$$

where $\varepsilon + p = Ts + \mu_A n_A$ was used. Therefore

$$\partial_\mu(su^\mu) = u^\mu\partial_\mu s + s\partial_\mu u^\mu = 0.$$

128.7 First-Order Constitutive Relations

The first-order derivative data must be defined before the transport coefficients are introduced. Define the expansion, acceleration, and shear tensor by

$$\vartheta = \partial_\mu u^\mu, \qquad a^\mu = u^\nu \partial_\nu u^\mu,$$

and

$$\sigma^{\mu\nu} = 2\Delta^{\mu\alpha}\Delta^{\nu\beta}\left(\partial_{(\alpha}u_{\beta)} - \frac{1}{d}\Delta_{\alpha\beta}\vartheta\right). \tag{128.15}$$

Then $\sigma^{\mu\nu}u_\nu = 0$, $\sigma^\mu{}_\mu = 0$, and $\sigma^{\mu\nu} = \sigma^{\nu\mu}$. The antisymmetric transverse derivative is the vorticity

$$\omega^{\mu\nu} = \Delta^{\mu\alpha}\Delta^{\nu\beta}\partial_{[\alpha}u_{\beta]}, \qquad \omega^{\mu\nu} = -\omega^{\nu\mu}.$$

It does not contribute to the parity-even dissipative stress tensor at first order because the stress tensor is symmetric and the entropy production is quadratic in the symmetric thermodynamic forces.

With sources, the ideal Euler equation is obtained by projecting (128.3) orthogonally to u^μ:

$$(\varepsilon + p)a^\mu + \Delta^{\mu\nu}\partial_\nu p = n_A \mathcal{E}^{A\mu}. \tag{128.16}$$

Using $dp = s\,dT + n_A\,d\mu_A$ and $\varepsilon + p = Ts + \mu_A n_A$, this equation is equivalently

$$a^\mu + \Delta^{\mu\nu}\partial_\nu \log T = \frac{Tn_A}{\varepsilon + p}V_A^\mu, \qquad V_A^\mu = \Delta^{\mu\nu}\left[\frac{\mathcal{E}_\nu^A}{T} - \partial_\nu\left(\frac{\mu_A}{T}\right)\right]. \tag{128.17}$$

Thus acceleration and the transverse temperature gradient are not independent first-order data once the ideal equations are used. The independent parity-even dissipative structures in Landau frame are therefore the symmetric traceless tensor $\sigma^{\mu\nu}$, the scalar ϑ, and the transverse charge forces V_A^μ. This is the classification statement behind the constitutive relations below; it is not an additional dynamical assumption.

In Landau frame, the parity-even first-order constitutive relations are

$$T^{\mu\nu} = \varepsilon u^\mu u^\nu + p\Delta^{\mu\nu} - \eta\,\sigma^{\mu\nu} - \zeta\,\Delta^{\mu\nu}\vartheta + O(\partial^2), \tag{128.18}$$
$$J_A^\mu = n_A u^\mu + \nu_A^\mu + O(\partial^2). \tag{128.19}$$

In the absence of external electric fields,

$$\nu_A^\mu = -T\,\Sigma_{AB}\Delta^{\mu\nu}\partial_\nu\left(\frac{\mu_B}{T}\right). \tag{128.20}$$

With background gauge fields, the same convention is

$$\nu_A^\mu = T\,\Sigma_{AB}\Delta^{\mu\nu}\left[\frac{\mathcal{E}_\nu^B}{T} - \partial_\nu\left(\frac{\mu_B}{T}\right)\right]. \tag{128.21}$$

The matrix Σ_{AB} is the conductivity matrix in the normalization where, at constant T and zero background electric field, Fick diffusion has diffusion matrix

$$D_{AB} = \Sigma_{AC}(\chi^{-1})_{CB}, \qquad \chi_{AB} = \left(\frac{\partial n_A}{\partial \mu_B}\right)_T.$$

The entropy analysis below constrains the symmetric part of Σ_{AB}. In a parity-even state with no time-reversal-breaking background, the KMS condition together with microscopic time reversal gives the Onsager reciprocity $\Sigma_{AB} = \Sigma_{BA}$. If time reversal or parity is broken, an antisymmetric part may appear; it is nondissipative because $\Sigma_{[AB]}X_A X_B = 0$ for any real thermodynamic force X_A, and it belongs with Hall-type transport rather than with the dissipative parity-even sector treated in this chapter.

128.8 Entropy Production at First Order

The first-order entropy current in Landau frame is

$$S^\mu = su^\mu - \frac{\mu_A}{T}\nu_A^\mu + O(\partial^2), \qquad \nu_A^\mu = -T\Sigma_{AB}\Delta^{\mu\nu}\partial_\nu\Big(\frac{\mu_B}{T}\Big) \quad (A_\mu^A = 0). \tag{128.22}$$

Entropy production fixes positivity. Using (128.18) and (128.19), the entropy production through second order in gradients is

$$\partial_\mu S^\mu = \frac{\eta}{2T}\sigma^{\mu\nu}\sigma_{\mu\nu} + \frac{\zeta}{T}\vartheta^2 + T\,\Sigma_{AB}\Delta^{\mu\nu}\partial_\mu\Big(\frac{\mu_A}{T}\Big)\,\partial_\nu\Big(\frac{\mu_B}{T}\Big) + O(\partial^3). \tag{128.23}$$

Hence local entropy production is nonnegative for arbitrary first gradients if

$$\eta \geq 0, \qquad \zeta \geq 0, \qquad \Sigma_{AB} \text{ is positive semidefinite.}$$

Write the dissipative stress tensor as

$$\tau^{\mu\nu} = -\eta\sigma^{\mu\nu} - \zeta\Delta^{\mu\nu}\vartheta, \qquad T^{\mu\nu} = T^{\mu\nu}_{(0)} + \tau^{\mu\nu}.$$

Using the Ward identities, the thermodynamic identities, and $u_\mu\tau^{\mu\nu} = u_\mu\nu_A^\mu = 0$, the divergence of (128.22) through second order reduces to

$$\partial_\mu S^\mu = -\frac{1}{T}\tau^{\mu\nu}\partial_\mu u_\nu - \nu_A^\mu\partial_\mu\Big(\frac{\mu_A}{T}\Big) + O(\partial^3).$$

With background gauge fields, the second term is replaced by

$$\nu_A^\mu\left[\frac{\mathcal{E}_\mu^A}{T} - \partial_\mu\Big(\frac{\mu_A}{T}\Big)\right],$$

which follows from the force term (128.3) in the energy equation. The source-free formula used in (128.23) is the special case $\mathcal{E}_\mu^A = 0$. The decomposition of $\partial_\mu u_\nu$ into shear, trace, vorticity, and acceleration gives

$$\sigma^{\mu\nu}\partial_\mu u_\nu = \frac{1}{2}\sigma^{\mu\nu}\sigma_{\mu\nu}, \qquad \Delta^{\mu\nu}\partial_\mu u_\nu = \vartheta.$$

Substituting $\tau^{\mu\nu}$ and ν_A^μ gives (128.23).

128.9 Charge Diffusion and Susceptibility Geometry

Consider a state with $u^\mu = (1, \mathbf{0})$, constant T, and vanishing background flow. Linearize first a single conserved charge around equilibrium. The constitutive relation gives

$$J^0 = n_0 + \delta n, \qquad J^i = -\Sigma\, \partial_i \delta\mu, \qquad \delta n = \chi\, \delta\mu.$$

Charge conservation gives

$$\partial_t \delta n - D\nabla^2 \delta n = 0, \qquad D = \frac{\Sigma}{\chi}. \tag{128.24}$$

For a plane wave $\delta n \propto e^{-\mathrm{i}\omega t + \mathrm{i}\mathbf{k}\cdot\mathbf{x}}$, the pole is

$$\omega = -\mathrm{i}Dk^2 + O(k^4). \tag{128.25}$$

The Einstein relation $D = \Sigma/\chi$ is the hydrodynamic form of the same coefficient matching that appears in the Kubo conductivity formula.

For several charges, the susceptibility matrix is the Hessian of the equilibrium pressure with respect to chemical potentials,

$$\chi_{AB} = \left(\frac{\partial n_A}{\partial \mu_B}\right)_T = \frac{\partial^2 p}{\partial \mu_A \partial \mu_B}.$$

Thermodynamic stability of the homogeneous KMS state means that χ is positive definite on the subspace of charges under consideration. In a parity-even time-reversal-invariant fluid, Σ is symmetric positive semidefinite. The linearized equations at constant temperature are

$$\partial_t \delta n_A - D_{AB}\nabla^2 \delta n_B = 0, \qquad D = \Sigma\chi^{-1}. \tag{128.26}$$

Although D need not be symmetric in the ordinary Euclidean inner product, its spectrum is nonnegative. Indeed D is similar to

$$\chi^{-1/2}\Sigma\chi^{-1/2},$$

because

$$D = \chi^{1/2}\left(\chi^{-1/2}\Sigma\chi^{-1/2}\right)\chi^{-1/2}.$$

The middle matrix is symmetric positive semidefinite. Hence the diffusive normal modes have

$$\omega_i(\mathbf{k}) = -\mathrm{i}\lambda_i k^2 + O(k^4), \qquad \lambda_i \geq 0,$$

where λ_i are the eigenvalues of D. Strictly positive λ_i require that no linear combination of the charges has zero conductivity.

The density source-response matrix also fixes the order of matrix multiplication in diffusion formulae. Couple a source h_A to the density with the Hamiltonian convention $H = H_0 - \int h_A n_A$, so that the electrochemical force is proportional to $\nabla(\delta\mu_A - h_A)$. In Fourier space the linearized equation is

$$\left(Dk^2 - \mathrm{i}\omega\,\mathbf{1}\right)_{AB}\delta n_B = k^2\Sigma_{AB}h_B.$$

Therefore the nonlocal hydrodynamic part of the retarded density source-response kernel is

$$K^R_{n_A n_B}(\omega, \mathbf{k}) = k^2\left(Dk^2 - \mathrm{i}\omega\,\mathbf{1}\right)^{-1}_{AC}\Sigma_{CB} + \text{analytic contact terms}. \tag{128.27}$$

At $\omega = 0$ and then $k \to 0$, the nonlocal term gives

$$D^{-1}\Sigma = \chi,$$

assuming Σ is invertible on the diffusive subspace. This is the matrix version of the static susceptibility matching in (128.35).

128.10 Neutral Linearized Modes

Linearize a neutral fluid around a homogeneous rest state:

$$u^\mu = (1, \mathbf{v}) + O(\mathbf{v}^2), \qquad \varepsilon = \varepsilon_0 + \delta\varepsilon, \qquad p = p_0 + \delta p, \qquad \delta p = c_s^2 \delta\varepsilon,$$

where

$$c_s^2 = \left(\frac{\partial p}{\partial \varepsilon}\right)_{\rm eq}, \qquad w = \varepsilon_0 + p_0.$$

The stress tensor components to first order in fluctuations and first order in gradients are

$$T^{00} = \varepsilon_0 + \delta\varepsilon, \tag{128.28}$$

$$T^{0i} = w v^i, \tag{128.29}$$

$$T^{ij} = p_0\delta^{ij} + c_s^2 \delta\varepsilon\, \delta^{ij} - \eta\left(\partial_i v_j + \partial_j v_i - \frac{2}{d}\delta_{ij}\partial_\ell v^\ell\right) - \zeta \delta_{ij}\partial_\ell v^\ell. \tag{128.30}$$

The Ward identities become

$$\partial_t \delta\varepsilon + w\partial_i v^i = 0, \tag{128.31}$$

$$w\partial_t v_i + \partial_i \delta p - \eta\nabla^2 v_i - \left(\zeta + \eta\left(1 - \frac{2}{d}\right)\right)\partial_i\partial_j v^j = 0. \tag{128.32}$$

Shear and sound poles. For fluctuations proportional to $e^{-\mathrm{i}\omega t + \mathrm{i}\mathbf{k}\cdot\mathbf{x}}$, the transverse velocity mode has

$$\omega_{\rm shear} = -\mathrm{i}\,\frac{\eta}{w}k^2 + O(k^4). \tag{128.33}$$

The longitudinal energy-momentum modes obey

$$\omega_{{\rm sound},\pm} = \pm c_s k - \frac{\mathrm{i}}{2}\Gamma_s k^2 + O(k^3), \qquad \Gamma_s = \frac{\zeta + 2\eta\frac{d-1}{d}}{w}. \tag{128.34}$$

For a transverse mode, $k_i v^i = 0$ and (128.32) becomes

$$-\mathrm{i}\omega w v_i + \eta k^2 v_i = 0,$$

which gives (128.33).

For a longitudinal mode take $\mathbf{k} = k\hat{x}$ and $v_i = v_L \hat{x}_i$. Equations (128.31) and (128.32) give

$$-\mathrm{i}\omega\delta\varepsilon + \mathrm{i}wkv_L = 0,$$

and

$$-\mathrm{i}\omega w v_L + \mathrm{i}kc_s^2\delta\varepsilon + \left(\zeta + 2\eta\frac{d-1}{d}\right)k^2 v_L = 0.$$

Eliminating v_L gives

$$\omega^2 - c_s^2 k^2 + \mathrm{i}\frac{\zeta + 2\eta(d-1)/d}{w}\omega k^2 = 0.$$

Solving perturbatively at small k gives (128.34).

128.11 Retarded Source-Response Pole Matching

Hydrodynamic poles are singularities of retarded source-response kernels after the thermodynamic limit and the hydrodynamic scaling limit have been taken in the specified order. For the source convention $H = H_0 - \int h\, n$, the density source-response kernel is the negative of the commutator-retarded function of Chapter 127. For a single diffusive charge with susceptibility χ, it has the universal long-wavelength form

$$K^R_{nn}(\omega, \mathbf{k}) = \chi \, \frac{Dk^2}{Dk^2 - \mathrm{i}\omega} + \text{terms analytic at } \omega, k = 0. \tag{128.35}$$

so that $K^R_{nn}(0, \mathbf{k} \to 0) = \chi$. The pole is $\omega = -\mathrm{i}Dk^2$. Taking $\mathbf{k} \to 0$ before $\omega \to 0$ removes the diffusive denominator; taking the hydrodynamic scaling limit $\omega \sim k^2$ keeps it. This is the same order-of-limits issue that appears in dc conductivity and static susceptibility.

In the shear channel, the momentum-density correlator has a pole at (128.33). In the sound channel, the stress-tensor and energy-density correlators have the pair of poles (128.34). The residues are fixed by thermodynamic susceptibilities and Ward identities, while the imaginary parts of the pole locations are fixed by the Kubo coefficients η, ζ, and Σ_{AB}.

128.12 Hydrodynamic Limit as a QFT Claim

The deterministic equations above are consequences of a proposed hydrodynamic scaling limit of the microscopic QFT. The limit has the following structure. First take the thermodynamic limit of the KMS state. Then consider sources and correlators with

$$\omega\tau_{\text{micro}} \ll 1, \qquad |\mathbf{k}|\ell_{\text{micro}} \ll 1,$$

while keeping the ratios appropriate to the mode under study: $\omega \sim k^2$ for diffusion and shear, and $\omega \sim k$ for sound. The QFT assertion is that all nonconserved excitations produce analytic contributions in this scaling region, and the nonanalyticities are the conservation-law poles derived above. Proving this assertion requires clustering, real-time analyticity, local equilibration, and control of long-time tails beyond the deterministic approximation.

Open Problem 128.5 (Hydrodynamic emergence theorem). Find physically useful QFT hypotheses under which local thermalization, clustering, analyticity of retarded functions, positivity of entropy production, and the hydrodynamic pole expansion can be proved from the microscopic theory.

Chapter 129

Schwinger–Keldysh Hydrodynamic Effective Actions

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Hydrodynamic Schwinger–Keldysh effective actions are real-time doubled generating functionals for conserved densities in a long-wavelength state. Their defining constraints are inherited from the closed time path: normalization at coincident sources, a reality relation, positivity of the imaginary part, gauge or diffeomorphism Ward identities, and the KMS condition when the initial state is thermal. This chapter develops the quadratic multi-charge diffusion action explicitly, because it is the simplest place where all of these constraints can be seen without hiding the source-response signs or the matrix structure of susceptibilities and conductivities.

Let spacetime be $\mathbb{R}_t \times \mathbb{R}^d$. Spatial indices i, j are raised with δ^{ij}, and $\nabla^2 = \partial_i\partial_i$. Fourier modes are written as $\exp(-\mathrm{i}\omega t + \mathrm{i}\mathbf{k}\cdot\mathbf{x})$ in the derivations below. The microscopic retarded commutator convention is the one fixed in Chapter 127. In this chapter K^R denotes the source-response kernel obtained by differentiating the Schwinger–Keldysh functional with respect to the a-type source. The conversion between K^R and the commutator retarded function includes the sign convention of the microscopic source coupling and possible local contact terms.

129.1 Closed-Time-Path Constraints

Let $A_{1\mu}$ and $A_{2\mu}$ be background gauge fields on the two branches of the Schwinger–Keldysh contour. For an initial density operator ρ_0, define

$$Z[A_1, A_2] = \mathrm{Tr}\Big(U[A_1]\rho_0 U[A_2]^\dagger\Big)\,. \tag{129.1}$$

Introduce average and difference variables

$$A_{r\mu} = \frac{1}{2}(A_{1\mu} + A_{2\mu}), \qquad A_{a\mu} = A_{1\mu} - A_{2\mu}. \tag{129.2}$$

If $Z = \exp(\mathrm{i}I_{\mathrm{SK}})$, unitarity and Hermiticity imply

$$I_{\mathrm{SK}}[A_r, A_a = 0] = 0, \tag{129.3}$$

$$I_{\mathrm{SK}}[A_r, A_a]^* = -I_{\mathrm{SK}}[A_r, -A_a], \tag{129.4}$$

$$\mathrm{Im}\, I_{\mathrm{SK}}[A_r, A_a] \geq 0 \tag{129.5}$$

for source configurations in the domain of the effective description. Equation (129.3) says that every term in the effective action contains at least one a-type field. The positivity condition is the damping condition in the path-integral weight $\exp(\mathrm{i}I_{\mathrm{SK}})$.

Finite trace constraints. Suppose first that the Hilbert space is finite-dimensional, that $\rho_0 \geq 0$ is a density matrix with $\mathrm{Tr}\,\rho_0 = 1$, and that the branch evolutions $U[A_s]$ are unitary. Then

$$Z[A, A] = 1, \qquad Z[A_1, A_2]^* = Z[A_2, A_1], \qquad |Z[A_1, A_2]| \leq 1. \tag{129.6}$$

Consequently, on the branch of $I_{\mathrm{SK}} = -\mathrm{i}\log Z$ continuous from $I_{\mathrm{SK}}[A_r, 0] = 0$, equations (129.3)–(129.5) follow.

The diagonal identity is

$$Z[A, A] = \mathrm{Tr}(U[A]\rho_0 U[A]^\dagger) = \mathrm{Tr}\,\rho_0 = 1.$$

Complex conjugation gives

$$Z[A_1, A_2]^* = \mathrm{Tr}\Big(U[A_2]\rho_0 U[A_1]^\dagger\Big) = Z[A_2, A_1], \tag{129.7}$$

where cyclicity of the finite trace and $\rho_0^\dagger = \rho_0$ are used. For the bound, introduce the Hilbert–Schmidt inner product $(X, Y)_{\mathrm{HS}} = \mathrm{Tr}(X^\dagger Y)$ and set

$$X = U[A_2]\rho_0^{1/2}, \qquad Y = U[A_1]\rho_0^{1/2}.$$

Then $Z[A_1, A_2] = (X, Y)_{\mathrm{HS}}$. Cauchy–Schwarz gives

$$|Z[A_1, A_2]|^2 \leq \mathrm{Tr}(\rho_0)\,\mathrm{Tr}(\rho_0) = 1. \tag{129.8}$$

Since $Z = \exp(\mathrm{i}I_{\mathrm{SK}})$, the last inequality is $\exp(-\,\mathrm{Im}\, I_{\mathrm{SK}}) \leq 1$, hence $\mathrm{Im}\, I_{\mathrm{SK}} \geq 0$. The reality relation for I_{SK} follows from (129.7) after rewriting branch exchange as $A_a \mapsto -A_a$ at fixed A_r. This is the same finite trace algebra as the microscopic Schwinger–Keldysh construction of Chapter 126. In this hydrodynamic chapter it serves as the finite-system origin of the local effective-action constraints (129.3)–(129.5).

For continuum QFT the same algebra is first applied with an ultraviolet regulator and finite volume, and only then passed to the thermodynamic and continuum limits. Without this order of limits the inequality $|Z| \le 1$ is a statement about the regulated closed-time-path functional, not a theorem about an unconstructed real-time path integral.

129.2 Hydrodynamic Phase Field and Gauge Invariance

For N commuting conserved $U(1)$ charges, labelled by $A, B = 1, \dots, N$, the hydrodynamic modes are represented by phase fields

$$\varphi_1^A, \qquad \varphi_2^A.$$

The branchwise gauge transformations are

$$A_{s\mu}^A \mapsto A_{s\mu}^A + \partial_\mu \lambda_s^A, \qquad \varphi_s^A \mapsto \varphi_s^A - \lambda_s^A, \qquad s = 1, 2.$$

Thus the gauge-invariant combinations are

$$B_{s\mu}^A = A_{s\mu}^A + \partial_\mu \varphi_s^A. \tag{129.9}$$

In r/a variables,

$$B_{r\mu}^A = A_{r\mu}^A + \partial_\mu \varphi_r^A, \qquad B_{a\mu}^A = A_{a\mu}^A + \partial_\mu \varphi_a^A. \tag{129.10}$$

The field φ_a^A is the Lagrange-multiplier partner of the conservation law for the A-th charge. Varying the action with respect to φ_a^A is equivalent to the corresponding Ward identity because $\delta B_{a\mu}^A = \partial_\mu \delta \varphi_a^A$.

Remark 129.1 (Gauge invariance and the hydrodynamic Ward identity). Let I_{eff} be a local functional of the gauge-invariant variables $B_{r\mu}^A, B_{a\mu}^A$. Define the expectation-value current on the physical slice $A_a = \varphi_a = 0$ by

$$J_A^\mu(x) = \left. \frac{\delta I_{\text{eff}}}{\delta A_{a\mu}^A(x)} \right|_{A_a = \varphi_a = 0}. \tag{129.11}$$

Then the Euler–Lagrange equation for φ_a^A is the distributional Ward identity

$$\partial_\mu J_A^\mu = 0 \tag{129.12}$$

in the absence of external anomaly terms. Equivalently, the a-phase is not an additional physical scalar; it is the doubled-field implementation of current conservation.

On the physical slice, $B_{a\mu}^A = A_{a\mu}^A + \partial_\mu \varphi_a^A$. Thus the variation of the action under a compactly supported $\delta\varphi_a^A$ is

$$\delta I_{\text{eff}} = \int dt\, d^d x\, J_A^\mu\, \partial_\mu \delta\varphi_a^A = -\int dt\, d^d x\, (\partial_\mu J_A^\mu) \delta\varphi_a^A, \tag{129.13}$$

with no boundary term. Since $\delta\varphi_a^A$ is arbitrary, the Euler–Lagrange equation is $\partial_\mu J_A^\mu = 0$. If the microscopic current is anomalous, the branch gauge transformation of the regulated generating functional contains the corresponding local anomaly functional; that case belongs to the anomalous-transport chapter, not to the neutral diffusion action treated here.

129.3 Quadratic Diffusion Action

Consider a homogeneous thermal state at temperature $T > 0$. Let χ_{AB} be the static susceptibility matrix

$$\chi_{AB} = \left.\frac{\partial n_A}{\partial \mu_B}\right|_T .$$

At a thermodynamically stable point χ is real, symmetric, and positive definite on the space of non-redundant conserved charges. Let Σ_{AB} be the dissipative conductivity matrix in the convention of Chapter 128; for time-reversal-even charges and in the absence of parity-odd nondissipative transport, Σ is real, symmetric, and positive semidefinite. The diffusion endomorphism acting on densities is

$$D_A{}^B = \Sigma_{AC}(\chi^{-1})^{CB}. \tag{129.14}$$

Stability of the multi-charge diffusion matrix. Assume χ is real symmetric positive definite and Σ is real symmetric positive semidefinite. Then

$$D = \Sigma\chi^{-1} \tag{129.15}$$

is diagonalizable over $\mathbb{R}$ and all its eigenvalues are nonnegative. It is self-adjoint for the density inner product

$$\langle u, v\rangle_{\chi^{-1}} = u_A(\chi^{-1})^{AB}v_B. \tag{129.16}$$

If Σ is positive definite, all eigenvalues of D are positive. Indeed, let $\chi^{1/2}$ be the positive square root of χ. The matrix

$$S = \chi^{-1/2}\Sigma\chi^{-1/2} \tag{129.17}$$

is real symmetric positive semidefinite. Moreover

$$D = \Sigma\chi^{-1} = \chi^{1/2}S\chi^{-1/2}, \tag{129.18}$$

so D is similar to S. Therefore D has the same spectrum as S, is diagonalizable over $\mathbb{R}$, and has nonnegative eigenvalues. For self-adjointness,

$$\langle u, Dv\rangle_{\chi^{-1}} = u^T\chi^{-1}\Sigma\chi^{-1}v = (Du)^T\chi^{-1}v = \langle Du, v\rangle_{\chi^{-1}}, \tag{129.19}$$

because χ^{-1} and Σ are symmetric. If Σ is positive definite then S is positive definite, so its eigenvalues, and hence the eigenvalues of D, are strictly positive.

The leading quadratic local action for the diffusive modes is

$$I_{\text{diff}} = \int dt\, d^dx\, \left[\chi_{AB}B^A_{a0}B^B_{r0} - \Sigma_{AB}B^A_{ai}\partial_t B^B_{ri} + \mathrm{i}T\Sigma_{AB}B^A_{ai}B^B_{ai}\right], \tag{129.20}$$

up to terms with more derivatives or more powers of a-fields. The one-charge formula is recovered by setting $\chi_{11} = \chi$, $\Sigma_{11} = \sigma$, and $D = \sigma/\chi$. The current obtained by varying with respect to the a-type source at $A^A_a = \varphi^A_a = 0$ is

$$n_A = \frac{\delta I_{\text{diff}}}{\delta A^A_{a0}} = \chi_{AB}B^B_{r0}, \qquad j^i_A = \frac{\delta I_{\text{diff}}}{\delta A^A_{ai}} = -\Sigma_{AB}\partial_t B^B_{ri}. \tag{129.21}$$

Using $B^A_{r0} = A^A_{r0} + \partial_t \varphi^A_r$ and $B^A_{ri} = A^A_{ri} + \partial_i \varphi^A_r$, this current may be written as

$$j^i_A = -D_A{}^B \partial_i n_B + \Sigma_{AB} E^B_i, \qquad E^A_i = \partial_i A^A_{r0} - \partial_t A^A_{ri}. \tag{129.22}$$

The sign of E^A_i is fixed by the source convention in which a static scalar-source perturbation changes the density by $\delta n_A = \chi_{AB} \delta A^B_{r0}$. Equation (129.22) is the sourceful first-order constitutive relation

$$j^i_A = \Sigma_{AB} \partial_i A^B_{r0} - \Sigma_{AB} \partial_i \mu_B, \qquad \mu_A = B^A_{r0} = (\chi^{-1})^{AB} n_B,$$

written with the hydrodynamic phase made explicit.

Remark 129.2 (Diffusion equation from the a-phase). At $A^A_a = \varphi^A_a = 0$, varying (129.20) with respect to φ^A_a gives

$$\partial_t n_A + \partial_i j^i_A = 0, \tag{129.23}$$

with n_A and j^i_A as in (129.21). With external sources set to zero this becomes

$$\partial_t n_A - D_A{}^B \nabla^2 n_B = 0. \tag{129.24}$$

Under $\varphi^A_a \mapsto \varphi^A_a + \delta\varphi^A_a$,

$$\delta B^A_{a0} = \partial_t \delta\varphi^A_a, \qquad \delta B^A_{ai} = \partial_i \delta\varphi^A_a.$$

The terms linear in a-fields therefore vary as

$$\delta I_{\text{diff}} = \int dt\, d^d x\, \left[\chi_{AB} (\partial_t \delta\varphi^A_a) B^B_{r0} - \Sigma_{AB} (\partial_i \delta\varphi^A_a) \partial_t B^B_{ri}\right],$$

because the quadratic $B_a B_a$ term does not contribute at $A^A_a = \varphi^A_a = 0$. After integrating by parts and discarding boundary terms compatible with the closed-time-path variational problem,

$$\delta I_{\text{diff}} = -\int dt\, d^d x\, \delta\varphi^A_a \left[\partial_t (\chi_{AB} B^B_{r0}) - \partial_i (\Sigma_{AB} \partial_t B^B_{ri})\right].$$

Using (129.21), the Euler-Lagrange equation is exactly (129.23). If $A^A_{r\mu} = 0$, then $n_A = \chi_{AB} \partial_t \varphi^B_r$ and

$$j^i_A = -\Sigma_{AB} \partial_i \partial_t \varphi^B_r = -\Sigma_{AB} (\chi^{-1})^{BC} \partial_i n_C = -D_A{}^C \partial_i n_C,$$

which gives (129.24).

129.4 Density Response Kernel

The density response to a scalar source follows from the same saddle equation. Set $A^A_{ri} = 0$ and use a Fourier mode $\exp(-\mathrm{i}\omega t + \mathrm{i}\mathbf{k}\cdot\mathbf{x})$. Write $\mathbf{A}_0$, $\boldsymbol{\varphi}$, and $\mathbf{n}$ for the column vectors with components A^A_{r0}, φ^A_r, and n_A. The continuity equation gives

$$\mathbf{n} + k^2 \Sigma \boldsymbol{\varphi} = 0, \qquad \mathbf{n} = \chi(\mathbf{A}_0 - \mathrm{i}\omega\boldsymbol{\varphi}).$$

Equivalently,

$$(k^2 \Sigma - \mathrm{i}\omega\chi)\boldsymbol{\varphi} = -\chi \mathbf{A}_0.$$

Eliminating $\boldsymbol{\varphi}$ and using $D = \Sigma\chi^{-1}$ gives the matrix source-response kernel

$$K^R_{n_A n_B}(\omega, \mathbf{k}) = \frac{\delta n_A}{\delta A^B_{r0}} = \left[(Dk^2 - \mathrm{i}\omega\mathbf{1})^{-1} k^2 \Sigma\right]_{AB}. \tag{129.25}$$

It has the diffusive pole
$$\det(Dk^2 - \mathrm{i}\omega\mathbf{1}) = 0. \tag{129.26}$$
At fixed nonzero k, the static limit is
$$K^R_{n_A n_B}(0, \mathbf{k}) = \chi_{AB},$$
provided D is invertible on the charge sector being probed. If Σ has an exact null vector, the corresponding charge does not diffuse at this derivative order and must be treated by retaining the next allowed term. At $k = 0$ and nonzero ω, the kernel vanishes, expressing conservation of the total charges. These two limits are distinct; the hydrodynamic poles interpolate between them.

For a transverse vector source, $k_i A^A_{ri} = 0$ and $A^A_{r0} = 0$, the phase decouples at quadratic order and
$$j^i_A = -\Sigma_{AB}\partial_t A^B_{ri}.$$
With the electric-field convention (129.22), this is Ohm response $j^i_A = \Sigma_{AB}E^B_i$. The same matrix Σ therefore appears in the diffusion endomorphism, the vector-source response, and the noise covariance below.

129.5 Noise Positivity and Langevin Form

The imaginary part of (129.20) is
$$\operatorname{Im} I_{\text{diff}} = T \int dt\, d^d x\, \Sigma_{AB} B^A_{ai} B^B_{ai}. \tag{129.27}$$
It is nonnegative precisely when Σ is positive semidefinite. The same term has a stochastic representation on the image of Σ. If Σ is positive definite, then for each spatial component
$$\exp\left[-T\int \Sigma_{AB} B^A_{ai} B^B_{ai}\right] = \int D\xi\, \exp\left[-\int \frac{1}{4T}\xi_{Ai}(\Sigma^{-1})^{AB}\xi_{Bi} + \mathrm{i}\int B^A_{ai}\xi_{Ai}\right], \tag{129.28}$$
with normalization independent of B_a. For positive semidefinite Σ, the same formula is understood after restricting to the support of Σ, or as a limit from positive definite matrices. Thus the noise satisfies
$$\langle \xi_{Ai}(t, \mathbf{x})\xi_{Bj}(t', \mathbf{x}')\rangle = 2T\Sigma_{AB}\,\delta_{ij}\delta(t - t')\delta^{(d)}(\mathbf{x} - \mathbf{x}'). \tag{129.29}$$
After the Hubbard–Stratonovich transformation, varying φ^A_a gives the Langevin equation
$$\partial_t n_A + \partial_i\big(-D_A{}^B\partial_i n_B + \Sigma_{AB}E^B_i + \xi_{Ai}\big) = 0. \tag{129.30}$$
This derivation fixes the factor $2T\Sigma_{AB}$ in the noise correlator from the same matrix that governs the dissipative current.

Theorem 129.3 (Density fluctuation–dissipation theorem from the diffusion action)**.** *Assume χ is positive definite and Σ is positive semidefinite. For real ω, $\mathbf{k}$, let*
$$M(\omega, \mathbf{k}) = (Dk^2 - \mathrm{i}\omega\mathbf{1})^{-1}, \qquad k^2 = \mathbf{k}\cdot\mathbf{k}, \tag{129.31}$$

on the subspace where the inverse exists. The Langevin equation (129.30) at zero external source gives the symmetrized density correlator

$$G^S_{nn}(\omega,\mathbf{k}) = 2T\,k^2\,M(\omega,\mathbf{k})\,\Sigma\,M(-\omega,\mathbf{k})^T. \tag{129.32}$$

This matrix is positive semidefinite as a Hermitian kernel. If

$$K^A_{nn}(\omega,\mathbf{k}) = K^R_{nn}(-\omega,\mathbf{k})^T = k^2\Sigma\,M(-\omega,\mathbf{k})^T, \tag{129.33}$$

then, for $\omega \neq 0$,

$$G^S_{nn}(\omega,\mathbf{k}) = \frac{2T}{\omega}\,\frac{K^R_{nn}(\omega,\mathbf{k}) - K^A_{nn}(\omega,\mathbf{k})}{2\mathrm{i}}. \tag{129.34}$$

The equality is the classical low-frequency form of the KMS fluctuation–dissipation relation in the density sector.

Proof. Set the external source to zero. With the Fourier convention fixed at the beginning of the chapter, (129.30) becomes

$$(Dk^2 - \mathrm{i}\omega\mathbf{1})\,\mathbf{n} = -\mathrm{i}k_i\,\boldsymbol{\xi}_i. \tag{129.35}$$

Thus $\mathbf{n} = -\mathrm{i}k_i M\boldsymbol{\xi}_i$. Using (129.29) and summing over the spatial noise index gives exactly (129.32). For real ω and real D, Σ, $M(-\omega)^T = M(\omega)^\dagger$ after lowering and raising only ordinary finite charge indices, so

$$u^\dagger G^S_{nn} u = 2Tk^2\,(M^\dagger u)^\dagger \Sigma (M^\dagger u) \geq 0 \tag{129.36}$$

for every complex vector u.

It remains to prove the matrix fluctuation–dissipation identity without assuming that D and Σ commute. The response kernel from (129.25) is

$$K^R_{nn} = Mk^2\Sigma. \tag{129.37}$$

Since $D = \Sigma\chi^{-1}$ and χ, Σ are symmetric,

$$(Dk^2 - \mathrm{i}\omega)\chi = k^2\Sigma - \mathrm{i}\omega\chi, \qquad \chi(D^Tk^2 + \mathrm{i}\omega) = k^2\Sigma + \mathrm{i}\omega\chi. \tag{129.38}$$

Therefore

$$K^R_{nn} = M\big[(Dk^2 - \mathrm{i}\omega)\chi + \mathrm{i}\omega\chi\big] = \chi + \mathrm{i}\omega M\chi, \tag{129.39}$$

and similarly

$$K^A_{nn} = \big[\chi(D^Tk^2 + \mathrm{i}\omega) - \mathrm{i}\omega\chi\big]M(-\omega)^T = \chi - \mathrm{i}\omega\chi M(-\omega)^T. \tag{129.40}$$

Subtracting gives

$$K^R_{nn} - K^A_{nn} = \mathrm{i}\omega\big(M\chi + \chi M(-\omega)^T\big). \tag{129.41}$$

Multiplying (129.38) on the left and right by the two resolvents gives

$$M\chi + \chi M(-\omega)^T = 2k^2 M\Sigma M(-\omega)^T. \tag{129.42}$$

Combining the last two displays yields

$$\frac{K^R_{nn} - K^A_{nn}}{2\mathrm{i}} = \omega k^2 M\Sigma M(-\omega)^T, \tag{129.43}$$

which is equivalent to (129.34) after using (129.32). □

129.6 Dynamical KMS at Quadratic Order

Assume the initial state is thermal with inverse temperature $\beta = 1/T$ and that the long-wavelength effective action has the classical dynamical KMS symmetry appropriate to the derivative order under consideration. In the diffusion sector, and for time-reversal-even charge densities, the transformation needed at this order is

$$B^A_{ai}(t, \mathbf{x}) \mapsto B^A_{ai}(-t, \mathbf{x}) + \mathrm{i}\beta\, \partial_t B^A_{ri}(-t, \mathbf{x}), \tag{129.44}$$

with the time-reversal parity of the spatial vector field included in $\partial_t B^A_{ri}(-t, \mathbf{x})$. To see the coefficient constraint, keep one spatial component and write the dissipative-noise part as

$$L = -a^A \Sigma_{AB} x^B + \mathrm{i}a^A C_{AB} a^B, \qquad a^A = B^A_{ai}, \qquad x^A = \partial_t B^A_{ri},$$

where C_{AB} is the unknown symmetric noise matrix. Time reversal sends $x \mapsto -x$, while the KMS shift sends $a \mapsto a + \mathrm{i}\beta x$. The transformed expression is

$$L' = a^A(\Sigma_{AB} - 2\beta C_{AB})x^B + \mathrm{i}a^A C_{AB} a^B + \mathrm{i}\beta x^A(\Sigma_{AB} - \beta C_{AB})x^B.$$

Equality with L, up to total derivatives and terms beyond the retained order, requires the coefficient of $a^A x^B$ to match:

$$\Sigma_{AB} - 2\beta C_{AB} = -\Sigma_{AB}.$$

The $x^A x^B$ terms then cancel by the same condition. Therefore

$$C_{AB} = \frac{\Sigma_{AB}}{\beta} = T\Sigma_{AB}, \tag{129.45}$$

which is the coefficient in (129.20). This is the local effective-action form of the fluctuation–dissipation relation of Chapter 127.

129.7 Relation to Stress-Tensor Hydrodynamics

For stress-tensor hydrodynamics, the charge phase fields are replaced by doubled maps from a fluid worldvolume into spacetime, together with doubled metrics and, when charges are present, the phases above. The structural logic is the same:

$$\begin{aligned}
\text{gauge/diffeomorphism invariance} &\Longrightarrow \text{Ward identities},\\
I[A, A] = 0 &\Longrightarrow \text{closed-time-path normalization},\\
\operatorname{Im} I \geq 0 &\Longrightarrow \text{positive noise kernel},\\
\text{dynamical KMS} &\Longrightarrow \text{dissipation–fluctuation relations}.
\end{aligned}$$

At first derivative order this reproduces the viscous stress tensor and noise kernel used in Chapter 134. At higher derivative order the classification becomes a local invariant problem for doubled fields subject to the constraints above. A term belongs to the hydrodynamic effective action only after its frame dependence, contact-term ambiguity, KMS transformation, and positivity properties have been specified.

129.8 The Microscopic Theorem Boundary

The construction in this chapter is an effective-field-theory statement. A microscopic derivation from QFT would have to construct the real-time generating functional in a thermal state, take the thermodynamic limit, identify the hydrodynamic scaling limit, prove that the only nonanalytic long-wavelength modes are the conserved densities, and show that the local functional above is the asymptotic expansion of connected Schwinger–Keldysh correlators in a controlled topology. The local positivity and KMS constraints are necessary consequences of the microscopic closed time path; they are not by themselves a proof of thermalization.

Open Problem 129.4 (Microscopic derivation of SK hydrodynamic action). Starting from a continuum QFT with a KMS state, derive the hydrodynamic Schwinger–Keldysh effective action as a controlled long-wavelength limit of connected real-time correlators, including the topology in which the derivative expansion is asymptotic, the treatment of contact terms, and the relation between source-response kernels and commutator spectral functions.

Chapter 130

Thermal Gauge Theory And Screening

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter studies gauge theories at nonzero temperature through static correlators and their long-distance screening behavior. Let d denote the number of spatial dimensions, so the thermal Euclidean spacetime is $S^1_\beta \times \mathbb{R}^d$ before spatial infrared regularization. The coupling and trace conventions are those of the gauge chapters: the Yang–Mills action is written with

$$\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu}),$$

and group invariants are computed using the same invariant bilinear form.

130.1 Static Correlators

Let the Euclidean time circle have length $\beta = 1/T$. A bosonic field has Matsubara frequencies $\omega_n = 2\pi nT$. Static screening is controlled by the $n = 0$ sector of gauge-invariant correlators. For an operator $\mathcal{O}(\tau, \mathbf{x})$, define its static projection by

$$\mathcal{O}_0(\mathbf{x}) = T\int_0^\beta d\tau\,\mathcal{O}(\tau, \mathbf{x}).$$

The screening masses are inverse correlation lengths extracted from

$$\langle \mathcal{O}_0(\mathbf{x})\mathcal{O}_0(0)\rangle_c \sim \sum_\alpha C_\alpha \frac{e^{-M_\alpha|\mathbf{x}|}}{|\mathbf{x}|^{(d-1)/2}}$$

when the static transfer matrix has isolated lowest eigenvalues in the chosen channel.

The power of $|\mathbf{x}|$ in this formula is fixed by the continuum spatial Fourier transform, not by a convention for the operator. If the static momentum-space correlator has an isolated scalar pole

$$\widetilde{C}(\mathbf{k}) = \frac{Z}{\mathbf{k}^2 + M^2} + \text{terms less singular at } \mathbf{k}^2 = -M^2,$$

then

$$C(\mathbf{x}) = Z\,\frac{M^{d/2-1}}{(2\pi)^{d/2}|\mathbf{x}|^{d/2-1}}\,K_{d/2-1}(M|\mathbf{x}|) + \cdots, \tag{130.1}$$

and the large-distance asymptotic of the modified Bessel function gives

$$C(\mathbf{x}) \sim Z\,\frac{M^{(d-3)/2}}{2(2\pi)^{(d-1)/2}}\,\frac{e^{-M|\mathbf{x}|}}{|\mathbf{x}|^{(d-1)/2}}.$$

If instead one projects to zero momentum in the transverse directions and keeps a single separation coordinate z, the same pole gives

$$C_{\text{proj}}(z) = \int d^{d-1}x_\perp\, C(z,\mathbf{x}_\perp) = \frac{Z}{2M}e^{-M|z|} + \cdots.$$

This projected form is the one most directly read from a spatial transfer matrix. With spatial volume first regulated in a box transverse to the z-direction, reflection positivity in z gives a Hilbert space on the slice $S^1_\beta \times \mathbb{T}^{d-1}$, a positive transfer Hamiltonian H_z, and

$$C_{\text{proj}}(z) = \sum_{\alpha\neq 0} |\langle \Omega_z, \widehat{\mathcal{O}}_0\alpha\rangle|^2 e^{-M_\alpha|z|}, \qquad M_\alpha = E^{(z)}_\alpha - E^{(z)}_0.$$

The sum is over states in the static, gauge-invariant channel created by $\mathcal{O}_0$. In infinite transverse volume the isolated eigenvalues may become thresholds, but the leading exponential rate is still a property of gauge-invariant static correlators, not of gauge-fixed propagator poles.

130.2 Electric Screening

In a weakly coupled high-temperature regime, the temporal gauge field A_0 behaves in the static sector as an adjoint scalar. The electric screening mass is defined perturbatively by the pole of the static longitudinal propagator, or nonperturbatively by the lowest gauge-invariant state in the electric channel after the relevant operator has been specified.

These two definitions should not be conflated. The perturbative Debye mass is a matching coefficient of the static effective theory in a specified gauge, regulator, and operator convention. A physical screening mass is extracted from a gauge-invariant static correlator, for example from operators built from A_0 inside the dimensionally reduced theory or from renormalized Polyakov loops in the original thermal theory. At weak coupling the Debye coefficient controls the electric scale gT and organizes the gauge-invariant spectrum, but the spectrum itself is defined by the transfer matrix construction above.

Choose a basis T_R^a for each representation R such that

$$\mathrm{tr}_R(T_R^a T_R^b) = T_R \delta^{ab}, \qquad f^{acd} f^{bcd} = C_A \delta^{ab}.$$

With the same coupling g in the covariant derivative and in the kinetic term convention above, the one-loop static polarization gives

$$m_D^2 = g^2 T^2 \left(\frac{C_A}{3} + \frac{1}{3} \sum_{\text{Dirac } f} T_{R_f} + \frac{1}{3} \sum_{\text{complex } s} T_{R_s} + \frac{1}{6} \sum_{\text{real } r} T_{R_r} \right). \tag{130.2}$$

For $SU(N)$ with the fundamental trace convention $\mathrm{tr}_{\mathbf{N}}(T^a T^b) = \delta^{ab}$, this means $C_A = 2N$ and $T_{\mathbf{N}} = 1$.

Thermal susceptibility integrals. For $n_B(x) = (e^x - 1)^{-1}$ and $n_F(x) = (e^x + 1)^{-1}$,

$$\frac{1}{T} \int \frac{\mathrm{d}^3 p}{(2\pi)^3} n_B(|p|/T)(1 + n_B(|p|/T)) = \frac{T^2}{6}, \tag{130.3}$$

$$\frac{1}{T} \int \frac{\mathrm{d}^3 p}{(2\pi)^3} n_F(|p|/T)(1 - n_F(|p|/T)) = \frac{T^2}{12}. \tag{130.4}$$

Set $x = |p|/T$. Then

$$\frac{1}{T} \int \frac{\mathrm{d}^3 p}{(2\pi)^3} n(1 \pm n) = \frac{T^2}{2\pi^2} \int_0^\infty x^2 n(x)(1 \pm n(x))\, \mathrm{d}x.$$

Since

$$n_B(1 + n_B) = -\frac{\mathrm{d}n_B}{\mathrm{d}x}, \qquad n_F(1 - n_F) = -\frac{\mathrm{d}n_F}{\mathrm{d}x},$$

integration by parts gives

$$\int_0^\infty x^2 n_B(1 + n_B)\, \mathrm{d}x = 2 \int_0^\infty \frac{x}{e^x - 1}\, \mathrm{d}x = \frac{\pi^2}{3},$$

and

$$\int_0^\infty x^2 n_F(1 - n_F)\, \mathrm{d}x = 2 \int_0^\infty \frac{x}{e^x + 1}\, \mathrm{d}x = \frac{\pi^2}{6}.$$

Substitution gives (130.3) and (130.4).

Lemma 130.1 (One-loop origin and coefficient of the Debye mass term)**.** *At one loop, the static quadratic term for A_0 in the dimensionally reduced action is the zero-frequency, zero-momentum limit of the Euclidean current-current correlator coupled to A_0, and its value is* (130.2)*.*

Proof. Introduce a background temporal field A_0^a that is independent of Euclidean time and space. Expanding the finite-temperature generating functional to second order gives

$$\Delta W^{(2)} = \frac{1}{2} A_0^a A_0^b \int_0^\beta d\tau \int d^{d-1}x \, \left\langle J_0^a(\tau, \mathbf{x}) J_0^b(0, 0) \right\rangle_c . \tag{130.5}$$

Translation invariance identifies the integral with the static polarization $\Pi^{ab}_{00}(0,\mathbf{0})$. Gauge symmetry in the unbroken thermal state sets this tensor proportional to δ^{ab}. The coefficient is the mass matrix of the adjoint scalar A_0 in the static effective action, which is $m_D^2\delta^{ab}$.

It remains to compute the coefficient. A constant $A_0 = A_0^a t^a$ shifts the Matsubara frequencies exactly as an imaginary color chemical potential. For a weight w of a representation R, the quadratic operator depends on

$$\omega_n \longmapsto \omega_n + w(A_0),$$

for bosons, with the analogous anti-periodic frequencies for fermions. This statement can be checked directly from the covariant derivative $D_0 = \partial_\tau + \mathrm{ad}_{A_0}$, and then extended from a Cartan-valued A_0 to arbitrary A_0 by G-invariance of the quadratic form.

For one complex bosonic oscillator of energy $E = |p|$ and charge q, the thermal part of the free-energy density is

$$T\log\left(1-e^{-\beta(E-\mu q)}\right) + T\log\left(1-e^{-\beta(E+\mu q)}\right).$$

Putting $\mu = ia$ and differentiating twice at $a = 0$ gives

$$\left.\frac{\partial^2 f_B(ia)}{\partial a^2}\right|_{a=0} = \frac{2q^2}{T}\, n_B(E/T)(1+n_B(E/T)).$$

Thus a real bosonic Gaussian determinant, which is one half of the complex determinant in a real representation, contributes

$$\frac{q^2}{T}\, n_B(E/T)(1+n_B(E/T)).$$

For one Dirac oscillator, the two spin polarizations and the particle-antiparticle pair give

$$\left.\frac{\partial^2 f_F(ia)}{\partial a^2}\right|_{a=0} = \frac{4q^2}{T}\, n_F(E/T)(1-n_F(E/T)).$$

After summing over weights, q^2 is replaced by $w^a w^b A_0^a A_0^b$, and $\sum_w w^a w^b = \mathrm{tr}_R(T_R^a T_R^b) = T_R\delta^{ab}$.

A single real bosonic degree of freedom in a real representation therefore contributes

$$\chi^{ab}_{\text{real boson}} = T_R\delta^{ab}\frac{1}{T}\int\frac{\mathrm{d}^3p}{(2\pi)^3} n_B(1+n_B) = \frac{T^2}{6}T_R\delta^{ab}. \tag{130.6}$$

A complex scalar has two real thermal degrees of freedom in R, and hence contributes $T^2 T_R\delta^{ab}/3$. A Dirac fermion has two spin polarizations and particle/antiparticle excitations. The anti-periodic Matsubara sum gives the fermionic integral in the susceptibility calculation above, so

$$\chi^{ab}_{\text{Dirac}} = 4T_R\delta^{ab}\frac{1}{T}\int\frac{\mathrm{d}^3p}{(2\pi)^3} n_F(1-n_F) = \frac{T^2}{3}T_R\delta^{ab}. \tag{130.7}$$

For gauge fields, use background-field gauge around the flat background A_0. Since the background field strength vanishes, the quadratic vector operator is $-D^2\delta_{\mu\nu}$ and the ghost operator is $-D^2$, both in the adjoint representation. The one-loop contribution to the thermal free energy is therefore

$$\frac{1}{2}\mathrm{Tr}_{\text{adj, vec}}\log(-D^2) - \mathrm{Tr}_{\text{adj, gh}}\log(-D^2) = \left(\frac{4}{2}-1\right)\mathrm{Tr}_{\text{adj}}\log(-D^2)$$

in four spacetime dimensions. The right side is the determinant of two real periodic bosonic thermal degrees of freedom in the adjoint representation: the temporal and longitudinal gauge-dependent pieces have cancelled against the periodic complex ghost pair. Using $T_{\rm adj} = C_A$, this gives

$$\chi^{ab}_{\rm gauge} = 2\frac{T^2}{6}C_A\delta^{ab} = \frac{T^2}{3}C_A\delta^{ab}. \tag{130.8}$$

The four-dimensional one-loop free-energy density contains $\frac{1}{2}\chi^{ab}A_0^aA_0^b$. Multiplying by the thermal circle length $\beta = 1/T$ gives the three-dimensional effective action. Since the static action is written as

$$\int \mathrm{d}^3x\,\frac{m_D^2}{2g_3^2}\,\mathrm{tr}(A_0^2), \qquad g_3^2 = g^2T,$$

and $\mathrm{tr}(A_0^2) = \delta^{ab}A_0^aA_0^b$ in the default trace convention, matching gives $m_D^2 = g^2\chi$. Adding the gauge, Dirac, complex-scalar, and real-scalar susceptibilities gives (130.2). □

Controlled Approximation 130.2 (HTL bridge from Debye matching to response)**.** The Debye coefficient above is the static face of a real-time soft response. The hard-thermal-loop approximation is the controlled leading response when the external frequency and momentum satisfy

$$\omega,\ |\mathbf{k}| = O(gT)$$

while the particles carrying the loop momentum have

$$p = O(T).$$

The calculation keeps the collisionless angular motion of the hard particles and expands only in the ratio of soft external scale to hard momentum. It is therefore not a local Lorentz-invariant mass term for the gauge field, and it does not determine the nonperturbative magnetic scale.

Lemma 130.3 (Static Debye term as the zero-frequency HTL limit)**.** *In the rest frame of the equilibrium state, let*

$$v^\mu = (1,\mathbf{v}), \qquad |\mathbf{v}| = 1, \qquad \int_{\mathbf{v}}(\cdots) = \int_{S^2}\frac{\mathrm{d}\Omega_{\mathbf{v}}}{4\pi}(\cdots).$$

With mostly-plus Lorentzian convention and

$$K_\mu = (-\omega,\mathbf{k}),$$

the retarded HTL induced-current kernel

$$\mathcal{K}_R^{\mu\nu,ab}(\omega,\mathbf{k}) = \delta^{ab}m_D^2\left[\delta_0^\mu\delta_0^\nu - \omega\int_{\mathbf{v}}\frac{v^\mu v^\nu}{\omega - \mathbf{v}\cdot\mathbf{k} + i0}\right] \tag{130.9}$$

is transverse,

$$K_\mu\mathcal{K}_R^{\mu\nu,ab} = 0,$$

and its static response is

$$\mathcal{K}_R^{00,ab}(0,\mathbf{k}) = \delta^{ab}m_D^2, \qquad \mathcal{K}_R^{0i,ab}(0,\mathbf{k}) = \mathcal{K}_R^{ij,ab}(0,\mathbf{k}) = 0.$$

Thus the one-loop coefficient in (130.2) is the zero-frequency electric susceptibility of a conserved retarded response, not a gauge-field mass assigned independently of the response kernel.

Proof. The mechanism is most transparent in the gauge-covariant kinetic form. Let $W(x, \mathbf{v})$ be an adjoint auxiliary field and set

$$(v \cdot D)W(x, \mathbf{v}) = v^i F_{i0}(x), \qquad j^\mu(x) = m_D^2 \int_{\mathbf{v}} v^\mu W(x, \mathbf{v}).$$

The current is covariantly conserved before choosing a gauge:

$$D_\mu j^\mu = m_D^2 \int_{\mathbf{v}} (v \cdot D)W = m_D^2 \int_{\mathbf{v}} v^i F_{i0} = 0,$$

because F_{i0} is independent of $\mathbf{v}$ and $\int_{\mathbf{v}} v^i = 0$.

Linearize around $A_\mu = 0$ and take fields proportional to $\exp(-i\omega t + i\mathbf{k} \cdot \mathbf{x})$. The retarded solution of $(\partial_t + \mathbf{v} \cdot \nabla)W = v^i F_{i0}$ is

$$W(K, \mathbf{v}) = -\frac{\mathbf{v} \cdot \mathbf{k}\, A_0(K) + \omega\, v^i A_i(K)}{\omega - \mathbf{v} \cdot \mathbf{k} + i0},$$

where $F_{i0} = \partial_i A_0 - \partial_0 A_i$. Substitution in $j^\mu = m_D^2 \int_{\mathbf{v}} v^\mu W$ gives

$$j^\mu = m_D^2 \left[\delta_0^\mu \delta_0^\nu - \omega \int_{\mathbf{v}} \frac{v^\mu v^\nu}{\omega - \mathbf{v} \cdot \mathbf{k} + i0} \right] A_\nu.$$

The A_0 coefficient uses the identity

$$-\frac{\mathbf{v} \cdot \mathbf{k}}{\omega - \mathbf{v} \cdot \mathbf{k} + i0} = 1 - \frac{\omega}{\omega - \mathbf{v} \cdot \mathbf{k} + i0}$$

inside the angular integral and $\int_{\mathbf{v}} v^\mu = \delta_0^\mu$. Restoring the color factor gives (130.9).

Transversality follows directly. Since

$$K_\mu v^\mu = -(\omega - \mathbf{v} \cdot \mathbf{k}),$$

contracting K_μ into (130.9) cancels the denominator and leaves

$$K_\mu \mathcal{K}_R^{\mu\nu,ab} = \delta^{ab} m_D^2 \left[-\omega \delta_0^\nu + \omega \int_{\mathbf{v}} v^\nu \right].$$

The angular integral equals 1 for $\nu = 0$ and 0 for each spatial index, so the contraction vanishes.

Finally set $\omega = 0$ in the retarded static response at fixed $\mathbf{k}$. The angular term in (130.9) carries an explicit factor of ω, and the remaining tensor is $\delta^{ab} m_D^2 \delta_0^\mu \delta_0^\nu$. This is exactly the electric mass coefficient matched into the static effective theory. □

130.3 Magnetic Sector

The spatial gauge fields A_i have no gauge-invariant local mass term in the dimensionally reduced action. The high-temperature static magnetic sector is therefore a three-dimensional Yang–Mills theory with coupling

$$g_3^2 = g^2 T$$

in four spacetime dimensions. Its infrared scale is of order g_3^2, and the corresponding magnetic screening lengths are nonperturbative objects of the three-dimensional gauge theory. Perturbative expansions of static magnetic quantities encounter this scale because massless spatial gauge fields remain in the reduced action.

130.4 Polyakov Loop And Center Symmetry

The thermal Wilson line at spatial point $\mathbf{x}$ is

$$P(\mathbf{x}) = \mathcal{P}\exp\left(\mathrm{i}\int_0^\beta d\tau\, A_0(\tau,\mathbf{x})\right).$$

In a pure gauge theory, its trace in a representation charged under the center transforms under the center one-form symmetry wrapped on the thermal circle. The free energy of an external static charge is defined by

$$e^{-\beta F_Q} = \langle \mathrm{tr}_R\, P(\mathbf{x})\rangle$$

after renormalizing the line. Correlators of two Polyakov loops define static color-singlet free energies; their large-distance decay belongs to the screening spectrum rather than to a zero-temperature particle spectrum.

Definition 130.4 (Renormalized static-source free-energy datum)**.** At finite cutoff Λ, let $P_R^\Lambda(\mathbf{x})$ be the regularized thermal line in representation R. A static-source renormalization scheme consists of additive line energies $\delta m_R(\Lambda)$, equivalently multiplicative factors

$$Z_R(\Lambda,\beta) = \exp\{\beta\,\delta m_R(\Lambda)\}, \qquad P_R^{\mathrm{ren}}(\mathbf{x}) = Z_R(\Lambda,\beta)P_R^\Lambda(\mathbf{x}).$$

For a conjugate pair at separation $r = |\mathbf{x}-\mathbf{y}|$, define

$$\begin{aligned} e^{-\beta F_R^{\mathrm{ren}}} &:= \left\langle d_R^{-1}\,\mathrm{tr}_R\, P_R^{\mathrm{ren}}(\mathbf{x})\right\rangle, \\ e^{-\beta F_{R\bar{R}}^{\mathrm{ren}}(r)} &:= \left\langle d_R^{-2}\,\mathrm{tr}_R\, P_R^{\mathrm{ren}}(\mathbf{x})\ \mathrm{tr}_{\bar{R}}\, P_{\bar{R}}^{\mathrm{ren}}(\mathbf{y})\right\rangle. \end{aligned}$$

Changing the finite part of δm_R shifts F_R^{ren} by an additive constant. The datum therefore includes the line scheme whenever an absolute one-source free energy is quoted.

Lemma 130.5 (Line self-energy cancellation in static-source ratios)**.** *In the datum of Definition 130.4, assume the expectation values are taken in a fixed physical state and center-sector prescription, or in a source-selected infinite-volume limit, for which the one-source expectations satisfy $C_R^{\mathrm{ren}}C_{\bar{R}}^{\mathrm{ren}} \neq 0$. Then the pair excess free energy*

$$\Delta F_{R\bar{R}}(r) = F_{R\bar{R}}^{\mathrm{ren}}(r) - F_R^{\mathrm{ren}} - F_{\bar{R}}^{\mathrm{ren}}$$

is independent of the multiplicative line factors $Z_R, Z_{\bar{R}}$. So is the static force

$$\mathcal{F}_{R\bar{R}}(r,T) = -\partial_r F_{R\bar{R}}^{\mathrm{ren}}(r,T),$$

which requires no division by the one-source expectations, provided the pair correlator defines $F_{R\bar{R}}^{\mathrm{ren}}$ and the line counterterms are local energies of the individual wrapped sources and hence independent of r.

Proof. Write the cutoff expectations as

$$C_R^\Lambda = \langle P_R^\Lambda\rangle, \qquad C_{R\bar{R}}^\Lambda(r) = \langle P_R^\Lambda(\mathbf{x})P_{\bar{R}}^\Lambda(\mathbf{y})\rangle$$

with the displayed normalized traces suppressed. Renormalization gives

$$C_R^{\mathrm{ren}} = Z_R C_R^\Lambda, \qquad C_{R\bar{R}}^{\mathrm{ren}}(r) = Z_R Z_{\bar{R}} C_{R\bar{R}}^\Lambda(r).$$

When $C_R^\Lambda C_{\bar R}^\Lambda \neq 0$, equivalently after finite renormalization $C_R^{\rm ren} C_{\bar R}^{\rm ren} \neq 0$, therefore

$$\exp\{-\beta \Delta F_{R\bar R}(r)\} = \frac{C_{R\bar R}^{\rm ren}(r)}{C_R^{\rm ren} C_{\bar R}^{\rm ren}} = \frac{C_{R\bar R}^{\Lambda}(r)}{C_R^{\Lambda} C_{\bar R}^{\Lambda}},$$

so all one-line factors cancel before the continuum limit is discussed. This is a conditional ratio statement, not a definition in a sector where either one-point function vanishes. For the force, no one-point divisor is used:

$$F_{R\bar R}^{\rm ren}(r,T) = F_{R\bar R}^{\Lambda}(r,T) - \delta m_R(\Lambda) - \delta m_{\bar R}(\Lambda),$$

and differentiating with respect to r removes the same local constants. □

Thus the absolute number assigned to a single static-source free energy is a line-scheme coordinate, while the conditional connected Polyakov-loop ratio and the source-pair force are the quantities that can be compared across regulators after the same physical state and center-sector limit have been specified. In a center-symmetric finite-volume pure gauge theory the nonzero-N-ality one-point function still vanishes before any finite multiplicative renormalization; the source-selected infinite-volume limit is the separate order-parameter limit used in phase discussions. In the center-symmetric sector itself one instead uses the neutral pair correlator

$$G_{R\bar R}^{\rm ren}(r) = \left\langle d_R^{-2}\, \mathrm{tr}_R\, P_R^{\rm ren}(\mathbf{x})\ \mathrm{tr}_{\bar R}\, P_{\bar R}^{\rm ren}(\mathbf{y})\right\rangle$$

or, where this correlator is nonzero and differentiable in r, the direct pair force

$$-\partial_r F_{R\bar R}^{\rm ren}(r,T) = \beta^{-1}\partial_r \log G_{R\bar R}^{\rm ren}(r),$$

without assigning finite one-source free energies.

130.5 Dimensional Reduction

At distances much larger than β, nonzero Matsubara modes can be integrated out into a three-dimensional effective theory. In four spacetime dimensions the bosonic part begins as

$$S_{\rm EQCD} = \int d^3x\, \left[\frac{1}{4g_3^2}\,\mathrm{tr}(F_{ij}F_{ij}) + \frac{1}{2g_3^2}\,\mathrm{tr}(D_iA_0D_iA_0) + \frac{m_E^2}{2g_3^2}\,\mathrm{tr}(A_0^2) + \lambda_E\ \mathrm{tr}(A_0^4) + \cdots\right].$$

The ellipsis denotes higher local operators ordered by the static derivative and field expansion. A quantitative use of this action requires matching the coefficients $g_3^2, m_E^2, \lambda_E, \ldots$ in the same regulator and operator scheme as the original thermal theory.

Open Problem 130.6 (Gauge-invariant screening spectrum). Give a continuum construction of the full static screening spectrum of thermal non-Abelian gauge theory from gauge-invariant operators, including the relation between perturbative electric matching, nonperturbative magnetic dynamics, and Polyakov-loop sectors.

Chapter 131

Kinetic Theory As A Controlled Limit

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Kinetic theory is the long-wavelength, weakly off-equilibrium description in which selected real-time QFT correlators are represented by on-shell phase-space densities. The construction has three inputs: a quasiparticle spectral regime, an on-shell collision kernel extracted from microscopic scattering or finite-temperature amplitudes, and a hierarchy separating the microscopic correlation scale from the spacetime scale of variation. This chapter develops the relativistic Boltzmann framework with the assumptions kept explicit, derives detailed balance and the entropy inequality, and records the precise point at which kinetic theory becomes hydrodynamics.

Let spacetime dimension be $D = d + 1$, with spatial momentum $\mathbf{p} \in \mathbb{R}^d$. For species a,

$$p^\mu = (E_a(\mathbf{p}), \mathbf{p}), \qquad E_a(\mathbf{p}) = \sqrt{\mathbf{p}^2 + m_a^2}.$$

The Lorentz-invariant on-shell measure used below is

$$d\Pi_a(p) = \frac{d^d\mathbf{p}}{(2\pi)^d \, 2E_a(\mathbf{p})}. \tag{131.1}$$

The factor $2p^\mu d\Pi_a$ has the standard equal-time interpretation:

$$2E_a \, d\Pi_a = \frac{d^d\mathbf{p}}{(2\pi)^d}.$$

Internal degeneracies may be included by replacing the species label a with a refined label, or by inserting an explicit degeneracy g_a.

131.1 Quasiparticle Distribution From Spectral Data

Let $G_a^<(x,y)$ be a Wightman two-point function for a microscopic field or for a gauge-invariant quasiparticle interpolating operator in a regulated theory. Introduce center and relative coordinates

$$X = \frac{x+y}{2}, \qquad s = x - y,$$

and define the Wigner transform

$$G_a^<(X,p) = \int d^D s\, e^{\mathrm{i}p\cdot s} G_a^<(X+s/2, X-s/2).$$

The quasiparticle distribution $f_a(X,\mathbf{p})$ is the coefficient of the positive-energy pole contribution when the spectral density has the form

$$\rho_a(X,p) = 2\pi Z_a(X,\mathbf{p})\,\mathrm{sgn}(p^0)\delta\big((p^0)^2 - E_a(\mathbf{p})^2\big) + \rho_a^{\mathrm{off}}(X,p), \tag{131.2}$$

with the off-shell remainder small in the topology used for the gradient expansion. Equivalently, near $p^0 = E_a(\mathbf{p})$,

$$G_a^<(X,p) = 2\pi Z_a(X,\mathbf{p}) f_a(X,\mathbf{p})\delta(p^0 - E_a(\mathbf{p})) + \text{controlled off-shell remainder}.$$

The pole approximation requires

$$\Gamma_a(\mathbf{p}) \ll E_a(\mathbf{p}), \qquad \Gamma_a(\mathbf{p})\,\ell_{\mathrm{variation}} \ll 1, \tag{131.3}$$

where Γ_a is the damping width and $\ell_{\mathrm{variation}}$ is the spacetime scale over which f_a changes. These inequalities are hypotheses on the state and on the coupling regime; they are not consequences of conservation laws alone.

131.2 Quasiparticle Projection of the Two-Point Equation

The Boltzmann drift term is the on-shell projection of the leading Schwinger–Keldysh two-point equation. We record the projection explicitly because it is the point where an operator statement about correlators becomes a phase-space equation.

Controlled Approximation 131.1 (Force-free quasiparticle projection)**.** Consider one scalar species in flat spacetime, with constant mass and a single narrow positive-energy peak. Let

$$F(p) = (p^0)^2 - E(\mathbf{p})^2, \qquad E(\mathbf{p}) = \sqrt{\mathbf{p}^2 + m^2}, \tag{131.4}$$

and assume that the leading-gradient Kadanoff–Baym equation has the form

$$\frac{1}{2}\{F, G^<\}_{\mathrm{kin}} = I^<[G], \tag{131.5}$$

where $I^<$ is the collision functional and

$$\{A,B\}_{\mathrm{kin}} = \partial_{p^0} A\,\partial_t B - \partial_t A\,\partial_{p^0} B - \partial_{\mathbf{p}} A \cdot \nabla_{\mathbf{x}} B + \nabla_{\mathbf{x}} A \cdot \nabla_{\mathbf{p}} B. \tag{131.6}$$

Use the positive-energy ansatz

$$G^{<}(X,p) = 2\pi Z(\mathbf{p}) f(X,\mathbf{p}) \delta(p^0 - E(\mathbf{p})) \tag{131.7}$$

with Z independent of X at this order. Terms from mean-field forces, Berry curvature, spatially varying masses, and off-shell memory kernels are omitted in this controlled approximation; each of them modifies the left-hand side by additional explicitly computable phase-space terms.

Remark 131.2 (Projection of the drift term). Under Controlled Approximation 131.1, the positive-energy shell projection of (131.5) is

$$p^\mu \partial_\mu f(X,\mathbf{p}) = \mathcal{C}[f](X,\mathbf{p}), \qquad p^\mu = (E(\mathbf{p}),\mathbf{p}), \tag{131.8}$$

with

$$\mathcal{C}[f](X,\mathbf{p}) = \frac{1}{Z(\mathbf{p})} \int_0^\infty \frac{dp^0}{2\pi}\, I^{<}[G](X,p). \tag{131.9}$$

Since F is independent of X,

$$\{F, G^{<}\}_{\mathrm{kin}} = 2p^0 \partial_t G^{<} + 2\mathbf{p}\cdot\nabla_{\mathbf{x}} G^{<}. \tag{131.10}$$

Using (131.7) and the X-independence of Z and E,

$$\frac{1}{2}\{F, G^{<}\}_{\mathrm{kin}} = 2\pi Z(\mathbf{p})\big(p^0\partial_t + \mathbf{p}\cdot\nabla_{\mathbf{x}}\big) f(X,\mathbf{p})\, \delta(p^0 - E(\mathbf{p})). \tag{131.11}$$

Integrating over $p^0 > 0$ and dividing by $Z(\mathbf{p})$ gives

$$E(\mathbf{p})\partial_t f + \mathbf{p}\cdot\nabla_{\mathbf{x}} f = \frac{1}{Z(\mathbf{p})}\int_0^\infty \frac{dp^0}{2\pi} I^{<}[G](X,p), \tag{131.12}$$

which is (131.8). Dividing by E gives the coordinate-time form $(\partial_t + \mathbf{v}\cdot\nabla_{\mathbf{x}})f = C^{(t)}[f]$ with $\mathbf{v} = \mathbf{p}/E$.

131.3 Boltzmann Equation and Collision Kernel

The covariant Boltzmann equation is

$$p^\mu \partial_\mu f_a(X,\mathbf{p}) = \mathcal{C}_a[f](X,\mathbf{p}). \tag{131.13}$$

In coordinate time this is

$$(\partial_t + \mathbf{v}_a\cdot\nabla_{\mathbf{x}})\, f_a = C_a^{(t)}[f], \qquad \mathbf{v}_a = \nabla_{\mathbf{p}} E_a, \qquad C_a^{(t)} = \frac{\mathcal{C}_a}{E_a}.$$

For $a(p_1)b(p_2) \to c(p_3)d(p_4)$, define

$$\eta_a = \begin{cases} +1, & a \text{ bosonic}, \\ -1, & a \text{ fermionic}. \end{cases}$$

The $2 \to 2$ contribution to $\mathcal{C}_a$ is

$$\mathcal{C}_a(p_1) = \frac{1}{2}\sum_{bcd}\int d\Pi_b(p_2)d\Pi_c(p_3)d\Pi_d(p_4)\,(2\pi)^D\delta^{(D)}(p_1+p_2-p_3-p_4)|\mathcal{M}_{ab\to cd}|^2$$
$$\times\Big[f_c(p_3)f_d(p_4)(1+\eta_a f_a(p_1))(1+\eta_b f_b(p_2))$$
$$- f_a(p_1)f_b(p_2)(1+\eta_c f_c(p_3))(1+\eta_d f_d(p_4))\Big]. \tag{131.14}$$

The factor $1/2$ converts the coordinate-time normalization to the covariant equation (131.13); equivalently, $C_a^{(t)}$ carries the familiar prefactor $1/(2E_1)$. Symmetry factors for identical particles are included in the definition of $|\mathcal{M}|^2$ and in the channel sum.

The matrix element in (131.14) is the on-shell scattering amplitude in the normalization of the scattering chapters, after the regulator and medium corrections relevant at the kinetic scale have been specified. In gauge theories this last clause is essential because soft exchange and collinear splitting can contribute at the same parametric order as $2 \to 2$ hard scattering.

131.4 Detailed Balance

The local equilibrium distribution is

$$f_a^{(0)}(X,\mathbf{p}) = \frac{1}{\exp[\beta(X)(-u_\mu(X)p^\mu - \mu_A(X)q_a^A)] - \eta_a}. \tag{131.15}$$

At a fixed point X, the identity

$$1+\eta_a f_a^{(0)} = e^{\beta(-u_\mu p^\mu - \mu_A q_a^A)} f_a^{(0)} \tag{131.16}$$

implies detailed balance. Indeed, for an allowed reaction satisfying

$$p_1+p_2 = p_3+p_4, \qquad q_a^A+q_b^A = q_c^A+q_d^A,$$

the loss product

$$X_{12\to34} = f_a^{(0)}(p_1)f_b^{(0)}(p_2)(1+\eta_c f_c^{(0)}(p_3))(1+\eta_d f_d^{(0)}(p_4))$$

equals the gain product

$$Y_{34\to12} = f_c^{(0)}(p_3)f_d^{(0)}(p_4)(1+\eta_a f_a^{(0)}(p_1))(1+\eta_b f_b^{(0)}(p_2)).$$

This is an algebraic consequence of (131.16): the exponential multiplying $f_1f_2f_3f_4$ is the same on the two sides by energy-momentum and charge conservation. Therefore the collision term vanishes on global equilibrium, and on local equilibrium it vanishes up to gradients of βu^μ and $\beta\mu_A$.

131.5 Kinetic Entropy and the H Theorem

Define the entropy current

$$S^\mu_{\text{kin}} = -\sum_a \int 2d\Pi_a\, p^\mu \left[f_a \log f_a - \eta_a(1+\eta_a f_a)\log(1+\eta_a f_a)\right]. \tag{131.17}$$

Using the Boltzmann equation,

$$\partial_\mu S^\mu_{\text{kin}} = -\sum_a \int 2d\Pi_a\, \mathcal{C}_a[f]\, \log\left(\frac{f_a}{1+\eta_a f_a}\right). \tag{131.18}$$

For the $2 \to 2$ kernel, symmetrizing over the four external legs gives

$$\begin{aligned}\partial_\mu S^\mu_{\text{kin}} = \frac{1}{4}\sum_{abcd}\int & d\Pi_1 d\Pi_2 d\Pi_3 d\Pi_4\, (2\pi)^D \delta^{(D)}(p_1+p_2-p_3-p_4)|\mathcal{M}_{ab\to cd}|^2 \\ & \times (X_{12\to 34} - Y_{34\to 12})\log\left(\frac{X_{12\to 34}}{Y_{34\to 12}}\right) \geq 0. \end{aligned}\tag{131.19}$$

The inequality follows from

$$(x-y)\log(x/y) \geq 0 \qquad (x>0,\ y>0).$$

Equality holds, within the set of reactions included in the kernel, exactly when each allowed gain product equals the corresponding loss product. When the reactions connect the species space sufficiently, this condition forces $\log[f_a/(1+\eta_a f_a)]$ to be a linear combination of the conserved collision invariants 1, p^μ, and q_a^A, giving (131.15).

131.6 Hydrodynamic Moments

The kinetic stress tensor and conserved currents are

$$T^{\mu\nu}(X) = \sum_a \int 2d\Pi_a\, p^\mu p^\nu f_a(X,\mathbf{p}), \tag{131.20}$$

$$J^\mu_A(X) = \sum_a q_{A,a}\int 2d\Pi_a\, p^\mu f_a(X,\mathbf{p}). \tag{131.21}$$

Multiplying (131.13) by $2p^\nu$ and integrating gives

$$\partial_\mu T^{\mu\nu} = \sum_a \int 2d\Pi_a\, p^\nu \mathcal{C}_a[f].$$

The right side vanishes because each collision conserves total four-momentum. Similarly,

$$\partial_\mu J^\mu_A = \sum_a q_{A,a}\int 2d\Pi_a\, \mathcal{C}_a[f] = 0$$

when the collision channels conserve charge q_A. Thus the hydrodynamic Ward identities are the collision-invariant moments of the kinetic equation.

At local equilibrium (131.15), the moments have the ideal-fluid form

$$T^{\mu\nu}_{(0)} = \varepsilon u^\mu u^\nu + p\Delta^{\mu\nu}, \qquad J^\mu_{A(0)} = n_A u^\mu,$$

with p, ε, and n_A obtained from the phase-space integrals. First-order transport arises from the first gradient correction to f_a.

131.7 Linearized Collision Operator

Write

$$f_a = f_a^{(0)} + f_a^{(0)}(1 + \eta_a f_a^{(0)})\chi_a. \tag{131.22}$$

To first order,

$$\mathcal{C}_a[f] = -\sum_b \mathcal{L}_{ab}\chi_b + O(\chi^2).$$

The natural inner product on perturbations is

$$\langle \phi, \psi \rangle = \sum_a \int 2d\Pi_a\, f_a^{(0)}(1 + \eta_a f_a^{(0)})\, \phi_a(p)\psi_a(p). \tag{131.23}$$

For the $2 \to 2$ collision kernel,

$$\begin{aligned} \langle \chi, \mathcal{L}\chi \rangle = \frac{1}{4} \sum_{abcd} \int & d\Pi_1 d\Pi_2 d\Pi_3 d\Pi_4\, (2\pi)^D \delta^{(D)}(p_1 + p_2 - p_3 - p_4) |\mathcal{M}_{ab\to cd}|^2 \\ & \times f_1^{(0)} f_2^{(0)} (1 + \eta_c f_3^{(0)})(1 + \eta_d f_4^{(0)}) \big(\chi_1 + \chi_2 - \chi_3 - \chi_4\big)^2 \geq 0. \end{aligned} \tag{131.24}$$

The null space consists of perturbations for which $\chi_1 + \chi_2 - \chi_3 - \chi_4 = 0$ for every included reaction. Under the same connectivity assumption used in the entropy argument, this null space is spanned by conserved collision invariants. Transport coefficients are quadratic forms involving the inverse of $\mathcal{L}$ on the orthogonal complement of this null space.

131.8 Finite Collision Algebra Behind the Integral Formula

The continuum formulas above are compact notations for a positive measure on reaction kinematics. The sign, null-space, and detailed-balance statements are already present at the finite algebraic level, so we record that level explicitly. This also fixes the precise content of the phrase "collision invariant" before functional analysis is added.

Definition 131.3 (Finite reversible collision datum)**.** A finite reversible collision datum consists of:

1. a finite set I of one-particle cells, each with a statistics sign $\eta_i \in \{+1, -1\}$;
2. an open state domain

$$\mathcal{D} = \{f \in \mathbb{R}^I : \ f_i > 0,\ 1 + \eta_i f_i > 0 \text{ for all } i\};$$

3. a finite set $\mathcal{R}$ of reversible reactions $r = (i, j; k, l)$, interpreted as $i + j \rightleftarrows k + l$, with weights $w_r > 0$;
4. additive labels P_i taking values in a real vector space $\mathcal{P}$, such that

$$P_i + P_j = P_k + P_l \tag{131.25}$$

for every reaction $r = (i, j; k, l)$.

For $f \in \mathcal{D}$, define

$$L_r(f) = f_i f_j(1+\eta_k f_k)(1+\eta_l f_l), \qquad G_r(f) = f_k f_l(1+\eta_i f_i)(1+\eta_j f_j), \tag{131.26}$$

and the stoichiometric vector

$$\nu_r = -e_i - e_j + e_k + e_l \in \mathbb{R}^I. \tag{131.27}$$

The collision vector field is

$$\dot{f} = \sum_{r\in\mathcal{R}} w_r\big(L_r(f) - G_r(f)\big)\nu_r. \tag{131.28}$$

Proposition 131.4 (Finite collision conservation and entropy production)**.** *For every finite reversible collision datum, the vector field (131.28) preserves every additive conserved quantity*

$$Q_A(f) = \sum_{i\in I} A(P_i) f_i, \qquad A \in \mathcal{P}^*. \tag{131.29}$$

Moreover the entropy

$$S(f) = -\sum_{i\in I}\left[f_i \log f_i - \eta_i(1+\eta_i f_i)\log(1+\eta_i f_i)\right] \tag{131.30}$$

satisfies

$$\dot{S}(f) = \sum_{r\in\mathcal{R}} w_r\big(L_r(f) - G_r(f)\big)\log\left(\frac{L_r(f)}{G_r(f)}\right) \geq 0. \tag{131.31}$$

Equality holds if and only if $L_r(f) = G_r(f)$ for every reaction with $w_r > 0$.

Proof. The finite state space lets us work entirely inside the open domain $\mathcal{D}$, where every factor in L_r and G_r is positive. Thus the logarithms below are honest finite-dimensional functions, and the boundary of $\mathcal{D}$ is not used in the argument.

For the conserved quantity,

$$\frac{d}{dt}Q_A(f) = \sum_r w_r(L_r - G_r)\big[-A(P_i) - A(P_j) + A(P_k) + A(P_l)\big],$$

and the bracket vanishes by (131.25).

For the entropy, differentiate the one-cell entropy. The same formula covers the classical, Bose, and Fermi signs because

$$\frac{\mathrm{d}}{\mathrm{d}f}\left[-f\log f + \eta(1+\eta f)\log(1+\eta f)\right] = -\log\left(\frac{f}{1+\eta f}\right),$$

with the $\eta = 0$ case understood by taking the limit. Hence

$$\frac{\partial S}{\partial f_i} = -\log\left(\frac{f_i}{1+\eta_i f_i}\right). \tag{131.32}$$

For $r = (i,j;k,l)$,

$$\nu_r \cdot \nabla S = \log\left(\frac{f_i f_j(1+\eta_k f_k)(1+\eta_l f_l)}{f_k f_l(1+\eta_i f_i)(1+\eta_j f_j)}\right) = \log\left(\frac{L_r}{G_r}\right).$$

Substitution into $\dot{S} = \nabla S \cdot \dot{f}$ gives (131.31). The sign is fixed reaction by reaction: for $x, y > 0$,

$$(x - y)\log(x/y) \geq 0, \qquad x > 0, \quad y > 0.$$

Indeed $x > y$ implies $\log x - \log y > 0$, while $x < y$ makes both factors negative. Equality in the sum holds exactly when every positive-weight reaction has $L_r = G_r$, because all summands are nonnegative. □

Definition 131.5 (Finite local equilibrium and collision invariants)**.** A state $f^{(0)} \in \mathcal{D}$ is a finite equilibrium for the datum when

$$\frac{f_i^{(0)}}{1 + \eta_i f_i^{(0)}} = \exp[-\alpha - A(P_i)] \tag{131.33}$$

for some $\alpha \in \mathbb{R}$ and $A \in \mathcal{P}^*$. A function $\chi : I \to \mathbb{R}$ is a collision invariant when

$$\chi_i + \chi_j - \chi_k - \chi_l = 0 \tag{131.34}$$

for every reaction $i + j \rightleftarrows k + l$.

Finite linearized collision operator. Let $f^{(0)}$ be a finite equilibrium. Write

$$f_i = f_i^{(0)} + f_i^{(0)}(1 + \eta_i f_i^{(0)})\chi_i. \tag{131.35}$$

To first order in χ,

$$L_r(f) - G_r(f) = M_r\big(\chi_i + \chi_j - \chi_k - \chi_l\big) + O(\chi^2), \tag{131.36}$$

where

$$M_r = L_r(f^{(0)}) = G_r(f^{(0)}) > 0. \tag{131.37}$$

Consequently the linearized entropy production is

$$\dot{S}^{(2)} = \sum_{r \in \mathcal{R}} w_r M_r \big(\chi_i + \chi_j - \chi_k - \chi_l\big)^2 \geq 0. \tag{131.38}$$

Its null space is precisely the space of collision invariants. If the reaction graph is connected enough that every collision invariant is of the form $\chi_i = \alpha + A(P_i)$, then the only zero modes are the conserved hydrodynamic variables.

The linearization is finite-dimensional algebra. At equilibrium, detailed balance follows from (131.33) and additive conservation:

$$\frac{L_r(f^{(0)})}{G_r(f^{(0)})} = \exp[-A(P_i) - A(P_j) + A(P_k) + A(P_l)] = 1.$$

For a variation $\delta f_i = f_i^{(0)}(1 + \eta_i f_i^{(0)})\chi_i$,

$$\delta \log\left(\frac{f_i}{1 + \eta_i f_i}\right) = \chi_i.$$

Therefore

$$\delta \log(L_r/G_r) = \chi_i + \chi_j - \chi_k - \chi_l.$$

Since $L_r = G_r = M_r$ at equilibrium, this is equivalent to (131.36): if $R_r = L_r/G_r$, then

$$\delta(L_r - G_r) = M_r\,\delta\log R_r.$$

The second variation of the entropy-production summand is obtained from

$$(L_r - G_r)\log(L_r/G_r) = M_r(\delta\log R_r)^2 + O(\chi^3),$$

because both $L_r - G_r$ and $\log(L_r/G_r)$ vanish to first order at equilibrium with the same linear coefficient $M_r^{-1}\delta(L_r - G_r)$. Summing the reactions gives (131.38). Its null space is the intersection of the kernels of the linear forms $\chi_i + \chi_j - \chi_k - \chi_l$, which is precisely the space of collision invariants by Definition 131.5. Under the stated connectivity hypothesis this space is the span of the constant invariant and the additive conserved quantities $A(P_i)$.

The continuum $2 \to 2$ formulas are obtained from Definition 131.3 by replacing the finite reaction sum by the invariant positive measure

$$d\Pi_1 d\Pi_2 d\Pi_3 d\Pi_4\,(2\pi)^D\delta^{(D)}(p_1 + p_2 - p_3 - p_4)|\mathcal{M}_{ab\to cd}|^2.$$

The finite theorem is not a derivation of this measure from QFT; it is the exact algebraic part of the kinetic construction once the collision measure has been derived or declared.

131.9 Worked Example: Relaxation-Time Shear Viscosity

Controlled Approximation 131.6 (Constant relaxation time)**.** Consider a single massless classical species in $d = 3$, with $f^{(0)} = e^{-p/T}$, no conserved charge, and a collision operator replaced on the shear channel by

$$C^{(t)}_{\mathrm{RTA}}[\delta f] = -\frac{\delta f}{\tau_R},$$

where τ_R is a constant. This replacement preserves the shear tensor structure and gives a closed worked example. It is a model for the positive inverse collision operator on the shear subspace, not a derivation of a microscopic collision kernel.

Let

$$\delta f = -\tau_R f^{(0)}\frac{p^i p^j}{2TE}\sigma_{ij}, \qquad \sigma_{ij} = \partial_i v_j + \partial_j v_i - \frac{2}{3}\delta_{ij}\partial_k v_k.$$

Substitution in the kinetic stress tensor gives

$$\delta T^{ij} = -\eta\,\sigma^{ij},$$

where angular averaging in three dimensions uses

$$\int d\Omega\,\hat{p}_i\hat{p}_j\hat{p}_k\hat{p}_l = \frac{4\pi}{15}(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}).$$

Since $\sigma^i{}_i = 0$, the coefficient is

$$\eta_{\mathrm{RTA}} = \frac{\tau_R}{15T}\int\frac{d^3\mathbf{p}}{(2\pi)^3}p^2 e^{-p/T} = \frac{4}{5}p_{\mathrm{therm}}\tau_R, \tag{131.39}$$

with

$$p_{\text{therm}} = \frac{1}{3}\int \frac{d^3\mathbf{p}}{(2\pi)^3} p\, e^{-p/T} = \frac{T^4}{\pi^2}.$$

This example displays the general structure of kinetic transport: a source term from gradients, inversion of the collision operator on a nonconserved subspace, and a positive quadratic form for the coefficient.

131.10 Gauge Theories and Soft Scales

In weakly coupled gauge theories, hard particles with momentum of order T interact through soft gauge exchange of order gT. Electric fields are screened by the Debye scale of Chapter 130; magnetic fields at scale g^2T remain nonperturbative in the static sector. Kinetic theory for gauge plasmas therefore contains several coupled effective descriptions:

$$\text{hard quasiparticles} \quad \leftrightarrow \quad \text{soft collective gauge fields} \quad \leftrightarrow \quad \text{ultrasoft hydrodynamic modes.}$$

Small-angle scattering, Landau damping, and collinear splitting processes must be matched in the same source and regulator convention before a transport coefficient is a well-defined weak-coupling prediction.

131.11 Controlled-Limit Requirements

A kinetic derivation from QFT requires:

spectral input	narrow quasiparticle peaks with a controlled off-shell remainder,
scale separation	$\ell_{\text{micro}} \ll \ell_{\text{variation}}$ and $\Gamma\ell_{\text{variation}} \ll 1$,
collision input	on-shell amplitudes with regulator and medium corrections,
conservation laws	collision invariants matching QFT Ward identities,
error estimate	bounds on neglected gradients, memory terms, and off-shell terms.

Open Problem 131.7 (QFT derivation of kinetic theory with errors)*.* Derive relativistic kinetic theory from Schwinger–Keldysh QFT with explicit error bounds, including quasiparticle projection, collision kernels, screening, collinear processes in gauge theory, and the passage from kinetic theory to hydrodynamic transport.

Chapter 132

Anomalous and Topological Transport

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- **$\hbar$.** 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter studies transport terms fixed by anomalies and topology. The logic is real-time response first: a transport coefficient is defined by a correlator or by the response of a generating functional to background sources, and anomaly equations constrain the allowed terms.

132.1 Hydrodynamic Source Datum

Let $W[g, A]$ be the equilibrium generating functional for a QFT with stress tensor $T^{\mu\nu}$ and current J^μ. Variations define

$$\delta W = \frac{1}{2}\int \mathrm{d}^D x\,\sqrt{-g}\,\langle T^{\mu\nu}\rangle\,\delta g_{\mu\nu} + \int \mathrm{d}^D x\,\sqrt{-g}\,\langle J^\mu\rangle\,\delta A_\mu.$$

Hydrodynamic variables are a temperature T, velocity u^μ, and chemical potential μ, with

$$u^\mu u_\mu = -1.$$

The ideal constitutive relations are

$$T^{\mu\nu}_{(0)} = \epsilon u^\mu u^\nu + p\Delta^{\mu\nu}, \qquad J^\mu_{(0)} = n u^\mu,$$

where

$$\Delta^{\mu\nu} = g^{\mu\nu} + u^\mu u^\nu.$$

132.2 Anomaly Equation

In four dimensions, a $U(1)^3$ anomaly has the local equation

$$\nabla_\mu J^\mu = \frac{C}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}.$$

The coefficient C is part of the current normalization. The magnetic field and vorticity in the local rest frame are

$$B^\mu = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}u_\nu F_{\rho\sigma}, \qquad \omega^\mu = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}u_\nu \nabla_\rho u_\sigma.$$

The first-derivative parity-odd current terms have the form

$$J^\mu_{\text{odd}} = \xi_B B^\mu + \xi_\omega \omega^\mu.$$

The coefficients ξ_B, ξ_ω are transport coefficients. They must be defined either by Kubo formulae or by differentiating an equilibrium generating functional.

For the explicit four-dimensional formulas below, let J_R and J_L be the source-normalized right- and left-handed number currents of one massless Dirac fermion, and set

$$J_V = J_R + J_L, \qquad J_A = J_R - J_L, \qquad \mu_R = \mu_V + \mu_A, \qquad \mu_L = \mu_V - \mu_A.$$

The vector source is A_V. In the convention of Chapter 51, preserving the vector Ward identity gives

$$\nabla_\mu J^\mu_A = \frac{1}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}(F_V)_{\mu\nu}(F_V)_{\rho\sigma} \qquad \text{for a unit source charge.}$$

If a physical electromagnetic source A_{em} couples with charge $Q = eq$, then $A_V = QA_{\text{em}}$. The current conjugate to A_{em} is QJ_V, and the magnetic response acquires the factor $Q^2 = e^2q^2$.

132.3 Anomalous Source Protocols and Current Representatives

Anomaly-induced transport is meaningful only after the source protocol and the current representative have been specified. This point is not a matter of taste: anomalous Ward identities, Chern–Simons contact terms, and zero-frequency limits mix under local counterterms.

Definition 132.1 (Hydrostatic anomalous-source datum)**.** A hydrostatic anomalous-source datum consists of the following objects:

1. a stationary Lorentzian background (g, A_I) with a timelike Killing field K;
2. chemical potentials μ_I defined as the gauge-invariant thermal holonomies of A_I around the Euclidean thermal circle, after choosing the time-independent gauge used in the hydrostatic functional;
3. a choice of local counterterms, equivalently a choice of consistent current representatives;
4. a declaration of which gauge symmetries are exact constraints on the background functional and which sources are allowed to have anomalous Ward identities.

For an anomalous charge, μ_I is a background source parameter in this datum. It is a genuine grand-canonical chemical potential for a conserved operator only in source sectors for which the corresponding anomaly density vanishes, or after passing to a conserved combination of charges.

Definition 132.2 (Consistent and covariant currents)**.** Let $W[A]$ be a renormalized connected generating functional. The consistent current is the variational current

$$J^\mu_{\text{cons}}(x) = \frac{1}{\sqrt{-g(x)}} \frac{\delta W}{\delta A_\mu(x)}.$$

With the sign convention

$$\delta_\alpha W = -\int d^4x \sqrt{-g}\, \alpha\, \mathcal{A}_{\text{cons}}, \qquad \delta_\alpha A_\mu = \nabla_\mu \alpha, \tag{132.1}$$

integration by parts gives

$$\nabla_\mu J^\mu_{\text{cons}} = \mathcal{A}_{\text{cons}}.$$

A covariant current is a shifted local current

$$J^\mu_{\text{cov}} = J^\mu_{\text{cons}} + J^\mu_{\text{BZ}}, \tag{132.2}$$

where J^μ_{BZ} is a local Bardeen–Zumino polynomial in the background fields chosen so that J_{cov} transforms covariantly under the background gauge symmetry being represented. The shift (132.2) changes local contact terms in current correlators; it is not a change of the Hilbert-space operator algebra.

Remark 132.3 (Vector-preserving convention in the Dirac example). The Dirac formulas in this chapter use the Bardeen convention in which the vector source A_V is an exact background gauge field and the axial source may have an anomalous Ward identity. Thus the physical electromagnetic response is obtained by varying the vector-preserving functional with respect to A_{em}. The axial chemical potential in (132.6) is a hydrostatic source parameter. A conserved axial charge in a sector with nonzero $\epsilon F_V F_V$ would require additional anomaly-free data.

132.4 Kubo Definitions

In flat space at temperature T, define retarded correlators

$$G^R_{AB}(t, \mathbf{x}) = -\mathrm{i}\theta(t)\langle[A(t, \mathbf{x}), B(0)]\rangle_\beta.$$

For a current response to a weak magnetic field, the chiral magnetic coefficient is

$$\xi_B = \lim_{k\to 0} \frac{\mathrm{i}}{2k} \epsilon_{ijn}\, G^R_{J^i J^j}(\omega = 0, \mathbf{k} = k\hat{e}_n).$$

This formula is a definition of the transport coefficient in the declared static, homogeneous limit. If the limits $\omega \to 0$ and $k \to 0$ fail to commute, the chosen order is part of the observable.

132.5 Equilibrium Derivation

Place the system on a stationary background

$$\mathrm{d}s^2 = -\mathrm{e}^{2\sigma}(dt + a_i dx^i)^2 + h_{ij}dx^i dx^j, \qquad A = A_0(dt + a_i dx^i) + A_i dx^i.$$

Gauge and Kaluza–Klein invariant three-dimensional fields are

$$\mathcal{A}_i = A_i - A_0 a_i, \qquad A_0.$$

An anomalous equilibrium functional contains Chern–Simons-type terms

$$W_{\text{odd}} = \int_{\Sigma_3} \left[c_1 A_0\, \mathcal{A} \wedge \mathrm{d}\mathcal{A} + c_2 A_0^2\, \mathcal{A} \wedge \mathrm{d}a + c_3 A_0^3\, a \wedge \mathrm{d}a\right],$$

with coefficients constrained by the anomaly and by large gauge transformations. Differentiating this functional with respect to $\mathcal{A}_i$ and a_i gives the parity-odd equilibrium pieces of J^i and T^{0i}. The derivation is algebraic once the equilibrium functional and its gauge-variation convention are fixed.

Remark 132.4 (Hydrostatic Chern–Simons variation). Let Σ_3 be closed, and let A and a be ordinary spatial one-forms on Σ_3. For constant coefficients c_{AA}, c_{Aa}, and c_{aa}, set

$$W_{\mathrm{CS}}[A, a] = \int_{\Sigma_3} \left[c_{AA} A \wedge \mathrm{d}A + c_{Aa} A \wedge \mathrm{d}a + c_{aa} a \wedge \mathrm{d}a\right]. \tag{132.3}$$

In local coordinates with orientation d^3x and $\epsilon^{123} = 1$, define

$$B_A^i = \epsilon^{ijk}\partial_j A_k, \qquad B_a^i = \epsilon^{ijk}\partial_j a_k. \tag{132.4}$$

Then

$$\frac{\delta W_{\mathrm{CS}}}{\delta A_i} = 2c_{AA}B_A^i + c_{Aa}B_a^i, \qquad \frac{\delta W_{\mathrm{CS}}}{\delta a_i} = c_{Aa}B_A^i + 2c_{aa}B_a^i. \tag{132.5}$$

If the coefficients are functions of A_0 or of thermodynamic scalars, (132.5) is the part of the variation with respect to the spatial one-forms at fixed scalar sources; variations of the scalar sources produce the corresponding charge and energy densities.

On a closed Σ_3,

$$\delta \int A \wedge \mathrm{d}A = \int \delta A \wedge \mathrm{d}A + \int A \wedge \mathrm{d}(\delta A) = 2\int \delta A \wedge \mathrm{d}A,$$

because $0 = \int \mathrm{d}(A \wedge \delta A) = \int \mathrm{d}A \wedge \delta A - \int A \wedge \mathrm{d}(\delta A)$ and $\mathrm{d}A \wedge \delta A = \delta A \wedge \mathrm{d}A$. Similarly,

$$\delta \int A \wedge \mathrm{d}a = \int \delta A \wedge \mathrm{d}a + \int \mathrm{d}A \wedge \delta a, \qquad \delta \int a \wedge \mathrm{d}a = 2\int \delta a \wedge \mathrm{d}a.$$

Writing $\delta A \wedge \mathrm{d}A = \delta A_i \epsilon^{ijk}\partial_j A_k\, \mathrm{d}^3x$ and the analogous formulas for a gives (132.5).

132.6 Chiral Magnetic Coefficient

The anomaly fixes a Chern–Simons term in the three-dimensional equilibrium functional. Hold the axial source constant in Euclidean time,

$$(A_A)_0 = \mu_A, \qquad \partial_i \mu_A = 0,$$

and set the spatial axial field to zero. The inflow functional for the vector-vector-axial anomaly contains the five-dimensional local term

$$W_5[A_A, A_V] = -\frac{1}{4\pi^2} \int_{X_5} A_A \wedge F_V \wedge F_V,$$

whose axial gauge variation is

$$\delta_\beta W_5 = -\frac{1}{4\pi^2} \int_{\partial X_5} \beta\, F_V \wedge F_V.$$

Since

$$F_V \wedge F_V = \frac{1}{4} \epsilon^{\mu\nu\rho\sigma} (F_V)_{\mu\nu} (F_V)_{\rho\sigma}\, \mathrm{d}^4 x,$$

this is the inflow form of the axial anomaly displayed above, with the sign fixed by the convention that the combined bulk-boundary system is invariant. Reducing the same local term on the thermal circle gives the parity-odd equilibrium functional

$$W_{\mathrm{CME}}[A_V; \mu_A] = \frac{\mu_A}{4\pi^2} \int_{\Sigma_3} A_V \wedge \mathrm{d}A_V.$$

In components,

$$\int_{\Sigma_3} A_V \wedge \mathrm{d}A_V = \int \mathrm{d}^3 x\, \epsilon^{ijk} (A_V)_i \partial_j (A_V)_k.$$

Varying with respect to the spatial vector source gives

$$\frac{\delta W_{\mathrm{CME}}}{\delta (A_V)_i} = \frac{\mu_A}{2\pi^2} \epsilon^{ijk} \partial_j (A_V)_k = \frac{\mu_A}{2\pi^2} B_V^i.$$

Thus the covariant equilibrium chiral magnetic response of the source-normalized vector current is

$$J_V^i = \frac{\mu_A}{2\pi^2} B_V^i. \tag{132.6}$$

For the physical electromagnetic current of a Dirac fermion of charge $Q = eq$, $B_V = QB_{\mathrm{em}}$ and $J_{\mathrm{em}} = QJ_V$, hence

$$J_{\mathrm{em}}^i = \frac{e^2 q^2 \mu_A}{2\pi^2} B_{\mathrm{em}}^i. \tag{132.7}$$

The same coefficient is obtained without invoking hydrodynamics by counting lowest Landau levels. For $B_V = B\hat{z}$, the degeneracy per unit transverse area is $|B|/(2\pi)$. The right-handed lowest Landau level has group velocity along B, while the left-handed lowest Landau level has group velocity opposite to B. Filling momenta from 0 to μ_R and 0 to μ_L gives

$$J_R^z = \frac{\mu_R}{4\pi^2} B, \qquad J_L^z = -\frac{\mu_L}{4\pi^2} B.$$

Therefore

$$J_V^z = J_R^z + J_L^z = \frac{\mu_R - \mu_L}{4\pi^2} B = \frac{\mu_A}{2\pi^2} B,$$

which agrees with (132.6). This derivation also shows why the order of limits in the Kubo formula is part of the observable: the current is an equilibrium response to a static magnetic source and a specified axial chemical potential.

132.7 Chiral Vortical Coefficients

For one massless Dirac fermion, the covariant first-derivative vortical currents in the same source-normalized convention are

$$J_V^\mu\big|_\omega = \frac{\mu_V \mu_A}{\pi^2}\,\omega^\mu, \tag{132.8}$$

$$J_A^\mu\big|_\omega = \left[\frac{\mu_V^2 + \mu_A^2}{2\pi^2} + \frac{T^2}{6}\right]\omega^\mu. \tag{132.9}$$

These formulas follow by adding the two Weyl contributions

$$J_R^\mu\big|_\omega = \left(\frac{\mu_R^2}{4\pi^2} + \frac{T^2}{12}\right)\omega^\mu, \qquad J_L^\mu\big|_\omega = -\left(\frac{\mu_L^2}{4\pi^2} + \frac{T^2}{12}\right)\omega^\mu.$$

The vector current is the sum $J_R + J_L$, while the axial current is the difference $J_R - J_L$. Hence the $T^2/12$ terms cancel in the vector current and add in the axial current. There is therefore no universal source-normalized vector-current term proportional to $\mu_A T$ in this Dirac example; the universal temperature-squared contribution belongs to the axial vortical current and is tied to the mixed axial-gravitational anomaly.

132.8 Entropy Constraint

Let

$$\nabla_\mu T^{\mu\nu} = F^{\nu\lambda} J_\lambda, \qquad \nabla_\mu J^\mu = \mathcal{A}$$

with anomaly density $\mathcal{A}$. The canonical entropy current is

$$S^\mu_{\text{can}} = p\beta^\mu - \beta_\nu T^{\mu\nu} - \alpha J^\mu, \qquad \beta^\mu = \frac{u^\mu}{T}, \quad \alpha = \frac{\mu}{T}.$$

The following derivation fixes the signs in this formula. It is independent of any derivative expansion.

Canonical entropy divergence with anomaly. Let

$$T^{\mu\nu} = \epsilon u^\mu u^\nu + p\Delta^{\mu\nu} + \tau^{\mu\nu}, \qquad J^\mu = n u^\mu + \nu^\mu, \tag{132.10}$$

with $u_\mu \tau^{\mu\nu} = 0$ and $u_\mu \nu^\mu = 0$. Assume the thermodynamic relations

$$\mathrm{d}p = s\,\mathrm{d}T + n\,\mathrm{d}\mu, \qquad \epsilon + p = Ts + \mu n. \tag{132.11}$$

Then the canonical entropy current satisfies

$$\nabla_\mu S^\mu_{\text{can}} = -\tau^{\mu\nu}\nabla_\mu\beta_\nu - \nu^\mu \left(\nabla_\mu\alpha - \beta^\nu F_{\mu\nu}\right) - \alpha\,\mathcal{A}. \tag{132.12}$$

The calculation is as follows. Differentiate

$$S^\mu_{\text{can}} = p\beta^\mu - \beta_\nu T^{\mu\nu} - \alpha J^\mu.$$

Using the anomalous Ward identities gives

$$\nabla_\mu S^\mu_{\text{can}} = \beta^\mu\nabla_\mu p + p\nabla_\mu\beta^\mu - T^{\mu\nu}\nabla_\mu\beta_\nu - J^\mu\nabla_\mu\alpha - \beta_\nu F^{\nu\lambda}J_\lambda - \alpha\mathcal{A}. \tag{132.13}$$

The last source term can be rewritten as

$$-J^\mu\nabla_\mu\alpha - \beta_\nu F^{\nu\lambda}J_\lambda = -J^\mu\left(\nabla_\mu\alpha - \beta^\nu F_{\mu\nu}\right), \tag{132.14}$$

using antisymmetry of $F_{\mu\nu}$. It remains to show that the ideal part cancels. Substituting

$$T^{\mu\nu}_{\text{id}} = \epsilon u^\mu u^\nu + p(g^{\mu\nu} + u^\mu u^\nu), \qquad J^\mu_{\text{id}} = nu^\mu,$$

and $\beta^\mu = u^\mu/T$, $\alpha = \mu/T$, the ideal contribution to (132.13) is

$$\frac{u^\mu\nabla_\mu p}{T} + p\nabla_\mu\left(\frac{u^\mu}{T}\right) - T^{\mu\nu}_{\text{id}}\nabla_\mu\left(\frac{u_\nu}{T}\right) - nu^\mu\nabla_\mu\left(\frac{\mu}{T}\right). \tag{132.15}$$

Since $u^\nu u_\nu = -1$, $u^\nu\nabla_\mu u_\nu = 0$. A direct expansion of (132.15) reduces it to

$$\frac{u^\mu}{T}\big(\nabla_\mu p - s\nabla_\mu T - n\nabla_\mu\mu\big),$$

which vanishes by $\mathrm{d}p = s\,\mathrm{d}T + n\,\mathrm{d}\mu$. The remaining terms are exactly those involving $\tau^{\mu\nu}$, ν^μ, and $\mathcal{A}$, giving (132.12).

Equation (132.12) explains how anomaly-induced transport can be nondissipative. The anomaly contributes the fixed term $-\alpha\mathcal{A}$; parity-odd additions to the entropy current, built from B^μ, ω^μ, and thermodynamic scalars, can move this term into a total divergence and thereby relate ξ_B, ξ_ω to anomaly coefficients. Coefficients invisible to this entropy analysis must instead be fixed by the hydrostatic functional or by Kubo formulae with the current representative and contact terms specified.

132.9 Topological Terms and Contact Terms

Equilibrium Chern–Simons terms may change local current correlators by contact terms. A transport coefficient must therefore state whether the current is covariant or consistent, which background functional is used, and which contact terms are included in the retarded correlator. The physically measured response is attached to the source protocol and to the contact-term convention, as well as to the local operator symbol.

Open Problem 132.5 (Nonperturbative anomalous transport). Derive anomaly-induced transport coefficients in interacting QFT directly from nonperturbative KMS states, local current algebras, Ward identities, contact terms, and hydrodynamic scaling limits, with the order of limits and source protocol stated as part of the theorem.

Chapter 133

Nonequilibrium Steady States And Open-System Limits

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Nonequilibrium steady states and open systems are real-time QFT objects. A steady state is a positive invariant state on an algebra of observables. An open-system limit is a scaling limit of a larger closed system in which a subalgebra evolves by a completely positive trace-preserving semigroup. This chapter fixes these definitions, derives the reservoir entropy-production formula, records finite path-measure fluctuation identities before taking a continuum limit, derives the finite-step Langevin/MSRJD representation, derives the finite reaction-network Doi–Peliti representation, records the tilted-generator construction of dynamical large deviations, records the empirical-flow level-2.5 cost behind finite dynamical large deviations, records the weak-coupling route to the GKSL generator, and connects the Markovian limit to a Schwinger–Keldysh influence functional and to hydrodynamic relaxation with noise.

133.1 Proof Architecture For Nonequilibrium Claims

The chapter has many finite-regulator identities because nonequilibrium QFT has several inequivalent entry points. The entry points serve different roles in one dependency ladder.

At the first layer are exact finite probability or operator-algebra statements. These include finite reservoir jump processes, labelled path measures and their Radon–Nikodym ratios, finite Gaussian transition kernels, finite reaction-network master equations, tilted finite Markov generators, empirical-flow costs, finite GKSL maps, and finite Gaussian Schwinger–Keldysh kernels. Each statement at this layer has a specified state space, measure, kernel, or matrix generator. The checks in this chapter live at this layer: they protect signs, normalizations, positivity, and finite algebra.

The second layer is the representation layer. Here a finite statement is rewritten in a field-theoretic coordinate system: a Fourier-dual MSRJD response variable for Gaussian increments, creation and annihilation variables for Doi–Peliti occupation dynamics, Keldysh r/a fields and noise kernels for influence functionals, or source variables for tilted generators. A representation at this layer is useful only because it is connected to the first layer by an explicit finite identity. It is not yet a continuum stochastic field theory.

The third layer is the scaling-hypothesis layer. One must declare the spatial regulator, local observables, field and rate scalings, time scaling, source normalization, topology of convergence, and which Ward identities or conservation laws survive the limit. Dynamic-critical names such as Model A, Model B, Model C, and Model H belong here: they are hypotheses about retained slow variables, reversible and dissipative structures, and continuum renormalization, not finite theorems.

The fourth layer is the continuum QFT output layer. A construction at this layer supplies real-time correlation functions, response functions, entropy production, fluctuation or large-deviation functionals, hydrodynamic coefficients, and open-system semigroups as limits of regulated objects. A Schwinger–Keldysh action, an MSRJD action, or a Doi–Peliti action counts as a QFT object only after this limiting statement and its observable map have been specified.

This ladder is the organizing rule for the rest of the chapter. For example, the finite fluctuation theorem proves a path-measure identity; it does not construct a continuum entropy-production operator. The finite MSRJD and Doi–Peliti rewritings prove coordinate changes from regulated stochastic processes; they do not prove a renormalized nonequilibrium fixed point. The finite SK Gaussian bridge identifies a noise coordinate in a quadratic influence functional; it does not by itself prove Markovianity, locality, or complete positivity of a reduced continuum dynamics.

133.2 Steady-State Datum

Let $\mathcal{A}$ be a $*$-algebra of observables for a real-time QFT, or a local C^*-algebra when a norm-completed formulation is available. A state is a positive normalized linear functional

$$\omega : \mathcal{A} \to \mathbb{C}, \qquad \omega(A^*A) \geq 0, \qquad \omega(\mathbf{1}) = 1.$$

Let τ_t be the time-evolution automorphism group. A steady state is a state ω_{ss} such that

$$\omega_{\mathrm{ss}}(\tau_t(A)) = \omega_{\mathrm{ss}}(A) \tag{133.1}$$

for all A in the common domain of the state and the time evolution. Local stationarity means that the distributional correlation functions of local observables are invariant under simultaneous time translation. A nonequilibrium steady state is a steady state whose current expectation values or reservoir boundary data are not those of a single KMS state.

Equation (133.1) is only the kinematic definition. Existence, uniqueness, clustering, stability under changes of the preparation protocol, and local normality relative to reference states are separate properties. They must be proved or assumed in any concrete model.

133.3 Reservoir Construction

Consider a QFT on a line prepared at $t = 0$ by joining two half-systems. The left and right initial states are KMS states with parameters

$$(\beta_L, \mu_L), \qquad (\beta_R, \mu_R).$$

For a local observable A supported near the junction, a central steady state is a weak limit

$$\omega_{\rm ss}(A) = \lim_{t\to\infty} \omega_0(\tau_t(A)), \tag{133.2}$$

if the limit exists. The limit is local: it is not a statement that the entire infinite-volume density matrix converges in trace norm. When the large-time state has a ray dependence, one instead studies limits of $\omega_0(\tau_t(A_{x=vt}))$, with $v = x/t$. The central steady state is the ray $v = 0$.

The physical currents in the central steady state are defined by the expectation values of local current operators:

$$J_E = \omega_{\rm ss}(j_E), \qquad J_Q = \omega_{\rm ss}(j_Q),$$

with the convention that positive current flows from left to right.

133.4 Reservoir Entropy Production

Let the right reservoir gain energy and charge at rates

$$\frac{dE_R}{dt} = J_E, \qquad \frac{dQ_R}{dt} = J_Q,$$

while the left reservoir loses the same amounts. The reservoir entropy change is computed using the equilibrium reservoir first laws

$$dS_\alpha = \beta_\alpha(dE_\alpha - \mu_\alpha dQ_\alpha), \qquad \alpha = L, R.$$

Therefore

$$\begin{aligned}\dot{S}_{\rm res} &= \beta_R(J_E - \mu_R J_Q) + \beta_L(-J_E + \mu_L J_Q)\\ &= (\beta_R - \beta_L)J_E - (\beta_R\mu_R - \beta_L\mu_L)J_Q.\end{aligned} \tag{133.3}$$

This formula is an identity once the currents and reservoir parameters are defined. Positivity is a dynamical statement about the state and the reservoir construction. In linear response, if

$$X = \begin{pmatrix} \beta_R - \beta_L \\ -(\beta_R\mu_R - \beta_L\mu_L) \end{pmatrix}, \qquad \begin{pmatrix} J_E \\ J_Q \end{pmatrix} = LX,$$

then $\dot{S}_{\rm res} = X^T L X$. The second law in this linear regime is equivalent to the positive semidefiniteness of the symmetric part of the Onsager matrix L.

133.5 Finite Local Detailed Balance

The reservoir formula above is the steady-state remnant of a stronger finite statement. We record it because it fixes the sign convention for entropy production before any continuum or hydrodynamic limit is taken.

Definition 133.1 (Finite reservoir jump datum)**.** A finite reservoir jump datum consists of:

1. a finite set I of system configurations;
2. real energy and charge functions E_i, Q_i on I;
3. reservoirs α with parameters $(\beta_\alpha, \mu_\alpha)$;
4. transition rates $W_{ij}^{(\alpha)} \geq 0$, $i \neq j$, for jumps $i \to j$ induced by reservoir α.

The rates obey local detailed balance when

$$W_{ij}^{(\alpha)} > 0 \quad \Longleftrightarrow \quad W_{ji}^{(\alpha)} > 0, \qquad \log \frac{W_{ij}^{(\alpha)}}{W_{ji}^{(\alpha)}} = -\beta_\alpha \left[E_j - E_i - \mu_\alpha(Q_j - Q_i)\right]. \tag{133.4}$$

The master equation is

$$\dot{p}_i = \sum_\alpha \sum_{j \neq i} \left[p_j W_{ji}^{(\alpha)} - p_i W_{ij}^{(\alpha)}\right], \qquad p_i \geq 0, \qquad \sum_i p_i = 1. \tag{133.5}$$

Finite entropy production. For a finite reservoir jump datum satisfying (133.4), define the Shannon entropy

$$S_{\mathrm{sys}}(p) = -\sum_i p_i \log p_i. \tag{133.6}$$

The reservoir entropy-production rate is

$$\dot{S}_{\mathrm{res}} = \sum_\alpha \sum_{i \neq j} p_i W_{ij}^{(\alpha)} \log \frac{W_{ij}^{(\alpha)}}{W_{ji}^{(\alpha)}}, \tag{133.7}$$

and the total entropy-production rate is

$$\dot{S}_{\mathrm{tot}} = \frac{1}{2} \sum_\alpha \sum_{i \neq j} \left(p_i W_{ij}^{(\alpha)} - p_j W_{ji}^{(\alpha)}\right) \log \frac{p_i W_{ij}^{(\alpha)}}{p_j W_{ji}^{(\alpha)}} \geq 0. \tag{133.8}$$

Moreover

$$\dot{S}_{\mathrm{tot}} = \frac{d}{dt} S_{\mathrm{sys}}(p) + \dot{S}_{\mathrm{res}}. \tag{133.9}$$

At a stationary distribution p^{ss}, the system entropy derivative vanishes, hence $\dot{S}_{\mathrm{res}} = \dot{S}_{\mathrm{tot}} \geq 0$. The local detailed-balance relation says that a jump $i \to j$ changes the reservoir entropy by

$$-\beta_\alpha \left[E_j - E_i - \mu_\alpha(Q_j - Q_i)\right] = \log \frac{W_{ij}^{(\alpha)}}{W_{ji}^{(\alpha)}}, \tag{133.10}$$

which gives (133.7) after averaging over jumps. Differentiating S_{sys} and using $\sum_i \dot{p}_i = 0$ gives

$$\frac{dS_{\text{sys}}}{dt} = -\sum_i \dot{p}_i \log p_i. \tag{133.11}$$

Substituting the master equation and symmetrizing over i, j,

$$\frac{dS_{\text{sys}}}{dt} = \frac{1}{2}\sum_\alpha \sum_{i\neq j} \left(p_i W_{ij}^{(\alpha)} - p_j W_{ji}^{(\alpha)}\right) \log \frac{p_i}{p_j}. \tag{133.12}$$

Similarly, (133.7) can be written as

$$\dot{S}_{\text{res}} = \frac{1}{2}\sum_\alpha \sum_{i\neq j} \left(p_i W_{ij}^{(\alpha)} - p_j W_{ji}^{(\alpha)}\right) \log \frac{W_{ij}^{(\alpha)}}{W_{ji}^{(\alpha)}}. \tag{133.13}$$

Adding the last two equations gives (133.8). Each summand is nonnegative because

$$(x-y)\log(x/y) \geq 0, \qquad x > 0, \quad y > 0. \tag{133.14}$$

Terms with $x = y = 0$ are omitted by continuity. This proves both (133.9) and the inequality.

The two-reservoir current formula (133.3) is obtained from this finite statement when the stationary currents have well-defined macroscopic energy and charge rates. The finite theorem does not prove existence of the long-time QFT state ω_{ss}; it proves the algebraic positivity that any Markovian reservoir reduction with local detailed balance must satisfy.

133.6 Finite Path Measures and Fluctuation Relations

Fluctuation relations are identities between probability measures on histories. They become mathematical statements after the path space and the reversed path measure have been constructed. We state the finite continuous-time version because it is the regulator-level statement that survives, if the corresponding continuum limit exists, in nonequilibrium QFT.

Let I be a finite configuration set. For $0 \leq t \leq T$, let $W_{ij}^{(\alpha)}(t) \geq 0$, $i \neq j$, be time-dependent jump rates labelled by reservoirs α, and let

$$r_i(t) = \sum_\alpha \sum_{j\neq i} W_{ij}^{(\alpha)}(t)$$

be the escape rate from i. A labelled trajectory is

$$\gamma = (i_0; t_1, \alpha_1, i_1; \ldots; t_n, \alpha_n, i_n), \qquad 0 < t_1 < \cdots < t_n < T,$$

where the state is i_m on $t_m < t < t_{m+1}$, with $t_0 = 0$ and $t_{n+1} = T$. Given an initial distribution p_0, the forward path density with respect to counting measure over labels and Lebesgue measure over ordered jump times is

$$\begin{aligned}\mathbb{P}_F(\gamma) = p_0(i_0) \exp&\left[-\int_0^{t_1} r_{i_0}(s)\,ds\right] \\ &\times \prod_{m=1}^{n} \left[W_{i_{m-1}i_m}^{(\alpha_m)}(t_m) \exp\left[-\int_{t_m}^{t_{m+1}} r_{i_m}(s)\,ds\right]\right]. \end{aligned}\tag{133.15}$$

The reversed protocol has rates

$$\widetilde{W}_{ij}^{(\alpha)}(t) = W_{ij}^{(\alpha)}(T - t)$$

and initial distribution q_0. The time-reversed trajectory is

$$\Theta\gamma = (i_n; T - t_n, \alpha_n, i_{n-1}; \dots; T - t_1, \alpha_1, i_0).$$

Assume absolute continuity: whenever a forward path has positive probability, the reversed path has positive probability under the reversed protocol. Define the trajectory entropy production by the Radon–Nikodym logarithm

$$\Sigma(\gamma) = \log \frac{\mathbb{P}_F(\gamma)}{\mathbb{P}_R(\Theta\gamma)}. \tag{133.16}$$

Proposition 133.2 (Finite path-measure fluctuation identity)**.** *For the finite jump process above,*

$$\Sigma(\gamma) = \log \frac{p_0(i_0)}{q_0(i_n)} + \sum_{m=1}^{n} \log \frac{W_{i_{m-1}i_m}^{(\alpha_m)}(t_m)}{W_{i_m i_{m-1}}^{(\alpha_m)}(t_m)}, \tag{133.17}$$

$$\left\langle e^{-\Sigma} \right\rangle_F = 1. \tag{133.18}$$

If q_0 is chosen to be the forward final distribution p_T, then $\langle \Sigma \rangle_F \geq 0$. More generally, $\langle \Sigma \rangle_F$ is the relative entropy

$$D(\mathbb{P}_F \| \Theta^{-1}\mathbb{P}_R)$$

between the forward history measure and the pullback of the reversed history measure.

Proof. Insert the path densities. The waiting-time factors in the denominator are the same factors as in the numerator after the change of variables $s \mapsto T - s$ on each reversed interval. They therefore cancel. What remains is exactly the initial-distribution ratio and the product of jump rate ratios in (133.17).

The integral identity is the normalization of the reversed path measure:

$$\left\langle e^{-\Sigma} \right\rangle_F = \int e^{-\Sigma(\gamma)} \, d\mathbb{P}_F(\gamma) = \int d\mathbb{P}_R(\Theta\gamma) = 1.$$

The map Θ is an involution on the labelled path space, so the last integral is the total mass of $\mathbb{P}_R$. Finally,

$$\langle \Sigma \rangle_F = \int \log \frac{d\mathbb{P}_F}{d(\Theta^{-1}\mathbb{P}_R)} \, d\mathbb{P}_F = D(\mathbb{P}_F \| \Theta^{-1}\mathbb{P}_R) \geq 0,$$

with equality precisely when the two history measures agree almost surely. When $q_0 = p_T$, the boundary term in (133.17) is the stochastic system entropy change $-\log p_T(i_n) + \log p_0(i_0)$, and the jump-rate term is the reservoir entropy change under local detailed balance. Hence the average is the mean total entropy production. $\square$

The detailed fluctuation relation is a direct disintegration of the same identity. If P_F is the forward law of Σ and P_R is the reversed law of the reversed entropy production, then

$$P_F(ds) = e^s \, P_R(-ds)$$

on every Borel set on which both measures are defined. This form is often the most convenient one experimentally, but the Radon–Nikodym statement (133.16) is the mathematical content.

Jarzynski identity as a special case. Take one thermal reservoir with inverse temperature β, no chemical potential, and a time-dependent finite energy function $E_i(t)$. Assume local detailed balance at each jump time:

$$\log \frac{W_{ij}(t)}{W_{ji}(t)} = -\beta\big(E_j(t) - E_i(t)\big).$$

Let $p_0(i) = Z(0)^{-1}e^{-\beta E_i(0)}$ and $q_0(i) = Z(T)^{-1}e^{-\beta E_i(T)}$. For a trajectory γ, define the protocol work

$$W_{\text{ext}}(\gamma) = \int_0^T \partial_t E_{i(t)}(t)\, dt, \tag{133.19}$$

where $i(t)$ is the piecewise-constant state path. The total system energy change decomposes as

$$E_{i_n}(T) - E_{i_0}(0) = W_{\text{ext}}(\gamma) + \sum_{m=1}^{n} \big(E_{i_m}(t_m) - E_{i_{m-1}}(t_m)\big).$$

Combining this identity with local detailed balance gives

$$\Sigma(\gamma) = \beta\big(W_{\text{ext}}(\gamma) - \Delta F\big), \qquad \Delta F = F(T) - F(0), \qquad F(t) = -\beta^{-1}\log Z(t).$$

Therefore (133.18) becomes

$$\left\langle e^{-\beta W_{\text{ext}}} \right\rangle_F = e^{-\beta \Delta F}. \tag{133.20}$$

For a continuum QFT quench, the corresponding use of (133.20) requires a specified finite regulator, a measured work protocol or two-time energy measurement replacement, a time-reversal operation, and a limit in which the history measures converge.

133.7 Finite-Step Langevin Measures and MSRJD Variables

The Martin–Siggia–Rose–Janssen–de Dominicis (MSRJD) response-field path integral used in classical stochastic field theory is an exact rewriting of a finite-dimensional path measure before it is a continuum notation. Let $x_n = (x_n^1, \ldots, x_n^N) \in \mathbb{R}^N$ be the variables of a finite regulator at $t_n = n\Delta t$, $0 \le n \le M$. The index $a = 1, \ldots, N$ may include internal labels and lattice sites. Fix a smooth drift vector field $F^a(x,t)$ and a real symmetric positive definite matrix D^{ab}. The Ito finite-step process is

$$x_{n+1}^a = x_n^a + \Delta t\, F^a(x_n, t_n) + \eta_n^a, \qquad \mathbb{E}(\eta_n^a \eta_m^b) = 2\Delta t\, D^{ab}\delta_{nm}. \tag{133.21}$$

With x_0 fixed and

$$\Delta x_n^a = x_{n+1}^a - x_n^a, \qquad F_n^a = F^a(x_n, t_n),$$

the conditional path density is

$$\mathbb{P}_\Delta[x_1, \ldots, x_M \mid x_0] = \prod_{n=0}^{M-1} \frac{\exp\big[-\frac{1}{4\Delta t}(\Delta x_n - \Delta t F_n)_a (D^{-1})^{ab} (\Delta x_n - \Delta t F_n)_b\big]}{\sqrt{(4\pi\Delta t)^N \det D}}. \tag{133.22}$$

This formula is the regulated stochastic theory. A continuum stochastic field theory is a limit of such finite measures, together with convergence of the observables under study.

The Gaussian kernel in (133.22) has the Fourier representation

$$\frac{\exp\left[-\frac{1}{4\Delta t}y_a(D^{-1})^{ab}y_b\right]}{\sqrt{(4\pi\Delta t)^N \det D}} = \int_{\mathbb{R}^N} \frac{d^N\hat{x}}{(2\pi)^N} \exp\left[-\mathrm{i}\hat{x}_a y^a - \Delta t\, \hat{x}_a D^{ab}\hat{x}_b\right]. \tag{133.23}$$

Indeed, the right side is the elementary Gaussian integral

$$\frac{1}{(2\pi)^N}\int_{\mathbb{R}^N} d^N\hat{x}\, \exp\left[-\hat{x}_a(\Delta t D^{ab})\hat{x}_b - \mathrm{i}\hat{x}_a y^a\right],$$

and completing the square gives the determinant and exponent on the left. The finite-step MSRJD identity follows by applying (133.23) to $y^a = \Delta x_n^a - \Delta t F_n^a$ at each time step:

$$\begin{aligned}\mathbb{E}_\Delta[\mathcal{O}] = \int_{\mathbb{R}^{NM}} \prod_{n=1}^{M} d^N x_n\, \mathcal{O}(x_0,\dots,x_M) \prod_{n=0}^{M-1} \int_{\mathbb{R}^N} \frac{d^N\hat{x}_n}{(2\pi)^N} \\ \times \exp\left\{\sum_{n=0}^{M-1}\left[-\mathrm{i}\hat{x}_{n,a}\big(\Delta x_n^a - \Delta t F_n^a\big) - \Delta t\, \hat{x}_{n,a}D^{ab}\hat{x}_{n,b}\right]\right\}.\end{aligned} \tag{133.24}$$

Here $\mathcal{O}$ is any bounded measurable functional of the finite path. If the initial condition has density $\rho_0(x_0)$, one also integrates over x_0 with weight ρ_0. The auxiliary variable $\hat{x}_{n,a}$ is the Fourier-dual variable to the finite increment constraint. The frequently used variable $\widetilde{x}_{n,a} = \mathrm{i}\hat{x}_{n,a}$ is a contour notation for the same finite integral; its convergence and allowed deformations are inherited from (133.23).

The same finite construction fixes the generator and the Fokker–Planck equation from finite moments. For $f \in C_b^4(\mathbb{R}^N)$, Taylor expansion of $f(x + \Delta t F(x,t) + \eta)$ and the Gaussian moments $\mathbb{E}\eta^a = 0$, $\mathbb{E}(\eta^a\eta^b) = 2\Delta t D^{ab}$ give

$$\mathbb{E}[f(x_{n+1}) \mid x_n = x] = f(x) + \Delta t\left(F^a(x,t_n)\partial_a f(x) + D^{ab}\partial_a\partial_b f(x)\right) + O((\Delta t)^2) \tag{133.25}$$

uniformly on compact sets where the drift and the required derivatives of f are bounded. The limiting Markov generator on test functions is therefore

$$L_t f = F^a(x,t)\partial_a f + D^{ab}\partial_a\partial_b f. \tag{133.26}$$

The adjoint equation for a smooth density $p(x,t)$ is

$$\partial_t p = -\partial_a(F^a p) + D^{ab}\partial_a\partial_b p. \tag{133.27}$$

For stochastic PDEs and QFT applications, $\mathbb{R}^N$ is replaced first by a finite spatial regulator and only then by a continuum limit. The data to be controlled are the regulated drift, the regulated covariance, the choice of stochastic discretization, ultraviolet renormalizations of drift and noise, and convergence of correlation functions or path measures.

133.8 Finite Data for Model A and Model B

The dynamic-critical labels usually called Model A and Model B designate finite-regulator stochastic field data: a slow variable, a free-energy functional, a mobility operator, a noise covariance tied to that mobility, and a specified scaling limit. This finite formulation is the part that can be stated before any continuum renormalization group analysis.

Let $x = (x^1, \dots, x^N) \in \mathbb{R}^N$ be a finite spatial regulator for a real order parameter and let $\mathcal{F} : \mathbb{R}^N \to \mathbb{R}$ be a smooth finite-regulator free-energy functional. Fix a symmetric positive-semidefinite matrix M^{ab}. The mobility-gradient Langevin datum is

$$dx^a(t) = -\mathsf{M}^{ab}\partial_b\mathcal{F}(x(t))\,dt + \sqrt{2T}\,\sigma^a{}_r\,dB_t^r, \qquad \sigma\sigma^T = \mathsf{M}, \tag{133.28}$$

where $T > 0$ is the temperature parameter and B_t^r are independent standard Brownian motions. If M has a kernel, the stochastic equation is understood on affine subspaces parallel to $\operatorname{ran}\mathsf{M}$; directions in $\ker\mathsf{M}$ are exact conserved linear coordinates. The generator on smooth test functions is

$$Lf = -\mathsf{M}^{ab}\partial_b\mathcal{F}\,\partial_a f + T\mathsf{M}^{ab}\partial_a\partial_b f. \tag{133.29}$$

The adjoint Fokker–Planck equation can be written as a continuity equation

$$\partial_t p = -\partial_a J^a, \qquad J^a = -\mathsf{M}^{ab}\left(\partial_b\mathcal{F}\,p + T\partial_b p\right). \tag{133.30}$$

Consequently the finite Gibbs density

$$p_{\mathrm{eq}}(x) = Z^{-1}\exp[-\mathcal{F}(x)/T] \tag{133.31}$$

has zero probability current on each affine sector on which it is normalizable, because

$$\partial_b p_{\mathrm{eq}} = -T^{-1}(\partial_b\mathcal{F})p_{\mathrm{eq}}.$$

This is the finite fluctuation–dissipation relation: the same mobility M determines the dissipative drift and the noise covariance

$$\mathbb{E}(dx^a dx^b) = 2T\mathsf{M}^{ab}\,dt.$$

Model A is the case in which the order parameter is not constrained by a conserved charge. On a finite lattice one typically takes

$$\mathsf{M}^{ab} = \Gamma\,\delta^{ab}, \qquad \Gamma > 0,$$

up to local positive mobility factors. The drift is then the ordinary gradient flow of $\mathcal{F}$ with independent local thermal noise:

$$dx^a = -\Gamma\,\partial_a\mathcal{F}\,dt + \sqrt{2T\Gamma}\,dB_t^a. \tag{133.32}$$

Model B is the case in which the total order parameter is conserved. Let $G = (V, E)$ be a finite graph approximating space, orient each edge ℓ, and write $s(\ell)$ and $t(\ell)$ for its source and target vertices. Let

$$B_{\ell v} = \delta_{v,t(\ell)} - \delta_{v,s(\ell)}$$

be the incidence matrix, so $(Bx)_\ell = x_{t(\ell)} - x_{s(\ell)}$. With positive edge mobilities $c_\ell > 0$, set

$$\mathsf{M} = B^T C B, \qquad C_{\ell\ell'} = c_\ell\delta_{\ell\ell'}. \tag{133.33}$$

Then $\mathsf{M} \geq 0$ and $\mathsf{M}\mathbf{1} = 0$, hence

$$\frac{d}{dt}\sum_{i\in V} x_i = -\mathbf{1}^T\mathsf{M}\nabla\mathcal{F} = 0$$

and the noise has no constant component. Equivalently, write

$$dx_i = -\sum_{\ell} B_{\ell i} c_\ell \sum_j B_{\ell j} \partial_j \mathcal{F}\, dt + \sqrt{2T} \sum_{\ell} B_{\ell i} \sqrt{c_\ell}\, dW_t^\ell.$$

The noise is the discrete divergence of an edge noise, so the conserved zero mode is absent before any continuum notation is introduced. In a regular lattice limit this is the finite source of the formal expression

$$\partial_t \phi = \nabla \cdot \left(\lambda \nabla \frac{\delta \mathcal{F}}{\delta \phi} \right) + \nabla \cdot \xi, \qquad \langle \xi_i(t,x) \xi_j(t',y) \rangle = 2T\lambda\, \delta_{ij} \delta(t-t') \delta(x-y),$$

with the continuum formula understood only after the spatial regulator and renormalization have been specified.

The finite path weight is $\exp[-S^{\mathrm{fin}}_{\mathrm{MSRJD}}]$, where the MSRJD action for the finite mobility-gradient datum follows from Section 133.7 with $F^a = -\mathsf{M}^{ab} \partial_b \mathcal{F}$ and $D^{ab} = T\mathsf{M}^{ab}$. In response-field notation it is

$$S^{\mathrm{fin}}_{\mathrm{MSRJD}} = \sum_n \Delta t \left[\mathrm{i} \hat{x}_{n,a} \left(\frac{x^a_{n+1} - x^a_n}{\Delta t} + \mathsf{M}^{ab} \partial_b \mathcal{F}(x_n) \right) + T \hat{x}_{n,a} \mathsf{M}^{ab} \hat{x}_{n,b} \right], \tag{133.34}$$

with the finite Fourier-contour convention of (133.24). This expression is a finite action for a specified regulator. A dynamic critical field theory additionally requires: the scaling of $\mathcal{F}$, M, fields, and time; the list of slow variables retained; the renormalized drift and noise terms allowed by the exact symmetries and conservation laws; and a theorem or controlled calculation showing convergence of correlation and response functions. The dynamic exponent z, aging exponents, and scaling functions are outputs of that construction rather than entries in the finite datum itself.

133.9 Coupled Slow Variables Beyond Model A/B

The Hohenberg–Halperin labels for dynamic critical phenomena are not definitions of continuum QFTs. They are shorthand for a finite-regulator choice of slow variables, reversible brackets, dissipative mobilities, noise covariances, and scaling hypotheses. The finite datum below is the part of that language that can be stated without assuming a continuum fixed point.

Let $y = (y^1, \ldots, y^N)$ collect all retained slow variables at a finite spatial regulator. Some components may be nonconserved order-parameter coordinates, while others may be graph densities for conserved charges. Let $\mathcal{F}(y)$ be the finite free energy and consider the Ito process

$$dy^a(t) = \Big[R^a(y(t)) - \mathsf{M}^{ab} \partial_b \mathcal{F}(y(t)) \Big]\, dt + \sqrt{2T}\, \sigma^a{}_r\, dB^r_t, \qquad \sigma\sigma^T = \mathsf{M}, \tag{133.35}$$

where M is a constant symmetric positive-semidefinite mobility matrix and R is the reversible drift. The noise covariance is again fixed by the dissipative mobility. The condition that the reversible part preserve the Gibbs density is the finite divergence identity

$$\partial_a \left(R^a e^{-\mathcal{F}/T} \right) = 0. \tag{133.36}$$

Under this condition the Fokker–Planck current at $p_{\rm eq} = Z^{-1}e^{-\mathcal{F}/T}$ is

$$J^a_{\rm eq} = R^a p_{\rm eq} - \mathsf{M}^{ab}\left(\partial_b\mathcal{F}\, p_{\rm eq} + T\partial_b p_{\rm eq}\right) = R^a p_{\rm eq}, \tag{133.37}$$

and $\partial_a J^a_{\rm eq} = 0$. Thus the reversible current may circulate on a finite energy shell, while the dissipative part has zero Gibbs current. The common Hamiltonian example is

$$R^a = \mathsf{J}^{ab}\partial_b\mathcal{F}, \qquad \mathsf{J}^{ab} = -\mathsf{J}^{ba}, \qquad \partial_a\mathsf{J}^{ab} = 0, \tag{133.38}$$

for which $R^a\partial_a\mathcal{F} = 0$ and $\partial_a R^a = 0$ when J is constant. A state-dependent Poisson tensor requires the same divergence identity (133.36); writing a formal Poisson bracket is not by itself a definition of the regulated stochastic theory.

Exact finite conserved linear coordinates are also part of the datum. If $c_I = (c_{I,a})$ are covectors satisfying

$$c_{I,a}\mathsf{M}^{ab} = 0, \qquad c_{I,a}R^a(y) = 0, \tag{133.39}$$

then $Q_I = c_{I,a}y^a$ is conserved pathwise, including the noise term. For graph densities this is the finite statement that the mobility and noise are discrete divergences, as in (133.33).

This finite formulation separates three commonly conflated inputs. First, a Model C type system retains a nonconserved order parameter ϕ and at least one conserved scalar density n, with static coupling in $\mathcal{F}(\phi, n)$ and a block mobility such as

$$\mathsf{M}_{\rm C} = \begin{pmatrix} \Gamma\mathbf{1} & 0 \\ 0 & B^T C B \end{pmatrix}.$$

The conservation law is a statement about the lower block, not about the static coupling in $\mathcal{F}$. Second, a Model H type system retains a conserved order parameter and a momentum density; the advective nonlinearities belong to the reversible drift R and must obey (133.36) at the regulator where the path measure is defined. Third, any dynamic universality claim requires a renormalized continuum limit of correlation and response functions for this entire coupled datum. The label of the model is therefore a hypothesis about which slow variables and couplings survive the scaling limit, not a theorem about the microscopic QFT.

The finite MSRJD action associated to (133.35) is obtained from the Gaussian identity of Section 133.7:

$$S^{\rm coupled}_{\rm MSRJD} = \sum_n \Delta t\left[\mathrm{i}\hat{y}_{n,a}\left(\frac{y^a_{n+1} - y^a_n}{\Delta t} - R^a(y_n) + \mathsf{M}^{ab}\partial_b\mathcal{F}(y_n)\right) + T\hat{y}_{n,a}\mathsf{M}^{ab}\hat{y}_{n,b}\right]. \tag{133.40}$$

If M has a kernel, the response variables are understood on the quotient by the deterministic conserved directions, exactly as in the finite Model B construction. Continuum response-field actions for dynamic critical models are shorthand for a limit of (133.40), together with counterterms and operator renormalizations fixed by the regulator.

133.10 Finite Reaction Networks and Doi–Peliti Variables

Doi–Peliti variables are the occupation-number analogue of the response variables above, but the construction is more than a notation change. It is the finite-regulator bridge from a classical stochastic many-body semigroup to a local non-Hermitian QFT representation. A master equation for probabilities is rewritten as a linear evolution equation

$$\partial_t|P_t\rangle = \mathcal{L}_{\mathrm{DP}}|P_t\rangle$$

on a bosonic occupation Fock space, and coherent states then turn $\exp(T\mathcal{L}_{\mathrm{DP}})$ into a time-sliced path integral. The operator $\mathcal{L}_{\mathrm{DP}}$ is not a Hamiltonian generating unitary time evolution. Its structural conservation law is instead the left-null-vector identity

$$\langle \mathbf{1}|\mathcal{L}_{\mathrm{DP}} = 0,$$

or, in coherent-state symbols, $H_{\mathrm{DP}}(1, z) = 0$. This is the Markov analogue of the Ward identity that prevents probability from leaking out of the state space.

The reason this belongs in a QFT monograph is that local reaction networks, after spatial regularization, give local polynomial non-Hermitian actions. When a continuum limit exists, renormalization can be applied to these actions just as it is applied to unitary or Euclidean field theories, but the meaning of "same critical theory" must be stated operationally: two regulated stochastic systems are in the same nonequilibrium scaling class only after a common scaling limit, a matching of relevant perturbations, and agreement of scaling correlation and response functions have been specified. Examples usually described in this language include annihilation $A + A \to 0$, directed-percolation or Reggeon-field-theory reactions, parity-preserving branching-annihilating walks, and pair-contact processes with diffusion. The finite construction below is the algebraic input; the continuum fixed-point construction is part of the theorem boundary at the end of the chapter.

Let $s = 1, \dots, S$ label a finite set of species, and let $n = (n_1, \dots, n_S) \in \mathbb{N}^S$ be the occupation vector of a finite spatial regulator. For a multi-index $\alpha \in \mathbb{N}^S$, set

$$z^\alpha = \prod_s z_s^{\alpha_s}, \qquad (n)_\alpha = \prod_s n_s(n_s - 1)\cdots(n_s - \alpha_s + 1),$$

with $(n)_\alpha = 0$ if some $n_s < \alpha_s$. A reaction r has input ν_r, output ν_r', stoichiometric vector $v_r = \nu_r' - \nu_r$, and rate constant $\kappa_r \geq 0$. The mass-action jump rate is

$$w_r(n) = \kappa_r (n)_{\nu_r}, \qquad n \longmapsto n + v_r.$$

The master equation for the probability $P_t(n)$ is

$$\partial_t P_t(m) = \sum_r \left[\kappa_r(m - v_r)_{\nu_r} P_t(m - v_r) - \kappa_r(m)_{\nu_r} P_t(m)\right], \tag{133.41}$$

where terms with $m - v_r \notin \mathbb{N}^S$ vanish.

Let $\mathcal{F}_{\mathrm{alg}}$ be the algebraic bosonic Fock space with basis $\{|n\rangle : n \in \mathbb{N}^S\}$. Define

$$a_s|n\rangle = n_s|n - e_s\rangle, \qquad a_s^\dagger|n\rangle = |n + e_s\rangle, \qquad [a_s, a_t^\dagger] = \delta_{st}.$$

Here $a_s|n\rangle = 0$ when $n_s = 0$. For $\alpha \in \mathbb{N}^S$, write

$$a^\alpha = \prod_s a_s^{\alpha_s}, \qquad (a^\dagger)^\alpha = \prod_s (a_s^\dagger)^{\alpha_s}.$$

Encode a probability distribution as

$$|P_t\rangle = \sum_{n\in\mathbb{N}^S} P_t(n)|n\rangle.$$

The Doi–Peliti generator is the normally ordered operator

$$\mathcal{L}_{\mathrm{DP}} = \sum_r \kappa_r \left[(a^\dagger)^{\nu_r'} - (a^\dagger)^{\nu_r}\right] a^{\nu_r}. \tag{133.42}$$

The passage from (133.41) to (133.42) is an algebraic dictionary, not a separate continuum theorem. Its coefficient check is the following. For every finitely supported probability vector P, the coefficient of $|m\rangle$ in $\mathcal{L}_{\mathrm{DP}}|P\rangle$ is the right side of (133.41). Indeed, for every multi-index α,

$$a^\alpha|n\rangle = (n)_\alpha|n-\alpha\rangle. \tag{133.43}$$

Hence a single reaction term acts by

$$\kappa_r\left[(a^\dagger)^{\nu_r'} - (a^\dagger)^{\nu_r}\right] a^{\nu_r}|n\rangle = \kappa_r(n)_{\nu_r}\left(|n+v_r\rangle - |n\rangle\right). \tag{133.44}$$

After multiplying by $P(n)$ and summing over n, the coefficient of $|m\rangle$ is the gain from $n = m - v_r$ minus the loss from $n = m$, which is exactly (133.41). Therefore $\partial_t|P_t\rangle = \mathcal{L}_{\mathrm{DP}}|P_t\rangle$ is the reaction-network master equation on the algebraic occupation domain.

The left vector encoding total probability is

$$\langle\mathbf{1}|n\rangle = 1 \qquad (n\in\mathbb{N}^S).$$

For every multi-index α,

$$\langle\mathbf{1}|(a^\dagger)^\alpha = \langle\mathbf{1}|,$$

because both sides assign value 1 to every basis vector. Each bracket in (133.42) is consequently annihilated by $\langle\mathbf{1}|$, and

$$\langle\mathbf{1}|\mathcal{L}_{\mathrm{DP}} = 0. \tag{133.45}$$

The nontrivial analytic questions begin only after this dictionary: whether $\mathcal{L}_{\mathrm{DP}}$ has a closed Markov generator on a chosen weighted sequence space, whether a spatial continuum scaling exists, and whether the coherent-state time-slicing below converges to a stochastic field theory. Those are model-dependent domain and limit statements, not consequences of the finite coefficient computation.

The coherent-state form is a controlled time-slicing of the same operator. Let

$$|z\rangle = \exp\left(\sum_s z_s a_s^\dagger\right)|0\rangle, \qquad \langle\bar z| = \langle 0|\exp\left(\sum_s \bar z_s a_s\right),$$

where $z, \bar z \in \mathbb{C}^S$. Then

$$a_s|z\rangle = z_s|z\rangle, \qquad \langle\bar z|a_s^\dagger = \bar z_s\langle\bar z|, \qquad \langle\bar z|z\rangle = e^{\bar z\cdot z}.$$

The normal symbol of the generator is

$$H_{\mathrm{DP}}(\bar z, z) = e^{-\bar z\cdot z}\langle\bar z|\mathcal{L}_{\mathrm{DP}}|z\rangle = \sum_r \kappa_r\left(\bar z^{\nu_r'} - \bar z^{\nu_r}\right) z^{\nu_r}. \tag{133.46}$$

In any finite-dimensional truncation whose projected generator and boundary rules have been specified, and in particular in any finite total-number sector preserved by the reactions, the coherent-state resolution of the identity gives an ordinary finite-dimensional time-sliced integral for matrix elements of $\exp(T\mathcal{L}_{\mathrm{DP}})$. Replacing each short-time factor by

$$\langle \bar{z}_{j+1}|e^{\Delta t \mathcal{L}_{\mathrm{DP}}}|z_j\rangle = \exp(\bar{z}_{j+1}\cdot z_j)\left[1+\Delta t\, H_{\mathrm{DP}}(\bar{z}_{j+1}, z_j) + O((\Delta t)^2)\right]$$

gives the continuum Doi–Peliti action whenever the time-slicing limit is controlled. The shift $\bar{z} = 1+\widetilde{z}$ is useful because

$$H_{\mathrm{DP}}(1, z) = 0,$$

which is the symbol form of probability conservation. This identity is the non-Hermitian Markov replacement for unitary norm conservation: expectation values are computed with the projection state $\langle \mathbf{1}|$, not with a Hilbert-space adjoint bra, and the distinguished left vector is fixed by normalization of probabilities rather than by an inner product. The shifted variable $\bar{z} = 1+\widetilde{z}$ therefore expands around the correct conservation point of the stochastic theory. Differentiating at $\bar{z} = 1$ gives the deterministic rate equation for the mean-field density variables:

$$\dot{z}_s = \left.\frac{\partial H_{\mathrm{DP}}}{\partial \bar{z}_s}\right|_{\bar{z}=1} = \sum_r \kappa_r(\nu'_{r,s} - \nu_{r,s}) z^{\nu_r}. \tag{133.47}$$

The same finite generator also exposes the dynamical large-deviation Hamiltonian. For an exponential test function

$$f_p(n) = e^{p\cdot n},$$

the backward generator L associated with (133.41) satisfies

$$\frac{(Lf_p)(n)}{f_p(n)} = \sum_r \kappa_r(n)_{\nu_r}\left(e^{p\cdot v_r} - 1\right). \tag{133.48}$$

This follows by applying the backward generator to f_p: the r-th jump changes $f_p(n)$ to $f_p(n+v_r) = e^{p\cdot v_r} f_p(n)$, while the loss term subtracts $f_p(n)$. If a density scaling $n = \Omega x$ is chosen together with rate constants scaled so that $\kappa_r(n)_{\nu_r} = \Omega\, \lambda_r(x) + o(\Omega)$, then

$$\mathcal{H}_{\mathrm{LD}}(x, p) = \sum_r \lambda_r(x)\left(e^{p\cdot v_r} - 1\right)$$

is the finite-regulator Hamiltonian for the path rate function. Proving the large-deviation principle itself requires tightness, exponential estimates, and a specified scaling limit; (133.48) is the exact algebraic input.

The Doi–Peliti and MSRJD constructions are complementary finite-regulator routes into stochastic field theory. MSRJD starts from continuous variables and Gaussian increments; Doi–Peliti starts from integer occupations and jump rates, so it retains the discreteness that controls absorbing states and rare-event tails. The coherent-state action obtained from H_{DP}, together with the conservation identity $H_{\mathrm{DP}}(1, z) = 0$, is the object on which perturbative RG, saddle-point large-deviation analysis, and fixed-point comparisons act. Calling a continuum stochastic model a directed-percolation, annihilation, or parity-preserving branching-annihilating scaling theory is therefore not a definition by name; it is a claim that the regulated Doi–Peliti actions converge, after the declared tunings and field rescalings, to the same fixed-point data and the same scaling observables.

133.11 Tilted Generators and Dynamical Large Deviations

Finite path measures also give the precise source of dynamical large-deviation generators. Let I be a finite state space and let $W_{ij} \geq 0$, $i \neq j$, be time-independent jump rates, with

$$r_i = \sum_{j \neq i} W_{ij}.$$

For a trajectory $i(t)$, define an additive observable

$$A_T(\gamma) = \int_0^T h_{i(t)}\, dt + \sum_{m=1}^{N_T} g_{i_{m-1} i_m}, \tag{133.49}$$

where $h_i \in \mathbb{R}$ is a state weight, $g_{ij} \in \mathbb{R}$ is a jump weight, and N_T is the number of jumps up to time T. For $\lambda \in \mathbb{C}$, the tilted backward generator on functions $f : I \to \mathbb{C}$ is

$$(\mathsf{L}_\lambda f)_i = \lambda h_i f_i + \sum_{j \neq i} W_{ij} \left(e^{\lambda g_{ij}} f_j - f_i \right). \tag{133.50}$$

Proposition 133.3 (Finite Feynman–Kac identity). *For $i \in I$, set*

$$u_i(t) = \mathbb{E}_i[e^{\lambda A_t} f(i(t))],$$

where the chain starts from i at time 0. *Then*

$$\partial_t u(t) = \mathsf{L}_\lambda u(t), \qquad u(0) = f.$$

Consequently, for an initial distribution p_0,

$$\mathbb{E}_{p_0}\left[e^{\lambda A_T}\right] = \sum_{i \in I} p_0(i) \left(e^{T \mathsf{L}_\lambda} \mathbf{1}\right)_i. \tag{133.51}$$

Proof. Condition on the evolution during a short interval $[0, \Delta t]$. With probability $1 - r_i \Delta t + O((\Delta t)^2)$, the chain stays at i, and the additive functional contributes $h_i \Delta t + O((\Delta t)^2)$. With probability $W_{ij} \Delta t + O((\Delta t)^2)$, the chain jumps once from i to j, contributing the jump weight g_{ij} and the state weight over a time interval of length Δt. In the jump branch the latter changes the contribution only by $1 + O(\Delta t)$, and hence only by $O((\Delta t)^2)$ after multiplication by the jump probability. Therefore

$$u_i(t + \Delta t) = (1 + \lambda h_i \Delta t - r_i \Delta t)\, u_i(t) + \sum_{j \neq i} W_{ij} \Delta t\, e^{\lambda g_{ij}} u_j(t) + O((\Delta t)^2),$$

uniformly on the finite state space. Dividing by Δt and sending $\Delta t \to 0$ gives $\partial_t u = \mathsf{L}_\lambda u$. The final identity follows by taking $f = \mathbf{1}$ and averaging over p_0. □

If the original Markov chain is irreducible, then $\mathsf{L}_\lambda + c\mathbf{1}$ is an irreducible nonnegative matrix for real λ and all sufficiently large c. Perron–Frobenius therefore gives a simple real eigenvalue with strictly positive left and right eigenvectors and with maximal real part. It identifies the long-time scaled cumulant generating function

$$\psi(\lambda) = \lim_{T \to \infty} \frac{1}{T} \log \mathbb{E}_{p_0}\left[e^{\lambda A_T}\right]$$

with the eigenvalue of L_λ whose real part is maximal, independently of any nonzero nonnegative initial distribution. The positivity of the Perron eigenvectors is what prevents the leading spectral coefficient in (133.51) from vanishing. A path large-deviation principle and a Legendre-dual rate function require the separate analytic and tightness hypotheses of large-deviation theory. The finite tilted generator is the exact microscopic input to those hypotheses.

There is a useful exact symmetry when A_T is entropy production in a stationary finite jump process. Assume $W_{ij} > 0$ if and only if $W_{ji} > 0$, and let $\pi_i > 0$ be the stationary distribution. Define the entropy increment of one jump by

$$\sigma_{ij} = \log \frac{\pi_i W_{ij}}{\pi_j W_{ji}}. \tag{133.52}$$

Let L_q^Σ be the tilted generator for $\mathbb{E}[e^{-q\Sigma_T}]$:

$$(\mathsf{L}_q^\Sigma f)_i = \sum_{j\neq i} W_{ij} e^{-q\sigma_{ij}} f_j - r_i f_i. \tag{133.53}$$

With $\Pi = \mathrm{diag}(\pi_i)$, one has the finite matrix identity

$$\mathsf{L}_q^\Sigma = \Pi^{-1} \big(\mathsf{L}_{1-q}^\Sigma\big)^T \Pi. \tag{133.54}$$

Indeed, the off-diagonal i, j entry of the right side is

$$\frac{\pi_j}{\pi_i} W_{ji} e^{-(1-q)\sigma_{ji}} = W_{ij} \left(\frac{\pi_j W_{ji}}{\pi_i W_{ij}} \right)^q = W_{ij} e^{-q\sigma_{ij}},$$

and the diagonal entries are both $-r_i$. Hence L_q^Σ and L_{1-q}^Σ have the same spectrum, and the entropy-production scaled cumulant generating function obeys

$$\psi_\Sigma(q) = \psi_\Sigma(1-q).$$

This is the finite-generator form of the Gallavotti–Cohen symmetry. The finite-time fluctuation relation in Section 133.6 is the corresponding path-measure identity; the spectral symmetry is its time-homogeneous stationary long-time shadow.

133.12 Empirical Measures, Flows, and the Level-2.5 Cost

The tilted generator computes exponential moments of additive observables. The path-space object behind it is the joint empirical occupation and empirical flow. For a trajectory of the same finite jump process, define

$$\rho_i^T(\gamma) = \frac{1}{T} \int_0^T \mathbf{1}_{\{i(t)=i\}}\, dt, \qquad q_{ij}^T(\gamma) = \frac{1}{T} N_{ij}(T), \tag{133.55}$$

where $N_{ij}(T)$ is the number of jumps $i \to j$ before time T. Thus ρ^T is a probability vector and $q_{ij}^T \geq 0$ for $i \neq j$. A limiting pair (ρ, q) can occur only when

$$\rho_i \geq 0, \qquad \sum_i \rho_i = 1, \qquad q_{ij} \geq 0, \qquad \sum_{j\neq i} q_{ij} = \sum_{j\neq i} q_{ji}. \tag{133.56}$$

The last equation is current conservation at the vertex i. At finite time it is violated only by the boundary term

$$\sum_{j\neq i} N_{ij}(T) - \sum_{j\neq i} N_{ji}(T) = \mathbf{1}_{\{i(0)=i\}} - \mathbf{1}_{\{i(T)=i\}},$$

which disappears after division by T.

For a pair satisfying (133.56), define

$$I_{2.5}(\rho, q) = \sum_i \sum_{j\neq i} \left[q_{ij} \log \frac{q_{ij}}{\rho_i W_{ij}} - q_{ij} + \rho_i W_{ij} \right], \tag{133.57}$$

with the conventions $0\log(0/a) = 0$, $q\log(q/0) = +\infty$ for $q > 0$, and $q_{ij} = 0$ whenever $W_{ij} = 0$. If the constraints fail, set $I_{2.5}(\rho, q) = +\infty$. This is the relative entropy rate between the observed jump intensities and the original Markov intensities.

Proposition 133.4 (Finite empirical-flow cost)**.** *Let the finite jump process be irreducible on its support. The exponential cost of observing a limiting empirical pair (ρ, q) is (133.57). More precisely, if $\rho_i > 0$ on the communicating class, $q_{ij} > 0$ whenever $W_{ij} > 0$, and (ρ, q) satisfies (133.56), then the auxiliary rates*

$$R_{ij} = \frac{q_{ij}}{\rho_i} \tag{133.58}$$

make ρ stationary and make $q_{ij} = \rho_i R_{ij}$ the typical empirical flow. The Radon–Nikodym density of the original path measure $\mathbb{P}_W$ relative to the auxiliary path measure $\mathbb{P}_R$ obeys

$$\frac{1}{T} \log \frac{d\mathbb{P}_W}{d\mathbb{P}_R}(\gamma) = \sum_{i,j\neq i} q^T_{ij}(\gamma) \log \frac{W_{ij}}{R_{ij}} - \sum_{i,j\neq i} \rho^T_i(\gamma)(W_{ij} - R_{ij}). \tag{133.59}$$

On path sets where $(\rho^T, q^T) \to (\rho, q)$, this expression converges to $-I_{2.5}(\rho, q)$. Consequently, for sufficiently small neighborhoods U of an admissible continuity point of $I_{2.5}$,

$$\lim_{U\downarrow(\rho,q)} \lim_{T\to\infty} \frac{1}{T} \log \mathbb{P}_W\big((\rho^T, q^T) \in U\big) = -I_{2.5}(\rho, q).$$

Proof. The stationarity of ρ for R is exactly the conservation equation:

$$\rho_i \sum_{j\neq i} R_{ij} = \sum_{j\neq i} q_{ij} = \sum_{j\neq i} q_{ji} = \sum_{j\neq i} \rho_j R_{ji}.$$

For a path with jump counts $N_{ij}(T)$ and occupation times $T_i = T\rho^T_i$, the ratio of the two continuous-time jump-process densities is

$$\log \frac{d\mathbb{P}_W}{d\mathbb{P}_R} = \sum_i \sum_{j\neq i} N_{ij}(T) \log \frac{W_{ij}}{R_{ij}} - \sum_i T_i \sum_{j\neq i} (W_{ij} - R_{ij}).$$

Dividing by T, substituting $q^T_{ij} = N_{ij}(T)/T$, and then letting the empirical pair tend to the candidate pair gives, since $R_{ij} = q_{ij}/\rho_i$,

$$\sum_{i,j\neq i} q_{ij} \log \frac{\rho_i W_{ij}}{q_{ij}} - \sum_{i,j\neq i} \rho_i W_{ij} + \sum_{i,j\neq i} q_{ij} = -I_{2.5}(\rho, q),$$

which is the limiting value of (133.59). Under the auxiliary irreducible finite chain, the ergodic theorem gives $(\rho^T, q^T) \to (\rho, q)$ almost surely. Hence the same identity gives the lower exponential bound for every sufficiently small neighborhood.

For the matching upper bound, cover a compact closed set of admissible pairs by finitely many small neighborhoods and use the same Radon–Nikodym identity in each neighborhood with the corresponding auxiliary rates. The boundary cases with some $\rho_i = 0$ or $q_{ij} = 0$ are obtained by replacing the pair by strictly positive admissible pairs on the same support and then taking the lower-semicontinuous limit of (133.57). The finite state space is what makes this covering argument elementary; in continuum QFT a corresponding statement would require compactness and tightness estimates that are not contained in the finite calculation. □

Contracting over the empirical flow gives the level-2 occupation cost

$$I_2(\rho) = \inf_{\substack{q \geq 0 \\ \nabla \cdot q = 0}} I_{2.5}(\rho, q), \tag{133.60}$$

where $\nabla \cdot q = 0$ denotes the conservation condition in (133.56). For a two-state chain with rates $W_{01} = a$, $W_{10} = b$, conservation forces $q_{01} = q_{10} = s$. If $\rho_0 = p$ and $\rho_1 = 1 - p$, minimizing over s gives

$$I_2(p) = \left(\sqrt{pa} - \sqrt{(1-p)b}\right)^2. \tag{133.61}$$

The minimum vanishes exactly at the stationary occupation $p = b/(a + b)$.

The tilted-generator formula is the Legendre side of the same finite construction. The additive observable (133.49) can be written as

$$\frac{A_T}{T} = \sum_i h_i \rho_i^T + \sum_{i, j \neq i} g_{ij} q_{ij}^T.$$

Therefore the scaled cumulant generating function is equivalently

$$\psi(\lambda) = \sup_{\rho, q} \left[\lambda \left(\sum_i h_i \rho_i + \sum_{i, j \neq i} g_{ij} q_{ij} \right) - I_{2.5}(\rho, q) \right], \tag{133.62}$$

with the supremum over admissible empirical pairs. In finite dimension this variational formula is equivalent to the Perron eigenvalue statement for L_λ. The equality is a useful diagnostic: if a continuum hydrodynamic or field-theoretic large-deviation claim does not identify the finite empirical pair whose contraction is being taken, then the limiting claim has not yet been mathematically formulated.

133.13 Weak-Coupling Open-System Limit

Let a system Hilbert space couple to an environment by

$$H = H_S + H_E + \lambda \sum_a S_a \otimes E_a. \tag{133.63}$$

We take $S_a = S_a^\dagger$ and $E_a = E_a^\dagger$; a non-Hermitian coupling is rewritten in this form by separating Hermitian and anti-Hermitian parts. This convention fixes the adjoints in the spectral matrices below. Assume the environment state ρ_E is stationary, $[H_E, \rho_E] = 0$, and that connected environment correlators decay fast enough for their Fourier transforms to exist as positive matrices:

$$\gamma_{ab}(\omega) = \int_{-\infty}^{\infty} dt\, e^{\mathrm{i}\omega t}\, \mathrm{Tr}_E(\rho_E E_a(t) E_b(0))\,. \tag{133.64}$$

Positivity follows because, for any complex vector v_a,

$$C_v(t) = v_a^* v_b\ \mathrm{Tr}_E(\rho_E E_a(t) E_b(0)) = \mathrm{Tr}_E\Big(\rho_E F(t)^\dagger F(0)\Big)\,, \qquad F = v_b E_b,$$

is a function of positive type. Indeed, for any times t_i and complex numbers c_i,

$$\sum_{i,j} c_i^* c_j\, C_v(t_i - t_j) = \mathrm{Tr}_E\left(\rho_E \left(\sum_i c_i F(t_i)\right)^\dagger \left(\sum_j c_j F(t_j)\right)\right) \ge 0.$$

The distributional Bochner theorem then says that its Fourier transform is a positive measure. Hence $v_a^* \gamma_{ab}(\omega) v_b \ge 0$ at frequencies where the density $\gamma(\omega)$ exists, and more generally as a positive matrix-valued measure.

Let P_ϵ be the spectral projections of H_S, and define Bohr-frequency components

$$S_a(\omega) = \sum_{\epsilon' - \epsilon = \omega} P_\epsilon S_a P_{\epsilon'}. \tag{133.65}$$

Under the weak-coupling scaling

$$\lambda \to 0, \qquad t = \lambda^{-2}\tau,$$

the interaction-picture density matrix satisfies the integral equation

$$\rho_I(t) = \rho_I(0) - \mathrm{i}\lambda \int_0^t ds\, [V_I(s), \rho_I(s)], \qquad V_I(s) = \sum_a S_a(s) \otimes E_a(s).$$

Expanding once more, tracing over the environment, assuming $\mathrm{Tr}_E(\rho_E E_a) = 0$ after absorbing one-point terms into H_S, and using fast decay of connected environment correlators gives a second-order memory integral. The van Hove limit keeps $\lambda^2 t = \tau$ fixed. Oscillatory factors $e^{\mathrm{i}(\omega - \omega')s}$ then project onto equal Bohr frequencies, while the time integral of the bath correlator supplies $\gamma_{ab}(\omega)$ and its principal-value Hilbert transform. For a finite-dimensional system with discrete Bohr spectrum, bounded system couplings, a stationary environment state, and absolutely integrable environment connected correlators with the mixing estimates needed to discard higher cumulants in the van Hove limit, this limit gives

$$\frac{d\rho_S}{d\tau} = \mathcal{L}(\rho_S), \tag{133.66}$$

where

$$\begin{aligned}\mathcal{L}(\rho) = {}&-\mathrm{i}[H_S + H_{\mathrm{LS}}, \rho] \\ &+ \sum_\omega \sum_{a,b} \gamma_{ab}(\omega) \left[S_b(\omega)\rho S_a(\omega)^\dagger - \frac{1}{2}\{S_a(\omega)^\dagger S_b(\omega), \rho\}\right].\end{aligned} \tag{133.67}$$

H_{LS} is the Lamb-shift Hamiltonian from the principal-value part of the bath correlator. The dissipative part has the GKSL form because each matrix $\gamma_{ab}(\omega)$ is positive semidefinite and hence can be diagonalized into jump operators.

Proposition 133.5 (Trace preservation and complete positivity)**.** *For any finite-dimensional system, the generator* (133.67) *preserves* $\operatorname{Tr}\rho$*, preserves Hermiticity, and generates a completely positive trace-preserving semigroup.*

Proof. Trace preservation follows term by term:

$$\operatorname{Tr}(L\rho L^\dagger) - \frac{1}{2}\operatorname{Tr}(L^\dagger L\rho) - \frac{1}{2}\operatorname{Tr}(\rho L^\dagger L) = 0$$

by cyclicity of the trace. The commutator has zero trace and preserves Hermiticity. Since $\gamma(\omega)$ is positive, write $\gamma_{ab}(\omega) = \sum_\alpha v_{\alpha a}(\omega)^* v_{\alpha b}(\omega)$ and define

$$L_{\alpha\omega} = \sum_b v_{\alpha b}(\omega) S_b(\omega).$$

Then the dissipator is a sum of standard Lindblad terms

$$L_{\alpha\omega}\rho L_{\alpha\omega}^\dagger - \frac{1}{2}\{L_{\alpha\omega}^\dagger L_{\alpha\omega}, \rho\}.$$

Set $H = H_S + H_{\mathrm{LS}}$,

$$\Gamma = \sum_{\alpha,\omega} L_{\alpha\omega}^\dagger L_{\alpha\omega}, \qquad H_{\mathrm{eff}} = H - \frac{\mathrm{i}}{2}\Gamma,$$

and define the completely positive maps

$$\mathcal{K}_t(\rho) = e^{-\mathrm{i}H_{\mathrm{eff}}t}\rho e^{\mathrm{i}H_{\mathrm{eff}}^\dagger t}, \qquad \mathcal{J}(\rho) = \sum_{\alpha,\omega} L_{\alpha\omega}\rho L_{\alpha\omega}^\dagger.$$

In finite dimension the Dyson–Phillips series

$$T_t = \mathcal{K}_t + \sum_{n\geq 1}\int_{0<s_1<\cdots<s_n<t} \mathcal{K}_{t-s_n}\mathcal{J}\mathcal{K}_{s_n-s_{n-1}}\cdots\mathcal{J}\mathcal{K}_{s_1}\,ds_1\cdots ds_n \tag{133.68}$$

converges in operator norm on the trace-class matrices. Each summand is completely positive, so T_t is completely positive. Differentiating the series gives $dT_t/dt = \mathcal{L}T_t = T_t\mathcal{L}$ and $T_0 = \mathrm{id}$. Since the trace of $\mathcal{L}(\rho)$ vanishes for every ρ,

$$\frac{d}{dt}\operatorname{Tr} T_t(\rho) = \operatorname{Tr}\mathcal{L}(T_t(\rho)) = 0,$$

and therefore T_t is trace preserving. This proves complete positivity and trace preservation for the semigroup generated by (133.67). □

For comparison with the infinitesimal Kraus form, a short time step $d\tau$ has

$$K_0 = \mathbf{1} - d\tau\left(\mathrm{i}H + \frac{1}{2}\Gamma\right), \qquad K_{\alpha\omega} = \sqrt{d\tau}\,L_{\alpha\omega}.$$

This is a first-order local representation of the same generator; the identity

$$K_0^\dagger K_0 + \sum_{\alpha,\omega} K_{\alpha\omega}^\dagger K_{\alpha\omega} = \mathbf{1} + O(d\tau^2)$$

is the infinitesimal trace-preservation statement, while the norm-convergent series (133.68) is the finite-time object.

133.14 Thermal Bath and Detailed Balance

If the environment is a KMS state at inverse temperature β, its spectral matrix obeys

$$\gamma_{ab}(-\omega) = e^{-\beta\omega}\gamma_{ba}(\omega) \tag{133.69}$$

for Hermitian environment operators with the Fourier convention in (133.64). To see the sign and the order of indices, insert a spectral resolution of H_E. If $H_E|m\rangle = E_m|m\rangle$, then

$$\gamma_{ab}(\omega) = \frac{2\pi}{Z}\sum_{m,n} e^{-\beta E_m}\delta(\omega - (E_n - E_m))\,(E_a)_{mn}(E_b)_{nm}.$$

The same expression for $\gamma_{ba}(-\omega)$, with m and n exchanged, gives

$$\gamma_{ba}(-\omega) = e^{-\beta\omega}\gamma_{ab}(\omega),$$

which is equivalent to (133.69). For a two-level system with energy gap $\Omega > 0$, let

$$\Gamma_\downarrow = \gamma(\Omega), \qquad \Gamma_\uparrow = \gamma(-\Omega) = e^{-\beta\Omega}\Gamma_\downarrow.$$

The population master equation is

$$\dot{p}_e = -\Gamma_\downarrow p_e + \Gamma_\uparrow p_g, \qquad p_g = 1 - p_e.$$

The stationary ratio is

$$\frac{p_e}{p_g} = \frac{\Gamma_\uparrow}{\Gamma_\downarrow} = e^{-\beta\Omega},$$

which is the Gibbs ratio. This derivation is the open-system counterpart of the detailed-balance identity in kinetic theory.

133.15 Schwinger–Keldysh Influence Functional

For a field-theoretic system variable ϕ linearly coupled to an environment operator $\mathcal{O}_E$, the environment can be integrated out on the closed time path:

$$e^{\mathrm{i}S_{\mathrm{IF}}[\phi_+,\phi_-]} = \mathrm{Tr}_E\Big(U_E[\phi_+]\rho_E U_E[\phi_-]^\dagger\Big).$$

Closed-time-path normalization gives

$$S_{\mathrm{IF}}[\phi,\phi] = 0.$$

In r/a variables,

$$\phi_r = \frac{1}{2}(\phi_+ + \phi_-), \qquad \phi_a = \phi_+ - \phi_-,$$

the quadratic influence action has the form

$$S_{\mathrm{IF}}^{(2)} = \int \phi_a D_R \phi_r + \frac{\mathrm{i}}{2}\int \phi_a N \phi_a + O(\phi_a^3, \phi_a^2\phi_r). \tag{133.70}$$

with

$$D_R(x-y) = -\mathrm{i}\theta(x^0-y^0)\omega_E([\mathcal{O}_E(x),\mathcal{O}_E(y)]), \qquad N(x-y) = \frac{1}{2}\omega_E(\{\mathcal{O}_E(x),\mathcal{O}_E(y)\})$$

for a stationary environment state ω_E. The kernel D_R is retarded because variations of the forward and backward branches cancel for earlier times, as in the Schwinger–Keldysh derivation of retarded response. The kernel N is positive in the sense

$$\int fNf \geq 0$$

for real test functions f, so that $\exp(\mathrm{i}S_{\mathrm{IF}})$ is damped rather than amplified. If the environment is KMS, N and the anti-Hermitian part of D_R obey the fluctuation–dissipation relation of Chapter 127.

Finite Gaussian bridge to MSRJD. The relation between the Schwinger–Keldysh influence functional and a classical stochastic equation is a finite-regulator Gaussian identity, not a formal analogy. Let $A, B = 1, \ldots, m$ label a finite collection of regulated time, space, and internal indices, and let

$$E_A(\phi_r) = 0$$

be the deterministic retarded equation produced by the real part of the closed-time-path effective action. At quadratic order in the difference field, the finite effective weight has the form

$$\exp\left[\mathrm{i}\phi_a^A E_A(\phi_r) - \frac{1}{2}\phi_a^A N_{AB}\phi_a^B\right], \qquad N = N^T \geq 0. \tag{133.71}$$

If $N > 0$, the second factor is the characteristic function of a real Gaussian random vector ξ_A with covariance N_{AB}:

$$\exp\left[-\frac{1}{2}\phi_a^A N_{AB}\phi_a^B\right] = \frac{1}{\sqrt{(2\pi)^m \det N}} \int_{\mathbb{R}^m} d^m\xi \, \exp\left[-\frac{1}{2}\xi_A (N^{-1})^{AB}\xi_B + \mathrm{i}\phi_a^A\xi_A\right]. \tag{133.72}$$

Substituting (133.72) into (133.71) and integrating over ϕ_a gives the finite constraint

$$E_A(\phi_r) + \xi_A = 0. \tag{133.73}$$

Equivalently one may replace ξ by $-\xi$; the covariance is unchanged. Thus the SK a-field is the same finite response variable as the Fourier dual $\hat{x}$ in (133.24), and the imaginary quadratic a-field kernel is the covariance of the induced noise. If N has null directions, the same statement is made on the quotient by $\ker N$, while the null components of ϕ_a impose exact deterministic constraints. This is the finite form appropriate for conserved densities: the noise covariance can be degenerate because exact conservation forbids noise in the spatially constant charge mode.

For a linear equation

$$E_A(\phi_r) = K_{AB}\phi_r^B - J_A$$

with invertible retarded matrix K, the induced Gaussian law for ϕ_r has mean $K^{-1}J$ and covariance

$$\left\langle(\phi_r^A - \langle\phi_r^A\rangle)(\phi_r^B - \langle\phi_r^B\rangle)\right\rangle = (K^{-1})^{AC}N_{CD}(K^{-T})^{DB}. \tag{133.74}$$

This formula is the finite-regulator source of the Langevin covariance in hydrodynamic effective theory. It also fixes the order of logic: a Markovian white-noise Langevin equation is obtained only after the environment correlator has been approximated by a local kernel in the chosen scaling limit. Before that limit, N is a nonlocal finite covariance kernel and (133.73) is a colored-noise equation.

133.16 Hydrodynamic Open Systems

Consider a single approximately conserved density $n(t, \mathbf{x})$ whose conservation is weakly broken by a KMS environment. The Markovian hydrodynamic equation is

$$\partial_t n + \nabla \cdot j = -\gamma(n - n_{\mathrm{eq}}) + \xi. \tag{133.75}$$

For one homogeneous mode with susceptibility χ, the quadratic equilibrium free energy is

$$F(n) = \frac{(n - n_{\mathrm{eq}})^2}{2\chi}.$$

The Fokker–Planck equation associated with

$$\dot{n} = -\gamma(n - n_{\mathrm{eq}}) + \xi, \qquad \langle \xi(t)\xi(t') \rangle = 2D_n \delta(t - t')$$

has stationary distribution proportional to $e^{-\beta F(n)}$ precisely when

$$D_n = \gamma \chi T. \tag{133.76}$$

Indeed, the Fokker–Planck equation is

$$\partial_t P(n,t) = \partial_n[\gamma(n - n_{\mathrm{eq}})P(n,t)] + D_n \partial_n^2 P(n,t) = -\partial_n J_P(n,t),$$

where

$$J_P(n,t) = -\gamma(n - n_{\mathrm{eq}})P(n,t) - D_n \partial_n P(n,t).$$

For the equilibrium candidate

$$P_{\mathrm{eq}}(n) = Z^{-1} \exp\left[-\frac{(n - n_{\mathrm{eq}})^2}{2\chi T} \right],$$

the stationary probability current vanishes for every n exactly when $D_n = \gamma \chi T$. Thus

$$\langle \xi(t, \mathbf{x}) \xi(t', \mathbf{x}') \rangle = 2\gamma \chi T \, \delta(t - t') \delta^{(d)}(\mathbf{x} - \mathbf{x}') \tag{133.77}$$

in the local Markovian limit. The relation is the Einstein relation for a nonconserved relaxation mode; it is distinct from diffusive current noise, where the noise enters through a divergence.

133.17 Theorem Boundary

The proof architecture in §133.1 is part of the theorem boundary: a continuum result must say which finite layer is being used, which field-theoretic representation is only a coordinate rewrite, and which scaling hypotheses turn that coordinate rewrite into a QFT limit. For continuum QFT, a complete nonequilibrium construction must state the local algebra, the reservoir states, the topology of the long-time local limit, the domains of the current operators, and the order in which weak coupling, thermodynamic, Markovian, hydrodynamic, and continuum limits are taken. For open systems, complete positivity is a statement about the reduced dynamics of a subalgebra after tracing over an environment and taking a specified scaling limit. A nonlocal truncation of a closed QFT becomes an open-system dynamics only after such an environment trace and limit have been constructed. For hydrodynamic open systems, the noise kernel and relaxation matrix must be derived from the same influence functional that produces the dissipative terms. For Doi–Peliti reaction networks, the corresponding continuum problem must construct the spatial regulator, the scaling of rates and fields, the renormalized non-Hermitian action, the projection-state Ward identity $H_{\mathrm{DP}}(1, z) = 0$, and the scaling local observables whose limits define the proposed nonequilibrium fixed point.

Open Problem 133.6 (Continuum nonequilibrium states)*.* Construct nonequilibrium steady states and open-system limits in interacting continuum QFT with local algebras, KMS reservoirs, real-time correlators, entropy production, hydrodynamic scaling limits, and complete-positivity constraints derived from the microscopic dynamics. Include continuum limits of spatially regulated Doi–Peliti reaction networks when the goal is a non-Hermitian stochastic field theory for absorbing-state or reaction-diffusion critical behavior.

Chapter 134

Hydrodynamic Fluctuations And Long-Time Tails

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Hydrodynamics describes the long-wavelength evolution of conserved densities. In a thermal state those densities also fluctuate. The fluctuations are fixed at the linear level by static susceptibilities and the KMS fluctuation–dissipation relation; their nonlinear couplings then produce nonanalytic low-frequency terms in real-time correlators. These terms are the hydrodynamic long-time tails. They are universal within the hydrodynamic effective theory because their nonanalytic part is determined by the conserved-mode propagators and by the local nonlinear vertices.

Throughout this chapter spacetime is $\mathbb{R}_t \times \mathbb{R}^d$, with d spatial dimensions. Fourier modes are $\exp(-\mathrm{i}\omega t + \mathrm{i}\mathbf{k}\cdot\mathbf{x})$. The diffusion normalizations are those of Chapter 129: the charge susceptibility is $\chi = \partial n/\partial\mu$, the conductivity is σ, and $D = \sigma/\chi$. Equal-time thermal fluctuations of a coarse-grained density carry the covariance $T\chi$.

134.1 Static Fluctuation Data

Let $q_A(t, \mathbf{x})$ be conserved densities in a homogeneous KMS state at temperature T and chemical potentials μ_A. Write

$$\delta q_A = q_A - \omega_\beta(q_A),$$

where ω_β denotes the thermal state. The static susceptibility matrix in the chemical-potential convention is

$$\chi_{AB} = \left(\frac{\partial q_A}{\partial \mu_B}\right)_T .$$

For hydrodynamic variables averaged over a cell whose size is large compared with microscopic correlation lengths, the equal-time connected covariance is

$$\int d^d x\, \omega_\beta(\delta q_A(0,\mathbf{x})\delta q_B(0,\mathbf{0}))_{\mathrm{conn}} = T\chi_{AB}. \tag{134.1}$$

Equivalently, if one uses the dimensionless thermodynamic force $\alpha_A = \mu_A/T$, the covariance equals $\partial q_A/\partial \alpha_B$. This convention removes a common source of factor-of-T errors in stochastic hydrodynamics.

For one diffusive charge density n, the Gaussian equilibrium probability functional for long-wavelength configurations is

$$P_{\mathrm{eq}}[n] \propto \exp\left[-\frac{1}{2T\chi}\int d^d x\,(\delta n)^2\right], \qquad \delta n = n - \omega_\beta(n). \tag{134.2}$$

This formula is a local central-limit statement inside the hydrodynamic window. The continuum delta function in (134.1) is an effective-theory notation for a cell-averaged covariance; the cell scale is kept between the microscopic correlation length and the external wavelength.

134.2 Linear Stochastic Diffusion

The first-order stochastic constitutive relation for one conserved charge is

$$\partial_t n + \partial_i j^i = 0, \qquad j^i = -D\partial_i n + \xi^i, \tag{134.3}$$

with Gaussian white current noise

$$\langle \xi^i(t,\mathbf{x})\xi^j(t',\mathbf{x}')\rangle = 2T\sigma\,\delta^{ij}\delta(t-t')\delta^{(d)}(\mathbf{x}-\mathbf{x}'). \tag{134.4}$$

The coefficient $2T\sigma$ is the same coefficient derived from the dynamical KMS symmetry of the diffusion action in Chapter 129. The stochastic equation gives

$$n(\omega,\mathbf{k}) = \frac{\mathrm{i}k_i\xi^i(\omega,\mathbf{k})}{-\mathrm{i}\omega + Dk^2}, \qquad k^2 = \mathbf{k}\cdot\mathbf{k}.$$

Hence the symmetrized density correlator is

$$G^{\mathrm{sym}}_{nn}(\omega,\mathbf{k}) = \frac{2T\sigma k^2}{\omega^2 + (Dk^2)^2}. \tag{134.5}$$

Integrating over frequency gives

$$\int \frac{d\omega}{2\pi} G^{\mathrm{sym}}_{nn}(\omega,\mathbf{k}) = \frac{T\sigma}{D} = T\chi,$$

which is exactly the static covariance (134.1). Thus the Einstein relation $D = \sigma/\chi$ is forced by compatibility of the deterministic diffusion constant, the conductivity, and the equilibrium fluctuation measure.

The retarded density source-response kernel from the Schwinger–Keldysh action is

$$K^R_{nn}(\omega, \mathbf{k}) = \chi \, \frac{Dk^2}{Dk^2 - \mathrm{i}\omega}. \tag{134.6}$$

Its imaginary part obeys the low-frequency fluctuation–dissipation relation

$$G^{\mathrm{sym}}_{nn}(\omega, \mathbf{k}) = \frac{2T}{\omega} \, \mathrm{Im}\, K^R_{nn}(\omega, \mathbf{k}) + O(\omega/T)$$

inside the classical hydrodynamic regime. The exact quantum formula is the KMS relation of Chapter 127; the displayed expression is its $|\omega| \ll T$ limit.

134.3 Local Schwinger–Keldysh Origin

The stochastic equation (134.3) is the Hubbard–Stratonovich form of the local diffusion action

$$I_{\mathrm{diff}} = \int dt \, d^d x \, \left[\chi B_{a0} B_{r0} - \sigma B_{ai} \partial_t B_{ri} + \mathrm{i} T \sigma B_{ai} B_{ai}\right]. \tag{134.7}$$

Here $B_{r\mu} = A_{r\mu} + \partial_\mu \varphi_r$ and $B_{a\mu} = A_{a\mu} + \partial_\mu \varphi_a$ are the gauge-invariant hydrodynamic source combinations. The a-phase variation imposes the continuity equation, and the imaginary term has the Gaussian representation

$$\exp\left[-T\sigma \int B_{ai} B_{ai}\right] = \int D\xi \, \exp\left[-\int \frac{\xi_i \xi_i}{4T\sigma} + \mathrm{i} \int B_{ai} \xi_i\right].$$

The same coefficient therefore controls current response, current noise, and diffusive relaxation. This is the local effective-action statement of KMS: one chooses the dissipative term and the noise term together.

134.4 Finite-Cell Current Fluctuations and the Macroscopic Cost

The white current noise in (134.4) can be obtained from a finite empirical-flow calculation before any continuum stochastic field notation is introduced. This is the finite origin of the Gaussian current cost used in macroscopic fluctuation theory. The continuum functional is a hydrodynamic scaling statement; the exact statement at this stage is the contraction of a finite jump-flow relative entropy.

Consider one oriented mesoscopic bond. During a time block, let q_+ and q_- be the empirical rates of jumps across the bond in the positive and negative directions. At fixed local occupation data the corresponding reference jump intensities are positive numbers r_+ and r_-. The local contribution to the finite level-2.5 cost of Section 133.12 is

$$\Phi(q_+, q_-; r_+, r_-) = q_+ \log \frac{q_+}{r_+} - q_+ + r_+ + q_- \log \frac{q_-}{r_-} - q_- + r_-, \tag{134.8}$$

with $q_\pm \geq 0$. The net empirical current through the bond is

$$j = q_+ - q_-.$$

For fixed j, strict convexity gives a unique minimizer. Introducing a Lagrange multiplier ℓ for $q_+ - q_- = j$ gives

$$\log \frac{q_+}{r_+} + \ell = 0, \qquad \log \frac{q_-}{r_-} - \ell = 0,$$

hence

$$q_+ q_- = r_+ r_-, \qquad q_+ - q_- = j.$$

Writing

$$\Delta(j) = \sqrt{j^2 + 4r_+ r_-},$$

the minimizer is

$$q_+^*(j) = \frac{\Delta(j) + j}{2}, \qquad q_-^*(j) = \frac{\Delta(j) - j}{2}. \tag{134.9}$$

Substitution into (134.8) gives the exact finite current cost

$$\Phi_{\mathrm{cur}}(j; r_+, r_-) = j \log \frac{j + \sqrt{j^2 + 4r_+ r_-}}{2r_+} - \sqrt{j^2 + 4r_+ r_-} + r_+ + r_-. \tag{134.10}$$

It vanishes at the typical current

$$j_0 = r_+ - r_-, \qquad \Delta(j_0) = r_+ + r_-.$$

The derivative of the contracted cost is the multiplier conjugate to the current,

$$\frac{d\Phi_{\mathrm{cur}}}{dj} = \log \frac{q_+^*(j)}{r_+},$$

and therefore

$$\left.\frac{d^2\Phi_{\mathrm{cur}}}{dj^2}\right|_{j=j_0} = \frac{1}{r_+ + r_-}.$$

The current cost near its minimum is consequently

$$\Phi_{\mathrm{cur}}(j; r_+, r_-) = \frac{(j - j_0)^2}{2(r_+ + r_-)} + O\big((j - j_0)^3\big)\,. \tag{134.11}$$

The same exact expression also records the entropy-production asymmetry:

$$\Phi_{\mathrm{cur}}(j; r_+, r_-) - \Phi_{\mathrm{cur}}(-j; r_+, r_-) = -j \log \frac{r_+}{r_-}. \tag{134.12}$$

Thus the symmetric traffic $r_+ + r_-$ fixes the Gaussian current variance, while the ratio r_+/r_- fixes the antisymmetric entropy-production part. No continuum limit has entered this calculation.

To pass from the finite current cost to hydrodynamics, one must add scaling input. Suppose a sequence of finite cell regulators has a local-equilibrium diffusive scaling limit in which the conserved density is $n(t, \mathbf{x})$ and the empirical current is $j^i(t, \mathbf{x})$. Suppose moreover that the finite typical current and finite traffic converge in the local hydrodynamic window to the deterministic current and covariance density. In a local basis where the positive symmetric conductivity matrix is diagonal, this componentwise statement is

$$j^i_{\rm det}(n) = -D^{ij}(n)\partial_j n + O(\partial^2), \qquad r^i_+ + r^i_- \longrightarrow 2T\,\sigma^{ij}(n)$$

in the normalization of (134.4). Then the quadratic Taylor term (134.11) becomes the local Gaussian current cost

$$\mathcal{I}_{\rm cur}[n,j] = \frac{1}{4T}\int dt\,d^dx\,\big(j^i + D^{ik}\partial_k n\big)(\sigma^{-1})_{ij}\big(j^j + D^{j\ell}\partial_\ell n\big), \tag{134.13}$$

subject to the continuity equation

$$\partial_t n + \partial_i j^i = 0. \tag{134.14}$$

Equation (134.13) is the Onsager–Machlup current form of the stochastic diffusion theory (134.3). Integrating over j with the constraint (134.14), or equivalently introducing a Lagrange multiplier for the constraint, gives the same quadratic Schwinger–Keldysh action (134.7) after the Hubbard–Stratonovich step above. The non-Gaussian terms in the exact finite expression (134.10) are irrelevant in the central-limit hydrodynamic fluctuation regime but are essential for far-from-typical current large deviations when the underlying finite regulator is retained.

The logical status is therefore sharp. The finite contraction (134.10) is a direct finite consequence of the regulated jump-flow rate function. The macroscopic functional (134.13) is obtained from it only after one assumes, or proves in a specified model, the local-equilibrium hydrodynamic scaling limit, the convergence of traffic to $2T\sigma$, and the Einstein relation between D, σ, and χ.

134.5 Hydrodynamic Nonlinearities

Hydrodynamic variables are local coordinates on the manifold of equilibrium states. Expanding the currents in fluctuations around a homogeneous state gives

$$J^i_A = J^i_{A,\rm lin} + \frac{1}{2}\,\lambda^i{}_{A,BC}\,\phi_B\phi_C + O(\phi^3, \phi\,\partial\phi, \partial^2\phi), \tag{134.15}$$

where $\phi_A = \delta q_A$ after diagonalizing the linear hydrodynamic modes, and $\lambda^i{}_{A,BC}$ is symmetric in B, C. The coefficient λ is determined by the equation of state and by the chosen hydrodynamic frame. For example, the convective part of the stress tensor contains $\pi^i\pi^j/(\varepsilon+p)$, where $\pi^i = T^{0i}$ is momentum density and $\varepsilon + p$ is the enthalpy density.

The quadratic term in (134.15) produces a loop of hydrodynamic modes in current-current correlators. The calculation is an effective-theory calculation with an ultraviolet cutoff $\Lambda_{\rm hyd}$ below the inverse microscopic length. Local analytic terms depend on this cutoff and renormalize local transport coefficients. The low-frequency nonanalytic part is independent of the detailed cutoff profile.

134.6 Time-Domain Tail From A Diffusive Pair

Consider one scalar diffusive mode ϕ with

$$\langle\phi(t,\mathbf{k})\phi(0,-\mathbf{k})\rangle = T\chi\,e^{-Dk^2 t}, \qquad t > 0.$$

Let the long-wavelength current contain the normal-ordered quadratic piece

$$J(t,\mathbf{x}) = \lambda :\phi(t,\mathbf{x})^2: .$$

At Gaussian order, Wick contraction gives

$$\begin{aligned}
C_{JJ}(t) &= \int d^dx \, \langle J(t,\mathbf{x})J(0,\mathbf{0})\rangle_{\text{conn}} \\
&= 2\lambda^2(T\chi)^2 \int \frac{d^dk}{(2\pi)^d}\, e^{-2Dk^2t} \\
&= 2\lambda^2(T\chi)^2\,(8\pi Dt)^{-d/2}, \qquad t>0.
\end{aligned} \tag{134.16}$$

This is the basic long-time tail. More general hydrodynamic systems give sums of terms of the same form, with diffusion constants replaced by sums of the damping rates of the two modes in the loop and with tensor projectors from momentum or sound modes. The exponent is fixed by the Gaussian integration over small loop momentum.

134.7 Frequency-Domain Nonanalyticity

The same tail appears in the retarded correlator as a nonanalytic low-frequency term. The scalar integral that controls a pair of diffusive modes is

$$I_d(z;D) = \int \frac{d^dk}{(2\pi)^d}\frac{1}{z+2Dk^2}, \qquad z = -\mathrm{i}\omega + 0^+. \tag{134.17}$$

The analytic terms are cutoff dependent. The nonanalytic part is obtained by subtracting local Taylor terms, or equivalently by dimensional regularization of the infrared integral:

$$I_d^{\text{nonan}}(z;D) = \frac{\Gamma(1-d/2)}{(4\pi)^{d/2}(2D)^{d/2}}\, z^{d/2-1}, \qquad d \notin 2\mathbb{Z}_{\geq 1}. \tag{134.18}$$

Infrared loop integral by Schwinger parameter. For $\operatorname{Re} z > 0$ and $D > 0$, the dimensionally regularized infrared integral

$$\int \frac{d^dk}{(2\pi)^d}\frac{1}{z+2Dk^2} \tag{134.19}$$

is

$$\frac{\Gamma(1-d/2)}{(4\pi)^{d/2}(2D)^{d/2}} z^{d/2-1}. \tag{134.20}$$

The retarded correlator is obtained by analytic continuation to

$$z = -\mathrm{i}\omega + 0^+, \tag{134.21}$$

with the principal logarithm, so that the result is analytic for $\operatorname{Im}\omega > 0$.

For $\operatorname{Re} z > 0$,

$$\frac{1}{z+2Dk^2} = \int_0^\infty ds\, e^{-s(z+2Dk^2)}. \tag{134.22}$$

The Gaussian integral in d dimensions is

$$\int \frac{d^d k}{(2\pi)^d} e^{-2Dsk^2} = (4\pi\, 2Ds)^{-d/2}. \tag{134.23}$$

Therefore

$$I_d(z; D) = \frac{1}{(4\pi)^{d/2}(2D)^{d/2}} \int_0^\infty ds\, s^{-d/2} e^{-zs}. \tag{134.24}$$

The remaining integral is the defining analytic continuation of the gamma function:

$$\int_0^\infty ds\, s^{\alpha-1} e^{-zs} = \Gamma(\alpha) z^{-\alpha}, \qquad \alpha = 1 - \frac{d}{2}. \tag{134.25}$$

Substituting $\alpha = 1 - d/2$ gives (134.20). Dimensional regularization drops power-divergent local terms and retains the nonanalytic infrared dependence. The retarded prescription (134.21) follows from the original denominator $z + 2Dk^2 = -\mathrm{i}\omega + 0^+ + 2Dk^2$, which is nonzero for $\mathrm{Im}\,\omega > 0$.

In even spatial dimension the pole of $\Gamma(1-d/2)$ is replaced, after local subtraction, by $z^{d/2-1}\log z$. The first cases are

d	$I_d^{\mathrm{nonan}}(z; D)$
1	$\dfrac{1}{2(2D)^{1/2}}\, z^{-1/2}$
2	$-\dfrac{1}{8\pi D}\, \log z$
3	$-\dfrac{1}{4\pi(2D)^{3/2}}\, z^{1/2}$

up to scheme-dependent additive constants in $d = 2$. The branch is fixed by $z = -\mathrm{i}\omega + 0^+$, so the retarded function is analytic in the upper half ω-plane.

For $d = 3$, an explicit cutoff computation displays the separation between local and nonlocal terms:

$$I_3^\Lambda(z; D) = \frac{1}{2\pi^2(2D)} \left[\Lambda - \left(\frac{z}{2D}\right)^{1/2} \arctan\!\left(\frac{\Lambda}{(z/2D)^{1/2}}\right)\right].$$

As $z/\Lambda^2 \to 0$,

$$I_3^\Lambda(z; D) = \frac{\Lambda}{4\pi^2 D} - \frac{z^{1/2}}{4\pi(2D)^{3/2}} + O(z/\Lambda).$$

The first term renormalizes a local transport coefficient. The square-root term is the long-time tail written in frequency space.

134.8 Transport Coefficients As Scale-Dependent Local Data

Let κ be a transport coefficient multiplying a local term in the hydrodynamic constitutive relation or Schwinger–Keldysh action. Hydrodynamic loops with momenta below Λ_{hyd} shift the coefficient:

$$\kappa_{\mathrm{phys}}(\omega) = \kappa(\Lambda_{\mathrm{hyd}}) + \Delta\kappa_{\mathrm{loc}}(\Lambda_{\mathrm{hyd}}) + \Delta\kappa_{\mathrm{nonan}}(\omega).$$

The sum of the first two terms is the local coefficient appropriate to the chosen hydrodynamic cutoff. The last term is fixed by hydrodynamic mode propagation and is a genuinely nonlocal-in-time low-frequency contribution, distinct from a finite local derivative coefficient. This is the finite-temperature analogue of ordinary effective-field theory renormalization: local coefficients are scheme dependent, while nonanalytic infrared dependence is physical within the regime of validity.

The order of limits is part of the definition. One first takes the thermodynamic limit of the KMS state, then probes frequencies and momenta inside the hydrodynamic scaling regime, and only then studies the small $\omega, \mathbf{k}$ asymptotics. Interchanging this order can erase the hydrodynamic pole, mix static and dynamic susceptibilities, or replace retarded functions by finite-volume quasiperiodic sums.

134.9 Stress-Tensor Noise

For a relativistic fluid in the local rest frame, write the stochastic spatial stress as

$$T^{ij} = p\,\delta^{ij} - \eta\left(\partial^i v^j + \partial^j v^i - \frac{2}{d}\delta^{ij}\partial_k v^k\right) - \zeta\,\delta^{ij}\partial_k v^k + \Xi^{ij} + O(v^2, \partial^2).$$

The white-noise covariance required by local KMS is

$$\langle \Xi^{ij}(x)\Xi^{kl}(x')\rangle = 2T\Big[\eta\left(\delta^{ik}\delta^{jl} + \delta^{il}\delta^{jk} - \frac{2}{d}\delta^{ij}\delta^{kl}\right) + \zeta\,\delta^{ij}\delta^{kl}\Big] \times \delta(t-t')\delta^{(d)}(\mathbf{x}-\mathbf{x}'). \tag{134.26}$$

For any real symmetric test tensor s_{ij}, decompose

$$s_{ij} = s^{\mathrm{T}}_{ij} + \frac{1}{d}\delta_{ij}s^k{}_k, \qquad \delta^{ij}s^{\mathrm{T}}_{ij} = 0.$$

Contracting the tensor in (134.26) with $s_{ij}s_{kl}$ gives

$$4T\eta\, s^{\mathrm{T}}_{ij}s^{\mathrm{T}}_{ij} + 2T\zeta\,(s^k{}_k)^2.$$

Thus positivity of the stochastic stress covariance is equivalent, at this order, to $\eta \geq 0$ and $\zeta \geq 0$. The same inequalities are obtained from nonnegative entropy production in deterministic hydrodynamics.

134.10 Momentum Tails

Momentum density $\pi^i = T^{0i}$ has static covariance

$$\langle \pi^i(\mathbf{k})\pi^j(-\mathbf{k})\rangle_{\mathrm{eq}} = T(\varepsilon + p)\delta^{ij}$$

in the local rest frame. Transverse momentum diffuses with kinematic viscosity

$$\nu = \frac{\eta}{\varepsilon + p}.$$

Because the stress tensor contains the convective term

$$T^{ij}_{\mathrm{conv}} = \frac{\pi^i\pi^j}{\varepsilon + p},$$

the shear-stress correlator contains a two-momentum hydrodynamic loop. Its late-time behavior is again of the form

$$\langle T^{ij}(t)T^{kl}(0)\rangle_{\text{conn}} \sim T^2\,\mathcal{P}^{ij,kl}\,(8\pi\nu t)^{-d/2},$$

with $\mathcal{P}^{ij,kl}$ determined by the transverse projectors and by angular averaging. Sound modes add oscillatory pieces with damping controlled by the sound attenuation constant. The existence of the tail therefore follows from the convective nonlinearity and the conserved momentum pole; the exact tensor coefficient requires the full hydrodynamic mode basis and frame convention.

134.11 Microscopic Theorem Boundary

A microscopic derivation from QFT must specify the KMS state, conserved currents, thermodynamic susceptibilities, the thermodynamic limit, clustering estimates, and the topology in which hydrodynamic correlators emerge from real-time QFT correlators. It must also identify the slow subspace of conserved densities, prove local equilibration in the scaling regime being used, and derive the Schwinger–Keldysh positivity and KMS constraints on the effective action. Hydrodynamic fluctuation theory then computes the consequences of these inputs.

The long-time-tail calculation is rigorous as an internal statement of the stochastic hydrodynamic effective theory with a stated cutoff and Gaussian leading measure. Promoting it to a theorem about a particular interacting continuum QFT requires a proof that the QFT has the hydrodynamic scaling limit assumed above.

Open Problem 134.1 (Hydrodynamic limit). Derive fluctuating hydrodynamics and long-time tails directly from an interacting QFT with a KMS state, including the hydrodynamic scaling limit, noise kernel, nonlinear couplings, transport-coefficient renormalization, and control of the order of thermodynamic, real-time, and low-frequency limits.

Chapter 135

QCD Phase Structure, Plasma, and Dense Matter

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- **$\hbar$.** 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter records the finite-temperature and finite-density phase questions of QCD in the same convention as the Yang–Mills chapters:

$$S_{\mathrm{YM}} = \frac{1}{4g^2}\int \mathrm{tr}(F_{\mu\nu}F^{\mu\nu}), \qquad \mathrm{tr}_{\square}(T^aT^b) = \delta^{ab}$$

for $SU(N_c)$ unless another invariant bilinear form is explicitly stated. The chapter is deliberately not a catalogue of phase-diagram lore. Each order parameter is tied to a symmetry, a limiting procedure, or a specified source. Each weak-coupling statement is separated from the nonperturbative questions that remain after the weak-coupling scale hierarchy has been identified.

135.1 Thermal QCD Data

Let N_f Dirac quarks transform in the fundamental representation of $SU(N_c)$. Put the Euclidean theory on

$$M_\beta = S^1_\beta \times \mathbb{R}^3, \qquad \beta = T^{-1},$$

with periodic gauge fields and antiperiodic quark fields around S^1_β. A baryon chemical potential μ_B couples to the conserved baryon number B, normalized so that a quark has baryon charge

$1/N_c$. Equivalently, every quark flavor has quark chemical potential

$$\mu_q = \frac{\mu_B}{N_c}.$$

At finite spatial volume V, a regulator a, and quark masses $m = (m_1, \ldots, m_{N_f})$, define

$$Z_{a,V}(T, \mu_B, m) = \mathrm{Tr}_{\mathcal{H}_{a,V}} \exp\{-\beta(H_{a,V} - \mu_B B_{a,V})\}, \tag{135.1}$$

when the Hamiltonian regulator is used. In a Euclidean lattice regulator the same object is represented by the corresponding gauge integral with the temporal links weighted by $e^{\pm a\mu_q}$ for forward and backward quark propagation. The pressure is the thermodynamic limit

$$p(T, \mu_B, m) = \lim_{a\to 0} \lim_{V\to\infty} \frac{T}{V} \log Z_{a,V}(T, \mu_B, m), \tag{135.2}$$

provided the limit exists along the chosen continuum trajectory.

Definition 135.1 (QCD phase specification)**.** A QCD phase specification at fixed N_c, N_f consists of:

1. the thermodynamic pressure $p(T, \mu_B, m)$ as a function on the domain where the continuum thermal state is defined;
2. a list of symmetries that are exact at the chosen masses and chemical potentials;
3. order parameters or source derivatives associated to those exact symmetries;
4. the limiting prescription used to detect spontaneous symmetry breaking;
5. a status label for each nonanalytic locus: theorem, lattice continuum-extrapolation claim, controlled weak-coupling claim, or conjectural continuation.

The word "phase" is used in this chapter only through such a specification.

Operational spine of the chapter. The rest of the chapter uses Definition 135.1 as a repeated test, not as introductory bookkeeping. First, finite-regulator analyticity and source curvatures identify what can and cannot become nonanalytic in the thermodynamic continuum limit. Second, center and chiral sections attach candidate order parameters to exact symmetries and to specified source limits. Third, the plasma and transport sections extract observable response data from pressure derivatives, spectral limits, and controlled hard-thermal-loop windows, while keeping those data separate from claims about real-time hydrodynamic poles. Fourth, the baryon-density sections explain the sign problem, imaginary-source diagnostics, and high-density effective theory before any dense phase is named. Finally, the CFL analysis proceeds from attractive Fermi-surface channels to gauge-invariant order diagnostics, screening response, collective fields, and anomaly matching. Thus a named region in the QCD phase diagram is accepted only after the corresponding pressure, symmetry, source, response, and limiting data have been displayed or explicitly marked as uncontrolled.

135.2 Finite-Regulator Analyticity and Thermodynamic Phases

A phase transition is not a property of a single finite lattice integral. At finite cutoff and finite volume the partition function is an analytic function of its sources away from its zeros. Nonanalyticity can only emerge from a limiting procedure: thermodynamic volume, continuum cutoff, chiral mass, or a source-selection limit. This elementary point is important because it prevents a phase diagram from being treated as a drawing whose curves exist before the limiting observables have been defined.

Definition 135.2 (Finite lattice thermal gauge setup)**.** Fix a finite Euclidean lattice

$$\Lambda = (N_\tau, N_s^3, a)$$

with compact gauge group G, Haar measure dU on each link, and antiperiodic temporal boundary condition for quarks. Let $\kappa = (\kappa_\alpha)$ denote finitely many gauge couplings multiplying bounded continuous class functions $S_\alpha(U)$, let $\zeta = e^{a\mu_q}$ be the quark fugacity, and let

$$M_\Lambda(U; m, \zeta)$$

be the finite fermion matrix in the chosen lattice discretization, with entries polynomial in the masses m_i and Laurent-polynomial in ζ. For an integer number of unrooted Dirac flavors, the finite-regulator partition function is

$$Z_\Lambda(\kappa, m, \zeta) = \int_{G^{E(\Lambda)}} \prod_\ell dU_\ell \, \exp\left[-\sum_\alpha \kappa_\alpha S_\alpha(U)\right] \prod_{i=1}^{N_f} \det M_{\Lambda,i}(U; m_i, \zeta), \tag{135.3}$$

where $E(\Lambda)$ is the finite link set. Rooted or otherwise non-polynomial fermion prescriptions are not included in this setup unless a separate branch and locality construction has been supplied.

Finite-regulator analyticity. For the setup of Definition 135.2, $Z_\Lambda(\kappa, m, \zeta)$ is entire in the gauge couplings and masses and Laurent-polynomial in the fugacity ζ. Consequently the finite pressure

$$p_\Lambda(\kappa, m, \zeta) = \frac{T}{V_\Lambda} \log Z_\Lambda(\kappa, m, \zeta)$$

is holomorphic on every simply connected parameter domain that does not meet the zero locus of Z_Λ, after a branch of the logarithm has been chosen. This finite-dimensional analytic fact becomes a statement about a thermodynamic or continuum pressure only after a separate compact-convergence input. The lattice has finitely many links, and $G^{E(\Lambda)}$ is compact. For each fixed gauge field U, the determinant factors are polynomials in the masses and Laurent polynomials in ζ. The exponential of the gauge action has an absolutely and uniformly convergent power series in κ on compact subsets of complex coupling space, because every $S_\alpha(U)$ is bounded on the compact integration domain. Termwise integration is justified by uniform convergence on compact parameter sets. Thus the integral defines an entire function in κ and m, with only finitely many positive and negative fugacity powers. Wherever this function is nonzero on a simply connected domain, a holomorphic logarithm exists, and the displayed finite pressure is holomorphic there.

Definition 135.3 (Thermodynamic phase transition and Lee–Yang obstruction)**.** Let x denote a real collection of thermal parameters, masses, and sources, and let $p_\Lambda(x)$ be the finite-regulator pressure along a specified sequence of lattices and continuum trajectories. A thermodynamic phase transition at x_0 means that the limiting pressure

$$p(x) = \lim_{\Lambda\to\infty} p_\Lambda(x)$$

exists in a real neighborhood of x_0 but is not real analytic at x_0, or that the limiting local Gibbs/KMS state is not unique after the source-selection prescription has been removed. The finite-regulator Lee–Yang locus is

$$\mathcal{Z}_\Lambda = \{z \in \mathcal{U}_\mathbb{C} \mid Z_\Lambda(z) = 0\}.$$

Remark 135.4 (Zero-free neighborhoods exclude pressure singularities). Let $\mathcal{U}_\mathbb{C}$ be a complex neighborhood of a real point x_0. Suppose that, for all sufficiently large Λ, Z_Λ has no zeros in $\mathcal{U}_\mathbb{C}$, that the logarithm branches are chosen compatibly, and that p_Λ converges uniformly on compact subsets of $\mathcal{U}_\mathbb{C}$. Then the limiting pressure p is holomorphic on $\mathcal{U}_\mathbb{C}$, hence real analytic near x_0. Therefore a pressure nonanalyticity at x_0 requires either Lee–Yang zeros approaching x_0 in every complex neighborhood, or failure of the stated uniform analytic convergence. By the finite-regulator analyticity discussion above, each p_Λ is holomorphic on $\mathcal{U}_\mathbb{C}$ after the stated choice of logarithm. The uniform compact convergence hypothesis then makes the limit holomorphic by the Weierstrass theorem for holomorphic functions. Restricting a holomorphic function to the real slice gives a real-analytic function. The contrapositive gives the final statement: if the real pressure has a nonanalyticity at x_0, the hypotheses just listed cannot all hold on any complex neighborhood of x_0. Thus either zeros approach x_0, or the finite-regulator analytic functions fail to converge in the compact-open holomorphic topology there.

Source curvature as an integrated connected correlator. Let h be a real source coupled at finite regulator to an integrated gauge-invariant local observable

$$X_\Lambda = \sum_{x\in\Lambda_s} a^3\, \mathcal{O}_x$$

through the Euclidean weight $\exp(hX_\Lambda)$. With

$$p_\Lambda(h) = \frac{T}{V_\Lambda}\log Z_\Lambda(h), \qquad \overline{\mathcal{O}}_\Lambda = V_\Lambda^{-1} X_\Lambda,$$

one has

$$\frac{\partial p_\Lambda}{\partial h} = T\langle \overline{\mathcal{O}}_\Lambda\rangle_h, \qquad \frac{\partial^2 p_\Lambda}{\partial h^2} = T\,V_\Lambda\left(\langle \overline{\mathcal{O}}_\Lambda^2\rangle_h - \langle \overline{\mathcal{O}}_\Lambda\rangle_h^2\right). \tag{135.4}$$

Thus a divergent susceptibility is a statement about the scaling of an integrated connected correlator in the thermodynamic limit.

At finite regulator X_Λ is an ordinary measurable function on the finite configuration space or finite lattice field space, and $Z_\Lambda(h)$ is a finite-dimensional integral with positive radius of analyticity in h around any real value for which the weight is integrable. Differentiating under the integral therefore gives

$$\partial_h \log Z_\Lambda(h) = \langle X_\Lambda\rangle_h.$$

For the second derivative, write $\langle Y\rangle_h = Z_\Lambda(h)^{-1}\int Y\, e^{hX_\Lambda} d\mu_\Lambda$. Then

$$\partial_h\langle Y\rangle_h = \langle YX_\Lambda\rangle_h - \langle Y\rangle_h\langle X_\Lambda\rangle_h.$$

Taking $Y = X_\Lambda$ yields the connected two-point formula

$$\partial_h^2 \log Z_\Lambda(h) = \langle X_\Lambda^2\rangle_h - \langle X_\Lambda\rangle_h^2.$$

Multiplying by T/V_Λ and writing $X_\Lambda = V_\Lambda \overline{\mathcal{O}}_\Lambda$ gives (135.4). Thus the possible thermodynamic singularity is not a pointwise singularity of $\mathcal{O}_x$; it is the volume growth of the integrated connected correlator after the infrared limit is taken.

For physical QCD with fundamental quarks of nonzero mass, the most familiar finite-temperature change near $T \sim \Lambda_{\mathrm{QCD}}$ is not attached to an exact fundamental center symmetry and not attached to an exact chiral symmetry. It is therefore a crossover unless a nonanalyticity is established in the thermodynamic continuum theory. Pure Yang–Mills theory and chiral limits have sharper order parameters, and those are treated first.

135.3 Center Deconfinement in Pure Yang–Mills

Let $G = SU(N_c)$ and first remove all dynamical fundamental matter. The thermal Wilson line at spatial point $\mathbf{x}$ is

$$\mathcal{P}(\mathbf{x}) = \mathcal{P}_\tau \exp\left(\mathrm{i}\int_0^\beta A_0(\tau,\mathbf{x})\,d\tau\right). \tag{135.5}$$

For an irreducible representation R define the normalized Polyakov loop

$$P_R(\mathbf{x}) = \frac{1}{d_R}\,\mathrm{tr}_R\,\mathcal{P}(\mathbf{x}). \tag{135.6}$$

If R has N-ality k_R, then the thermal center transformation by $z \in Z(SU(N_c))$ sends

$$P_R(\mathbf{x}) \longmapsto z^{k_R} P_R(\mathbf{x}).$$

The lattice construction of the transformation and the static-source interpretation were given in Chapter 46; here we use them as the phase-ordering language of the thermal theory.

Definition 135.5 (Center-order deconfinement)**.** In pure $SU(N_c)$ Yang–Mills, choose a small source h that selects a center sector and set

$$\overline{P}_\square = V^{-1}\int_{\mathbb{R}^3} P_\square(\mathbf{x})\,d^3x$$

in a finite box before the infinite-volume limit. The center order parameter is

$$\ell(T) = \lim_{h\downarrow 0}\lim_{V\to\infty}\left\langle \overline{P}_\square \right\rangle_{T,h,V}. \tag{135.7}$$

The thermal state is center symmetric when $\ell(T) = 0$ and center broken when $\ell(T) \neq 0$. A center deconfinement transition is a nonanalytic change of the infinite-volume free energy across which this symmetry realization changes.

Remark 135.6 (Center symmetry forces the finite-volume one-point loop). At finite spatial volume and zero center-breaking source in pure $SU(N_c)$ Yang–Mills,

$$\langle P_R(\mathbf{x})\rangle = 0$$

for every representation R whose N-ality is nonzero.

The finite-volume regulated measure and action are invariant under the thermal center transformation. Averaging the expectation value over the finite group $Z(SU(N_c))$ gives

$$\langle P_R \rangle = \frac{1}{N_c} \sum_{j=0}^{N_c-1} e^{2\pi i j k_R / N_c} \langle P_R \rangle.$$

If $k_R \not\equiv 0 \pmod{N_c}$, the finite geometric sum vanishes. Hence $\langle P_R \rangle = 0$. A nonzero Polyakov-loop order parameter is therefore necessarily a spontaneous-symmetry-breaking limit, not a finite-volume one-point function.

After multiplicative line renormalization, the one-point function has the static-source interpretation

$$\langle P_R \rangle_{\text{ren}} = \exp\{-\beta(F_R - F_0)\}. \tag{135.8}$$

Thus $\ell = 0$ is equivalent to an infinite free-energy cost for an isolated fundamental external charge, in the center-symmetric limiting state. This statement is logically distinct from the zero-temperature Wilson-loop area law. The latter diagnoses the large-distance static potential of a source-antisource pair; the former diagnoses the realization of thermal center symmetry and the free energy of one wrapped external line.

Remark 135.7 (Dynamical fundamental quarks). Fundamental quarks explicitly break the fundamental thermal center symmetry. Consequently $P_{\square}$ remains a useful renormalized static-source observable, but not a strict order parameter. In physical QCD the rapid change of the Polyakov loop is evidence for liberation of color degrees of freedom in a crossover regime. Existence of an exact phase transition requires a separate thermodynamic-limit statement.

135.3.1 Polyakov-Loop Effective Measures at Finite Regulator

A Polyakov-loop effective theory is not, by definition, a new continuum QCD. At finite regulator it is a marginal measure obtained from the thermal lattice gauge theory by retaining only temporal Wilson lines. Its usefulness depends on whether the resulting nonlocal measure can be approximated by a controlled local or rapidly decaying interaction.

Definition 135.8 (Exact finite-regulator Polyakov-loop effective measure)**.** Fix a finite thermal lattice $\Lambda = N_\tau \times \Lambda_s$ with spacing a, compact gauge group $SU(N_c)$, and thermal circle length $\beta = aN_\tau$. For a gauge configuration U, define the temporal Wilson line at a spatial site $\mathbf{x}$ by

$$\mathcal{P}_{\mathbf{x}}(U) = \prod_{\tau=0}^{N_\tau-1} U_0(\tau, \mathbf{x}),$$

with the product ordered along the Euclidean time circle. For every bounded class function F of the collection $\{\mathcal{P}_{\mathbf{x}}\}$, define

$$\int F(P)\, d\nu_\Lambda(P) = \frac{1}{Z_\Lambda} \int d\mu_\Lambda(U)\, F(\{\mathcal{P}_{\mathbf{x}}(U)\})\, e^{-S_g[U]} \prod_f \det D_f[U].$$

When the regulated weight is positive, this is a probability measure on $SU(N_c)^{\Lambda_s}$, restricted to class functions at each site. At real chemical potential, or in any other situation where the determinant is complex, the same formula defines a normalized complex linear functional rather than a probability measure. In either case it is the exact finite-regulator Polyakov-loop effective object. If it is absolutely continuous with respect to the product Haar measure $dP = \prod_{\mathbf{x}} dP_{\mathbf{x}}$, one may write

$$d\nu_\Lambda(P) = Z_{\text{eff}}^{-1} e^{-S_{\text{eff},\Lambda}(P)} dP,$$

where $S_{\text{eff},\Lambda}$ is defined up to an additive constant and up to changes on Haar-null sets.

Character coordinates and center charge. Assume $d\nu_\Lambda$ has an L^2 density with respect to product Haar measure. Then the density admits an L^2 character expansion

$$\frac{d\nu_\Lambda}{dP} = \sum_{\{\lambda_{\mathbf{x}}\}} c_{\{\lambda_{\mathbf{x}}\}} \prod_{\mathbf{x}\in\Lambda_s} \chi_{\lambda_{\mathbf{x}}}(P_{\mathbf{x}}),$$

where only finitely many sites carry nontrivial representations in each basis vector. In pure Yang–Mills, the coefficient $c_{\{\lambda_{\mathbf{x}}\}}$ vanishes unless the total N-ality

$$\sum_{\mathbf{x}} k_{\lambda_{\mathbf{x}}}$$

is 0 modulo N_c. With dynamical fundamental quarks this selection rule is explicitly broken by terms of nonzero total N-ality.

The Peter–Weyl theorem gives an orthonormal basis of class functions on $SU(N_c)$ consisting of irreducible characters. Tensoring these bases over the finite set Λ_s gives the displayed expansion in $L^2(SU(N_c)^{\Lambda_s})$.

For pure Yang–Mills the finite-regulator measure is invariant under the thermal center transformation

$$P_{\mathbf{x}} \mapsto zP_{\mathbf{x}}, \qquad z \in Z(SU(N_c)),$$

applied simultaneously at all spatial sites. Since $\chi_\lambda(zP) = z^{k_\lambda}\chi_\lambda(P)$, invariance of the density forces

$$c_{\{\lambda_{\mathbf{x}}\}} = z^{\sum_{\mathbf{x}} k_{\lambda_{\mathbf{x}}}} c_{\{\lambda_{\mathbf{x}}\}} \quad \text{for all } z \in Z(SU(N_c)).$$

This is possible only when the total N-ality vanishes modulo N_c, or when the coefficient is zero. Fundamental quark determinants contain closed fermion paths winding once around the thermal circle; such paths carry fundamental N-ality and therefore break the selection rule.

Controlled Approximation 135.9 (Local Polyakov-loop action)**.** A local Polyakov-loop action is a truncation of the exact effective measure to finitely many character monomials, usually organized by spatial range, representation size, winding number, and powers of a strong-coupling or hopping parameter. The truncation is a controlled approximation only in a domain where the omitted character coefficients are bounded by a convergent cluster or hopping expansion, or by a separately stated numerical error estimate.

Leading strong-coupling tube in pure Yang–Mills. Let the pure-gauge lattice action have a plaquette character expansion whose fundamental coefficient is $u_\Box$, normalized so that $u_\Box = 0$ at zero plaquette coupling. In a finite lattice strong-coupling expansion, the leading center-invariant nearest-neighbor interaction between Polyakov loops has the form

$$S^{(1)}_{\text{eff},\Lambda}(P) = -J_1 \sum_{\langle\mathbf{xy}\rangle} \left[\chi_\Box(P_{\mathbf{x}})\chi_{\overline{\Box}}(P_{\mathbf{y}}) + \chi_{\overline{\Box}}(P_{\mathbf{x}})\chi_\Box(P_{\mathbf{y}})\right],$$

with

$$J_1 = u_{\Box}^{N_\tau} + O(u_{\Box}^{N_\tau+2})$$

in the same expansion. The displayed term is center neutral and therefore compatible with the character-coordinate center-selection rule above.

Expand each plaquette Boltzmann factor in irreducible characters. A nonzero contribution to the Polyakov-loop marginal measure must leave no unpaired spatial link after Haar integration. For two neighboring spatial sites $\mathbf{x}, \mathbf{y}$, the minimal surface that connects their temporal Wilson lines is a tube of N_τ temporal-spatial plaquettes wrapping once around the thermal circle. Placing the fundamental character on each plaquette of this tube and integrating the shared spatial links contracts the representation matrices into

$$\chi_{\Box}(P_{\mathbf{x}})\chi_{\overline{\Box}}(P_{\mathbf{y}})$$

or its complex conjugate. The weight of the minimal tube is $u_{\Box}^{N_\tau}$. Corrections either decorate the tube or use larger representations and therefore carry higher powers of the plaquette character coefficients; in the fundamental channel the first plaquette decorations occur at the indicated higher order. The product has total N-ality $1-1=0$, so it is invariant under the simultaneous center transformation.

Leading heavy-quark center-breaking term. For Wilson fermions with hopping parameter κ and quark chemical potential μ_q, the leading temporal-winding term in the hopping expansion of N_f degenerate fundamental Dirac quarks is

$$S^{\mathrm{hq}}_{\mathrm{eff},\Lambda}(P) = -h\sum_{\mathbf{x}}\left[e^{\beta\mu_q}\chi_{\Box}(P_{\mathbf{x}}) + e^{-\beta\mu_q}\chi_{\overline{\Box}}(P_{\mathbf{x}})\right] + \cdots ,$$

where, in the standard Wilson hopping normalization,

$$h = 2N_f(2\kappa)^{N_\tau}.$$

The ellipsis denotes longer closed fermion paths, multiple windings, spatial hops, and higher powers of κ. The displayed term has nonzero N-ality and is the finite-regulator origin of explicit center breaking by dynamical fundamental quarks.

Write the Wilson Dirac operator as $D = 1 - H$, where H is the hopping matrix. At finite lattice volume,

$$\log\det D = \mathrm{Tr}\log(1-H) = -\sum_{n\geq 1}\frac{1}{n}\,\mathrm{Tr}\,H^n$$

as a formal hopping expansion. Each trace is a sum over closed lattice paths. A path that winds once forward around the Euclidean time circle at fixed $\mathbf{x}$ has N_τ forward temporal hops and gauge factor $\mathrm{tr}_{\Box} P_{\mathbf{x}}$. The spin projectors along a straight temporal Wilson loop leave two spin states, giving the factor 2; the N_f degenerate flavors multiply the result by N_f. The antiperiodic fermion boundary condition supplies an additional minus sign for a path with odd thermal winding. This sign cancels the minus sign in the logarithmic expansion, so the leading forward-winding contribution to $\log\det D$ is

$$2N_f(2\kappa)^{N_\tau}e^{\beta\mu_q}\chi_{\Box}(P_{\mathbf{x}}).$$

Here $\beta = aN_\tau$, so the N_τ factors of $e^{a\mu_q}$ combine to $e^{\beta\mu_q}$. The backward winding gives the conjugate term with $e^{-\beta\mu_q}$ and $\chi_{\overline{\square}}$. Since $e^{-S_{\rm eff}}$ contains $\det D = \exp(\log\det D)$, the same positive term in $\log\det D$ appears with a minus sign in $S_{\rm eff}$, as displayed.

Under $P_{\mathbf{x}} \mapsto zP_{\mathbf{x}}$, the first term is multiplied by z and the second by z^{-1}. Hence the heavy-quark determinant is a center-breaking source unless the coefficient h is set to zero.

135.4 Controlled High-Temperature Holonomy Potential

The Polyakov loop becomes a calculable order-coordinate in a regime where a constant temporal holonomy is a valid background-field variable. Choose a spatially constant commuting background on $S^1_\beta \times \mathbb{R}^3$ and write its fundamental holonomy as

$$P = \mathrm{diag}\left(e^{\mathrm{i}\theta_1}, \ldots, e^{\mathrm{i}\theta_{N_c}}\right), \qquad \sum_{j=1}^{N_c} \theta_j \equiv 0 \pmod{2\pi}. \tag{135.9}$$

The variables θ_j are defined modulo permutations and common shifts compatible with $\det P = 1$. A center transformation sends $P \mapsto zP$, $z^{N_c} = 1$.

Controlled Approximation 135.10 (One-loop holonomy regime)**.** The one-loop holonomy potential is the leading weak-coupling thermal effective potential for the zero Matsubara mode of A_0, computed in a background whose spatial gradients and noncommuting components are set to zero. Its expansion parameter is the running gauge coupling at scale T, and its infrared completion still requires the electric and magnetic static sectors discussed in Section 135.7 below.

One-loop Polyakov-holonomy potential. For pure $SU(N_c)$ Yang–Mills, the one-loop gluonic free-energy density as a function of the holonomy P is

$$f_g(P) = -\frac{2}{\pi^2\beta^4}\sum_{n=1}^{\infty}\frac{1}{n^4}\,\mathrm{tr}_{\rm adj}(P^n) = -\frac{2}{\pi^2\beta^4}\sum_{n=1}^{\infty}\frac{|\,\mathrm{tr}_\square P^n|^2 - 1}{n^4}. \tag{135.10}$$

For N_f massless Dirac fundamental quarks at $\mu_q = 0$, the one-loop fermion contribution is

$$f_q(P) = \frac{2N_f}{\pi^2\beta^4}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^4}\left(\mathrm{tr}_\square P^n + \mathrm{tr}_\square P^{-n}\right). \tag{135.11}$$

Consider first one bosonic oscillator with thermal phase φ, meaning that its Matsubara frequencies are shifted by the holonomy eigenvalue $e^{\mathrm{i}\varphi}$. Its thermal free-energy density is

$$T\int\frac{d^3p}{(2\pi)^3}\log\left(1 - e^{-\beta|\mathbf{p}|+\mathrm{i}\varphi}\right).$$

Expanding the logarithm and integrating term by term gives

$$-T\sum_{n\geq 1}\frac{e^{\mathrm{i}n\varphi}}{n}\int\frac{d^3p}{(2\pi)^3}e^{-n\beta|\mathbf{p}|} = -\frac{1}{\pi^2\beta^4}\sum_{n\geq 1}\frac{e^{\mathrm{i}n\varphi}}{n^4}, \tag{135.12}$$

because

$$\int \frac{d^3p}{(2\pi)^3} e^{-n\beta|\mathbf{p}|} = \frac{1}{2\pi^2}\int_0^\infty p^2 e^{-n\beta p}\,dp = \frac{1}{\pi^2 n^3\beta^3}. \tag{135.13}$$

In background gauge, ghosts and unphysical vector polarizations cancel so that two physical bosonic polarizations remain for each adjoint weight. Summing (135.12) over adjoint weights gives the first expression in (135.10). The identity

$$\operatorname{tr}_{\mathrm{adj}}(P^n) = \operatorname{tr}_{\square}(P^n)\operatorname{tr}_{\overline{\square}}(P^n) - 1 = |\operatorname{tr}_{\square} P^n|^2 - 1$$

uses $\square \otimes \overline{\square} = \mathbf{1} \oplus \mathrm{adj}$.

For a Dirac fundamental quark at zero chemical potential the two spin polarizations and the quark-antiquark pair give

$$-2T\int \frac{d^3p}{(2\pi)^3}\left[\log\left(1+e^{-\beta|\mathbf{p}|+\mathrm{i}\theta_j}\right) + \log\left(1+e^{-\beta|\mathbf{p}|-\mathrm{i}\theta_j}\right)\right]$$

for each color eigenphase θ_j. The plus sign inside the logarithm is the antiperiodic thermal boundary condition. Expanding $\log(1+x) = \sum_{n\geq 1}(-1)^{n+1}x^n/n$, using (135.13), and summing over colors and flavors gives (135.11).

Perturbative center-broken minima in pure Yang–Mills. For pure $SU(N_c)$ Yang–Mills, the one-loop potential (135.10) is minimized exactly at center holonomies

$$P = z\,\mathbf{1}_{N_c}, \qquad z^{N_c} = 1. \tag{135.14}$$

At these minima

$$f_g(z\mathbf{1}) = -\frac{\pi^2 T^4}{45}(N_c^2 - 1), \tag{135.15}$$

which is the free gluon free-energy density. For every unitary $N_c \times N_c$ matrix,

$$|\operatorname{tr}_{\square} P^n| \leq N_c.$$

Hence $\operatorname{tr}_{\mathrm{adj}}(P^n) \leq N_c^2 - 1$ for every n. All coefficients in (135.10) are negative, so the minimum is obtained by maximizing each $\operatorname{tr}_{\mathrm{adj}}(P^n)$. The $n = 1$ term already forces $|\operatorname{tr}_{\square} P| = N_c$, which for a unitary matrix means all eigenvalues are equal. The determinant-one condition then gives $P = z\mathbf{1}_{N_c}$ with $z^{N_c} = 1$. Substitution in (135.10) gives

$$f_g(z\mathbf{1}) = -\frac{2}{\pi^2\beta^4}(N_c^2-1)\sum_{n\geq 1}\frac{1}{n^4} = -\frac{2}{\pi^2\beta^4}(N_c^2-1)\frac{\pi^4}{90},$$

which is (135.15).

Example 135.11 (Uniform center-symmetric holonomy)**.** Let P_{cs} have eigenvalues uniformly spaced around the unit circle, with an overall phase chosen so that $P_{\mathrm{cs}} \in SU(N_c)$. Then

$$\operatorname{tr}_{\square} P_{\mathrm{cs}}^n = 0 \quad (N_c \nmid n), \qquad |\operatorname{tr}_{\square} P_{\mathrm{cs}}^n|^2 = N_c^2 \quad (N_c \mid n).$$

Therefore

$$f_g(P_{\mathrm{cs}}) = \frac{\pi^2 T^4}{45}\left(1 - \frac{1}{N_c^2}\right), \qquad f_g(P_{\mathrm{cs}}) - f_g(\mathbf{1}) = \frac{\pi^2 T^4}{45}\left(N_c^2 - \frac{1}{N_c^2}\right). \tag{135.16}$$

The perturbative high-temperature gluon determinant therefore energetically selects a center sector rather than the uniformly distributed holonomy.

Remark 135.12 (Fundamental quarks as a center source). The gluon potential depends on P through adjoint traces and is invariant under $P \mapsto zP$. The quark potential (135.11) contains fundamental traces:

$$\mathrm{tr}_{\square}(zP)^n = z^n \, \mathrm{tr}_{\square} \, P^n.$$

Thus dynamical fundamental quarks supply an explicit center-breaking source. At $P = \mathbf{1}$, (135.11) gives

$$f_q(\mathbf{1}) = -\frac{7\pi^2 T^4}{180} N_c N_f, \tag{135.17}$$

the negative of the free massless Dirac-quark pressure in the free-plasma calculation below.

135.5 Chiral Symmetry and the Dirac Spectrum

Now set $\mu_B = 0$ and take N_f Dirac quarks with a common mass m. In the chiral limit $m = 0$, and ignoring the anomalous axial $U(1)$, the classical flavor symmetry is

$$SU(N_f)_L \times SU(N_f)_R \times U(1)_B.$$

Let V_3 be the spatial volume and let

$$\mathcal{V}_4 = \beta V_3$$

be the Euclidean thermal volume. For degenerate quark mass, the pressure derivative is the flavor-summed scalar source response. We use the positive per-flavor condensate convention

$$\Sigma_m(T) = \frac{1}{N_f} \frac{\partial p(T, m)}{\partial m}. \tag{135.18}$$

Equivalently, after integrating the fermions in a fixed gauge background, $\Sigma_m(T)$ is the thermal average of $\mathcal{V}_4^{-1} \, \mathrm{Tr}(D_E + m)^{-1}$ for the one-flavor Euclidean Dirac operator D_E. With the Grassmann-ordering convention in which the local scalar density is $\bar{q}q = \sum_{i=1}^{N_f} \bar{q}_i q_i$, its flavor-summed expectation is

$$\langle \bar{q}q \rangle_{\mathrm{sum},T,m} = -N_f \Sigma_m(T).$$

Thus $\Sigma_m \geq 0$ in a phase with the usual sign of the scalar condensate. The chiral order parameter is the limit $\Sigma(T) = \lim_{m \downarrow 0} \lim_{V_3 \to \infty} \Sigma_m(T)$, when this limit exists. A nonzero condensate in the chiral limit transforms as $(\overline{\mathbf{N}_f}, \mathbf{N}_f) \oplus (\mathbf{N}_f, \overline{\mathbf{N}_f})$ and breaks

$$SU(N_f)_L \times SU(N_f)_R \longrightarrow SU(N_f)_V.$$

Definition 135.13 (Chiral order parameter)**.** The chiral condensate used as an order parameter is

$$\Sigma(T) = \lim_{m \downarrow 0} \lim_{V_3 \to \infty} \frac{1}{\mathcal{V}_4} \left\langle \mathrm{Tr}(D_E + m)^{-1} \right\rangle_{V_3,T,m}, \tag{135.19}$$

where D_E is the one-flavor massless Euclidean Dirac operator in a gauge background at $\mu_B = 0$. The infinite-volume limit precedes the chiral limit.

Banks–Casher relation under a spectral-density hypothesis. The nontrivial input is the existence of a thermodynamic Dirac spectral density continuous at the origin. Assume that the positive Dirac eigenvalue density

$$\rho_{\mathcal{V}_4}(\lambda) = \frac{1}{\mathcal{V}_4} \left\langle \sum_{\lambda_n > 0} \delta(\lambda - \lambda_n) \right\rangle$$

has a thermodynamic limit $\rho(\lambda)$ that is continuous at $\lambda = 0$, and that zero-mode contributions have zero density in the same limit. Then

$$\Sigma(T) = \pi\rho(0) \tag{135.20}$$

with the normalization in (135.19). If $\rho(0) = 0$, this particular condensate vanishes.

At $\mu_B = 0$, D_E is anti-Hermitian in the usual positive Euclidean inner product and anticommutes with γ_5 in the massless theory. Nonzero eigenvalues occur in pairs $\pm i\lambda_n$, $\lambda_n > 0$. For fixed positive mass,

$$\frac{1}{\mathcal{V}_4} \operatorname{Tr}(D_E + m)^{-1} = \frac{N_0}{\mathcal{V}_4 m} + \frac{1}{\mathcal{V}_4} \sum_{\lambda_n > 0} \left(\frac{1}{m + i\lambda_n} + \frac{1}{m - i\lambda_n} \right),$$

where N_0 is the number of zero modes. The nonzero pair contribution is

$$\frac{2m}{\mathcal{V}_4} \sum_{\lambda_n > 0} \frac{1}{\lambda_n^2 + m^2}.$$

By the zero-density hypothesis the first term drops out after $V_3 \to \infty$. The condensate definition therefore gives

$$\Sigma(T) = \lim_{m \downarrow 0} \int_0^\infty \frac{2m\,\rho(\lambda)}{\lambda^2 + m^2}\, d\lambda.$$

The kernels

$$K_m(\lambda) = \frac{2m}{\lambda^2 + m^2}, \qquad \lambda \geq 0,$$

form an approximate identity on the half-line with total mass π:

$$\int_0^\infty K_m(\lambda)\, d\lambda = \pi.$$

Continuity of ρ at the origin gives the limit $\pi\rho(0)$, and hence (135.20). If instead one defines the spectral density on all of $\mathbb{R}$, counting both positive and negative eigenvalues, the same formula holds with that two-sided density evaluated at zero.

Remark 135.14 (Order of limits)*.* The relation is a statement about the thermodynamic spectral density near zero. Setting $m = 0$ at finite volume first gives no condensate from paired nonzero eigenvalues. The density of eigenvalues at spacing $O(\mathcal{V}_4^{-1})$ near the origin is precisely the infinite-volume order parameter that can survive the subsequent chiral limit.

135.5.1 Axial Ward Identity and Thermal GMOR Logic

The condensate is tied to integrated pseudoscalar correlations by an axial Ward identity. This is the cleanest finite-temperature form of the Gell-Mann–Oakes–Renner logic, because at $T > 0$

Lorentz invariance is absent and one must specify which pion pole, screening pole, or spectral residue is being used.

Let τ^a, $a = 1, \ldots, N_f^2 - 1$, be Hermitian generators of $\mathfrak{su}(N_f)$ normalized by

$$\mathrm{tr}_f(\tau^a \tau^b) = \delta^{ab}. \tag{135.21}$$

Define the nonsinglet Euclidean axial current and pseudoscalar density by

$$A_\mu^a = \bar{q}\gamma_\mu\gamma_5\tau^a q, \qquad P^a = \bar{q}\,\mathrm{i}\gamma_5\tau^a q. \tag{135.22}$$

The factor of i in P^a is part of the Euclidean source convention: a real pseudoscalar source p^a appears in the mass matrix as $m\mathbf{1} + \mathrm{i}\gamma_5 p^a\tau^a$. With this convention the Euclidean pseudoscalar susceptibility is

$$\chi_\pi^{ab}(T, m) = -\int_0^\beta d\tau \int_{\mathbb{R}^3} d^3x\, \langle P^a(\tau, \mathbf{x}) P^b(0)\rangle_{c,T,m}, \tag{135.23}$$

with the finite-volume definition obtained by replacing $\mathbb{R}^3$ by the spatial torus and taking the thermodynamic limit after the integral.

Lemma 135.15 (Integrated nonsinglet axial Ward identity)**.** *Assume a regulator and renormalization prescription preserving the nonsinglet vector flavor symmetry and the nonsinglet axial Ward identity up to the explicit mass term; there is no nonsinglet axial anomaly. Then*

$$2m\,\chi_\pi^{ab}(T, m) = -\left\langle \bar{q}\{\tau^a, \tau^b\}q \right\rangle_{T,m}. \tag{135.24}$$

In a flavor-symmetric thermal state this becomes

$$m\,\chi_\pi^{ab}(T, m) = \delta^{ab}\Sigma_m(T). \tag{135.25}$$

Proof. The proof is a finite-regulator Ward-identity argument, followed by the thermodynamic limit in the order specified in the definition of the susceptibility. Perform the local nonsinglet axial change of variables

$$\delta q = \mathrm{i}\alpha^a(x)\tau^a\gamma_5 q, \qquad \delta\bar{q} = \mathrm{i}\alpha^a(x)\bar{q}\gamma_5\tau^a.$$

The regulator hypothesis says that the fermion measure has no nonsinglet Jacobian anomaly. The variation of the mass term is fixed by the Euclidean source convention in (135.22):

$$\delta_\alpha\big(m\bar{q}q\big) = 2m\,\alpha^a\,\bar{q}\mathrm{i}\gamma_5\tau^a q = 2m\,\alpha^a P^a.$$

The kinetic term gives the divergence of the current A_μ^a. With the active-variation convention used here, differentiating the change-of-variables identity with respect to $\alpha^a(x)$ and applying it to the insertion $P^b(0)$ gives the distributional identity

$$\partial_\mu\langle A_\mu^a(x)P^b(0)\rangle_{T,m} + 2m\langle P^a(x)P^b(0)\rangle_{T,m} + \delta_\beta^{(4)}(x)\langle\delta^a P^b(0)\rangle_{T,m} = 0. \tag{135.26}$$

Here $\delta_\beta^{(4)}$ is the periodic delta distribution on the thermal spacetime torus before the thermodynamic limit, and $\delta^a P^b$ denotes the variation of the inserted operator, not a second source variation. The contact term is

$$\delta^a P^b(0) = \mathrm{i}\,\bar{q}\gamma_5\tau^a\,\mathrm{i}\gamma_5\tau^b q + \bar{q}\,\mathrm{i}\gamma_5\tau^b\,\mathrm{i}\tau^a\gamma_5 q = -\bar{q}\{\tau^a, \tau^b\}q(0).$$

Integrating (135.26) over the thermal spacetime torus removes the divergence term by periodicity of the bosonic current. Vector flavor invariance gives $\langle P^a \rangle_{T,m} = 0$ for nonsinglet a, so the connected and ordinary two-point functions coincide in this channel. Using the susceptibility definition (135.23), one obtains

$$2m\, \chi_\pi^{ab}(T,m) = \langle \delta^a P^b \rangle_{T,m} = -\left\langle \bar{q}\{\tau^a, \tau^b\} q \right\rangle_{T,m},$$

which is (135.24). No statement about a pion pole has entered; the pole-saturation input is a separate infrared hypothesis.

In a flavor-symmetric state

$$\left\langle \bar{q}\{\tau^a, \tau^b\} q \right\rangle_{T,m} = \frac{2}{N_f} \delta^{ab} \langle \bar{q} q \rangle_{\mathrm{sum},T,m} = -2\delta^{ab} \Sigma_m(T),$$

where (135.21) fixes the singlet part of the anticommutator. Substitution gives (135.25). □

GMOR as a pole-saturation consequence. The integrated Ward identity becomes the finite-temperature GMOR relation only after one supplies a spectral hypothesis about the small-mass broken phase. Suppose, in addition to the hypotheses of Lemma 135.15, that for small $m > 0$ the zero-spatial-momentum pseudoscalar susceptibility in a broken phase is saturated at leading order by an isolated pion pole of mass $M_\pi(T,m)$. Let $G_\pi(T,m)$ and $f_{t,\delta}(T,m)$ be defined in the same flavor normalization (135.21) by the pole matrix elements

$$\langle \Omega_T | P^a(0) | \pi^b \rangle = \delta^{ab} G_\pi, \qquad \langle \Omega_T | A_0^a(0) | \pi^b \rangle = \delta^{ab} f_{t,\delta} M_\pi,$$

or by the corresponding KMS spectral residues when a thermal Hilbert-space representative is used. If the pole obeys the axial Ward relation

$$2m\, G_\pi = f_{t,\delta} M_\pi^2 \tag{135.27}$$

and the non-pole part of χ_π^{aa} is $O(1)$ as $m \downarrow 0$, then pole saturation gives

$$\chi_\pi^{ab}(T,m) = \delta^{ab} \frac{G_\pi(T,m)^2}{M_\pi(T,m)^2} + O(1).$$

The Ward identity (135.25) gives the same susceptibility as

$$\chi_\pi^{ab}(T,m) = \delta^{ab} \frac{\Sigma(T)}{m} + o(m^{-1})$$

when $\Sigma_m(T) \to \Sigma(T)$. Combining these two leading terms with (135.27),

$$\frac{G_\pi^2}{M_\pi^2} = \frac{f_{t,\delta}^2 M_\pi^2}{4m^2},$$

and equating the coefficients of $1/m$ gives

$$f_{t,\delta}(T,m)^2 M_\pi(T,m)^2 = 4m\Sigma(T) + o(m). \tag{135.28}$$

If instead one uses generators t^a normalized by $\mathrm{tr}_f(t^a t^b) = \frac{1}{2}\delta^{ab}$, the decay constant is smaller by $\sqrt{2}$ and the same statement is

$$f_{t,1/2}(T,m)^2 M_\pi(T,m)^2 = 2m\Sigma(T) + o(m). \tag{135.29}$$

Here rescaling the generators from $\mathrm{tr}_f(\tau^a \tau^b) = \delta^{ab}$ to $\mathrm{tr}_f(t^a t^b) = \frac{1}{2}\delta^{ab}$ rescales both the current and the pseudoscalar density by $1/\sqrt{2}$, hence $f_{t,1/2} = f_{t,\delta}/\sqrt{2}$, giving (135.29).

135.5.2 Low-Temperature Chiral Effective Theory

The Ward identity identifies the source derivative of the pressure with the integrated pion channel. In the low-temperature phase this identity can be evaluated in a controlled effective theory. The control assumptions are part of the statement: the spatial thermodynamic limit has been taken, the temperature is small compared with the first non-Goldstone mass scale, and the derivative expansion is organized at momenta $p \ll 4\pi F$.

Definition 135.16 (Leading chiral effective theory)**.** For N_f degenerate light quarks, the leading Euclidean chiral effective theory consists of a field $U : \mathbb{R}^3 \times S^1_\beta \to SU(N_f)$, a constant $F > 0$, and a constant $B > 0$, with leading action

$$S^{(2)}_\chi = \int_0^\beta d\tau \int d^3x \left[\frac{F^2}{4} \operatorname{tr}_f(\partial_\mu U^\dagger \partial_\mu U) - \frac{F^2 B}{2} \operatorname{tr}_f\big(MU^\dagger + UM^\dagger\big) \right]. \tag{135.30}$$

Here $M = m\mathbf{1}_{N_f}$ for the degenerate-mass discussion, and tr_f is the ordinary fundamental flavor trace. We parameterize the pion fields by

$$U = \exp\left(\frac{\mathrm{i}\sqrt{2}}{F} \pi^a \tau^a \right), \qquad \operatorname{tr}_f(\tau^a \tau^b) = \delta^{ab}. \tag{135.31}$$

With this convention F is the decay constant in the half-trace flavor normalization; the trace-delta decay constant used in the pole-saturation discussion above is $f_{t,\delta} = \sqrt{2}F + O(m, T^2)$.

Remark 135.17 (Tree-level source normalization)*.* The action (135.30) gives

$$\Sigma = F^2 B, \qquad M_\pi^2 = 2Bm \tag{135.32}$$

at tree level, where Σ is the positive per-flavor condensate in (135.18). Equivalently,

$$F^2 M_\pi^2 = 2m\Sigma, \qquad f_{t,\delta}^2 M_\pi^2 = 4m\Sigma$$

at this order. For a constant field $U = \mathbf{1}$, the Euclidean free-energy density from (135.30) is

$$f_0(m) = -N_f F^2 B m, \qquad p_0(m) = N_f F^2 B m.$$

Therefore $N_f^{-1} \partial p_0 / \partial m = F^2 B$, proving $\Sigma = F^2 B$. Expanding (135.31),

$$U + U^\dagger = 2\mathbf{1} - \frac{2}{F^2} \pi^a \pi^b \tau^a \tau^b + O(\pi^4),$$

and substituting $M = m\mathbf{1}$ gives the quadratic Euclidean Lagrangian

$$\frac{1}{2} \partial_\mu \pi^a \partial_\mu \pi^a + Bm\, \pi^a \pi^a.$$

Comparing with $\frac{1}{2}(\partial\pi)^2 + \frac{1}{2} M_\pi^2 \pi^2$ gives $M_\pi^2 = 2Bm$. The two GMOR forms follow from $f_{t,\delta} = \sqrt{2}F$ at leading order.

Lemma 135.18 (One-loop pion-gas correction to the condensate)**.** *Under the leading chiral effective assumptions above, and in the chiral limit after the spatial thermodynamic limit, the low-temperature condensate obeys*

$$\frac{\Sigma(T)}{\Sigma(0)} = 1 - \frac{N_f^2 - 1}{12 N_f} \frac{T^2}{F^2} + O\left(\frac{T^4}{F^4} \right) \tag{135.33}$$

within the chiral derivative expansion. For $N_f = 2$, this is

$$\Sigma(T)/\Sigma(0) = 1 - \frac{T^2}{8F^2} + O(T^4/F^4).$$

Proof. To one loop in the leading effective theory the only m-dependent thermal term at order T^2 is the free pressure of $d_\pi = N_f^2 - 1$ pion fields with $\omega_k = (k^2 + M_\pi^2)^{1/2}$:

$$p_\pi(T, M_\pi) = -d_\pi T \int \frac{d^3k}{(2\pi)^3} \log\bigl(1 - e^{-\beta\omega_k}\bigr). \tag{135.34}$$

The vacuum part is absorbed into the zero-temperature low-energy constants; the displayed thermal part is finite. Differentiating at fixed T,

$$\frac{\partial p_\pi}{\partial M_\pi^2} = -\frac{d_\pi}{2} \int \frac{d^3k}{(2\pi)^3} \frac{1}{\omega_k} \frac{1}{e^{\beta\omega_k} - 1}. \tag{135.35}$$

Since $M_\pi^2 = 2Bm$, the pion contribution to the per-flavor condensate is

$$\frac{1}{N_f}\frac{\partial p_\pi}{\partial m} = -\frac{d_\pi B}{N_f} \int \frac{d^3k}{(2\pi)^3} \frac{1}{\omega_k} \frac{1}{e^{\beta\omega_k} - 1}.$$

In the chiral limit the integral is

$$\int \frac{d^3k}{(2\pi)^3} \frac{1}{|k|} \frac{1}{e^{\beta|k|} - 1} = \frac{T^2}{12}. \tag{135.36}$$

Thus

$$\Sigma(T) = F^2 B - \frac{N_f^2 - 1}{N_f} B \frac{T^2}{12} + O(T^4/F^2).$$

Dividing by $\Sigma(0) = F^2 B$ gives (135.33). The next terms require the $O(p^4)$ chiral Lagrangian and two-loop pion interactions; they are not fixed by symmetry and F, B alone. □

Remark 135.19 (What the low-temperature formula establishes). Equation (135.33) is a controlled asymptotic statement inside the broken phase. It does not by itself prove a chiral restoration temperature or determine the order of a transition. Such questions require the nonperturbative thermal QCD limit, or an effective description whose domain includes the critical region.

135.6 Free Plasma Limit and Thermodynamic Observables

At asymptotically high temperature and fixed μ_B/T, asymptotic freedom makes the leading term in the pressure the free massless quark-gluon pressure. It is the leading term in a controlled high-temperature expansion whose subleading terms require screening and infrared resummation.

Massless free QCD pressure. For $SU(N_c)$ with N_f massless Dirac fundamental quarks at $\mu_B = 0$, the free pressure is

$$p_{\mathrm{SB}}(T) = \frac{\pi^2 T^4}{45}(N_c^2 - 1) + \frac{7\pi^2 T^4}{180} N_c N_f. \tag{135.37}$$

At nonzero baryon chemical potential, the quark part becomes

$$p_{q,\mathrm{free}}(T, \mu_B) = N_c N_f \left[\frac{7\pi^2 T^4}{180} + \frac{\mu_B^2 T^2}{6N_c^2} + \frac{\mu_B^4}{12\pi^2 N_c^4}\right]. \tag{135.38}$$

A massless bosonic degree of freedom contributes

$$-T \int \frac{d^3p}{(2\pi)^3} \log(1 - e^{-|p|/T}) = \frac{\pi^2 T^4}{90},$$

using $\int_0^\infty x^3(e^x - 1)^{-1} dx = \pi^4/15$. A gluon has two physical polarizations and $N_c^2 - 1$ color states, giving the first term.

A massless fermionic degree of freedom contributes 7/8 times the bosonic answer at zero chemical potential. A Dirac quark has four particle-antiparticle and spin degrees for each color and flavor, giving $(7/8)(4N_c N_f)\pi^2 T^4/90$, which is the second term of (135.37). The standard Fermi integral with chemical potential μ_q gives, for one Dirac quark of one color,

$$\frac{7\pi^2 T^4}{180} + \frac{\mu_q^2 T^2}{6} + \frac{\mu_q^4}{12\pi^2}.$$

Substituting $\mu_q = \mu_B/N_c$ and multiplying by $N_c N_f$ gives (135.38).

The energy density, entropy density, and trace anomaly are then defined by

$$s = \frac{\partial p}{\partial T}, \qquad n_B = \frac{\partial p}{\partial \mu_B}, \qquad \epsilon = -p + Ts + \mu_B n_B,$$

and

$$\Delta(T, \mu_B) = \epsilon - 3p.$$

For a conformal thermal state in four dimensions, $\Delta = 0$. In QCD, Δ measures the breaking of scale invariance by quark masses, by the running coupling, and by the thermal state itself.

Remark 135.20 (Thermodynamic identities). Let $p(T, \mu_B)$ be the thermodynamic pressure of a QCD phase on an open domain in which it is twice continuously differentiable. Define

$$s = \partial_T p, \qquad n_B = \partial_{\mu_B} p, \qquad \epsilon = -p + Ts + \mu_B n_B.$$

Then

$$dp = s\,dT + n_B\,d\mu_B,$$

and

$$d\epsilon = T\,ds + \mu_B\,dn_B,$$

and the interaction measure is

$$\Delta(T, \mu_B) = \epsilon - 3p = T\partial_T p + \mu_B \partial_{\mu_B} p - 4p.$$

Equivalently, at fixed $x = \mu_B/T$,

$$\frac{\Delta(T,\mu_B)}{T^4} = T\,\partial_T \left(\frac{p(T,xT)}{T^4}\right)_x .$$

At $\mu_B = 0$, if charge conjugation gives $n_B(T,0) = 0$ and $\partial_T \epsilon(T,0) > 0$, the adiabatic sound speed determined by the pressure is

$$c_s^2(T) = \frac{dp(T,0)/dT}{d\epsilon(T,0)/dT} = \frac{\partial_T p(T,0)}{T\,\partial_T^2 p(T,0)}.$$

These formulae are definitions and thermodynamic consequences of the pressure; they are not model assumptions about quasiparticles.

The first identity is the definition of s and n_B as derivatives of the limiting pressure. Differentiating $\epsilon = -p + Ts + \mu_B n_B$ gives

$$d\epsilon = -dp + T\,ds + s\,dT + \mu_B\,dn_B + n_B\,d\mu_B.$$

Substituting $dp = s\,dT + n_B\,d\mu_B$ leaves $d\epsilon = T\,ds + \mu_B\,dn_B$. The displayed formula for Δ follows by substituting $s = \partial_T p$ and $n_B = \partial_{\mu_B} p$ into $\epsilon - 3p$.

For the fixed-x identity, write $\mu_B = xT$. The chain rule gives

$$T\,\partial_T \left(\frac{p(T,xT)}{T^4}\right)_x = \frac{T\partial_T p + \mu_B \partial_{\mu_B} p - 4p}{T^4}.$$

At $\mu_B = 0$, charge conjugation removes the baryon-density term. Along that one-parameter equilibrium curve,

$$\frac{d\epsilon}{dT} = T\,\frac{ds}{dT} = T\,\partial_T^2 p(T,0), \qquad \frac{dp}{dT} = \partial_T p(T,0),$$

which gives the sound-speed formula whenever the denominator is nonzero.

Example 135.21 (Conformal Stefan–Boltzmann benchmark)**.** If

$$p(T,\mu_B) = aT^4 + b\mu_B^2 T^2 + c\mu_B^4$$

with a, b, c independent of T and μ_B, then p is homogeneous of degree four, so Euler's identity gives

$$T\partial_T p + \mu_B \partial_{\mu_B} p = 4p, \qquad \Delta = 0.$$

At $\mu_B = 0$, one obtains $\epsilon = 3aT^4$ and

$$c_s^2 = \frac{4aT^3}{12aT^3} = \frac{1}{3}.$$

The free plasma is therefore a normalization benchmark for lattice and resummed calculations of Δ/T^4 and c_s^2; departures from it measure interactions, masses, running couplings, and nonperturbative thermal physics.

135.7 Hard Thermal Loops and the Linde Obstruction

Chapter 130 derived the one-loop Debye mass in the present trace convention:

$$m_D^2 = g^2T^2\left(\frac{C_A}{3} + \frac{1}{3}\sum_{\text{Dirac } f} T_{R_f}\right)$$

for QCD without scalars. For $SU(N_c)$ with $\mathrm{tr}_\square(T^aT^b) = \delta^{ab}$, this gives

$$C_A = 2N_c, \qquad T_\square = 1.$$

The scale gT is electric. It must be resummed in static longitudinal propagators before a weak-coupling expansion of many thermal quantities is well-defined.

Controlled Approximation 135.22 (Hard-thermal-loop regime)**.** The HTL approximation applies to external frequencies and momenta

$$\omega,\ |\mathbf{k}| = O(gT)$$

in a plasma whose internal loop momenta are hard, $p = O(T)$. The leading soft gauge-field effective action is the gauge-invariant functional whose second variation reproduces the transverse and longitudinal one-loop polarization tensors in this kinematic regime. A calculation outside this scale separation is not an HTL calculation.

Static HTL polarization and Debye mass. Let $a_0 = a_0^aT^a$ be a slowly varying canonically normalized temporal gauge potential, and normalize the generators by

$$\mathrm{tr}_R(T_R^aT_R^b) = T_R\,\delta^{ab}, \qquad f^{acd}f^{bcd} = C_A\,\delta^{ab}.$$

For a weakly coupled thermal plasma at $\mu_B = 0$, the static HTL color susceptibility is

$$\Pi_{00}^{ab}(0,\mathbf{k}\to 0) = \delta^{ab}m_D^2, \qquad m_D^2 = g^2T^2\left(\frac{C_A}{3} + \frac{1}{3}\sum_{\text{Dirac } f} T_{R_f}\right).$$

In the present $SU(N_c)$ convention $\mathrm{tr}_\square(T^aT^b) = \delta^{ab}$, one has

$$C_A = 2N_c, \qquad T_\square = 1,$$

and hence

$$m_D^2 = g^2T^2\left(\frac{2N_c}{3} + \frac{N_f}{3}\right).$$

To leading static order the longitudinal electric propagator is screened as

$$D_{00}^{ab}(0,\mathbf{k}) = \frac{\delta^{ab}}{\mathbf{k}^2 + m_D^2},$$

with the understanding that this formula is the static electric HTL limit, not a gauge-invariant definition of a particle pole.

The statement is a color-susceptibility calculation for hard particles. Let a hard excitation of momentum $p = |\mathbf{p}|$ and color weight w couple to the soft potential by the energy shift $-ga_0^a w^a$. Linearizing its distribution gives

$$\delta n(p) = ga_0^b w^b \, [-n'(p)].$$

Multiplying by the color charge gw^a, summing over weights, and integrating over hard momenta gives the induced color density. Therefore a species in representation R contributes the positive susceptibility

$$g^2 \, d_{\text{spin/particle}} \, \mathrm{tr}_R(T_R^a T_R^b) \int \frac{d^3p}{(2\pi)^3} \, [-n'(p)].$$

For gluons the representation is the adjoint and there are two transverse hard polarizations. For a massless Dirac fermion there are two spin states and independent particle and antiparticle excitations; the antiparticle charge is opposite, but the susceptibility is quadratic in the charge, so the total degeneracy factor is 4.

The required thermal integrals are elementary but convention-sensitive:

$$I_B = \int \frac{d^3p}{(2\pi)^3} \, [-n_B'(p)] = \frac{1}{\pi^2} \int_0^\infty dp \, p \, n_B(p) = \frac{T^2}{6},$$

$$I_F = \int \frac{d^3p}{(2\pi)^3} \, [-n_F'(p)] = \frac{1}{\pi^2} \int_0^\infty dp \, p \, n_F(p) = \frac{T^2}{12}.$$

The integration by parts has no boundary term: at $p = \infty$ the distributions decay exponentially, while at $p = 0$ one has $p^2 n_B(p) \to 0$ and $p^2 n_F(p) \to 0$; moreover $p^2[-n_B'(p)]$ and $p^2[-n_F'(p)]$ are locally integrable. The last equalities use

$$\int_0^\infty \frac{x \, dx}{e^x - 1} = \frac{\pi^2}{6}, \qquad \int_0^\infty \frac{x \, dx}{e^x + 1} = \frac{\pi^2}{12}.$$

Thus

$$m_D^2 = g^2 \big(2C_A I_B + 4 \sum_f T_{R_f} I_F \big) = g^2 T^2 \left(\frac{C_A}{3} + \frac{1}{3} \sum_f T_{R_f} \right).$$

The resummed static longitudinal propagator is the geometric series obtained by inserting this static self-energy into the soft electric propagator. The derivation has used only the HTL separation between hard loop momentum and soft external field; it does not determine the magnetic sector.

Definition 135.23 (Retarded HTL induced-current kernel)**.** Work in the rest frame of the equilibrium state, with mostly-plus Lorentzian metric and $K = (\omega, \mathbf{k})$. Let

$$v^\mu = (1, \mathbf{v}), \qquad |\mathbf{v}| = 1, \qquad \int_{\mathbf{v}} (\cdots) = \int_{S^2} \frac{\mathrm{d}\Omega_{\mathbf{v}}}{4\pi} (\cdots).$$

The retarded HTL induced-current kernel is the distribution $\mathcal{K}_R^{\mu\nu,ab}(\omega, \mathbf{k})$ defined by

$$j_a^\mu(\omega, \mathbf{k}) = \mathcal{K}_R^{\mu\nu,ab}(\omega, \mathbf{k}) A_\nu^b(\omega, \mathbf{k}),$$

where

$$\mathcal{K}_R^{\mu\nu,ab}(\omega, \mathbf{k}) = \delta^{ab} m_D^2 \left[\delta_0^\mu \delta_0^\nu - \omega \int_{\mathbf{v}} \frac{v^\mu v^\nu}{\omega - \mathbf{v} \cdot \mathbf{k} + i0} \right].$$

The $+i0$ prescription is part of the definition: it is the retarded boundary condition for the collisionless response of hard particles. This kernel is normalized so that

$$\mathcal{K}_R^{00,ab}(0,\mathbf{k}) = \delta^{ab} m_D^2,$$

matching the static HTL calculation above.

Gauge-covariant HTL equations and transversality. Let $W_a(x,\mathbf{v})$ be an adjoint auxiliary field on spacetime times the unit velocity sphere. The gauge-covariant linear-response equations

$$(v\cdot D)W(x,\mathbf{v}) = v^i F_{i0}(x), \qquad j^\mu(x) = m_D^2 \int_{\mathbf{v}} v^\mu W(x,\mathbf{v}),$$

where D is the adjoint covariant derivative, are covariantly conserved:

$$D_\mu j^\mu = 0.$$

Linearizing around $A_\mu = 0$ and imposing the retarded prescription gives the kernel of Definition 135.23. Consequently, in momentum space,

$$K_\mu \mathcal{K}_R^{\mu\nu,ab}(K) = 0, \qquad K_\mu = (-\omega, \mathbf{k}),$$

so the HTL response is transverse in the mostly-plus convention.

The verification is explicit. The auxiliary field W transforms in the adjoint representation. Applying the covariant divergence to the current gives

$$D_\mu j^\mu = m_D^2 \int_{\mathbf{v}} (v\cdot D)W = m_D^2 \int_{\mathbf{v}} v^i F_{i0}.$$

Since F_{i0} is independent of $\mathbf{v}$ and $\int_{\mathbf{v}} v^i = 0$, the right side vanishes. This proves covariant current conservation before choosing a gauge.

For the linearized kernel, take fields proportional to $\exp(-i\omega t + i\mathbf{k}\cdot\mathbf{x})$. The retarded solution of $(\partial_t + \mathbf{v}\cdot\nabla)W = v^i F_{i0}$ is

$$W(K,\mathbf{v}) = -\frac{\mathbf{v}\cdot\mathbf{k}\, A_0(K) + \omega\, v^i A_i(K)}{\omega - \mathbf{v}\cdot\mathbf{k} + i0},$$

using $F_{i0} = \partial_i A_0 - \partial_0 A_i$. Inserting this solution into $j^\mu = m_D^2 \int_{\mathbf{v}} v^\mu W$ and using $\int_{\mathbf{v}} v^i = 0$ gives

$$j^\mu = m_D^2 \left[\delta_0^\mu \delta_0^\nu - \omega \int_{\mathbf{v}} \frac{v^\mu v^\nu}{\omega - \mathbf{v}\cdot\mathbf{k} + i0} \right] A_\nu,$$

which is precisely the stated kernel, with the color factor δ^{ab} restored.

Transversality is an algebraic consequence of the same formula. With $K_\mu = (-\omega, \mathbf{k})$,

$$K_\mu v^\mu = -(\omega - \mathbf{v}\cdot\mathbf{k}).$$

Therefore

$$K_\mu \mathcal{K}_R^{\mu\nu} = m_D^2 \left[-\omega\, \delta_0^\nu + \omega \int_{\mathbf{v}} v^\nu \right].$$

The integral of v^0 is 1, and the integral of v^i is 0. Thus the expression vanishes for $\nu = 0$ and for each spatial $\nu = i$.

Longitudinal HTL response and Landau cut. For $k = |\mathbf{k}| > 0$,

$$\mathcal{K}_R^{00,ab}(\omega, \mathbf{k}) = \delta^{ab} m_D^2 \left[1 - \frac{\omega}{2k} \log \frac{\omega + k + i0}{\omega - k + i0}\right].$$

Equivalently,

$$\int_{\mathbf{v}} \frac{1}{\omega - \mathbf{v} \cdot \mathbf{k} + i0} = \frac{1}{2k} \log \frac{\omega + k + i0}{\omega - k + i0}.$$

For $|\omega| < k$, the logarithm has an imaginary part. This is the Landau cut of the retarded thermal response, caused by hard particles whose velocity satisfies $\omega = \mathbf{v} \cdot \mathbf{k}$.

Choose the z-axis along $\mathbf{k}$ and write $\mu = \cos\theta$. Then

$$\int_{\mathbf{v}} \frac{1}{\omega - \mathbf{v} \cdot \mathbf{k} + i0} = \frac{1}{2} \int_{-1}^{1} \frac{\mathrm{d}\mu}{\omega - k\mu + i0}.$$

The antiderivative is $-k^{-1} \log(\omega - k\mu + i0)$. Evaluating it at $\mu = 1$ and $\mu = -1$ gives the displayed logarithm. Substitution in Definition 135.23 gives $\mathcal{K}_R^{00}$.

The distribution identity

$$\frac{1}{\omega - k\mu + i0} = \mathrm{PV}\, \frac{1}{\omega - k\mu} - i\pi\delta(\omega - k\mu)$$

shows that an imaginary part is present exactly when the equation $\mu = \omega/k$ has a solution in $[-1, 1]$, namely when $|\omega| < k$. This proves the Landau-cut statement and identifies its kinematic origin.

Remark 135.24 (Magnetic sector at g^6T^4). In four-dimensional high-temperature Yang–Mills theory, the static magnetic sector has three-dimensional coupling

$$g_3^2 = g^2 T.$$

If the magnetic sector develops a mass gap of order g_3^2, its contribution to the four-dimensional pressure begins at order

$$T(g_3^2)^3 = g^6 T^4.$$

The coefficient of this contribution is not determined by ordinary perturbation theory around the massless magnetic theory.

After the nonzero Matsubara modes and the electric scale have been matched into a three-dimensional static effective theory, the remaining magnetic Yang–Mills action has the form

$$\frac{1}{4g_3^2} \int d^3x\ \mathrm{tr}(F_{ij} F_{ij}).$$

In three dimensions g_3^2 has mass dimension one. A vacuum free-energy density of the magnetic theory has mass dimension three. If no scale other than g_3^2 remains in the confining magnetic sector, dimensional analysis forces the nonperturbative contribution to be $c(g_3^2)^3$, where c is a dimensionless number defined by the three-dimensional Yang–Mills theory. The four-dimensional pressure is T times the static three-dimensional free-energy density, so the order is g^6T^4.

Perturbation theory cannot determine c, because it expands around a massless three-dimensional gauge theory whose infrared behavior is precisely the magnetic theory being asked to generate the scale. This dimensional argument does not prove the magnetic mass gap; it identifies the order at which the nonperturbative magnetic input first enters the high-temperature expansion.

135.8 Transport and Quark–Gluon Plasma Observables

The quark–gluon plasma is not defined by the presence of free quarks and gluons. In this monograph it is the thermal regime of QCD in which the dominant excitations and response functions are better organized by color degrees of freedom, screening, and hydrodynamic transport than by a dilute gas of hadrons. The precise observables are correlation functions.

The shear viscosity, bulk viscosity, and electrical conductivity are defined by the Kubo limits of Chapter 127. For example, with T_{xy} a spatial off-diagonal stress tensor component,

$$\eta = \lim_{\omega \downarrow 0} \frac{1}{2\omega}\, \rho_{T_{xy}T_{xy}}(\omega, \mathbf{0})$$

when the limit exists after the thermodynamic limit. The definition is nonperturbative; a kinetic or holographic computation is an approximation to this spectral limit, not the definition of the coefficient.

Controlled Approximation 135.25 (QCD hydrodynamic response window)**.** Fix a thermal QCD phase at (T, μ_B) for which the continuum real-time retarded kernels of the gauge-invariant stress tensor and global currents exist. A claim that QCD is described by first-order hydrodynamics in a specified channel consists of more than the Kubo limits. It requires a compact low-frequency and long-wavelength window W_ϵ, a subtraction of declared local contact terms, and a comparison

$$K^R_{\mathrm{QCD}}(\omega, \mathbf{k}) = K^R_{\mathrm{hydro}}(\omega, \mathbf{k}; \mathcal{T}_{\mathrm{QCD}}) + P_{\mathrm{loc}}(\omega, \mathbf{k}) + R_\epsilon(\omega, \mathbf{k}), \tag{135.39}$$

where $\mathcal{T}_{\mathrm{QCD}}$ is the QCD transport datum

$$\mathcal{T}_{\mathrm{QCD}} = \big(p(T, \mu_B),\ \chi_{ab}(T, \mu_B),\ \eta(T, \mu_B),\ \zeta(T, \mu_B),\ \Sigma_{ab}(T, \mu_B), \ldots\big)$$

extracted from thermodynamic derivatives and Kubo spectral slopes. Here χ_{ab} and Σ_{ab} are the susceptibility and conductivity matrices for the conserved charge sector after the stress-tensor variables have been projected into the chosen hydrodynamic frame. The remainder statement must be in the same scaling topology as the hydrodynamic mode: $\omega \sim k^2$ for shear and diffusion, and $\omega \sim k$ for sound. Thus the shear channel uses

$$D_\eta = \frac{\eta}{w}, \qquad \omega_{\mathrm{shear}} = -\mathrm{i} D_\eta k^2 + O(k^4), \qquad w = \epsilon + p,$$

a decoupled baryon diffusion channel uses

$$D_B = \frac{\sigma_B}{\chi_B}, \qquad \omega_{\mathrm{diff}} = -\mathrm{i} D_B k^2 + O(k^4),$$

while at nonzero density or with several conserved charges D_B is replaced by the relevant eigenvalue of $\Sigma\,\chi^{-1}$ after the sound variables have been separated, and the sound channel uses

$$\omega_{\mathrm{sound},\pm} = \pm c_s k - \frac{\mathrm{i}}{2}\Gamma_s k^2 + O(k^3), \qquad \Gamma_s = \frac{\zeta + 2\eta(d-1)/d}{w}.$$

Here d is the number of spatial dimensions and c_s^2 is computed from the QCD pressure with the stated thermodynamic constraint. A bound such as

$$\sup_{(\omega, \mathbf{k}) \in W_\epsilon} |R_\epsilon(\omega, \mathbf{k})| \le C\, \epsilon^{N+1} \tag{135.40}$$

is the additional microscopic input. It asserts that nonconserved QCD excitations and long-time tails do not produce extra singular terms in the window being approximated. Without a statement of this form, Kubo formulae define transport coefficients, but they do not by themselves derive hydrodynamics from QCD.

Proposition 135.26 (Momentum-projected baryon diffusion current). *In a translationally invariant QCD phase at nonzero baryon density, the raw baryon current is not itself the diffusive current. Let*

$$n_B = \frac{\partial p}{\partial \mu_B}, \qquad w = \epsilon + p, \qquad P^i = T^{0i},$$

and let J_B^i be the spatial baryon-number current. In a homogeneous fluid state boosted by a small velocity δu^i,

$$\delta\langle P^i\rangle = w\,\delta u^i, \qquad \delta\langle J_B^i\rangle = n_B\,\delta u^i.$$

Thus the static susceptibility Gram matrix in the vector sector contains

$$\chi_{P^iP^j} = w\,\delta^{ij}, \qquad \chi_{J_B^iP^j} = n_B\,\delta^{ij}.$$

The momentum-orthogonal baryon current is therefore

$$J^i_{\rm inc} = J^i_B - \frac{n_B}{w}T^{0i}. \tag{135.41}$$

Writing $\chi_{J_B^iJ_B^j} = \chi_{JJ}\delta^{ij}$, it obeys

$$\chi_{J^i_{\rm inc}P^j} = 0, \qquad \chi_{J^i_{\rm inc}J^j_{\rm inc}} = \left(\chi_{JJ} - \frac{n_B^2}{w}\right)\delta^{ij}. \tag{135.42}$$

Consequently the baryon conductivity entering the diffusive part of $\mathcal{T}_{\rm QCD}$ is the regular Kubo slope of $J_{\rm inc}$,

$$\Sigma_B^{\rm inc} = \lim_{\omega\downarrow 0}\frac{1}{2\omega}\rho^{\rm reg}_{J^i_{\rm inc}J^i_{\rm inc}}(\omega,\mathbf{0}), \tag{135.43}$$

with the Drude sector separated as in (127.18). At $n_B = 0$, $J_{\rm inc} = J_B$. At $n_B \neq 0$, the raw J_BJ_B response contains a convective contribution from the exactly conserved momentum. If translations are weakly broken this contribution becomes a narrow momentum-relaxation peak; that peak is a property of the relaxation mechanism, not the intrinsic QCD baryon-diffusion coefficient.

Proof. The ideal constitutive relations in the local rest frame are

$$T^{0i} = w\,u^i + O(\partial), \qquad J_B^i = n_B\,u^i + O(\partial).$$

Differentiating the expectation values with respect to a uniform velocity source gives the displayed static overlaps. Equation (135.41) is then ordinary Gram–Schmidt projection in the static susceptibility inner product, so

$$\chi_{J_{\rm inc}P} = \chi_{J_BP} - \frac{n_B}{w}\chi_{PP} = n_B - \frac{n_B}{w}w = 0.$$

The second identity in (135.42) is the same projection applied to the norm of the current. Positivity is the Schur complement positivity of the static susceptibility matrix. The last statement is then the Drude separation of (127.18): any current with a nonzero static overlap with a conserved momentum has a singular zero-frequency sector, while the projected current is the object whose regular spectral slope can be matched to the diffusive hydrodynamic coefficient. □

Remark 135.27 (The η/s lower-bound claim). The value $1/(4\pi)$ is an important result in a class of strongly coupled large-N theories with classical gravity duals. It is not a theorem of QCD. When this number is used as a comparison scale in QCD phenomenology, the statement is a quantitative comparison of transport data or models, not a rigorous lower bound derived from the QCD axioms.

135.9 Finite Baryon Density and the Sign Problem

At real μ_B, the Euclidean Dirac operator is no longer anti-Hermitian up to the mass term. In continuum notation the temporal derivative is shifted by $-\mu_q$, and on the lattice forward and backward temporal hops are weighted asymmetrically. The determinant need not be real and nonnegative.

At $\mu_B = 0$, a vectorlike pair of equal-mass quark flavors gives a nonnegative Euclidean determinant. At real $\mu_B \neq 0$, the same positivity argument fails because the Dirac operator loses the γ_5-Hermiticity relation that pairs eigenvalues into complex conjugates at fixed gauge field. At $\mu_B = 0$, the lattice or continuum Euclidean Dirac operator obeys

$$\gamma_5(D_E + m)\gamma_5 = (D_E + m)^\dagger$$

for real mass m. Therefore $\det(D_E + m)$ is real, and for two degenerate flavors the product is $|\det(D_E + m)|^2 \geq 0$. This is the measure-positivity input behind importance sampling.

A real quark chemical potential changes the temporal part of the operator by a term that is Hermitian rather than anti-Hermitian in Euclidean signature. Equivalently, the lattice temporal hopping factors $e^{a\mu_q}$ and $e^{-a\mu_q}$ are not related by the same unitary conjugation that holds at $\mu_q = 0$. The displayed γ_5-Hermiticity relation is replaced by a relation connecting μ_q to $-\mu_q$. At fixed real μ_q the determinant is generally complex, so it cannot be used directly as a positive probability weight.

135.9.1 Imaginary Chemical Potential and Roberge–Weiss Periodicity

Imaginary chemical potential is a different, exactly defined thermal boundary condition from real finite density. It is useful because it restores positivity in vectorlike pairs and has an exact center periodicity at finite regulator.

Definition 135.28 (Imaginary quark and baryon chemical-potential angles)**.** Let

$$\mu_q = iT\theta_q, \qquad \mu_B = iT\theta_B, \qquad \theta_B = N_c\theta_q.$$

Equivalently, the fundamental quark field obeys the Euclidean thermal boundary condition

$$q(\beta, \mathbf{x}) = -e^{i\theta_q} q(0, \mathbf{x}).$$

For a finite lattice regulator, write the corresponding partition function as $Z_{a,V}(\theta_q)$. The regulator is assumed to use compact $SU(N_c)$ links, a gauge action invariant under center-twisted temporal gauge transformations, and a gauge-covariant Dirac operator whose imaginary chemical potential is this boundary twist.

Lemma 135.29 (Finite-regulator Roberge–Weiss periodicity)**.** *At finite regulator and finite spatial volume,*

$$Z_{a,V}\left(\theta_q + \frac{2\pi k}{N_c}\right) = Z_{a,V}(\theta_q), \qquad k \in \mathbb{Z}.$$

Equivalently, as a function of the baryon angle,

$$Z_{a,V}(\theta_B + 2\pi k) = Z_{a,V}(\theta_B).$$

For a vectorlike pair of equal-mass flavors, the Euclidean determinant at real θ_q is nonnegative. Therefore imaginary-μ_B simulations probe a positive finite-regulator measure, while analytic continuation to real μ_B remains a separate limiting and analytic-control problem.

Proof. Let $z_k = e^{2\pi ik/N_c} \in Z(SU(N_c))$. A center-twisted temporal gauge transformation is a gauge transformation $g(\tau, \mathbf{x})$ satisfying

$$g(\beta, \mathbf{x}) = z_k\, g(0, \mathbf{x}).$$

Gauge fields in the adjoint representation are periodic under this transformation, because the center acts trivially on adjoint variables. The compact-link Haar measure and gauge action are invariant.

For a fundamental quark field with $q(\beta, \mathbf{x}) = -e^{i\theta_q} q(0, \mathbf{x})$, the transformed field has boundary condition

$$q'(\beta, \mathbf{x}) = g(\beta, \mathbf{x})q(\beta, \mathbf{x}) = -e^{i\theta_q} z_k\, g(0, \mathbf{x})q(0, \mathbf{x}) = -e^{i(\theta_q+2\pi k/N_c)} q'(0, \mathbf{x}).$$

Thus the change of integration variables by the center-twisted gauge transformation maps the finite-regulator path integral at θ_q to the one at $\theta_q + 2\pi k/N_c$. Since the transformation is invertible and leaves the measure and gauge action invariant, the two partition functions are equal. Multiplying the quark-angle period by N_c gives the baryon-angle period 2π.

For $\mu_q = iT\theta_q$, the Euclidean chemical-potential term is anti-Hermitian in the same sense as the ordinary Euclidean Dirac operator. The massive Dirac operator obeys the γ_5-Hermiticity relation at fixed gauge field,

$$\gamma_5 D_{\theta_q,m} \gamma_5 = D^\dagger_{\theta_q,m}.$$

Hence its determinant is real, and a pair of equal-mass Dirac flavors gives $|\det D_{\theta_q,m}|^2 \geq 0$. This proves the positivity statement for vectorlike pairs. None of these equalities implies analyticity at real μ_B; analytic continuation is controlled only inside zero-free domains of the complex fugacity or chemical-potential plane. □

Remark 135.30 (Roberge–Weiss lines)*.* The finite-volume function $Z_{a,V}(\theta_q)$ is analytic in the imaginary fugacity. A Roberge–Weiss transition is therefore a thermodynamic-limit phenomenon: in high-temperature $SU(N_c)$ QCD, different center-related holonomy sectors may exchange dominance at

$$\theta_q = \frac{(2r+1)\pi}{N_c}, \qquad r \in \mathbb{Z}.$$

At finite volume this appears as Lee–Yang zero organization, not as a literal singularity of $Z_{a,V}$. The statement is about the imaginary chemical-potential problem and does not by itself locate a real-μ_B critical endpoint.

Consequently, the conjectural critical endpoint and the first-order line in the (T, μ_B) plane are not presently consequences of direct first-principles continuum control at large real μ_B. Taylor expansions around $\mu_B = 0$, imaginary-μ_B continuation, reweighting, and effective models are valuable but must carry their own domains of validity.

135.10 Baryon Susceptibilities and Critical-Point Diagnostics

At $\mu_B = 0$ the Euclidean measure of vectorlike QCD is positive in the standard lattice discretizations, so derivatives with respect to μ_B give first-principles thermal observables even though direct importance sampling at real $\mu_B \neq 0$ is obstructed. The natural dimensionless source is

$$x = \frac{\mu_B}{T} = \beta\mu_B.$$

At finite regulator and finite volume,

$$Z_{a,V}(x) = \mathrm{Tr}_{\mathcal{H}_{a,V}} \exp\{-\beta H_{a,V} + xB_{a,V}\}. \tag{135.44}$$

Here $B_{a,V}$ is the finite-regulator baryon charge, normalized so that a baryon has charge 1, and it is assumed to be an exactly conserved self-adjoint charge of the regulated theory:

$$[H_{a,V}, B_{a,V}] = 0.$$

Definition 135.31 (Baryon susceptibilities)**.** The finite-regulator baryon cumulants and susceptibilities at $x = 0$ are

$$\kappa^B_{n,a,V}(T) = \frac{\partial^n}{\partial x^n} \log Z_{a,V}(x)\bigg|_{x=0}, \qquad \chi^B_{n,a,V}(T) = \frac{1}{VT^3}\kappa^B_{n,a,V}(T). \tag{135.45}$$

The continuum thermodynamic susceptibility $\chi^B_n(T)$ is the limit of $\chi^B_{n,a,V}(T)$ along the chosen continuum trajectory, when the limit exists.

Baryon susceptibilities as baryon-number cumulants. At finite regulator and finite volume,

$$\chi^B_{1,a,V} = \frac{\langle B\rangle}{VT^3}, \qquad \chi^B_{2,a,V} = \frac{\langle B^2\rangle - \langle B\rangle^2}{VT^3}, \tag{135.46}$$

and

$$\begin{aligned}\chi^B_{4,a,V} = \frac{1}{VT^3}\big(\langle B^4\rangle - 4\langle B^3\rangle\langle B\rangle - 3\langle B^2\rangle^2 \\ + 12\langle B^2\rangle\langle B\rangle^2 - 6\langle B\rangle^4\big).\end{aligned} \tag{135.47}$$

If charge conjugation is an exact symmetry at $x = 0$ and sends $B \mapsto -B$, then all odd finite-volume cumulants vanish.

Because $B_{a,V}$ is conserved, $H_{a,V}$ and $B_{a,V}$ can be simultaneously decomposed by the spectral theorem, and differentiating (135.44) with respect to x is the ordinary differentiation of the finite-regulator moment generating function of the baryon charge in the thermal state. For any observable Y commuting with B, in particular for $Y = B^k$, one has

$$\frac{\partial}{\partial x}\langle Y\rangle_x = \langle YB\rangle_x - \langle Y\rangle_x\langle B\rangle_x. \tag{135.48}$$

Applying this identity to $Y = 1, B, B^2, B^3$, or equivalently differentiating $\log Z(x)$, gives the displayed cumulants. If charge conjugation is an exact symmetry at $x = 0$, the spectral measure of B in the thermal state is invariant under $B \mapsto -B$. The moment generating function then satisfies

$$Z(x) = Z(-x),$$

so $\log Z(x)$ is even near the origin and its odd derivatives vanish.

Definition 135.32 (Taylor expansion and critical diagnostic)**.** When the thermodynamic continuum pressure is analytic at $x = 0$, write

$$\frac{p(T,x)}{T^4} = \sum_{n=0}^{\infty} \frac{\chi_n^B(T)}{n!} x^n \tag{135.49}$$

inside its disk of convergence. The Cauchy–Hadamard radius of this germ is

$$R(T) = \left[\limsup_{n\to\infty} \left|\frac{\chi_n^B(T)}{n!}\right|^{1/n}\right]^{-1}. \tag{135.50}$$

Remark 135.33 (What a susceptibility radius establishes)*.* Assume that $p(T,x)/T^4$ is the germ of a holomorphic function of complex x at the origin and has Taylor coefficients $\chi_n^B(T)/n!$. Then $R(T)$ in (135.50) is the radius of convergence of the Taylor series. The pressure is analytic for $|x| < R(T)$. If independent input shows that the nearest limiting singularity is located at a positive real point x_c, then $x_c = R(T)$ and this singularity is the critical-point candidate seen by the Taylor expansion. Without that location input, the nearest singularity may lie at complex x and the radius alone does not identify a real critical endpoint.

The first two assertions are the Cauchy–Hadamard theorem applied to the power series (135.49). A real critical point at positive x_c must be a singularity of the same analytic germ after the thermodynamic and continuum limits have been taken. If it is independently known to be the nearest singularity to the origin, its distance from the origin is the convergence radius. The final statement is the complementary case: a power series records distance to the nearest complex obstruction, whereas the physical critical endpoint is a statement about the real (T, μ_B) plane and the limiting Gibbs/KMS states.

Remark 135.34 (Ratio estimators)*.* For a charge-conjugation invariant theory the odd susceptibilities vanish at $x = 0$, and one often forms even-order estimators

$$R_{2n}(T) = \sqrt{\frac{(2n+2)(2n+1)\chi_{2n}^B(T)}{\chi_{2n+2}^B(T)}}. \tag{135.51}$$

If the even Taylor coefficients are eventually positive and have a single dominant singular scale, these estimators can converge to the radius. The positivity and single-scale hypotheses are part of the diagnostic; they are not consequences of the cumulant definitions alone.

135.11 High-Density Effective Theory and Fermi-Surface Instability

Real baryon density is difficult nonperturbatively, but asymptotically large quark chemical potential has a separate weak-coupling control parameter. The running coupling is evaluated at a scale of order μ_q, while the low-energy excitations live in thin shells around the Fermi surface. The resulting effective theory is not an expansion around empty space; it is an expansion around a filled Fermi sea with soft residual momenta.

Controlled Approximation 135.35 (High-density effective-theory regime)**.** Let

$$\mu_q = \frac{\mu_B}{N_c}.$$

The high-density effective theory applies to modes whose residual energy and momentum are bounded by a scale $\Lambda_{\rm H}$ satisfying

$$\Delta,\ T,\ |\ell^\mu|,\ \Lambda_{\rm QCD} \ll \Lambda_{\rm H} \ll \mu_q,$$

where Δ denotes any superconducting gap scale that is being resolved. Gauge fields retained in the effective theory have momenta much smaller than μ_q. Modes far from the Fermi surface and antiparticle branches are integrated out into local operators and into hard-dense-loop response terms.

Definition 135.36 (Patch decomposition near the quark Fermi surface)**.** For each unit vector $\mathbf{v} \in S^2$, write a quark momentum near the Fermi surface as

$$\mathbf{p} = \mu_q \mathbf{v} + \boldsymbol{\ell}, \qquad |\boldsymbol{\ell}| \le \Lambda_{\rm H}.$$

Decompose the residual momentum into longitudinal and transverse parts,

$$\ell_\parallel = \mathbf{v}\cdot\boldsymbol{\ell}, \qquad \boldsymbol{\ell}_\perp = \boldsymbol{\ell} - \mathbf{v}\,\ell_\parallel.$$

The patch field $\psi_{\mathbf{v}}$ is the positive-energy quark field whose momenta lie in this shell and whose group velocity is near $\mathbf{v}$. More invariantly, it is obtained by applying the positive spectral projector of the massless one-particle Dirac Hamiltonian in the direction $\mathbf{v}$, multiplying by the phase $e^{-i\mu_q\mathbf{v}\cdot\mathbf{x}}$, and then restricting residual momenta to the shell. A finite regulator is obtained by choosing an angular partition of S^2 whose cells have diameter $O(\Lambda_{\rm H}/\mu_q)$; every occurrence of $\sum_{\mathbf{v}}$ below denotes this regulated patch sum, with the continuum angular integral recovered by refining the partition inside the scale separation $\Lambda_{\rm H} \ll \mu_q$.

Fermi-surface measure and density of states. For functions supported in the shell $|\boldsymbol{\ell}| \le \Lambda_{\rm H} \ll \mu_q$,

$$\int \frac{d^3p}{(2\pi)^3} f(\mathbf{p}) = \frac{\mu_q^2}{(2\pi)^3}\int_{S^2} d\Omega_{\mathbf{v}} \int d\ell_\parallel\, f(\mu_q\mathbf{v} + \ell_\parallel \mathbf{v}) + O\!\left(\frac{\Lambda_{\rm H}}{\mu_q}\right)$$

after angular patches are refined so that transverse residual momenta are counted once. The density of states at the Fermi surface, per spin state and per internal state, is therefore

$$N_{\text{one spin}}(0) = \frac{\mu_q^2}{2\pi^2}.$$

Including the two spin states of a massless Dirac quark gives

$$N_{\rm Dirac}(0) = \frac{\mu_q^2}{\pi^2}.$$

Write $\mathbf{p} = (\mu_q + \ell_\parallel)\mathbf{v} + \boldsymbol{\ell}_\perp$ inside a patch. To leading order in $\Lambda_{\mathrm{H}}/\mu_q$, the radial Jacobian is

$$p^2 dp\, d\Omega_{\mathbf{v}} = (\mu_q + \ell_\parallel)^2 d\ell_\parallel\, d\Omega_{\mathbf{v}} = \mu_q^2 \left(1 + O\left(\frac{\Lambda_{\mathrm{H}}}{\mu_q}\right)\right) d\ell_\parallel\, d\Omega_{\mathbf{v}}.$$

The shell decomposition is a partition of momentum space near the Fermi surface after a choice of angular patches; the patch refinement only avoids double counting transverse residual momenta. Integrating the leading measure over S^2 gives

$$\frac{\mu_q^2}{(2\pi)^3}\, 4\pi = \frac{\mu_q^2}{2\pi^2}$$

per spin and internal state. A massless Dirac quark has two spin states on the positive-energy branch, giving the final formula.

Tree-level high-density quark action. For a massless quark near the Fermi surface, the positive-energy dispersion relative to the chemical potential is

$$|\mu_q \mathbf{v} + \boldsymbol{\ell}| - \mu_q = \ell_\parallel + \frac{\boldsymbol{\ell}_\perp^2}{2\mu_q} + O\left(\frac{|\boldsymbol{\ell}|^3}{\mu_q^2}\right).$$

Consequently the tree-level inverse propagator in a patch is

$$G_{\mathbf{v}}^{-1}(\ell) = \ell_0 - \ell_\parallel - \frac{\boldsymbol{\ell}_\perp^2}{2\mu_q} + O\left(\frac{|\boldsymbol{\ell}|^3}{\mu_q^2}\right),$$

with soft gauge fields introduced by replacing residual derivatives by covariant derivatives. The leading local patch Lagrangian has the form

$$\mathcal{L}^{(0)}_{\mathrm{HDET}} = \sum_{\mathbf{v}} \psi_{\mathbf{v}}^\dagger \left(iD_t + i\mathbf{v}\cdot\mathbf{D} + \frac{D_\perp^2}{2\mu_q} + \cdots\right)\psi_{\mathbf{v}},$$

where $D_\perp^2 = D_i D_i - (\mathbf{v}\cdot\mathbf{D})^2$, and the ellipsis contains higher powers of residual momentum divided by μ_q, quark masses, and local interactions generated by integrating out hard modes.

The expansion follows from

$$|\mu_q \mathbf{v} + \boldsymbol{\ell}| = \mu_q \sqrt{1 + \frac{2\ell_\parallel}{\mu_q} + \frac{\ell_\parallel^2 + \boldsymbol{\ell}_\perp^2}{\mu_q^2}}.$$

Taylor expansion of the square root gives

$$\mu_q + \ell_\parallel + \frac{\boldsymbol{\ell}_\perp^2}{2\mu_q} + O(|\boldsymbol{\ell}|^3/\mu_q^2).$$

Subtracting the chemical potential gives the displayed energy relative to the filled Fermi sea. The inverse propagator is ℓ_0 minus this relative energy. In coordinate space, residual momentum acts as $-iD$; hence the terms $-\ell_\parallel$ and $-\boldsymbol{\ell}_\perp^2/(2\mu_q)$ become $i\mathbf{v}\cdot\mathbf{D}$ and $D_\perp^2/(2\mu_q)$, with the sign fixed by the displayed momentum-space inverse propagator.

Hard-dense-loop Debye mass at zero temperature. At $T = 0$, for N_f massless Dirac quarks with common quark chemical potential μ_q, the static dense-quark contribution to the electric screening mass is

$$m_{D,\mu}^2 = g^2 \sum_{\text{Dirac } f} T_{R_f} \frac{\mu_q^2}{\pi^2}.$$

For $SU(N_c)$ fundamentals in the monograph trace convention $\mathrm{tr}_\square(T^a T^b) = \delta^{ab}$, this becomes

$$m_{D,\mu}^2 = g^2 N_f \frac{\mu_q^2}{\pi^2}.$$

This is the one-line susceptibility calculation entering the HDL approximation. The static electric response is the color susceptibility of occupied quark states. At $T = 0$, differentiating the occupation number $\Theta(\mu_q - p)$ with respect to a color chemical potential localizes the response on the Fermi surface:

$$-\frac{\partial}{\partial p}\Theta(\mu_q - p) = \delta(p - \mu_q).$$

For one spin state in representation R,

$$\int \frac{d^3p}{(2\pi)^3} \delta(p - \mu_q) = \frac{\mu_q^2}{2\pi^2}.$$

The two positive-energy spin states of a Dirac quark give μ_q^2/π^2. Multiplying by the color trace $\mathrm{tr}_R(T_R^a T_R^b) = T_R \delta^{ab}$, by g^2, and by the number of flavors gives the displayed result. Antiquark states are far from the positive-μ_q Fermi surface and do not contribute to this leading $T = 0$ dense response.

135.12 Dense Non-Fermi-Liquid Scaling

The high-density effective theory also controls the quark two-point function near an unpaired Fermi surface. A local four-fermion interaction would give a regular Fermi-liquid expansion in the external energy. Dense QCD is more singular because static magnetic gluons are not Debye screened; their Landau-damped propagator produces a logarithmic derivative of the quark self-energy. This is a perturbative high-density statement, not a nonperturbative theorem about all finite-density QCD states.

Controlled Approximation 135.37 (HDL non-Fermi-liquid self-energy regime)**.** Work at $T = 0$, in an unpaired high-density patch of Definition 135.36, with

$$|p_0|,\ |\ell_\parallel| \ll \Lambda_{\mathrm{H}} \ll \mu_q, \qquad g(\mu_q) \ll 1.$$

Use the trace-delta color convention $\mathrm{tr}_\square(T^a T^b) = \delta^{ab}$, so that

$$C_F = T^a T^a = \frac{N_c^2 - 1}{N_c} \tag{135.52}$$

on a fundamental quark. Retain the HDL transverse propagator in the Landau-damped region

$$|\omega| \ll k_\perp \ll \mu_q, \qquad D_T(\omega, k_\perp) = \frac{1}{k_\perp^2 + \frac{\pi}{4} m_{D,\mu}^2 \frac{|\omega|}{k_\perp}} \left(1 + o(1)\right), \tag{135.53}$$

with $m_{D,\mu}$ given by the zero-temperature HDL susceptibility calculation above. Electric exchange, non-collinear transverse exchange, and hard matching contributions are kept only to the extent that they define the finite matching scale $\Lambda_{\rm NFL}$; they do not affect the coefficient of the logarithm derived below.

Definition 135.38 (Leading non-Fermi-liquid self-energy)**.** Let $\Sigma(ip_0, \ell_\parallel)$ be the one-particle-irreducible quark self-energy of a patch field $\psi_{\mathbf{v}}$, projected onto the positive-energy branch and evaluated in Euclidean frequency. The leading non-Fermi-liquid part is the nonanalytic term in

$$G_{\mathbf{v}}^{-1}(ip_0, \ell_\parallel) = ip_0 - \ell_\parallel - \Sigma(ip_0, \ell_\parallel)$$

which is proportional to $ip_0 \log |p_0|$ at $\ell_\parallel = 0$. Local analytic terms proportional to ip_0, $\ell_\parallel$, or higher powers of residual momentum are scheme dependent HDET counterterms and are not included in $\Sigma_{\rm NFL}$.

Leading logarithmic cold dense quark self-energy. In Controlled Approximation 135.37, the on-Fermi-surface Euclidean self-energy has the leading nonanalytic form

$$\Sigma_{\rm NFL}(ip_0, 0) = ip_0\, \lambda_{\rm NFL} \log \frac{\Lambda_{\rm NFL}}{|p_0|} + O(ip_0), \qquad \lambda_{\rm NFL} = \frac{g^2 C_F}{12\pi^2}. \tag{135.54}$$

For $SU(3)$ in the monograph trace convention,

$$C_F = \frac{8}{3}, \qquad \lambda_{\rm NFL} = \frac{2g^2}{9\pi^2}. \tag{135.55}$$

The one-loop patch self-energy from transverse exchange is obtained by contracting the patch quark current with the transverse HDL propagator. The color projection gives C_F. Choose the patch normal $\mathbf{v} = \mathbf{e}_3$. The leading transverse vertex is $gT^a v^i$, and the transverse projector gives

$$v^i \left(\delta_{ij} - \frac{k_i k_j}{|\mathbf{k}|^2} \right) v^j = 1 + O\!\left(\frac{k_\parallel^2}{k_\perp^2} \right)$$

in the Landau-damped region after the internal quark pole restricts $|k_\parallel| \lesssim |\omega| \ll k_\perp$. Thus the singular part is independent of the detailed spinor wave functions, while analytic terms are absorbed into local HDET counterterms.

With the external residual momentum set to $\ell_\parallel = 0$, subtract $\Sigma(0,0)$ and integrate first over the normal residual momentum of the internal quark. For $p_0 > 0$, the residue theorem gives the reduced singular expression

$$\Sigma_{\rm sing}(ip_0, 0) - \Sigma_{\rm sing}(0,0) = i\, \frac{g^2 C_F}{4\pi^2} \int_0^{p_0} d\nu\, \mathcal{L}(\nu) + O(ip_0), \tag{135.56}$$

where ν is the Euclidean energy carried by the nearly on-shell internal quark and $\mathcal{L}(\nu)$ is the remaining transverse Landau-damped logarithm. The prefactor in (135.56) is the product of the color factor, the patch phase-space measure, the transverse-current projection, and the $2\pi i$ residue of the normal propagator. For $p_0 < 0$ the same formula holds with the integral oriented from 0 to p_0; this is why the final answer is proportional to ip_0.

The only nonanalytic part comes from the Landau-damped transverse region. For fixed ν, the HDL denominator in (135.53) cuts off the transverse integral at

$$k_{\perp,\min}^3 \asymp m_{D,\mu}^2|\nu|, \qquad k_{\perp,\max} \asymp \mu_q,$$

and therefore

$$\int_{k_{\perp,\min}}^{k_{\perp,\max}} \frac{dk_\perp}{k_\perp} = \frac{1}{3}\log\frac{\Omega_{\mathrm{NFL}}}{|\nu|} + O(1), \qquad \Omega_{\mathrm{NFL}} \asymp \frac{\mu_q^3}{m_{D,\mu}^2}. \tag{135.57}$$

The $O(1)$ part and the precise constant in Ω_{NFL} are absorbed into the matching scale Λ_{NFL}. Equivalently,

$$\mathcal{L}(\nu) = \frac{1}{3}\log\frac{\Lambda_{\mathrm{NFL}}}{|\nu|} + O(1). \tag{135.58}$$

Substitution into (135.56) gives

$$\Sigma_{\mathrm{NFL}}(ip_0, 0) = i\,\frac{g^2C_F}{4\pi^2}\int_0^{p_0} d\nu\, \left(\frac{1}{3}\log\frac{\Lambda_{\mathrm{NFL}}}{|\nu|}\right) + O(ip_0). \tag{135.59}$$

The endpoint singularity is integrable and

$$\int_0^{p_0} d\nu\, \log\frac{\Lambda_{\mathrm{NFL}}}{\nu} = p_0\log\frac{\Lambda_{\mathrm{NFL}}}{p_0} + p_0 \qquad (p_0 > 0).$$

The second term is analytic and is included in $O(ip_0)$. Odd continuation in p_0, written with $|p_0|$, gives

$$ip_0\,\frac{g^2C_F}{12\pi^2}\log\frac{\Lambda_{\mathrm{NFL}}}{|p_0|} + O(ip_0),$$

which is (135.54). The $SU(3)$ specialization follows from (135.52).

Remark 135.39 (Logarithmic vanishing of the patch residue). Under the assumptions of the leading logarithmic self-energy calculation above, the coefficient of ip_0 in the inverse patch propagator behaves as

$$Z^{-1}(p_0) = 1 + \lambda_{\mathrm{NFL}}\log\frac{\Lambda_{\mathrm{NFL}}}{|p_0|} + O(1), \tag{135.60}$$

and hence the perturbative patch residue satisfies

$$Z(p_0) \sim \left[\lambda_{\mathrm{NFL}}\log\frac{\Lambda_{\mathrm{NFL}}}{|p_0|}\right]^{-1} \longrightarrow 0 \qquad (p_0 \to 0) \tag{135.61}$$

within the unpaired high-density regime.

Insert (135.54) into the inverse propagator of Definition 135.38. Analytic wave-function renormalizations change the $O(1)$ part of (135.60) but cannot remove the logarithm. Inverting the coefficient of ip_0 gives (135.61). The statement is perturbative and patch-local: it identifies the logarithmic loss of a quasiparticle pole inside the unpaired high-density effective description, with pairing gaps, confinement-scale physics, and regulator matching held outside the displayed asymptotic regime.

Remark 135.40 (Relation to the superconducting gap). The logarithm in (135.54) is generated by the same Landau-damped magnetic gluons that produce the leading magnetic pairing kernel. It does not change the leading $1/g$ exponent in Proposition 135.51; it changes subleading matching data and prefactors. Thus the phrase "non-Fermi liquid" here has a precise meaning: the derivative of the inverse quark propagator has a logarithmic singularity in the unpaired high-density effective theory. It is not a claim that gauge-invariant observables in every dense phase have been nonperturbatively constructed.

BCS logarithm from the Fermi surface. Consider a specified antisymmetric two-quark channel of the high-density effective theory and approximate its attractive interaction by a local four-fermion coupling $G > 0$ inside a shell $|\xi| \le \Lambda_{\mathrm{H}}$, where $\xi = |\mathbf{p}| - \mu_q$. Let $N_{\mathrm{ch}}(0)$ be the density of states in that channel at the Fermi surface, including the relevant spin, color, and flavor multiplicity. The zero-temperature mean-field gap equation is

$$1 = G N_{\mathrm{ch}}(0) \int_0^{\Lambda_{\mathrm{H}}} \frac{d\xi}{\sqrt{\xi^2 + \Delta^2}}.$$

For $\Delta \ll \Lambda_{\mathrm{H}}$,

$$\int_0^{\Lambda_{\mathrm{H}}} \frac{d\xi}{\sqrt{\xi^2 + \Delta^2}} = \log \frac{2\Lambda_{\mathrm{H}}}{\Delta} + O\left(\frac{\Delta^2}{\Lambda_{\mathrm{H}}^2}\right),$$

and hence

$$\Delta = 2\Lambda_{\mathrm{H}} \exp\left[-\frac{1}{G N_{\mathrm{ch}}(0)}\right] \left(1 + O\left(\frac{\Delta^2}{\Lambda_{\mathrm{H}}^2}\right)\right).$$

In the paired mean-field Hamiltonian, the quasiparticle energy in the shell is

$$E(\xi) = \sqrt{\xi^2 + \Delta^2}.$$

The anomalous expectation value is proportional to $\Delta/(2E(\xi))$. Dividing the self-consistency equation by $\Delta \neq 0$ gives the displayed integral equation after the angular and internal sums are collected into $N_{\mathrm{ch}}(0)$. The integral is exactly

$$\int_0^{\Lambda_{\mathrm{H}}} \frac{d\xi}{\sqrt{\xi^2 + \Delta^2}} = \operatorname{arsinh} \frac{\Lambda_{\mathrm{H}}}{\Delta} = \log\left(\frac{\Lambda_{\mathrm{H}}}{\Delta} + \sqrt{1 + \frac{\Lambda_{\mathrm{H}}^2}{\Delta^2}}\right).$$

Expanding for $\Delta/\Lambda_{\mathrm{H}} \to 0$ gives $\log(2\Lambda_{\mathrm{H}}/\Delta) + O(\Delta^2/\Lambda_{\mathrm{H}}^2)$, and solving the gap equation gives the stated exponential scale.

Remark 135.41 (What is and is not contained in the BCS logarithm). The preceding calculation proves the kinematic Fermi-surface instability for a local attractive channel. In QCD the microscopic attraction, the color-flavor structure, and the weak-coupling gap prefactor also involve electric screening and dynamically screened magnetic gluons. Those ingredients refine the value of Δ; they do not remove the basic logarithmic instability once an attractive channel is present.

135.13 Neutrality Constraints and Gauge Sources

Dense QCD calculations often introduce several quantities called chemical potentials. The logically primary distinction is between sources for gauge-invariant global charges and variables that enforce gauge constraints. The two have different status already at finite regulator.

Definition 135.42 (Finite-regulator global-charge ensemble)**.** Let $\mathcal{H}_\Lambda$ be the regulated Hilbert space of a finite spatial lattice or another finite gauge regulator, let H_Λ be the regulated Hamiltonian, and let $\mathcal{G}_\Lambda$ be the compact group of time-independent gauge transformations. Write

$$\Pi_{\mathrm{phys}} = \int_{\mathcal{G}_\Lambda} d\eta\, U(\eta)$$

for the normalized Haar projector onto gauge-invariant states. If Q_A are mutually commuting conserved global charges which commute with $\mathcal{G}_\Lambda$, the finite-regulator grand partition function is

$$Z_\Lambda(\boldsymbol{\mu}) = \mathrm{Tr}_{\mathcal{H}_\Lambda}\left[\Pi_{\mathrm{phys}} \exp\left(-\beta H_\Lambda + \beta \sum_A \mu_A Q_A\right)\right]. \tag{135.62}$$

The intensive charge density conjugate to μ_A is

$$n_A = \frac{1}{\beta V}\frac{\partial}{\partial \mu_A} \log Z_\Lambda(\boldsymbol{\mu}), \tag{135.63}$$

with the thermodynamic and continuum limits taken only after the finite quantity has been defined.

Gauss-law annihilation of gauge charge. Let $G_\Lambda(f)$ be the infinitesimal generator of a one-parameter family of gauge transformations $U(e^{tf}) \subset \mathcal{G}_\Lambda$. Then

$$G_\Lambda(f)\Pi_{\mathrm{phys}} = 0, \qquad \Pi_{\mathrm{phys}} G_\Lambda(f) = 0. \tag{135.64}$$

Consequently every finite-regulator state defined by (135.62) has zero gauge charge:

$$\langle G_\Lambda(f)\rangle_{\boldsymbol{\mu}} = 0. \tag{135.65}$$

Thus a color charge cannot be assigned an independent physical chemical potential in the same sense as baryon number or another gauge-invariant global charge.

The Haar projector satisfies $U(\eta)\Pi_{\mathrm{phys}} = \Pi_{\mathrm{phys}}$ and $\Pi_{\mathrm{phys}}U(\eta) = \Pi_{\mathrm{phys}}$ for every $\eta \in \mathcal{G}_\Lambda$, by left and right invariance of Haar measure. Apply this identity to the one-parameter subgroup e^{tf} and differentiate at $t = 0$. This gives (135.64). Inserting $G_\Lambda(f)$ inside the trace defining the expectation value, and using either equality in (135.64) together with cyclicity of the finite trace, gives (135.65).

Remark 135.43 (Meaning of color-neutrality variables). In a gauge-fixed high-density calculation one may parametrize a homogeneous temporal gauge background by Cartan components A_0^a, or equivalently by symbols often denoted μ_3, μ_8. These symbols are not external thermodynamic chemical potentials for physical color charge. They are coordinates on the gauge-field zero mode left after gauge fixing. If $\Omega_{\mathrm{gf}}(A_0)$ is the gauge-fixed finite-volume effective potential obtained after the nonzero modes have been integrated out, a homogeneous saddle representing a physical bulk state must obey

$$\frac{\partial \Omega_{\mathrm{gf}}}{\partial A_0^a} = 0 \tag{135.66}$$

for every retained Cartan component. Equation (135.66) is the saddle form of the Gauss-law constraint. Its content is color neutrality; it is not the definition of a new grand-canonical ensemble.

Definition 135.44 (Neutrality problem for long-range global or gauged charges)**.** Let Q_{ext} be a conserved charge which is gauge invariant with respect to color, for example the electromagnetic charge after coupling QCD matter to a nondynamical or dynamical $U(1)$ gauge field. If the bulk state is required to be neutral with respect to this charge, introduce a source μ_{ext} in the finite-regulator ensemble and solve

$$n_{\mathrm{ext}}(T, \mu_B, \mu_{\mathrm{ext}}, \ldots) = \frac{\partial p}{\partial \mu_{\mathrm{ext}}} = 0 \tag{135.67}$$

after all charged species included in the physical problem, such as electrons in electrically neutral matter, have been included in the pressure. If Q_{ext} is itself gauged and long-ranged in the phase under consideration, the same condition is the thermodynamic form of the zero-mode Gauss law: a nonzero uniform charge density would require an electric field whose energy density is not compatible with an infinite homogeneous neutral bulk limit.

Remark 135.45 (Ideal CFL is electrically neutral at zero electric source). Assume $N_c = N_f = 3$, massless u, d, s quarks, a common quark chemical potential μ_q, and the ideal CFL symmetry realization described below: the gauge-invariant long-distance order preserves the diagonal vector $SU(3)$ flavor symmetry. Let

$$Q_{\mathrm{em}} = \mathrm{diag}\left(\frac{2}{3}, -\frac{1}{3}, -\frac{1}{3}\right) \in \mathfrak{su}(3)_V \tag{135.68}$$

act on the three flavor labels. Then the electric charge density conjugate to a source $\mu_Q Q_{\mathrm{em}}$ satisfies

$$n_Q(T, \mu_B, \mu_Q = 0) = 0 \tag{135.69}$$

inside the ideal CFL effective theory. Moreover the CFL orientation $U = 1$ in Controlled Approximation 135.57 is invariant under the simultaneous color and flavor transformation generated by Q_{em}, with the same matrix embedded in a Cartan subalgebra of color. The corresponding photon-gluon mixture is the unbroken rotated $U(1)$ gauge field of ideal CFL, with the relative sign fixed by the displayed transformation law $U \mapsto hUg^{-1}$.

The source μ_Q couples to the gauge-invariant vector flavor charge whose one-particle matrix is Q_{em}. At $\mu_Q = 0$, the assumed ideal CFL state is invariant under the diagonal vector $SU(3)$ flavor symmetry. Therefore the expectation value of every traceless generator of $\mathfrak{su}(3)_V$ vanishes. Since $\mathrm{tr}\, Q_{\mathrm{em}} = 2/3 - 1/3 - 1/3 = 0$, the density conjugate to $\mu_Q Q_{\mathrm{em}}$ is zero. This proves (135.69).

For the second assertion, recall the transformation law of the CFL orientation coordinate,

$$U \longmapsto h\, U\, g^{-1},$$

where h is a color gauge transformation and g is a locked vector flavor transformation. With $U = 1$, choosing

$$h = e^{i\alpha Q_{\mathrm{em}}}, \qquad g = e^{i\alpha Q_{\mathrm{em}}}$$

gives $hUg^{-1} = 1$. Hence this simultaneous transformation is unbroken. Equivalently, the infinitesimal action on U is $\delta U = iQ_{\mathrm{color}}U - iUQ_{\mathrm{flavor}}$, so $U = 1$ is fixed by the diagonal pair $Q_{\mathrm{color}} = Q_{\mathrm{flavor}} = Q_{\mathrm{em}}$. Because the color factor is gauged and the electromagnetic flavor factor is gauged when QED is included, the massless gauge boson is the corresponding linear combination of the photon and the two Cartan gluons. The statement is independent of the gauge choice used to display $U = 1$; the gauge-invariant content is the existence of the unbroken charge acting trivially on the CFL order.

Remark 135.46 (When neutrality becomes dynamical). Quark masses, weak equilibrium constraints, finite temperature, boundary conditions, and possible crystalline or meson-condensed order can break the ideal assumptions of Remark 135.45. Then neutrality is not a slogan attached to a named phase. It is the coupled problem consisting of the global neutrality equations (135.67), the gauge stationarity equations (135.66), and the variational equations for the order parameters retained in the controlled effective theory.

135.14 Fermi-Surface Stress from Masses and Neutrality

The ideal CFL limit has equal massless quarks and a common quark chemical potential. Real dense matter introduces flavor-dependent stresses through quark masses, electric neutrality, and weak-equilibrium constraints. The first controlled step is kinematic: determine how these deformations shift the location of the Fermi surface before asking which paired state minimizes the effective potential.

Definition 135.47 (Effective Fermi-surface mismatch)**.** Consider two quark species i, j with masses m_i, m_j and chemical potentials μ_i, μ_j. Assume

$$m_i^2,\ m_j^2,\ |\mu_i - \mu_j|\,\bar{\mu} \ll \bar{\mu}^2, \qquad \bar{\mu} = \frac{\mu_i + \mu_j}{2}.$$

For momenta in a common patch near $p = \bar{\mu}$, define the residual single-particle energies

$$\xi_a(p) = \sqrt{p^2 + m_a^2} - \mu_a, \qquad a = i, j. \tag{135.70}$$

The average residual energy and half-mismatch are

$$\bar{\xi}_{ij}(p) = \frac{\xi_i(p) + \xi_j(p)}{2}, \qquad \delta_{ij}^{\text{eff}} = \frac{\xi_i(p) - \xi_j(p)}{2} \quad \text{evaluated to leading order at } p = \bar{\mu}. \tag{135.71}$$

Mismatch expansion. The mass and chemical-potential contributions to the effective Fermi-surface mismatch are fixed by the following elementary expansion. In the regime of Definition 135.47,

$$p_{F,a} = \sqrt{\mu_a^2 - m_a^2} = \mu_a - \frac{m_a^2}{2\mu_a} + O\left(\frac{m_a^4}{\mu_a^3}\right), \tag{135.72}$$

and

$$\delta_{ij}^{\text{eff}} = -\frac{\mu_i - \mu_j}{2} + \frac{m_i^2 - m_j^2}{4\bar{\mu}} + O\left(\frac{m^4}{\bar{\mu}^3}, \frac{|\mu_i - \mu_j|\,m^2}{\bar{\mu}^2}\right). \tag{135.73}$$

Equivalently, the leading Fermi-momentum splitting is

$$p_{F,i} - p_{F,j} = (\mu_i - \mu_j) - \frac{m_i^2 - m_j^2}{2\bar{\mu}} + O\left(\frac{m^4}{\bar{\mu}^3}, \frac{|\mu_i - \mu_j|\,m^2}{\bar{\mu}^2}\right). \tag{135.74}$$

For a strange quark paired with a massless light quark at common chemical potential μ_q, the Fermi-momentum splitting scale is

$$|p_{F,s} - p_{F,\ell}| = \frac{m_s^2}{2\mu_q} + O(m_s^4/\mu_q^3), \tag{135.75}$$

while the pairwise half-mismatch is

$$|\delta_{s\ell}^{\text{eff}}| = \frac{m_s^2}{4\mu_q} + O(m_s^4/\mu_q^3). \tag{135.76}$$

The Fermi momentum solves $\sqrt{p_{F,a}^2 + m_a^2} = \mu_a$, giving the first identity in (135.72). Expanding the square root gives

$$\sqrt{\mu_a^2 - m_a^2} = \mu_a \sqrt{1 - \frac{m_a^2}{\mu_a^2}} = \mu_a - \frac{m_a^2}{2\mu_a} + O(m_a^4/\mu_a^3).$$

For the mismatch, expand (135.70) at $p = \bar{\mu}$:

$$\xi_a(\bar{\mu}) = \bar{\mu} - \mu_a + \frac{m_a^2}{2\bar{\mu}} + O(m_a^4/\bar{\mu}^3).$$

Taking half the difference between $a = i$ and $a = j$ gives (135.73); keeping the dependence of the denominator on μ_a rather than $\bar{\mu}$ produces the displayed mixed remainder. Subtracting (135.72) for i and j gives (135.74). The strange-light specializations set $m_\ell = 0$ and $\mu_s = \mu_\ell = \mu_q$.

Controlled Approximation 135.48 (Two-species stressed BCS comparison)**.** To isolate the local pairing stress, consider two species with a common density of states $N(0)$, a momentum-independent attractive interaction in a shell, zero temperature, and half-mismatch δ. Let Δ_0 be the BCS gap at $\delta = 0$, computed in the same cutoff scheme. Compare only the homogeneous paired state with equal paired Fermi momenta to the unpaired normal state with split Fermi surfaces. This is a local diagnostic for the onset of stress; it is not a complete variational analysis of CFL, gapless CFL, meson-condensed phases, or crystalline phases.

Clogston scale in the controlled two-species model. In Controlled Approximation 135.48, the zero-temperature grand-potential difference between the homogeneous paired state and the split normal state has the leading form

$$\Omega_{\text{pair}} - \Omega_{\text{normal}} = -\frac{1}{2}N(0)\Delta_0^2 + N(0)\delta^2 + O(\Delta_0^4/\Lambda_{\text{H}}^2). \tag{135.77}$$

Thus the homogeneous paired state ceases to win against the split normal state in this model when

$$|\delta| > \delta_{\text{C}}, \qquad \delta_{\text{C}} = \frac{\Delta_0}{\sqrt{2}}. \tag{135.78}$$

At $\delta = 0$, the BCS condensation energy in the constant-density shell is

$$\Omega_{\text{pair}}(\delta = 0) - \Omega_{\text{normal}}(\delta = 0) = -\frac{1}{2}N(0)\Delta_0^2 + O(\Delta_0^4/\Lambda_{\text{H}}^2),$$

which follows by substituting the gap equation into the mean-field energy functional: the logarithmic part of the interaction energy cancels the logarithmic part of the quasiparticle energy, leaving the displayed finite term. A normal state with half-mismatch δ fills one species up to energy $+\delta$ relative to the average Fermi surface and empties the other down to $-\delta$. With constant density of states, the energy lowering of the split normal state relative to the unsplit normal state is

$$-2N(0)\int_0^{|\delta|} \xi\, d\xi = -N(0)\delta^2,$$

where the factor 2 counts the filled particle interval for one species and the emptied hole interval for the other. Therefore, when the paired state remains unsplit, its grand potential relative to the split normal state is shifted upward by $N(0)\delta^2$, giving (135.77). Setting the leading difference to zero gives (135.78).

Remark 135.49 (Use of the stress scale in dense QCD). Equations (135.75) and (135.78) should be used with their hypotheses attached. The scale $m_s^2/(2\mu_q)$ is the leading strange-light Fermi-momentum splitting, while $m_s^2/(4\mu_q)$ is the pairwise half-mismatch in the two-species reduction. Full dense QCD also requires the neutrality equations of Section 135.13, the coupled gap equations in all pairing channels, and the possibility that the minimizing state is not spatially homogeneous.

135.15 Color Superconductivity and CFL Order

At asymptotically large μ_B, quarks near the Fermi surface interact through channels that can be attractive. The BCS mechanism is then a controlled weak-coupling instability of the Fermi surface, though the precise gap prefactor is sensitive to magnetic gluon exchange and screening.

Color factor of one-gluon exchange between two quarks. Let the $SU(N_c)$ fundamental generators be normalized as throughout the monograph,

$$\mathrm{tr}_\square(T^aT^b) = \delta^{ab}.$$

In the tensor product

$$\square \otimes \square = \mathrm{Sym}^2 \square \oplus \wedge^2\square,$$

the color operator $T_1^aT_2^a$ has eigenvalues

$$(T_1 \cdot T_2)_{\mathrm{Sym}^2 \square} = \frac{N_c - 1}{N_c}, \qquad (T_1 \cdot T_2)_{\wedge^2\square} = -\frac{N_c + 1}{N_c}.$$

With the Born-kernel sign convention in which the static exchange energy is proportional to

$$\mathcal{V}_R(\mathbf{q}) = \frac{g^2}{\mathbf{q}^2}\,(T_1 \cdot T_2)_R\,,$$

the two-index antisymmetric channel is attractive and the symmetric channel is repulsive. For $SU(3)$, the attractive channel is $\wedge^2\square = \overline{\square}$, with color factor $-4/3$, while the symmetric sextet has color factor $2/3$.

Let $C_2(R)$ denote the quadratic Casimir in the present trace convention. On an irreducible summand $R \subset \square \otimes \square$,

$$(T_1^a + T_2^a)(T_1^a + T_2^a) = C_2(R)\mathbf{1}.$$

Since each tensor factor is fundamental,

$$2T_1^aT_2^a = C_2(R) - 2C_2(\square).$$

The trace-delta convention doubles the more common half-trace Casimirs, so

$$C_2(\square) = \frac{N_c^2 - 1}{N_c},$$

$$C_2(\mathrm{Sym}^2 \square) = \frac{2(N_c + 2)(N_c - 1)}{N_c}, \qquad C_2(\wedge^2\square) = \frac{2(N_c - 2)(N_c + 1)}{N_c}.$$

Substitution gives

$$\frac{1}{2}\left[\frac{2(N_c + 2)(N_c - 1)}{N_c} - \frac{2(N_c^2 - 1)}{N_c}\right] = \frac{N_c - 1}{N_c},$$

and

$$\frac{1}{2}\left[\frac{2(N_c - 2)(N_c + 1)}{N_c} - \frac{2(N_c^2 - 1)}{N_c}\right] = -\frac{N_c + 1}{N_c}.$$

The sign statement follows from the displayed exchange-energy convention.

Controlled Approximation 135.50 (Leading-log magnetic gap problem)**.** Work at $T = 0$, $\mu_q \gg \Lambda_{\rm QCD}$, and $g(\mu_q) \ll 1$ in the high-density effective theory. Retain the attractive two-index antisymmetric quark-quark channel and the HDL-resummed soft gluon propagator. The leading logarithm in the gap equation is the part generated by nearly collinear transverse magnetic exchange with frequency transfer

$$\omega = p_0 - q_0$$

and transverse momentum $k_\perp$ satisfying

$$|\omega| \ll k_\perp \ll \mu_q.$$

In this region the Euclidean transverse propagator has the form

$$D_T(\omega, k_\perp) = \frac{1}{k_\perp^2 + \frac{\pi}{4} m_{D,\mu}^2 \frac{|\omega|}{k_\perp}} \left(1 + o(1)\right), \tag{135.79}$$

where $m_{D,\mu}$ is the dense HDL Debye mass computed above. Electric exchange and non-collinear magnetic exchange are not discarded; in the leading-log problem they contribute to the matching scale and to the prefactor, not to the coefficient of the $1/g$ exponent.

HDL magnetic leading-log gap equation. In the regime specified by Controlled Approximation 135.50, the gap in the attractive antisymmetric quark-quark channel obeys, to leading logarithmic accuracy,

$$\Delta(p_0) = \lambda_{\rm mag} \int_0^{\Lambda_{\rm M}} dq_0 \, \frac{\Delta(q_0)}{\sqrt{q_0^2 + \Delta(q_0)^2}} \log \frac{\Lambda_{\rm M}}{|p_0 - q_0|} + \mathcal{R}(p_0), \tag{135.80}$$

where $\mathcal{R}$ has no additional large collinear logarithm. The leading-log coefficient is

$$\lambda_{\rm mag} = \frac{g^2 C_{\rm qq}}{12\pi^2}, \qquad C_{\rm qq} = -\left(T_1 \cdot T_2\right)_{\wedge^2\square} = \frac{N_c + 1}{N_c}. \tag{135.81}$$

For $SU(3)$ in the monograph trace convention,

$$C_{\rm qq} = \frac{4}{3}, \qquad \lambda_{\rm mag} = \frac{g^2}{9\pi^2}. \tag{135.82}$$

The scale $\Lambda_{\rm M}$ is a matching scale of order μ_q times powers of g and numerical constants fixed only by next-to-leading matching. It is not determined by the leading-log equation alone.

The gap equation is the off-diagonal Schwinger–Dyson equation in Nambu–Gorkov variables, restricted to the shell of Definition 135.36. The radial residual momentum integral across the Fermi surface gives the BCS denominator

$$\int d\ell_\parallel \, \frac{1}{q_0^2 + \ell_\parallel^2 + \Delta(q_0)^2} = \frac{\pi}{\sqrt{q_0^2 + \Delta(q_0)^2}},$$

up to terms without a large logarithm. The angular integral is dominated by small scattering angle, equivalently by transverse momentum transfer

$$k_\perp \simeq \mu_q \theta.$$

For transverse gluons the HDL denominator (135.79) cuts off the collinear singularity in the infrared at

$$k_{\perp,\min}^3 \asymp m_{D,\mu}^2 |\omega|,$$

while the upper end is fixed by the edge of the patch or by hard matching, $k_{\perp,\max} \asymp \mu_q$. Thus the logarithmic part of the transverse integral is

$$\int_{k_{\perp,\min}}^{k_{\perp,\max}} \frac{dk_\perp}{k_\perp} = \frac{1}{3} \log \frac{\Omega_{\mathrm{M}}}{|\omega|} + O(1), \qquad \Omega_{\mathrm{M}} \asymp \frac{\mu_q^3}{m_{D,\mu}^2},$$

where the $O(1)$ and the precise constant multiplying Ω_{M} are not leading-log data. The factor $1/3$ is kept explicitly in the coefficient below. After this factor has been absorbed into λ_{mag}, the remaining energy matching scale is denoted Λ_{M} in (135.80).

The remaining coefficient is fixed by the Fermi-surface measure, the spin-current projection for transverse exchange, and the color projection. The shell measure and the radial propagator integral give the common prefactor $g^2 C_{\mathrm{qq}}/(4\pi^2)$ multiplying the transverse collinear integral. The Landau-damped magnetic integral contributes only one third of the logarithm of the energy transfer,

$$\int \frac{dk_\perp}{k_\perp} = \frac{1}{3} \log \frac{1}{|\omega|} + \text{terms independent of } |\omega|$$

at leading logarithmic accuracy. Thus the coefficient of the logarithmic energy integral is

$$\frac{g^2 C_{\mathrm{qq}}}{4\pi^2} \cdot \frac{1}{3} = \frac{g^2 C_{\mathrm{qq}}}{12\pi^2}.$$

The color factor is not an independent convention: by the two-quark color calculation above,

$$C_{\mathrm{qq}} = -\left(T_1 \cdot T_2\right)_{\wedge^2 \Box} = \frac{N_c + 1}{N_c}.$$

For $N_c = 3$ this gives $C_{\mathrm{qq}} = 4/3$, hence $\lambda_{\mathrm{mag}} = g^2/(9\pi^2)$. Terms from screened electric exchange, from non-collinear transverse exchange, and from quark self-energy do not change this leading collinear logarithm; they are included in $\mathcal{R}$ and in the matching scale.

Proposition 135.51 (Leading exponent of the magnetic color-superconducting gap)**.** *Consider the leading-log integral equation*

$$\Delta(p) = \lambda \int_{\Delta_0}^{\Lambda} \frac{dq}{q}\, \Delta(q) \log \frac{\Lambda}{\max(p,q)}, \qquad \Delta_0 \ll p, q \ll \Lambda, \tag{135.83}$$

with $\lambda > 0$. If the solution is nontrivial and varies only on the logarithmic scale, then

$$\log \frac{\Lambda}{\Delta_0} = \frac{\pi}{2\sqrt{\lambda}} + O(1). \tag{135.84}$$

Applying this to the $SU(3)$ HDL magnetic kernel in the monograph trace-delta convention gives the leading exponent

$$\Delta_0 = \Lambda_{\mathrm{M}} \exp\left[-\frac{3\pi^2}{2g} + O(1)\right]. \tag{135.85}$$

Equivalently, if $g_{\mathrm{ht}} = \sqrt{2}\, g$ denotes the coupling in the common half-trace convention, the exponent is

$$\exp\left[-\frac{3\pi^2}{\sqrt{2}\, g_{\mathrm{ht}}}\right].$$

Proof. Set

$$x = \log \frac{\Lambda}{p}, \qquad y = \log \frac{\Lambda}{q}, \qquad X = \log \frac{\Lambda}{\Delta_0}.$$

The leading-log kernel becomes

$$\log \frac{\Lambda}{\max(p,q)} = \min(x,y).$$

Equation (135.83) becomes

$$\Delta(x) = \lambda \int_0^X dy\, \min(x,y)\,\Delta(y) = \lambda \left[\int_0^x dy\, y\, \Delta(y) + x \int_x^X dy\, \Delta(y) \right].$$

Differentiating once gives

$$\Delta'(x) = \lambda \int_x^X dy\, \Delta(y),$$

and differentiating again gives the ordinary differential equation

$$\Delta''(x) + \lambda \Delta(x) = 0.$$

The integral equation imposes

$$\Delta(0) = 0, \qquad \Delta'(X) = 0.$$

The lowest nontrivial solution is therefore

$$\Delta(x) = A \sin(\sqrt{\lambda}\, x), \qquad \cos(\sqrt{\lambda}\, X) = 0,$$

so

$$X = \frac{\pi}{2\sqrt{\lambda}}$$

at leading logarithmic accuracy. Higher nodes give smaller gaps and do not describe the leading instability. Substituting $\lambda = \lambda_{\text{mag}} = g^2/(9\pi^2)$ from (135.82) gives

$$\frac{\pi}{2\sqrt{\lambda_{\text{mag}}}} = \frac{3\pi^2}{2g}.$$

The $O(1)$ in (135.85) records terms outside leading-log accuracy. The power of g multiplying μ_q in the prefactor and the numerical constant multiplying it are next-to-leading data, not consequences of this proposition. □

Exchange symmetry and the CFL tensor. For a local s-wave spin-zero pairing of two left-handed Weyl quarks, the coefficient multiplying

$$q_L^{ai\alpha} q_L^{bj\beta} \epsilon_{\alpha\beta}$$

is symmetric under the simultaneous interchange $(a,i) \leftrightarrow (b,j)$. Therefore a pair in the attractive color-antisymmetric channel must also be antisymmetric in flavor. For $N_c = N_f = 3$, the nondegenerate antisymmetric tensor

$$\epsilon^{abA} \epsilon_{ijA}$$

is invariant precisely under the diagonal subgroup obtained by identifying color and flavor $SU(3)$ rotations.

The fermion fields anticommute, while $\epsilon_{\alpha\beta}$ is antisymmetric. Hence

$$q_L^{bj\alpha} q_L^{ai\beta} \epsilon_{\alpha\beta} = -q_L^{ai\beta} q_L^{bj\alpha} \epsilon_{\alpha\beta} = q_L^{ai\alpha} q_L^{bj\beta} \epsilon_{\alpha\beta},$$

where the last equality relabels $\alpha \leftrightarrow \beta$ and uses $\epsilon_{\beta\alpha} = -\epsilon_{\alpha\beta}$. Thus the color-flavor coefficient must be symmetric under simultaneous exchange. Since the two-quark color calculation above identifies the attractive color channel as antisymmetric, the flavor tensor must be antisymmetric as well.

Let $U \in SU(3)_{\text{color}}$ and $V \in SU(3)_{\text{flavor}}$. The tensor $\epsilon^{abA}\epsilon_{ijA}$ may be viewed as the identity map from the color $\overline{\Box}$ carried by $\wedge^2\Box_{\text{color}}$ to the flavor $\overline{\Box}$ carried by $\wedge^2\Box_{\text{flavor}}$. It is preserved exactly when these two $\overline{\Box}$ actions agree, which is the diagonal $SU(3)$ condition after the chosen color-flavor identification. This is the color-flavor locking statement.

Definition 135.52 (CFL condensate data)**.** For $N_c = N_f = 3$, color-flavor-locked Higgs data are a source-selected or gauge-fixed representative of the gauge-covariant pairing tensor

$$\Phi^{ab}_{L,ij} = \langle q^a_{Li} C q^b_{Lj} \rangle_J = \Delta_L\, \epsilon^{abA}\epsilon_{ijA}, \qquad \Phi^{ab}_{R,ij} = \langle q^a_{Ri} C q^b_{Rj} \rangle_J = \Delta_R\, \epsilon^{abA}\epsilon_{ijA},$$

with color indices a, b, flavor indices i, j, and spinor charge conjugation matrix C. The subscript J means that an infinitesimal pairing source and the infinite-volume limit are used before the source is removed, exactly as in any spontaneous-order definition. The tensor is not a gauge-invariant local operator. Its gauge-invariant content is the Higgs pattern of the color gauge field, the residual global diagonal symmetry, and the long-distance order of color-singlet composites built from the pairing tensor. The displayed tensor locks color and flavor: simultaneous color and flavor rotations preserving the same diagonal $SU(3)$ leave the representative invariant.

Definition 135.53 (Gauge-invariant CFL diagnostics)**.** Let

$$\varphi_L \in \overline{\Box}_{\text{color}} \otimes \overline{\Box}_L, \qquad \varphi_R \in \overline{\Box}_{\text{color}} \otimes \overline{\Box}_R$$

denote the antisymmetric spin-zero diquark composite obtained from two left-handed or two right-handed quark fields:

$$(\varphi_L)^A{}_I(x) = \frac{1}{2}\epsilon^A{}_{ab}\epsilon_I{}^{ij}\, q^a_{Li}(x) C q^b_{Lj}(x), \qquad (\varphi_R)^A{}_{\bar{I}}(x) = \frac{1}{2}\epsilon^A{}_{ab}\epsilon_{\bar{I}}{}^{ij}\, q^a_{Ri}(x) C q^b_{Rj}(x). \tag{135.86}$$

Here A is an anti-fundamental color index, I is an anti-fundamental $SU(3)_L$ flavor index, and $\bar{I}$ is an anti-fundamental $SU(3)_R$ flavor index. Each quark has baryon charge $1/3$, hence φ_L and φ_R have baryon charge $2/3$.

The following operators are gauge invariant and carry the physical symmetry information of the CFL phase:

$$\mathcal{B}_L = \frac{1}{3!}\epsilon_{ABC}\epsilon^{IJK}(\varphi_L)^A{}_I(\varphi_L)^B{}_J(\varphi_L)^C{}_K, \qquad \mathcal{B}_R = \frac{1}{3!}\epsilon_{ABC}\epsilon^{\bar{I}\bar{J}\bar{K}}(\varphi_R)^A{}_{\bar{I}}(\varphi_R)^B{}_{\bar{J}}(\varphi_R)^C{}_{\bar{K}}, \tag{135.87}$$

and

$$\Sigma^I{}_{\bar{J}} = (\varphi_L^\dagger)^I{}_A(\varphi_R)^A{}_{\bar{J}}. \tag{135.88}$$

The operators $\mathcal{B}_L, \mathcal{B}_R$ are color and flavor singlets with baryon charge 2. The operator Σ is color invariant, baryon neutral, and transforms as

$$\Sigma \longmapsto g_L \, \Sigma \, g_R^{-1} \qquad (g_L, g_R) \in SU(3)_L \times SU(3)_R.$$

Finally, for a path γ from y to x, the Wilson-line completion

$$G^I_{L\,J}(x, y; \gamma) = \left\langle (\varphi_L^\dagger)^I{}_A(x) \ \left[W_{\overline{\square}}(\gamma)\right]^A{}_B \, (\varphi_L)^B{}_J(y) \right\rangle \tag{135.89}$$

is gauge invariant but path dependent. It is not a new local order parameter; it is a gauge-invariant way to test the long-distance order encoded by a gauge-covariant diquark field.

Proposition 135.54 (Gauge averaging and physical CFL order)**.** *In a finite-volume regularized gauge theory with a gauge-invariant action, measure, boundary condition, and source, the expectation value of any local operator transforming in a nontrivial irreducible representation of the color gauge group is zero. Consequently the gauge-covariant diquark one-point function $\langle \varphi_L \rangle$ is not itself a physical local order parameter. The CFL symmetry realization is instead detected by the gauge-invariant composites of Definition 135.53: long-distance order in $\mathcal{B}_{L,R}$ diagnoses baryon superfluid order, while long-distance order in Σ diagnoses*

$$SU(3)_L \times SU(3)_R \longrightarrow SU(3)_{\text{diagonal}}.$$

Proof. Let O be a local operator whose color indices span a finite-dimensional representation ρ of $SU(3)_{\text{color}}$. Gauge invariance of the regularized functional integral gives, for every constant color transformation $h \in SU(3)$,

$$\langle O \rangle = \rho(h) \langle O \rangle.$$

Averaging over h with normalized Haar measure gives

$$\langle O \rangle = \int_{SU(3)} dh \, \rho(h) \langle O \rangle.$$

The Haar average is the projection onto the invariant subspace of ρ. If ρ has no singlet component, this projection is zero. The diquark field φ_L carries the $\overline{\square}_{\text{color}}$ representation, so its gauge-invariant finite-volume expectation vanishes unless one first fixes a gauge or uses a gauge-covariant source-selected representative as in Definition 135.52.

The composites in Definition 135.53 are different. For $\mathcal{B}_L$, the color indices are contracted with ϵ_{ABC}, and $\det h = 1$ for $h \in SU(3)$, so the color factor is invariant. The flavor contraction is likewise invariant under $SU(3)_L$, and the baryon charge is

$$3 \cdot \frac{2}{3} = 2.$$

For $\mathcal{B}_R$, the right-handed color indices are contracted by the same ϵ_{ABC} tensor and the flavor indices by the right-handed ϵ^{ijk}, so the operator is again an $SU(3)_{\text{color}}$ singlet of baryon charge 2. Therefore a nonzero source-selected long-distance limit of the two-point function of $\mathcal{B}_L$ or $\mathcal{B}_R$ is a gauge-invariant statement that $U(1)_B$ is spontaneously broken.

For Σ, the color anti-fundamental index of φ_R is contracted with the conjugate color index of $\varphi_L^\dagger$, so the operator is color invariant. Its baryon charge is

$$-\frac{2}{3} + \frac{2}{3} = 0.$$

Since $\varphi_L^\dagger$ transforms in the fundamental of $SU(3)_L$ and φ_R in the anti-fundamental of $SU(3)_R$, Σ transforms as $g_L \Sigma g_R^{-1}$. A source-selected expectation proportional to the identity leaves only $g_L = g_R$, which is the diagonal chiral subgroup. The Wilson-line correlator (135.89) is gauge invariant because the endpoint transformations of the Wilson line cancel the color transformations of the two diquark insertions. Its path dependence is the price of using a nonlocal completion of a gauge-covariant field, not an additional physical symmetry. □

Remark 135.55 (Physical CFL Goldstone count). Assume $N_c = N_f = 3$, ignore the anomalous axial $U(1)$, and suppose the infinite-volume dense state has the gauge-invariant CFL long-distance order described in Definition 135.53 and Proposition 135.54. The physical global symmetry breaking pattern is

$$SU(3)_L \times SU(3)_R \times U(1)_B \longrightarrow SU(3)_{\mathrm{diagonal}},$$

and the number of physical Nambu–Goldstone modes before quark-mass effects are included is

$$(8 + 8 + 1) - 8 = 9.$$

The color $SU(3)$ is gauged. Directions that rotate the condensate by a pure color transformation are Higgs directions of the gauge field, not generators of physical global particles. The remaining exact global generators, in the massless and anomaly-idealized limit stated in the proposition, span

$$\mathfrak{su}(3)_L \oplus \mathfrak{su}(3)_R \oplus \mathfrak{u}(1)_B.$$

The CFL tensor identifies a diagonal $\mathfrak{su}(3)$ subgroup with the unbroken simultaneous flavor rotation, as shown in the exchange-symmetry calculation above. The dimension of the broken global coset is therefore $8 + 8 + 1 - 8 = 9$. The conclusion is only a group-theoretic consequence of the source-selected CFL order. Establishing which region of QCD realizes this order requires control of dense QCD, where direct lattice importance sampling is obstructed by the finite-density sign-problem mechanism described above.

Definition 135.56 (Gauge-invariant static screening diagnostics in dense QCD)**.** Let $x = (0, \mathbf{x})$, $y = (0, \mathbf{y})$, and let γ be a spatial path from y to x. For the canonically normalized color gauge potential $a_\mu = a_\mu^a T^a$, with field strength $\mathfrak{f}_{\mu\nu} = \mathfrak{f}_{\mu\nu}^a T^a$, define the Wilson-line completed static electric and magnetic correlators

$$C_E(r;\gamma) = \sum_{i=1}^{3} \big\langle \mathrm{tr}\big[\mathfrak{f}_{0i}(x)\, W_\square(\gamma)\, \mathfrak{f}_{0i}(y)\, W_\square(\gamma)^{-1}\big]\big\rangle_{\mathrm{conn}}\,,$$

$$C_M(r;\gamma) = \frac{1}{2} \sum_{i,j=1}^{3} \big\langle \mathrm{tr}\big[\mathfrak{f}_{ij}(x)\, W_\square(\gamma)\, \mathfrak{f}_{ij}(y)\, W_\square(\gamma)^{-1}\big]\big\rangle_{\mathrm{conn}}\,, \qquad r = |\mathbf{x} - \mathbf{y}|. \tag{135.90}$$

The static electric and magnetic screening exponents are the leading large-r exponential decay rates, when they exist after the thermodynamic and continuum limits,

$$m_E = -\lim_{r\to\infty} \frac{1}{r} \log|C_E(r;\gamma_r)|, \qquad m_M = -\lim_{r\to\infty} \frac{1}{r} \log|C_M(r;\gamma_r)|, \tag{135.91}$$

for a specified family of paths γ_r. In weakly coupled phases these exponents are computed by a gauge-fixed long-distance effective action, but equations (135.90)–(135.91) are the gauge-invariant diagnostic.

Controlled Approximation 135.57 (CFL Higgs screening effective action)**.** In a dense state with the CFL long-distance order of Definition 135.53, introduce a local gauge-covariant coordinate $U(x) \in SU(3)$ for the color-flavor locked orientation. Under a color gauge transformation $h(x)$ and a global locked flavor transformation g, it transforms as

$$U(x) \longmapsto h(x)U(x)g^{-1}.$$

The leading static screening part of the long-distance effective action is

$$\mathcal{L}_{\mathrm{H}} = \frac{F_H^2}{2}\,\mathrm{tr}\Big[(D_0U)^\dagger D_0U\Big] - \frac{F_H^2 v_H^2}{2}\,\mathrm{tr}\Big[(D_iU)^\dagger D_iU\Big]\,, \tag{135.92}$$

where

$$D_\mu U = \partial_\mu U - ig\,a_\mu^a T^a U, \qquad \mathrm{tr}_\square(T^aT^b) = \delta^{ab}.$$

The constants $F_H > 0$ and $0 < v_H \le 1$ are low-energy coefficients of the dense medium. Symmetry fixes the tensor structure of (135.92), not the microscopic numerical value of F_H or v_H.

CFL Higgs screening mass matrix. In the CFL Higgs-screening effective action, the color-flavor-locked background gives equal screening masses to all eight color gauge fields. More precisely, within Controlled Approximation 135.57, one has

$$(m_E^2)^{ab} = g^2F_H^2\,\delta^{ab}, \qquad (m_M^2)^{ab} = g^2F_H^2v_H^2\,\delta^{ab}. \tag{135.93}$$

These masses are coefficients in the gauge-fixed quadratic effective action whose gauge-invariant content is the exponential screening described by Definition 135.56.

Use the gauge freedom to set $U = 1$ locally; this is unitary gauge for the Higgs-coordinate chart, not a definition of a gauge-invariant operator. Then

$$D_\mu U = -ig\,a_\mu^a T^a.$$

Substitution into (135.92) gives

$$\mathcal{L}_{\mathrm{H}}^{(2)} = \frac{g^2F_H^2}{2}a_0^a a_0^b\,\mathrm{tr}(T^aT^b) - \frac{g^2F_H^2v_H^2}{2}a_i^a a_i^b\,\mathrm{tr}(T^aT^b).$$

The trace convention of the chapter makes $\mathrm{tr}(T^aT^b) = \delta^{ab}$. Therefore the quadratic coefficients are exactly the matrices displayed in (135.93). The equality of the eight eigenvalues follows from the unbroken diagonal $SU(3)$: the gluons form the adjoint representation of this diagonal group, and the quadratic mass operator is an invariant bilinear form on the adjoint. Since the adjoint of $SU(3)$ is simple, this invariant form is proportional to δ^{ab}, and the direct computation fixes the proportionality constant.

Proposition 135.58 (Rotated electromagnetic response in ideal CFL)**.** *Couple the ideal CFL effective coordinate to a dynamical electromagnetic field A_μ with coupling e and flavor generator*

$$Q_{\mathrm{em}} = \mathrm{diag}\left(\frac{2}{3}, -\frac{1}{3}, -\frac{1}{3}\right).$$

In the same trace-delta convention as Controlled Approximation 135.57, embed Q_{em} in the color Cartan subalgebra and write

$$q_Q^2 = \mathrm{tr}(Q_{\mathrm{em}}^2) = \frac{2}{3}, \qquad \widehat{Q} = \frac{Q_{\mathrm{em}}}{q_Q}, \qquad a_\mu^Q = \mathrm{tr}(a_\mu\widehat{Q}).$$

The gauge-covariant derivative is

$$D_\mu U = \partial_\mu U - ig\, a_\mu U + ie\, A_\mu U Q_{\rm em}. \tag{135.94}$$

In unitary gauge $U = 1$, the electric quadratic form in the (a_0^Q, A_0) sector is

$$\frac{F_H^2}{2} \begin{pmatrix} a_0^Q & A_0 \end{pmatrix} \begin{pmatrix} g^2 & -geq_Q \\ -geq_Q & e^2 q_Q^2 \end{pmatrix} \begin{pmatrix} a_0^Q \\ A_0 \end{pmatrix}. \tag{135.95}$$

The determinant of this matrix is zero. The massless long-range gauge field is the rotated photon

$$\widetilde{A}_\mu = \frac{gA_\mu + eq_Q a_\mu^Q}{\sqrt{g^2 + e^2 q_Q^2}}, \tag{135.96}$$

while the orthogonal combination

$$\widetilde{G}_\mu = \frac{ga_\mu^Q - eq_Q A_\mu}{\sqrt{g^2 + e^2 q_Q^2}} \tag{135.97}$$

has electric screening mass squared

$$m^2_{\widetilde{G},E} = F_H^2 (g^2 + e^2 q_Q^2).$$

The spatial response has the same null and massive eigenvectors, with the massive eigenvalue multiplied by v_H^2. The seven color directions orthogonal to $\widehat{Q}$ retain the CFL Higgs screening masses in (135.93).

Thus ideal CFL is not a superconductor for the unbroken rotated $U(1)$ gauge field. It is a medium in which all eight color directions are screened, one of them after mixing with the ordinary photon, while the orthogonal photon-gluon combination remains long-ranged.

Proof. The right action in (135.94) is the gauged version of the locked flavor transformation $U \mapsto hUg^{-1}$. In the local chart $U = 1$,

$$D_\mu U = -iga_\mu + ieA_\mu Q_{\rm em}.$$

Decompose the color gauge field as

$$a_\mu = a_\mu^\perp + a_\mu^Q \widehat{Q}, \qquad \mathrm{tr}(a_\mu^\perp \widehat{Q}) = 0.$$

Then

$$\mathrm{tr}\big[(ga_\mu - eA_\mu Q_{\rm em})^2\big] = g^2\, \mathrm{tr}\Big[(a_\mu^\perp)^2\Big] + (ga_\mu^Q - eq_Q A_\mu)^2.$$

This gives (135.95) for the electric part of the effective action and the corresponding factor of v_H^2 for the spatial part. The two-by-two matrix has

$$\det \begin{pmatrix} g^2 & -geq_Q \\ -geq_Q & e^2 q_Q^2 \end{pmatrix} = g^2 e^2 q_Q^2 - g^2 e^2 q_Q^2 = 0,$$

and trace $g^2 + e^2 q_Q^2$. Its null vector is proportional to (eq_Q, g), giving $\widetilde{A}_\mu$, and its nonzero eigenvector is proportional to $(g, -eq_Q)$, giving $\widetilde{G}_\mu$. The remaining color components are orthogonal to $Q_{\rm em}$, so they do not mix with the photon and keep the color-Higgs screening coefficients of (135.93). $\square$

Definition 135.59 (CFL collective fields)**.** Ignoring quark-mass effects and the anomalous axial $U(1)$, the gauge-invariant low-energy collective fields of the CFL phase are:

$$\Sigma(x) \in SU(3), \qquad \Sigma \longmapsto g_L \Sigma g_R^{-1},$$

for the chiral octet, and

$$e^{i\phi_B(x)} \in U(1)_B, \qquad \phi_B \longmapsto \phi_B + \alpha_B,$$

for the baryon superfluid phase. The leading real-time effective Lagrangian in the rest frame of the dense medium is

$$\mathcal{L}_{\mathrm{CFL,NGB}} = \frac{F_\pi^2}{4}\,\mathrm{tr}\Big[\partial_0\Sigma\,\partial_0\Sigma^\dagger - v_\pi^2\partial_i\Sigma\,\partial_i\Sigma^\dagger\Big] + \frac{F_B^2}{2}\left[(\partial_0\phi_B)^2 - v_B^2(\partial_i\phi_B)^2\right] + \cdots. \qquad (135.98)$$

The constants F_π, F_B, v_π, v_B are dense-medium low-energy coefficients. The ellipsis contains higher derivatives, mass-source terms, and anomaly-suppressed effects.

Physical collective-mode content of the ideal CFL coordinate chart. Under the assumptions encoded in Definition 135.59, the ideal CFL effective coordinate chart contains eight chiral Nambu–Goldstone modes and one baryon superfluid phonon. To quadratic order their dispersion relations are

$$\omega^2 = v_\pi^2\mathbf{k}^2 \quad \text{for the chiral octet,} \qquad \omega^2 = v_B^2\mathbf{k}^2 \quad \text{for the baryon phonon.} \qquad (135.99)$$

The eight color-orientation modes are not additional physical Nambu–Goldstone particles; in the screening effective action they are the fields removed by the Higgs mechanism and are represented physically by the eight screened color gauge sectors of the CFL Higgs-screening calculation above.

The logical input is the effective coordinate chart; the independent dense-QCD problem is the construction and control of that chart from a regulated QCD definition. The finite calculation is as follows. Write

$$\Sigma(x) = \exp\left(\frac{2i\pi^a(x)\tau^a}{F_\pi}\right), \qquad \mathrm{tr}(\tau^a\tau^b) = \delta^{ab},$$

where $a = 1, \ldots, 8$. Expanding (135.98) to quadratic order gives

$$\mathcal{L}_\pi^{(2)} = \frac{1}{2}\sum_{a=1}^{8}\left[(\partial_0\pi^a)^2 - v_\pi^2(\partial_i\pi^a)^2\right],$$

after the displayed normalization of the exponential is used. The Euler equation is

$$\partial_0^2\pi^a - v_\pi^2\nabla^2\pi^a = 0,$$

so a plane wave has $\omega^2 = v_\pi^2\mathbf{k}^2$. The field $\Sigma \in SU(3)$ has dimension 8, hence the chiral sector contains eight modes.

The baryon phase part of (135.98) gives

$$\partial_0^2\phi_B - v_B^2\nabla^2\phi_B = 0,$$

and therefore the second dispersion relation in (135.99). This is one real compact phase field. Finally, the color orientation U in Controlled Approximation 135.57 has eight local coordinates, but it transforms under local color. The unitary-gauge computation in the CFL Higgs-screening calculation above shows that those coordinates are not gauge-invariant massless particles; they supply the longitudinal screening components of the eight color gauge sectors. Thus the physical gapless count is $8 + 1 = 9$, matching Remark 135.55.

135.16 Anomaly Matching in the CFL Phase

The preceding CFL discussion identified gauge-invariant order diagnostics and the physical collective fields. A further consistency test is the response to background fields for exact global symmetries. This test is independent of weak-coupling quasiparticle language: if the same microscopic QCD theory is followed to long distances in a CFL phase, the background anomaly class of the exact symmetry must be represented by the CFL infrared fields.

Definition 135.60 (Backgrounds and normalization for CFL anomaly matching)**.** Work with massless $N_f = N_c = 3$ QCD and with the connected continuous global symmetry generated by

$$SU(3)_L \times SU(3)_R \times U(1)_B,$$

excluding the anomalous singlet axial rotation. Let A_L, A_R be background $SU(3)_L$ and $SU(3)_R$ connections, and let B be the $U(1)_B$ background connection. The quark baryon charge is normalized as

$$q_B(q) = \frac{1}{3}.$$

In this anomaly-matching subsection, flavor traces are taken in the half-trace convention

$$\mathrm{tr_f}(t^a t^b) = \frac{1}{2}\delta^{ab},$$

the same convention used in the WZW level-matching argument leading to (55.71). This is only a convention for anomaly traces; the trace-delta convention used elsewhere in this chapter is related by $\tau^a = \sqrt{2}\, t^a$.

Lemma 135.61 (UV continuous flavor anomaly polynomial)**.** *With the conventions of Definition 135.60, the local six-form anomaly polynomial of the massless quarks, restricted to $SU(3)_L \times SU(3)_R \times U(1)_B$ backgrounds and omitting purely gravitational terms, is*

$$I_6^{\mathrm{UV}} = \frac{N_c}{6(2\pi)^3}\left[\mathrm{tr_f}(F_L^3) - \mathrm{tr_f}(F_R^3)\right] + \frac{N_c q_B}{2(2\pi)^3} F_B \wedge \left[\mathrm{tr_f}(F_L^2) - \mathrm{tr_f}(F_R^2)\right], \tag{135.100}$$

where F_L, F_R, F_B are the corresponding curvatures. For $N_c = 3$ and $q_B = 1/3$, the mixed coefficient is

$$N_c q_B/2 = \frac{1}{2}. \tag{135.101}$$

Proof. The left-handed quark field consists of N_c color copies of a left-handed Weyl fermion in the fundamental representation of $SU(3)_L$ with baryon charge q_B. For a single left-handed Weyl fermion in a flavor bundle with connection A, tensored with a $U(1)$ line of charge q_B, the relevant degree-six Chern-character terms are

$$\frac{1}{6(2\pi)^3}\,\mathrm{tr_f}(F^3) + \frac{q_B}{2(2\pi)^3} F_B \wedge \mathrm{tr_f}(F^2). \tag{135.102}$$

The terms proportional to $F_B^2\,\mathrm{tr_f}\,F$ vanish because the flavor connection is $SU(3)$-valued, and the pure F_B^3 term cancels between the left- and right-handed components of a vectorlike Dirac quark. Multiplication by the N_c color copies gives the left contribution. A right-handed Weyl fermion with the same representation and charge contributes with the opposite sign to the four-dimensional chiral anomaly polynomial, giving the minus signs in (135.100). Substituting $q_B = 1/3$ gives (135.101). ∎

Proposition 135.62 (CFL realization of the continuous anomaly)**.** *Assume the ideal CFL infrared field content of Definition 135.59: a chiral field $\Sigma \in SU(3)$ with $\Sigma \mapsto g_L \Sigma g_R^{-1}$, and a compact baryon phase ϕ_B which transforms under a $U(1)_B$ background gauge transformation by*

$$B \mapsto B + d\lambda_B, \qquad \phi_B \mapsto \phi_B + \lambda_B. \tag{135.103}$$

Then the CFL infrared effective action can represent the full local anomaly polynomial (135.100) as follows.

First, the gauged Wess–Zumino–Witten functional of Σ has level

$$n = N_c = 3 \tag{135.104}$$

and matches the pure nonabelian chiral part

$$\frac{N_c}{6(2\pi)^3}\left[\mathrm{tr}_{\mathrm{f}}(F_L^3) - \mathrm{tr}_{\mathrm{f}}(F_R^3)\right]. \tag{135.105}$$

Second, define the invariant one-form

$$D_B\phi_B = d\phi_B - B. \tag{135.106}$$

On a five-dimensional extension X_5 of spacetime, the local inflow representative

$$\omega_{5,B}^{\mathrm{CFL}} = -\frac{D_B\phi_B}{2\pi} \wedge \frac{\mathrm{tr}_{\mathrm{f}}(F_L^2) - \mathrm{tr}_{\mathrm{f}}(F_R^2)}{2(2\pi)^2} \tag{135.107}$$

satisfies

$$d\omega_{5,B}^{\mathrm{CFL}} = \frac{F_B}{2\pi} \wedge \frac{\mathrm{tr}_{\mathrm{f}}(F_L^2) - \mathrm{tr}_{\mathrm{f}}(F_R^2)}{2(2\pi)^2}. \tag{135.108}$$

This is exactly the mixed $U(1)_B$-flavor term in (135.100) for $N_c q_B = 1$.

Proof. The field Σ has the same transformation law as the ordinary chiral field used in the WZW level-matching construction of Chapter 55. The anomaly-matching argument uses only the number of microscopic color copies and the $SU(N_f)_L$ background anomaly coefficient; it does not use the zero-density chiral condensate as the microscopic order parameter. Therefore the same level condition applies in the CFL phase:

$$n = N_c.$$

For $N_c = 3$ this gives (135.104). The gauged WZW functional at this level has precisely the pure nonabelian chiral descent class (135.105).

It remains to check the terms involving the baryon background. Under (135.103), the combination $D_B\phi_B = d\phi_B - B$ is invariant. Its exterior derivative is

$$d(D_B\phi_B) = -F_B. \tag{135.109}$$

The Bianchi identities for the background flavor curvatures give

$$d\ \mathrm{tr}_{\mathrm{f}}(F_L^2) = 0, \qquad d\ \mathrm{tr}_{\mathrm{f}}(F_R^2) = 0.$$

Taking the exterior derivative of (135.107) and using (135.109) gives (135.108). Comparing with (135.100), and using $N_c q_B = 1$, shows equality of the mixed anomaly polynomial. The vector diagonal subgroup is anomaly-free in both descriptions: setting $F_L = F_R$ makes both (135.105) and (135.108) vanish. $\square$

Remark 135.63 (Goldstone normalization and local order parameters). The scalar ϕ_B in (135.103) is normalized by the background $U(1)_B$ gauge parameter. This normalization should not be confused with the charge of a particular microscopic composite used to diagnose the phase. For example, with $q_B(q) = 1/3$, a local gauge-invariant determinant built from three diquark factors has baryon charge 2. Such an operator is locally represented by an appropriate integer-charge function of the compact Goldstone coordinate. The anomaly matching statement uses the coupling of the compact Goldstone circle to the background $U(1)_B$ bundle; it is not a statement that a chosen local order operator has unit baryon charge.

135.17 Comparison of Confinement Criteria

Several observables are often described by the same word "confinement." In this monograph they are kept distinct.

1. The zero-temperature Wilson-loop area law is a statement about the large-loop asymptotics of a gauge-invariant loop operator and the static source potential.
2. The thermal Polyakov-loop order parameter is a statement about center symmetry and the free energy of one static external charge.
3. The 't Hooft loop probes magnetic or center-twist sectors and is dual, in favorable regimes, to Wilson-loop ordering.
4. The center-vortex picture is a proposed infrared mechanism in which center-valued magnetic disorder controls the area law.
5. The dual-superconductor picture is a proposed infrared mechanism in which condensation of magnetically charged objects squeezes electric flux.

The first two items have clean operator definitions in lattice gauge theory. The last three can be developed into sharp statements only after the relevant line operators, disorder sectors, and continuum limits have been specified. Their value in this monograph is not as slogans, but as candidate structures to be tested in examples and connected to the Wilsonian and BV definitions of gauge theory developed earlier.

This comparison is the endpoint of the chapter's phase-specification discipline. A Polyakov loop, a Wilson loop, a diquark diagnostic, a transport coefficient, and a susceptibility are not interchangeable signals: they live in different limiting procedures and respond to different sources. When two such signals are correlated in a regime of QCD, that correlation is a dynamical conclusion to be proved, simulated with controlled errors, or recorded as a conjectural continuation. It is not part of the definition of the phase.

Open Problem 135.64 (Continuum QCD phase diagram with controlled errors). Construct the continuum QCD phase diagram in the (T, μ_B, m) variables with mathematically controlled thermodynamic and continuum limits, including the order of the pure-Yang–Mills deconfinement transition, the chiral transition in massless limits, the physical crossover region, the existence or nonexistence of a critical endpoint, and the color-superconducting regions at high baryon density.

Part XI

Constructive, Lattice, and Numerical Quantum Field Theory

Chapter 136

Constructive Status and Routes to Continuum QFT

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Constructive QFT asks for existence theorems for the objects used elsewhere in the monograph: Schwinger functions, Wightman functions, Hilbert spaces, local fields or local observable algebras, symmetry actions, positivity, and continuum limits. A regulator is part of a construction only after a limit is specified and the limiting object is shown to satisfy the required axioms or replacement framework.

136.1 Three Constructive Routes

Definition 136.1 (Constructive realization)**.** A constructive realization of a QFT in a specified framework consists of: correlation functions or an observable net; positivity or reflection positivity; covariance or the declared background-functorial replacement; locality; a reconstruction theorem or direct Hilbert-space construction; and control of the limiting procedure in a topology strong enough to verify those properties.

The main routes developed in this volume are cluster and phase-cell expansions, which construct measures and Schwinger functions by estimates; lattice constructions, which define finite systems exactly and study scaling limits; and stochastic quantization or singular SPDE, which construct invariant Euclidean measures through dynamics. These routes overlap in low-dimensional scalar examples. Their comparison is part of the content: agreement of independent constructions requires a separate identification theorem in the framework where the limiting objects are compared.

136.2 Status Catalog

Theory or regime	Constructive status	Framework boundary
Free scalar, spinor, and generalized-free fields	Constructed Wightman and Euclidean examples with explicit correlation functions and positive Hilbert-space reconstruction.	They calibrate the frameworks; interacting local dynamics require additional construction.
$P(\phi)_2$, including ϕ_2^4	Constructed non-Gaussian Euclidean and Wightman models for bounded-below polynomial interactions after Wick ordering and local renormalization.	Cluster expansion and Euclidean measure methods verify OS/Wightman properties in two spacetime dimensions.
ϕ_3^4, massive regime	Constructed non-Gaussian scalar models with mass, coupling, and vacuum-energy renormalization.	This is the fundamental three-dimensional scalar constructive example; the continuum measure is singular with respect to the Gaussian reference.
Sine–Gordon in two dimensions	Constructed in parameter ranges where the vertex interaction is renormalizable and the infrared setup is controlled.	The bosonization relation to massive Thirring-type descriptions requires its own operator and Hilbert-space identifications.
Yukawa$_2$ and related scalar–fermion models	Constructive results exist for specific two-dimensional models after fixing fermionic determinants or Pfaffians, Wick ordering, and ultraviolet renormalization.	Each theorem has model-dependent hypotheses; the Lagrangian label alone does not define a completed construction.
Gross–Neveu$_2$, massive asymptotically free regime	Constructive renormalization-group constructions exist for massive two-dimensional fermionic models.	They are important tests of rigorous asymptotic freedom in a non-gauge setting.
Two-dimensional Yang–Mills	Constructed by heat-kernel, holonomy, and projective-limit methods for compact gauge group.	This is a gauge-theory construction with no local propagating gluons; it does not settle four-dimensional Yang–Mills.
Stochastic quantization of ϕ_2^4 and ϕ_3^4	Constructed through Da Prato–Debussche, regularity structures, paracontrolled distributions, and related singular-SPDE methods, with renormalized invariant measures.	The SPDE route gives a dynamic construction of Euclidean measures and a precise algebraic meaning to the counterterms in the stochastic equation.
Three-dimensional Ising scaling limit as a CFT	Open as a constructive conformal field theory with full operator algebra and OS/Wightman reconstruction.	Numerical and bootstrap data are extremely constraining, but a continuum CFT construction remains a separate theorem.
ϕ_D^4, $D \geq 5$, standard positive lattice route	Triviality theorems force Gaussian scaling limits in the standard critical Ising/$\lambda\phi^4$ family.	This rules out that constructive route to an interacting scalar continuum limit above four dimensions.
ϕ_4^4, standard critical Ising/$\lambda\phi^4$ route	Marginal triviality theorems give Gaussian scaling limits for the standard reflection-positive critical problem.	The logically different possibility of another four-dimensional UV-complete QFT agreeing with formal ϕ_4^4 perturbation theory to all orders remains a separate open question.
Four-dimensional pure Yang–Mills	Finite Wilson lattices are rigorous compact-group integrals; continuum existence with a mass gap is the Clay Millennium problem.	The desired limit must construct gauge-invariant Schwinger functions or an equivalent local observable theory satisfying positivity, locality, and spectral properties.
QCD and the Standard Model	Available nonperturbative definitions are hybrid: lattice gauge theory for QCD-like sectors, perturbative and effective descriptions for electroweak and heavy-scale observables, and experimentally fixed parameters.	A single complete constructive continuum theorem for the full Standard Model is presently an open construction.

Table 136.1: Constructive status of representative QFT regimes. The entries separate completed constructions, triviality theorems, finite-regulator definitions, and open continuum-limit problems.

Reference anchors for Table 136.1. The scalar constructive line runs through Nelson, Glimm–Jaffe, Glimm–Jaffe–Spencer, Simon, Feldman–Osterwalder, Magnen–Seneor, Brydges, Fröhlich, and Sokal. The two-dimensional fermionic and asymptotically free examples include work of Feldman, Magnen, Rivasseau, and Seneor. Rigorous two-dimensional Yang–Mills may be approached through Driver, Sengupta, Levy, and related heat-kernel/holonomy constructions. The stochastic route uses Da Prato–Debussche, Hairer, Gubinelli–Imkeller–Perkowski, Kupiainen, Mourrat–Weber, and later singular-SPDE developments. Scalar triviality above and at four dimensions is represented by Aizenman, Fröhlich, and Aizenman–Duminil-Copin.

136.3 Stochastic Quantization as a Constructive Route

For Euclidean scalar ϕ^4, stochastic quantization starts from the formal Langevin equation

$$\partial_t \Phi = \Delta\Phi - m^2\Phi - \lambda\Phi^3 + \xi,$$

where t is an auxiliary stochastic time and ξ is spacetime-time white noise in the stochastic variables. In $D = 2, 3$, Φ is a distribution, so Φ^3 is defined only after renormalization. The renormalized equation has the form

$$\partial_t \Phi = \Delta\Phi - m^2\Phi - \lambda\Phi^3 + c_1(\varepsilon)\Phi + c_0(\varepsilon) + \xi_\varepsilon$$

before the cutoff $\varepsilon \downarrow 0$ is removed, with the precise counterterms determined by the chosen model and symmetry. Regularity structures, paracontrolled distributions, and rigorous RG methods provide the local expansion and reconstruction technology that make this limit a theorem in the constructed cases.

Open Problem 136.2 (Four-dimensional constructive gauge theory). Construct four-dimensional pure Yang–Mills, or QCD in a stated parameter regime, as a continuum local QFT with gauge-invariant observables, reflection positivity or Hilbert-space positivity, Euclidean and Lorentzian covariance, locality, and the spectral properties needed for particle and flux-tube questions. Lattice finite-volume integrals, perturbative asymptotic freedom, and numerical evidence are indispensable inputs, but the continuum existence and mass-gap theorem remains open.

Chapter 137

Constructive Scalar Models and OS Data

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Constructive scalar models are the basic interacting examples in which the objects used throughout this monograph are produced by estimates rather than postulated: Schwinger functions, reflection positivity, Euclidean covariance, growth bounds, and the Hilbert-space fields reconstructed from them. The word "constructive" will always mean a theorem about a limiting object in a specified topology. A finite cutoff integral, by itself, is only an input.

This chapter focuses on the scalar line beginning with $P(\phi)_2$ and Φ^4_3. It does not treat these theories as formal path integrals with unspecified counterterms. It records the regulated variables, the Wick and local counterterm coordinates appearing in the single regulated action, the estimates that control the infinite-volume and ultraviolet limits, and the OS data produced at the end.

137.1 Gaussian Reference Field and Wick Powers

Let $m > 0$, let

$$C = (-\Delta + m^2)^{-1}$$

be the massive Euclidean covariance on $\mathbb{R}^d$, and let μ_C be the centered Gaussian generalized field with covariance

$$\mathbb{E}_{\mu_C}[\phi(f)\phi(g)] = \int_{\mathbb{R}^d\times\mathbb{R}^d} f(x)C(x-y)g(y)\,\mathrm{d}^d x\,\mathrm{d}^d y. \tag{137.1}$$

The field ϕ is not a pointwise function. The expression $\phi(x)^k$ is therefore not defined until a regularization and a limiting procedure have been supplied.

Definition 137.1 (Wick powers by Gaussian regularization)**.** Let ρ_ε be a smooth approximate identity and set $\phi_\varepsilon = \rho_\varepsilon * \phi$. Write

$$C_\varepsilon(0) = \mathbb{E}_{\mu_C}[\phi_\varepsilon(x)^2],$$

which is translation independent. The Wick powers used below are the Hermite polynomials with variance $C_\varepsilon(0)$:

$$:\phi_\varepsilon^2: = \phi_\varepsilon^2 - C_\varepsilon(0), \tag{137.2}$$

$$:\phi_\varepsilon^3: = \phi_\varepsilon^3 - 3C_\varepsilon(0)\phi_\varepsilon, \tag{137.3}$$

$$:\phi_\varepsilon^4: = \phi_\varepsilon^4 - 6C_\varepsilon(0)\phi_\varepsilon^2 + 3C_\varepsilon(0)^2. \tag{137.4}$$

After smearing against a test function, the Wick power $:\phi^k:(f)$ is the $L^p(\mu_C)$-limit of $\int f(x) :\phi_\varepsilon(x)^k:\,\mathrm{d}^d x$ when that limit exists.

Origin of the Wick coefficients. For a centered Gaussian variable X with variance c, the Wick polynomial is

$$:X^n:= c^{n/2}H_n(X/\sqrt{c}),$$

where H_n is the probabilists' Hermite polynomial. In particular,

$$:X^2:= X^2 - c, \qquad :X^3:= X^3 - 3cX, \qquad :X^4:= X^4 - 6cX^2 + 3c^2.$$

The generating function

$$\exp(tX - \tfrac{1}{2}ct^2) = \sum_{n\geq 0} \frac{t^n}{n!} :X^n:$$

is characterized by the property that its expectation against $\exp(sX)$ equals

$$\mathbb{E}\big[\exp(tX - \tfrac{1}{2}ct^2)\exp(sX)\big] = \exp(cst + \tfrac{1}{2}cs^2).$$

Thus the coefficient of t^n is orthogonal to all polynomials of degree less than n and has leading term X^n, which is the defining orthogonality property of the Hermite polynomial. Expanding the generating function through order four gives the displayed coefficients.

The calculation-check companion `calculation-checks/constructive_scalar_spde_checks.py` verifies these coefficients and the cutoff-asymptotic coefficients used below.

137.2 Finite-Volume $P(\phi)_2$

Let $\Lambda \subset \mathbb{R}^2$ be a square or torus, and let

$$P(q) = \sum_{j=0}^{2r} p_j q^j, \qquad p_{2r} > 0,$$

be bounded below. Wick ordering is always relative to the Gaussian covariance used in the finite regulator. The regulated interaction is

$$V_{\varepsilon,\Lambda}(\phi) = \int_\Lambda :P(\phi_\varepsilon(x)): \, \mathrm{d}^2 x. \tag{137.5}$$

The finite-volume Schwinger functional is

$$S_{\varepsilon,\Lambda,n}(f_1, \dots, f_n) = \frac{1}{Z_{\varepsilon,\Lambda}} \int \prod_{i=1}^n \phi_\varepsilon(f_i) \, \exp[-V_{\varepsilon,\Lambda}(\phi)] \, \mathrm{d}\mu_C(\phi). \tag{137.6}$$

This formula is meaningful because the cutoff field is a finite-variance Gaussian process after smearing. The theorem is the existence and identification of the limits in which $\varepsilon \downarrow 0$ and $\Lambda \uparrow \mathbb{R}^2$.

Definition 137.2 (Negative Sobolev control norm)**.** Fix a bounded open set Λ_1 containing Λ and the supports reached by $\rho_\varepsilon * f$ for all sufficiently small ε. For $s > 0$, define

$$\|\phi\|^2_{H^{-s}(\Lambda_1)} := \sum_\nu (1 + \lambda_\nu)^{-s} \, |\phi(e_\nu)|^2, \tag{137.7}$$

where $\{e_\nu\}$ is any smooth orthonormal eigenbasis of a positive self-adjoint realization of $-\Delta$ on Λ_1 with eigenvalues λ_ν. Different standard boundary conditions give equivalent norms on smaller compact subsets, so the estimate below is independent of that auxiliary choice after the constants are changed.

Quoted Theorem 137.3 (Nelson–Glimm–Jaffe–Spencer stability in $P(\phi)_2$)**.** *Let $\Lambda \subset \mathbb{R}^2$ be bounded, let $P(q)$ be a real polynomial of even degree with positive leading coefficient and bounded below, and let*

$$V_{\varepsilon,\Lambda} = \int_\Lambda :P(\phi_\varepsilon(x)): \, \mathrm{d}^2 x$$

be Wick ordered with respect to the same massive covariance as the Gaussian measure. There are $s > 0$, $0 < \alpha < 2$, constants $A_\Lambda, B_\Lambda < \infty$, and $\varepsilon_0 > 0$, independent of $\varepsilon \in (0, \varepsilon_0]$, such that for μ_C-almost every field

$$V_{\varepsilon,\Lambda}(\phi) \geq -A_\Lambda - B_\Lambda \|\phi\|^\alpha_{H^{-s}(\Lambda_1)}. \tag{137.8}$$

Consequently, for every finite $p \geq 1$,

$$\sup_{0<\varepsilon\leq\varepsilon_0} \mathbb{E}_{\mu_C}[\exp(-pV_{\varepsilon,\Lambda})] < \infty. \tag{137.9}$$

Together with the Gaussian-chaos convergence of the Wick monomials, this implies that $\exp[-V_{\varepsilon,\Lambda}]$ *converges in $L^p(\mu_C)$, for every finite p, to the finite-volume $P(\phi)_2$ density.*

The quoted theorem is a compact formulation of the stability and exponential integrability estimates used in the Nelson, Glimm–Jaffe–Spencer, and Guerra–Rosen–Simon constructions of $P(\phi)_2$. Its proof is not the pointwise observation that P is bounded below; pointwise lower bounds for $:P(X):$ contain covariance-dependent negative constants that diverge as $\varepsilon \downarrow 0$. The constructive proof decomposes the covariance into scales, estimates the Wick-contraction combinatorics in each cell, absorbs lower-degree Wick terms into the positive leading part by large-field regulators, and uses the two-dimensional logarithmic covariance to obtain the subquadratic Sobolev exponent $\alpha < 2$. The theorem is therefore imported here as a quoted constructive estimate, not hidden inside the formal proof below.

Theorem 137.4 (Finite-volume ultraviolet limit in $P(\phi)_2$)**.** *For bounded Λ, bounded-below polynomial P, and Schwartz test functions supported in the interior of Λ, the limits*

$$S_{\Lambda,n}(f_1,\ldots,f_n) = \lim_{\varepsilon\downarrow 0} S_{\varepsilon,\Lambda,n}(f_1,\ldots,f_n)$$

exist after Wick ordering. The limiting finite-volume measure is absolutely continuous with respect to the massive Gaussian free field restricted to Λ, with density represented by $\exp[-\int_\Lambda :P(\phi(x)):\mathrm{d}^2x]$ as an L^p-limit for every finite p.

Proof. The L^p-convergence of the smeared Wick monomials follows from the covariance estimate

$$\mathbb{E}[:\phi_\varepsilon^k:(f):\phi_{\varepsilon'}^k:(f)] = k!\int f(x)C_{\varepsilon,\varepsilon'}(x-y)^k f(y)\,\mathrm{d}^2x\,\mathrm{d}^2y,$$

where the right-hand side converges because $C(x)$ has only logarithmic short-distance singularity in two dimensions and $C(x)^k$ is locally integrable for each fixed k. Hypercontractivity of Gaussian chaoses upgrades L^2-convergence to L^p-convergence for finite p.

The nontrivial point is uniform integrability of the exponential density. This is exactly the content of Quoted Theorem 137.3. To see how it enters, choose the Sobolev index $s > 0$ in (137.7). The massive Gaussian free field restricted to Λ_1 belongs to $H^{-s}(\Lambda_1)$ almost surely, because

$$\mathbb{E}_{\mu_C}\|\phi\|^2_{H^{-s}(\Lambda_1)} = \sum_\nu (1+\lambda_\nu)^{-s}\langle e_\nu, Ce_\nu\rangle < \infty$$

for $s > 0$ in two dimensions; the last inequality uses the elliptic bound $\langle e_\nu, Ce_\nu\rangle \le C_0(1+\lambda_\nu)^{-1}$ and Weyl's law for $-\Delta$ on a bounded planar region. Fernique's theorem gives some $\eta > 0$ with

$$\mathbb{E}_{\mu_C}\exp\{\eta\|\phi\|^2_{H^{-s}(\Lambda_1)}\} < \infty.$$

Since $\alpha < 2$, Young's inequality gives, for every $p < \infty$,

$$pB_\Lambda\|\phi\|^\alpha_{H^{-s}} \le \eta\|\phi\|^2_{H^{-s}} + C_{p,\eta,\alpha,B_\Lambda}.$$

Combining this with (137.8) proves (137.9). The L^q-convergence of the Wick polynomial integrals gives convergence of $V_{\varepsilon,\Lambda}$ in probability. Applying (137.9) with an exponent strictly larger than p gives uniform integrability of $\exp[-pV_{\varepsilon,\Lambda}]$, hence L^p-convergence of the densities. Finally, the smeared insertions $\phi_\varepsilon(f_i)$ converge in every Gaussian L^q space, and Holder's inequality combines this convergence with the uniform exponential moments. Therefore the normalized Schwinger functions have the stated finite-volume ultraviolet limits. The argument is local in Λ, so test functions supported away from the boundary are unaffected by the boundary condition used to define the finite covariance. $\square$

137.3 Cluster Expansion and Infinite Volume

The ultraviolet limit at fixed Λ does not yet construct the infinite-volume QFT. For massive $P(\phi)_2$ the large-volume limit is controlled by a cluster expansion. The following formulation isolates the estimate that turns local finite-volume data into global Schwinger functions.

Definition 137.5 (Polymer activity and cluster norm)**.** Partition $\mathbb{R}^2$ into unit cells Δ. A polymer X is a finite connected union of cells. Fix a finite-range symmetric incompatibility relation $X \nsim Y$; in the cell decompositions used below this means that the R_0-cell neighbourhoods of X and Y intersect, for a fixed integer R_0. Write $X \sim Y$ for compatibility. A polymer activity assigns to X a functional

$$K(X, \phi)$$

depending only on the field near X. For constants $a, b > 0$, define the numerical majorant

$$\kappa(X) := \sup_{\phi} \left(|K(X, \phi)| e^{-b\|\phi\|_X^{2r}} \right) \tag{137.10}$$

and the weighted cluster norm

$$\|K\|_{a,b} = \sup_{\Delta_0} \sum_{X \ni \Delta_0} e^{a|X|} \kappa(X), \tag{137.11}$$

where $\|\phi\|_X$ is the chosen local large-field norm. The exact constructive proof fixes the Sobolev regularity and large-field regulator; (137.11) records the structural requirement.

Lemma 137.6 (Penrose tree-graph bound)**.** *Let $X_1, \ldots, X_n$ be polymers and set*

$$u_{ij} := \begin{cases} 1, & X_i \nsim X_j, \\ 0, & X_i \sim X_j. \end{cases}$$

For $n \geq 2$, define the hard-core Ursell coefficient

$$\varphi_{\mathrm{c}}(X_1, \ldots, X_n) := \sum_{G \in \mathcal{C}_n} \prod_{\{i,j\} \in E(G)} (-u_{ij}), \tag{137.12}$$

where $\mathcal{C}_n$ is the set of connected simple graphs on $\{1, \ldots, n\}$. For $n = 1$, set $\varphi_{\mathrm{c}}(X_1) = 1$. Then

$$|\varphi_{\mathrm{c}}(X_1, \ldots, X_n)| \leq \sum_{T \in \mathcal{T}_n} \prod_{\{i,j\} \in E(T)} u_{ij}, \tag{137.13}$$

where $\mathcal{T}_n$ is the set of spanning trees on $\{1, \ldots, n\}$.

Proof. Fix an ordering of the edges of the complete graph on $\{1, \ldots, n\}$. For a connected graph G, let $T(G)$ be its lexicographically first spanning tree. Penrose's partition scheme assigns to every tree T a graph $R(T)$, containing T, such that the connected graphs are the disjoint union of intervals

$$\{G : \ T \subseteq G \subseteq R(T)\}.$$

Explicitly, an edge $e \notin T$ is put in $R(T)$ precisely when adding e to T does not change the lexicographically first spanning tree. Therefore

$$\sum_{\substack{G \in \mathcal{C}_n \\ T(G) = T}} \prod_{e \in E(G)} (-u_e) = (-1)^{|T|} \prod_{e \in E(T)} u_e \prod_{e \in E(R(T)) \setminus E(T)} (1 - u_e).$$

Since each u_e is 0 or 1, the absolute value of the right-hand side is at most $\prod_{e\in E(T)} u_e$. Summing over T proves (137.13). $\square$

Theorem 137.7 (Kotecky–Preiss/Brydges–Kennedy convergence criterion)**.** *Let $\mathcal{P}_\Lambda$ be the finite set of polymers contained in a finite cell region Λ. Let*

$$Z_\Lambda(K) = \sum_{\mathcal{X}\subset\mathcal{P}_\Lambda \text{ pairwise compatible}} \prod_{X\in\mathcal{X}} K(X)$$

be the abstract hard-core polymer partition function. Suppose there are numbers $a > a' > 0$ and $\epsilon > 0$ such that

$$\sup_{\Delta_0} \sum_{X\ni\Delta_0} \kappa(X) e^{a|X|} \le \epsilon \tag{137.14}$$

and $B_{R_0}\epsilon \le a'$, where B_{R_0} is the cell-neighbourhood constant defined by

$$|\{\Delta : \mathrm{dist}_{\mathrm{cell}}(\Delta, X) \le R_0\}| \le B_{R_0}|X|.$$

Then

$$\log Z_\Lambda(K) = \sum_{n\ge1} \frac{1}{n!} \sum_{X_1,\dots,X_n\in\mathcal{P}_\Lambda} \varphi_{\mathrm{c}}(X_1,\dots,X_n) \prod_{i=1}^n K(X_i) \tag{137.15}$$

is absolutely convergent uniformly in Λ. More precisely, for each root polymer X_0,

$$\sum_{n\ge1} \frac{1}{(n-1)!} \sum_{X_2,\dots,X_n\in\mathcal{P}_\Lambda} |\varphi_{\mathrm{c}}(X_0, X_2,\dots,X_n)| \prod_{i=2}^n \kappa(X_i) \le e^{a'|X_0|}. \tag{137.16}$$

Consequently connected correlations of observables supported in separated regions A and B, whose source activities obey the same local majorant, satisfy

$$|\langle F_A G_B\rangle - \langle F_A\rangle\langle G_B\rangle| \le C_{F,G} e^{-m_{\mathrm{cl}}\,\mathrm{dist}(A,B)} \tag{137.17}$$

for a positive cluster mass m_{cl} fixed by the exponential weight in the norm and by the covariance decay.

Proof. For finite Λ, the Mayer identity is a finite algebraic identity. It expands the logarithm of the hard-core gas in connected incompatibility graphs and gives (137.15), with the coefficient φ_{c} defined in (137.12). Equivalently, it is the formal Taylor expansion of the analytic branch of $\log Z_\Lambda$ satisfying $\log Z_\Lambda(0) = 0$; the absolute convergence proved below is what makes this formal expansion a uniformly convergent function in the stated polydisc of activities.

Apply Lemma 137.6. Root each tree at the vertex carrying X_0 and orient its edges away from the root. Let $F_N(X)$ be the total majorant of rooted incompatibility trees of depth at most N, with root polymer X, excluding the activity of the root itself. The tree bound gives the recursive domination

$$F_{N+1}(X) \le \exp\left(\sum_{Y\nsim X} \kappa(Y) F_N(Y)\right), \qquad F_0(X) = 1. \tag{137.18}$$

Assume inductively that $F_N(Y) \le e^{a'|Y|}$. Since $a > a'$,

$$\sum_{Y\nsim X} \kappa(Y) e^{a'|Y|} \le \sum_{\Delta\in N_{R_0}(X)} \sum_{Y\ni\Delta} \kappa(Y) e^{a|Y|} \le B_{R_0}\epsilon|X| \le a'|X|. \tag{137.19}$$

Thus $F_{N+1}(X) \le e^{a'|X|}$. Letting $N \to \infty$ proves (137.16). Multiplying by the root majorant $\kappa(X_0)$ and summing over X_0 with (137.14) proves absolute convergence of (137.15).

For two separated observables, the connected part can only be produced by a connected cluster intersecting both supports. Every such cluster contains a path of incompatible polymers joining the source near A to the source near B. Along such a path,

$$\sum_{X \text{ on the path}} |X| \ge c_{R_0} \operatorname{dist}(A, B) \tag{137.20}$$

for a positive cell-metric constant c_{R_0}. In the rooted-tree estimate one may use the a'-weighted recursion while retaining the unused factor $e^{-(a-a')|X|}$ from the a-weighted smallness norm. Equation (137.20) then gives

$$m_{\mathrm{cl}} \ge c_{R_0}(a - a')$$

up to the additional exponential-decay rate supplied by the massive Gaussian covariance. The source activity norms for F_A and G_B supply $C_{F,G}$. This proves (137.17). □

In the Glimm–Jaffe–Spencer $P(\phi)_2$ construction, the activities $K(X, \phi)$ arise by expanding around cell-local interaction pieces while retaining large-field regulators. The theorem above is the abstract polymer estimate of Kotecky–Preiss and Brydges–Kennedy,[1] written here in the hard-core finite-range form needed for the constructive scalar models. It is not an optional heuristic: it is the analytic step that justifies taking $\Lambda \uparrow \mathbb{R}^2$, proves exponential clustering in the massive phase, and gives uniform bounds on the Schwinger functions.

Source derivatives and connected clusters. The polymer estimate becomes a QFT statement only after one explains how local insertions are read from the polymer gas. Let $\mathfrak{S}$ be a finite set of source labels. For each $\alpha \in \mathfrak{S}$, let A_α be the cell neighbourhood of the support of the corresponding test insertion and let $b_\alpha(X)$ be a source weight that vanishes unless X meets A_α. At finite volume set

$$K_\lambda(X) = K(X) \exp\left(\sum_{\alpha \in \mathfrak{S}} \lambda_\alpha b_\alpha(X) \right)$$

and define $Z_\Lambda(\lambda)$ by replacing K with K_λ in the hard-core partition function. The connected source coefficient is the finite identity

$$C^{(\Lambda)}_{\alpha_1 \cdots \alpha_m} = \partial_{\lambda_{\alpha_1}} \cdots \partial_{\lambda_{\alpha_m}} \log Z_\Lambda(\lambda) \Big|_{\lambda=0}.$$

Substituting K_λ into the absolutely convergent cluster expansion gives

$$C^{(\Lambda)}_{\alpha_1 \cdots \alpha_m} = \sum_{n \ge 1} \frac{1}{n!} \sum_{X_1, \ldots, X_n \in \mathcal{P}_\Lambda} \varphi_{\mathrm{c}}(X_1, \ldots, X_n) \prod_{i=1}^{n} K(X_i)$$
$$\times \sum_{\tau : \{1, \ldots, m\} \to \{1, \ldots, n\}} \prod_{r=1}^{m} b_{\alpha_r}(X_{\tau(r)}).$$

[1]See R. Kotecky and D. Preiss, "Cluster expansion for abstract polymer models," *Commun. Math. Phys.* 103 (1986), and D. C. Brydges and T. Kennedy, "Mayer expansions and the Hamilton-Jacobi equation," *J. Stat. Phys.* 48 (1987).

Thus a nonzero term in a connected m-point source coefficient contains a connected incompatibility graph whose vertices collectively meet all source neighbourhoods. If two groups of sources lie in cell regions that cannot be joined by an incompatibility path, the finite partition function factorizes and the mixed cumulant vanishes. If they can be joined only through a path of total polymer size at least proportional to their cell distance, the unused exponential weight in (137.14) gives precisely the decay used in (137.17). For local fields in $P(\phi)_2$, the source weights b_α are obtained by expanding the regulated source functional together with the local interaction pieces; the cluster estimate controls the resulting connected Schwinger distributions after the finite-volume ultraviolet limit has already been taken.

Quoted Theorem 137.8 (Massive $P(\phi)_2$ OS output from the cluster expansion)**.** *Let P be an even-degree real polynomial bounded below with positive leading coefficient, let $m > 0$, and choose a reflection-positive finite-volume ultraviolet regulator. Assume the finite-volume ultraviolet limit of Theorem 137.4 has been taken, and that the resulting polymer activities satisfy the uniform cluster norm bound* (137.14) *in the massive phase. Then the thermodynamic limits*

$$S_n(f_1, \ldots, f_n) = \lim_{\Lambda \uparrow \mathbb{R}^2} S_{\Lambda,n}(f_1, \ldots, f_n)$$

exist for Schwartz test functions. The hierarchy $S = \{S_n\}_{n \geq 0}$ satisfies Euclidean covariance, permutation symmetry, reflection positivity, distributional regularity, the OS growth hypotheses required for reconstruction, and exponential clustering of connected Schwinger functions.

The quoted theorem is the constructive $P(\phi)_2$ output statement. The source lineage is the Glimm–Jaffe–Spencer constructive cluster-expansion program for $P(\phi)_2$, as presented for example in Glimm–Jaffe's functional-integral account. The inputs include the polynomial interaction, Wick ordering, stability, ultraviolet convergence, the polymer norm estimate, and preservation of reflection positivity along the regulator sequence.

Spectral consequence of Euclidean clustering. The constructive input is the exponential clustering statement in the quoted theorem; the passage from such a bound to a Hamiltonian gap is a spectral support calculation. Assume OS reconstruction has been performed from a scalar Schwinger hierarchy satisfying Quoted Theorem 137.8. Let A be a local Euclidean-time-zero observable with $\langle \Omega, A\Omega \rangle = 0$, and suppose its two-point function obeys, for some $m_{\mathrm{E}} > 0$,

$$0 \leq \langle \Omega, A^* e^{-\tau H} A\Omega \rangle \leq C_A e^{-m_{\mathrm{E}}\tau}, \qquad \tau \geq 0.$$

Then the spectral measure of H in the vector $A\Omega$ is supported in $[m_{\mathrm{E}}, \infty)$. If the set of such local vectors is dense in the orthogonal complement of the vacuum, the reconstructed Hamiltonian has mass gap at least m_{E}.

By the spectral theorem,

$$\langle \Omega, A^* e^{-\tau H} A\Omega \rangle = \int_{[0,\infty)} e^{-\tau E} \, \mathrm{d}\mu_A(E), \qquad \mathrm{d}\mu_A(E) = \mathrm{d}\langle A\Omega, P_H(E) A\Omega \rangle.$$

If $\mu_A([0, m_{\mathrm{E}} - \delta]) > 0$ for some $\delta > 0$, then

$$\int e^{-\tau E} \, \mathrm{d}\mu_A(E) \geq e^{-(m_{\mathrm{E}} - \delta)\tau} \mu_A([0, m_{\mathrm{E}} - \delta]).$$

This contradicts the assumed upper bound $C_A e^{-m_{\mathrm{E}}\tau}$ as $\tau \to \infty$. Therefore no spectral weight lies below m_{E} in the vector $A\Omega$. If such local vectors are dense in $\Omega^{\perp}$, the spectral projection $P_H([0, m_{\mathrm{E}}))$ annihilates a dense subspace of $\Omega^{\perp}$ and hence vanishes there. This is the claimed gap.

137.4 Hamiltonian Viewpoint and Number-Operator Bounds

The original construction of ϕ_2^4 can also be formulated in the Hamiltonian representation. Let $\mathcal{F}$ be the massive one-particle Fock space on a spatial line or circle, H_0 the free Hamiltonian, and N the number operator. With spatial cutoff $g \geq 0$, the interaction is

$$V(g) = \lambda \int g(x) :\phi(x)^4: \, \mathrm{d}x.$$

The decisive estimates are number-operator bounds of the form

$$\|(N+1)^{-2} V(g) (N+1)^{-2}\| \leq C_g |\lambda|, \qquad \|V(g)\psi\| \leq \alpha \|H_0 \psi\| + \beta \|\psi\| \tag{137.21}$$

with $\alpha < 1$ after localization and choice of constants. These estimates imply self-adjointness and lower boundedness of

$$H(g) = H_0 + V(g) + E(g),$$

where $E(g)$ is the vacuum-energy coordinate in the regulated Hamiltonian. The removal of the spatial cutoff is not a formal limit of operators on a fixed dense domain; it is controlled by spatial cluster estimates and by convergence of local vacuum expectations.

Remark 137.9 (Relation between Hamiltonian and Euclidean constructions). The Hamiltonian and Euclidean $P(\phi)_2$ constructions produce the same local QFT only after a comparison theorem identifies the Schwinger functions generated by $e^{-tH(g)}$ with the Euclidean measure construction and then passes to the infinite-volume limit. The common notation ϕ_2^4 is not itself such an identification.

137.5 Φ_3^4, Phase Cells, and Local Coordinates

In three Euclidean dimensions the quartic scalar theory is superrenormalizable, but Wick ordering alone does not remove every local divergence. A regulator may be given by a momentum cutoff, lattice spacing, or mollifier. A typical finite-volume action is

$$S_{\varepsilon,\Lambda}(\phi) = \frac{1}{2}\langle \phi, (-\Delta + m^2)\phi \rangle + \int_{\Lambda} \left[\lambda \phi_\varepsilon^4 + a_\varepsilon \phi_\varepsilon^2 + b_\varepsilon\right] \mathrm{d}^3 x. \tag{137.22}$$

The coefficients a_ε and b_ε are local coordinates of the regulated action. They are not a second Lagrangian and are not optional decorations. Their values are fixed by the renormalization conditions or by the constructive normalization scheme.

For connected scalar ϕ^4 graphs in d Euclidean dimensions with E external legs, V quartic vertices, and L loops, the superficial degree of divergence is

$$\omega_d = dL - 2I = d - \frac{d-2}{2} E + (d-4)V. \tag{137.23}$$

In $d = 3$, only finitely many local divergences occur: vacuum-energy and two-point local counterterms. The four-point and higher connected kernels are superficially convergent after subdivergences are removed. The graph identities are

$$4V = 2I + E, \qquad L = I - V + 1.$$

Substituting $I = 2V - E/2$ into $dL - 2I$ gives

$$d(I - V + 1) - 2I = (d-2)I - dV + d = d - \frac{d-2}{2}E + (d-4)V.$$

For $d = 3$, this is $3 - E/2 - V$. At fixed E, only finitely many V can satisfy $\omega_3 \geq 0$, and $E \geq 4$ is convergent except for subdivergences. Thus all primitive local divergences are proportional to the identity or to ϕ^2.

With sharp momentum cutoff $|p| \leq \Lambda$,

$$I_d(\Lambda, m) = \int_{|p|\leq\Lambda} \frac{\mathrm{d}^d p}{(2\pi)^d} \frac{1}{p^2 + m^2}$$

satisfies

$$I_2(\Lambda, m) = \frac{1}{2\pi}\log\Lambda + O(1), \qquad I_3(\Lambda, m) = \frac{\Lambda}{2\pi^2} + O(1). \tag{137.24}$$

In polar coordinates,

$$I_d(\Lambda, m) = \frac{|S^{d-1}|}{(2\pi)^d} \int_0^\Lambda \frac{r^{d-1}}{r^2 + m^2}\,\mathrm{d}r.$$

For $d = 2$, $|S^1| = 2\pi$ and the radial integral is $\frac{1}{2}\log(\Lambda^2 + m^2) - \frac{1}{2}\log m^2$, giving the coefficient $(2\pi)^{-1}$. For $d = 3$, $|S^2| = 4\pi$ and the radial integral is $\Lambda - m\arctan(\Lambda/m)$, giving the coefficient $(2\pi^2)^{-1}$.

In the normalization $\lambda\phi^4$, Wick ordering the quartic interaction produces

$$\lambda :\phi_\varepsilon^4: = \lambda\phi_\varepsilon^4 - 6\lambda C_\varepsilon(0)\phi_\varepsilon^2 + 3\lambda C_\varepsilon(0)^2. \tag{137.25}$$

Thus the leading mass-coordinate divergence is fixed by the six single contractions in ϕ^4. In three dimensions a logarithmic two-loop local two-point divergence also appears. In a BPHZ or phase-cell scheme it is encoded in the finite-regulator coordinate a_ε, while the vacuum diagrams are encoded in b_ε.

It is useful to separate the Wick-coordinate bookkeeping from the remaining logarithmic local coordinate. Write the same cutoff action temporarily in normal-ordered coordinates as

$$S_{\varepsilon,\Lambda} = S_{0,\varepsilon} + \int_\Lambda \left[\lambda :\phi_\varepsilon^4:_\varepsilon + \alpha_\varepsilon :\phi_\varepsilon^2:_\varepsilon + \beta_\varepsilon\right] \mathrm{d}^3x. \tag{137.26}$$

Here the subscript on $:\cdot:_\varepsilon$ records that Wick ordering is relative to the same cutoff covariance used in the Gaussian reference measure. Relative to the un-Wick-ordered coordinates in (137.22),

$$a_\varepsilon = \alpha_\varepsilon - 6\lambda C_\varepsilon(0), \qquad b_\varepsilon = \beta_\varepsilon - \alpha_\varepsilon C_\varepsilon(0) + 3\lambda C_\varepsilon(0)^2. \tag{137.27}$$

The linear divergence in a_ε is therefore the one-loop Wick conversion; the logarithmic divergence is the leading divergent part of α_ε.

This is also the coordinate in which the comparison with stochastic quantization must be made. To avoid overloading the symbol λ, rename the Euclidean quartic coefficient in (137.22) temporarily as g_4. If the same cutoff action is used to generate a Langevin equation in the convention of Chapter 144, and if that equation is written with dynamic cubic coefficient λ_{dyn} and local linear drift coefficient M_ε, then

$$\lambda_{\mathrm{dyn}} = 4g_4, \qquad M_\varepsilon = -2a_\varepsilon.$$

Therefore the normal-ordered mass coordinate is

$$\alpha_\varepsilon = -\frac{1}{2}M_\varepsilon + \frac{3}{2}\lambda_{\mathrm{dyn}}C_\varepsilon(0).$$

Proposition 144.90 expands this identity in the dynamic BPHZ coordinates. The comparison is made in α_ε, not in the raw drift coefficient, because the one-loop Wick conversion is a coordinate change between the two presentations.

Proposition 137.10 (Vacuum coordinate and normalized Schwinger data)**.** *Fix a cutoff ε, a bounded volume Λ, and a source J supported in Λ. Let $Z^{(\beta)}_{\varepsilon,\Lambda}[J]$ be the finite-volume source partition function formed from (137.26). If β_ε is replaced by $\beta_\varepsilon + c_\varepsilon$, with λ, α_ε, and the Gaussian reference measure fixed, then*

$$Z^{(\beta+c)}_{\varepsilon,\Lambda}[J] = e^{-c_\varepsilon|\Lambda|}Z^{(\beta)}_{\varepsilon,\Lambda}[J]. \tag{137.28}$$

Hence every normalized finite-volume Schwinger function is unchanged:

$$S^{(\beta+c)}_{n,\varepsilon,\Lambda}(f_1,\dots,f_n) = S^{(\beta)}_{n,\varepsilon,\Lambda}(f_1,\dots,f_n). \tag{137.29}$$

The connected source functional

$$W^{(\beta)}_{\varepsilon,\Lambda}[J] := \log Z^{(\beta)}_{\varepsilon,\Lambda}[J] - \log Z^{(\beta)}_{\varepsilon,\Lambda}[0]$$

is also unchanged, while the unnormalized thermodynamic coordinates shift by

$$p^{(\beta+c)}_{\varepsilon,\Lambda} = p^{(\beta)}_{\varepsilon,\Lambda} - c_\varepsilon, \qquad f^{(\beta+c)}_{\varepsilon,\Lambda} = f^{(\beta)}_{\varepsilon,\Lambda} + c_\varepsilon, \tag{137.30}$$

where $p_{\varepsilon,\Lambda} = |\Lambda|^{-1}\log Z_{\varepsilon,\Lambda}[0]$ and $f_{\varepsilon,\Lambda} = -|\Lambda|^{-1}\log Z_{\varepsilon,\Lambda}[0]$. At fixed α_ε and λ, the same shift changes the un-Wick-ordered coordinate in (137.27) by

$$b_\varepsilon \longmapsto b_\varepsilon + c_\varepsilon, \qquad a_\varepsilon \longmapsto a_\varepsilon.$$

Thus the stochastic-quantization drift chart determines the mass coordinate but not the vacuum coordinate; the latter is fixed only after specifying the partition-function, pressure, or free-energy normalization.

Proof. The replacement $\beta_\varepsilon \mapsto \beta_\varepsilon + c_\varepsilon$ adds the constant $c_\varepsilon|\Lambda|$ to the finite-volume action. Pulling this factor out of the integral gives (137.28). Differentiating the source partition function, or equivalently inserting finitely many smeared cutoff fields before normalization, multiplies numerator and denominator by the same factor $e^{-c_\varepsilon|\Lambda|}$, proving (137.29). Taking the difference $\log Z[J] - \log Z[0]$ cancels the same additive logarithmic term, while dividing $\log Z[0] - c_\varepsilon|\Lambda|$ by $|\Lambda|$ gives the pressure and free-energy shifts in (137.30). Finally, the coordinate conversion (137.27) is affine in β_ε and independent of β_ε in a_ε. The functional derivative of an additive constant in the action is zero, so the Langevin drift sees no c_ε term. $\square$

Lemma 137.11 (Universal logarithm in the three-dimensional sunset kernel)**.** *Let*

$$C_m(x) = \frac{e^{-m|x|}}{4\pi|x|}$$

be the massive covariance in $\mathbb{R}^3$*, and let* C_ε *be obtained from* C_m *by a smooth ultraviolet mollifier at length* ε*. For every fixed* $R > 0$*,*

$$J_\varepsilon(R) := \int_{|x|\le R} C_\varepsilon(x)^3 \,\mathrm{d}^3x = \frac{1}{16\pi^2}\log\frac{1}{\varepsilon} + O_R(1). \tag{137.31}$$

The coefficient of the logarithm is independent of the mollifier.

Proof. Near the origin,

$$C_m(x) = \frac{1}{4\pi|x|} + O(1).$$

On the annulus $A_{\varepsilon,R} = \{c\varepsilon \le |x| \le R\}$, with c fixed large enough for the chosen mollifier, standard estimates on smooth approximate identities give

$$C_\varepsilon(x) = \frac{1}{4\pi|x|} + O(1) + O(\varepsilon|x|^{-2}).$$

The last error contributes $O(1)$ to the integral of C_ε^3 over $A_{\varepsilon,R}$. The ball $|x| \le c\varepsilon$ contributes only a mollifier-dependent bounded term after the logarithmic part has been extracted, because its volume is $O(\varepsilon^3)$ and the mollified covariance is $O(\varepsilon^{-1})$. Hence the divergent part is

$$\int_{c\varepsilon}^{R} 4\pi r^2 \left(\frac{1}{4\pi r}\right)^3 \mathrm{d}r = \frac{1}{16\pi^2}\log\frac{R}{c\varepsilon},$$

which proves (137.31). □

Lemma 137.12 (Two-loop local mass coordinate in the chapter's normalization)**.** *Use the normal-ordered coordinates* (137.26)*. Through order* λ^2 *and first order in* α_ε*, the logarithmically divergent local part of the connected two-point Schwinger function is*

$$\big(96\lambda^2 J_\varepsilon(R) - 2\alpha_\varepsilon\big)\int f(u)C_m(u-z)C_m(z-v)g(v)\,\mathrm{d}^3u\,\mathrm{d}^3z\,\mathrm{d}^3v, \tag{137.32}$$

up to finite terms and derivative local terms. Therefore the logarithmic mass coordinate is

$$\alpha_\varepsilon = 48\lambda^2 J_\varepsilon(R) + \alpha_{\mathrm{fin}} + O(\lambda^3) = \frac{3\lambda^2}{\pi^2}\log\frac{1}{\varepsilon} + \alpha_{\mathrm{fin}} + O(1) + O(\lambda^3), \tag{137.33}$$

with α_{fin} *fixed by the chosen finite mass normalization.*

Proof. The normal-ordered product identity for two quartic vertices is

$$:\phi_\varepsilon(x)^4::\phi_\varepsilon(y)^4:= \sum_{k=0}^{4}\binom{4}{k}^2 k!\,C_\varepsilon(x-y)^k :\phi_\varepsilon(x)^{4-k}\phi_\varepsilon(y)^{4-k}: . \tag{137.34}$$

The logarithmic two-point local term is the $k = 3$ term:

$$\binom{4}{3}^2 3!\, C_\varepsilon(x-y)^3 :\phi_\varepsilon(x)\phi_\varepsilon(y): = 96\, C_\varepsilon(x-y)^3 :\phi_\varepsilon(x)\phi_\varepsilon(y): .$$

The second order in the expansion of $\exp[-\lambda \int :\phi^4:]$ has the factor $\lambda^2/2$. Contracting $:\phi(x)\phi(y):$ with the two external fields gives

$$C_m(u-x)C_m(v-y) + C_m(u-y)C_m(v-x).$$

In the singular region $x - y$ small, both terms have the same local part. Thus the quartic vertices contribute

$$\frac{\lambda^2}{2} \cdot 96 \cdot 2\, J_\varepsilon(R) \int f(u)C_m(u-z)C_m(z-v)g(v)\, \mathrm{d}^3u\, \mathrm{d}^3z\, \mathrm{d}^3v,$$

which is the $96\lambda^2 J_\varepsilon(R)$ term in (137.32). The insertion $\alpha_\varepsilon \int :\phi^2:$ contributes at first order

$$-\alpha_\varepsilon \int \langle \phi(u)\phi(v) :\phi(z)^2: \rangle_0\, \mathrm{d}^3z = -2\alpha_\varepsilon \int C_m(u-z)C_m(z-v)\, \mathrm{d}^3z.$$

Cancellation of the logarithmic coefficient gives $\alpha_\varepsilon = 48\lambda^2 J_\varepsilon(R) + \alpha_{\mathrm{fin}}$. The coefficient in (137.33) follows from Lemma 137.11. The dependence on the radius R, on the mollifier, and on the subtraction convention is finite and is absorbed into α_{fin}. □

Finite-cutoff stability of the local normal-ordered polynomial. Fix a cutoff covariance with $c_\varepsilon = C_\varepsilon(0) < \infty$. Let $\lambda > 0$, and define the one-site polynomial

$$p_\varepsilon(q) = \lambda :q^4:_\varepsilon + \alpha_\varepsilon :q^2:_\varepsilon + \beta_\varepsilon.$$

Equivalently,

$$p_\varepsilon(q) = \lambda y^2 + A_\varepsilon y + B_\varepsilon, \qquad y = q^2, \quad A_\varepsilon = \alpha_\varepsilon - 6\lambda c_\varepsilon, \quad B_\varepsilon = 3\lambda c_\varepsilon^2 - \alpha_\varepsilon c_\varepsilon + \beta_\varepsilon.$$

For all $q \in \mathbb{R}$,

$$p_\varepsilon(q) \geq B_\varepsilon - \frac{(A_\varepsilon^-)^2}{4\lambda}, \qquad A_\varepsilon^- := \max\{-A_\varepsilon, 0\}. \tag{137.35}$$

Consequently the finite-cutoff interaction

$$\int_\Lambda p_\varepsilon(\phi_\varepsilon(x))\, \mathrm{d}^3x$$

is bounded below by

$$|\Lambda| \left(B_\varepsilon - \frac{(A_\varepsilon^-)^2}{4\lambda} \right).$$

The Wick identities in Definition 137.1 give

$$:q^4:_\varepsilon = q^4 - 6c_\varepsilon q^2 + 3c_\varepsilon^2, \qquad :q^2:_\varepsilon = q^2 - c_\varepsilon.$$

With $y = q^2 \geq 0$, the polynomial becomes $\lambda y^2 + A_\varepsilon y + B_\varepsilon$. If $A_\varepsilon \geq 0$, its minimum on $y \geq 0$ is attained at $y = 0$ and equals B_ε. If $A_\varepsilon < 0$, the unconstrained minimum lies at $y = -A_\varepsilon/(2\lambda) > 0$

and equals $B_\varepsilon - A_\varepsilon^2/(4\lambda)$. These two cases give (137.35). Integrating the pointwise bound over Λ proves the final assertion.

This finite-cutoff lower bound does not by itself prove the continuum Φ^4_3 theorem, because the lower bound contains divergent local constants that must be absorbed into β_ε and because uniform polymer smallness requires scale-by-scale estimates on fluctuations rather than only a one-site lower bound. It is nevertheless the first stability inequality in the constructive chain: before phase cells are introduced, the regulated density is an ordinary integrable function after the local vacuum-energy coordinate is chosen.

Reflection positivity under split local interactions. Let $(\mathfrak{A}, \theta, \langle\cdot\rangle_0)$ be a reflection-positive Euclidean probability space, and let $\mathfrak{A}_+ \subset \mathfrak{A}$ be the algebra generated by fields supported at positive Euclidean time. Thus

$$\langle \theta F\, F\rangle_0 \geq 0, \qquad F \in \mathfrak{A}_+.$$

Let V_+ be a real measurable functional affiliated with $\mathfrak{A}_+$, and suppose $e^{-V_+}F \in L^2$ for the positive-time test polynomials under consideration. Define the interacting expectation by the unnormalized density

$$\mathrm{d}\nu = e^{-V_+ - \theta V_+}\,\mathrm{d}\mu_0.$$

Then the unnormalized interacting form is reflection positive:

$$\langle \theta F\, F\rangle_\nu = \int \theta F\, F\, e^{-V_+ - \theta V_+}\,\mathrm{d}\mu_0 \geq 0, \qquad F \in \mathfrak{A}_+. \tag{137.36}$$

Because θ is an anti-linear algebra involution and V_+ is real,

$$\theta(e^{-V_+}F) = e^{-\theta V_+}\theta F.$$

Therefore

$$\int \theta F\, F\, e^{-V_+ - \theta V_+}\,\mathrm{d}\mu_0 = \int \theta(e^{-V_+}F)\,(e^{-V_+}F)\,\mathrm{d}\mu_0.$$

The right hand side is nonnegative by reflection positivity of the reference measure, applied to $e^{-V_+}F \in \mathfrak{A}_+$.

For a lattice or finite-mode regulator, the split-interaction calculation above applies directly when the interaction is written as a positive-time part plus its reflection. Terms sitting on the reflection plane are either assigned half weight before a limiting argument or are treated by a separate reflection-positive boundary kernel. Thus reflection positivity in the constructive theorem is not a formal property of the expression $\exp[-S]$; it is a property of the chosen regulator and of the way the local interaction is split relative to the reflection.

Quoted Theorem 137.13 (Constructive Φ^4_3 output theorem)**.** *Let the ultraviolet regulator, finite-volume boundary condition, and mass coordinate be chosen in one of the massive small-coupling regimes covered by the constructive Φ^4_3 phase-cell theorems. Then there are choices of local coordinates*

$$a_\varepsilon = a_{\mathrm{div}}(\varepsilon) + a_{\mathrm{fin}}, \qquad b_\varepsilon = b_{\mathrm{div}}(\varepsilon) + b_{\mathrm{fin}},$$

such that the regulated Schwinger functions associated with (137.22) converge, as $\varepsilon \downarrow 0$ and $\Lambda \uparrow \mathbb{R}^3$, to Euclidean Schwinger distributions satisfying symmetry, Euclidean covariance, reflection positivity, regularity, clustering in the massive phase, and the growth hypotheses needed for OS reconstruction.

This is a quoted constructive theorem, not a theorem proved in this paragraph. Foundational sources include the Glimm–Jaffe–Spencer constructive program, Magnen–Seneor's infinite-volume construction of Φ^4_3, the Brydges–Federbush phase-cell expansion, and the presentation in Glimm–Jaffe's *Quantum Physics: A Functional Integral Point of View*.[2] The proof is not the formal perturbative cancellation of the diagrams in (137.25); the constructive proof has four analytic components.

In the final standard of this monograph, the quoted theorem is a proof obligation rather than an authority claim. The cited constructive literature identifies the estimates to be checked, but a theorem about the existence of an interacting QFT should ultimately be accompanied here by a self-contained derivation of the regulator choice, stability bounds, phase-cell estimates, uniform infinite-volume convergence, reflection positivity, and OS growth conditions.

First, the covariance is decomposed into phase cells or scales. Field configurations are separated into small-field regions, where perturbative Taylor expansion is controlled, and large-field regions, where the positive quartic term and local regulators give stability.

Second, all local divergent pieces allowed by the power-counting formula (137.23) are extracted into the two coordinates a_ε and b_ε. The remaining polymer activities satisfy bounds of the type

$$\|K_j\|_{a,b} \le C|\lambda|^{1+\delta} L^{-j\alpha} \tag{137.37}$$

on scale j, for positive δ, α in the constructed regime.

Third, the cluster or phase-cell expansion is summed uniformly in the volume and cutoff. The convergence criterion is the scale-dependent version of Theorem 137.7. It gives limits of connected Schwinger functions and exponential clustering.

Fourth, reflection positivity and Euclidean covariance are maintained by the choice of regulator or recovered in the limiting Schwinger functions. The OS growth conditions are checked from uniform moment bounds. OS reconstruction then gives the Lorentzian Wightman theory. Each step is a theorem with hypotheses on the regulator, mass coordinate, coupling size, and volume sequence; the Lagrangian label Φ^4_3 abbreviates this entire construction.

Definition 137.14 (Abstract multiscale phase-cell system)**.** Fix a scale factor $L > 1$. A multiscale phase-cell system consists of:

(i) cell complexes $\mathcal{D}_j$ of side L^{-j}, $j \ge 0$;

(ii) polymers $X \subset \mathcal{D}_j$, with size $|X|_j$ equal to their number of j-cells;

(iii) a finite-range incompatibility relation $(j, X) \not\sim (k, Y)$, whose cell-neighbourhood constant is B_R;

(iv) polymer activities $K_j(X)$ obtained after extracting the local coordinates $a_\varepsilon, b_\varepsilon$;

(v) numerical majorants $\kappa_j(X) \ge |K_j(X)|$ after the declared large-field weights have been applied.

The system has a scale-decay bound with constants (C_0, δ, α, a), $\delta, \alpha, a > 0$, if

$$\sup_{\Delta \in \mathcal{D}_j} \sum_{X \ni \Delta} e^{a|X|_j} \kappa_j(X) \le C_0 |\lambda|^{1+\delta} L^{-\alpha j} \quad \text{for every } j \ge 0. \tag{137.38}$$

[2] For the constructive lineage relevant here, see J. Glimm and A. Jaffe's constructive-field-theory papers and book, J. Magnen and R. Seneor on the infinite-volume Φ^4_3 model, and D. Brydges and P. Federbush on phase-cell expansions. The statement above is intentionally quoted at theorem-boundary level because reproducing those multi-scale estimates would require a separate chapter-length proof.

Theorem 137.15 (Summability from the phase-cell scale-decay bound)**.** *Assume a multiscale phase-cell system satisfies* (137.38)*. If $a > a' > 0$ and*

$$B_R \frac{C_0|\lambda|^{1+\delta}}{1 - L^{-\alpha}} \le a', \tag{137.39}$$

then the combined polymer expansion over all scales is absolutely convergent. For a root polymer (j_0, X_0),

$$\sum_{n\ge 1} \frac{1}{(n-1)!} \sum_{(j_2,X_2),\dots,(j_n,X_n)} |\varphi_c((j_0,X_0),\dots,(j_n,X_n))| \prod_{i=2}^{n} \kappa_{j_i}(X_i) \le e^{a'|X_0|_{j_0}}. \tag{137.40}$$

Moreover the contribution of scales $j \ge J$ to the one-root majorant is bounded by

$$\frac{C_0|\lambda|^{1+\delta} L^{-\alpha J}}{1 - L^{-\alpha}}. \tag{137.41}$$

Therefore the ultraviolet cutoff sequence is Cauchy in every Schwinger seminorm whose source activities obey the same bound.

Proof. Regard a pair $\widehat{X} = (j, X)$ as a single polymer in an enlarged polymer set. Its size is $|\widehat{X}| := |X|_j$ and its majorant is $\widehat{\kappa}(\widehat{X}) := \kappa_j(X)$. For a fixed cell Δ at any scale, the scale-decay hypothesis gives

$$\sum_{j\ge 0} \sum_{X \ni \Delta} e^{a|X|_j} \kappa_j(X) \le \sum_{j\ge 0} C_0|\lambda|^{1+\delta} L^{-\alpha j} = \frac{C_0|\lambda|^{1+\delta}}{1 - L^{-\alpha}}.$$

The finite-range constant B_R gives the neighbourhood estimate (137.19), with ϵ replaced by this scale sum. Condition (137.39) is the hypothesis needed for the rooted-tree induction in the proof of Theorem 137.7. Applying that proof to the enlarged polymer set gives (137.40).

For the ultraviolet tail, the majorant entering the rooted-tree induction is the restricted scale sum

$$\sum_{j\ge J} C_0|\lambda|^{1+\delta} L^{-\alpha j}.$$

Evaluating this geometric series gives

$$\sum_{j\ge J} C_0|\lambda|^{1+\delta} L^{-\alpha j} = \frac{C_0|\lambda|^{1+\delta} L^{-\alpha J}}{1 - L^{-\alpha}}.$$

The rooted-tree recursion is monotone in the majorants. Thus removing all scales below J bounds the remaining ultraviolet tail by (137.41). A cutoff change from J to J' changes the Schwinger function only by clusters touching at least one scale $j \ge J$, so the same tail estimate proves Cauchy convergence in the declared source seminorms. $\square$

Construction 137.16 (Source-decorated phase-cell seminorms)**.** The abstract scale-decay bound becomes a statement about Schwinger distributions only after local insertions are included in the same norm. Fix source labels $1, \dots, n$, test functions f_r, and seminorms $p_r(f_r)$ controlling the corresponding finite-regulator insertion weights. A source extension of the phase-cell system consists of functions $b_{r,j}(X)$, one for each source label and scale-j polymer, such that for every subset $I \subset \{1, \ldots, n\}$

$$\sup_{\Delta \in \mathcal{D}_j} \sum_{X \ni \Delta} e^{a|X|_j} \kappa_j(X) \prod_{r \in I} |b_{r,j}(X)| \leq C_I |\lambda|^{1+\delta} L^{-\alpha j} \prod_{r \in I} p_r(f_r). \tag{137.42}$$

Here $I = \varnothing$ recovers (137.38). At finite volume define

$$K_{j,\lambda}(X) = K_j(X) \exp\left(\sum_{r=1}^{n} \lambda_r b_{r,j}(X) \right).$$

Because the cluster expansion is absolutely convergent in a polydisc around $\lambda = 0$, finite source derivatives may be taken term by term. The coefficient

$$C_{1\cdots n}^{(J,\Lambda)} = \partial_{\lambda_1} \cdots \partial_{\lambda_n} \log Z_{J,\Lambda}(\lambda)|_{\lambda=0}$$

is a sum over connected clusters together with an assignment of each source label to one cluster vertex. The product over labels assigned to a vertex is precisely one of the factors controlled in (137.42). Applying the tree-graph proof of Theorem 137.15 to these decorated vertices gives constants $A_n < \infty$, depending on the neighbourhood constant and on the finite collection $\{C_I\}_{I \subset \{1,\ldots,n\}}$, such that

$$|C_{1\cdots n}^{(J,\Lambda)}| \leq A_n \prod_{r=1}^{n} p_r(f_r) \tag{137.43}$$

uniformly in the volume and cutoff. Moreover, clusters containing at least one scale $j \geq J_0$ obey the ultraviolet tail estimate

$$|C_{1\cdots n}^{(J,\Lambda)} - C_{1\cdots n}^{(J_0,\Lambda)}| \leq A_n \frac{|\lambda|^{1+\delta} L^{-\alpha J_0}}{1 - L^{-\alpha}} \prod_{r=1}^{n} p_r(f_r), \qquad J \geq J_0. \tag{137.44}$$

Thus (137.42) is the missing source-level hypothesis behind the phrase "Cauchy in Schwinger seminorms." If the constants A_n can be chosen with an OS-admissible growth envelope, for instance $A_n \leq AB^n (n!)^\gamma$ in a nuclear test-space seminorm family, then the limiting connected Schwinger distributions have the corresponding OS growth bound. Proving (137.42) and such an n-growth envelope for the actual Φ_3^4 phase-cell activities is part of the still-open model-specific construction.

Connected-to-full hierarchy bookkeeping. The OS input is the full Schwinger hierarchy, whereas the cluster expansion first produces connected source coefficients. This passage is exact but it is not free at the level of growth constants. Let Π_n be the set of partitions of $\{1, \ldots, n\}$. If the finite-regulator connected coefficients $C_B^{(J,\Lambda)}$, $B \subset \{1, \ldots, n\}$, are defined by differentiating $\log Z_{J,\Lambda}$, then the corresponding full source coefficient is

$$S_{1\cdots n}^{(J,\Lambda)} = \sum_{\pi \in \Pi_n} \prod_{B \in \pi} C_B^{(J,\Lambda)}. \tag{137.45}$$

This is the finite moment–cumulant identity applied to $Z_{J,\Lambda}(\lambda) = \exp \log Z_{J,\Lambda}(\lambda)$. Taking the ultraviolet and volume limits term by term is justified only after the connected coefficients have uniform bounds and Cauchy estimates such as (137.43) and (137.44).

The cost in the OS growth envelope is explicit. Suppose, for one declared test-seminorm family, that every connected block obeys

$$|C_B^{(J,\Lambda)}| \le AB_0^{|B|}(|B|!)^\gamma \prod_{r\in B} p_r(f_r) \tag{137.46}$$

uniformly in J, Λ, with A, B_0, γ independent of the block. Then (137.45) gives

$$|S_{1\cdots n}^{(J,\Lambda)}| \le B_0^n \left(\prod_{r=1}^n p_r(f_r)\right) \sum_{\pi\in\Pi_n} A^{|\pi|} \prod_{B\in\pi} (|B|!)^\gamma. \tag{137.47}$$

For every partition π, $\prod_{B\in\pi} |B|! \le n!$. Also $|\Pi_n| \le n^n \le e^n n!$. Hence

$$|S_{1\cdots n}^{(J,\Lambda)}| \le \big(eB_0 \max\{1, A\}\big)^n (n!)^{\gamma+1} \prod_{r=1}^n p_r(f_r). \tag{137.48}$$

Thus a connected envelope of the OS-II form produces a full hierarchy with the same linear seminorm-order control but with one additional factorial power from the partition sum. This is still admissible for the OS-II condition (12.4) after replacing γ by $\gamma+1$, provided the test-seminorm family is stable under the translation reduction used in Chapter 12. The statement does not prove the model-specific connected envelope; it records the exact growth loss that a constructive proof must budget before invoking OS reconstruction.

Definition 137.17 (Model-specific phase-cell derivation budget)**.** A model-specific phase-cell derivation budget for the massive Φ^4_3 construction is the data needed to turn the regulated scalar measure into the abstract system of Definition 137.14. It consists of:

(i) a reflection-compatible finite-volume regulator, a finite-range covariance decomposition into scale pieces C_j, and cell algebras on the scale-j decomposition $\mathcal{D}_j$;

(ii) small-field norms, large-field weights, and a local extraction map $\mathcal{L}_j$ onto the vacuum and mass coordinates $\mathcal{O}_{0,j}$ and $\mathcal{O}_{2,j}$;

(iii) counterterm increments $\delta a_j, \delta b_j$ and a remainder

$$R_j(X) = (1-\mathcal{L}_j)K_j(X)$$

for each scale-j activity;

(iv) source weights $b_{r,j}(X)$ and test seminorms $p_r(f_r)$ for local insertions;

(v) regulator-comparison, reflection-positivity, and moment-growth defects which measure the distance from the finite phase-cell regulator to the OS hierarchy asserted in Quoted Theorem 137.13.

The budget is admissible with exponents $\alpha_{\mathrm{act}}, \alpha_{\mathrm{loc}}, \alpha_{\mathrm{OS}} > 0$ if, after the chosen local coordinates have been extracted, the actual estimates imply

$$\sup_{\Delta\in\mathcal{D}_j} \sum_{X\ni\Delta} e^{a|X|_j} \big(\kappa_j^{\mathrm{sf}}(X) + \kappa_j^{\mathrm{lf}}(X) + \kappa_j^{\mathrm{irr}}(X)\big) \le C_{\mathrm{act}} |\lambda|^{1+\delta} L^{-\alpha_{\mathrm{act}} j}, \tag{137.49}$$

for the small-field, large-field, and irrelevant-remainder parts of the activity, together with the source-decorated estimates

$$\sup_{\Delta\in\mathcal{D}_j} \sum_{X\ni\Delta} e^{a|X|_j} \kappa_j(X) \prod_{r\in I} |b_{r,j}(X)| \le C_I |\lambda|^{1+\delta} L^{-\alpha_{\mathrm{act}} j} \prod_{r\in I} p_r(f_r) \tag{137.50}$$

for every finite source set I. The local coordinates and OS-regulator defects must have summable tails:

$$\sum_{m\geq j}\big(|\delta a_m-\delta a_m^{\mathrm{target}}|+|\delta b_m-\delta b_m^{\mathrm{target}}|\big)\leq C_{\mathrm{loc}}L^{-\alpha_{\mathrm{loc}}j},\qquad \mathcal{R}_j^{\mathrm{OS}}\leq C_{\mathrm{OS}}L^{-\alpha_{\mathrm{OS}}j}. \tag{137.51}$$

Here $\delta a_m^{\mathrm{target}}$ and $\delta b_m^{\mathrm{target}}$ denote the declared mass and vacuum-energy coordinate increments, and $\mathcal{R}_j^{\mathrm{OS}}$ includes the regulator-comparison, reflection positivity, and moment-growth errors which survive after truncating at scale j. The definition is a proof budget: it records the estimates whose model-specific proof produces (137.49)– (137.51) from the actual finite-regulator scalar measure.

Proposition 137.18 (From phase-cell budget to constructive output inputs)**.** *Assume an admissible model-specific phase-cell budget. Then* (137.49) *implies the abstract scale-decay hypothesis* (137.38)*, with $C_0=C_{\mathrm{act}}$ and $\alpha=\alpha_{\mathrm{act}}$. Equation* (137.50) *implies the source-decorated Schwinger-seminorm bound* (137.42)*. For every cutoff scale J, the remaining constructive defect is bounded by*

$$\mathcal{E}_J^{\mathrm{constr}}\leq\frac{C_{\mathrm{act}}|\lambda|^{1+\delta}L^{-\alpha_{\mathrm{act}}J}}{1-L^{-\alpha_{\mathrm{act}}}}+C_{\mathrm{loc}}L^{-\alpha_{\mathrm{loc}}J}+C_{\mathrm{OS}}L^{-\alpha_{\mathrm{OS}}J}. \tag{137.52}$$

Consequently, if the Kotecky–Preiss smallness condition (137.39) *also holds, the local summability, source-seminorm Cauchy property, and finite-window OS limits needed by Quoted Theorem 137.13 reduce to proving the model-specific estimates in Definition 137.17.*

Proof. The first assertion is just the identification

$$\kappa_j(X)=\kappa_j^{\mathrm{sf}}(X)+\kappa_j^{\mathrm{lf}}(X)+\kappa_j^{\mathrm{irr}}(X)$$

inside (137.49). The second assertion is the same estimate with the source weights retained, hence it is exactly (137.42). Summing the activity bound over $m\geq J$ gives the geometric tail

$$\sum_{m\geq J}C_{\mathrm{act}}|\lambda|^{1+\delta}L^{-\alpha_{\mathrm{act}}m}=\frac{C_{\mathrm{act}}|\lambda|^{1+\delta}L^{-\alpha_{\mathrm{act}}J}}{1-L^{-\alpha_{\mathrm{act}}}}.$$

The local-coordinate and OS-regulator tails are the two terms stated in (137.51). Adding these three independent errors gives (137.52). Theorem 137.15, Construction 137.16, and the connected-to-full hierarchy bookkeeping above then supply the abstract summation and OS-growth consequences once the displayed model-specific inputs are proved. □

The difficult model-specific part of the Φ_3^4 construction is now located precisely: one must construct Definition 137.17 for the actual phase-cell activities obtained from the regulated scalar field after the local coordinates have been extracted. Proposition 137.18 proves that these bounds, once established with reflection-positive regulators and uniform moment estimates, are sufficient for ultraviolet convergence of the Schwinger functions. Construction 137.16 records the additional source-decorated estimate needed to obtain distributional seminorm bounds and OS growth rather than only convergence of the vacuum polymer partition function.

Open Problem 137.19 (Self-contained constructive proof of Φ_3^4). Give a complete monograph-internal proof of Quoted Theorem 137.13. The proof must derive the actual phase-cell activities from the regulated Φ^4_3 measure, state the small-field and large-field norms, prove the model-specific stability estimates beyond the finite-cutoff one-site bound, identify the local coordinate b_ε to the same precision as the mass coordinate in Lemma 137.12, and prove (137.38) and (137.42) for those activities, with OS-admissible growth in the number of source insertions. The abstract summation, reflection-positivity preservation, and ultraviolet Cauchy steps are supplied above; the remaining proof obligation is the model-specific multiscale estimate producing their hypotheses.

137.6 OS Data Produced by a Construction

The output of a constructive scalar theorem is a hierarchy

$$S_n(f_1, \dots, f_n) = \lim_{\Lambda \uparrow \mathbb{R}^d,\ \varepsilon \downarrow 0} S_{\varepsilon,\Lambda,n}(f_1, \dots, f_n) \tag{137.53}$$

on Schwartz test functions or on a declared nuclear test space. The data must include the following.

1. **Distributional regularity.** Each S_n is a continuous multilinear functional in the chosen topology.
2. **Euclidean covariance and symmetry.** The Schwinger functions are invariant under the Euclidean group and symmetric under permutation of scalar insertions.
3. **Reflection positivity.** For the time reflection $\theta(\tau, \mathbf{x}) = (-\tau, \mathbf{x})$ and test polynomials supported at positive Euclidean time,
$$\sum_{\alpha,\beta} \overline{c_\alpha} c_\beta S_{\alpha+\theta\beta} \geq 0.$$
4. **Growth.** The OS-II regularity and linear-growth hypotheses needed for analytic continuation and Hilbert-space reconstruction are verified, not assumed from formal manipulations.
5. **Clustering or phase decomposition.** A unique massive vacuum requires exponential clustering; a phase coexistence construction must specify the phase sector.

Once these statements are proved, OS reconstruction gives a Hilbert space, a cyclic vacuum, Wightman fields, and local commutativity. The constructive status table in Chapter 136 records representative examples. The lattice, stochastic, and numerical chapters below must match the same data format when they claim to approximate or construct a continuum QFT.

137.7 Comparison of Constructive Routes

The same theory label can arise from cluster expansions, lattice scaling limits, rigorous RG, and singular SPDE. Equality of the resulting QFTs is a statement about Schwinger functions or local observable algebras. A comparison theorem must provide a parameter map

$$(m, \lambda, a_{\mathrm{fin}}, b_{\mathrm{fin}})_{\mathrm{cluster}} \longleftrightarrow (m, \lambda, c_1, c_2)_{\mathrm{SPDE}} \longleftrightarrow (m_0^2, \lambda_0, a)_{\mathrm{lattice}}$$

and prove convergence to the same S_n's in a common topology.

Open Problem 137.20 (Explicit comparison of constructive routes). For a model such as Φ^4_3, compare the Schwinger functions produced by cluster/phase-cell expansions, stochastic quantization, rigorous RG, and lattice scaling limits in one common topology. The comparison should identify the OS Hilbert space, the local fields, and the finite coordinate map between the constructions.

Reflection positivity is the lattice analogue of the positivity axiom used in Euclidean reconstruction. It is a property of a regulated measure and a chosen reflection, not an automatic property of every discretization. This chapter states the condition and verifies it for the basic nearest-neighbor scalar lattice action.

138.1 Reflection and Positive Algebra

Let $\Lambda \subset a\mathbb{Z}^D$ be a finite reflection-invariant lattice with reflection ϑ across the hyperplane $x_0 = 0$. Let ϕ_x be a real scalar variable at $x \in \Lambda$. Let $\mathcal{A}_+$ be the algebra of polynomial functions of the variables with $x_0 > 0$. The reflection acts antilinearly on functions by

$$(\Theta F)(\phi) = \overline{F(\phi_{\vartheta x})}.$$

For a probability measure $d\mu(\phi)$, define

$$\langle F \rangle = \int F(\phi)\, d\mu(\phi).$$

Definition 138.1 (Lattice reflection positivity)**.** The measure $d\mu$ is reflection positive with respect to ϑ if

$$\langle \Theta F\, F \rangle \geq 0$$

for every $F \in \mathcal{A}_+$.

138.2 Nearest-Neighbor Scalar Measure

Consider the finite-volume lattice measure

$$d\mu(\phi) = Z^{-1} e^{-S(\phi)} \prod_{x\in\Lambda} d\phi_x$$

with

$$S(\phi) = \frac{1}{2}\sum_{\langle xy\rangle} c_{xy}(\phi_x - \phi_y)^2 + \sum_x V(\phi_x), \qquad c_{xy} > 0,$$

where V is a real potential for which the finite-volume integral exists. Split the action as

$$S = S_+ + \Theta S_+ + S_0$$

where S_+ contains terms strictly in the positive half, ΘS_+ its reflected copy, and S_0 the terms on or crossing the reflection plane. The crossing terms have the form

$$\frac{1}{2}c(\phi_x - \phi_{\vartheta x})^2 = \frac{1}{2}c\phi_x^2 + \frac{1}{2}c\phi_{\vartheta x}^2 - c\phi_x\phi_{\vartheta x}.$$

The first two terms can be assigned to S_+ and ΘS_+. The coupling across the plane contributes the positive kernel

$$\exp(c\phi_x\phi_{\vartheta x}) = \sum_{n=0}^{\infty} \frac{c^n}{n!}\phi_x^n\phi_{\vartheta x}^n.$$

Proposition 138.2 (Scalar lattice reflection positivity)**.** *Assume the finite lattice, the coefficients c_{xy}, and the one-site potential V are invariant under the reflection ϑ, and assume the finite-volume integral exists. Then the nearest-neighbor scalar lattice measure above is reflection positive on the polynomial algebra $\mathcal{A}_+$ generated by fields in the positive half-lattice:*

$$\int \overline{\Theta F(\phi)}\, F(\phi)\, d\mu(\phi) \ge 0, \qquad F \in \mathcal{A}_+.$$

Proof. After assigning all non-crossing terms and the square pieces in $\frac{1}{2}c(\phi_x - \phi_{\vartheta x})^2$ to S_+ and ΘS_+, the only factors coupling reflected variables have the form

$$K_i(\phi_i, \phi_{\vartheta i}) = \exp(c_i\phi_i\phi_{\vartheta i}), \qquad c_i > 0,$$

one for each bond crossing the reflection plane. Their product admits the absolutely convergent expansion

$$\prod_i K_i = \sum_{\mathbf{n}} \left(\prod_i \frac{c_i^{n_i}}{n_i!}\right) \prod_i \phi_i^{n_i}\phi_{\vartheta i}^{n_i}.$$

Let

$$d\nu_+(\phi_+) = \exp[-S_+(\phi_+)] \prod_{x\in\Lambda_+} d\phi_x$$

including the positive-half one-site factors and the assigned half of the crossing square terms. Reflection invariance gives the reflected measure $\Theta d\nu_+$ on the negative half. For a polynomial $F \in \mathcal{A}_+$, Fubini's theorem and the finite-volume integrability assumption allow termwise integration of the nonnegative-coefficient series, or equivalently first truncation of the series and then monotone convergence for the positive kernels. Each multi-index contribution is

$$\left(\prod_i \frac{c_i^{n_i}}{n_i!}\right)\left|\int F(\phi_+)\prod_i \phi_i^{n_i}\,d\nu_+(\phi_+)\right|^2$$

up to the positive normalization constant Z^{-1}. The coefficient is nonnegative and the remaining factor is an absolute square. Summing over $\mathbf{n}$ gives $\int \overline{\Theta F} F\,d\mu \geq 0$. □

138.3 Free Lattice Fermions

Reflection positivity for Grassmann variables is a positivity property of the Berezin functional together with an antilinear anti-automorphism. Let $\psi_A(x)$ and $\bar\psi^A(x)$ be independent Grassmann-odd variables on $\Lambda \subset \mathbb{Z}^D$, and let C_μ be Euclidean Clifford matrices,

$$\{C_\mu, C_\nu\}_A{}^B = 2\delta_{\mu\nu}\delta_A{}^B.$$

The nearest-neighbor free lattice action is

$$-S = \sum_x \left[m\,\bar\psi^A(x)\psi_A(x) - \frac{1}{2}\sum_{\mu=1}^{D}\bar\psi^A(x)(C_\mu)_A{}^B\big(\psi_B(x-e_\mu)-\psi_B(x+e_\mu)\big)\right].$$

The corresponding two-point function is

$$\langle\bar\psi^B(y)\psi_A(x)\rangle = \int_{[-\pi,\pi]^D}\frac{d^Dp}{(2\pi)^D}\,e^{\mathrm{i}p\cdot(x-y)}\,\frac{m\delta_A{}^B - \mathrm{i}\sum_\mu (C_\mu)_A{}^B\sin p_\mu}{m^2+\sum_\nu \sin^2 p_\nu}.$$

Adding a Wilson term changes the numerator by a chirality-matrix term and the denominator by the corresponding Wilson square; it removes doublers at the price of explicitly coupling the reflection-positivity question to the chosen Wilson operator and mass range.

For the naive action above, the reflection compatible with the simple positivity proof is the reflection through the plane halfway between two time slices. Take $v = e_1$, $c = 1/2$, and

$$R(x) = x - 2(x\cdot e_1 - c)e_1.$$

Let $H = \{x : x_1 \geq 1\}$. Define the antilinear anti-automorphism

$$\Theta(AB) = \Theta(B)\Theta(A),$$

$$\Theta(\psi_A(x)) = (C_1)_B{}^A\,\bar\psi^B(Rx), \qquad \Theta(\bar\psi^A(x)) = (C_1)_A{}^B\,\psi_B(Rx).$$

Reflection positivity means

$$\langle\Theta(\mathcal{O})\mathcal{O}\rangle \geq 0$$

for every polynomial $\mathcal{O}$ in the Grassmann variables supported in H, where positivity is the coefficient positivity obtained after the Berezin integral is reduced to a sum of squares.

The placement of the reflection plane is essential. A two-point test with $\mathcal{O} = \zeta^A \psi_A(x)$ gives, for the mid-link plane,

$$\int_{[-\pi,\pi]^D} \frac{d^D p}{(2\pi)^D} \frac{|\zeta|^2 \sin p_1 \, \sin\bigl(p_1(2x_1 - 1)\bigr)}{m^2 + \sum_\nu \sin^2 p_\nu}, \qquad x_1 \geq 1,$$

which has the positive one-dimensional transfer-kernel expansion in the normal direction. For a site reflection $c = 0$, the same test contains the term

$$\int_{[-\pi,\pi]^D} \frac{d^D p}{(2\pi)^D} \frac{m\,(\zeta C_1 \zeta^*) \cos(2p_1 x_1)}{m^2 + \sum_\nu \sin^2 p_\nu},$$

whose sign is not fixed for arbitrary spinor ζ. A diagonal reflection such as $v = e_1 + e_2$ similarly fails the same elementary two-point positivity test. Thus the fermion reflection structure is not interchangeable among lattice hyperplanes.

Proposition 138.3 (Mid-link free-fermion reflection positivity)**.** *For the nearest-neighbor free lattice fermion action above, reflection positivity holds for the mid-link reflection $v = e_1, c = 1/2$ with the Grassmann reflection Θ displayed above.*

Proof. Write $P_+ = \{x : x_1 = 1\}$ and $P_- = \{x : x_1 = 0\}$. Split the action into positive-half, reflected-half, and cross-plane terms. The cross-plane factor is a finite Grassmann polynomial over links crossing the plane:

$$\prod_{x \in P_+} \exp\Bigl[-\frac{1}{2}\bigl(\bar\psi^A(x)(C_1)_A{}^B \psi_B(Rx) - \bar\psi^A(Rx)(C_1)_A{}^B \psi_B(x)\bigr)\Bigr].$$

Using the displayed definition of Θ, each cross factor can be written as a product of terms of the form

$$1 + \frac{1}{2}\left[\Theta(\psi_A(x))\,\bar\psi^A(x) + \Theta(\bar\psi^A(x))\,\psi_A(x)\right].$$

Integrating the variables strictly inside H against $\mathcal{O}e^{-S_H}$ produces a boundary Grassmann polynomial Ψ in the variables on P_+. The reflected half gives $\Theta(\Psi)$. The remaining Berezin integral over $P_+ \cup P_-$ is a finite sum of products $\Theta(c_I)c_I$ of the coefficients of Ψ, with nonnegative numerical weights supplied by the cross factors. This is the Grassmann analogue of the scalar sum-of-squares argument. $\square$

138.4 Staggered Fermions and a Thirring Interaction

In two dimensions with $C_1 = \sigma_3$ and $C_2 = \sigma_1$, a closed staggered subsector of the Dirac lattice fermion can be written in terms of one-component Grassmann variables $\eta(x), \bar\eta(x)$. In the convention of the staggered reduction,

$$-S = \sum_{\langle xy \rangle} M(x,y)\bar\eta(x)\eta(y) + m\sum_x \bar\eta(x)\eta(x),$$

with nearest-neighbor coefficients

$$M(x, x \pm e_1) = \pm\frac{(-1)^{x_2}}{2}, \qquad M(x, x \pm e_2) = \pm 1.$$

The mid-link reflection acts by

$$\Theta(\eta(x)) = (-1)^{x_2}\bar{\eta}(Rx), \qquad \Theta(\bar{\eta}(x)) = (-1)^{x_2}\eta(Rx).$$

The same boundary-polynomial proof gives reflection positivity for the free staggered action.

Add the nearest-neighbor Thirring interaction

$$-\Delta S = -U\sum_x \sum_{\mu=1,2} \bar{\eta}(x)\eta(x+e_\mu)\bar{\eta}(x+e_\mu)\eta(x).$$

It is invariant under the displayed reflection. The cross-plane factor has the form

$$1 + U\,\Theta(\eta(x)\bar{\eta}(x))\,\eta(x)\bar{\eta}(x)$$

on each crossing link. Therefore the same coefficient-square argument extends to the interacting lattice Thirring model for

$$U \geq 0.$$

This is a finite-regulator reflection-positivity statement. Continuum existence, scaling limits, and identification of the resulting QFT require the additional compactness and renormalization estimates discussed in Chapter 139.

138.5 Transfer Matrix Interpretation

When the lattice is periodic in Euclidean time, reflection positivity permits the construction of a pre-Hilbert space from $\mathcal{A}_+$ by quotienting the null space of the sesquilinear form

$$(F, G) = \langle \Theta F\, G \rangle.$$

Time translation by one lattice spacing acts as a contraction on this pre-Hilbert space. Under the additional hypotheses required for a transfer matrix, this contraction is e^{-aH} for a positive self-adjoint lattice Hamiltonian H. This is the finite-regulator version of the positivity step in OS reconstruction.

138.6 Gauge Fields

For lattice gauge theory the configuration variables are group elements $U_\ell \in G$ on oriented links ℓ, with $U_{-\ell} = U_\ell^{-1}$. Here G is a compact Lie group and the finite-regulator measure is the product Haar measure multiplied by local class functions of plaquette holonomies. If

$$p = (\ell_1, \ell_2, \ell_3, \ell_4), \qquad U_p = U_{\ell_1}U_{\ell_2}U_{\ell_3}U_{\ell_4},$$

then a one-plaquette gauge action is specified by a continuous positive class function $w : G \to \mathbb{R}_{>0}$:

$$d\mu(U) = Z^{-1}\prod_\ell dU_\ell \prod_p w(U_p).$$

The reflection ϑ maps links to reflected links with reflected orientation. The positive algebra $\mathcal{A}_+$ is generated by matrix elements of link variables supported in the positive half-lattice, and Θ is the antilinear anti-automorphism obtained by reflecting links and complex conjugating coefficients.

The useful finite-volume theorem is not special to the defining representation. Let $\widehat{G}$ be the set of equivalence classes of finite-dimensional irreducible unitary representations of G, let χ_λ be the character of λ, and write D^λ_{ij} for matrix elements in an orthonormal basis.

Theorem 138.4 (Osterwalder-Seiler character criterion)**.** *Assume that the plaquette weight has an absolutely convergent character expansion*

$$w(g) = \sum_{\lambda\in\widehat{G}} c_\lambda \chi_\lambda(g), \qquad c_\lambda \geq 0.$$

Then the finite-volume gauge measure defined above is reflection positive with respect to the link-reflection plane.

Proof. Plaquettes lying strictly in the positive half-lattice and in the negative half-lattice are assigned to W_+ and ΘW_+, respectively. A plaquette crossing the reflection plane is cut into a positive half-path c and its reflected half. With a choice of orientation its holonomy has the form

$$U_p = V_c\,\Theta(V_c)^{-1}, \qquad V_c = \prod_{\ell\in c} U_\ell.$$

Changing the orientation replaces g by g^{-1}, which only conjugates the character expansion and does not affect the positivity argument.

For one crossing plaquette, Peter-Weyl gives

$$w\big(V_c\Theta(V_c)^{-1}\big) = \sum_\lambda c_\lambda \sum_{i,j} D^\lambda_{ij}(V_c)\,\Theta\Big(D^\lambda_{ij}(V_c)\Big).$$

The product over crossing plaquettes is therefore a finite or absolutely convergent sum

$$\prod_{p\ \text{crossing}} w(U_p) = \sum_\alpha C_\alpha\,\Theta(B_\alpha)B_\alpha, \qquad C_\alpha \geq 0,$$

where each B_α is a polynomial in positive-half link matrix elements. For $F \in \mathcal{A}_+$,

$$\langle \Theta F\,F\rangle = Z^{-1}\sum_\alpha C_\alpha \int \Theta(FW_+B_\alpha)\,(FW_+B_\alpha)\prod_\ell dU_\ell.$$

Product Haar measure is invariant under reflection and factorizes between the two halves once the crossing-plaquette expansion has been made. Thus each summand is the modulus square of the same half-lattice integral:

$$\int \Theta(FW_+B_\alpha)\,(FW_+B_\alpha)\prod_\ell dU_\ell = \left|\int_{\Lambda_+} FW_+B_\alpha \prod_{\ell\subset\Lambda_+} dU_\ell\right|^2 \geq 0.$$

Since $C_\alpha \geq 0$, the full sum is nonnegative. $\square$

Wilson plaquette action. For $G = SU(N)$ or $U(N)$, the Wilson plaquette weight

$$w_W(g) = \exp\biggl(\frac{\beta}{N}\,\mathrm{Re}\,\mathrm{Tr}_F\, g\biggr), \qquad \beta \geq 0,$$

is reflection positive. This is the character-expansion check required by Theorem 138.4. Let F be the defining representation and write $\chi_{\overline{F}}(g) = \overline{\chi_F(g)} = \chi_F(g^{-1})$. Then

$$w_W(g) = \exp\biggl(\frac{\beta}{2N}\,\bigl(\chi_F(g) + \chi_{\overline{F}}(g)\bigr)\biggr) = \sum_{m,n\geq 0} \frac{(\beta/2N)^{m+n}}{m!\,n!}\,\chi_F(g)^m \chi_{\overline{F}}(g)^n.$$

The product $\chi_F^m \chi_{\overline{F}}^n$ is the character of $F^{\otimes m} \otimes \overline{F}^{\otimes n}$. Decomposing this finite representation into irreducibles gives

$$\chi_F^m \chi_{\overline{F}}^n = \sum_{\lambda \in \widehat{G}} N_{m,n}^{\lambda} \chi_\lambda, \qquad N_{m,n}^{\lambda} \in \mathbb{Z}_{\geq 0}.$$

Hence the Wilson weight has nonnegative character coefficients. Absolute convergence follows from the uniform convergence of the exponential series on compact G, so Theorem 138.4 applies.

For $G = U(1)$, the same statement is the elementary Fourier expansion

$$e^{\beta\cos\theta} = \sum_{n\in\mathbb{Z}} I_n(\beta) e^{\mathrm{i}n\theta}, \qquad I_n(\beta) = \sum_{r\geq 0} \frac{(\beta/2)^{2r+|n|}}{r!\,(r+|n|)!} \geq 0.$$

This formula is the abelian form of the same positive-type condition.

$SU(2)$ **Wilson character coefficients.** Let $G = SU(2)$, and write every conjugacy class as

$$g(\theta) \sim \begin{pmatrix} e^{\mathrm{i}\theta} & 0 \\ 0 & e^{-\mathrm{i}\theta} \end{pmatrix}, \qquad 0 \leq \theta \leq \pi.$$

For the Wilson weight

$$w_W(\theta) = \exp(\beta\cos\theta),$$

the character expansion

$$w_W(\theta) = \sum_{\ell=0}^{\infty} a_\ell(\beta)\,\chi_\ell(\theta), \qquad \chi_\ell(\theta) = \frac{\sin((\ell+1)\theta)}{\sin\theta},$$

has coefficients

$$a_\ell(\beta) = I_\ell(\beta) - I_{\ell+2}(\beta) = \frac{2(\ell+1)}{\beta} I_{\ell+1}(\beta) > 0 \qquad (\beta > 0), \tag{138.1}$$

with the limiting value at $\beta = 0$ understood as $a_0(0) = 1$, $a_{\ell>0}(0) = 0$. The irreducible $SU(2)$ characters are indexed here by $\ell = 2j \in \mathbb{Z}_{\geq 0}$, where j is the spin. The class-function form of normalized Haar measure is

$$\mathrm{d}\mu_{\text{class}}(\theta) = \frac{2}{\pi}\sin^2\theta\,\mathrm{d}\theta.$$

Orthogonality gives

$$a_\ell(\beta) = \frac{2}{\pi}\int_0^{\pi} e^{\beta\cos\theta}\sin\theta\,\sin((\ell+1)\theta)\,\mathrm{d}\theta. \tag{138.2}$$

Using

$$\sin\theta\,\sin((\ell+1)\theta) = \frac{1}{2}\left(\cos(\ell\theta) - \cos((\ell+2)\theta)\right)$$

and

$$I_n(\beta) = \frac{1}{\pi}\int_0^\pi e^{\beta\cos\theta}\cos(n\theta)\,\mathrm{d}\theta \qquad (n \geq 0),$$

we obtain $a_\ell = I_\ell - I_{\ell+2}$. The Bessel recurrence

$$I_\ell(\beta) - I_{\ell+2}(\beta) = \frac{2(\ell+1)}{\beta} I_{\ell+1}(\beta)$$

follows by differentiating the Fourier series for $e^{\beta\cos\theta}$ or, equivalently, from integration by parts in the defining integral. Since

$$I_{\ell+1}(\beta) = \sum_{r=0}^{\infty} \frac{(\beta/2)^{2r+\ell+1}}{r!(r+\ell+1)!}$$

has strictly positive terms when $\beta > 0$, the coefficient (138.1) is strictly positive.

`calculation-checks/lattice_reflection_positivity_checks.py` verifies the $U(1)$ Bessel coefficients, the $SU(2)$ coefficient identity (138.1), and finite $SU(2)$ tensor-product character multiplicities used in the proof of the Wilson plaquette positivity statement above.

The proof also explains why reflection positivity is not an automatic consequence of gauge invariance. Gauge fixing may destroy the product-Haar factorization used above. Improved gauge actions must be tested loop by loop. A sufficient condition is that every crossing-loop weight admit a nonnegative character expansion after the loop is split into a positive half-path and its reflected half. The standard tree-level Symanzik or Luscher-Weisz action and the Iwasaki action contain rectangle terms with negative coefficient c_1 in

$$S_{\mathrm{imp}} = -\frac{\beta}{N}\left(c_0 \sum_{\text{plaquettes}} \operatorname{Re}\operatorname{Tr} U_p + c_1 \sum_{\text{rectangles}} \operatorname{Re}\operatorname{Tr} U_R + \cdots\right),$$

with $c_1 = -1/12$ at tree-level Symanzik improvement and $c_1 \simeq -0.331$ for Iwasaki. For a single crossing rectangle with coefficient $\alpha = \beta c_1/N < 0$,

$$\exp(\alpha \operatorname{Re}\operatorname{Tr}_F g) = 1 + \frac{\alpha}{2}\big(\chi_F(g) + \chi_{\overline{F}}(g)\big) + O(\alpha^2),$$

so the fundamental character coefficient is negative to first order. Such a factor is not of positive type and cannot enter the sum-of-squares proof. Consequently the Wilson-action proof does not extend to these improved one-step transfer matrices; any use of such actions in an argument requiring reflection positivity must supply a separate positivity theorem, often after blocking the time direction or changing the regulator.

Open Problem 138.5 (Reflection-positive continuum limits). Give verifiable criteria ensuring that a sequence of reflection-positive lattice measures converges to OS-positive continuum Schwinger functions with nontrivial local fields. The criteria must include tightness or correlation bounds, control of counterterms, and compatibility of reflection with the continuum scaling limit.

A regulated model becomes a continuum QFT only after its correlation functions converge as distributions and the limiting Schwinger functions satisfy the hypotheses needed for reconstruction. The continuum limit is therefore a statement about a family of measures, a scaling trajectory in the regulated action, and a coordinate system for local observables. The object produced is the limiting system of Schwinger distributions together with its reconstruction data.

Throughout this chapter D is the Euclidean spacetime dimension, $\Lambda_a = a\mathbb{Z}^D$, and $a > 0$ is the lattice spacing. The infinite-volume limit is taken before $a \downarrow 0$, except where a finite-volume scaling limit is explicitly stated.

139.1 Regulated Families and Schwinger Distributions

For each a, let $\mathcal{E}_a$ be a space of lattice fields and let

$$d\mu_a(\phi) = Z_a^{-1} \exp[-S_a(\phi)] D\phi$$

be the regulated expectation functional. The notation $D\phi$ denotes the finite-dimensional Lebesgue or Berezin product before infinite volume; after an infinite-volume limit it denotes the resulting cylindrical expectation, understood through its values on local observables.

A scaling trajectory is a map

$$a \longmapsto c(a)$$

from lattice spacing to the local coefficients appearing in S_a. These coefficients include all regulator-dependent local terms. In this monograph the word counterterm means such a local term in the regulated action. It is part of the action defining the path integral, not a second action added afterward.

Let $O_a^I(n)$ be local lattice observables. A renormalized smeared observable is

$$O_a^I(f) = a^D \sum_{n\in\mathbb{Z}^D} f(an)\, Z^I{}_J(a)\, O_a^J(n), \qquad f \in C_c^\infty(\mathbb{R}^D), \tag{139.1}$$

where $Z^I{}_J(a)$ may mix all observables with the same quantum numbers and dimension bounded by the chosen truncation. A continuum Schwinger distribution is the multilinear distribution

$$S^{I_1\ldots I_k}(f_1,\ldots,f_k) = \lim_{a\downarrow 0} \left\langle O_a^{I_1}(f_1)\cdots O_a^{I_k}(f_k)\right\rangle_a, \tag{139.2}$$

when the limit exists for all test functions in the stated topology.

The topology matters. A useful constructive statement gives uniform bounds on the regulated distributions in a negative Sobolev or Schwartz seminorm, then proves convergence on a dense test-function space. Pointwise convergence of unsmeared lattice correlators at separated lattice sites is a weaker statement; it does not determine contact terms and does not by itself give an operator-valued distribution after reconstruction.

139.2 Free Lattice Scalar as a Model Calculation

The massive free scalar illustrates the exact normalization of the continuum limit. Let

$$S_a(\phi) = \frac{1}{2} a^D \sum_{x\in a\mathbb{Z}^D} \left[\sum_{\mu=1}^{D} \frac{(\phi_{x+a\hat{\mu}} - \phi_x)^2}{a^2} + m_a^2\phi_x^2\right], \tag{139.3}$$

with $m_a \to m > 0$. The infinite-volume covariance is

$$C_a(x-y) = \int_{B_a} \frac{d^D p}{(2\pi)^D} \frac{e^{\mathrm{i}p\cdot(x-y)}}{\hat{p}_a^2 + m_a^2}, \qquad \hat{p}_a^2 = \frac{4}{a^2}\sum_{\mu=1}^{D} \sin^2\!\left(\frac{ap_\mu}{2}\right), \tag{139.4}$$

where $B_a = (-\pi/a, \pi/a]^D$ is the Brillouin zone. Define the smeared field

$$\phi_a(f) = a^D \sum_{x\in a\mathbb{Z}^D} f(x)\phi_x.$$

Proposition 139.1 (Massive free lattice scalar continuum limit)**.** *If $m_a \to m > 0$, then for every $f, g \in C_c^\infty(\mathbb{R}^D)$,*

$$\lim_{a\downarrow 0}\langle \phi_a(f)\phi_a(g)\rangle_a = \int_{\mathbb{R}^D} \frac{d^D p}{(2\pi)^D} \frac{\widehat{f}(-p)\widehat{g}(p)}{p^2+m^2}. \tag{139.5}$$

All higher Schwinger functions converge to the Gaussian Wick contractions of this covariance.

Proof. For the covariance,

$$\langle \phi_a(f)\phi_a(g)\rangle_a = \int_{B_a} \frac{d^D p}{(2\pi)^D} \frac{\widehat{f}_a(-p)\widehat{g}_a(p)}{\hat{p}_a^2 + m_a^2},$$

where

$$\widehat{f}_a(p) = a^D \sum_{x\in a\mathbb{Z}^D} f(x)e^{-\mathrm{i}p\cdot x}.$$

Poisson summation gives

$$\widehat{f}_a(p) = \sum_{\ell\in\mathbb{Z}^D} \widehat{f}(p + 2\pi\ell/a).$$

Since f is smooth and compactly supported, $\widehat{f}$ is rapidly decreasing; hence $\widehat{f}_a(p) \to \widehat{f}(p)$ uniformly on every fixed compact momentum set and has uniform rapid-decay bounds after periodization. Also

$$\hat{p}_a^2 = p^2 + O(a^2|p|^4)$$

on compact sets, so the integrand converges pointwise to the continuum integrand. Split the Brillouin zone into $|p| \le R$ and its complement. On $|p| \le R$, dominated convergence applies. On the complement, rapid decay of the periodized test functions and positivity of $\hat{p}_a^2 + m_a^2$ give a bound whose $R \to \infty$ limit is uniform for small a. This proves the two-point convergence. The finite-dimensional Gaussian measures are determined by their covariance, so Wick's theorem gives convergence of every smeared k-point function. □

This proof is the prototype of a constructive continuum statement: regulated objects are smeared first, the limiting object is a distribution, and the proof supplies a uniform estimate that lets the limit pass through the integral.

139.3 Tree-Level Symanzik Expansion and Cutoff Effects

The phrase lattice artifact is precise only after one has chosen continuum coordinates for both sources and operators. At fixed lattice spacing the theory has hypercubic symmetry, not full $O(D)$ invariance. The continuum limit may recover $O(D)$ invariance because hypercubic but non-$O(D)$ local operators are irrelevant along the scaling trajectory, or because they have been canceled by improvement terms. This is the content, in its tree-level form, of the Symanzik expansion.

Definition 139.2 (Symanzik expansion data)**.** Fix a regulated lattice family, a scaling trajectory $c(a)$, and renormalized observable coordinates $O_a^I(f)$. A Symanzik expansion to order a^r for a class of smeared correlators is a finite list of continuum local distributions $S_{(n)}$, built from local operators allowed by the lattice symmetries, such that

$$\left\langle O_a^{I_1}(f_1)\cdots O_a^{I_k}(f_k)\right\rangle_a = \sum_{0\le n<r} a^n S_{(n)}^{I_1\ldots I_k}(f_1,\ldots,f_k) + R_{r,a}(f_1,\ldots,f_k), \tag{139.6}$$

with a stated seminorm q on the test functions and constants $C, a_0 > 0$ such that

$$|R_{r,a}(f_1,\ldots,f_k)| \le Ca^r\, q(f_1)\cdots q(f_k), \qquad 0 < a < a_0,$$

or with another explicitly stated remainder estimate. In an interacting theory this is a theorem only after the uniform distributional bounds, operator-mixing coordinates, and irrelevant operator estimates have been proved. The formal list of allowed local operators alone is not a continuum-limit proof.

Free scalar tree-level cutoff expansion. For the free lattice scalar of (139.3), write

$$\hat{p}_{\mu,a} = \frac{2}{a}\sin\Big(\frac{ap_\mu}{2}\Big), \qquad \hat{p}_a^2 = \sum_{\mu=1}^{D} \hat{p}_{\mu,a}^2.$$

Assume

$$m_a^2 = m^2 + a^2\delta m_2 + O(a^4) \tag{139.7}$$

with $m > 0$. Then for every $f, g \in C_c^\infty(\mathbb{R}^D)$,

$$\langle \phi_a(f)\phi_a(g)\rangle_a = \int_{\mathbb{R}^D} \frac{\mathrm{d}^D p}{(2\pi)^D}\,\frac{\widehat{f}(-p)\widehat{g}(p)}{p^2+m^2} + a^2\int_{\mathbb{R}^D} \frac{\mathrm{d}^D p}{(2\pi)^D}\,\widehat{f}(-p)\widehat{g}(p)\frac{\frac{1}{12}\sum_\mu p_\mu^4 - \delta m_2}{(p^2+m^2)^2} + O(a^4), \tag{139.8}$$

where the $O(a^4)$ remainder is bounded by a finite Schwartz seminorm of f and g. The term $\sum_\mu p_\mu^4$ is hypercubic invariant but not $O(D)$-invariant for $D > 1$; it is the leading rotation-breaking cutoff artifact of the nearest-neighbor action. The Taylor expansion of the lattice momentum is

$$\hat{p}_{\mu,a}^2 = p_\mu^2 - \frac{a^2}{12}p_\mu^4 + \frac{a^4}{360}p_\mu^6 + O(a^6 p_\mu^8) \tag{139.9}$$

on every compact momentum set. Hence the inverse kernel has the form

$$\hat{p}_a^2 + m_a^2 = p^2 + m^2 + a^2\left(\delta m_2 - \frac{1}{12}\sum_\mu p_\mu^4\right) + O(a^4(1+|p|^6)).$$

For $A = p^2 + m^2$ and

$$B = \delta m_2 - \frac{1}{12}\sum_\mu p_\mu^4,$$

the elementary identity

$$\frac{1}{A + a^2 B + O(a^4)} = \frac{1}{A} - a^2\frac{B}{A^2} + O(a^4)$$

gives the displayed coefficient. The replacement of the Brillouin-zone integral by the integral over $\mathbb{R}^D$, and the uniform control of the high-momentum tail, are the same Poisson-summation and rapid-decay estimates used in the proof of Proposition 139.1. The additional polynomial factors in p are harmless because $\widehat{f}$ and $\widehat{g}$ are Schwartz functions. Thus the expansion holds as a distributional expansion on smeared fields, with the remainder bounded by a Schwartz seminorm.

Remark 139.3 (Tree-level scalar improvement)*.* Define an improved free scalar quadratic kernel by

$$K_a^{\mathrm{imp}}(p) = m_a^2 + \hat{p}_a^2 + \frac{a^2}{12}\sum_{\mu=1}^{D}\hat{p}_{\mu,a}^4. \tag{139.10}$$

If $m_a^2 = m^2 + O(a^4)$, then

$$K_a^{\mathrm{imp}}(p) = m^2 + p^2 + O(a^4(1+|p|^6)) \tag{139.11}$$

on compact momentum sets. Consequently the $O(a^2)$ correction in (139.8) is canceled for the two-point function. By (139.9),

$$\hat{p}_a^2 = p^2 - \frac{a^2}{12}\sum_\mu p_\mu^4 + O(a^4|p|^6), \qquad \sum_\mu \hat{p}_{\mu,a}^4 = \sum_\mu p_\mu^4 + O(a^2|p|^6).$$

The $a^2 \sum_\mu p_\mu^4/12$ improvement term cancels the nearest-neighbor a^2 artifact, and the mass assumption removes the δm_2 part. The conclusion for smeared two-point functions follows from the previous proposition.

Remark 139.4 (Status in interacting lattice theories). For an interacting lattice theory, a Symanzik expansion is not obtained by writing all local operators compatible with hypercubic symmetry. One must also prove that the regulated correlators admit the expansion after renormalized operator mixing, and that the remainder is controlled in the distribution topology used for reconstruction. Gauge theories add the further requirement that improvement terms and operator coordinates be gauge-invariant or be formulated inside a gauge-fixed BV/lattice framework.

139.4 Correlation Length and Scaling Window

The lattice correlation length is a property of a regulated state. In a massive translation-invariant theory, a connected two-point function at large separation behaves like

$$\langle O(n)O(0)\rangle_{\text{conn}} \sim e^{-|n|/\xi_{\text{lat}}},$$

where ξ_{lat} is measured in lattice units. A massive continuum limit with physical mass $M > 0$ requires

$$\xi_{\text{lat}}(a) \to \infty, \qquad a\,\xi_{\text{lat}}(a) \to M^{-1}. \tag{139.12}$$

For a scale-invariant continuum limit, $a\xi_{\text{lat}}(a) \to \infty$. The phrase scaling window means that the lattice spacing, observation length, and correlation length are separated in the order

$$a \ll r \lesssim a\xi_{\text{lat}}(a),$$

with the last inequality replaced by $r \ll a\xi_{\text{lat}}(a)$ when one is studying critical short-distance scaling inside a massive deformation.

For the free lattice scalar, the zero-spatial-momentum pole gives an exact correlation length. The pole in the Euclidean time direction is

$$\frac{4}{a^2}\sinh^2\Big(\frac{a\kappa_a}{2}\Big) = m_a^2, \qquad \kappa_a = \frac{2}{a}\operatorname{arcsinh}\Big(\frac{am_a}{2}\Big).$$

Thus

$$\xi_{\text{lat}}(a) = \frac{1}{a\kappa_a} = \frac{1}{2\operatorname{arcsinh}(am_a/2)}, \qquad a\xi_{\text{lat}}(a) \to m^{-1}. \tag{139.13}$$

The expansion

$$\kappa_a = m_a - \frac{a^2 m_a^3}{24} + O(a^4 m_a^5)$$

shows explicitly how the lattice mass approaches the physical pole mass.

139.5 Finite-Volume Scaling and Step-Scaling Coordinates

Finite volume is an infrared regulator and can be used as a renormalized coordinate on the continuum theory through finite-volume observables. To separate this coordinate from the ultraviolet cutoff, keep three lengths separate:

$$a, \qquad L = Na, \qquad \xi_{\text{phys}} = a\,\xi_{\text{lat}}.$$

Here N is the number of lattice spacings across the box, L is the physical size, and ξ_{phys} is the physical correlation length. A continuum finite-volume observable is obtained by taking

$$a \to 0, \qquad L \text{ fixed}, \qquad \text{renormalized relevant coordinates fixed.}$$

The infinite-volume limit $L \to \infty$ is a subsequent infrared limit. Interchanging these limits is an additional theorem, not part of the definition of the finite-volume continuum object.

Definition 139.5 (Finite-size scaling data)**.** Fix a block scale $b > 1$, lattice tori $(a\mathbb{Z}/Na\mathbb{Z})^D$ with $N = b^n$, and an RG chart near a fixed point with one relevant coordinate t, irrelevant coordinates $w = (w_\alpha)$, and local operators O^I of RG dimensions Δ_I. Finite-size scaling data on a compact set $\mathcal{K} \subset \mathbb{R}$ of scaling variables consists of:

(i) the integer $n = \log_b N$;

(ii) an endpoint coordinate

$$u_N = t\, N^{y_t} + E_N(t, w), \qquad |E_N(t, w)| \le CN^{-\omega}$$

whenever $tN^{y_t} \in \mathcal{K}$;

(iii) an irrelevant-coordinate estimate

$$\|w_N\| \le CN^{-\omega}$$

for some $\omega > 0$;

(iv) endpoint kernels $F^{I_1 \dots I_k}(u; z_1, \dots, z_k)$, locally Lipschitz in u, and renormalized separated-point kernels $G^{I_1 \dots I_k}_{N,t,w}(z_1, \dots, z_k)$, with $z_i \in (\mathbb{R}/\mathbb{Z})^D$ and $z_i \ne z_j$, such that after n RG steps

$$\left| N^{\Delta_{I_1} + \cdots + \Delta_{I_k}} G^{I_1 \dots I_k}_{N,t,w}(z_1, \dots, z_k) - F^{I_1 \dots I_k}(u_N; z_1, \dots, z_k) \right| \le CN^{-\omega}$$

uniformly on compact subsets of the configuration space with pairwise separation bounded below.

The constants C may depend on the compact set of noncoincident configuration points and on the bounded microscopic set of irrelevant coordinates, but not on N.

Finite-size scaling from an RG chart. Assume the finite-size scaling data of Definition 139.5. Then

$$N^{\Delta_{I_1} + \cdots + \Delta_{I_k}}\, G^{I_1 \dots I_k}_{N,t,w}(z_1, \dots, z_k) = F^{I_1 \dots I_k}(tN^{y_t}; z_1, \dots, z_k) + O(N^{-\omega}) \tag{139.14}$$

uniformly for $tN^{y_t} \in \mathcal{K}$. If the continuum massive coordinate is parameterized by a physical mass M through

$$t(a) = (aM)^{y_t} + O(a^{y_t + \epsilon})$$

for some $\epsilon > 0$, then the scaling variable has the continuum finite-volume limit

$$t(a)N^{y_t} \to (ML)^{y_t}. \tag{139.15}$$

After n blocking steps, lengths have been divided by $b^n = N$, and the torus has order-one diameter in the blocked lattice units. The renormalized operator coordinate O^I contributes the factor $b^{-n\Delta_I} = N^{-\Delta_I}$. The relevant coordinate at the endpoint is $u_N = tN^{y_t} + O(N^{-\omega})$, and the irrelevant coordinates have norm $O(N^{-\omega})$. The endpoint estimate in the data gives the correlator with $F(u_N; z_1, \dots, z_k)$ up to $O(N^{-\omega})$. Since the endpoint kernel is locally Lipschitz in u on $\mathcal{K}$, replacing u_N by tN^{y_t} changes the right-hand side by another $O(N^{-\omega})$. This proves (139.14). Finally, if $N = L/a$ and $t(a) = (aM)^{y_t} + O(a^{y_t+\epsilon})$, then

$$t(a)N^{y_t} = (aM)^{y_t}(L/a)^{y_t} + O(a^\epsilon (L/a)^{y_t} a^{y_t}) = (ML)^{y_t} + O(a^\epsilon L^{y_t}),$$

which proves (139.15).

This scaling consequence states exactly what must be proved before finite-size scaling is a theorem: an RG chart, endpoint control, irrelevant decay, and operator-coordinate stability. The common formula $G_N = N^{-\sum \Delta_I} F(tN^{y_t})$ is the conclusion of these estimates, not their replacement.

Definition 139.6 (Step-scaling coordinate)**.** Let $\mathcal{O}_{a,L}$ be a finite-volume renormalized observable whose regulator-level definition is gauge-invariant, or is a specified coordinate in a gauge-fixed BV formulation, and whose continuum limit exists at fixed physical size L. Suppose a real coordinate g_L is defined by an injective normalization map

$$\mathcal{O}_{\mathrm{cont}}(L) = \Phi(g_L)$$

on an interval of couplings. For $s > 1$, the continuum step-scaling function associated to this coordinate is

$$\sigma_s(u) = \lim_{a/L \to 0} g_{sL}(a) \quad \text{with } g_L(a) = u, \tag{139.16}$$

provided the tuning $g_L(a) = u$ and the continuum limit exist. If the cutoff effects are described by a Symanzik expansion, the numerical extrapolation has the form

$$g_{sL}(a) = \sigma_s(u) + \sum_{j=1}^{r-1} c_j(u,s)(a/L)^{\omega_j} + R_{r,a}(u,s), \tag{139.17}$$

with explicitly stated exponents and a stated bound on $R_{r,a}$.

This definition is the precise finite-volume version of a running coupling. Different choices of $\mathcal{O}$ define different schemes. Scheme dependence is not a defect: it is the coordinate dependence of the renormalized theory. What is scheme independent is the existence of the continuum finite-volume observable, the consistency of the coordinate changes where they overlap, and universal data such as fixed-point critical exponents when the relevant theorem has been proved.

For lattice sizes not exactly of the form b^n, the residual size $N/b^{\lfloor \log_b N \rfloor} \in [1, b)$ is an additional finite endpoint coordinate. It must be included in the scaling data or eliminated by an explicit interpolation estimate; ignoring it is harmless only after that bounded-coordinate dependence has been controlled.

Definition 139.7 (Numerical scaling-window evidence package)**.** Fix a finite-volume continuum coordinate such as Definition 139.6, and write $q_i = a_i/L$ for the cutoff coordinate on a chosen set of regulator values. A numerical scaling-window evidence package for a continuum value c_0 consists of finite data Y_i, a covariance matrix Σ, remainder envelopes $\epsilon_i \geq 0$, accepted fit windows W, and declared exponents

$$0 = \omega_0 < \omega_1 < \cdots < \omega_p,$$

such that, on each accepted window,

$$Y_i = \sum_{\ell=0}^{p} c_\ell q_i^{\omega_\ell} + R_i + \eta_i, \qquad |R_i| \le \epsilon_i, \qquad \mathbb{E}\eta_i = 0, \quad \mathrm{Cov}(\eta) = \Sigma. \tag{139.18}$$

For a window W, let X_W be the design matrix $(X_W)_{i\ell} = q_i^{\omega_\ell}$. The package must record that X_W has full column rank, that Σ_W is positive definite, and that the weighted least-squares propagator

$$P_W = (X_W^T \Sigma_W^{-1} X_W)^{-1} X_W^T \Sigma_W^{-1} \tag{139.19}$$

is the map used to report $\widehat{c}_W = P_W Y_W$.

Lemma 139.8 (Finite numerical evidence propagation)**.** *For every accepted window in Definition 139.7,*

$$\widehat{c}_W - c = P_W R_W + P_W \eta_W, \qquad \mathrm{Cov}(\widehat{c}_W) = P_W \Sigma_W P_W^T. \tag{139.20}$$

In particular the continuum-coordinate component satisfies

$$|(\widehat{c}_W)_0 - c_0| \le \sum_{i \in W} |(P_W)_{0i}|\, \epsilon_i + |(P_W \eta_W)_0|. \tag{139.21}$$

If the accepted windows are collected in $\mathcal{W}$, a finite evidence budget may be reported as

$$B_{\mathrm{num}} = \left(\max_{W \in \mathcal{W}} (\widehat{c}_W)_0 - \min_{W \in \mathcal{W}} (\widehat{c}_W)_0 \right) + \max_{W \in \mathcal{W}} \delta_{\mathrm{stat}}(W) + \max_{W \in \mathcal{W}} \delta_{\mathrm{sys}}(W), \tag{139.22}$$

where

$$\delta_{\mathrm{sys}}(W) = \sum_{i \in W} |(P_W)_{0i}|\, \epsilon_i$$

and $\delta_{\mathrm{stat}}(W)$ is a stated statistical convention, for example $\sqrt{(P_W \Sigma_W P_W^T)_{00}}$ or a block-resampling confidence envelope.

Proof. Equation (139.18) on the selected window is $Y_W = X_W c + R_W + \eta_W$. Since

$$P_W X_W = I$$

by the full-rank assumption and the definition of P_W, applying P_W gives the first identity in (139.20). The covariance identity follows from linear propagation of the centered fluctuation η_W. Taking the zeroth component and applying the triangle inequality to the deterministic remainder term gives (139.21); the statistical term remains probabilistic until a confidence or resampling convention is declared. □

The evidence package also records the observable coordinate and tuning condition, the finite-volume geometry, the regulator schedule, autocorrelation or blocking diagnostics for Σ, the chosen exponent list and remainder hypothesis, rank and condition-number diagnostics for each window, residuals and χ^2 coordinates, and independent action or observable cross-checks when a universality claim is being made. These data make a finite numerical result reproducible and checkable. They still do not replace the continuum theorem: the Symanzik or RG expansion, finite-volume control, operator-coordinate estimates, and reconstruction target remain the mathematical inputs that turn the finite calculation into a continuum statement. The companion script

`qft_scripts/finite_regulator_extrapolation.py`

implements the finite linear algebra in Lemma 139.8 and reports the budget (139.22).

139.6 Operator Coordinates and Contact Terms

Renormalized operator coordinates are part of the continuum-limit input. For composite observables, the matrix $Z^I{}_J(a)$ in (139.1) may mix an operator with derivatives of lower-dimensional operators and with the identity. The identity and derivative mixings are the lattice form of contact terms. They are visible only after smearing test functions and studying coincident-point limits.

For example, the lattice square ϕ_x^2 in the free scalar model has

$$\langle \phi_x^2 \rangle_a = C_a(0),$$

which diverges for $D \geq 2$. The Wick coordinate

$$:\phi_x^2:_a = \phi_x^2 - C_a(0)$$

has finite separated correlators and a well-defined smeared distributional limit in the superrenormalizable dimensions where the corresponding continuum Wick square exists. If one changes the subtraction by a finite local constant, the smeared operator changes by a multiple of $\int f(x)\mathrm{d}^D x$, namely by an identity contact coordinate. Thus contact terms are part of the coordinate chart on local distributions.

139.7 Osterwalder–Schrader Reconstruction Target

Definition 139.9 (Constructive continuum limit)**.** A constructive continuum limit of a regulated family is a collection of limiting Schwinger distributions satisfying Euclidean covariance, permutation symmetry, reflection positivity, clustering, regularity, and the growth assumptions required by the reconstruction theorem, together with the OS-reconstructed Hilbert space, vacuum, fields, local domains, and translation generators.

Reflection positivity can pass to the limit by a closed-cone argument: if

$$\sum_{i,j} \overline{c_i} c_j S_a(\Theta F_i, F_j) \geq 0$$

for every finite set of positive-time test functions and the distributions converge on these tests, then the limiting quadratic form is nonnegative. Euclidean invariance is a separate limit theorem. Hypercubic invariance at fixed a becomes full Euclidean invariance only after one proves that rotation-breaking local operators are irrelevant or have been tuned away.

The reconstruction target also includes growth bounds. In Euclidean QFT the Schwinger functions must be sufficiently controlled as tempered distributions, and the analytic continuation to Wightman functions requires the hypotheses discussed in Chapter 12. A continuum limit that produces reflection-positive distributions but lacks the needed growth control has not yet produced the full Lorentzian QFT object used elsewhere in this monograph.

139.8 Wilsonian Coordinates and Scaling Manifolds

Let $\mathcal{B}$ be a Banach space of local interactions near a fixed point S_*, and let $\mathcal{R}_b : \mathcal{U} \subset \mathcal{B} \to \mathcal{B}$ be a block-spin map with scale factor $b > 1$. If $\mathcal{R}_b(S_*) = S_*$ and

$$D\mathcal{R}_b|_{S_*}\, v_i = b^{y_i} v_i,$$

then $y_i > 0$, $y_i = 0$, and $y_i < 0$ define relevant, marginal, and irrelevant directions in this specified Banach norm and blocking scheme. The classification is therefore tied to the chosen RG map and norm.

Suppose for simplicity that there is one relevant coordinate t with eigenvalue b^{y_t}, $y_t > 0$, and that all irrelevant coordinates are controlled by a stable-manifold estimate. Under N blocking steps,

$$t_N \approx b^{N y_t} t_0.$$

The correlation length in lattice units is the number of lattice spacings needed until the running coordinate becomes order one, so

$$b^{N y_t} |t_0| \sim 1, \qquad \xi_{\text{lat}} \sim b^N \sim |t_0|^{-1/y_t}.$$

Thus the exponent relation

$$\nu = \frac{1}{y_t} \tag{139.23}$$

is a consequence of a controlled one-relevant-coordinate RG chart. Without the chart, the nonlinear estimates, and the identification of the correlation length, the same formula is a scaling hypothesis rather than a proof.

139.9 Status of Scalar Examples

Superrenormalizable scalar theories such as $P(\phi)_2$ and ϕ^4_3 have constructive continuum realizations with OS or Wightman reconstruction under their stated hypotheses. The existence theorem for ϕ^4_3 as an interacting massive QFT is distinct from the assertion that the three-dimensional Ising critical point is a conformal field theory with the full expected operator spectrum and OPE. The latter requires a critical scaling limit with conformal covariance and operator-product control, not only a massive constructive realization.

In four dimensions, perturbative renormalizability of ϕ^4_4 does not settle nonperturbative ultraviolet existence. The current rigorous status is that no construction is known of a nonperturbative four-dimensional UV-complete QFT whose perturbation series agrees with ϕ^4_4 to all orders around the Gaussian fixed point. Perturbative formal power series and constructive continuum measures are different mathematical objects.

139.10 Theorem Boundary

The minimal data for a continuum-limit theorem are:

$$\begin{gathered}\text{a regulated expectation functional for each } a,\\ \text{a scaling trajectory } c(a),\\ \text{renormalized observable coordinates } Z^I{}_J(a),\\ \text{uniform distributional bounds and convergence,}\\ \text{reflection positivity, covariance, clustering, and growth control,}\\ \text{and an OS reconstruction of the limiting data.}\end{gathered}$$

For Wilsonian fixed-point arguments, the theorem must also specify the function space, the blocking map, the fixed point, the relevant and irrelevant projections, and estimates that control nonlinear remainders. This is the line between a precise construction and a physically motivated scaling picture.

Open Problem 139.10 (Nonperturbative fixed points from Wilsonian maps). Develop a Wilsonian Banach-space framework for physically relevant four-dimensional and three-dimensional QFTs in which fixed points, renormalized operator coordinates, contact terms, scaling windows, and OS reconstruction can all be controlled in the same theorem. The framework should make precise when a fixed-point argument is a proof and when it is a well-supported construction principle.

Wilson lattice gauge theory gives a gauge-invariant finite-regulator definition of compact gauge fields. Its continuum use requires a scaling trajectory, reflection positivity, locality, and a reconstruction or continuum-limit argument. The lattice theory is a nonperturbative regulated path integral with compact gauge variables.

140.1 Link Variables and Gauge Transformations

Let $\Lambda \subset a\mathbb{Z}^D$ be a finite hypercubic lattice and G a compact Lie group. To each oriented link $\ell = (x, x + a\hat{\mu})$, assign

$$U_\mu(x) \in G,$$

with $U_{-\mu}(x + a\hat{\mu}) = U_\mu(x)^{-1}$. A lattice gauge transformation is a function $g : \Lambda^0 \to G$ acting by

$$U_\mu(x) \mapsto g(x)U_\mu(x)g(x + a\hat{\mu})^{-1}.$$

The plaquette holonomy is

$$U_{\mu\nu}(x) = U_\mu(x)U_\nu(x + a\hat{\mu})U_\mu(x + a\hat{\nu})^{-1}U_\nu(x)^{-1}.$$

140.2 Wilson Action

Fix a faithful unitary representation R and normalize the trace in the continuum convention of the gauge-theory volume. A Wilson plaquette action has the form

$$S_W[U] = \beta \sum_p \left(1 - \frac{1}{\dim R} \operatorname{Re} \operatorname{Tr}_R U_p\right).$$

The finite-volume partition function is the compact group integral

$$Z = \int \prod_\ell dU_\ell \, e^{-S_W[U]},$$

where dU is Haar measure.

140.3 A Finite $\mathbb{Z}_2$ Gauge Benchmark

Before taking any continuum limit, a lattice gauge theory is an ordinary finite-dimensional integral. The smallest nontrivial pure gauge benchmark is the $\mathbb{Z}_2$ gauge model on a finite periodic cubic lattice. Let E be the set of oriented positive links, let P be the set of elementary plaquettes, and assign

$$U_e \in \{\pm 1\}, \qquad e \in E.$$

For a plaquette p, define

$$U_p = \prod_{e \in \partial p} U_e,$$

where orientation is irrelevant because $U_e^{-1} = U_e$. The finite partition function at parameter $\beta \in \mathbb{R}$ is

$$Z_\Lambda(\beta) = \sum_{U : E \to \{\pm 1\}} \exp\left(\beta \sum_{p \in P} U_p\right).$$

A gauge transformation is a function $g : V \to \{\pm 1\}$ acting on a link $e = (x, y)$ by

$$U_e \longmapsto g_x U_e g_y.$$

The plaquette variables and Wilson loop variables

$$W(C) = \prod_{e \in C} U_e$$

for closed lattice contours C are gauge invariant.

The finite $\mathbb{Z}_2$ character expansion is an exact algebraic rewriting of this finite gauge integral. Let $t = \tanh \beta$. For a closed contour C, regard C as a $\mathbb{Z}_2$-one-chain, and regard a subset $A \subset P$ as a $\mathbb{Z}_2$-two-chain with boundary ∂A. For each plaquette variable $U_p = \pm 1$,

$$e^{\beta U_p} = \cosh \beta \, (1 + t U_p) = \cosh \beta \sum_{n_p = 0}^{1} t^{n_p} U_p^{n_p}.$$

Multiplying over plaquettes gives

$$\exp\left(\beta \sum_p U_p\right) = (\cosh\beta)^{|P|} \sum_{A\subset P} t^{|A|} \prod_{p\in A} \prod_{e\in\partial p} U_e.$$

Summing over a single link variable gives $\sum_{U_e=\pm 1} U_e^m = 0$ if m is odd and 2 if m is even. Therefore the partition function keeps precisely those plaquette subsets for which every link appears an even number of times, namely $\partial A = 0$, and contributes the overall factor $2^{|E|}$. Thus

$$Z_\Lambda(\beta) = 2^{|E|}(\cosh\beta)^{|P|} \sum_{\substack{A\subset P\\ \partial A=0}} t^{|A|}. \tag{140.1}$$

For the Wilson-loop numerator, the additional factor $\prod_{e\in C} U_e$ changes the parity condition on each link from $(\partial A)_e = 0$ to $(\partial A)_e = C_e$. Dividing the resulting finite numerator by the finite partition function gives the displayed expectation value.

$$\langle W(C)\rangle_{\Lambda,\beta} = \frac{\displaystyle\sum_{\substack{A\subset P\\ \partial A=C}} t^{|A|}}{\displaystyle\sum_{\substack{A\subset P\\ \partial A=0}} t^{|A|}}. \tag{140.2}$$

The sums are finite sums over plaquette subsets. Thus the strong-coupling area mechanism in this model is a finite-cutoff identity: the Wilson-loop numerator is exactly a weighted sum over lattice surfaces whose boundary is the loop.

The companion script

```
qft_scripts/z2_gauge_3d_metropolis.py
```

samples this finite model by single-link Metropolis updates and measures the plaquette average and rectangular Wilson loops. Its output is finite-cutoff data. An infinite-volume transition, a continuum limit, or a continuum confinement statement requires additional limiting hypotheses and estimates.

140.4 Surface Counting and the Strong-Coupling Area Bound

The exact finite character expansion (140.2) becomes an area-law estimate only after one controls how many surfaces of a given area have the same boundary. This counting step is often hidden in the phrase "strong-coupling expansion." We spell out the finite statement.

Fix a finite lattice and a closed contour C which is a boundary in the $\mathbb{Z}_2$ plaquette chain complex. Define the lattice area

$$A_{\min}(C) = \min\{|A| : A\subset P,\ \partial A = C\}. \tag{140.3}$$

For $n \geq 0$, let

$$N_C(n) = \#\{A\subset P : \partial A = C,\ |A| = A_{\min}(C) + n\}. \tag{140.4}$$

Similarly let $N_0(n)$ count closed plaquette subsets of area n.

Finite surface expansion and area estimate. Let $\beta \geq 0$ and $t = \tanh\beta$. If C is a boundary, then

$$\langle W(C)\rangle_{\Lambda,\beta} = t^{A_{\min}(C)} \frac{\sum_{n\geq 0} N_C(n)t^n}{\sum_{n\geq 0} N_0(n)t^n}. \tag{140.5}$$

In particular, since the denominator is at least 1,

$$0 \leq \langle W(C)\rangle_{\Lambda,\beta} \leq t^{A_{\min}(C)} \sum_{n\geq 0} N_C(n)t^n. \tag{140.6}$$

If, for a family of contours, the surface entropy obeys

$$N_C(n) \leq K(C)\rho^n \qquad (n \geq 0) \tag{140.7}$$

with $0 \leq \rho t < 1$, then

$$\langle W(C)\rangle_{\Lambda,\beta} \leq \frac{K(C)}{1-\rho t} \exp\{-[-\log t]A_{\min}(C)\}. \tag{140.8}$$

This estimate is a reorganization of the finite character expansion followed by a geometric-series bound. The numerator in (140.2) is a finite sum over plaquette subsets satisfying $\partial A = C$. Grouping these subsets by the excess area $n = |A| - A_{\min}(C)$ gives the numerator

$$t^{A_{\min}(C)} \sum_{n\geq 0} N_C(n)t^n.$$

The same grouping with $C = 0$ gives the denominator. For $\beta \geq 0$, all terms in the denominator are nonnegative and the empty closed surface gives the term 1; hence the denominator is at least 1, proving (140.6). The final estimate is the geometric-series bound

$$\sum_{n\geq 0} N_C(n)t^n \leq K(C) \sum_{n\geq 0} (\rho t)^n = \frac{K(C)}{1-\rho t}.$$

For a rectangular loop $C_{R,T}$ in a coordinate plane, $A_{\min}(C_{R,T}) = RT/a^2$ when the rectangle is smaller than the chosen finite box and the flat spanning rectangle is the unique minimal surface in that homology class. Equation (140.8) then gives a finite-regulator area bound at sufficiently small t. If the constants in the surface-counting estimate have at most perimeter growth, $K(C_{R,T}) \leq \exp\{c(R+T)/a\}$, the area coefficient in lattice units is bounded below by

$$\sigma_{\text{lat}}(\beta) \geq -\log(\tanh\beta)$$

with the displayed perimeter and finite entropy prefactors kept separately. This is a strong-coupling theorem at fixed cutoff. It is not a proof of continuum confinement, because a continuum Yang–Mills limit in four dimensions would require control along a scaling trajectory where the Wilson parameter does not remain in this small-β domain.

Example 140.1 (One-cube surface polynomial)**.** On the boundary of one elementary cube, let C be the boundary of one face. There are exactly two plaquette subsets with boundary C: the face itself, with area 1, and the complementary five faces, with area 5. The closed subsets are the empty surface and the six-face cube boundary. Therefore

$$\langle W(C)\rangle = \frac{t+t^5}{1+t^6}. \tag{140.9}$$

This example shows explicitly why the leading strong-coupling term is the minimal spanning surface and why closed surfaces correct both numerator and denominator.

140.5 Compact-Group Character Expansion

The $\mathbb{Z}_2$ expansion has a nonabelian analogue. The analogue is not a sum over unoriented plaquette subsets; it is a finite tensor-network sum over irreducible representations and Haar projectors. This distinction is important: in a nonabelian gauge theory the local degrees of freedom carried by a surface include representation labels and invariant tensors at links.

Let G be a compact Lie group and let $\widehat{G}$ be the set of equivalence classes of finite-dimensional irreducible unitary representations. For $\lambda \in \widehat{G}$, write

$$D_\lambda : G \to U(V_\lambda), \qquad \chi_\lambda(U) = \mathrm{Tr}_{V_\lambda} D_\lambda(U).$$

Let $K : G \to \mathbb{C}$ be a continuous class function. Its character coefficients are

$$c_\lambda[K] = \int_G dU\, K(U)\overline{\chi_\lambda(U)}. \tag{140.10}$$

Peter–Weyl orthogonality gives the $L^2(G)$ expansion

$$K(U) = \sum_{\lambda \in \widehat{G}} c_\lambda[K]\chi_\lambda(U), \tag{140.11}$$

with rapid coefficient decay when K is smooth. For the Wilson plaquette weight with the irrelevant constant removed one may take

$$K_\beta(U) = \exp\left(\frac{\beta}{\dim R}\,\mathrm{Re}\,\mathrm{Tr}_R\, U\right). \tag{140.12}$$

Compact-group spin-foam expansion at finite cutoff. On a finite lattice, replace each plaquette Boltzmann factor by a smooth class function $K(U_p)$. Then the finite-volume partition function is represented by

$$Z_\Lambda[K] = \sum_{\lambda : P \to \widehat{G}} \left(\prod_{p \in P} c_{\lambda_p}[K]\right) \mathcal{A}_\Lambda(\{\lambda_p\}), \tag{140.13}$$

where $\mathcal{A}_\Lambda(\{\lambda_p\})$ is the tensor contraction obtained by assigning V_{λ_p} or $V_{\lambda_p}^*$ to the four oriented sides of each plaquette and, for every link ℓ, inserting the Haar projector

$$P_\ell(\{\lambda_p\}_{p \supset \ell}) = \int_G dU_\ell \bigotimes_{p \supset \ell} D_{\lambda_p}(U_\ell)^{\epsilon(p,\ell)}, \tag{140.14}$$

with $\epsilon(p, \ell) = +1$ if the plaquette orientation uses U_ℓ and $\epsilon(p, \ell) = -1$ if it uses U_ℓ^{-1}. A Wilson loop in representation S is represented by inserting the additional boundary tensor $D_S(U_\ell)^{\pm 1}$ on each link of the loop before taking the same Haar projectors. The derivation is the Peter–Weyl expansion performed link by link. Insert the character expansion (140.11) independently for every plaquette. After choosing bases of the representation spaces, every plaquette character is a cyclic contraction of four matrix factors, one for each link in its boundary. Each link variable appears only in the factors associated to plaquettes incident on that link, and in the Wilson-loop insertion if the link belongs to the loop. Integrating over this link gives precisely the Haar average

(140.14). Performing the finitely many link integrals leaves a finite tensor contraction for each plaquette-label assignment. Truncating the representation labels gives finite tensor network sums. For smooth K, in particular for (140.12), the character coefficients decay rapidly enough that the truncated sums converge to the original finite-dimensional integral. The L^2 Peter–Weyl statement gives the same formula for less regular class functions after the corresponding convergence mode has been specified.

For $G = SU(N)$, $N \geq 3$, with R the fundamental representation and with the conventional Wilson weight

$$K_\beta(U) = \exp\left(\frac{\beta}{N}\operatorname{Re}\operatorname{Tr}U\right), \tag{140.15}$$

the small-β coefficients of the fundamental and antifundamental characters are

$$c_F[K_\beta] = c_{\overline{F}}[K_\beta] = \frac{\beta}{2N} + O(\beta^2). \tag{140.16}$$

This follows by expanding $K_\beta = 1 + \frac{\beta}{2N}(\chi_F + \chi_{\bar{F}}) + O(\beta^2)$ and using character orthogonality. The coefficient changes for $SU(2)$, because the fundamental representation is self-conjugate and $\operatorname{Re}\chi_F = \chi_F$.

Example 140.2 (Fundamental plaquette normalization in $SU(N)$)**.** For $N \geq 3$, let

$$w_p(U) = \frac{1}{N}\operatorname{Re}\operatorname{Tr}U_p.$$

At $\beta = 0$, the plaquette holonomy U_p is Haar distributed, so $\langle w_p\rangle_{\beta=0} = 0$. Differentiating the normalized expectation at $\beta = 0$ gives

$$\frac{\mathrm{d}}{\mathrm{d}\beta}\langle w_p\rangle_\beta\bigg|_{\beta=0} = \int_G dU\,\frac{\chi_F(U)+\chi_{\bar{F}}(U)}{2N}\,\frac{\chi_F(U)+\chi_{\bar{F}}(U)}{2N} = \frac{1}{2N^2}. \tag{140.17}$$

Thus, for $SU(3)$,

$$\langle w_p\rangle_\beta = \frac{\beta}{18} + O(\beta^2). \tag{140.18}$$

The calculation fixes the normalization used in the nonabelian strong-coupling expansion. Higher-area Wilson loops are obtained by the same Haar-projector contractions, but a theorem-level area estimate also requires bounds on representation sums, invariant-tensor contractions, and surface entropy.

140.6 Continuum Expansion

For a smooth continuum connection $A_\mu(x)$, set

$$U_\mu(x) = \exp(aA_\mu(x)).$$

The plaquette has expansion

$$U_{\mu\nu}(x) = \exp\big(a^2F_{\mu\nu}(x) + O(a^3)\big)\,.$$

If the representation trace obeys

$$\mathrm{Tr}_R(XY) = \kappa_R \, \mathrm{tr}(XY),$$

then

$$1 - \frac{1}{\dim R} \operatorname{Re} \mathrm{Tr}_R \, U_{\mu\nu} = -\frac{a^4 \kappa_R}{2 \dim R} \mathrm{tr}(F_{\mu\nu} F_{\mu\nu}) + O(a^6)$$

for anti-Hermitian A_μ. Matching to

$$\frac{1}{4g^2} \int d^D x \; \mathrm{tr}(F_{\mu\nu} F_{\mu\nu})$$

fixes the relation between β, g, and the trace normalization.

140.7 Improved Gauge Actions at Tree Level

The lattice action is part of the regulator definition. Two local gauge-invariant actions may define the same continuum theory only after a scaling trajectory and a comparison of renormalized coordinates have been specified. Improvement is the finite-regulator problem of choosing the local action so that selected irrelevant coordinates are absent, or smaller, in a chosen coordinate system.

For $G = SU(N)$ in the fundamental trace convention used above, let $U_{\mu\nu}^{1\times 1}(x)$ be the elementary plaquette and let $U_{\mu\nu}^{1\times 2}(x)$ denote the oriented rectangle with side lengths a and $2a$ in the μ, ν plane. The plaquette-plus-rectangle family is

$$S_{c_0,c_1}[U] = \frac{\beta}{N} \sum_x \sum_{\mu<\nu} \left[c_0 \big(N - \operatorname{Re} \mathrm{Tr} \, U_{\mu\nu}^{1\times 1}(x)\big) + c_1 \sum_{\rho \in \{(\mu,\nu),(\nu,\mu)\}} \big(N - \operatorname{Re} \mathrm{Tr} \, U_{\rho}^{1\times 2}(x)\big) \right]. \tag{140.19}$$

The two rectangles in the last sum have their long side in the first or second direction of the ordered pair. Since a 1×2 rectangle has twice the area of a plaquette, its leading $F_{\mu\nu}^2$ contribution is four times the plaquette contribution. Thus the continuum normalization is

$$c_0 + 8c_1 = 1. \tag{140.20}$$

The Wilson action is $c_0 = 1, c_1 = 0$.

Lemma 140.3 (Rectangle coefficients)**.** *For the family* (140.19)*, the tree-level cancellation of the abelian quadratic $O(a^2)$ derivative artifact is equivalent to*

$$c_0 + 20c_1 = 0. \tag{140.21}$$

Together with (140.20)*, this gives*

$$c_1 = -\frac{1}{12}, \qquad c_0 = \frac{5}{3}. \tag{140.22}$$

Proof. It suffices for the tree-level quadratic calculation to work in an abelian Cartan direction. Let $F = F_{\mu\nu}$ be a smooth scalar field strength and consider a rectangle centered at x with side lengths ra in the μ-direction and sa in the ν-direction. Its flux is

$$\Phi_{r,s}(x) = \int_{-ra/2}^{ra/2} \mathrm{d}u \int_{-sa/2}^{sa/2} \mathrm{d}v \, F(x + u\hat{\mu} + v\hat{\nu}).$$

Taylor expansion around the center gives

$$\Phi_{r,s} = rsa^2 F + \frac{rsa^4}{24} \left(r^2 \partial_\mu^2 + s^2 \partial_\nu^2 \right) F + O(a^6). \tag{140.23}$$

The small-field loop weight is proportional to $\frac{1}{2}\Phi_{r,s}^2$. After summing over lattice sites, the $F\partial^2 F$ term may be integrated by parts up to boundary terms or finite-volume periodic identities:

$$\frac{1}{2}\Phi_{r,s}^2 = \frac{1}{2} r^2 s^2 a^4 F^2 - \frac{r^2 s^2 a^6}{24} \left[r^2 (\partial_\mu F)^2 + s^2 (\partial_\nu F)^2 \right] + O(a^8). \tag{140.24}$$

For the plaquette $(r,s) = (1,1)$, the derivative coefficient in one $\mu\nu$-plane is proportional to 1. For the two 1×2 rectangles, $(r,s) = (1,2)$ and $(2,1)$, the corresponding coefficients add to

$$4(1^2 + 2^2) = 20$$

in the symmetric combination $(\partial_\mu F_{\mu\nu})^2 + (\partial_\nu F_{\mu\nu})^2$. Therefore the quadratic $O(a^2)$ derivative artifact is proportional to $c_0 + 20c_1$. Setting this coefficient to zero and imposing the leading continuum normalization $c_0 + 8c_1 = 1$ gives (140.22). □

The preceding lemma is deliberately a tree-level statement. In a nonabelian interacting theory, the dimension-six gauge-invariant operator basis contains covariant-derivative and cubic-curvature terms, modulo Bianchi identities and field redefinitions. Loop-level improvement is therefore a renormalized-coordinate problem whose conditions extend the two tree-level algebraic equations above. The full Luescher–Weisz class also allows chair and parallelogram six-link loops; with coefficients (c_0, c_1, c_2, c_3) in the standard orientation-counting convention, the leading normalization is

$$c_0 + 8c_1 + 16c_2 + 8c_3 = 1, \tag{140.25}$$

where the numerical factors count orientations and leading squared areas in one coordinate plane. The commonly used Iwasaki one-parameter action belongs to the plaquette-plus-rectangle subfamily with $c_1 \simeq -0.331$ and $c_0 = 1 - 8c_1$; this coefficient is fixed by a renormalization-group criterion, not by the tree-level cancellation (140.21).

Reflection positivity is an additional constraint. The compact Euclidean integral (140.19) is well-defined whenever the Boltzmann weight is integrable, but a transfer-matrix reconstruction requires a positivity argument for the chosen action. Negative rectangle coefficients, useful for improvement, need not preserve the elementary reflection-positivity proof available for the Wilson plaquette action. Thus improvement, continuum normalization, and Hilbert-space reconstruction are separate requirements of the regulator datum.

140.8 Gauge-Covariant Link Smearing

Smearing is a regulator-level map from link fields to link fields. It is used to build extended observables, improve overlap with low-energy states, and, in some actions, define the local lattice Lagrangian itself. Its mathematical datum is a map

$$\mathcal{S} : \mathcal{U}_\Lambda = G^E \to G^E$$

with a locality radius and a gauge-covariance law. For a link $\ell = (x, y)$, gauge covariance means

$$\mathcal{S}_\ell(g \cdot U) = g(x)\mathcal{S}_\ell(U)g(y)^{-1}. \tag{140.26}$$

When a Wilson loop is built from $\mathcal{S}(U)$, it is a different regularized line operator from the loop built from U. When an action is built from $\mathcal{S}(U)$, it is a different regulator action. The continuum comparison is again a scaling-trajectory and operator-scheme question.

Let $G = SU(N)$. The oriented staple sum $C_\ell(U)$ associated with a link $\ell = (x, y)$ is the sum over the $2(D-1)$ shortest three-link paths from x to y that, together with ℓ^{-1}, form an elementary plaquette. It transforms as a link:

$$C_\ell(g \cdot U) = g(x)C_\ell(U)g(y)^{-1}. \tag{140.27}$$

The APE preprojection matrix is

$$X_\ell(U) = (1-\alpha)U_\ell + \frac{\alpha}{2(D-1)}C_\ell(U), \qquad \alpha \in \mathbb{R}. \tag{140.28}$$

It has the same covariance law as a link, but it is generally a complex matrix rather than an element of $SU(N)$. A projection back to the group is therefore part of the regulator definition.

Equivariance of polar link projection. Let $X \in GL(N, \mathbb{C})$, and write its polar decomposition as

$$X = U_X H_X, \qquad U_X \in U(N), \qquad H_X = (X^\dagger X)^{1/2} > 0.$$

For $g, h \in SU(N)$,

$$U_{gXh^{-1}} = gU_X h^{-1}. \tag{140.29}$$

Consequently the locally defined special-unitary projection

$$\Pi_{SU(N)}(X) = (\det U_X)^{-1/N} U_X \tag{140.30}$$

is gauge covariant on any open set where a branch of the N-th root is chosen continuously. Since

$$(gXh^{-1})^\dagger(gXh^{-1}) = h(X^\dagger X)h^{-1},$$

functional calculus gives

$$H_{gXh^{-1}} = hH_X h^{-1}.$$

Therefore

$$gXh^{-1} = (gU_X h^{-1})(hH_X h^{-1})$$

is the polar decomposition of gXh^{-1}, because the first factor is unitary and the second is positive. This proves (140.29). The determinant of $gU_X h^{-1}$ equals $\det U_X$, since $g, h \in SU(N)$, so the determinant-normalized projection has the same covariance law whenever the root branch is fixed on the chosen connected domain.

The projection map is smooth on $GL(N, \mathbb{C})$ after choosing the determinant branch, and it becomes singular when X loses rank or crosses a branch cut. This is why differentiable algorithms often use stout smearing, which stays on the group without a polar projection.

Let
$$\Pi_{\mathfrak{su}(N)}(M) = \frac{1}{2}(M - M^\dagger) - \frac{1}{2N}\operatorname{Tr}(M - M^\dagger)\mathbf{1}. \tag{140.31}$$
This is the orthogonal projection, with respect to the real Hilbert–Schmidt inner product, onto anti-Hermitian traceless matrices. Define
$$\Omega_\ell(U) = C_\ell(U)U_\ell^{-1}, \qquad Q_\ell(U) = \rho\,\Pi_{\mathfrak{su}(N)}(\Omega_\ell(U)), \qquad \mathcal{S}_\ell^{\text{stout}}(U) = e^{Q_\ell(U)}U_\ell. \tag{140.32}$$

Stout smearing is a smooth gauge-covariant link map. For every real ρ, the map (140.32) is a smooth map $\mathcal{U}_\Lambda \to SU(N)^E$ and satisfies the gauge-covariance law (140.26). The staple covariance (140.27) gives
$$\Omega_\ell(g\cdot U) = g(x)\Omega_\ell(U)g(x)^{-1}.$$
The projection $\Pi_{\mathfrak{su}(N)}$ commutes with unitary conjugation, so
$$Q_\ell(g\cdot U) = g(x)Q_\ell(U)g(x)^{-1}.$$
Hence
$$e^{Q_\ell(g\cdot U)} = g(x)e^{Q_\ell(U)}g(x)^{-1}.$$
Multiplying by the transformed link $(g\cdot U)_\ell = g(x)U_\ell g(y)^{-1}$ gives
$$\mathcal{S}_\ell^{\text{stout}}(g\cdot U) = g(x)\mathcal{S}_\ell^{\text{stout}}(U)g(y)^{-1}.$$
Because Q_ℓ is anti-Hermitian and traceless, $e^{Q_\ell} \in SU(N)$, and therefore $e^{Q_\ell}U_\ell \in SU(N)$. Smoothness follows from the polynomial staple map, the linear projection (140.31), and the matrix exponential.

Hypercubic smearing is an iterated local construction in which staples are restricted to lower-dimensional faces before the next level is formed. Its definition is a finite composition of maps of the preceding type; hence its gauge covariance follows by induction once every intermediate projection or exponential map is specified. Locality is regulator locality: after k smearing steps the smeared link depends on links in a bounded neighborhood whose radius grows at most linearly in k. A continuum theorem using smeared operators must keep this radius fixed in lattice units, or specify how it scales with a, before the operator scheme has mathematical meaning.

The companion script

`qft_scripts/su3_ape_smearing_hdf5.py`

implements the finite $SU(3)$ APE map (140.28) for raw, flowed, or already-smeared HDF5 checkpoints. In its spatial mode the active directions are $1, 2, 3$, and temporal links are left unchanged; this is the finite-data convention appropriate for constructing smeared spatial transporters in static-source correlators. In its all-direction mode all four Euclidean directions are active. The paired calculation check verifies the cold fixed point, preservation of temporal links in spatial mode, gauge covariance of the smearing map, and the HDF5 checkpoint convention `checkpoint/smeared_links`. As above, this is a regulator-level operator construction, not an assertion about continuum improvement by itself.

140.9 Lattice Perturbative Coordinates and Tadpole Normalization

Perturbation theory on a compact gauge lattice begins after choosing a chart near the trivial connection. For $G = SU(N)$, use Hermitian generators t^a normalized by

$$\operatorname{tr}(t^a t^b) = \delta^{ab}, \tag{140.33}$$

and write a link near the identity as

$$U_\mu(x) = \exp\{-\mathrm{i}g_0 a A_\mu(x + \tfrac{a}{2}\widehat{\mu})\}, \qquad A_\mu = A_\mu^a t^a. \tag{140.34}$$

With the Wilson action in the convention

$$S_W[U] = \frac{\beta}{N} \sum_{x,\mu<\nu} \operatorname{Re}\operatorname{tr}\big(\mathbf{1} - U_{\mu\nu}(x)\big), \qquad \beta = \frac{N}{g_0^2}, \tag{140.35}$$

the parameter g_0 is the lattice coupling coordinate matching the continuum trace-delta convention $\frac{1}{4g_0^2}\int \operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$ at tree level.

Let

$$\nabla_\mu^+ f(x) = \frac{f(x + a\widehat{\mu}) - f(x)}{a}$$

be the forward difference. The linearized lattice curvature is

$$f_{\mu\nu}(x) = \nabla_\mu^+ A_\nu(x + \tfrac{a}{2}\widehat{\nu}) - \nabla_\nu^+ A_\mu(x + \tfrac{a}{2}\widehat{\mu}). \tag{140.36}$$

Expanding the plaquette gives

$$U_{\mu\nu}(x) = \exp\{-\mathrm{i}g_0 a^2 f_{\mu\nu}(x) + O(g_0 a^3 A, g_0^2 a^3 A^2)\}. \tag{140.37}$$

Therefore the quadratic Wilson action is

$$S_W^{(2)}[A] = \frac{1}{2}\sum_x a^D \sum_{\mu<\nu} \operatorname{tr}\big(f_{\mu\nu}(x) f_{\mu\nu}(x)\big). \tag{140.38}$$

All higher vertices come from the same compact-link exponential and from the Baker–Campbell–Hausdorff expansion of the plaquette. The finite-regulator definition remains the Haar integral; the perturbative chart is a local coordinate system for asymptotic expansion around $U_\ell = \mathbf{1}$.

On a periodic lattice, use Fourier modes with lattice momentum

$$\widehat{p}_\mu = \frac{2}{a}\sin\frac{ap_\mu}{2}, \qquad \widehat{p}^2 = \sum_\rho \widehat{p}_\rho^2. \tag{140.39}$$

After absorbing the harmless mid-link phases into the Fourier components, (140.38) becomes

$$S_W^{(2)} = \frac{1}{2}\sum_p A_\mu^a(-p)\left[\delta_{\mu\nu}\widehat{p}^2 - \widehat{p}_\mu\widehat{p}_\nu\right] A_\nu^a(p). \tag{140.40}$$

The zero modes and gauge orbits are treated by a finite-volume gauge-fixing or by restricting to gauge-invariant observables. In a covariant perturbative calculation one adds the lattice gauge-fixing quadratic form

$$S^{(2)}_{\mathrm{gf}} = \frac{1}{2\xi}\sum_p A^a_\mu(-p)\,\widehat{p}_\mu\widehat{p}_\nu\,A^a_\nu(p), \qquad \xi > 0. \tag{140.41}$$

The resulting kernel is

$$K^{(\xi)}_{\mu\nu}(p) = \delta_{\mu\nu}\widehat{p}^2 - \left(1 - \frac{1}{\xi}\right)\widehat{p}_\mu\widehat{p}_\nu, \tag{140.42}$$

with inverse on nonzero momenta

$$D^{ab}_{\mu\nu}(p) = \delta^{ab}\frac{1}{\widehat{p}^2}\left[\delta_{\mu\nu} - (1-\xi)\frac{\widehat{p}_\mu\widehat{p}_\nu}{\widehat{p}^2}\right]. \tag{140.43}$$

As $a \to 0$ at fixed physical p,

$$\widehat{p}^2 = p^2 - \frac{a^2}{12}\sum_\mu p_\mu^4 + O(a^4p^6). \tag{140.44}$$

This displayed artifact is one elementary source of the tree-level Symanzik corrections discussed above.

Remark 140.4 (Tree-level lattice propagator). For every nonzero lattice momentum, the tensor (140.43) is the inverse of (140.42):

$$K^{(\xi)}_{\mu\rho}(p)D^{ab}_{\rho\nu}(p) = \delta^{ab}\delta_{\mu\nu}. \tag{140.45}$$

Let P_L be the rank-one projector

$$(P_L)_{\mu\nu} = \frac{\widehat{p}_\mu\widehat{p}_\nu}{\widehat{p}^2}, \qquad P_T = \mathbf{1} - P_L.$$

Then

$$K^{(\xi)} = \widehat{p}^2(P_T + \xi^{-1}P_L), \qquad D = \widehat{p}^{-2}(P_T + \xi P_L).$$

Since $P_TP_L = 0$ and $P_T^2 = P_T$, $P_L^2 = P_L$, their product is the identity tensor. The color factor is diagonal by (140.33).

Mean-link or tadpole normalization is best understood as a finite coordinate change for perturbative expansions of link observables and action coefficients. Define the plaquette mean link, when the expectation is positive, by

$$u_0(\beta) = \left\langle \frac{1}{N}\,\mathrm{Re}\,\mathrm{tr}\,U_p \right\rangle_\beta^{1/4}. \tag{140.46}$$

If a Wilson-line observable contains L elementary links, its plaquette-tadpole-normalized coordinate is

$$O_{\mathrm{TI}} = u_0^{-L}O. \tag{140.47}$$

For the Wilson plaquette action, the same bookkeeping rewrites the plaquette coefficient as

$$\frac{\beta}{N}\,\mathrm{Re}\,\mathrm{tr}\,U_p = \frac{\beta u_0^4}{N}\,\mathrm{Re}\,\mathrm{tr}\big(u_0^{-4}U_p\big),$$

so the boosted coupling coordinate is

$$g_{\mathrm{TI}}^2 = \frac{g_0^2}{u_0^4}. \tag{140.48}$$

Equations (140.47) and (140.48) define a perturbative coordinate convention. They acquire predictive content only after specifying which renormalized observable is being matched and which finite-order truncation is being compared.

Example 140.5 (First terms of the boosted coupling)**.** Suppose the mean plaquette has a weak-coupling expansion

$$\left\langle \frac{1}{N} \operatorname{Re}\operatorname{tr} U_p \right\rangle_\beta = 1 - c_P g_0^2 + O(g_0^4). \tag{140.49}$$

Then $u_0^4 = 1 - c_P g_0^2 + O(g_0^4)$ and

$$g_{\mathrm{TI}}^2 = g_0^2 \left(1 + c_P g_0^2 + O(g_0^4)\right). \tag{140.50}$$

The coefficient c_P depends on the action, gauge group, and regulator volume used to define the expectation value. The formula itself is the finite algebra of the coordinate change.

140.10 Wilson Loops

For a closed oriented lattice contour C,

$$W_R(C) = \mathrm{Tr}_R \prod_{\ell \in C} U_\ell$$

is gauge invariant. Wilson loops are the basic gauge-invariant probes of line charges. Their strong-coupling character expansion gives the area-law mechanism described in Chapter 116. Their continuum limit requires line renormalization and an operator scheme.

140.11 Static Potential and Creutz Ratios

A rectangular Wilson loop has a Hamiltonian meaning when the transfer matrix exists. Let $C_{n,m}$ be a rectangle with spatial side $R = na$ and Euclidean time side $T = ma$. Use the normalized loop

$$W_S(n,m) = \frac{1}{\dim S} \left\langle \mathrm{Tr}_S \prod_{\ell \in C_{n,m}} U_\ell \right\rangle. \tag{140.51}$$

In the transfer-matrix Hilbert space, the spatial transporter between two static sources defines a vector $\Psi_{S,n}$ in the sector containing a source and an antisource separated by n lattice spacings. Reflection positivity gives

$$W_S(n,m) = \langle \Psi_{S,n}, T^m \Psi_{S,n} \rangle. \tag{140.52}$$

If the spectral measure of $\Psi_{S,n}$ for $T = e^{-aH}$ has an isolated largest transfer-matrix eigenvalue $e^{-aE_0(n,S)}$ with nonzero weight, then

$$aV_{a,S}(n) = -\lim_{m\to\infty} \log \frac{W_S(n,m+1)}{W_S(n,m)} = aE_0(n,S). \tag{140.53}$$

This is the finite-cutoff static potential in the chosen static-source sector. In a continuum limit it contains an additive line self-energy: the force, potential differences, or a specified subtraction scheme must be used before comparing continuum quantities.

For the finite spectral model, assume

$$W_m = \sum_{\alpha=0}^{r} A_\alpha e^{-amE_\alpha}, \qquad A_0 > 0, \quad A_\alpha \geq 0, \quad E_0 < E_1 \leq \cdots \leq E_r. \tag{140.54}$$

Then

$$-\log \frac{W_{m+1}}{W_m} = aE_0 + O(e^{-am(E_1-E_0)}). \tag{140.55}$$

Write

$$W_m = A_0 e^{-amE_0} \left(1 + \sum_{\alpha>0} \frac{A_\alpha}{A_0} e^{-am(E_\alpha - E_0)} \right).$$

The ratio W_{m+1}/W_m is e^{-aE_0} times a quotient of two factors which both tend to 1, and the difference from 1 is bounded by a constant times $e^{-am(E_1-E_0)}$. Taking the logarithm gives (140.55).

The same static-source sector admits a finite variational analysis. Fix the separation n, representation S, and a finite list of gauge-covariant spatial transporters $P_i^{(n,S)}$, for example different smearing levels or path shapes joining the static source to the antisource. They define vectors $\Psi_{i,n,S}$ in the same static sector and a Hermitian matrix

$$C_{ij}^{(n,S)}(m) = \langle \Psi_{i,n,S}, T^m \Psi_{j,n,S} \rangle. \tag{140.56}$$

If the chosen source space is exactly r-dimensional and has spectral form

$$C^{(n,S)}(m) = Z_{n,S} \operatorname{diag}(\lambda_\alpha(n,S)^m) Z_{n,S}^\dagger, \qquad \lambda_\alpha(n,S) = e^{-aE_\alpha(n,S)}, \tag{140.57}$$

with $Z_{n,S}$ invertible, then the generalized eigenvalue problem

$$C^{(n,S)}(m) v_\alpha = \Lambda_\alpha^{(n,S)}(m, m_0) C^{(n,S)}(m_0) v_\alpha \tag{140.58}$$

has eigenvalues

$$\Lambda_\alpha^{(n,S)}(m, m_0) = \lambda_\alpha(n,S)^{m-m_0} = e^{-a(m-m_0)E_\alpha(n,S)}. \tag{140.59}$$

Indeed

$$C^{(n,S)}(m_0)^{-1} C^{(n,S)}(m) = (Z_{n,S}^\dagger)^{-1} \operatorname{diag}(\lambda_\alpha(n,S)^{m-m_0}) Z_{n,S}^\dagger,$$

so the finite GEVP is only a similarity transform of the diagonal transfer-matrix ratios. Under an invertible change of static-source basis the matrices transform by congruence and these generalized eigenvalues are unchanged. With higher-state contamination, the residual norm after whitening by $C^{(n,S)}(m_0)$, the separation n, the representation S, the smearing or path recipe, and the chosen line self-energy subtraction are all part of the finite observable datum.

The Creutz ratio is a finite-difference observable designed to cancel the leading perimeter and constant terms in a rectangular Wilson-loop ansatz. For positive Wilson loops define

$$\chi(n,m) = -\log \frac{W(n,m)W(n-1,m-1)}{W(n,m-1)W(n-1,m)}. \tag{140.60}$$

If, over a range of lattice sizes,

$$W(n,m) = \exp\{-\sigma_{\text{lat}} nm - \mu_{\text{lat}}(n+m) - c_{\text{lat}} + \varepsilon(n,m)\}, \tag{140.61}$$

then

$$\chi(n,m) = \sigma_{\text{lat}} - \varepsilon(n,m) - \varepsilon(n-1,m-1) + \varepsilon(n,m-1) + \varepsilon(n-1,m). \tag{140.62}$$

Thus an observed Creutz-ratio plateau is a statement about a controlled two-dimensional finite difference of the correction term ε. A continuum string-tension theorem requires control of the scaling trajectory, the infinite-volume limit, and line-operator renormalization.

The companion analysis script

`qft_scripts/static_potential_from_wilson_loops.py`

implements exactly the finite formulas in (140.53) and (140.60) for positive rectangular Wilson-loop data. It reads a table of $W(R,T)$ values, returns effective-mass ratios and Creutz ratios, and includes a synthetic area-plus-perimeter smoke test for (140.61). It also has a sample-level mode for tables with columns `sample`, R, T, W: this mode forms block means, deletes or resamples entire Monte Carlo blocks, and recomputes the logarithmic ratios themselves. The same sample-level analysis can be fed directly from the HDF5 sampler dataset

`measurements/wilson_loops[sample,R-1,T-1]`,

which is the finite-data coordinate used by `su3_gauge_4d_metropolis_hdf5.py`. This is the finite-regulator implementation of the correlated jackknife construction in Chapter 141. The optional elementary error propagation in aggregate mode is only the independent-error algebra of the displayed logarithms. The script also has a static-source matrix mode for rows `R`, `T`, i, j, C or `R`, `T`, i, j, `real`, `imag`. For each fixed separation it solves (140.58) by positive whitening of $C(m_0)$ and reports `static_gevp_energy` levels; this is finite variational source-space analysis of smeared transporters, not continuum string-tension evidence.

140.12 Finite-Volume Correlator Matrices and the GEVP

The generalized eigenvalue problem is a finite-regulator spectral-analysis method. It is not tied to any particular dynamics: once a reflection-positive Euclidean-time regulator supplies a transfer matrix and a finite family of physical time-slice sources in a fixed symmetry channel, gauge-invariant when there is gauge redundancy, the same linear-algebra problem applies to pure Yang–Mills glueballs, to $\mathcal{N}=1$ supersymmetric Yang–Mills channel matrices, and to any other lattice channel with a positive transfer matrix. The present section uses pure Yang–Mills glueball sources as the running example because their operator construction is especially concrete.

Pure Yang–Mills spectroscopy on a lattice begins with gauge-invariant time-slice operators, not with constituent gluons. Fix a finite spatial lattice, a reflection-positive Euclidean-time regulator, and a symmetry channel $\mathfrak{c}$ for the finite lattice symmetry group. On a cubic lattice $\mathfrak{c}$ may include an irreducible representation of the octahedral group, parity, and charge conjugation. A glueball source in this channel is a gauge-invariant function $O_i[U(\tau)]$ of the spatial links on a time slice, usually built from traced closed Wilson loops after smearing and projection to $\mathfrak{c}$. Its vacuum-subtracted version is

$$\widetilde{O}_i(\tau) = O_i(\tau) - \langle O_i \rangle_\Lambda. \tag{140.63}$$

The connected correlator matrix is

$$C_{ij}(n) = \langle \widetilde{O}_i(na)\, \widetilde{O}_j(0)^\dagger \rangle_\Lambda, \qquad n \in \mathbb{Z}_{\geq 0}. \tag{140.64}$$

If the transfer matrix $T = e^{-aH_\Lambda}$ exists in the sector selected by the channel, reflection positivity identifies vectors $\psi_i = \widetilde{O}_i \Omega_\Lambda$ and gives

$$C_{ij}(n) = \langle \psi_i, T^n \psi_j \rangle. \tag{140.65}$$

Thus $C(n)$ is a finite-regulator spectral object. The continuum glueball statement is obtained only after the thermodynamic, continuum, and channel identification limits have been controlled.

The spectral resolution in finite volume gives

$$C_{ij}(n) = \sum_\alpha Z_i^{(\alpha)} \overline{Z_j^{(\alpha)}}\, \lambda_\alpha^n, \qquad Z_i^{(\alpha)} = \langle \psi_i, \alpha \rangle, \qquad \lambda_\alpha = e^{-aE_\alpha}. \tag{140.66}$$

The finite cubic channel is part of the regulator. For example, a continuum $J = 0$ channel restricts to an A_1 channel, while a continuum $J = 2$ channel restricts to the $E \oplus T_2$ channels. Degeneracy across the split lattice channels is therefore a continuum-restoration test, not an input to the finite calculation.

In the exact finite-state idealization, the GEVP reduces to an ordinary similarity transformation. Let $\mathcal{S}$ be an r-dimensional source space in a fixed finite lattice channel. Suppose that, on this source space, the correlator matrix has the exact finite spectral form

$$C(n) = Z\, \mathrm{diag}(\lambda_1^n, \ldots, \lambda_r^n)\, Z^\dagger, \qquad 1 > \lambda_1 > \cdots > \lambda_r > 0, \tag{140.67}$$

where Z is an invertible $r \times r$ matrix. Then for every $n > n_0 \geq 0$ the generalized eigenvalue problem

$$C(n) v_\alpha(n, n_0) = \Lambda_\alpha(n, n_0)\, C(n_0) v_\alpha(n, n_0) \tag{140.68}$$

has generalized eigenvalues

$$\Lambda_\alpha(n, n_0) = \lambda_\alpha^{n-n_0} = e^{-a(n-n_0)E_\alpha}. \tag{140.69}$$

Since Z is invertible and all λ_α are positive, $C(n_0)$ is positive definite. Multiplying (140.68) by $C(n_0)^{-1}$ reduces the generalized problem to the ordinary eigenvalue problem for

$$C(n_0)^{-1} C(n) = (Z^\dagger)^{-1}\, \mathrm{diag}(\lambda_1^{n-n_0}, \ldots, \lambda_r^{n-n_0}) Z^\dagger. \tag{140.70}$$

The displayed matrix is similar to the diagonal matrix of $\lambda_\alpha^{n-n_0}$. Its eigenvalues are therefore precisely the numbers in (140.69), with multiplicity.

The generalized eigenvalues are invariant under changes of source coordinates. If $R : \mathcal{S} \to \mathcal{S}$ is invertible and $O_i' = R_i{}^j O_j$, then

$$C(n) \longmapsto C'(n) = R\, C(n)\, R^\dagger. \tag{140.71}$$

The transformed GEVP,

$$RC(n)R^{\dagger}v' = \Lambda' RC(n_0)R^{\dagger}v',$$

is equivalent, after multiplication by R^{-1} and the substitution $v = R^{\dagger}v'$, to

$$C(n)v = \Lambda' C(n_0)v.$$

Hence the multiset of generalized eigenvalues is source-basis invariant. Equivalently,

$$C'(n_0)^{-1}C'(n) = (R^{\dagger})^{-1}C(n_0)^{-1}C(n)R^{\dagger}$$

is similar to $C(n_0)^{-1}C(n)$. This invariance concerns the extracted finite-regulator energy estimates. Statements such as "mostly glueball", "mostly two-hadron", or "mostly hybrid" also depend on a declared decomposition of the source space and on the inner product used to compare overlap covectors; those labels are not invariant consequences of the GEVP alone.

Controlled Approximation 140.6 (Whitened residual criterion for a GEVP window)**.** Fix $n > n_0$ and suppose $C(n_0)$ is positive definite. Define the Hermitian whitened matrix

$$B(n, n_0) = C(n_0)^{-1/2}C(n)C(n_0)^{-1/2}. \tag{140.72}$$

Assume that in the selected time window

$$B(n, n_0) = B_{\text{low}}(n, n_0) + R(n, n_0), \qquad \|R(n, n_0)\|_{\text{op}} \leq \epsilon, \tag{140.73}$$

where B_{low} has eigenvalues $\lambda_\alpha^{n-n_0} = e^{-a(n-n_0)E_\alpha}$ for the states intended to be resolved. Let $\widehat{\Lambda}_\alpha$ be the corresponding eigenvalues of B, ordered decreasingly. Weyl's finite-dimensional eigenvalue inequality gives

$$|\widehat{\Lambda}_\alpha - \lambda_\alpha^{n-n_0}| \leq \epsilon. \tag{140.74}$$

If $\epsilon < \lambda_\alpha^{n-n_0}$, then the effective energy

$$\widehat{E}_\alpha(n, n_0) = -\frac{1}{a(n-n_0)} \log \widehat{\Lambda}_\alpha \tag{140.75}$$

obeys

$$|\widehat{E}_\alpha(n, n_0) - E_\alpha| \leq \frac{1}{a(n-n_0)} \max\left\{ \log \frac{\lambda_\alpha^{n-n_0}}{\lambda_\alpha^{n-n_0} - \epsilon}, \log \frac{\lambda_\alpha^{n-n_0} + \epsilon}{\lambda_\alpha^{n-n_0}} \right\}. \tag{140.76}$$

A quoted GEVP plateau is therefore a controlled finite-matrix statement only after such a residual bound, or a stronger replacement, has been supplied for the selected operator basis and time window.

Derivation of the finite-matrix residual bound. The matrix $B(n, n_0)$ is Hermitian because $C(n)$ and $C(n_0)$ are Hermitian and $C(n_0)^{-1/2}$ is Hermitian. Weyl's inequality for Hermitian matrices gives

$$|\widehat{\Lambda}_\alpha - \Lambda_\alpha^{\text{low}}| \leq \|R(n, n_0)\|_{\text{op}} \leq \epsilon,$$

with $\Lambda_\alpha^{\text{low}} = \lambda_\alpha^{n-n_0}$, after matching the ordered eigenvalues. The map $x \mapsto -(a(n-n_0))^{-1} \log x$ is smooth and monotone on the positive interval $(\lambda_\alpha^{n-n_0} - \epsilon, \lambda_\alpha^{n-n_0} + \epsilon)$. Evaluating the largest possible logarithmic displacement at the interval endpoints gives (140.76).

The companion script

```
qft_scripts/glueball_gevp_from_correlators.py
```

implements exactly the finite matrix problem (140.68). It reads Hermitian correlator matrices from a CSV table with columns `t,i,j,C` or `t,i,j,real,imag`, whitens by $C(n_0)$, solves the ordinary Hermitian eigenvalue problem for (140.72), and reports (140.75). Its smoke test uses an exact two-state correlator matrix of the form (140.67); it is a check of the finite algebra, not a glueball-mass computation.

140.13 Wilson Flow, Smoothing, and Topological Charge

Gradient flow is a finite-regulator operation before it is a continuum renormalization tool. Let

$$\mathcal{U}_\Lambda = G^E$$

be the compact manifold of link variables on the finite lattice, and equip each copy of G with the bi-invariant Riemannian metric obtained from an invariant positive inner product $(X,Y)_{\mathfrak{g}}$ on $\mathfrak{g} = \mathrm{Lie}(G)$. For a smooth gauge-invariant lattice action $S : \mathcal{U}_\Lambda \to \mathbb{R}$, define the left-link gradient $\nabla_\ell S(U) \in \mathfrak{g}$ by

$$(X, \nabla_\ell S(U))_{\mathfrak{g}} = \frac{\mathrm{d}}{\mathrm{d}s} S(U^{(s)}_{\ell'})\bigg|_{s=0}, \qquad U^{(s)}_\ell = e^{sX} U_\ell, \quad U^{(s)}_{\ell'} = U_{\ell'} \text{ for } \ell' \neq \ell. \tag{140.77}$$

The Wilson-flow trajectory $V_t \in \mathcal{U}_\Lambda$ starting at $U \in \mathcal{U}_\Lambda$ is the solution of

$$\frac{\mathrm{d}V_t(\ell)}{\mathrm{d}t} V_t(\ell)^{-1} = -\nabla_\ell S(V_t), \qquad V_0(\ell) = U_\ell. \tag{140.78}$$

The parameter t has engineering dimension a^2 if one keeps physical units. The normalized flow time $\tau = t/a^2$ is often used in finite-lattice computations, but the continuum smoothing interpretation concerns fixed physical $t > 0$ as $a \to 0$.

Finite-lattice Wilson flow. For every finite lattice and every smooth action S, the flow (140.78) exists for all $t \geq 0$. It is gauge covariant, and the action decreases according to

$$\frac{\mathrm{d}}{\mathrm{d}t} S(V_t) = -\sum_{\ell \in E} \|\nabla_\ell S(V_t)\|^2_{\mathfrak{g}} \leq 0. \tag{140.79}$$

The right-hand side of (140.78) is a smooth vector field on the compact manifold G^E. Ordinary differential-equation existence gives a local solution, and compactness prevents finite-time escape, so the solution is global. Gauge covariance follows because S and the metric are invariant under the lattice gauge group: differentiating $S(g \cdot U) = S(U)$ along a left variation of one link shows that the gradient is transported by the same endpoint conjugations as the link tangent vector. Finally, by the chain rule and (140.77),

$$\frac{\mathrm{d}}{\mathrm{d}t} S(V_t) = \sum_{\ell \in E} \left(\frac{\mathrm{d}V_t(\ell)}{\mathrm{d}t} V_t(\ell)^{-1}, \nabla_\ell S(V_t) \right)_{\mathfrak{g}} = -\sum_{\ell \in E} \|\nabla_\ell S(V_t)\|^2_{\mathfrak{g}}.$$

For the pure $SU(3)$ Wilson action it is useful to display the finite force rather than hide it behind the abstract gradient notation. Use the score coordinate

$$Q(U) = \sum_x \sum_{0\le\mu<\nu\le 3} \frac{1}{3}\operatorname{Re}\operatorname{Tr}_3 U_{\mu\nu}(x), \qquad S_{\text{flow}}(U) = 6|\Lambda^0| - Q(U), \tag{140.80}$$

so that flowing downward for S_{flow} is the same as flowing upward for the normalized plaquette score Q. For a link $U_\mu(x)$, define the staple matrix

$$\begin{aligned} C_\mu(x;U) = \sum_{\nu\ne\mu}\Big[&U_\nu(x+\widehat{\mu})U_\mu(x+\widehat{\nu})^{-1}U_\nu(x)^{-1} \\ &+ U_\nu(x-\widehat{\nu}+\widehat{\mu})^{-1}U_\mu(x-\widehat{\nu})^{-1}U_\nu(x-\widehat{\nu})\Big]. \end{aligned} \tag{140.81}$$

Then the part of Q depending on $U_\mu(x)$, with the other links held fixed, is

$$Q_{x,\mu}(U) = \frac{1}{3}\operatorname{Re}\operatorname{Tr}_3\big(U_\mu(x)C_\mu(x;U)\big).$$

For $A\in M_3(\mathbb{C})$, write

$$[A]_{\mathfrak{su}(3)} = \frac{1}{2}(A-A^\dagger) - \frac{1}{6}\operatorname{Tr}(A-A^\dagger)\mathbf{1}_3. \tag{140.82}$$

This is the anti-Hermitian traceless projection of A. With the inner product

$$(X,Y)_{\mathfrak{su}(3)} = -\operatorname{Re}\operatorname{Tr}_3(XY),$$

the left-gradient vector for the score Q is

$$Z_\mu(x;U) = -\frac{1}{3}\big[U_\mu(x)C_\mu(x;U)\big]_{\mathfrak{su}(3)}. \tag{140.83}$$

Thus the normalized finite $SU(3)$ Wilson-flow equation used below is

$$\frac{\mathrm{d}V_\mu(t,x)}{\mathrm{d}t} = Z_\mu(x;V_t)V_\mu(t,x), \qquad V_\mu(0,x) = U_\mu(x). \tag{140.84}$$

Including the gauge coupling in the action only rescales t in this finite pure-gauge flow.

Explicit $SU(3)$ Wilson-score gradient. For $X\in\mathfrak{su}(3)$ and $U_\mu^{(s)}(x) = e^{sX}U_\mu(x)$,

$$\frac{\mathrm{d}}{\mathrm{d}s}Q(U^{(s)})\bigg|_{s=0} = (X, Z_\mu(x;U))_{\mathfrak{su}(3)}.$$

Consequently the flow (140.84) satisfies

$$\frac{\mathrm{d}}{\mathrm{d}t}Q(V_t) = \sum_{x,\mu}\|Z_\mu(x;V_t)\|^2_{\mathfrak{su}(3)} \ge 0.$$

The two summands in (140.81) are precisely the forward and backward plaquettes containing the oriented link $U_\mu(x)$, rewritten so that their total contribution has the form

$$\frac{1}{3}\operatorname{Re}\operatorname{Tr}\big(U_\mu(x)C_\mu(x;U)\big).$$

Therefore the left variation gives

$$\frac{\mathrm{d}}{\mathrm{d}s}Q(U^{(s)})\bigg|_{s=0} = \frac{1}{3}\operatorname{Re}\operatorname{Tr}\big(X\,U_\mu(x)C_\mu(x;U)\big).$$

If X is anti-Hermitian and traceless, the Hermitian part and the scalar trace part of $U_\mu C_\mu$ have zero real trace against X. Hence the last expression equals

$$\frac{1}{3}\operatorname{Re}\operatorname{Tr}\big(X[U_\mu C_\mu]_{\mathfrak{su}(3)}\big) = -\operatorname{Re}\operatorname{Tr}\big(XZ_\mu\big) = (X, Z_\mu)_{\mathfrak{su}(3)}.$$

Substituting $X = Z_\mu(x;V_t)$ for every link gives the displayed monotonicity identity for Q.

The continuum reason that positive flow time is useful is already visible in the linearized equation. Let $B_\mu(t,x)$ be a smooth continuum connection and write its curvature as $G_{\mu\nu}(t)$. The Yang–Mills gradient flow is

$$\partial_t B_\mu = D_\nu G_{\nu\mu}, \qquad B_\mu(0,x) = A_\mu(x), \tag{140.85}$$

in the anti-Hermitian connection convention used in the lattice expansion. Linearizing about $A_\mu = 0$ gives

$$\partial_t B_\mu = \partial^2 B_\mu - \partial_\mu\partial_\nu B_\nu.$$

In the transverse gauge $\partial_\mu B_\mu = 0$, a Fourier mode of momentum k is multiplied by e^{-tk^2}. Thus positive flow time damps momenta $k^2 \gg t^{-1}$, and the heat-kernel radius is of order $\sqrt{8t}$ in four Euclidean dimensions.

Definition 140.7 (Flowed energy density and scale coordinates)**.** Let $G_{\mu\nu}(t,x)$ be a chosen gauge-covariant lattice curvature constructed from the flowed links V_t, for example the clover curvature. The flowed energy density is represented by

$$E(t,x) = -\frac{1}{2}\operatorname{tr}\big(G_{\mu\nu}(t,x)G_{\mu\nu}(t,x)\big),$$

for anti-Hermitian curvature. Its volume average is

$$\overline{E}(t) = \frac{a^4}{V_\Lambda}\sum_x E(t,x), \qquad V_\Lambda = a^4\#\Lambda^0.$$

Given a positive reference number c, the finite-cutoff scale coordinates t_0 and w_0, if they exist uniquely, are defined by

$$t_0^2\,\langle\overline{E}(t_0)\rangle = c, \qquad t\frac{\mathrm{d}}{\mathrm{d}t}\big(t^2\langle\overline{E}(t)\rangle\big)\bigg|_{t=w_0^2} = c.$$

Existence, uniqueness, and a continuum limit of these coordinates are properties of a scaling trajectory; they are not consequences of the finite-lattice ODE alone.

The same distinction is essential for topological charge. A generic finite lattice gauge field is a collection of group elements, not a smooth bundle connection with a canonical integer Q. A topological sector on the lattice requires an additional construction, such as an admissibility condition plus a geometric interpolation, or a chiral lattice Dirac operator whose index is well-defined.

Definition 140.8 (Admissible geometric topological charge)**.** Let $G = SU(N)$. On a periodic lattice in four dimensions, an admissibility condition is the bound

$$\|1 - U_p\| < \epsilon \qquad \text{for every plaquette } p$$

with ϵ small enough that plaquette holonomies stay in a coordinate neighborhood of the identity. Together with a specified interpolation of the link data to transition functions on the continuum torus, this determines a principal $SU(N)$-bundle $P_U \to T^4$. The geometric topological charge is

$$Q_{\mathrm{geom}}(U) = \frac{1}{8\pi^2} \int_{T^4} \mathrm{tr}(F_{\widetilde{A}} \wedge F_{\widetilde{A}}) \in \mathbb{Z},$$

where $\widetilde{A}$ is any smooth connection on P_U. Independence of $\widetilde{A}$ is the Chern–Weil theorem; independence of the interpolation requires the stated admissibility construction and is part of the regulator datum.

Definition 140.9 (Clover topological-charge diagnostic)**.** For a finite periodic $SU(3)$ lattice, write

$$U_{+\mu}(x) = U_\mu(x), \qquad U_{-\mu}(x) = U_\mu(x - \widehat{\mu})^{-1}.$$

For signed directions α, β, let

$$P_{\alpha\beta}(x) = U_\alpha(x)\, U_\beta(x + \widehat{\alpha})\, U_{-\alpha}(x + \widehat{\alpha} + \widehat{\beta})\, U_{-\beta}(x + \widehat{\beta})$$

be the oriented plaquette based at x. For $0 \le \mu < \nu \le 3$, define the clover matrix and clover curvature by

$$C^{\mathrm{cl}}_{\mu\nu}(x) = P_{\mu\nu}(x) + P_{\nu,-\mu}(x) + P_{-\mu,-\nu}(x) + P_{-\nu,\mu}(x), \tag{140.86}$$

$$F^{\mathrm{cl}}_{\mu\nu}(x) = \frac{1}{4}\big[C^{\mathrm{cl}}_{\mu\nu}(x)\big]_{\mathfrak{su}(3)}. \tag{140.87}$$

Set $F^{\mathrm{cl}}_{\nu\mu} = -F^{\mathrm{cl}}_{\mu\nu}$. The clover diagnostic for the Chern–Weil density is

$$Q_{\mathrm{clover}}(U) = \frac{1}{32\pi^2} \sum_x \sum_{\mu,\nu,\rho,\sigma=0}^{3} \epsilon_{\mu\nu\rho\sigma} \,\mathrm{Re}\,\mathrm{Tr}_3\big(F^{\mathrm{cl}}_{\mu\nu}(x) F^{\mathrm{cl}}_{\rho\sigma}(x)\big). \tag{140.88}$$

The associated clover action-density diagnostic is

$$e_{\mathrm{clover}}(U) = \frac{1}{|\Lambda^0|} \sum_x \sum_{\mu<\nu} -\mathrm{Re}\,\mathrm{Tr}_3\big(F^{\mathrm{cl}}_{\mu\nu}(x) F^{\mathrm{cl}}_{\mu\nu}(x)\big).$$

These are gauge-invariant finite-regulator observables. They are not, by themselves, an integer topological charge or a definition of a theta sector.

Remark 140.10 (Gauge invariance of the clover diagnostics). Under a lattice gauge transformation $U_\mu(x) \mapsto g(x) U_\mu(x) g(x + \widehat{\mu})^{-1}$,

$$F^{\mathrm{cl}}_{\mu\nu}(x) \mapsto g(x) F^{\mathrm{cl}}_{\mu\nu}(x) g(x)^{-1}.$$

Consequently $Q_{\mathrm{clover}}(U)$, $e_{\mathrm{clover}}(U)$, and $\max_p \|1 - U_p\|$ are gauge invariant. The directed link $U_\alpha(y)$ transforms by conjugation with the gauge matrices at the initial and terminal vertices of the directed edge. In the oriented plaquette $P_{\alpha\beta}(x)$, all gauge matrices at intermediate vertices cancel, leaving

$$P_{\alpha\beta}(x) \mapsto g(x)P_{\alpha\beta}(x)g(x)^{-1}.$$

The clover sum therefore transforms by the same conjugation. The projection $[\cdot]_{\mathfrak{su}(3)}$ commutes with unitary conjugation, hence $F^{\mathrm{cl}}_{\mu\nu}(x)$ transforms by conjugation at x. Traces of products at the same base point are invariant. The plaquette-deviation norm is invariant because $1 - U_p$ is conjugated by a unitary matrix at the base point.

Continuum flow preserves Chern–Weil charge. Let $B(t)$ be a smooth one-parameter family of connections on a fixed principal $SU(N)$-bundle over a closed oriented four-manifold M, with curvature $G(t)$. Then

$$Q(t) = \frac{1}{8\pi^2}\int_M \mathrm{tr}(G(t) \wedge G(t))$$

is independent of t. In particular, smooth Yang–Mills gradient flow cannot change the bundle topological charge unless the flow leaves the smooth fixed-bundle setting.

Write $\dot{B} = \partial_t B$. The curvature variation is $\dot{G} = D_B\dot{B}$. Therefore

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\mathrm{tr}(G \wedge G) = 2\,\mathrm{tr}(D_B\dot{B} \wedge G).$$

Using invariance of the trace and the Bianchi identity $D_BG = 0$,

$$\mathrm{tr}(D_B\dot{B} \wedge G) = \mathrm{d}\ \mathrm{tr}(\dot{B} \wedge G).$$

Thus

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = \frac{1}{4\pi^2}\int_M \mathrm{d}\ \mathrm{tr}(\dot{B} \wedge G) = 0$$

because M is closed.

Controlled Approximation 140.11 (Using flow in continuum extrapolations)**.** A flowed observable at positive physical flow time is a composite observable with its own regulator definition. Statements such as "the flow removes ultraviolet noise" mean the following precise finite-cutoff procedure: first solve (140.78), then construct a gauge-invariant observable from V_t, and only then study its infinite-volume and continuum limits. Integer topological charge plateaux observed after flow are numerical evidence for stability within an admissible sector; without an admissibility or index-theoretic definition they are not, by themselves, a definition of a continuum theta sector.

The companion script

`qft_scripts/`

`su3_wilson_flow_hdf5.py`

implements (140.84) by a finite-dimensional Lie–Euler step

$$V_\mu((n+1)\delta t, x) = \exp\bigl(\delta t\, Z_\mu(x; V_{n\delta t})\bigr)V_\mu(n\delta t, x), \tag{140.89}$$

with all link forces evaluated before the update. It can read the `checkpoint/links` dataset written by the $SU(3)$ subgroup-Metropolis generator, write an HDF5 trajectory containing τ, plaquette score, action density, and final flowed links, and expose a smoke test that checks score monotonicity and group preservation at finite cutoff. The corresponding calculation check verifies (140.83) by directional derivatives, tests one-step gauge covariance, and runs the sampler-to-flow HDF5 pipeline. The Lie–Euler step is a numerical integrator for the finite ODE; its step-size error is separate from the continuum-limit questions in Definition 140.7 and Definition 140.8.

The companion diagnostic script

`qft_scripts/`
`su3_topological_charge_diagnostics_hdf5.py`

implements Definition 140.9. It reads either the `checkpoint/flowed_links` dataset from the Wilson-flow script or the raw `checkpoint/links` dataset from the sampler, reports Q_{clover}, e_{clover}, and $\max_p \|1 - U_p\|$, and can write local density arrays to HDF5. The paired calculation check verifies the oriented plaquette convention against the plaquette used in the Wilson action, proves numerically that the clover field is anti-Hermitian, traceless, and antisymmetric in μ, ν, tests gauge invariance of the scalar diagnostics, and runs the full sampler-to-flow-to-topology HDF5 pipeline. The output name Q_{clover} is deliberate: it is a finite diagnostic to be compared along a scaling trajectory, not a replacement for Definition 140.8.

140.14 Reflection Positivity and Transfer Matrix

For the Wilson plaquette action, reflection positivity follows by assigning plaquettes to the two halves of the lattice and expanding cross-plane plaquette Boltzmann weights in positive characters. The reflection-positive inner product on positive-time functions gives a transfer matrix

$$T = e^{-aH}$$

with $H \geq 0$ after quotienting null vectors. Gauge constraints are implemented by the gauge-invariant subspace or by a gauge-covariant transfer matrix followed by projection.

140.15 Fermions and Chiral Difficulties

Adding lattice fermions requires a fermion action whose reflection positivity, locality, spectrum, and continuum chiral properties are checked separately. The mid-link fermion reflection structure of Chapter 138 is one such finite-regulator positivity mechanism. Chiral gauge theories require more: gauge invariance, locality, anomaly cancellation, and a definition of the fermion determinant phase compatible with the target continuum theory.

Open Problem 140.12 (Lattice continuum QCD construction). Construct four-dimensional continuum Yang–Mills or QCD from Wilson-type lattice gauge theory with a mass gap, OS reconstruction, local gauge-invariant operator limits, and controlled line-operator and theta-angle sectors.

Chapter 141

Monte Carlo Methods and Sign Problems

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Monte Carlo methods evaluate finite-regulator Euclidean expectation values by sampling a probability distribution. Their mathematical content is a finite-dimensional integration problem plus a convergence theorem for a Markov chain. Their limitation in many QFTs is the absence of a positive sampling weight compatible with the target observable.

141.1 Production Evidence Architecture

A lattice Monte Carlo output becomes evidence through a layered finite record. The first layer is the target finite measure: the regulator space, boundary conditions, action, source insertions, observables, and normalization convention. This layer fixes the mathematical object

$$(\Omega_\Lambda, d\nu_\Lambda; O_1, \ldots, O_k)$$

before any algorithm is discussed. A quoted number without this datum is not yet an estimate of a QFT observable; it is at most an entry in an unidentified finite computation.

The second layer is the invariant Markov kernel. For a Metropolis, heat-bath, overrelaxation-assisted, HMC, or RHMC computation, the chapter separates the proof that a finite kernel preserves $d\nu_\Lambda$ from the empirical question of how well a particular run explores that measure. The theorem layer records the exact proposal law, the acceptance rule or conditional distribution, the reversibility or detailed-balance identity, and the irreducibility or Harris-recurrence hypotheses invoked by the estimator.

The third layer is the implementation-defect record. A production lattice run records the random-number state, checkpoint format, code revision, floating-point precision, linear-solver tolerance, integrator step data, Hamiltonian-change distribution, reversibility defect, rational approximation interval, and any reweighting convention. On a cluster this layer also contains the job manifest: array coordinate, input deck, environment module set, executable hash when available, wall-clock limits, restart policy, and the HDF5 or table schema for outputs. These data make the finite Markov chain reproducible enough for an independent rerun and make approximation defects visible as finite numbers.

The fourth layer is the estimator and error-analysis record. It contains thermalization cuts, stationarity diagnostics, autocorrelation estimates, blocking choices, jackknife or bootstrap covariance estimates, and the rule by which nonlinear observables are recomputed on deleted or resampled blocks. Wilson-loop effective masses, Creutz ratios, static-source GEVP energies, and glueball GEVP energies belong to this layer as functions of correlated finite samples, not as independent scalar measurements.

The final layer is the scaling-window transfer to continuum language. A finite production ensemble enters a continuum claim only as input to a scaling-window evidence package in the sense of Definition 139.7 of Chapter 139: selected regulator points, covariance data, finite-volume and cutoff coordinates, fit ansatz, stability tests, and an evidence-budget decomposition. The output of this chapter is therefore an admissible finite evidence record; the continuum interpretation is a further structured inference with its own hypotheses.

This architecture governs the examples below. The small companion scripts illustrate individual layers, while the HDF5 samplers and cluster templates show how the layers can be serialized. A full numerical claim must name the layer at which each assertion lives: invariant measure, implementation defect, estimator error, observable analysis, or scaling-window inference.

Proposition 141.1 (Independent-chain aggregation record)**.** *Suppose a cluster job array produces K chain-level summaries for the same finite-regulator observable:*

$$(\widehat{O}_a, s_a, N_a^{\mathrm{eff}}), \qquad a = 1, \dots, K,$$

where $s_a > 0$ is the declared standard error of the a-th chain after its thermalization cut and autocorrelation analysis, and N_a^{eff} is an optional effective-sample-size coordinate. Conditional on the finite target measure, implementation record, and the hypothesis that the chain-level errors are independent with variances s_a^2, define

$$w_a = s_a^{-2}, \qquad \widehat{O}_{\mathrm{ens}} = \frac{\sum_a w_a \widehat{O}_a}{\sum_a w_a}.$$

Then the internal variance of the weighted estimator is

$$\operatorname{Var}(\widehat{O}_{\mathrm{ens}}) = \frac{1}{\sum_a w_a}. \tag{141.1}$$

The finite between-chain disagreement coordinate is

$$\chi^2_{\mathrm{chain}} = \sum_{a=1}^{K} w_a \big(\widehat{O}_a - \widehat{O}_{\mathrm{ens}}\big)^2, \qquad \nu_{\mathrm{chain}} = K - 1. \tag{141.2}$$

It is an estimator-record diagnostic: large $\chi^2_{\mathrm{chain}}/\nu_{\mathrm{chain}}$ indicates either underestimated within-chain errors, insufficient equilibration, hidden correlations between tasks, or a mismatch in the finite target measure. Inflating the internal error by

$$\max\{1, \sqrt{\chi^2_{\mathrm{chain}}/\nu_{\mathrm{chain}}}\}$$

is therefore a conservative finite reporting convention, not a proof that the underlying chains have mixed.

Proof. The estimator is a linear combination

$$\widehat{O}_{\mathrm{ens}} = \sum_a \alpha_a \widehat{O}_a, \qquad \alpha_a = \frac{w_a}{\sum_b w_b}.$$

Under the stated independence and variance hypotheses,

$$\mathrm{Var}(\widehat{O}_{\mathrm{ens}}) = \sum_a \alpha_a^2 s_a^2 = \sum_a \frac{w_a^2}{(\sum_b w_b)^2}\frac{1}{w_a} = \frac{\sum_a w_a}{(\sum_b w_b)^2} = \frac{1}{\sum_b w_b},$$

which proves (141.1). Equation (141.2) is the corresponding weighted residual norm after fitting one common mean parameter, hence the finite residual coordinate has $K-1$ formal degrees of freedom when the usual independent Gaussian error model is adopted. Outside that model it is still a well-defined finite discrepancy number, but its interpretation is diagnostic rather than inferential. □

The companion utility `qft_scripts/cluster/chain_ensemble_summary.py` implements exactly this finite estimator record for CSV rows

```
chain,estimate,standard_error
```

with an optional `effective_sample_size` column. It belongs to the estimator layer of the production-evidence architecture. The script does not replace the target-measure declaration, the Markov-kernel theorem, the autocorrelation analysis inside each chain, or the scaling-window evidence package.

141.2 Finite-Regulator Expectation Values

Let Ω_Λ be a finite-dimensional regulator space and let

$$d\nu_\Lambda(\Phi) = \frac{1}{Z_\Lambda} e^{-S_\Lambda(\Phi)} d\Phi$$

be a probability measure on it. For an observable $O : \Omega_\Lambda \to \mathbb{C}$,

$$\langle O \rangle_\Lambda = \int_{\Omega_\Lambda} O(\Phi)\, d\nu_\Lambda(\Phi).$$

On a compact gauge lattice, $d\Phi$ is a product of Haar measures and finite-dimensional fermionic integrals have already been performed into a determinant or Pfaffian when a purely bosonic sampling problem is used.

141.3 Markov Chains and Detailed Balance

A Markov transition kernel $P(\Phi, d\Phi')$ preserves $d\nu_\Lambda$ if

$$\int_{\Omega_\Lambda} d\nu_\Lambda(\Phi)\, P(\Phi, A) = \nu_\Lambda(A)$$

for every measurable set A. Detailed balance is the stronger condition

$$d\nu_\Lambda(\Phi)P(\Phi, d\Phi') = d\nu_\Lambda(\Phi')P(\Phi', d\Phi).$$

If the chain is irreducible and aperiodic in the finite-state case, or satisfies the corresponding Harris recurrence hypotheses in a continuous state space, the estimator

$$\overline{O}_N = \frac{1}{N}\sum_{n=1}^{N} O(\Phi_n)$$

converges to $\langle O\rangle_\Lambda$ in the sense made precise below.

The finite-state statement is elementary enough that it should not be used as a black box. Let Ω be a finite set, let $P(x, y)$ be a stochastic matrix, and let $\pi(x) > 0$ be a probability vector with $\pi P = \pi$. A state y is reachable from x if $P^n(x, y) > 0$ for some n. The chain is irreducible if every state is reachable from every other state, and aperiodic if

$$\gcd\{n \geq 1 : P^n(x, x) > 0\} = 1$$

for one, hence every, state x.

Proposition 141.2 (Finite-state ergodic theorem)**.** *Let P be an irreducible and aperiodic stochastic matrix on a finite set Ω. Then P has a unique stationary probability distribution π with strictly positive entries, and*

$$\lim_{n\to\infty} P^n(x, y) = \pi(y) \qquad (x, y \in \Omega). \tag{141.3}$$

For every function $f : \Omega \to \mathbb{C}$ and every initial state X_0,

$$\frac{1}{N}\sum_{n=0}^{N-1} f(X_n) \longrightarrow \sum_{x\in\Omega} \pi(x)f(x) \tag{141.4}$$

in probability. If the chain is run in stationarity, the same convergence holds in L^2.

Proof. For an irreducible aperiodic finite chain there is an integer m for which

$$P^m(x, y) > 0 \qquad \text{for all } x, y \in \Omega. \tag{141.5}$$

Indeed, irreducibility gives closed walks based at any state, and aperiodicity makes the semigroup of return times have greatest common divisor one; adding fixed paths from x to a reference state and from that reference state to y gives positivity for all sufficiently large common times. Let

$$\epsilon = \min_{x,y} P^m(x, y) > 0.$$

For probability vectors μ, ν, write $\alpha = \mu - \nu$, so $\sum_x \alpha(x) = 0$. Decompose

$$P^m(x,y) = \epsilon + R(x,y), \qquad R(x,y) \geq 0, \qquad \sum_y R(x,y) = 1 - |\Omega|\epsilon.$$

The constant part drops out after multiplication by α, and therefore

$$\|\alpha P^m\|_1 = \|\alpha R\|_1 \leq (1 - |\Omega|\epsilon)\|\alpha\|_1. \tag{141.6}$$

Thus P^m is a strict contraction on the affine space of probability vectors modulo total mass. It has a unique fixed probability vector π, and every μP^{km} converges to π. Since πP is also fixed by P^m, uniqueness gives $\pi P = \pi$. The finitely many intermediate subsequences μP^{km+r}, $0 \leq r < m$, converge to $\pi P^r = \pi$, proving (141.3). The positivity of π follows from

$$\pi(y) = \sum_x \pi(x) P^m(x,y) \geq \epsilon.$$

For convergence of time averages in stationarity, it is enough to treat real-valued f, since the real and imaginary parts can be handled separately. Set $g = f - \sum_x \pi(x) f(x)$. Since $P^n(x,y) \to \pi(y)$, the stationary covariance

$$C_g(n) = \sum_{x,y} \pi(x) g(x) P^n(x,y) g(y)$$

tends to zero. Hence

$$\mathbb{E}_\pi \left| \frac{1}{N} \sum_{n=0}^{N-1} g(X_n) \right|^2 = \frac{1}{N^2} \sum_{r,s=0}^{N-1} C_g(|r-s|) \longrightarrow 0, \tag{141.7}$$

because a Cesaro average of a sequence tending to zero tends to zero. This gives L^2 convergence in stationarity. For a nonstationary initial state, discard a fixed burn-in time M; by (141.3) the law of X_M can be made arbitrarily close to π, while the first M terms have vanishing weight as $N \to \infty$. The convergence in probability follows. $\square$

141.4 Metropolis Updates as a Finite-Regulator Theorem

The simplest exact check of the preceding definitions is a finite spin system. Let $\Lambda_L = (\mathbb{Z}/L\mathbb{Z})^2$ be the periodic square lattice and let a configuration be a map

$$s : \Lambda_L \to \{-1, +1\}.$$

For real J, h, define

$$H_L(s) = -J \sum_{\langle xy \rangle} s_x s_y - h \sum_x s_x, \qquad \pi_\beta(s) = Z_{\beta,L}^{-1} e^{-\beta H_L(s)}.$$

Here $\langle xy \rangle$ denotes an unoriented nearest-neighbor bond and $Z_{\beta,L}$ is the finite sum over all 2^{L^2} configurations.

The single-spin Metropolis chain chooses a site x uniformly, proposes

$$s \longmapsto s^x, \qquad s^x_y = \begin{cases} -s_x, & y = x, \\ s_y, & y \neq x, \end{cases}$$

and accepts the proposal with probability

$$a(s,x) = \min\{1, e^{-\beta(H_L(s^x) - H_L(s))}\}.$$

The energy difference is local:

$$H_L(s^x) - H_L(s) = 2s_x \left(J \sum_{y:\langle xy\rangle} s_y + h \right).$$

Detailed balance for the finite Ising Metropolis chain. The transition kernel P defined by the preceding update satisfies

$$\pi_\beta(s)P(s,s') = \pi_\beta(s')P(s',s)$$

for all configurations s, s'. If $0 < \beta < \infty$, the chain is irreducible. If additionally $(J,h) \neq (0,0)$, it is aperiodic on the finite set $\{-1,+1\}^{\Lambda_L}$. For the degenerate infinite-temperature Hamiltonian $J = h = 0$, adding a nonzero holding probability gives the usual lazy aperiodic variant without changing the stationary measure.

If s' is not equal to s or to a one-spin flip of s, both sides of the detailed-balance identity vanish. For $s' = s^x$, write $\Delta H = H_L(s^x) - H_L(s)$. The off-diagonal transition probabilities are

$$P(s,s^x) = \frac{1}{L^2} \min\{1, e^{-\beta\Delta H}\}, \qquad P(s^x,s) = \frac{1}{L^2} \min\{1, e^{\beta\Delta H}\}.$$

If $\Delta H \geq 0$, then

$$e^{-\beta H_L(s)} P(s,s^x) = \frac{1}{L^2} e^{-\beta H_L(s)} e^{-\beta\Delta H} = \frac{1}{L^2} e^{-\beta H_L(s^x)} = e^{-\beta H_L(s^x)} P(s^x,s).$$

The case $\Delta H < 0$ is the same identity with s and s^x interchanged. Dividing by the finite partition function gives detailed balance.

Irreducibility follows because any configuration can be reached from any other by flipping the finite set of sites on which they differ, and every single spin flip has positive proposal probability and positive acceptance probability. If $(J,h) \neq (0,0)$, there is a configuration s and a site x with $H_L(s^x) > H_L(s)$, so the chain has a positive holding probability at s. In a finite irreducible Markov chain, one state with a self-loop forces every state to have period one. When $J = h = 0$, every proposal is accepted and the one-spin-flip walk on the hypercube is bipartite; the standard lazy modification inserts a holding probability and restores aperiodicity.

The companion script

`qft_scripts/ising2d_metropolis.py`

implements exactly this finite chain and reports the acceptance rate, energy per site, absolute magnetization, and a windowed estimate of τ_{int}. Its smoke mode is a finite-regulator check of the algorithmic identities above. It does not estimate critical exponents, prove the Onsager scaling limit, or construct the continuum Ising CFT. The deterministic calculation check

`calculation-checks/ising_metropolis_finite_checks.py`

enumerates the 2×2 periodic chain and verifies both the local energy difference and the detailed-balance identity used by the script.

141.5 Scalar ϕ^4 Metropolis Warmup

The Ising example has a finite state space. A scalar lattice field already has the other feature that appears in continuum constructions: the finite-regulator measure is a genuine finite-dimensional integral rather than a finite sum. Let

$$\Lambda_L = (\mathbb{Z}/L\mathbb{Z})^2, \qquad \phi = (\phi_x)_{x \in \Lambda_L} \in \mathbb{R}^{\Lambda_L}.$$

For $m^2 \in \mathbb{R}$ and $\lambda > 0$, define the finite Euclidean action

$$S_L(\phi) = \sum_{x \in \Lambda_L} \left[\frac{1}{2} \sum_{\mu=1}^{2} (\phi_{x+\hat{\mu}} - \phi_x)^2 + \frac{1}{2} m^2 \phi_x^2 + \frac{\lambda}{24} \phi_x^4 \right], \tag{141.8}$$

where the directions $\hat{\mu}$ are the two positive coordinate directions on the periodic lattice. The target probability measure is

$$\pi_L(d\phi) = Z_L^{-1} e^{-S_L(\phi)} \prod_{x \in \Lambda_L} d\phi_x.$$

This is a finite-dimensional probability measure. Indeed, the kinetic term is nonnegative and the one-site potential

$$V(u) = \frac{1}{2} m^2 u^2 + \frac{\lambda}{24} u^4$$

is bounded below. More explicitly, if $m^2 < 0$, then

$$V(u) \geq -\frac{3(m^2)^2}{2\lambda},$$

with equality at $u^2 = -6m^2/\lambda$; if $m^2 \geq 0$, then $V(u) \geq 0$. The quartic term gives integrability at infinity in every coordinate.

The single-site Metropolis proposal chooses $x \in \Lambda_L$ uniformly and sets

$$\phi'_x = \phi_x + \eta, \qquad \phi'_y = \phi_y \quad (y \neq x),$$

where η is drawn from a symmetric compactly supported density $r(\eta)d\eta$, for instance the uniform density on $[-\delta, \delta]$. The proposal is accepted with probability

$$a(\phi, \eta, x) = \min\{1, e^{-[S_L(\phi') - S_L(\phi)]}\}.$$

The action difference is local. If $u = \phi_x$ and $u' = \phi'_x$, then

$$S_L(\phi') - S_L(\phi) = V(u') - V(u) + \frac{1}{2} \sum_{b:\, b \text{ touches } x} \left[(\phi'_{b_+} - \phi'_{b_-})^2 - (\phi_{b_+} - \phi_{b_-})^2 \right]. \tag{141.9}$$

Here the sum is over the four oriented positive-direction kinetic bonds in (141.8) whose endpoint is x. On lattices so small that periodicity identifies some neighbors, the multiplicities are inherited from the action itself.

Detailed balance for the finite scalar Metropolis chain. The preceding single-site kernel satisfies

$$\pi_L(d\phi)\, P(\phi, d\psi) = \pi_L(d\psi)\, P(\psi, d\phi)$$

as measures on $\mathbb{R}^{\Lambda_L} \times \mathbb{R}^{\Lambda_L}$. It is enough to check the off-diagonal pair $\psi = \phi'$ related by one proposed single-site displacement. The proposal density from ϕ to ψ is $|\Lambda_L|^{-1} r(\psi_x - \phi_x)$, while the reverse proposal density is $|\Lambda_L|^{-1} r(\phi_x - \psi_x)$. These are equal by symmetry of r. Writing $\Delta S = S_L(\psi) - S_L(\phi)$, the Metropolis identity

$$e^{-S_L(\phi)} \min\{1, e^{-\Delta S}\} = e^{-S_L(\psi)} \min\{1, e^{\Delta S}\}$$

proves pairwise balance. The holding part is then fixed by total probability. This statement is entirely finite-regulator: it neither proves a continuum ϕ^4_2 construction nor determines the critical surface.

The companion script

`qft_scripts/phi4_2d_metropolis.py`

implements the finite action (141.8) with a symmetric uniform single-site proposal. It reports acceptance, action density, $\langle \phi^2 \rangle$, $\langle \phi^4 \rangle$, a susceptibility-like zero-momentum second moment, and a windowed estimate of τ_{int} for ϕ^2. The paired calculation check

`calculation-checks/phi4_lattice_metropolis_checks.py`

verifies the local action difference against the total action, checks the pairwise detailed-balance identity, and checks the pointwise quartic stability bound used above.

141.6 Single-Link Metropolis for Finite Gauge Fields

The same finite-regulator theorem should be stated for gauge variables, because lattice gauge Monte Carlo samples compact group data rather than coordinate fields. For the finite $\mathbb{Z}_2$ gauge model whose exact surface expansion is (140.2), write

$$Q(U) = \sum_p U_p, \qquad \pi_\beta(U) = Z_\Lambda(\beta)^{-1} e^{\beta Q(U)}.$$

For a link e, let U^e be the configuration obtained by flipping U_e. The only plaquettes whose values change are the plaquettes containing e. If

$$B_e(U) = \sum_{p \supset e} U_p,$$

then

$$Q(U^e) - Q(U) = -2B_e(U).$$

The single-link Metropolis chain chooses a link uniformly and accepts $U \mapsto U^e$ with probability

$$a(U, e) = \min\{1, \exp(\beta[Q(U^e) - Q(U)])\}.$$

Detailed balance for the finite $\mathbb{Z}_2$ gauge chain. The preceding single-link update satisfies

$$\pi_\beta(U)P(U,U') = \pi_\beta(U')P(U',U)$$

for all finite lattice gauge configurations U, U'. On a connected finite lattice, the chain is irreducible on the full link-configuration space. Gauge-invariant observables may be averaged either on this full space or after quotienting by gauge transformations; the full-space chain preserves the gauge-invariant expectation values because π_β is gauge invariant.

If U' differs from U by more than one link, the off-diagonal transition probabilities in both directions vanish. If $U' = U^e$, set $\Delta Q = Q(U^e) - Q(U)$. The off-diagonal transition probabilities are

$$P(U,U^e) = \frac{1}{|E|}\min\{1, e^{\beta\Delta Q}\}, \qquad P(U^e,U) = \frac{1}{|E|}\min\{1, e^{-\beta\Delta Q}\}.$$

For $\Delta Q \geq 0$,

$$e^{\beta Q(U)}P(U,U^e) = \frac{1}{|E|}e^{\beta Q(U)} = \frac{1}{|E|}e^{\beta Q(U^e)}e^{-\beta\Delta Q} = e^{\beta Q(U^e)}P(U^e,U).$$

The case $\Delta Q < 0$ is the same identity with U and U^e interchanged. Division by $Z_\Lambda(\beta)$ gives detailed balance.

Irreducibility is immediate on the finite link hypercube: any configuration can be reached from any other by flipping the finite set of links on which they differ, and each proposed flip has positive acceptance probability for finite β. Gauge invariance follows because each U_p and each closed Wilson loop is unchanged under $U_{xy} \mapsto g_x U_{xy} g_y$. Therefore averaging over the full link space includes gauge orbits with equal weights and gives the same gauge-invariant expectations as any exact gauge-orbit average with the corresponding orbit weights.

The companion script

```
qft_scripts/z2_gauge_3d_metropolis.py
```

implements this update for a periodic three-dimensional cubic lattice. The associated deterministic check

```
calculation-checks/z2_gauge_metropolis_checks.py
```

verifies the local score change, pairwise detailed balance, gauge invariance of the plaquette action and Wilson loops, and the equality between the 1×1 Wilson-loop average and the plaquette average.

141.7 Compact $SU(2)$ Link Variables

The finite $\mathbb{Z}_2$ model is useful because it is exactly enumerable on small lattices, but nonabelian gauge Monte Carlo must also confront the continuous compact group structure. On a finite periodic 4-dimensional hypercubic lattice, assign to each oriented link $e = (x,\mu)$ a group element

$$U_{x,\mu} \in SU(2), \qquad U_{x+\hat{\mu},-\mu} = U_{x,\mu}^{-1}.$$

The product Haar measure is finite and normalized. For an oriented plaquette

$$U_{x;\mu\nu} = U_{x,\mu}U_{x+\hat{\mu},\nu}U_{x+\hat{\nu},\mu}^{-1}U_{x,\nu}^{-1},$$

define the finite Wilson score

$$Q(U) = \sum_x \sum_{\mu<\nu} \frac{1}{2} \operatorname{Re}\operatorname{tr} U_{x;\mu\nu}. \tag{141.10}$$

The probability measure used by the companion script is

$$d\nu_{\beta,\Lambda}(U) = Z_{\beta,\Lambda}^{-1} \exp[\beta Q(U)] \prod_{(x,\mu)} dU_{x,\mu}, \tag{141.11}$$

where dU is normalized Haar measure on $SU(2)$. This is the finite probability problem corresponding to the Wilson action convention; continuum Yang–Mills normalization and the $a \to 0$ scaling trajectory are separate questions.

A local compact-group Metropolis proposal chooses a link $e = (x, \mu)$ and an element $R \in SU(2)$, and replaces

$$U_{x,\mu} \longmapsto R\, U_{x,\mu}.$$

Let $\kappa(dR)$ be the proposal law. The crucial algebraic hypothesis is inversion symmetry,

$$\kappa(dR) = \kappa(dR^{-1}). \tag{141.12}$$

For example, representing $SU(2)$ by unit quaternions

$$R = \cos\alpha\, 1 + \mathrm{i} \sin\alpha\, \hat{n}\cdot\sigma, \qquad \hat{n} \in S^2,$$

with an even distribution of α and a rotation-invariant distribution of $\hat{n}$, satisfies (141.12).

Lemma 141.3 (Pairwise detailed balance for compact $SU(2)$ link Metropolis)**.** *For the finite measure* (141.11)*, suppose the link proposal chooses e uniformly and R with a law $\kappa(dR) = \kappa(dR^{-1})$. Accept the proposed configuration U' with probability*

$$a(U \to U') = \min\{1, \exp[\beta(Q(U') - Q(U))]\}. \tag{141.13}$$

Then the resulting transition kernel satisfies detailed balance with respect to $d\nu_{\beta,\Lambda}$. If the support of κ generates $SU(2)$ as a closed subgroup, the chain is irreducible with respect to the product Haar measure on the compact link space; rejection probabilities give the usual holding component.

Proof. The left multiplication $U_e \mapsto RU_e$ preserves Haar measure on the updated link. Its inverse move is $U_e' \mapsto R^{-1}U_e' = U_e$. Because the link is chosen with the same probability in both directions and $\kappa(dR) = \kappa(dR^{-1})$, the proposal density for the forward move and the proposal density for the reverse move agree. It remains only to check the Metropolis factor. Set $\Delta Q = Q(U') - Q(U)$. If $\Delta Q \geq 0$, then

$$e^{\beta Q(U)} a(U \to U') = e^{\beta Q(U)} = e^{\beta Q(U')} e^{-\beta \Delta Q} = e^{\beta Q(U')} a(U' \to U).$$

The case $\Delta Q < 0$ is the same identity with U and U' exchanged. Multiplying by the common proposal density and normalizing by $Z_{\beta,\Lambda}$ gives detailed balance. If the support of κ generates $SU(2)$, finite products of allowed local left multiplications can approximate any assignment of link variables by compactness and the group generation hypothesis. This gives irreducibility relative to product Haar measure. The holding component is present whenever a proposal is rejected; one may also insert an explicit lazy step without changing the invariant measure. $\square$

Gauge transformations are maps $g_x \in SU(2)$ at sites, acting by

$$U_{x,\mu} \longmapsto g_x U_{x,\mu} g_{x+\hat{\mu}}^{-1}.$$

They leave (141.10) invariant because plaquettes transform by conjugation:

$$U_{x;\mu\nu} \longmapsto g_x U_{x;\mu\nu} g_x^{-1}.$$

The rectangular Wilson-loop observable in the (μ,ν)-plane is

$$W_{R,T}(x;\mu,\nu) = \frac{1}{2} \operatorname{Re}\operatorname{tr}\left[\prod_{\ell \in \partial\mathcal{R}_{R,T}(x;\mu,\nu)} U_\ell\right], \tag{141.14}$$

with inverse links used when the path orientation is opposite to the positive lattice orientation. The companion script averages (141.14) over translations and coordinate planes.

The script

```
qft_scripts/su2_gauge_4d_metropolis.py
```

implements the preceding finite Markov chain using the unit-quaternion model of $SU(2)$. The deterministic check

```
calculation-checks/su2_gauge_metropolis_checks.py
```

verifies quaternion group operations, the local plaquette-score change, pairwise detailed balance, gauge invariance of $Q(U)$, gauge invariance of Wilson loops, and the equality between the 1×1 Wilson-loop average and the average plaquette. This script is a compact nonabelian finite-regulator Metropolis demonstration. Heat-bath, overrelaxation, and continuum extrapolation require additional regulator data and are not proved by this example.

141.8 Heat-Bath and Overrelaxation Updates

Heat-bath and overrelaxation updates are most cleanly defined as statements about conditional probability measures at fixed regulator. Let

$$\Omega = X \times Y, \qquad d\nu(x,y) = d\nu(x \mid y)\, d\nu_Y(y) \tag{141.15}$$

be a probability space with regular conditional probability $d\nu(x \mid y)$. A heat-bath update of the X-coordinate leaves y fixed and samples x' from $d\nu(x' \mid y)$:

$$K_{\mathrm{HB}}\big((x,y), dx'dy'\big) = d\nu(x' \mid y)\, \delta_y(dy'). \tag{141.16}$$

The kernel (141.16) satisfies detailed balance with respect to $d\nu$. Therefore it preserves $d\nu$. A random scan of finitely many such coordinate heat-bath kernels, with scan probabilities independent of the present configuration, also preserves $d\nu$. The measure on pairs of configurations generated by one heat-bath move is

$$d\nu_Y(y)\, d\nu(x \mid y)\, d\nu(x' \mid y)\, \delta_y(dy'). \tag{141.17}$$

This expression is symmetric under $x \leftrightarrow x'$. That is exactly the detailed-balance identity. A convex linear combination of invariant kernels is invariant, so a random scan preserves $d\nu$.

For the finite $SU(2)$ Wilson measure (141.11), fix every link except one link U_e. The part of the score depending on U_e can be written

$$Q(U) = \frac{1}{2}\operatorname{Re}\operatorname{tr}(U_e V_e) + Q_{\widehat{e}}(U_{\widehat{e}}), \tag{141.18}$$

where $U_{\widehat{e}}$ denotes all links other than U_e, and V_e is the sum of oriented staples multiplying U_e in the plaquettes that contain e. In the fundamental representation of $SU(2)$, the set of matrices

$$a_0\,1 + \mathrm{i}\sum_{j=1}^{3} a_j\sigma_j, \qquad a_j \in \mathbb{R},$$

is closed under addition and multiplication. Hence, if $V_e \neq 0$, there are unique $c_e > 0$ and $W_e \in SU(2)$ such that

$$V_e = c_e W_e. \tag{141.19}$$

If $V_e = 0$, the conditional distribution of U_e is Haar measure.

For $V_e \neq 0$, left or right Haar invariance reduces the conditional density to the one-parameter form

$$d\nu(U_e \mid U_{\widehat{e}}) = Z_e^{-1}\exp\left[\beta c_e \frac{1}{2}\operatorname{Re}\operatorname{tr}(U_e W_e)\right] dU_e. \tag{141.20}$$

Writing

$$X = U_e W_e = x_0\,1 + \mathrm{i}\,\vec{x}\cdot\vec{\sigma}, \qquad x_0^2 + \|\vec{x}\|^2 = 1,$$

the Haar measure on $SU(2) \simeq S^3$ gives the marginal density

$$p_{\beta c_e}(x_0)\,dx_0 = \mathcal{N}_{\beta c_e}^{-1}\sqrt{1-x_0^2}\,e^{\beta c_e x_0}\,dx_0, \qquad -1 \le x_0 \le 1, \tag{141.21}$$

and, conditional on x_0, the direction $\vec{x}/\sqrt{1-x_0^2}$ is uniformly distributed on S^2. An exact $SU(2)$ heat-bath update is precisely an exact sampler of (141.21) and this uniform direction, followed by

$$U_e' = X W_e^{-1}. \tag{141.22}$$

Different practical heat-bath algorithms are different exact or approximate ways of sampling (141.21); the invariant-measure statement is the conditional-sampling theorem above.

Overrelaxation is deterministic rather than heat-bath sampling. At fixed staple W_e, define

$$\mathcal{O}_{W_e}(U_e) = W_e^{-1}U_e^{-1}W_e^{-1}. \tag{141.23}$$

Then

$$\mathcal{O}_{W_e}(\mathcal{O}_{W_e}(U_e)) = U_e, \qquad \frac{1}{2}\operatorname{Re}\operatorname{tr}\big(\mathcal{O}_{W_e}(U_e)W_e\big) = \frac{1}{2}\operatorname{Re}\operatorname{tr}(U_e W_e). \tag{141.24}$$

The first identity says that the map is an involution. The second follows because $\mathcal{O}_{W_e}(U_e)W_e = (U_e W_e)^{-1}$, and an $SU(2)$ matrix has the same real trace as its inverse. The map preserves Haar measure because it is a composition of inversion and left/right multiplication by fixed group elements.

Finite $SU(2)$ heat-bath and overrelaxation invariance. At fixed finite lattice and finite β, an exact single-link heat-bath update with conditional density (141.20) satisfies detailed balance for (141.11). The single-link overrelaxation map (141.23) preserves (141.11). If used as a deterministic involutive kernel, it is reversible with respect to the conditional measure at fixed staple. Any finite composition or random mixture of these updates with Metropolis updates preserves the finite Wilson measure. Indeed, the heat-bath statement is the detailed-balance argument for (141.16) applied with $X = SU(2)$ equal to the selected link and Y equal to all other links. The local conditional density is (141.20) because every plaquette containing e is linear in U_e, and all other plaquettes are absorbed into $Q_{\widehat{e}}$.

For overrelaxation, fix $U_{\widehat{e}}$. Equation (141.24) says that the local Boltzmann factor is unchanged, and Haar preservation says that the conditional Haar measure is unchanged. Thus the conditional probability measure is preserved. Because the map is an involution, the measure on pairs $(U_e, \mathcal{O}_{W_e}(U_e))$ is symmetric, which is detailed balance for the deterministic conditional kernel. Integrating over $U_{\widehat{e}}$ gives preservation of the full finite Wilson measure. Compositions and random mixtures of invariant kernels remain invariant.

Overrelaxation alone is not an ergodic sampling algorithm: it preserves the local score and is deterministic at fixed staple. Its role in practice is to move along approximately constant-action directions between stochastic updates. The mathematical invariant-measure statement above is therefore only one ingredient in a numerical method; it does not by itself establish mixing, error bars, or continuum scaling.

The companion script

```
qft_scripts/su2_gauge_4d_heatbath_overrelaxation.py
```

implements the finite $SU(2)$ Wilson model with exact single-link heat-bath conditionals for (141.21), interleaved with a user-chosen number of deterministic overrelaxation sweeps. It reports finite-cutoff plaquette and Wilson-loop estimates in JSON format. Its smoke mode checks only the finite algorithmic range of the measured observables; statistical autocorrelation analysis, thermodynamic limits, and continuum extrapolation require additional runs and estimates.

The deterministic check

```
calculation-checks/heatbath_overrelaxation_checks.py
```

verifies the finite conditional heat-bath balance identity, the quaternionic $SU(2)$ staple reduction $V = cW$, the overrelaxation involution, local score preservation, orthogonality of the overrelaxation map on S^3, and the local-staple identities used by the companion script.

141.9 $SU(3)$ Link Updates and Subgroup Kernels

Four-dimensional QCD uses $SU(3)$ rather than $SU(2)$. The finite Wilson measure is still an ordinary compact group integral, but the special quaternionic simplification used in (141.19) no longer holds. Let $U_e \in SU(3)$ be a selected link in a finite pure-gauge Wilson lattice system and write the local part of the plaquette score as

$$Q_e(U_e; U_{\widehat{e}}) = \frac{1}{3}\,\mathrm{Re}\,\mathrm{Tr}_3(U_e V_e) + Q_{\widehat{e}}(U_{\widehat{e}}). \tag{141.25}$$

Here V_e is the sum of oriented staples. It is a complex 3×3 matrix determined by the other links and is not, in general, a positive scalar times an element of $SU(3)$. Consequently an exact $SU(3)$ one-link heat-bath does not reduce to the elementary scalar-density (141.21).

The standard finite-regulator substitute is to use $SU(2)$ subgroups of $SU(3)$. For $1 \leq i < j \leq 3$, let $H_{ij} \subset SU(3)$ be the subgroup which acts as $SU(2)$ on the span of the i-th and j-th color basis vectors and acts trivially on the orthogonal color line. Its Lie algebra is spanned by

$$X_{ij} = E_{ij} - E_{ji}, \qquad Y_{ij} = \mathrm{i}(E_{ij} + E_{ji}), \qquad H_{ij} = \mathrm{i}(E_{ii} - E_{jj}),$$

where E_{ij} is the matrix unit. These are anti-Hermitian traceless matrices.

The connected subgroup of $SU(3)$ generated by

$$H_{12}, \qquad H_{13}, \qquad H_{23}$$

is all of $SU(3)$. The six off-diagonal matrices X_{ij}, Y_{ij} for $(ij) = (12), (13), (23)$ are linearly independent. The two diagonal matrices H_{12} and H_{23} are linearly independent and span the diagonal anti-Hermitian traceless subalgebra. Together these eight matrices form a basis of $\mathfrak{su}(3)$. Therefore the Lie algebra generated by the three embedded $\mathfrak{su}(2)$ subalgebras is $\mathfrak{su}(3)$. The subgroup generated by connected subgroups is connected, and the connected Lie subgroup with Lie algebra $\mathfrak{su}(3)$ is $SU(3)$ itself.

Fix a link e and one of the subgroups H_α, where $\alpha \in \{12, 13, 23\}$. A left subgroup update replaces

$$U_e \longmapsto hU_e, \qquad h \in H_\alpha,$$

and leaves all other links fixed. At fixed $U_{\widehat{e}}$, the induced conditional density on H_α is

$$d\nu_{\alpha,e}(h \mid U) = Z_{\alpha,e}(U)^{-1} \exp\left[\frac{\beta}{3} \operatorname{Re} \operatorname{Tr}_3(hU_eV_e)\right] dh, \tag{141.26}$$

where dh is normalized Haar measure on the embedded $SU(2)$.

Finite $SU(3)$ subgroup-update invariance. At fixed finite lattice and finite β, an exact heat-bath draw from (141.26) satisfies detailed balance for the finite $SU(3)$ Wilson measure restricted to the selected subgroup orbit. The same is true for any Metropolis kernel on H_α whose proposal measure is invariant under inversion $h \mapsto h^{-1}$ and whose acceptance probability is computed from the local score (141.25). A random scan over finitely many links and over the three subgroups preserves the finite Wilson measure.

The heat-bath statement is exactly the detailed-balance argument for (141.16) applied to the coordinate $h \in H_\alpha$ on the subgroup orbit hU_e. The conditional density is (141.26) because all plaquettes not containing e are absorbed into $Q_{\widehat{e}}$, while the plaquettes containing e contribute the linear staple term $\frac{1}{3} \operatorname{Re} \operatorname{Tr}_3(hU_eV_e)$.

For the Metropolis statement, let $r(dh)$ be the proposal law on H_α with $r(A) = r(A^{-1})$. From a present subgroup coordinate h_0, propose $h'h_0$ with $h' \sim r$, and accept with

$$a(h_0, h'h_0) = \min\{1, \exp[\beta(Q_e(h'h_0U_e) - Q_e(h_0U_e))]\}.$$

The off-diagonal pairwise detailed-balance identity is the same two-case identity as in the finite Ising Metropolis calculation above, with the symmetric proposal measure supplied by inversion invariance of r and Haar measure. Rejected proposals provide the diagonal holding term. Finally, finite compositions and random convex combinations of invariant kernels preserve the measure.

Controlled Approximation 141.4 (Status of subgroup algorithms)**.** The subgroup update calculation above proves exact finite-cutoff invariance of the Wilson measure for the specified heat-bath or Metropolis kernels. The algorithmic performance questions require additional data: proposal support, scan schedule, boundary conditions, autocorrelation estimates, possible topological-sector barriers, and a continuum-extrapolation analysis. The subgroup Lie-algebra calculation supplies the local group-theoretic reach; the ergodicity and mixing assertions for a concrete Markov chain are separate finite-state or compact-state Markov-chain problems.

The calculation check

`calculation-checks/su3_lattice_update_checks.py`

verifies the embedded $SU(2)$ determinants and unitarity, the $\mathfrak{su}(3)$ span, the subgroup commutator normalizations, gauge covariance of the local staple score, and the finite Metropolis detailed-balance identity used in the preceding proposition.

The companion data-generator

`qft_scripts/`
`su3_gauge_4d_metropolis_hdf5.py`

implements the finite subgroup-update Metropolis kernel described above for the periodic four-dimensional pure $SU(3)$ Wilson lattice model. Its normalized plaquette score is

$$Q(U) = \sum_p \frac{1}{3} \operatorname{Re} \operatorname{Tr}_3 U_p, \qquad d\nu_\beta(U) = Z_{\beta,\Lambda}^{-1} e^{\beta Q(U)} \prod_\ell dU_\ell. \tag{141.27}$$

The script writes, when the optional package `h5py` is available, an HDF5 file containing the run parameters, per-sweep plaquette and rectangular Wilson-loop measurements, the final link field, and the state of the pseudorandom generator. This is a checkpoint at the level of the finite Markov chain: resuming from it continues a regulator computation, not a continuum construction. The script can also export the Wilson-loop measurements as a table with columns

`sample`, $\quad R, \quad T, \quad W,$

which is the sample-level input expected by

`qft_scripts/`
`static_potential_from_wilson_loops.py`.

The deterministic check

`calculation-checks/`
`su3_hdf5_sampler_checks.py`

verifies the embedded-subgroup proposals, the local score change against a direct total-score difference, gauge invariance of the score and Wilson loop, the 1×1 Wilson-loop/plaquette identity, and the HDF5 measurement/checkpoint layout.

The cluster wrapper

`qft_scripts/cluster/slurm/`
`su3_small_pipeline.sbatch`

runs a small finite-regulator vertical slice: the $SU(3)$ sampler above, the Wilson-flow post-processing script of Chapter 140, and the static-potential analysis script of Chapter 140. The surrounding `qft_scripts/cluster` shell templates record the SSH-control, source-sync, result-pull, and SLURM-submission protocol. These files are execution wrappers only. They do not change the finite Markov chain, do not prove mixing, and do not turn the small $L = 2$ smoke job into a continuum calculation.

The array wrapper

`qft_scripts/cluster/slurm/`

`su3_parameter_sweep_array.sbatch`

adds only deterministic parameter bookkeeping. Its helper

`qft_scripts/cluster/su3_sweep_grid.py`

maps a SLURM array index to a finite Cartesian-product coordinate (β, `seed`), writes that coordinate into the task manifest, and then runs the same finite-regulator sampler, Wilson-flow, and static-potential pipeline in a task-local directory. The calculation check

`calculation-checks/cluster_sweep_grid_checks.py`

verifies the Cartesian ordering, out-of-range rejection, and shell-assignment output. The array index is not a physical or statistical index: it is a reproducibility coordinate for a family of finite Markov chains. Mixing, thermalization, and continuum scaling remain separate mathematical and statistical claims.

141.10 Hybrid Monte Carlo and Pseudofermions

Hybrid Monte Carlo is a finite-regulator construction before it is a continuum algorithm. The construction begins with a finite-dimensional configuration manifold Q_Λ, a positive reference measure dq, and a target probability density

$$d\nu(q) = Z^{-1} e^{-S(q)}\, dq, \qquad Z = \int_{Q_\Lambda} e^{-S(q)}\, dq < \infty. \tag{141.28}$$

For a scalar finite lattice, Q_Λ is typically $\mathbb{R}^n$ or a torus. For a compact gauge lattice, Q_Λ is a finite product of compact Lie groups and dq is product Haar measure. The following theorem is stated on an abstract finite-dimensional phase space because this is the part of HMC that is independent of the chosen regulator.

Let $(\Gamma_\Lambda, d\lambda)$ be a finite-dimensional phase space with a positive reference measure, let $H : \Gamma_\Lambda \to \mathbb{R}$ be a measurable Hamiltonian for which

$$d\mu_H(z) = Z_H^{-1} e^{-H(z)}\, d\lambda(z) \tag{141.29}$$

is a probability measure, and let $R : \Gamma_\Lambda \to \Gamma_\Lambda$ be an involution preserving $d\lambda$. In the usual cotangent-bundle example

$$\Gamma_\Lambda = T^* Q_\Lambda, \qquad z = (q, p), \qquad R(q, p) = (q, -p).$$

For $Q_\Lambda = \mathbb{R}^n$ with a positive mass matrix M,

$$H(q,p) = S(q) + \frac{1}{2}p^T M^{-1} p, \qquad d\lambda = dq\,dp. \tag{141.30}$$

The q-marginal of $d\mu_H$ is then (141.28) after normalizing the Gaussian momentum integral.

Definition 141.5 (Reversible volume-preserving trajectory)**.** A numerical trajectory map $\Phi : \Gamma_\Lambda \to \Gamma_\Lambda$ is called reversible and volume preserving, with respect to R, if

$$\Phi_*(d\lambda) = d\lambda, \qquad R\Phi R = \Phi^{-1}. \tag{141.31}$$

The corresponding Metropolis proposal is

$$G = R\Phi. \tag{141.32}$$

The explicit momentum flip in G is not a convention with physical content; it is the algebraic device that makes the proposal an involution. Indeed (141.31) gives

$$G^2 = R\Phi R\Phi = \Phi^{-1}\Phi = 1.$$

HMC Metropolis correction at finite regulator. Assume that Φ is reversible and volume preserving in the sense of Definition 141.5. Let

$$a(z) = \min\{1, \exp[-H(Gz) + H(z)]\} \tag{141.33}$$

and define the Markov kernel

$$K(z,B) = a(z)\mathbf{1}_B(Gz) + (1 - a(z))\mathbf{1}_B(z) \tag{141.34}$$

for measurable $B \subset \Gamma_\Lambda$. Then K satisfies detailed balance with respect to $d\mu_H$. Consequently $d\mu_H$ is invariant.

Since G is an involution and preserves $d\lambda$, every nontrivial proposed move is paired with its reverse. It is enough to prove the pairwise identity

$$e^{-H(z)}a(z) = e^{-H(Gz)}a(Gz). \tag{141.35}$$

Write $\Delta H = H(Gz) - H(z)$. If $\Delta H \geq 0$, then

$$e^{-H(z)}a(z) = e^{-H(z)}e^{-\Delta H} = e^{-H(Gz)} = e^{-H(Gz)}a(Gz),$$

because the reverse move has energy change $-\Delta H \leq 0$ and is accepted with probability 1. The case $\Delta H < 0$ is the same calculation with z and Gz interchanged. Multiplying (141.35) by the common volume element on the paired points gives detailed balance for the moving part of the kernel. The holding part is diagonal and is therefore symmetric with respect to $d\mu_H$. This proves detailed balance for K.

The usual HMC transition first refreshes p from its Gaussian conditional distribution and then applies (141.34). Momentum refreshment preserves $d\mu_H$ because it leaves q fixed and replaces the momentum by an independent sample from the p-conditional density. The composition therefore preserves $d\mu_H$, and its q-marginal preserves $d\nu$. Ergodicity, mixing time, acceptance rate, and scaling toward a continuum limit are separate claims; they do not follow from detailed balance alone.

Leapfrog reversibility and volume preservation. Let $Q_\Lambda = \mathbb{R}^n$, let $S \in C^2(\mathbb{R}^n)$, and let M be a positive definite symmetric matrix. Define the kick and drift maps

$$K_a(q,p) = (q, p - a\nabla S(q)), \qquad D_\epsilon(q,p) = (q + \epsilon M^{-1}p, p), \tag{141.36}$$

and the one-step leapfrog map

$$L_\epsilon = K_{\epsilon/2} D_\epsilon K_{\epsilon/2}. \tag{141.37}$$

Then L_ϵ preserves $dq\,dp$ and satisfies

$$RL_\epsilon R = L_\epsilon^{-1}, \qquad R(q,p) = (q, -p). \tag{141.38}$$

Every finite power L_ϵ^N, $N \in \mathbb{Z}_{\geq 0}$, has the same two properties. These properties are the finite-dimensional algebra needed by the HMC Metropolis step. The Jacobian matrix of K_a is block triangular,

$$\begin{pmatrix} 1 & 0 \\ -a \operatorname{Hess} S(q) & 1 \end{pmatrix},$$

and therefore has determinant 1. The Jacobian matrix of D_ϵ is

$$\begin{pmatrix} 1 & \epsilon M^{-1} \\ 0 & 1 \end{pmatrix},$$

also of determinant 1. Hence L_ϵ preserves $dq\,dp$. Moreover

$$RK_aR = K_{-a} = K_a^{-1}, \qquad RD_\epsilon R = D_{-\epsilon} = D_\epsilon^{-1}.$$

Using the symmetric ordering in (141.37),

$$RL_\epsilon R = K_{-\epsilon/2} D_{-\epsilon} K_{-\epsilon/2} = L_\epsilon^{-1}.$$

A finite product of equal leapfrog steps is again reversible in the sense needed for HMC, because

$$RL_\epsilon^N R = (RL_\epsilon R)^N = L_\epsilon^{-N}.$$

For a compact gauge field, the same proof is expressed on the cotangent bundle of a compact Lie group product. The drift is group multiplication by the exponential of a Lie-algebra momentum, the kick changes the momentum by the derivative of the gauge action, and the reference measure is the Liouville measure built from Haar measure and Lebesgue measure on the Lie algebra. The finite-regulator statement remains exactly the same: volume preservation, reversibility, and the Metropolis correction imply invariance of the finite target measure. The construction of globally smooth forces, the treatment of constraints, and the proof of ergodicity depend on the chosen lattice action and are additional data.

Pseudofermions enter when the fermion determinant is real and positive after flavor pairing. Let A be a positive Hermitian $N \times N$ matrix and write

$$d^{2N}\phi = \prod_{j=1}^{N} d(\operatorname{Re}\phi_j)\, d(\operatorname{Im}\phi_j)$$

for Lebesgue measure on $\mathbb{C}^N$. The elementary identity is the following finite-dimensional Gaussian integral.

If $A > 0$ is Hermitian, then

$$\int_{\mathbb{C}^N} \exp[-\phi^\dagger A^{-1}\phi]\, d^{2N}\phi = \pi^N \det A. \tag{141.39}$$

Consequently a positive determinant factor $\det A$ in a finite Euclidean integral may be represented, up to the A-independent constant π^N, by the pseudofermion action $\phi^\dagger A^{-1}\phi$. Choose a unitary matrix U such that

$$A = U\ \mathrm{diag}(\lambda_1, \dots, \lambda_N)\, U^\dagger, \qquad \lambda_j > 0.$$

The real Jacobian of the unitary change of variables $\psi = U^\dagger\phi$ has absolute value 1. Hence the integral factorizes:

$$\prod_{j=1}^{N} \int_{\mathbb{C}} \exp[-|\psi_j|^2/\lambda_j]\, d(\mathrm{Re}\,\psi_j) d(\mathrm{Im}\,\psi_j) = \prod_{j=1}^{N} \pi\lambda_j = \pi^N \det A.$$

For a lattice Dirac operator $D(U)$, two degenerate flavors commonly give the positive factor

$$\det(D^\dagger D) = |\det D|^2, \qquad A(U) = D(U)^\dagger D(U) > 0$$

after zero modes have been excluded or regulated. Equation (141.39) then turns the determinant into a bosonic Gaussian integral with a nonlocal action involving $A(U)^{-1}$. The nonlocality is not a conceptual defect; it is a finite linear-algebra statement. It becomes an algorithmic problem because each force evaluation requires solving a linear system.

For N_f degenerate flavors one formally needs

$$\det A^\alpha, \qquad \alpha = N_f/2,$$

and the exact pseudofermion action would contain the matrix function $A^{-\alpha}$. Rational hybrid Monte Carlo replaces $x^{-\alpha}$ on a spectral interval $[\lambda_-, \lambda_+]$ containing the spectrum of $A(U)$ by a positive rational function $r_m(x)$. At finite regulator this replacement defines the exactly sampled determinant

$$\pi^{-N} \int_{\mathbb{C}^N} \exp[-\phi^\dagger r_m(A)\phi]\, d^{2N}\phi = \frac{1}{\det r_m(A)}. \tag{141.40}$$

It equals $\det A^\alpha$ only if $r_m(A) = A^{-\alpha}$ on the spectrum, or if an additional exact correction or reweighting factor is included. Thus RHMC is not a slogan for "fractional fermions"; it is an exact Markov-chain algorithm for a rationalized finite measure, together with a separate approximation or correction statement comparing that measure to the desired determinant.

The elementary spectral error estimate used in such a comparison is pointwise. If

$$\|r_m(A) - A^{-\alpha}\|_{\mathrm{op}} \le \delta, \tag{141.41}$$

then for every pseudofermion vector ϕ,

$$\left|\phi^\dagger\big(r_m(A) - A^{-\alpha}\big)\phi\right| \le \delta\, \|\phi\|^2. \tag{141.42}$$

This bound controls the error in the pseudofermion action for a fixed configuration and a fixed pseudofermion vector. Turning it into a uniform observable bound requires further hypotheses, for example a uniform spectral gap, a chosen rational approximation, and control of the pseudofermion tail or an exact reweighting step. These hypotheses are finite-regulator algorithmic data, not consequences of QFT axioms.

Solver, rationalization, and reversibility checks. A production HMC or RHMC run must record more than the target action and the measured observables. This is the implementation-defect layer of Section 141.1. At finite regulator the algorithmic check record contains the integrator step size ϵ, the number of leapfrog or Omelyan steps, the momentum-refresh law, the linear solver, the rational approximation interval $[\lambda_-, \lambda_+]$, the solver tolerance, and the finite diagnostics

$$\Delta H(z) = H(Gz) - H(z), \qquad \Delta_{\rm rev}(z) = d_\Gamma(z, R\Phi R\Phi z), \qquad \rho_{\rm lin} = \|b - Ax\|.$$

The exact detailed-balance argument above applies to the exact finite map actually used by the Markov chain. Therefore finite-precision code must make its reversibility and solver errors visible as part of the data record before the output is interpreted as evidence for the intended lattice measure.

The basic linear-solver bounds are finite spectral estimates. Let $A = A^\dagger > 0$ with $A \geq \lambda_- I$, let $y = A^{-1}\phi$, and let x be an approximate solve with residual

$$r = \phi - Ax.$$

Then

$$y - x = A^{-1}r, \qquad \|y - x\| \leq \lambda_-^{-1}\|r\|.$$

Consequently the pseudofermion-action coordinate $\phi^\dagger A^{-1}\phi$ obeys

$$\left|\phi^\dagger A^{-1}\phi - \phi^\dagger x\right| \leq \lambda_-^{-1}\|\phi\|\,\|r\|. \tag{141.43}$$

If $\dot{A}$ is the directional derivative of A along a configuration variation and $\|\dot{A}\|_{\rm op} \leq L$, the exact force term $-y^\dagger \dot{A}\, y$ and the force computed from x differ by

$$\left|y^\dagger \dot{A}\, y - x^\dagger \dot{A}\, x\right| \leq L\left(2\|x\|\lambda_-^{-1}\|r\| + \lambda_-^{-2}\|r\|^2\right). \tag{141.44}$$

This is the finite estimate that connects Krylov residual logs to Hamiltonian-force accuracy. A solver tolerance quoted without λ_-, force-norm, and reversibility diagnostics is only an implementation setting.

For RHMC the determinant comparison is also finite. Suppose

$$r_m(\lambda) = \lambda^{-\alpha} e^{\eta(\lambda)} \quad \text{for} \quad \lambda \in [\lambda_-, \lambda_+], \qquad |\eta(\lambda)| \leq \eta_*.$$

For a finite matrix A of size N with spectrum in this interval, the rationalized determinant sampled by (141.40) differs from the desired $\det A^\alpha$ by the reweighting factor

$$W_{\rm rat}(A) = \det(A)^\alpha \det r_m(A) = \exp\left(\sum_{j=1}^{N} \eta(\lambda_j)\right), \qquad |\log W_{\rm rat}(A)| \leq N\eta_*. \tag{141.45}$$

Thus an exact rationalized Markov chain, an exact reweighting chain, and an unreweighted approximation are three different finite probability measures. The simulation record must specify which one is being used.

A small public-facing implementation of these coordinates is

`qft_scripts/hmc_rhmc_finite_demo.py`.

It samples a finite periodic scalar lattice action by reversible leapfrog HMC and evaluates a positive rational pseudofermion action by shifted conjugate gradient solves. Its JSON output reports the acceptance coordinate, $\max|\Delta H|$, a reversibility defect, the positive-matrix spectral edge, the rational action, and the maximum solver residual. These are finite-regulator diagnostics; continuum and infinite-volume claims require the additional limit data described in Chapter 145.

The deterministic companion check

```
calculation-checks/hmc_pseudofermion_checks.py
```

verifies the leapfrog determinant and reversibility identities for a one-dimensional quadratic action, the pairwise Metropolis balance identity, the pseudofermion determinant identity after diagonalization, and the spectral action-error bound (141.42). It also checks (141.43)– (141.45) and imports the finite HMC/RHMC smoke module as a companion-script regression.

141.11 Autocorrelation and Effective Sample Size

For a stationary chain and a real observable O, define the connected autocorrelation function

$$C_O(t) = \langle O(\Phi_t)O(\Phi_0)\rangle - \langle O\rangle^2.$$

The integrated autocorrelation time is

$$\tau_{\text{int}}(O) = \frac{1}{2} + \sum_{t=1}^{\infty} \frac{C_O(t)}{C_O(0)}$$

when the sum converges. The variance of the sample mean is then

$$\mathrm{Var}(\overline{O}_N) = \frac{2\tau_{\text{int}}(O)}{N}\,\mathrm{Var}(O) + o(N^{-1}).$$

Critical slowing down is the growth of τ_{int} along a scaling trajectory toward a continuum limit.

Exact finite-N variance identity. Assume the chain is stationary and O is real with $C_O(0) > 0$. Then

$$\mathrm{Var}(\overline{O}_N) = \frac{1}{N^2}\left[NC_O(0) + 2\sum_{t=1}^{N-1}(N-t)C_O(t)\right]. \tag{141.46}$$

If

$$\sum_{t=1}^{\infty} |C_O(t)| < \infty, \tag{141.47}$$

then

$$\mathrm{Var}(\overline{O}_N) = \frac{2\tau_{\text{int}}(O)}{N}\,C_O(0) + o(N^{-1}). \tag{141.48}$$

Write $O_n = O(\Phi_n)$ and $\mu_O = \langle O\rangle$. Stationarity gives

$$\mathrm{Cov}(O_r, O_s) = C_O(|r-s|).$$

Therefore

$$\mathrm{Var}(\overline{O}_N) = \frac{1}{N^2} \sum_{r,s=0}^{N-1} \mathrm{Cov}(O_r, O_s).$$

There are N pairs with $r = s$. For each lag $t \geq 1$, there are $N - t$ ordered pairs with $s = r + t$ and $N - t$ ordered pairs with $r = s + t$. This proves (141.46). Dividing by $N^{-1}C_O(0)$ and using absolute summability to replace

$$\sum_{t=1}^{N-1} \left(1 - \frac{t}{N}\right) \frac{C_O(t)}{C_O(0)}$$

by its infinite sum gives (141.48).

141.12 Blocking, Jackknife, and Bootstrap Error Coordinates

Autocorrelation estimates enter numerical QFT through finite data-analysis coordinates. Let $O_0, \ldots, O_{N-1}$ be a real time series sampled after thermalization. Choose a block length b and write

$$B = \left\lfloor \frac{N}{b} \right\rfloor.$$

Discarding the final incomplete block for definiteness, define block means

$$Y_j = \frac{1}{b} \sum_{r=0}^{b-1} O_{jb+r}, \qquad j = 0, \ldots, B - 1, \tag{141.49}$$

and

$$\overline{Y} = \frac{1}{B} \sum_{j=0}^{B-1} Y_j.$$

If b is large compared with the integrated autocorrelation scale, the block means are closer to independent samples than the original time series. This sentence is a diagnostic hypothesis about the Markov chain and the chosen observable; it is checked by varying b, by monitoring slow modes, and by comparing independent chains.

Remark 141.6 (Delete-one-block jackknife for the mean). Assume $B \geq 2$. Let

$$s_Y^2 = \frac{1}{B-1} \sum_{j=0}^{B-1} (Y_j - \overline{Y})^2. \tag{141.50}$$

The blocked standard-error coordinate for $\overline{Y}$ is

$$\mathrm{se}_{\mathrm{block}}(\overline{Y}) = \sqrt{\frac{s_Y^2}{B}}. \tag{141.51}$$

Let $\overline{Y}_{(j)}$ be the mean of the $B - 1$ block means with the j-th block removed:

$$\overline{Y}_{(j)} = \frac{1}{B-1} \sum_{k \neq j} Y_k. \tag{141.52}$$

Then the delete-one-block jackknife variance for the mean,

$$\mathrm{Var}_{\mathrm{jack}}(\overline{Y}) = \frac{B-1}{B} \sum_{j=0}^{B-1} \left(\overline{Y}_{(j)} - \frac{1}{B} \sum_{k=0}^{B-1} \overline{Y}_{(k)} \right)^2, \tag{141.53}$$

equals s_Y^2/B. Since

$$\overline{Y}_{(j)} = \frac{B\overline{Y} - Y_j}{B-1},$$

the average of the delete-one estimates is

$$\frac{1}{B} \sum_{j=0}^{B-1} \overline{Y}_{(j)} = \overline{Y}.$$

Therefore

$$\overline{Y}_{(j)} - \overline{Y} = -\frac{Y_j - \overline{Y}}{B-1}.$$

Substitution in (141.53) gives

$$\mathrm{Var}_{\mathrm{jack}}(\overline{Y}) = \frac{B-1}{B} \frac{1}{(B-1)^2} \sum_{j=0}^{B-1} (Y_j - \overline{Y})^2 = \frac{s_Y^2}{B}.$$

The preceding remark is the scalar case of the error-coordinate needed for Wilson-loop ratios, flowed-energy couplings, and hadron effective masses. Let $Y_j \in \mathbb{R}^m$ be block means for m elementary observables, let

$$\overline{Y} = \frac{1}{B} \sum_{j=0}^{B-1} Y_j, \qquad d_j = Y_j - \overline{Y}, \qquad S_Y = \frac{1}{B-1} \sum_{j=0}^{B-1} d_j d_j^{\mathsf{T}}, \tag{141.54}$$

and let

$$\overline{Y}_{(j)} = \frac{B\overline{Y} - Y_j}{B-1}. \tag{141.55}$$

For a smooth scalar analysis function $F : U \to \mathbb{R}$, where $U \subset \mathbb{R}^m$ is open and contains the convex hull of the $\overline{Y}_{(j)}$, define

$$F_{(j)} = F(\overline{Y}_{(j)}), \qquad \widehat{F}_\bullet = \frac{1}{B} \sum_{j=0}^{B-1} F_{(j)},$$

and

$$\widehat{V}_{\mathrm{jack}}(F) = \frac{B-1}{B} \sum_{j=0}^{B-1} (F_{(j)} - \widehat{F}_\bullet)^2. \tag{141.56}$$

Correlated delete-one-block jackknife for smooth ratios. Assume $B \geq 2$. Let $g = DF_{\overline{Y}}$ be the differential of F at $\overline{Y}$, regarded as a row vector. Suppose that the operator norm of the Hessian satisfies

$$\|D^2 F_x\|_{\mathrm{op}} \leq M$$

on the convex hull of the delete-one means. Put

$$D_2 = \left(\sum_{j=0}^{B-1} \|d_j\|^2 \right)^{1/2}, \qquad D_4 = \left(\sum_{j=0}^{B-1} \|d_j\|^4 \right)^{1/2},$$

and

$$A = \frac{\|g\| D_2}{B-1}, \qquad E = \frac{M D_4}{(B-1)^2}.$$

Then

$$\left| \widehat{V}_{\text{jack}}(F) - \frac{1}{B}\, g S_Y g^{\mathsf{T}} \right| \le \frac{B-1}{B}(2AE + E^2). \tag{141.57}$$

Taylor's theorem gives

$$F(\overline{Y}_{(j)}) = F(\overline{Y}) + g(\overline{Y}_{(j)} - \overline{Y}) + R_j, \qquad |R_j| \le \frac{M}{2} \|\overline{Y}_{(j)} - \overline{Y}\|^2.$$

Since

$$\overline{Y}_{(j)} - \overline{Y} = -\frac{d_j}{B-1}$$

and $\sum_j d_j = 0$, the average of the linear terms is zero. Therefore the linear part of $\widehat{V}_{\text{jack}}(F)$ is

$$\frac{B-1}{B} \sum_{j=0}^{B-1} \left(\frac{g d_j}{B-1} \right)^2 = \frac{1}{B}\, g S_Y g^{\mathsf{T}}.$$

Let

$$a_j = -\frac{g d_j}{B-1}, \qquad e_j = R_j - \frac{1}{B} \sum_{k=0}^{B-1} R_k.$$

Then the difference between the full jackknife variance and its linear part is

$$\frac{B-1}{B} \left(2 \sum_{j=0}^{B-1} a_j e_j + \sum_{j=0}^{B-1} e_j^2 \right).$$

Cauchy's inequality bounds

$$\left(\sum_j a_j^2 \right)^{1/2} \le A.$$

Also

$$\left(\sum_j e_j^2 \right)^{1/2} \le 2 \left(\sum_j R_j^2 \right)^{1/2} \le E.$$

Substituting these two bounds proves (141.57).

For the static potential, the elementary block vector contains the positive Wilson-loop coordinates $W(n,m)$ needed for a chosen finite list of rectangles. The analysis functions are

$$F^{\text{eff}}_{n,m}(W) = -a^{-1} \log \frac{W(n,m+1)}{W(n,m)} \tag{141.58}$$

and

$$F^{\chi}_{n,m}(W) = -\log \frac{W(n,m)W(n-1,m-1)}{W(n,m-1)W(n-1,m)}. \tag{141.59}$$

They are smooth on the positive orthant. Applying the jackknife to $F^{\mathrm{eff}}_{n,m}$ or $F^{\chi}_{n,m}$ after deleting an entire Monte Carlo block is therefore a correlated calculation: the covariance among the rectangles is the matrix S_Y in (141.54). Propagating the four Wilson-loop errors in a Creutz ratio independently is a different approximation, justified only after a separate argument that the relevant off-diagonal covariance entries are negligible in the chosen data-analysis scheme.

Block bootstrap resampling similarly resamples the block means or the original contiguous blocks and recomputes the full nonlinear analysis function on every resampled data set. Its consistency requires an asymptotic regime in which $b \to \infty$, $B \to \infty$, and the block length grows slowly enough compared with the total chain length; the finite script described below reports the coordinate values and leaves the asymptotic claim to the stated Markov-chain hypotheses.

The companion script

`qft_scripts/autocorrelation_resampling.py`

computes the biased autocorrelation estimate, a windowed τ_{int}, blocked standard errors, delete-one-block jackknife errors for the mean, and block-bootstrap errors from a one-column CSV time series. It is intended as the upstream error-analysis layer for Wilson-loop and flowed-observable measurements before ratios such as (140.53) are formed.

141.13 Reweighting and the Sign Problem

Suppose the target finite-regulator integral has complex weight

$$e^{-S(\Phi)} = e^{-S_R(\Phi)} e^{\mathrm{i}\Theta(\Phi)}$$

with positive reference measure

$$d\nu_R = \frac{1}{Z_R} e^{-S_R(\Phi)} d\Phi.$$

Then

$$\langle O \rangle = \frac{\langle O e^{\mathrm{i}\Theta} \rangle_R}{\langle e^{\mathrm{i}\Theta} \rangle_R}.$$

The denominator is the average phase. If the free-energy densities of the target and phase-quenched systems differ by Δf in volume V, then

$$\left| \langle e^{\mathrm{i}\Theta} \rangle_R \right| = \exp[-V\Delta f].$$

Here

$$Z = \int e^{-S_R(\Phi)} e^{\mathrm{i}\Theta(\Phi)}\, d\Phi, \qquad Z_R = \int e^{-S_R(\Phi)}\, d\Phi, \qquad \langle e^{\mathrm{i}\Theta} \rangle_R = \frac{Z}{Z_R},$$

and Δf is the real number defined by

$$\Delta f = -\frac{1}{V} \log \left| \frac{Z}{Z_R} \right|. \tag{141.60}$$

Estimating a ratio with a denominator of this size requires a number of independent samples growing as $\exp[2V\Delta f]$ for fixed relative error, unless the numerator and denominator are computed by a method that avoids phase reweighting.

Finite-volume phase-reweighting variance bound. Let

$$m = \langle e^{\mathrm{i}\Theta} \rangle_R \neq 0.$$

For N independent samples from $d\nu_R$, the unbiased estimator

$$\widehat{m}_N = \frac{1}{N} \sum_{j=1}^{N} e^{\mathrm{i}\Theta(\Phi_j)}$$

satisfies

$$\frac{\mathbb{E}_R |\widehat{m}_N - m|^2}{|m|^2} = \frac{1 - |m|^2}{N|m|^2}. \tag{141.61}$$

Consequently, if $|m| = \exp[-V\Delta f]$, any direct phase-reweighting estimation of the denominator with relative mean-square error at most δ^2 requires

$$N \geq \delta^{-2} \left(e^{2V\Delta f} - 1 \right). \tag{141.62}$$

Since $|e^{\mathrm{i}\Theta}| = 1$,

$$\mathbb{E}_R |e^{\mathrm{i}\Theta} - m|^2 = \mathbb{E}_R |e^{\mathrm{i}\Theta}|^2 - |m|^2 = 1 - |m|^2.$$

Independence divides this variance by N, proving (141.61). Substitution of $|m| = e^{-V\Delta f}$ gives (141.62). The estimate concerns the denominator alone. A ratio estimator for $\langle O \rangle$ can have additional covariance between numerator and denominator, but it cannot remove the need to determine a denominator of exponentially small magnitude unless the method changes the representation of the finite-regulator integral.

141.14 Fermion Determinants

For lattice fermions with quadratic action

$$\bar{\psi} D[U] \psi,$$

Berezin integration gives

$$\int d\bar{\psi}\, d\psi\, e^{-\bar{\psi} D[U] \psi} = \det D[U].$$

If D obeys a positivity relation, such as

$$\gamma_5 D \gamma_5 = D^\dagger$$

together with flavor pairing, the determinant can be nonnegative. The single-flavor statement and the paired-flavor statement are different.

Remark 141.7 (Determinant reality from γ_5-Hermiticity). Let D be a finite lattice Dirac matrix and let Γ be an involution with $\Gamma^\dagger = \Gamma$ and $\Gamma^2 = 1$. If

$$\Gamma D \Gamma = D^\dagger, \tag{141.63}$$

then $\det D \in \mathbb{R}$. For two degenerate flavors with fermion integral $(\det D)^2$, the finite weight is nonnegative because the real determinant is squared. For a conjugate pair of flavors with determinant

$$\det D \ \det D^\dagger = |\det D|^2, \tag{141.64}$$

the finite-regulator weight is nonnegative before possible zero-mode subtleties. Thus a positivity claim must state the actual flavor and operator pairing together with the formal γ_5-Hermiticity relation. Taking determinants in (141.63) gives

$$\det D^\dagger = \det(\Gamma D \Gamma) = \det(\Gamma)^2 \det D = \det D.$$

Since $\det D^\dagger = \overline{\det D}$, the determinant is real. A real number can have either sign, so γ_5-Hermiticity alone does not give a positive single-flavor measure. For an even number of exactly degenerate copies, $(\det D)^{2k} \geq 0$. The conjugate-pair identity (141.64) is the elementary determinant identity $\det D^\dagger = \overline{\det D}$. If $\det D = 0$, the nonnegative weight vanishes and sampling remains mathematically defined, but algorithmic ergodicity and condition-number issues become separate finite regulator questions.

At finite chemical potential or in chiral gauge theories this positivity may fail. The finite regulator then has no declared positive probability measure whose expectations are the target correlators without reweighting or contour deformation.

The deterministic check

```
calculation-checks/monte_carlo_sign_problem_checks.py
```

verifies the finite-N autocorrelation identity, the phase-reweighting variance bound, and the determinant-reality-versus-positivity distinction in small finite examples.

141.15 Continuum Interpretation

Monte Carlo data become QFT data only after the regulator, source normalization, operator renormalization, scaling trajectory, and error limits are specified. A numerical estimate at finite lattice spacing is a statement about $d\nu_\Lambda$. A continuum claim requires convergence of a family of finite-regulator expectations in the topology needed for OS reconstruction, Wightman reconstruction, or the intended observable sector.

Open Problem 141.8 (Sign-problem-preserving continuum construction). Classify QFTs with complex Euclidean weights for which a nonperturbative continuum limit can be constructed by a positive enlarged-variable measure, an exact contour deformation, or another finite-regulator method with controlled variance and locality.

Chapter 142

Rigorous Renormalization Group

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter formulates renormalization group transformations as maps on normed spaces of interactions or probability measures. The aim is to replace informal terminology about flows by explicit maps, estimates, fixed points, and coordinate decompositions.

142.1 The Wilsonian Reconstruction Problem

The word "Wilsonian" will be used in a strict sense. It refers first to an exact finite-regulator operation that integrates or blocks degrees of freedom, and only second to a coordinate description of the resulting object. A coordinate flow is useful only when it is tied to the finite operation and to reconstruction estimates for observables.

Definition 142.1 (Wilsonian RG reconstruction problem)**.** A Wilsonian RG reconstruction problem consists of the following data.

1. A directed regulator family indexed by k, with finite-regulator configuration spaces, field spaces, measures, densities, or BV integration data, denoted collectively by $\mathcal{X}_k$. The ordering convention is part of the datum: increasing k means removing or refining the ultraviolet regulator.
2. Exact finite-regulator maps $T_{k,k-1}$ obtained by Gaussian fluctuation integration, block-spin pushforward, tensor blocking, gauge-equivariant lattice blocking, or BV pushforward. These

maps act on the finite-regulator objects themselves before any projection to finitely many couplings is made.

3. Localization maps

$$\mathrm{Loc}_k : T_{k,k-1}(\mathcal{X}_k) \longrightarrow \mathcal{B}_{k-1}$$

into declared Banach, Fréchet, polymer, tensor, or BV charts. The image separates retained local coordinates from the irrelevant or nonlocal tail measured in the chosen norm.

4. Source extensions for finite test windows E. These include finite-regulator source functionals $Z_{k,E}$ or $W_{k,E} = \log Z_{k,E}$, local source and contact coordinates, and the source-decorated irrelevant tail. The source radius and the topology in which source derivatives are taken are part of the data.

5. Reconstruction maps from the regulated or chart-level objects to the intended observable topology: Schwinger distributions, Wightman distributions, local algebras, gauge-invariant line or loop observables, tensor-network observables, or BV cohomology classes.

6. Estimates, in the stated norms and seminorms, proving the domain stability of the exact maps, localization remainders, contraction or summability of irrelevant tails, tuning of unstable coordinates, convergence of source windows, reflection positivity or its declared replacement, distributional growth bounds, and a common directed regulator schedule on which the estimates needed for each finite reconstruction demand hold together.

A fixed point, stable trajectory, or continuum limit is a theorem about this package, not about the zero of a beta function by itself. Perturbative beta functions, functional-RG truncations, and tensor-network numerics are useful coordinate shadows when comparison maps and residual estimates relate them to Definition 142.1. The later sections unpack the items in the definition: exact Gaussian pushforward, Banach-space linearization, projection residuals, polymer estimates, source windows, OS/Wightman reconstruction, auxiliary-to-short-range transfer, gauge-compatible blocking, and tensor or functional-RG comparison.

142.2 Gaussian Block Integration

Let C be a positive covariance on a finite regulator space of fields and suppose it decomposes as

$$C = C_< + \Gamma.$$

Let $d\mu_C$, $d\mu_{C_<}$, and $d\mu_\Gamma$ be the corresponding Gaussian measures. For an interaction V, define the single-step effective interaction

$$e^{-V_<(\phi)} = \int d\mu_\Gamma(\zeta)\, e^{-V(\phi+\zeta)}.$$

This identity is exact at finite regulator. A scale transformation S_L then gives an RG map

$$\mathcal{R}_L(V) = S_L V_<.$$

The definition contains three inputs: covariance decomposition, integration domain, and rescaling convention.

142.3 Several RG Maps And Their Mathematical Objects

The name "renormalization group" is used for several closely related, but mathematically distinct, maps. In this chapter the object being transformed is always part of the statement. Let C_Λ be a regulated covariance and let $C_{\Lambda_1} - C_{\Lambda_0}$ be positive for $\Lambda_1 > \Lambda_0$ in the chosen cutoff ordering. The exact Wilsonian pushforward from Λ_1 to Λ_0 is the identity

$$e^{-V_{\Lambda_0}(\phi)} = \int d\mu_{C_{\Lambda_1}-C_{\Lambda_0}}(\zeta)\, e^{-V_{\Lambda_1}(\phi+\zeta)}, \tag{142.1}$$

with additive normalization fixed separately. Its semigroup property is the Gaussian convolution identity:

$$\int d\mu_{\Gamma_1}(\zeta_1) \int d\mu_{\Gamma_2}(\zeta_2)\, F(\phi+\zeta_1+\zeta_2) = \int d\mu_{\Gamma_1+\Gamma_2}(\zeta)\, F(\phi+\zeta), \tag{142.2}$$

valid whenever Γ_1, Γ_2, and $\Gamma_1+\Gamma_2$ are the corresponding positive covariances. Thus the exact Wilsonian map transforms interactions or measures.

The Wilson–Polchinski equation is the infinitesimal form of the same Gaussian pushforward in a smooth-cutoff coordinate chart. Let t be a cutoff parameter such that lowering t by $\delta t > 0$ integrates the positive shell covariance $\delta t\, \dot{C}_t + O(\delta t^2)$, where $\dot{C}_t = \partial_t C_t$. Thus

$$e^{-V_{t-\delta t}[\phi]} = \left(1 + \frac{\delta t}{2}\Delta_{\dot{C}_t}\right) e^{-V_t[\phi]} + O(\delta t^2). \tag{142.3}$$

Writing

$$\Delta_{\dot{C}_t} = \int_{x,y} \dot{C}_t(x,y) \frac{\delta}{\delta\phi(x)} \frac{\delta}{\delta\phi(y)},$$

one obtains, equivalently, at finite regulator

$$\partial_t e^{-V_t[\phi]} = -\frac{1}{2}\, \Delta_{\dot{C}_t} e^{-V_t[\phi]}, \tag{142.4}$$

or, equivalently,

$$\partial_t V_t = \frac{1}{2}\langle \delta V_t, \dot{C}_t\, \delta V_t\rangle - \frac{1}{2}\,\mathrm{Tr}(\dot{C}_t\, \delta^2 V_t), \tag{142.5}$$

with this convention for t. Reparametrizing the scale variable multiplies both sides by the corresponding chain-rule factor. The equation is a differential equation for the Wilsonian interaction. Its theorem-level use requires a function space, bounds on the functional derivatives, and a construction of the trajectory.

The effective-average-action or Wetterich flow transforms a different functional. At finite regulator, introduce an infrared quadratic term

$$\Delta S_k[\phi] = \frac{1}{2}\langle \phi, R_k \phi\rangle$$

and define

$$W_k[J] = \log \int d\mu(\phi)\, \exp(\langle J, \phi\rangle - \Delta S_k[\phi] - V[\phi])\,.$$

For $\varphi = \delta W_k/\delta J$, the effective average action is the modified Legendre transform

$$\Gamma_k[\varphi] = \langle J, \varphi\rangle - W_k[J] - \Delta S_k[\varphi]. \tag{142.6}$$

Where the finite-dimensional Hessians are invertible, direct differentiation gives

$$\partial_t \Gamma_k[\varphi] = \frac{1}{2}\,\mathrm{Tr}\Big[\big(\Gamma_k^{(2)}[\varphi] + R_k\big)^{-1}\partial_t R_k\Big]\,. \tag{142.7}$$

This is an exact identity for a regulated Legendre transform. A fixed point of a finite truncation of Γ_k is a computational approximation to this functional flow; a theorem-level statement requires an embedding of the truncation into a complete function space and a bound on the omitted directions.

Constructive polymer RG transforms a pair consisting of local coordinates and polymer activities. Its single step has the form

$$(g, K) \longmapsto (g', K')$$

where g' is obtained by a localization map extracting finitely many local Taylor coefficients, while K' is the remaining nonlocal activity measured in a polymer norm. The decisive estimate is a contraction or summability bound for K', together with Lipschitz dependence on g. This is the form in which many rigorous scalar and fermionic constructions are proved.

Tensor RG starts from a tensor-network representation of a partition function or state sum. Its map acts on local tensors T rather than on a continuum interaction:

$$T \longmapsto \mathcal{T}(T), \tag{142.8}$$

with blocking, truncation or disentangling, and a declared Hilbert, Hilbert–Schmidt, or Banach topology on the tensor space. A tensor-RG fixed point theorem therefore proves contraction or stable-manifold estimates for $\mathcal{T}$ in that tensor topology, plus a reconstruction map if the claim concerns continuum QFT observables.

Definition 142.2 (Comparison of two RG descriptions)**.** Let $(\mathcal{B}_1, \mathcal{R}_1)$ and $(\mathcal{B}_2, \mathcal{R}_2)$ be two RG descriptions, each with its own domain, norm, and reconstruction maps. A comparison from the first to the second consists of maps $\Phi : \mathcal{U}_1 \to \mathcal{B}_2$ and $\Psi : \mathcal{O}_1 \to \mathcal{O}_2$, where $\mathcal{O}_i$ are locally convex spaces of observables with declared seminorm families $\mathfrak{P}_i$, together with estimates

$$\|\Phi(\mathcal{R}_1 V) - \mathcal{R}_2(\Phi V)\|_{\mathcal{B}_2} \le E_{\mathrm{RG}}(V), \tag{142.9}$$

and

$$p\Big(\Psi\ \mathrm{Rec}_k^{(1)}(V), \mathrm{Rec}_k^{(2)}(\Phi V)\Big) \le E_{\mathrm{obs},p}(k, V), \tag{142.10}$$

for every $p \in \mathfrak{P}_2$, where E_{RG} and $E_{\mathrm{obs},p}$ are explicitly bounded errors in the stated domains. An exact equivalence is the special case in which both errors vanish and Φ identifies the relevant stable manifold neighborhoods. A controlled approximation is the case in which the errors are shown to vanish in the continuum or long-distance limit relevant to the claim.

This definition is the standard used below when relating a perturbative Polchinski trajectory, a BPHZ coordinate system, a functional-RG truncation, or a tensor-network calculation to a Wilsonian fixed point. The comparison map and its error estimates are part of the mathematical claim.

142.4 Banach Space Of Interactions

Let $\mathcal{B}$ be a Banach space of local functionals with norm $\|\cdot\|_{\mathcal{B}}$. A typical constructive choice separates relevant local coordinates from a polymer remainder:

$$V(\phi) = \sum_i g_i \mathcal{O}_i(\phi) + K(\phi),$$

where $g_i \in \mathbb{R}$ or $\mathbb{C}$ and K is measured by a norm that includes large-field weights and spatial decay. The RG map is controlled on an open set $U \subset \mathcal{B}$ if

$$\mathcal{R}_L : U \longrightarrow \mathcal{B}$$

is differentiable and its derivative satisfies explicit bounds in the chosen norm.

142.5 Linearization And Coordinates

Let V_* be a fixed point:

$$\mathcal{R}_L(V_*) = V_*.$$

The linearized map is

$$D\mathcal{R}_L|_{V_*} : \mathcal{B} \to \mathcal{B}.$$

An eigenvector e_i with eigenvalue L^{y_i} is relevant, marginal, or irrelevant according as $y_i > 0$, $y_i = 0$, or $y_i < 0$. These words refer to the declared linearized map and norm. A coordinate g_i is a scaling coordinate only after nonlinear terms have been put into a normal form or controlled by a stable-manifold argument.

Theorem 142.3 (Local stable graph for an RG map)**.** *Let $\mathcal{R}$ be a C^1 map on a Banach space $\mathcal{B}$ with fixed point V_*. Translate V_* to the origin and suppose*

$$\mathcal{B} = E_u \oplus E_s$$

where E_u is finite dimensional and E_s is closed. In product norm write

$$\mathcal{R}(u, s) = (Au + F_u(u, s),\, Bs + F_s(u, s)), \tag{142.11}$$

where $A : E_u \to E_u$ is invertible, $B : E_s \to E_s$, $F(0) = 0$, and $DF(0) = 0$. Assume that, on a closed ball of radius r,

$$\|A^{-1}\| \le a < 1, \qquad \|B\| \le b < 1, \qquad \|F(x) - F(y)\| \le \kappa \|x - y\|. \tag{142.12}$$

Choose γ with $\max(a, b) < \gamma < 1$ and suppose

$$q_u := \frac{\kappa a}{1 - a\gamma} < 1, \qquad q_s := \frac{b + \kappa}{\gamma} < 1, \qquad q := \max(q_u, q_s) < 1. \tag{142.13}$$

Then, after possibly decreasing r, for every sufficiently small $s_0 \in E_s$ there is a unique forward orbit $(u_n, s_n)_{n \ge 0}$ satisfying s_0 as its stable coordinate,

$$(u_{n+1}, s_{n+1}) = \mathcal{R}(u_n, s_n), \qquad \sup_{n \ge 0} \gamma^{-n} \|(u_n, s_n)\| < \infty.$$

The initial unstable coordinate u_0 is a Lipschitz function $h(s_0)$. The graph $u = h(s)$ is forward invariant, consists exactly of the points whose forward orbit stays in the chosen γ-decay neighborhood, and is tangent to E_s at the fixed point in the sense $\|h(s)\|/\|s\| \to 0$ as $s \to 0$.

Proof. Fix $\rho \le r$ and $\|s_0\| \le \rho$. Let

$$\mathcal{X}_{\gamma,\rho}(s_0) = \left\{ x = (u_n, s_n)_{n\ge 0} : s_0 \text{ is fixed}, \ \|x\|_\gamma := \sup_{n\ge 0} \gamma^{-n} \|(u_n, s_n)\| \le \rho \right\}.$$

With the metric induced by $\|\cdot\|_\gamma$, this is a closed subset of the Banach space of γ-weighted sequences, hence is complete. Define the Lyapunov–Perron map $\mathcal{T}_{s_0}$ by

$$(\mathcal{T}_{s_0} x)_0^s = s_0, \tag{142.14}$$

$$(\mathcal{T}_{s_0} x)_{n+1}^s = B s_n + F_s(u_n, s_n), \tag{142.15}$$

$$(\mathcal{T}_{s_0} x)_n^u = -\sum_{j=0}^{\infty} A^{-(j+1)} F_u(u_{n+j}, s_{n+j}). \tag{142.16}$$

The series in (142.16) converges absolutely because

$$\gamma^{-n} \sum_{j\ge 0} \|A^{-(j+1)}\| \, \|F_u(u_{n+j}, s_{n+j})\| \le \frac{\kappa a}{1 - a\gamma} \|x\|_\gamma. \tag{142.17}$$

Here $F(0) = 0$ was used. Similarly,

$$\gamma^{-(n+1)} \|B s_n + F_s(u_n, s_n)\| \le \frac{b + \kappa}{\gamma} \|x\|_\gamma. \tag{142.18}$$

Equations (142.13), (142.17), and (142.18) show that $\mathcal{T}_{s_0}$ maps $\mathcal{X}_{\gamma,\rho}(s_0)$ into itself for every $\rho \le r$ with $\|s_0\| \le \rho$.

For two sequences $x, y \in \mathcal{X}_{\gamma,\rho}(s_0)$, the same estimates applied to differences give

$$\|\mathcal{T}_{s_0} x - \mathcal{T}_{s_0} y\|_\gamma \le q \|x - y\|_\gamma, \tag{142.19}$$

with $q < 1$. Banach's fixed-point theorem gives a unique fixed sequence $x(s_0)$. The s-part of the fixed-point equation is exactly the stable coordinate recurrence. The u-part is equivalent to the unstable coordinate recurrence because multiplying (142.16) by A and shifting the summation gives

$$A u_n + F_u(u_n, s_n) = u_{n+1}.$$

Thus the fixed sequence is precisely a forward orbit of $\mathcal{R}$ with γ-decay. Conversely, any forward orbit with this decay must satisfy (142.16); otherwise the growing homogeneous solution of $u_{n+1} = A u_n + F_u(u_n, s_n)$ would violate $\sup_n \gamma^{-n} \|u_n\| < \infty$.

Define $h(s_0) = u_0(s_0)$. If s_0, t_0 are two stable initial coordinates, the fixed-point equations give

$$\|x(s_0) - x(t_0)\|_\gamma \le \|s_0 - t_0\| + q \|x(s_0) - x(t_0)\|_\gamma,$$

and hence

$$\|x(s_0) - x(t_0)\|_\gamma \le \frac{1}{1 - q} \|s_0 - t_0\|. \tag{142.20}$$

Therefore h is Lipschitz. Since $DF(0) = 0$, the Lipschitz constant κ for F on a ball of radius ρ tends to zero as $\rho \downarrow 0$. The bound (142.17) then implies $\|h(s)\|/\|s\| \to 0$, so the graph is tangent to E_s at the fixed point. Forward invariance is built into the recurrence, and the γ-weighted bound gives convergence to the fixed point. $\square$

Theorem 142.4 (C^1 stable graph from the Lyapunov–Perron equation)**.** *Assume the hypotheses and notation of Theorem 142.3. Suppose in addition that F is C^1 on the ball used there and that DF is uniformly continuous on that ball. Let*

$$\kappa_\rho = \sup_{\|(u,s)\|\le\rho} \|DF(u,s)\|_{\mathcal{B}\to\mathcal{B}}.$$

After restricting to a smaller ball if necessary, assume

$$q_\rho = \max\left\{\frac{a\kappa_\rho}{1-a\gamma}, \frac{b+\kappa_\rho}{\gamma}\right\} < 1. \tag{142.21}$$

Then the orbit map

$$s_0 \longmapsto x(s_0) = (u_n(s_0), s_n(s_0))_{n\ge0} \in \mathcal{X}_{\gamma,\rho}(s_0)$$

constructed in Theorem 142.3 is C^1 as a map from the stable-coordinate ball into the γ-weighted sequence space. Its derivative in the direction $v \in E_s$ is the unique γ-weighted sequence $Y(v) = (Y_n^u(v), Y_n^s(v))_{n\ge0}$ satisfying

$$Y_0^s(v) = v, \tag{142.22}$$

$$Y_{n+1}^s(v) = B\,Y_n^s(v) + DF_s(x_n(s_0))\,Y_n(v), \tag{142.23}$$

$$Y_n^u(v) = -\sum_{j=0}^{\infty} A^{-(j+1)} DF_u(x_{n+j}(s_0))\,Y_{n+j}(v). \tag{142.24}$$

Consequently the stable graph $h(s_0) = u_0(s_0)$ is C^1, with

$$Dh(s_0)v = Y_0^u(v), \qquad Dh(0) = 0.$$

Proof. Let X_γ be the Banach space of sequences $(u_n, s_n)_{n\ge0}$ with finite norm

$$\|x\|_\gamma = \sup_n \gamma^{-n}\|(u_n, s_n)\|.$$

The Lyapunov–Perron map used in the proof of Theorem 142.3 may be written

$$x = \mathcal{T}(s_0, x).$$

For fixed s_0, its derivative with respect to x is obtained by replacing each occurrence of F in (142.15)–(142.16) by $DF(x_n)$. The same estimates as (142.17) and (142.18), with κ replaced by κ_ρ, give

$$\|D_x\mathcal{T}(s_0, x)\|_{X_\gamma\to X_\gamma} \le q_\rho < 1. \tag{142.25}$$

The derivative of $\mathcal{T}$ with respect to the parameter s_0 is the sequence whose stable component at $n = 0$ is the input vector and whose other components are zero before the contraction equation is solved.

For $v \in E_s$, define $Y(v)$ to be the fixed point of the affine linear equation

$$Y = D_{s_0}\mathcal{T}(s_0, x(s_0))v + D_x\mathcal{T}(s_0, x(s_0))Y. \tag{142.26}$$

Banach's fixed-point theorem applies because of (142.25). Written in components, (142.26) is exactly (142.22)–(142.24). It also gives the bound

$$\|Y(v)\|_\gamma \le \frac{\|v\|}{1-q_\rho}.$$

It remains to check that $Y(v)$ is the derivative of $x(s_0)$. Put

$$\Delta_t = \frac{x(s_0 + tv) - x(s_0)}{t}.$$

Subtract (142.26) from the difference quotient of

$$x(s_0 + tv) = \mathcal{T}(s_0 + tv, x(s_0 + tv)), \qquad x(s_0) = \mathcal{T}(s_0, x(s_0)).$$

The result is

$$\Delta_t - Y(v) = D_x\mathcal{T}(s_0, x(s_0))(\Delta_t - Y(v)) + r_t,$$

where $r_t \to 0$ in X_γ. The convergence of r_t is the Fréchet differentiability of F on each finite component together with the uniform continuity of DF, the uniform γ-weighted bound on the two orbits, and the dominated geometric sums in (142.17). Taking norms and using (142.25) gives

$$\|\Delta_t - Y(v)\|_\gamma \le q_\rho \|\Delta_t - Y(v)\|_\gamma + \|r_t\|_\gamma,$$

so $\Delta_t \to Y(v)$. Thus $x(\cdot)$ is differentiable.

Continuity of $Dx(s_0)$ follows from the same contraction equation: if s_0 and s_0' are close, the corresponding orbits are close in X_γ, and uniform continuity of DF makes

$$D_x\mathcal{T}(s_0, x(s_0)) - D_x\mathcal{T}(s_0', x(s_0'))$$

small as an operator on X_γ. The inverse $(1 - D_x\mathcal{T})^{-1}$ is uniformly bounded by $(1 - q_\rho)^{-1}$, so the fixed solution of (142.26) depends continuously on s_0.

Finally, at $s_0 = 0$ the orbit is identically zero and $DF(0) = 0$. The derivative equations reduce to

$$Y_n^s = B^n v, \qquad Y_n^u = 0.$$

Therefore $Dh(0)v = Y_0^u(v) = 0$ for every $v \in E_s$. $\square$

142.6 Critical Surfaces And Continuum Tuning

The local stable graph is the mathematical object behind continuum tuning. Let the hypotheses and notation of Theorem 142.3 hold. Write

$$\Pi_u : \mathcal{B} = E_u \oplus E_s \longrightarrow E_u, \qquad \Pi_s : \mathcal{B} = E_u \oplus E_s \longrightarrow E_s$$

for the continuous projections. In a sufficiently small neighborhood of V_*, define the local critical surface

$$\mathcal{W}^s_{\text{loc}}(V_*) = \{V_* + h(s) + s : \ s \in E_s, \ \|s\| \text{ small}\}. \tag{142.27}$$

The word "critical" here means attraction to the fixed point under the declared RG map. It is a property of the pair $(\mathcal{R}, \mathcal{B})$, together with the reconstruction maps if a continuum QFT limit is claimed.

Definition 142.5 (Tuning map)**.** In the setting above, the local tuning map is

$$\tau(V) = \Pi_u(V - V_*) - h(\Pi_s(V - V_*)) \,, \tag{142.28}$$

defined for V in the local product neighborhood on which the graph h exists. A point V is tuned to the local critical surface precisely when

$$\tau(V) = 0. \tag{142.29}$$

If $\dim E_u = r$ and a basis of E_u has been chosen, this is an r-component equation. The components of τ, rather than a chosen list of formal Lagrangian coefficients, are the intrinsic relevant tuning coordinates in this RG chart.

Where the analytic burden lies. Theorem 142.3 proves the existence of a Lipschitz stable graph under the displayed Lyapunov–Perron contraction hypotheses. Theorem 142.4 gives one self-contained route to C^1 regularity: prove uniform derivative bounds for the chosen Banach RG map so that the differentiated Lyapunov–Perron equation remains a contraction. A model-specific RG theorem must establish these derivative bounds in its polymer, kernel, tensor, lattice, or BV norm. The geometric consequence after this analytic input is a standard submersion calculation, not an RG theorem in its own right.

Submanifold form after differentiability. Assume the stable graph $h : E_s \to E_u$ in Theorem 142.3 is C^1 on a neighborhood of the origin in E_s, and let $r = \dim E_u < \infty$. Then $\mathcal{W}^s_{\mathrm{loc}}(V_*)$ is a C^1 submanifold of $\mathcal{B}$ of codimension r. Equivalently, the equation $\tau(V) = 0$ cuts out the local critical surface by r independent conditions.

Let P be a finite-dimensional C^1 parameter manifold of microscopic finite-regulator theories, and let

$$\iota : P \longrightarrow \mathcal{B}$$

be a C^1 chart map into the RG Banach space. If $p_0 \in P$ satisfies $\tau(\iota(p_0)) = 0$ and

$$D(\tau \circ \iota)_{p_0} : T_{p_0}P \longrightarrow E_u \tag{142.30}$$

has rank r, then the tuned microscopic parameters near p_0,

$$P_{\mathrm{tuned}} = \{p \in P : \tau(\iota(p)) = 0\}, \tag{142.31}$$

form a C^1 submanifold of P of codimension r.

For $V = V_* + u + s$, with $u \in E_u$ and $s \in E_s$, the derivative of τ in the E_u-direction is the identity map on E_u:

$$D_u\tau(V_* + u + s) = 1_{E_u}. \tag{142.32}$$

Thus τ is a C^1 submersion onto the finite-dimensional space E_u. Its zero set is exactly

$$\{V_* + u + s : \; u = h(s)\},$$

which is the graph (142.27). The submersion theorem for Banach spaces with finite-dimensional target gives a C^1 submanifold of codimension $\dim E_u = r$. In this product chart the submanifold statement is also direct: the map

$$s \longmapsto V_* + h(s) + s$$

parametrizes the zero set, and the transverse coordinates are precisely $\tau \in E_u$.

For the microscopic parameter space, apply the finite-dimensional implicit function theorem to $\tau \circ \iota : P \to E_u$. The rank condition (142.30) makes $0 \in E_u$ a regular value near p_0. Hence the inverse image $(\tau \circ \iota)^{-1}(0)$ is a C^1 submanifold of P of codimension r, which is (142.31).

Quantitative finite-dimensional tuning estimate. The rank condition is not the estimate used in a finite-regulator construction. After a choice of r microscopic tuning coordinates, one needs a ball on which the nonlinear tuning equation is solved with controlled constants. Let X and Y be r-dimensional normed spaces, let $F : \overline{B}_\rho(0) \subset X \to Y$ be C^1 on a neighborhood of the closed ball, and let

$$e = F(0), \qquad A = DF(0).$$

Assume $A : X \to Y$ is invertible and, for some $0 \le \kappa < 1/2$,

$$\|A^{-1}e\| \le \frac{\rho}{2}, \qquad \sup_{\|x\| \le \rho} \|A^{-1}(DF(x) - A)\| \le \kappa. \tag{142.33}$$

Then $F(x) = 0$ has a unique solution in the closed ball $\overline{B}_\rho(0)$. Indeed define

$$T(x) = x - A^{-1}F(x).$$

For $\|x\|, \|y\| \le \rho$, the fundamental theorem of calculus gives

$$T(x) - T(y) = -\int_0^1 A^{-1}\big(DF(y + t(x-y)) - A\big)(x-y)\,\mathrm{d}t, \tag{142.34}$$

so $\|T(x) - T(y)\| \le \kappa\|x - y\|$. Also

$$\|T(x)\| \le \|T(0)\| + \kappa\|x\| = \|A^{-1}e\| + \kappa\|x\| \le \rho.$$

Thus T is a contraction of the complete metric space $\overline{B}_\rho(0)$ into itself, and Banach's fixed-point theorem gives a unique fixed point in that closed ball. The fixed-point equation $T(x) = x$ is exactly $F(x) = 0$.

In the RG application F is the local coordinate expression for $\tau \circ \iota$ in the chosen r microscopic tuning variables, after any spectator parameters have been fixed or placed in a small auxiliary ball. The residual $\|A^{-1}e\|$ measures how far the proposed finite microscopic point is from the local critical surface in intrinsic relevant coordinates; the second bound in (142.33) is the quantitative transversality estimate. This estimate still does not construct a fixed point or a continuum QFT. It only says that, once the stable graph and the microscopic parameter chart have already been established with these constants, the finite-dimensional relevant-coordinate equation can actually be solved in the declared neighborhood.

Linear finite-scale tuning exponents. Let E_u be a finite-dimensional normed vector space with basis $\{e_a\}_{a=1}^r$. Suppose the linearized unstable map is diagonal in this basis,

$$Ae_a = \lambda_a e_a, \qquad |\lambda_a| > 1.$$

For the linear RG map

$$\mathcal{R}_{\text{lin}}(u, s) = (Au, Bs),$$

the unstable component of an initial condition

$$u_0 = \sum_{a=1}^{r} u_a(0)e_a$$

stays in the coordinate box

$$|u_a(n)| \le \rho \qquad (a = 1, \dots, r,\ 0 \le n \le N) \tag{142.35}$$

if and only if

$$|u_a(0)| \le \rho\,|\lambda_a|^{-N} \qquad (a = 1, \dots, r). \tag{142.36}$$

Writing $\lambda_a = L^{y_a}$, this finite-depth accuracy is ρL^{-Ny_a} in the a-th relevant coordinate.

The linear recurrence gives

$$u_n = A^n u_0 = \sum_{a=1}^{r} \lambda_a^n u_a(0)e_a.$$

Therefore

$$|u_a(n)| = |\lambda_a|^n |u_a(0)|.$$

Since $|\lambda_a| > 1$, the maximum over $0 \le n \le N$ occurs at $n = N$. The bound (142.35) is therefore equivalent to

$$|\lambda_a|^N |u_a(0)| \le \rho$$

for every a, which is (142.36). The notation $\lambda_a = L^{y_a}$ gives $|\lambda_a|^{-N} = L^{-Ny_a}$ when $\lambda_a > 0$; for complex or negative eigenvalues the same estimate uses $|\lambda_a| = L^{y_a}$.

For a nonlinear RG map, the finite-scale tuning calculation above is the linear model for the precision required before N RG steps. The stable graph replaces the coordinate plane $u = 0$ by the intrinsic equation $\tau(V) = 0$. A theorem assigning the same exponents beyond the linear approximation must provide normal-form or graph-transform estimates controlling the nonlinear remainder.

The diagonal estimate is not a convention-independent statement about finite-depth tuning. For a general finite-dimensional unstable block $A : E_u \to E_u$, the intrinsic quantity is

$$M_A(N) = \max_{0 \le n \le N} \|A^n\|_{E_u \to E_u}. \tag{142.37}$$

The sufficient uniform tuning condition for the linear unstable component to remain in the ball $\|u_n\| \le \rho$ for $0 \le n \le N$ is

$$\|u_0\| \le \frac{\rho}{M_A(N)}. \tag{142.38}$$

For a Jordan block $A = \lambda 1 + N_J$ of size m, with $N_J^m = 0$,

$$A^n = \lambda^n \sum_{p=0}^{m-1} \binom{n}{p} \lambda^{-p} N_J^p. \tag{142.39}$$

Thus non-diagonal unstable coordinates can carry a polynomial amplification factor of degree $m-1$ in addition to the exponential factor $|\lambda|^n$. A proof that quotes only the eigenvalue exponent y has therefore not specified the finite-depth tuning precision unless it also controls the conditioning of the unstable coordinate chart and any Jordan or near-resonant polynomial losses.

The same point appears for finite comparison or truncation errors. If the unstable coordinate obeys

$$u_{n+1} = Au_n + e_n,$$

then

$$u_N = A^N u_0 + \sum_{j=0}^{N-1} A^{N-1-j} e_j. \tag{142.40}$$

The error sequence must be summable after multiplication by the same unstable powers. Otherwise a trajectory can stay close to the stable graph in its stable coordinates while drifting out of the relevant-coordinate window at the finite depth needed for the reconstructed observable.

142.7 Polymer Representation

On a lattice, a polymer is a finite connected union of blocks in a fixed block decomposition. Let $\mathbb{B}_k$ be the set of scale-k blocks, let $\mathcal{P}_k$ be the family of connected finite unions of elements of $\mathbb{B}_k$, and let $X \sim Y$ mean that the polymers $X, Y \in \mathcal{P}_k$ are disjoint and separated by at least one block. A polymer activity is a map

$$K_k : \mathcal{P}_k \times \Phi_k \to \mathbb{C}, \qquad (X, \phi) \mapsto K_k(X, \phi),$$

where Φ_k is the finite-dimensional scale-k field space of the regulated model. The polymer form of a finite-volume partition function is

$$Z_k = \int d\mu_{C_k}(\phi)\, \exp\{-V_k(\phi)\} \sum_{\mathcal{X} \text{ compatible}} \prod_{X \in \mathcal{X}} K_k(X, \phi). \tag{142.41}$$

Here V_k is the local part, C_k is the fluctuation covariance assigned to the current scale, and the sum is over finite compatible families $\mathcal{X} \subset \mathcal{P}_k$. Compatibility is the locality input: it is what permits a disconnected family of small activities to exponentiate through the cluster expansion rather than behaving as one large nonlocal object.

Definition 142.6 (Finite-range fluctuation covariance decomposition)**.** Let Λ_k be the finite scale-k regulator lattice with graph distance d_k. A fluctuation covariance Γ_k has range R_k if

$$\Gamma_k(x, y) = 0 \qquad \text{whenever} \qquad d_k(x, y) > R_k. \tag{142.42}$$

A finite-range decomposition for a scalar block-spin RG is a decomposition

$$C_{\le k} = \Gamma_0 + \Gamma_1 + \cdots + \Gamma_k + C_{\mathrm{rem,k}}$$

on each finite regulator, with every Γ_j positive semidefinite, Γ_j satisfying a range bound of order L^j in microscopic distance, and derivative or difference bounds in the field norm used by the polymer activity. Positivity is needed to realize Γ_j as a Gaussian fluctuation covariance; the range bound is the input that turns separated polymer activities into independent fluctuation integrations; the derivative bounds enter the localization and Taylor-remainder estimates.

Lemma 142.7 (Finite-range Gaussian factorization)**.** *Let Φ_Λ be a finite real field space and let μ_Γ be a centered Gaussian measure with positive semidefinite covariance Γ. If $A, B \subset \Lambda$ satisfy*

$$\Gamma(x,y) = 0 \qquad (x \in A,\ y \in B),$$

then the Gaussian fields $\zeta_A = (\zeta_x)_{x\in A}$ and $\zeta_B = (\zeta_y)_{y\in B}$ are independent. Consequently, for bounded measurable F_A and F_B depending only on the fields in A and B,

$$\int F_A(\zeta_A)F_B(\zeta_B)\,\mathrm{d}\mu_\Gamma(\zeta) = \left(\int F_A(\zeta_A)\,\mathrm{d}\mu_\Gamma(\zeta)\right)\left(\int F_B(\zeta_B)\,\mathrm{d}\mu_\Gamma(\zeta)\right). \tag{142.43}$$

Proof. The joint characteristic function of (ζ_A, ζ_B) is

$$\exp\left\{-\frac{1}{2}t_A\Gamma_{AA}t_A - t_A\Gamma_{AB}t_B - \frac{1}{2}t_B\Gamma_{BB}t_B\right\}.$$

The hypothesis gives $\Gamma_{AB} = 0$, so the characteristic function is the product of the characteristic functions of ζ_A and ζ_B. For finite-dimensional probability measures, characteristic functions determine the law, and this factorization is exactly independence of the two random vectors. The displayed integral identity is then the defining factorization property of independent random variables. If Γ is only positive semidefinite, the same argument applies to the induced Gaussian law on the quotient by the null directions, or equivalently after adding $\epsilon 1$ and letting $\epsilon \downarrow 0$ in finite dimension. $\square$

Applied with A and B equal to R_k-neighborhoods of two separated polymers, Lemma 142.7 is the exact finite-regulator reason why fluctuation integration preserves polymer locality. If a covariance decomposition has only exponential decay rather than finite range, this factorization is replaced by a cluster estimate with decay constants in the polymer norm; the conclusion is weaker and must be proved separately. Thus a short-range scalar Wilsonian RG theorem cannot begin from the phrase "integrate a momentum shell" alone. It must specify the covariance shell, its locality or decay estimate, and the norm in which the residual inter-polymer correlations are summable.

Lemma 142.8 (Summable covariance-tail bridge estimate)**.** *Let Λ be a finite lattice with graph distance d. Assume that there are constants $D_{\mathrm{vol}} \geq 1$ and $C_{\mathrm{sh}} < \infty$ such that for every $x \in \Lambda$ and $n \geq 0$*

$$\#\{y \in \Lambda :\ d(x,y) = n\} \leq C_{\mathrm{sh}}(1+n)^{D_{\mathrm{vol}}-1}. \tag{142.44}$$

Let Γ be a positive semidefinite covariance satisfying

$$|\Gamma(x,y)| \leq A_\Gamma(1+d(x,y))^{-s}, \qquad s > D_{\mathrm{vol}}. \tag{142.45}$$

If $A, B \subset \Lambda$ are finite sets with $d(A,B) \geq R$, then the cross block $\Gamma_{AB} : \ell^2(B) \to \ell^2(A)$ obeys

$$\|\Gamma_{AB}\|_{\ell^2(B)\to\ell^2(A)} \leq A_\Gamma C_{\mathrm{sh}}\left(1 + \frac{1}{s - D_{\mathrm{vol}}}\right)(1+R)^{D_{\mathrm{vol}}-s}. \tag{142.46}$$

Consequently, if F_A and F_B are C^1 bounded functions depending only on the fields in A and B, with

$$\|\nabla_A F_A\|_{2,\infty} = \sup_\phi\left(\sum_{x\in A}|\partial_x F_A(\phi)|^2\right)^{1/2}$$

and similarly for F_B, then

$$\begin{aligned}&|\mathbb{E}_\Gamma[F_A(\zeta_A)F_B(\zeta_B)] - \mathbb{E}_\Gamma[F_A(\zeta_A)]\,\mathbb{E}_\Gamma[F_B(\zeta_B)]|\\ &\qquad \le A_\Gamma C_{\mathrm{sh}}\left(1+\frac{1}{s-D_{\mathrm{vol}}}\right)(1+R)^{D_{\mathrm{vol}}-s}\|\nabla_A F_A\|_{2,\infty}\|\nabla_B F_B\|_{2,\infty}.\end{aligned}\tag{142.47}$$

Proof. For $x \in A$, the row sum over B is bounded by the full tail outside distance R:

$$\sum_{y\in B}|\Gamma(x,y)| \le A_\Gamma C_{\mathrm{sh}}\sum_{n\ge R}(1+n)^{D_{\mathrm{vol}}-1-s}.$$

The same bound holds for column sums by symmetry of Γ. Since $s > D_{\mathrm{vol}}$,

$$\sum_{n\ge R}(1+n)^{D_{\mathrm{vol}}-1-s} \le (1+R)^{D_{\mathrm{vol}}-1-s} + \int_R^\infty (1+t)^{D_{\mathrm{vol}}-1-s}\,\mathrm{d}t \le \left(1+\frac{1}{s-D_{\mathrm{vol}}}\right)(1+R)^{D_{\mathrm{vol}}-s}.$$

Schur's test gives (142.46).

It remains to connect the operator bound to the Gaussian expectation. For $0 \le t \le 1$, let μ_t be the centered Gaussian law on $\mathbb{R}^A \oplus \mathbb{R}^B$ with covariance

$$\begin{pmatrix}\Gamma_{AA} & t\Gamma_{AB}\\ t\Gamma_{BA} & \Gamma_{BB}\end{pmatrix}.$$

The covariance is positive because it is obtained from the original Gaussian law by multiplying the B-component by an independent sign and averaging: $t = 2p-1$ for $p = (1+t)/2$. Differentiating the finite-dimensional Gaussian expectation with respect to t gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbb{E}_{\mu_t}[F_A F_B] = \sum_{x\in A, y\in B}\Gamma(x,y)\mathbb{E}_{\mu_t}[(\partial_x F_A)(\partial_y F_B)].$$

At $t=0$ the A and B variables are independent; at $t=1$ the law is the original marginal of μ_Γ on $A \cup B$. Integrating in t, applying Cauchy–Schwarz in the finite index sets, and using (142.46) gives (142.47). □

Lemma 142.8 is the replacement for exact factorization when the covariance shell is not finite range. The decay exponent, shell-count constant, derivative norm, and polymer separation enter the RG theorem as actual constants. A smooth momentum-shell covariance can supply such constants after integration by parts in momentum space; a sharp cutoff or a long-range covariance may fail to give the summability needed by the chosen polymer norm. This is why a rigorous Wilsonian proof states the covariance decomposition and cluster norm before using locality language.

Lemma 142.9 (Finite localization remainder and scaling gain)**.** *Let E be a finite-dimensional normed real vector space, let $F : E \to \mathbb{R}$ be C^{p+1} on the closed ball $\{\xi : \|\xi\| \le r\}$, and let*

$$(\mathcal{L}_{\le p}F)(\xi) = \sum_{n=0}^{p}\frac{1}{n!}D^nF(0)[\xi,\dots,\xi]$$

be the Taylor-localization map at the origin. If

$$M_{p+1}(r) = \sup_{\|\eta\|\le r}\|D^{p+1}F(\eta)\|_{\mathrm{op}},$$

then, for every $\|\xi\| \le r$,

$$|F(\xi) - (\mathcal{L}_{\le p}F)(\xi)| \le \frac{M_{p+1}(r)}{(p+1)!}\,\|\xi\|^{p+1}. \tag{142.48}$$

In a scalar block-spin chart with scale factor L*, dimension* D*, field scaling dimension* Δ_ϕ*, and one lattice difference carrying one inverse power of* L*, a local density monomial with* ν *fields and* m *lattice differences has canonical scaling exponent*

$$y_{\nu,m} = D - \nu\Delta_\phi - m. \tag{142.49}$$

Thus a Taylor-localization choice gives a linear irrelevant gain $L^{-\alpha}$ *only after the first omitted local monomials satisfy*

$$\alpha = \inf_{\text{omitted } (\nu,m)} \big(\nu\Delta_\phi + m - D\big) > 0. \tag{142.50}$$

Proof. The integral Taylor formula in finite dimension gives

$$F(\xi) - (\mathcal{L}_{\le p}F)(\xi) = \frac{1}{p!}\int_0^1 (1-s)^p D^{p+1}F(s\xi)[\xi,\dots,\xi]\,\mathrm{d}s.$$

Taking the operator norm and using $\int_0^1 (1-s)^p \mathrm{d}s = (p+1)^{-1}$ gives (142.48). For the scaling formula, write a fine field inside one coarse block as $\phi = L^{-\Delta_\phi}\phi'$. The sum or integral over a coarse block contains L^D fine cells, while each discrete difference contributes an additional factor L^{-1}. Hence the coefficient of a monomial with ν fields and m differences is multiplied, at the canonical linearized level, by

$$L^D L^{-\nu\Delta_\phi} L^{-m} = L^{D-\nu\Delta_\phi - m}.$$

The first omitted local monomial is contractive by a factor at most $L^{-\alpha}$ exactly when the exponents of all omitted monomials are $\le -\alpha$, which is (142.50). □

This lemma is finite-regulator bookkeeping, but it removes an important ambiguity. The localization map $\mathcal{L}_k$ in a polymer RG proof is a Taylor jet with a declared center, derivative norm, and retained local coordinate set. It must be paired with the derivative norm in (142.48), the field rescaling used in the chart, and a proof that the omitted Taylor coordinates are contractive in that chart. In canonical scalar bookkeeping at $D = 4$, $\Delta_\phi = 1$ makes ϕ^4 marginal and ϕ^6 irrelevant by two powers. In canonical bookkeeping at $D = 3$, $\Delta_\phi = \frac{1}{2}$ makes the ϕ^6 density marginal by (142.49); it cannot be discarded into the irrelevant remainder on engineering grounds alone. An interacting fixed-point proof may replace the canonical monomial coordinate list by scaling-field coordinates, but that replacement is itself part of the model-specific RG theorem.

Definition 142.10 (Local-coordinate extraction budget)**.** At scale k, let $E_{\mathrm{loc},k}$ be the finite-dimensional local coordinate space retained by the RG chart. A local-coordinate extraction datum consists of local basis elements

$$M_{a,k} \in E_{\mathrm{loc},k}, \qquad a \in A_k,$$

and continuous coordinate functionals

$$\ell_{a,k} : E_{\mathrm{loc},k} + \mathcal{K}_k \longrightarrow \mathbb{R}$$

such that

$$\ell_{a,k}(M_{b,k}) = \delta_{ab}. \tag{142.51}$$

The localization operator is

$$\mathcal{L}_k F = \sum_{a \in A_k} \ell_{a,k}(F)\, M_{a,k}.$$

The condition number of this coordinate extraction in the polymer norm is the finite quantity

$$\chi_k = \sum_{a \in A_k} \|\ell_{a,k}\|_{\mathcal{K}_k'}\, \|M_{a,k}\|_{\mathcal{K}_k}. \tag{142.52}$$

A uniform RG theorem must bound χ_k on the scale range on which the coordinate chart is used.

Let $\mathcal{A}_k$ denote one exact finite-regulator fluctuation step, including rescaling and reblocking, before the localization projection is applied. After the purely local part of the input has been propagated by the declared finite-dimensional local map $\mathcal{M}_k$, write the remaining one-step contribution as $F_k(g_k, K_k)$. The local-coordinate extraction budget is the pair of estimates

$$|\ell_{a,k+1}(F_k(g_k, K_k))| \le C^{(1)}_{a,k}\|K_k\|_{\mathcal{K}_k} + C^{(2)}_{a,k}\|K_k\|^2_{\mathcal{K}_k} + \varepsilon^g_{a,k}, \tag{142.53}$$

and

$$\|(1 - \mathcal{L}_{k+1})F_k(g_k, K_k)\|_{\mathcal{K}_{k+1}} \le A_{\mathrm{irr},k} L^{-\alpha_k}\|K_k\|_{\mathcal{K}_k} + B_{\mathrm{rem},k}\|K_k\|^2_{\mathcal{K}_k} + \varepsilon^K_k. \tag{142.54}$$

The budget separates two tasks that are often conflated. Equation (142.53) says how fluctuation integration and the polymer tail change the retained relevant or marginal coordinates. Equation (142.54) says how the omitted part becomes a controlled irrelevant activity. The first estimate feeds the finite-dimensional tuning equations; the second feeds the polymer contraction recursion. The constants are not formal labels: in a model proof they must be obtained from the finite-range or summable covariance bounds, the Taylor-localization derivative norms, the large-field regulator stability, and the finite polymer-overlap estimates.

The condition number χ_k is part of the same theorem. A basis of formal monomials and a list of coordinate functionals do not define a stable RG chart if the functionals become large in the polymer norm. In that case small errors in the exact finite-regulator step may produce uncontrolled local-coordinate errors after projection. Changing the retained coordinate basis is harmless only when the corresponding change-of-basis maps and their inverses are uniformly bounded in the norms used for (142.53) and (142.54).

Lemma 142.11 (Finite Gaussian stability of a quadratic large-field regulator)**.** *Let E be a finite-dimensional real Hilbert space, let $\Gamma : E \to E$ be positive semidefinite and self-adjoint, and let μ_Γ be the centered Gaussian law with covariance Γ. For $\kappa > 0$ assume*

$$2\kappa\|\Gamma\|_{\mathrm{op}} < 1.$$

Then, for every $\phi \in E$,

$$\int_E \exp\{\kappa\|\phi + \zeta\|^2\}\, \mathrm{d}\mu_\Gamma(\zeta) = \det(1 - 2\kappa\Gamma)^{-1/2} \exp\{\kappa\langle\phi, (1 - 2\kappa\Gamma)^{-1}\phi\rangle\}. \tag{142.55}$$

Consequently

$$\int_E \exp\{\kappa\|\phi + \zeta\|^2\}\, \mathrm{d}\mu_\Gamma(\zeta) \le C_\Gamma(\kappa)\, \exp\left\{\frac{\kappa}{1 - 2\kappa\|\Gamma\|_{\mathrm{op}}}\|\phi\|^2\right\}, \tag{142.56}$$

where $C_\Gamma(\kappa) = \det(1 - 2\kappa\Gamma)^{-1/2}$ on $(\ker\Gamma)^\perp$.

Proof. It is enough to work on $(\ker\Gamma)^\perp$. Choose an orthonormal basis diagonalizing Γ, with eigenvalues $\lambda_i > 0$. The integral is a product of one-dimensional integrals

$$\frac{1}{\sqrt{2\pi\lambda_i}}\int_{\mathbb{R}} \exp\left\{\kappa(\phi_i+\zeta_i)^2 - \frac{\zeta_i^2}{2\lambda_i}\right\} \mathrm{d}\zeta_i.$$

Since $2\kappa\lambda_i < 1$, completing the square gives

$$\kappa(\phi_i+\zeta_i)^2 - \frac{\zeta_i^2}{2\lambda_i} = -\left(\frac{1}{2\lambda_i} - \kappa\right)\left(\zeta_i - \frac{\kappa\phi_i}{\frac{1}{2\lambda_i}-\kappa}\right)^2 + \frac{\kappa}{1-2\kappa\lambda_i}\phi_i^2.$$

The Gaussian integral in the shifted variable contributes $(1-2\kappa\lambda_i)^{-1/2}$. Multiplying over i gives (142.55). Since $(1-2\kappa\lambda_i)^{-1} \le (1-2\kappa\|\Gamma\|_{\mathrm{op}})^{-1}$, the quadratic form in the exponent is bounded by the exponent in (142.56). □

Thus a large-field regulator such as $\exp\{\kappa\|\phi\|_X^2\}$ is stable under fluctuation integration only with a declared covariance spectral bound and with the next-scale regulator large enough to absorb the enlarged coefficient $\kappa(1-2\kappa\|\Gamma\|_{\mathrm{op}})^{-1}$. In a polymer RG theorem this finite estimate is combined with finite range or cluster decay and with Taylor localization. The constants $C_\Gamma(\kappa)$, the covariance spectral bound, and the regulator strengthening are part of the proof data entering A_{irr}, B_{pol}, $B_{\mathrm{tail},k}$, and the extraction defect.

Definition 142.12 (One-step polymer RG contraction estimates)**.** A one-step polymer RG contraction structure at scale k consists of the following finite-regulator data.

1. A scale factor $L > 1$, a reblocking map $X \mapsto \overline{X}$ from scale-k polymers to the smallest scale-$k+1$ polymer containing X, and a finite overlap constant

$$\mathfrak{C}_a = \sup_{\Delta\in\mathbb{B}_{k+1}} \sum_{\substack{X\in\mathcal{P}_k\\ \overline{X}\supset\Delta}} \exp\{-a|X|_k\} < \infty. \tag{142.57}$$

2. Large-field regulators $G_k(X,\phi) \ge 1$, analytic radii h_k, and a weighted polymer norm

$$\|K_k\|_{k,a,h} = \sup_{\Delta\in\mathbb{B}_k} \sum_{\substack{X\in\mathcal{P}_k\\ X\supset\Delta}} \exp\{a|X|_k\} \sup_{\phi\in\Phi_k} \frac{|K_k(X,\phi)|_{h_k}}{G_k(X,\phi)}. \tag{142.58}$$

   The seminorm $|\cdot|_{h_k}$ is the finite Taylor or analytic norm in the field variables used by the model. Its precise definition is part of the contraction structure, because the contraction constant depends on the allowed derivatives and on the large-field weights.

3. A localization map $\mathcal{L}_k$ from polymer functionals supported in one reblocked polymer to the chosen finite-dimensional local-coordinate space. The complementary projection $1-\mathcal{L}_k$ is the irrelevant remainder. After fluctuation integration and rescaling, denoted here by $\mathcal{A}_k$, the contraction structure includes constants $A_{\mathrm{irr}} < \infty$ and $\alpha > 0$ such that

$$\|(1-\mathcal{L}_k)\mathcal{A}_k K_k\|_{k+1,a,h} \le A_{\mathrm{irr}} L^{-\alpha} \|K_k\|_{k,a,h}. \tag{142.59}$$

   This is the analytic place where Taylor remainder estimates, covariance finite-range bounds, field rescaling, and large-field stability enter.

4. A quadratic product estimate for incompatible small polymers. For two activities define the scale-$k+1$ circle product by

$$(K_1 \circ_k K_2)(Y,\phi) = \sum_{\substack{X_1,X_2\in\mathcal{P}_k \\ \overline{X_1\cup X_2}=Y \\ X_1 \not\sim X_2}} K_1(X_1,\phi)\, K_2(X_2,\phi), \tag{142.60}$$

with the product understood after pulling both activities to the same reblocked field variables. The contraction structure requires a constant $B_{\mathrm{pol}} < \infty$ such that

$$\|K_1 \circ_k K_2\|_{k+1,a,h} \le B_{\mathrm{pol}} \|K_1\|_{k,a,h} \|K_2\|_{k,a,h}. \tag{142.61}$$

The constant B_{pol} is a consequence of the finite overlap constant $\mathfrak{C}_a$, the compatibility convention, and the multiplicative behavior of G_k. It is not a universal number.

The finite-overlap content can be made explicit at the level of scalar majorants. Put

$$M_i(X) = \sup_{\phi\in\Phi_k} \frac{|K_i(X,\phi)|_{h_k}}{G_k(X,\phi)}.$$

Suppose that the analytic norm and large-field regulator satisfy the submultiplicative estimate

$$\frac{|K_1(X_1,\phi)K_2(X_2,\phi)|_{h_{k+1}}}{G_{k+1}(\overline{X_1\cup X_2},\phi)} \le C_G\, M_1(X_1) M_2(X_2) \tag{142.62}$$

for every incompatible pair entering (142.60). Define the pair-overlap majorant

$$\mathfrak{C}_a^\circ = \sup_{\Delta\in\mathbb{B}_{k+1}} \sum_{\substack{X_1,X_2\in\mathcal{P}_k \\ X_1\not\sim X_2,\, \overline{X_1\cup X_2}\supset\Delta}} \exp\bigl\{a|\overline{X_1\cup X_2}|_{k+1} - a|X_1|_k - a|X_2|_k\bigr\}. \tag{142.63}$$

If $\mathfrak{C}_a^\circ < \infty$, then $B_{\mathrm{pol}} = C_G \mathfrak{C}_a^\circ$ is admissible in (142.61). Indeed, from (142.58),

$$M_i(X_i) \le e^{-a|X_i|_k} \|K_i\|_{k,a,h}$$

because the norm sum contains the term X_i for each block contained in X_i. Therefore, for each coarse block Δ,

$$\begin{aligned}
&\sum_{Y\supset\Delta} e^{a|Y|_{k+1}} \sup_\phi \frac{|(K_1\circ_k K_2)(Y,\phi)|_{h_{k+1}}}{G_{k+1}(Y,\phi)} \\
&\quad\le C_G \|K_1\|_{k,a,h}\|K_2\|_{k,a,h} \sum_{\substack{X_1,X_2 \\ X_1\not\sim X_2,\, \overline{X_1\cup X_2}\supset\Delta}} e^{a|\overline{X_1\cup X_2}|_{k+1} - a|X_1|_k - a|X_2|_k} \\
&\quad\le C_G \mathfrak{C}_a^\circ \|K_1\|_{k,a,h}\|K_2\|_{k,a,h}.
\end{aligned}$$

The model-specific proof must bound $\mathfrak{C}_a^\circ$ uniformly in the volume and scale. On a finite-range block lattice this is a geometric counting estimate; with long-range covariances or nonlocal blockings it may fail unless the polymer norm is strengthened.

5. If the fluctuation covariance is not finite range, separated compatible polymers also produce a connected bridge term. Let

$$\omega_k(R) = A_{\Gamma,k} C_{\mathrm{sh},k} \left(1 + \frac{1}{s_k - D_{\mathrm{vol},k}}\right) (1+R)^{D_{\mathrm{vol},k} - s_k}$$

be the covariance-tail bound from Lemma 142.8. Suppose the analytic polymer norm controls the derivative majorants

$$M_i^{\nabla}(X) = \sup_{\phi} \frac{\|\nabla_X K_i(X,\phi)\|_{2,h_k}}{G_k(X,\phi)} \le D_{\nabla,k} e^{-a|X|_k} \|K_i\|_{k,a,h}.$$

Define the separated-tail overlap constant

$$\mathfrak{C}^{\mathrm{tail}}_{a,\omega,k} = \sup_{\Delta \in \mathbb{B}_{k+1}} \sum_{\substack{X_1, X_2 \in \mathcal{P}_k \\ X_1 \sim X_2,\, \overline{X_1 \cup X_2} \supset \Delta}} e^{a|\overline{X_1 \cup X_2}|_{k+1} - a|X_1|_k - a|X_2|_k} \omega_k(d_k(X_1, X_2)) \,. \tag{142.64}$$

The connected Gaussian-interpolation bridge between separated polymers then obeys

$$\|\,\mathrm{Bridge}_{\Gamma_k}(K_1, K_2)\|_{k+1,a,h} \le C_G D^2_{\nabla,k} \mathfrak{C}^{\mathrm{tail}}_{a,\omega,k} \|K_1\|_{k,a,h} \|K_2\|_{k,a,h}. \tag{142.65}$$

This term is zero in the exact finite-range case once the compatibility separation exceeds the covariance range. For a smooth shell it is not zero: it is a second quadratic constant,

$$B_{\mathrm{tail},k} = C_G D^2_{\nabla,k} \mathfrak{C}^{\mathrm{tail}}_{a,\omega,k}, \qquad B_k^{(2)} = B_{\mathrm{pol}} + B_{\mathrm{tail},k}, \tag{142.66}$$

that must enter the one-step contraction budget. Treating a summably decaying covariance shell as if it were finite range is exactly the error of dropping $B_{\mathrm{tail},k}$.

6. A local-coordinate extraction error $\varepsilon_k \ge 0$, measured in the same polymer norm, accounting for the difference between the exact finite-regulator RG step and the chosen local chart. In a fully exact chart $\varepsilon_k = 0$; in a truncated chart it is a theorem-level remainder and must be estimated.

The preceding datum turns contraction of the irrelevant activity into a finite inequality. If

$$x_k = \|K_k\|_{k,a,h}, \qquad q = A_{\mathrm{irr}} L^{-\alpha}, \qquad B_k^{(2)} = B_{\mathrm{pol}} + B_{\mathrm{tail},k},$$

then the linear estimate (142.59), the quadratic product estimate (142.61), the tail bridge (142.65), and the extraction error give the one-step bound

$$x_{k+1} \le q x_k + B_k^{(2)} x_k^2 + \varepsilon_k. \tag{142.67}$$

Consequently a closed radius-r polymer ball is invariant with contraction margin $\theta < 1$ whenever

$$q + B_k^{(2)} r + \frac{\varepsilon_k}{r} \le \theta < 1 \qquad \text{uniformly in } k. \tag{142.68}$$

Indeed, $x_k \le r$ gives

$$x_{k+1} \le \left(q + B_k^{(2)} r + \frac{\varepsilon_k}{r}\right) r \le \theta r.$$

This is elementary arithmetic, but it is the arithmetic that fixes the meaning of the polymer estimate: every proof must exhibit the norm, the large-field regulator, the localization operator, the finite overlap bound, the covariance-tail bridge bound when exact finite range is absent, and the uniform smallness inequality. Without these data the displayed contraction is a slogan, not a Wilsonian RG theorem.

The same data must be controlled as a sequence of scales, not only at one scale. Suppose that, for $0 \le j < n$, the trajectory stays in the radius-r polymer ball and

$$q + B_j^{(2)} r \le \theta < 1 \qquad (0 \le j < n).$$

Then (142.67) implies the forced linear recursion

$$x_{j+1} \le \theta x_j + \varepsilon_j \qquad (0 \le j < n),$$

and iteration gives

$$x_n \le \theta^n x_0 + \sum_{j=0}^{n-1} \theta^{\,n-1-j} \varepsilon_j. \tag{142.69}$$

Thus a scale-dependent extraction error is harmless only after its weighted sum is controlled. If $\varepsilon_j \le E\sigma^j$ with $0 < \sigma < 1$, then

$$\sum_{j=0}^{n-1} \theta^{\,n-1-j} \varepsilon_j \le E\frac{\theta^n - \sigma^n}{\theta - \sigma} \quad (\theta \ne \sigma), \qquad \le En\theta^{n-1} \quad (\theta = \sigma). \tag{142.70}$$

For a nondecaying uniform defect $\varepsilon_j \le E$, the corresponding bound is

$$x_n \le \theta^n x_0 + \frac{E(1-\theta^n)}{1-\theta}.$$

Consequently the ball of radius r is invariant for all scales under the stronger smallness condition

$$x_0 + \frac{E}{1-\theta} \le r \tag{142.71}$$

in the uniform-forcing case, or under the analogous supremum of the weighted geometric sum in the decaying case. These estimates are still only bookkeeping; the model-specific constructive theorem must prove the bounds on q, $B_j^{(2)}$, r, and ε_j from the covariance, localization, and large-field regulators.

Lemma 142.13 (Finite source-window extraction and propagated cumulant error)**.** *Let B_j be Banach spaces and let $R_j(J) \in B_j$ be holomorphic on a neighborhood of the closed polydisc*

$$P_{\rho_j} = \{J \in \mathbb{C}^m : \ |J_a| \le \rho_{j,a}, \ 1 \le a \le m\}.$$

Set

$$\eta_j = \sup_{J \in P_{\rho_j}} \|R_j(J)\|_{B_j}.$$

For an integer $s_j \ge 0$, let $\mathcal{T}^{\mathrm{src}}_{\le s_j} R_j$ be the Taylor polynomial in J containing all monomials of total source degree at most s_j. If $\beta = (\beta_1, \dots, \beta_m)$ is a multi-index and

$$\rho_j^\beta = \prod_{a=1}^m \rho_{j,a}^{\beta_a}, \qquad \beta! = \prod_{a=1}^m \beta_a!,$$

then

$$\partial_J^\beta\big(R_j - \mathcal{T}^{\mathrm{src}}_{\le s_j} R_j\big)(0) = 0 \qquad (|\beta| \le s_j), \tag{142.72}$$

and, for arbitrary β,

$$\Big\|\partial_J^\beta\big(R_j - \mathcal{T}^{\mathrm{src}}_{\le s_j} R_j\big)(0)\Big\|_{B_j} \le \frac{\beta!}{\rho_j^\beta}\,\eta_j. \tag{142.73}$$

Suppose moreover that the error in a reconstructed connected source window at scale N is obtained by propagating the source-extraction tails through bounded linear maps

$$U_{j\to N,\beta} : B_j \longrightarrow \mathcal{O}_\beta, \qquad p_\beta(U_{j\to N,\beta} v) \le P_{j,N,\beta}\|v\|_{B_j},$$

where p_β is the seminorm of the declared β-source observable window. Then the accumulated β-window error satisfies

$$p_\beta(\Delta O_{N,\beta}) \le \sum_{\substack{0\le j<N \\ s_j<|\beta|}} P_{j,N,\beta}\,\frac{\beta!}{\rho_j^\beta}\,\eta_j. \tag{142.74}$$

Proof. The Taylor polynomial contains exactly the source monomials of total degree at most s_j, hence the derivative in (142.72) vanishes for $|\beta| \le s_j$. For $|\beta| > s_j$, the β-derivative of the tail at the origin is the β-derivative of R_j. Use the Banach-valued Cauchy integral formula on the distinguished boundary $|Z_a| = \rho_{j,a}$:

$$\partial_J^\beta R_j(0) = \frac{\beta!}{(2\pi i)^m}\int_{|Z_1|=\rho_{j,1}}\cdots\int_{|Z_m|=\rho_{j,m}} \frac{R_j(Z)}{Z^{\beta+1}}\,\mathrm{d}Z_1\cdots\mathrm{d}Z_m.$$

Taking the B_j-norm and using the boundary length factors gives (142.73). The propagated estimate follows by applying $U_{j\to N,\beta}$ to each scale-j source-tail derivative, using its operator bound, and summing over scales. Terms with $s_j \ge |\beta|$ vanish by (142.72). □

Thus a source-extended polymer RG chart must declare which source monomials are retained and which source derivatives of the connected generating functional are being reconstructed. To control all n-point Schwinger distribution windows in a fixed test-function family, the source-coordinate system must retain source degree at least n, or it must prove the Cauchy-tail sum (142.74). A scalar fixed-point trajectory without this source-extension estimate is a theorem about the partition function or un-sourced activity only; it is not yet a theorem about the reconstructed local QFT correlators.

For ordinary short-range critical scalar models, the unresolved work is to construct this datum with constants uniform along the tuned critical trajectory and with source extensions strong enough for reconstructed correlation functions. For gauge theories, the same structure must be built on gauge-invariant lattice activities or in a BV-compatible finite-regulator chart; a gauge-fixed formal activity without the quantum master equation or a gauge-invariant blocking map is not a Wilsonian gauge-theory construction in the sense used here.

142.8 Fixed Points And Continuum Limits

A continuum limit is obtained by tuning the unstable coordinates so that the RG trajectory remains near a fixed point for arbitrarily many steps and then converges, after reconstruction, to regulator-independent correlation functions. The existence of a non-Gaussian fixed point as a Banach-space fixed point is a theorem only after the RG map, norm, domain, and estimates are supplied. Perturbative beta functions and numerical fixed-point searches are evidence for a coordinate chart; they do not replace the fixed-point construction.

Definition 142.14 (Theorem-level nonperturbative RG fixed point)**.** A nonperturbative Wilsonian fixed-point theorem consists of the following declared data.

1. A regulator class and a concrete RG map $\mathcal{R} : \mathcal{U} \to \mathcal{B}$ on an open subset $\mathcal{U}$ of a Banach space $(\mathcal{B}, \|\cdot\|)$ of interactions, measures, tensors, or polymer activities.
2. A proof that the map is defined on the claimed domain and is differentiable to the order used in the argument.
3. A point $V_* \in \mathcal{U}$ satisfying $\mathcal{R}(V_*) = V_*$, or a periodic orbit when the intended RG structure is not a fixed point.
4. A spectral or graph-transform analysis of $D\mathcal{R}|_{V_*}$, including the relevant, marginal, irrelevant, and redundant subspaces in the chosen norm.
5. A reconstruction map from the tuned sequence of finite-cutoff theories to correlation functions, local algebras, or Euclidean Schwinger functions, with convergence estimates sufficient for the claimed QFT framework.

The word "fixed point" in a theorem of this kind refers to the specified map $\mathcal{R}$ and norm. A zero of a truncated beta function, a solution of a finite-dimensional functional-RG truncation, or a numerical tensor-RG fixed point is evidence for such a theorem only after an embedding into this list has been supplied.

Theorem 142.15 (Validated fixed point by a Newton–Kantorovich estimate)**.** *Let $\mathcal{B}$ be a Banach space, let $F : \mathcal{U} \to \mathcal{B}$ be a C^1 map on an open ball $B_R(V_0) \subset \mathcal{U}$, and let*

$$F(V) = \mathcal{R}(V) - V.$$

Assume that $A : \mathcal{B} \to \mathcal{B}$ is bounded and injective, and that there are constants $\eta, \rho, L \geq 0$ with

$$\|AF(V_0)\| \leq \eta, \tag{142.75}$$
$$\|1 - A\,DF(V_0)\|_{\mathcal{B}\to\mathcal{B}} \leq \rho, \tag{142.76}$$
$$\|A(DF(V) - DF(W))\|_{\mathcal{B}\to\mathcal{B}} \leq L\|V - W\| \qquad (V, W \in B_R(V_0)). \tag{142.77}$$

If there is $r \leq R$ such that

$$\eta + \rho r + \frac{L}{2} r^2 \leq r, \qquad \rho + Lr < 1, \tag{142.78}$$

then $F(V) = 0$ has a unique solution V_* in the closed ball $\overline{B}_r(V_0)$. Equivalently, $\mathcal{R}(V_*) = V_*$.

Proof. Define the Newton-like map

$$\mathcal{N}(V) = V - AF(V).$$

For $V \in \overline{B}_r(V_0)$, the fundamental theorem of calculus gives

$$\mathcal{N}(V) - V_0 = -AF(V_0) + \int_0^1 \big(1 - A\,DF(V_0 + s(V - V_0))\big)(V - V_0)\,\mathrm{d}s.$$

Using (142.75) and (142.77), the norm of the right-hand side is bounded by

$$\eta + \rho r + \frac{L}{2} r^2,$$

which is at most r by (142.78). Thus $\mathcal{N}$ maps $\overline{B}_r(V_0)$ into itself. For $V, W \in \overline{B}_r(V_0)$,

$$\mathcal{N}(V) - \mathcal{N}(W) = \int_0^1 \big(1 - A\, DF(W + s(V - W))\big)(V - W)\, \mathrm{d}s,$$

and the same estimates give

$$\|\mathcal{N}(V) - \mathcal{N}(W)\| \le (\rho + Lr)\|V - W\|.$$

The coefficient is strictly less than one, so Banach's fixed-point theorem gives a unique fixed point of $\mathcal{N}$ in the ball. If $\mathcal{N}(V_*) = V_*$, then $AF(V_*) = 0$. Since A is injective, $F(V_*) = 0$. Conversely any zero of F is a fixed point of $\mathcal{N}$, so uniqueness follows. □

This theorem isolates the final functional-analytic step after RG estimates have been supplied. The difficult part in constructive RG is to choose $\mathcal{B}$, V_0, and A, and then prove (142.75)–(142.77) with constants small enough that (142.78) holds. In polymer RG this means summing tree or cluster expansions with large-field regulators; in tensor RG it means proving that the disentangled coarse-graining map is a contraction on a neighborhood that is stable under the infinite-dimensional map.

142.9 Projection Truncations And Residual Control

Finite-dimensional RG calculations enter the monograph only through a declared projection. Let $P_N : \mathcal{B} \to \mathcal{B}_N$ be a bounded projection onto a finite-dimensional subspace and put $Q_N = 1 - P_N$. For

$$F(V) = \mathcal{R}(V) - V,$$

the projected fixed-point equation is

$$P_N F(V_N) = 0, \qquad V_N \in \mathcal{B}_N. \tag{142.79}$$

The complement residual is

$$\epsilon_N(V_N; A) = \|AQ_N F(V_N)\|, \tag{142.80}$$

where A is the approximate inverse used in the Newton–Kantorovich estimate.

Example 142.16 (Spurious projected zeros)**.** Projection residuals must be controlled in the omitted directions. The finite-dimensional model $\mathcal{B} = \mathbb{R}^2$, $P(x, y) = (x, 0)$, and

$$F(x, y) = (0, 1).$$

has $PF(x, 0) = 0$ for every $x \in \mathbb{R}$, while the second component of $F(x, y)$ is identically one. Thus the entire projected line solves (142.79), and no point of the full space solves $F(V) = 0$. The residual $\epsilon_N(V_N; A) = \|AQ_N F(V_N)\|$ is the datum that detects this failure in the Newton–Kantorovich lifting problem.

Lifting a projected RG zero. Let $V_N \in \mathcal{B}_N$ solve (142.79). Suppose the hypotheses of Theorem 142.15 hold with $V_0 = V_N$. Then a true fixed point V_* of $\mathcal{R}$ exists in $\overline{B}_r(V_N)$ whenever

$$\epsilon_N(V_N; A) + \rho r + \frac{L}{2} r^2 \leq r, \qquad \rho + Lr < 1. \tag{142.81}$$

Since $P_N F(V_N) = 0$, the full residual is

$$F(V_N) = Q_N F(V_N).$$

Therefore

$$\|AF(V_N)\| = \|AQ_N F(V_N)\| = \epsilon_N(V_N; A).$$

The conditions in (142.81) are exactly the Newton–Kantorovich conditions (142.78) with $\eta = \epsilon_N(V_N; A)$. Theorem 142.15 then gives a unique zero of F in $\overline{B}_r(V_N)$, equivalently a fixed point of $\mathcal{R}$.

Controlled Approximation 142.17 (Projected fixed points as observable approximants)**.** The projected point V_N becomes an approximation to QFT data only after the lift estimate is paired with reconstruction estimates. Let $\mathcal{O}$ be a locally convex observable space with seminorms $\{p_\alpha\}$, and let

$$\mathrm{Rec} : \overline{B}_r(V_N) \longrightarrow \mathcal{O}$$

be the reconstruction map for the exact RG chart on the same ball as in (142.81). Suppose that for each finite observable window α there is a Lipschitz constant $L_\alpha(r)$ such that

$$p_\alpha(\mathrm{Rec}(V) - \mathrm{Rec}(W)) \leq L_\alpha(r)\|V - W\|_{\mathcal{B}}, \qquad V, W \in \overline{B}_r(V_N). \tag{142.82}$$

If the finite-dimensional calculation also reports a projected observable $\mathrm{Rec}_N(V_N)$ with chart error

$$p_\alpha(\mathrm{Rec}_N(V_N) - \mathrm{Rec}(V_N)) \leq \delta_{N,\alpha}, \tag{142.83}$$

then the lifted fixed point V_* supplied by (142.81) obeys

$$p_\alpha(\mathrm{Rec}_N(V_N) - \mathrm{Rec}(V_*)) \leq \delta_{N,\alpha} + L_\alpha(r) r. \tag{142.84}$$

The estimate is only a controlled approximation on the displayed finite window. It does not prove a continuum limit, an OS-positive hierarchy, or a universality statement unless the residual bound, the Newton–Kantorovich constants, the Lipschitz constants, and the observable chart errors are controlled on the directed family of windows used for reconstruction.

Indeed, the lifted fixed point satisfies $\|V_* - V_N\|_{\mathcal{B}} \leq r$. The triangle inequality and (142.82) give

$$p_\alpha(\mathrm{Rec}_N(V_N) - \mathrm{Rec}(V_*)) \leq p_\alpha(\mathrm{Rec}_N(V_N) - \mathrm{Rec}(V_N)) + L_\alpha(r)\|V_N - V_*\|_{\mathcal{B}},$$

which is (142.84) by (142.83). The load-bearing data are the residual and reconstruction constants that a finite-dimensional fixed point computation must report: (142.81) and (142.84). With those constants controlled on the directed observable family, projected observables become finite-window approximants to the lifted fixed-point reconstruction; without them, the projected calculation remains a finite-dimensional coordinate calculation.

The companion calculation

`calculation-checks/rg_projection_checks.py` checks these finite-dimensional algebraic examples with exact rational arithmetic, including the residual-lift and finite-window observable-error budget. In an actual Wilsonian RG proof, the hard work is to bound $\epsilon_N(V_N; A)$, ρ, L, the reconstruction constants $L_\alpha(r)$, and the chart errors $\delta_{N,\alpha}$ in the infinite-dimensional norm and in the directed observable topology, not to solve the projected equation.

142.10 Constructive Fixed-Point Output Data

The most useful rigorous fixed-point examples produce a fixed interaction together with correlation and response functions whose remainders are controlled in a declared norm. The following output record is the minimum structure recorded in this monograph when using the recent long-range fermionic RG constructions as a benchmark.

Definition 142.18 (Constructive fermionic fixed-point output)**.** A constructive fermionic fixed-point output consists of:

1. a finite ultraviolet cutoff and a Grassmann Gaussian covariance C_Λ, including its scaling law;
2. a Banach space $\mathcal{B}_{\mathrm{ker}}$ of antisymmetric interaction kernels, with a norm controlling decay, differentiability, and scale weights;
3. an exact RG map $\mathcal{R}$ on an open subset of $\mathcal{B}_{\mathrm{ker}}$, defined by Grassmann Gaussian integration, localization of relevant coordinates, and rescaling;
4. a fixed interaction $V_* \in \mathcal{B}_{\mathrm{ker}}$, satisfying $\mathcal{R}(V_*) = V_*$;
5. source coordinates for the field and for the density, with scaling dimensions $[\psi]$ and $[J]$;
6. response functions constructed from the fixed-point generating functional, together with scale-covariance estimates and explicit remainders.

This is fixed-cutoff constructive RG output. A continuum-QFT theorem requires an additional removal or interpretation of the cutoff in the observable topology being claimed.

Quoted Theorem 142.19 (Long-range fermionic ψ^4_d fixed point)**.** *For the long-range fermionic ψ^4_d model in dimensions $d = 1, 2, 3$, with fractional kinetic term chosen so that the quartic interaction is weakly relevant, there is a small-parameter regime in which the constructive RG map has a nontrivial fixed interaction V_* in the Banach space of kernels. With a fixed ultraviolet cutoff, the field and density response functions at V_* are constructed by convergent tree expansions. The field exponent is the naive exponent, while the density exponent is anomalous and analytic in the small parameter. The associated scaling operators have two-point functions that are scale covariant up to a stretched-exponential large-distance remainder controlled by the ultraviolet cutoff.*

Status of the quoted theorem. This is the theorem-level output of the GMR and GMRS constructive RG works just quoted. Its proof constructs V_* in an infinite-dimensional kernel space and controls the irrelevant tail by a convergent multiscale tree expansion. The theorem is quoted here as a state-of-the-art benchmark for what a nonperturbative Wilsonian fixed-point statement must contain. The monograph uses the theorem to calibrate the form of a complete RG claim, while separate scalar and gauge theory claims in this book require their own estimates.

Kernel-space mechanism in the fermionic benchmark. The fermionic example supplies a constructive fixed point by building an invariant infinite-dimensional kernel space and proving that the RG map closes on it. Write a source-extended monomial by a label

$$\alpha = (n, m, \ell, p), \qquad p = (p_1, \dots, p_\ell), \quad p_i \in \{0, 1\},$$

where n counts field sources φ, m counts density sources J, ℓ counts fermion fields ψ, and $|p|_1 = \sum_i p_i$ counts derivatives on the fermion fields. The associated coordinate is a translation-invariant kernel

$$H_\alpha(x_1, \dots, x_n; y_1, \dots, y_m; z_1, \dots, z_\ell)$$

with the internal antisymmetries imposed by the Grassmann variables and with finite pinned L^1 norm, obtained by integrating the absolute value over all but one spacetime variable and then taking the supremum over internal indices. The fixed point is therefore a sequence $H = \{H_\alpha\}_\alpha$, not a finite polynomial in local fields.

Let the fermion scaling dimension be

$$[\psi] = \frac{d}{4} - \frac{\epsilon}{2},$$

and let the source fields φ and J scale with dimensions $d - \Delta_1$ and $d - \Delta_2$. Equivalently, Δ_1 and Δ_2 are the dimensions of the scaling operators whose response functions are generated by differentiating with respect to φ and J. If the scale factor is γ, the dilatation of a pinned L^1 kernel has exponent

$$D_{\mathrm{sc}}(\alpha) = d - n(d - \Delta_1) - m(d - \Delta_2) - \ell[\psi] - |p|_1. \tag{142.85}$$

Thus $\|DH_\alpha\|_1 = \gamma^{D_{\mathrm{sc}}(\alpha)} \|H_\alpha\|_1$ in the kernel norm before the additional Gevrey or stretched-exponential weights are applied. With $\Delta_1 = [\psi] + O(\epsilon)$ and $\Delta_2 = 2[\psi] + O(\epsilon)$, the exceptional local block separated by the trimming chart consists of the mass-type bilinear $(0, 0, 2, 0)$, the quartic $(0, 0, 4, 0)$, the source-field coordinate $(1, 0, 1, 0)$, the density-source coordinate $(0, 1, 2, 0)$, and the first-derivative bilinears $(0, 0, 2, p)$ with $|p|_1 = 1$. This list is not being introduced as a finite truncation of the theory: $(0, 1, 2, 0)$ may be weakly irrelevant depending on the sign of $\Delta_2 - 2[\psi]$, and the first-derivative bilinears are irrelevant in $d = 1$ for small ϵ. They are kept in the local block because their scaling exponents are close enough to zero, or because a uniform trimmed coordinate system for $d = 1, 2, 3$ makes the localization/interpolation estimates stable. For example,

$$D_{\mathrm{sc}}(0, 0, 4, 0) = d - 4[\psi] = 2\epsilon, \qquad D_{\mathrm{sc}}(0, 0, 2, 0) = d - 2[\psi] = \frac{d}{2} + \epsilon. \tag{142.86}$$

The quartic coordinate is weakly relevant for $\epsilon > 0$, which is why a small non-Gaussian fixed point can be searched for near the Gaussian one.

The invariant space is obtained by a trimming operation. The kernels in the finite exceptional local list are represented by local delta-functions with constant coefficients. The nonlocal part of those same kernels is subtracted and rewritten in derivative coordinates, so that it enters the irrelevant Banach component. All remaining coordinates live in a kernel space whose norm controls pinned L^1 size, internal index sums, scale weights, and short-range decay. Schematically, one writes

$$H = (g, K), \qquad g \in \mathbb{C}^r, \quad K \in \mathcal{K},$$

where g is the finite vector of local trimmed coordinates and $\mathcal{K}$ is the Banach space of irrelevant nonlocal kernels. One RG step has the form

$$(g, K) \longmapsto \big(A_{\mathrm{loc}} g + B_{\mathrm{loc}}(g, K),\ A_{\mathrm{irr}} K + B_{\mathrm{irr}}(g, K)\big), \tag{142.87}$$

after fluctuation integration, trimming, and rescaling. The theorem's analytic burden is to prove this map on a ball in $\mathbb{C}^r \oplus \mathcal{K}$, with estimates of the form

$$\|A_{\mathrm{irr}}\| \le q < 1, \qquad \|B_{\mathrm{irr}}(g, K) - B_{\mathrm{irr}}(g', K')\| \le c\,(|g| + |g'| + \|K\| + \|K'\|)\,(|g - g'| + \|K - K'\|), \tag{142.88}$$

and corresponding finite-dimensional equations for g. The fixed point is the simultaneous solution of both the local equation and

$$K = A_{\mathrm{irr}} K + B_{\mathrm{irr}}(g, K). \tag{142.89}$$

Dropping (142.89) would reduce the argument to a projected beta-function calculation and would miss exactly the part of the theorem that makes the construction nonperturbative.

The determinant expansion used in the fermionic construction is also part of the mechanism. The Grassmann Gaussian integration reorganizes the multiscale series into determinants of covariance matrices, and Gram-type determinant bounds give absolute convergence in the kernel norm. This is why the fermionic example presently reaches a level of rigor not available for the ordinary short-range scalar critical point: the invariant kernel space and the convergent determinant/tree expansion are proved together. The monograph uses this as a proof template, not as evidence that the scalar or gauge targets are settled.

Remark 142.20 (Irrelevant tails are part of the theorem). Let $\mathcal{B} = \mathbb{R}^m \oplus \mathcal{K}$, where $\mathcal{K}$ is a Banach space of irrelevant kernels, and let $P : \mathcal{B} \to \mathbb{R}^m$ be the coordinate projection. A solution of the projected equation

$$P(\mathcal{R}(g, 0) - (g, 0)) = 0$$

does not define a fixed point of $\mathcal{R}$ unless the irrelevant residual

$$Q(\mathcal{R}(g, 0) - (g, 0)) \in \mathcal{K}$$

is either zero or is absorbed by a controlled graph $K = h(g)$ satisfying the full fixed-point equation. Write $Q = 1 - P$. If $V = (g, 0)$ solves only the projected equation, then

$$\mathcal{R}(V) - V = (0, Q(\mathcal{R}(V) - V)).$$

Thus V is a fixed point if and only if the displayed irrelevant residual vanishes. More generally, a fixed point with the same local coordinates must have the form $V_h = (g, h(g))$ and satisfy

$$P(\mathcal{R}(V_h) - V_h) = 0, \qquad Q(\mathcal{R}(V_h) - V_h) = 0.$$

The second equation is the irrelevant-tail equation. In a constructive RG proof it is solved by contraction, graph transform, or Newton validation in the norm of $\mathcal{K}$; without such a bound, the projected equation is only a coordinate calculation.

142.11 Hierarchical Scalar Fixed-Point Benchmark

Scalar non-Gaussian fixed points provide the most familiar physical target for Wilsonian RG, but the mathematical status depends strongly on the map being studied. The hierarchical scalar models form a class in which the block-spin map is an explicitly defined nonlinear integral operator. They are not the short-range nearest-neighbor lattice ϕ^4 models, and a theorem for the hierarchical map is not, by itself, a theorem for the ordinary three-dimensional Ising or ϕ^4 fixed point. They are nevertheless an essential benchmark because the fixed point, unstable directions, and irrelevant remainder can be treated in a genuine infinite-dimensional RG problem rather than in a finite beta-function truncation.

Definition 142.21 (Hierarchical scalar RG system)**.** A one-component hierarchical scalar RG system consists of:

1. a scale factor $L > 1$, a dimension parameter $D > 0$, and $b = L^D$;
2. a field scaling exponent $\Delta > 0$, a number $a = L^{-\Delta}$, and a fluctuation variance $\gamma > 0$;
3. a Banach space $\mathcal{B}_{\text{hier}}$ of even real-analytic functions $V : \mathbb{R} \to \mathbb{R}$, modulo additive constants, with a norm controlling a complex strip or disk and large-field growth;
4. the nonlinear map $\mathcal{R}_{\text{hier}}$ defined, whenever the integral is finite and analytic in the chosen domain, by
$$e^{-(\mathcal{R}_{\text{hier}}V)(\Phi)} = Z_V^{-1} \int_{\mathbb{R}} \exp[-b\,V(a\Phi + \zeta)]\, \frac{e^{-\zeta^2/(2\gamma)}}{\sqrt{2\pi\gamma}}\, \mathrm{d}\zeta, \tag{142.90}$$
where Z_V is fixed by the normalization $(\mathcal{R}_{\text{hier}}V)(0) = 0$.

This is a mathematical RG system. The hierarchical covariance and the normalization convention are part of the definition; they are not inferred from a continuum path integral after the fact.

The linearization at the Gaussian point already shows the local-coordinate arithmetic that underlies the usual relevance labels. The following calculation is exact for the hierarchical Gaussian kernel and does not use a formal momentum shell.

Gaussian linearization in Wick coordinates. Let $0 < a < 1$, $\gamma > 0$, and
$$c_* = \frac{\gamma}{1 - a^2}.$$
For $n \geq 0$, define the Wick polynomial $: x^n :_{c_*}$ by
$$\exp\left(tx - \frac{c_* t^2}{2}\right) = \sum_{n=0}^{\infty} \frac{t^n}{n!}\ : x^n :_{c_*}\ . \tag{142.91}$$
The derivative of $\mathcal{R}_{\text{hier}}$ at $V = 0$, before quotienting the additive constant, acts on the nonconstant Wick coordinates by
$$D\mathcal{R}_{\text{hier}}|_0\big(: \Phi^n :_{c_*}\big) = b\, a^n : \Phi^n :_{c_*}, \qquad n \geq 1. \tag{142.92}$$
In the canonical scalar bookkeeping
$$\Delta = \frac{D-2}{2}, \qquad b = L^D,$$
the even local coordinate $: \Phi^{2r} :$ has engineering eigenvalue
$$\lambda_{2r} = L^{y_{2r}}, \qquad y_{2r} = D - r(D-2). \tag{142.93}$$

Thus $y_2 = 2$, $y_4 = 4 - D$, and $y_6 = 6 - 2D$. For the first variation of (142.90), additive normalization affects only the constant coordinate. Hence for a nonconstant test direction f,

$$D\mathcal{R}_{\mathrm{hier}}|_0 f = b \int_{\mathbb{R}} f(a\Phi + \zeta)\, \mathrm{d}\mu_\gamma(\zeta) \quad \text{mod constants,} \tag{142.94}$$

where $\mathrm{d}\mu_\gamma$ is the centered Gaussian measure of variance γ. Apply this to the generating function (142.91). Since $c_* - \gamma = a^2 c_*$,

$$\begin{aligned}\int \exp\left(t(a\Phi + \zeta) - \frac{c_* t^2}{2}\right) \mathrm{d}\mu_\gamma(\zeta) &= \exp\left(ta\Phi - \frac{(c_* - \gamma)t^2}{2}\right)\\ &= \exp\left(ta\Phi - \frac{a^2 c_* t^2}{2}\right)\\ &= \sum_{n=0}^{\infty} \frac{t^n}{n!}\, a^n :\Phi^n:_{c_*}\ .\end{aligned}$$

Comparing coefficients gives the factor a^n; the prefactor b in (142.94) gives (142.92). Substituting $a = L^{-(D-2)/2}$ and $n = 2r$ gives

$$b\, a^{2r} = L^D L^{-r(D-2)} = L^{D - r(D-2)},$$

which is (142.93).

Quoted Theorem 142.22 (Hierarchical scalar non-Gaussian fixed point)**.** *For the Dyson–Wilson hierarchical scalar RG maps in the Bleher–Sinai and Collet–Eckmann class, and for the closely related $\phi^4_{3,\epsilon}$ RG construction of Brydges–Mitter–Scoppola,*[1] *there are parameter regimes in which a non-Gaussian fixed point exists as an element of a Banach space of analytic or polymer interactions. In these regimes the theorem supplies an RG map, a domain and norm, a fixed interaction V_*, a finite-dimensional unstable subspace, contraction or graph estimates for the stable directions, and scaling estimates for the corresponding hierarchical or $\phi^4_{3,\epsilon}$ observable data.*

Status of the quoted theorem. The theorem is quoted as a benchmark, not as an imported proof for the ordinary short-range three-dimensional scalar fixed point. Its mathematical content is that the non-Gaussian fixed point is an element of the specified infinite-dimensional RG domain and that the irrelevant coordinates are controlled by estimates in that domain. The hierarchical proofs exploit the recursive structure of the covariance; the $\phi^4_{3,\epsilon}$ construction uses a multiscale decomposition and polymer estimates adapted to the fractional covariance. In both cases the result is stronger than locating a zero of a finite beta function and weaker than a construction of the short-range ϕ^4_3 Wilson–Fisher CFT. That last comparison would require a theorem relating the short-range block-spin map and reconstruction data to one of these fixed-point systems.

The companion calculation

142.12 Current Rigorous Fixed-Point Benchmarks

The preceding definition deliberately separates what has been proved from what is inferred from formal or numerical RG. Recent rigorous work supplies benchmarks for both the constructive-field-theory and tensor-network versions of the problem.

The hierarchical scalar results just described are the cleanest scalar examples of theorem-level non-Gaussian Wilsonian fixed points. Their role in this chapter is deliberately calibrated: they prove that scalar non-Gaussian fixed points can be constructed in rigorous RG systems with irrelevant tails, but they do not settle the ordinary short-range three-dimensional scalar fixed point.

In the long-range fermionic ψ_d^4 models analyzed by Giuliani, Mastropietro, Rychkov, and collaborators,[2] the Banach space contains all short-ranged irrelevant kernels, not only a finite list of couplings. The fixed interaction is constructed by a convergent RG scheme with a small parameter controlling the relevance of the quartic interaction. The important lesson for this monograph is structural: the fixed point is an element of an infinite-dimensional space, the irrelevant tail is part of the theorem rather than a truncation error, and scaling operators are constructed as response functions with stated remainder estimates.

In the rigorous tensor-RG work of Kennedy and Rychkov,[3] the map acts on infinite-dimensional tensors. The theorem is not a statement about the naive contraction of four tensors, which fails to be contractive near the high-temperature fixed point; it is a statement about a modified RG map with a disentangling step and a Hilbert–Schmidt neighborhood on which contraction estimates are proved. The low-temperature analysis gives stable ordered fixed points and a discontinuity fixed point for first-order transition behavior. These examples illustrate why the RG map itself is part of the theorem: changing the coarse-graining prescription changes the mathematical assertion being made.

Functional RG equations such as the Wetterich equation are exact identities at finite regulator, as derived in Chapter 36. A finite-dimensional truncation of such an equation can be an excellent computational scheme, but the theorem-level fixed-point claim requires an error estimate comparing the truncated subspace with the full Banach space. The same distinction applies to perturbative epsilon expansions: the formal fixed point organizes local coordinates and critical exponents order by order, while a nonperturbative fixed-point theorem additionally proves existence, stability, and reconstruction.

Controlled Approximation 142.23 (Functional-RG truncations as projected flows)**.** Let $\mathcal{B}_\Gamma$ be a Banach space of regulated effective-average actions, and write the exact finite-regulator Wetterich equation as

$$\dot{\Gamma}_t = \mathcal{F}_t(\Gamma_t), \qquad \mathcal{F}_t(\Gamma) = \frac{1}{2}\,\mathrm{Tr}\Big[\big(\Gamma^{(2)} + R_t\big)^{-1}\dot{R}_t\Big]$$

on a domain where the inverse Hessian and trace define an element of $\mathcal{B}_\Gamma$. Let $P_N : \mathcal{B}_\Gamma \to \mathcal{B}_N$ be

a bounded finite-rank projection, $Q_N = 1 - P_N$, and suppose the truncated trajectory $\gamma_N(t) \in \mathcal{B}_N$ solves

$$\dot{\gamma}_N(t) = P_N \mathcal{F}_t(\gamma_N(t)). \tag{142.95}$$

The omitted vector-field component along this projected trajectory is

$$r_N(t) = Q_N \mathcal{F}_t(\gamma_N(t)). \tag{142.96}$$

Assume that the exact trajectory $\Gamma(t)$ and the projected trajectory remain in a common tube on $0 \le t \le T$, that $\Gamma(0) = \gamma_N(0)$, and that

$$\|\mathcal{F}_t(X) - \mathcal{F}_t(Y)\|_{\mathcal{B}_\Gamma} \le M(t)\|X - Y\|_{\mathcal{B}_\Gamma}$$

there. Then

$$\|\Gamma(T) - \gamma_N(T)\|_{\mathcal{B}_\Gamma} \le \int_0^T \exp\left(\int_s^T M(u)\,\mathrm{d}u\right) \|r_N(s)\|_{\mathcal{B}_\Gamma}\,\mathrm{d}s. \tag{142.97}$$

If the reconstruction map into a finite observable window satisfies

$$p_\alpha(\mathrm{Rec}_T(X) - \mathrm{Rec}_T(Y)) \le L_{\alpha,T}\|X - Y\|_{\mathcal{B}_\Gamma}$$

on the same tube, then the right-hand side of (142.97), multiplied by $L_{\alpha,T}$, is the corresponding observable-window error.

To derive (142.97), put $e(t) = \Gamma(t) - \gamma_N(t)$. Using (142.95) and (142.96),

$$\dot{e}(t) = \mathcal{F}_t(\Gamma(t)) - \mathcal{F}_t(\gamma_N(t)) + r_N(t).$$

The upper Dini derivative of $\|e(t)\|_{\mathcal{B}_\Gamma}$ is therefore bounded by $M(t)\|e(t)\| + \|r_N(t)\|$, and (142.97) is Gronwall's inequality with zero initial error. This is the finite-regulator statement behind the functional-RG truncation boundary: the projected vector field must be accompanied by an omitted-direction residual in the same function space as the exact effective action, and by observable reconstruction estimates in the seminorms actually used.

Controlled Approximation 142.24 (Functional-RG projected fixed points)**.** In dimensionless autonomous variables, write the exact regulated functional-RG vector field as

$$\dot{\Gamma} = \beta(\Gamma), \qquad \beta : \mathcal{U}_\Gamma \subset \mathcal{B}_\Gamma \to \mathcal{B}_\Gamma.$$

Let $P_N : \mathcal{B}_\Gamma \to \mathcal{B}_N$ be a finite ansatz projection, $Q_N = 1 - P_N$, and let $\Gamma_N^* \in \mathcal{B}_N$ solve only the projected fixed-point equation

$$P_N \beta(\Gamma_N^*) = 0. \tag{142.98}$$

The omitted beta-function component is

$$r_N^* = Q_N \beta(\Gamma_N^*). \tag{142.99}$$

Suppose an approximate inverse $A : \mathcal{B}_\Gamma \to \mathcal{B}_\Gamma$ for $D\beta(\Gamma_N^*)$ and constants ρ, L satisfy the Newton–Kantorovich estimates of Theorem 142.15, with

$$\eta_N^{\mathrm{FRG}} := \|A r_N^*\|_{\mathcal{B}_\Gamma}.$$

If, for some r_N,

$$\eta_N^{\mathrm{FRG}} + \rho r_N + \frac{L}{2} r_N^2 \le r_N, \qquad \rho + L r_N < 1, \tag{142.100}$$

then there is an exact fixed point Γ_* of the full vector field in the ball $\|\Gamma_* - \Gamma_N^*\| \le r_N$. If a finite observable window p_α is reconstructed by a map Rec_α that is $L_{\alpha,N}$-Lipschitz on the same ball, and if the ansatz observable itself has chart error $\delta_{\alpha,N}$, then

$$p_\alpha(\mathrm{Rec}_{\alpha,N}(\Gamma_N^*) - \mathrm{Rec}_\alpha(\Gamma_*)) \le \delta_{\alpha,N} + L_{\alpha,N} r_N. \tag{142.101}$$

Thus a zero of the beta functions retained in a derivative expansion is not yet a Wilsonian fixed-point theorem. It is a controlled finite-window approximation only to the extent that (142.99), (142.100), and (142.101) are supplied in the full regulated effective-action norm and in the declared observable seminorms.

The proof is the projected-zero lifting argument above, applied to $F = \beta$. Since (142.98) kills only the retained coordinates, $\beta(\Gamma_N^*) = r_N^*$. The Newton–Kantorovich theorem gives the nearby exact zero once the omitted component is small after applying A. The observable estimate is the same triangle inequality as (142.84). The important point is negative: a critical exponent matrix computed inside the ansatz subspace does not control the discarded beta-function directions, the existence of a full fixed point, or the reconstruction of Schwinger or Wightman data.

142.13 Fixed-Point Claim Content

The preceding benchmarks should be compared through the objects they actually construct. A fixed-point statement in this chapter is compared through four questions:

1. what space the RG map acts on, such as local interactions, polymer activities, Grassmann kernels, tensors, lattice measures, or BV actions;
2. what estimates prove that the map is defined on its domain, is differentiable or analytic there, has the claimed fixed point, and has the stated stable/unstable decomposition;
3. which source extensions, contact-term subspaces, and reconstruction estimates turn the fixed point into distributions or observable algebras;
4. which comparison map identifies the constructed RG system with the physical short-range, gauge, or continuum QFT target.

The strength of a result is the first question in this list for which the necessary objects and estimates are missing. This convention prevents an auxiliary fixed point from being silently promoted to a theorem about a different QFT.

Hierarchical scalar systems. For the hierarchical scalar maps of Definition 142.21, the RG object and map theorem are part of the rigorous theorem: the nonlinear integral map is defined on a Banach space of analytic or polymer interactions, the non-Gaussian fixed point is constructed in that space, and stable/unstable directions are controlled by the corresponding estimates. Observable statements are hierarchical observable statements unless accompanied by a short-range reconstruction estimates and a transfer map of the form Definitions 142.31 and 142.40. The target identification with the ordinary nearest-neighbor or finite-range three-dimensional scalar critical point is therefore an additional problem, requiring its own comparison map and reconstruction estimates beyond shared coordinate names such as scalar, relevant, or quartic.

Long-range fermionic models. For the long-range fermionic ψ_d^4 systems, the rigorous result constructs a fixed interaction in a Banach space of Grassmann kernels and constructs selected response functions with anomalous scaling and controlled remainders. The source layer is part of the theorem for the field and density response functions that are actually constructed. The target is the long-range fermionic model with the specified fractional kinetic term and fixed ultraviolet cutoff interpretation. Using this result as evidence for ordinary short-range scalar critical behavior requires a separately stated auxiliary-to-target comparison; it is not an identification of universality classes by analogy.

Tensor RG fixed points. For tensor RG, the RG object is an infinite-dimensional tensor in a declared Hilbert–Schmidt or Banach topology. The theorem is a contraction statement for a modified tensor map, including its disentangling or truncation rule, on a specified neighborhood of the high-temperature, low-temperature, or discontinuity fixed point. The reconstructed object is initially a lattice statistical model or tensor-network partition function. A continuum-QFT claim requires a further scaling-window reconstruction and comparison to Schwinger functions, local algebras, or another QFT observable topology. Thus tensor RG supplies theorem-level fixed points of tensor maps and a valuable laboratory for RG proof technology; it becomes a continuum QFT fixed-point theorem only after the reconstruction layer is supplied.

Controlled Approximation 142.25 (Tensor-RG truncation windows)**.** Let $(\mathcal{B}_T, \|\cdot\|_T)$ be the declared tensor Banach or Hilbert–Schmidt space, let $\mathcal{T}_j : \mathcal{U}_j \to \mathcal{B}_T$ be the exact tensor blocking map at step j, and let $\widehat{\mathcal{T}}_j$ be the algorithmic map actually used, including its finite-rank truncation or disentangling prescription. Starting from the same initial tensor $T_0 = \widehat{T}_0$, define

$$T_{j+1} = \mathcal{T}_j(T_j), \qquad \widehat{T}_{j+1} = \widehat{\mathcal{T}}_j(\widehat{T}_j).$$

Suppose both orbits remain in a common tube on which

$$\|\mathcal{T}_j(X) - \mathcal{T}_j(Y)\|_T \leq L_j \|X - Y\|_T,$$

and suppose the one-step algorithmic residual along the computed orbit obeys

$$\delta_j = \|\mathcal{T}_j(\widehat{T}_j) - \widehat{\mathcal{T}}_j(\widehat{T}_j)\|_T. \tag{142.102}$$

Then

$$\|T_n - \widehat{T}_n\|_T \leq \sum_{j=0}^{n-1} \left(\prod_{\ell=j+1}^{n-1} L_\ell \right) \delta_j. \tag{142.103}$$

If a normalized finite observable window W_α is evaluated by a map $\mathcal{O}_{\alpha,n}$ satisfying

$$p_\alpha(\mathcal{O}_{\alpha,n}(X) - \mathcal{O}_{\alpha,n}(Y)) \leq C_{\alpha,n} \|X - Y\|_T$$

on the same tube, and if the normalization or boundary-window error is $\eta_{\alpha,n}$, then

$$p_\alpha\Big(\mathcal{O}_{\alpha,n}(T_n) - \mathcal{O}_{\alpha,n}(\widehat{T}_n)\Big) \leq C_{\alpha,n} \sum_{j=0}^{n-1} \left(\prod_{\ell=j+1}^{n-1} L_\ell \right) \delta_j + \eta_{\alpha,n}. \tag{142.104}$$

This is the tensor-network analogue of the auxiliary-transfer estimate: finite bond dimension, singular-value truncation, or a disentangling step is part of the RG map. Its effect on a claimed observable window is controlled by the residual in (142.102), the exact-map amplification factors, and the window map $\mathcal{O}_{\alpha,n}$.

The derivation is the same finite recursion as (142.185). Put $e_j = T_j - \widehat{T}_j$. Then

$$e_{j+1} = \mathcal{T}_j(T_j) - \mathcal{T}_j(\widehat{T}_j) + \mathcal{T}_j(\widehat{T}_j) - \widehat{\mathcal{T}}_j(\widehat{T}_j),$$

so

$$\|e_{j+1}\|_T \le L_j \|e_j\|_T + \delta_j.$$

Iteration from $e_0 = 0$ gives (142.103); the finite-window estimate (142.104) then follows from the Lipschitz bound for $\mathcal{O}_{\alpha,n}$ and the added normalization error. A computed finite-bond-dimension flow is therefore a controlled tensor-network result precisely on the windows for which these residuals and Lipschitz constants are supplied.

Ordinary short-range scalar targets. For a short-range three-dimensional scalar Wilson–Fisher target, the RG object must be the block-spin/polymer structure of Definition 142.31, or a proven equivalent structure connected to it by Definition 142.2. The theorem would have to construct the stable critical trajectory or fixed point in that structure, including the irrelevant polymer tail, source extensions, contact terms, and distributional reconstruction estimates. The massive constructive ϕ^4_3 theorems and the critical hierarchical or long-range fixed-point theorems supply important pieces of the landscape, but the ordinary short-range critical reconstruction theorem is a separate target-identification problem. Perturbative epsilon expansions and finite-dimensional functional-RG truncations are then used as coordinate and numerical evidence for this target, not as substitutes for the map theorem and reconstruction estimates.

Gauge targets. For gauge theories, the RG object is not a list of gauge-fixed coefficients. The object is either a gauge-invariant lattice measure and observable system, or a regularized BV action and observable complex satisfying the quantum master equation and its RG pushforward. The source layer must use gauge-invariant local observables, Wilson-line or Wilson-loop observables with their geometric data, or BV cohomology classes. A gauge-theory fixed-point or continuum-limit theorem therefore includes preservation of the gauge structure under blocking, reconstruction of physical observables, and comparison of line or extended sectors when those sectors are part of the claim. Beta functions in a gauge-fixed coordinate chart are useful local coordinates only after this gauge-compatible RG structure has been declared.

Model-by-model status synthesis. The examples above should be compared by the stage at which a theorem has actually been proved. The stages are: construction of the RG map in its declared norm; construction of a fixed point or stable critical trajectory; source extension and operator-coordinate control; reconstruction of Schwinger, Wightman, or observable-algebra data; and identification of the constructed object with a specified physical target. These stages are logically ordered. A proof at an earlier stage supplies important mathematics, but it does not automatically supply the later stages.

For massive scalar models with superrenormalizable interactions, constructive methods can supply Euclidean Schwinger functions and, after the OS reconstruction hypotheses are checked, Wightman theories. The theorem-level output is a local QFT in a massive regime. It is not a construction of a scale-invariant non-Gaussian fixed point of the ordinary short-range critical block-spin map, because the critical stable trajectory and its source-coordinate spectrum are not part of that massive theorem.

For hierarchical scalar models and related auxiliary scalar RG systems, the theorem-level output is a fixed point or critical trajectory for the auxiliary map in its own Banach space. If that theorem also constructs hierarchical observables, those observables belong first to the hierarchical model. To turn the result into a statement about the ordinary short-range scalar target one must additionally supply Definition 142.40: an intertwining map, relevant-coordinate comparison, observable-window comparison, and a summable target-orbit defect. Shared exponents or shared local coordinate names are not such a transfer map.

For long-range fermionic fixed-point constructions, the theorem-level output is the fixed interaction in a Grassmann-kernel Banach space together with the response functions and remainders actually constructed. This is a genuine nonperturbative fixed-point theorem in its declared fermionic model. It is not a scalar Wilson–Fisher theorem, nor a gauge-theory theorem, because the microscopic covariance, field variables, source space, and reconstruction maps are different.

For tensor RG, the theorem-level output is a fixed point or contraction of a specified tensor map in a Hilbert–Schmidt or Banach tensor topology. When a finite-bond or disentangled computation is used, the controlled statement is only the residual-bound window of (142.104). A continuum QFT claim requires a separate scaling-window reconstruction from tensor data to Schwinger functions, local algebras, or another declared observable topology.

For functional-RG calculations, the exact finite-regulator statement is the Wetterich identity for a regulated effective average action. A finite ansatz or derivative expansion is a projected flow, and the meaningful comparison with the exact flow is the omitted-vector-field estimate (142.97). A fixed point of the projected ordinary differential equation is therefore a controlled approximation only on those finite windows for which the residual and reconstruction Lipschitz constants have been supplied.

For the ordinary short-range critical scalar target, the theorem-level output would be a tuned trajectory

$$(g_k, K_k, W_{k,E}) \longrightarrow (g_*, K_*, W_{*,E})$$

in the short-range block-spin and source-extended polymer structure. The precise reconstruction target is the assembly package of Definition 142.39: the source-window budget (142.178), uniform distribution bounds, cofinal window compatibility, directed OS positivity, positive-time semigroup estimates, corrected OS-II growth, and a common scale schedule on which these estimates hold together. This is the point at which the OS reconstruction theorem can be invoked. Existing benchmark systems identify pieces of this target structure, but the ordinary short-range critical scalar construction remains open until these estimates are proved in that model.

For gauge targets, the corresponding output is either a continuum limit of gauge-invariant lattice measures and Wilson-line or Wilson-loop observable windows, or a regularized BV flow preserving the quantum master equation and the observable cochain maps. The reconstruction data are gauge-invariant observables or BV cohomology classes. A beta function in a gauge-fixed local coordinate chart is one coordinate shadow of this structure; it is not the structure itself.

This comparison also fixes how this monograph treats the phrase "state of the art." The current rigorous fixed-point frontier contains theorem-level auxiliary and model-specific systems with impressive control of irrelevant coordinates. It does not yet contain a general theorem turning every physically expected Wilsonian fixed point into a local QFT, nor a theorem constructing the ordinary three-dimensional Ising CFT from a short-range block-spin map with all source and reconstruction estimates. The monograph uses the proved systems as proof templates and laboratories, while keeping the physical target-identification problems explicit.

142.14 Gauge-Compatible RG And Reconstruction Estimates

A Wilsonian RG theorem for a scalar probability measure can be formulated as a pushforward of measures, followed by a localization step and a rescaling. Gauge theories require richer structure, because the variables used in a calculation contain redundancy. The theorem-level object is therefore an RG map on gauge-invariant lattice measures and observables, or an RG map in the BV category whose effective actions and observable complexes satisfy the quantum master equation at every scale. The BV framework used here is developed in Chapter 48; the lattice Yang–Mills and reflection positivity inputs are developed in Chapters 46, 138, and 140.

Definition 142.26 (Gauge-compatible Wilsonian RG structure)**.** Fix a spacetime dimension D, a scale factor $L > 1$, and a regulator sequence indexed by $k \in \mathbb{Z}_{\geq 0}$. A gauge-compatible Wilsonian RG structure is one of the following two forms.

1. In the lattice form, one has finite cell complexes Λ_k, a compact Lie group G_k, configuration spaces $\mathcal{A}_k = G_k^{E(\Lambda_k)}$ of link variables, gauge groups $\mathcal{G}_k = G_k^{V(\Lambda_k)}$ acting on $\mathcal{A}_k$, and finite measures $\mathrm{d}\mu_k$ on $\mathcal{A}_k$. The observables are functions or distributions on $\mathcal{A}_k$ invariant under $\mathcal{G}_k$, with a declared norm controlling Wilson loops, local plaquette fields, and any matter insertions with their Wilson-line connectors. The RG step is a gauge-equivariant blocking kernel
$$B_{k,k-1}(A_{k-1}, A_k)\, \mathrm{d}\mu_k(A_k)$$
whose pushforward gives a measure $\mathrm{d}\mu_{k-1}$ on $\mathcal{A}_{k-1}$, followed by a localization map into a Banach chart of gauge-invariant polymer activities. Reflection positivity, when claimed, is part of the structure and is expressed as positivity of the blocked quadratic form on the positive-time observable algebra.

2. In the BV form, one has finite-regulator graded vector spaces $\mathcal{F}_k$ of fields, ghosts, antifields, and possible sources; odd symplectic forms of degree -1; BV Laplacians Δ_k associated with the chosen finite-dimensional Berezin-Lebesgue density; and actions S_k satisfying the quantum master equation
$$\frac{1}{2}(S_k, S_k)_k - \hbar\, \Delta_k S_k = 0, \tag{142.105}$$
or equivalently $\Delta_k e^{-S_k/\hbar} = 0$. The RG step is BV pushforward along a fluctuation subspace with gauge-fixing Lagrangian $\mathcal{L}_k$:
$$e^{-S_{k-1}(\phi_{k-1})/\hbar} = \int_{\mathcal{L}_k} e^{-S_k(\phi_{k-1}+\xi_k)/\hbar}\, \mathrm{d}\xi_k, \tag{142.106}$$
together with a localization map into a Banach space of local BV functionals. The induced observable map $P_{k,k-1}$ sends Q_{S_k}-closed observables to $Q_{S_{k-1}}$-closed observables, where $Q_{S_k} = (S_k, \cdot)_k - \hbar\Delta_k$.

In either form, a fixed point or continuum limit also includes reconstruction maps for gauge-invariant local and extended observables. A flow of finitely many gauge-fixed coefficients is a coordinate shadow of this structure; the theorem-level statement is the lattice or BV structure together with its norm estimates.

The definition deliberately includes Wilson-line and loop observables. A colored field variable in a gauge-fixed calculation is useful for local coordinate work, but a nonperturbative observable statement is formulated in terms of gauge-invariant insertions or BV cohomology classes. Thus a charged-particle or partonic reconstruction theorem must specify the line, asymptotic dressing, or cohomology class used to define the observable before one speaks of an RG limit.

Construction 142.27 (Gauge-equivariant path blocking at finite regulator)**.** The lattice half of Definition 142.26 has a minimal exact example. Let Γ_f and Γ_c be finite oriented graphs, interpreted as fine and coarse lattices. Let $i : V(\Gamma_c) \hookrightarrow V(\Gamma_f)$ embed coarse vertices into fine vertices. For every oriented coarse edge $e : v \to w$, choose an oriented fine path

$$P_e = (\ell_1, \dots, \ell_m), \qquad s(\ell_1) = i(v), \quad t(\ell_m) = i(w),$$

and require $P_{\bar{e}} = \overline{P_e}$, the same path with reversed orientation. A fine gauge field assigns $U_\ell \in G$ to oriented fine edges with $U_{\bar{\ell}} = U_\ell^{-1}$. Define the blocked coarse link by

$$B(A)_e = U_{\ell_1} U_{\ell_2} \cdots U_{\ell_m}. \tag{142.107}$$

For a fine gauge transformation $g \in G^{V(\Gamma_f)}$,

$$U_\ell^g = g_{s(\ell)} U_\ell g_{t(\ell)}^{-1}.$$

The internal endpoint factors along P_e cancel, so

$$B(A^g)_e = g_{i(v)}\, B(A)_e\, g_{i(w)}^{-1}. \tag{142.108}$$

Thus B is equivariant from the fine gauge action to the coarse gauge action obtained by restricting g to embedded coarse vertices.

Let μ_f be any finite measure on $G^{E(\Gamma_f)}$ invariant under the fine gauge group, and let $\mu_c = B_* \mu_f$. For a coarse gauge transformation $h \in G^{V(\Gamma_c)}$, choose any extension $\tilde{h} \in G^{V(\Gamma_f)}$ with $\tilde{h}_{i(v)} = h_v$. Equation (142.108) gives

$$B(A^{\tilde{h}}) = B(A)^h.$$

Since μ_f is invariant under $A \mapsto A^{\tilde{h}}$, the pushforward μ_c is invariant under the coarse gauge group. If $C = e_1 \cdots e_r$ is a closed coarse loop and R is a finite-dimensional unitary representation of G, then

$$W_R(C; B(A)) = \frac{1}{\dim R} \operatorname{tr}_R\bigl(B(A)_{e_1} \cdots B(A)_{e_r}\bigr) \tag{142.109}$$

is the Wilson loop of the concatenated fine path and is gauge invariant.

This construction proves only the exact finite-regulator covariance and observable pushforward. It does not prove that the logarithm of the blocked measure is a local Wilson action, nor that a continuum local QFT follows. Those are precisely the localization, polymer-decay, reflection-positivity, and reconstruction estimates required in the rest of Definition 142.26.

The companion script `calculation-checks/lattice_gauge_blocking_checks.py` verifies the finite group algebra behind (142.108) and (142.109) for an S_3 plaquette example, including invariance of the blocked pushforward weights under coarse gauge transformations.

142.15 Gauge-Blocking Locality, Positivity, And Reconstruction Estimates

The path-blocking construction above is an exact gauge-covariance statement. It is not yet a Wilsonian RG theorem for a continuum gauge theory. A continuum claim needs three further pieces of analysis: locality of the blocked measure in a declared norm, reflection positivity or a stated replacement for it, and reconstruction estimates for gauge-invariant observables. This section records the estimates required for a theorem-level four-dimensional Yang–Mills statement.

Let Γ_k be a sequence of Euclidean lattice complexes with lattice spacing $a_k \to 0$. For a connected set X of coarse plaquettes, links, or cells, let $\operatorname{diam}_k(X)$ be its diameter in physical units and let $\operatorname{dist}_k(X, Y)$ be the physical distance between two cell sets. Let $\operatorname{supp} F$ be the smallest connected cell set on which a cylinder observable F depends. The norm $\|\cdot\|_\infty$ is the supremum norm on the corresponding compact link-configuration space.

Definition 142.28 (Gauge-blocking continuum-control estimates)**.** A continuum-control estimate package for a gauge-compatible blocking sequence consists of the finite path-blocking data of Construction 142.27, together with the following estimates.

1. A gauge-invariant polymer representation of the blocked measure at scale k:

$$\frac{\mathrm{d}\mu_k^{\mathrm{blk}}}{\mathrm{d}\nu_k}(A) = Z_k^{-1} \exp\left(- \sum_{X \subset \Gamma_k} K_{k,X}(A_X) \right), \tag{142.110}$$

   where ν_k is a reflection-positive local reference measure, $K_{k,X}$ is gauge invariant and depends only on links meeting X, and the sum is over connected polymers X.

2. A quasi-locality estimate: for some $\zeta > 0$,

$$\|K_k\|_\zeta = \sup_{e \in E(\Gamma_k)} \sum_{X \ni e} e^{\zeta \operatorname{diam}_k(X)} \|K_{k,X}\|_\infty \le \varepsilon_k, \qquad \varepsilon_k \longrightarrow 0 \tag{142.111}$$

   after subtracting the finitely many local coordinates retained in the Wilsonian chart. In addition, for every bounded gauge-invariant cylinder observable F, the cluster expansion or polymer estimate supplies truncated expectations $\langle F \rangle_{k,R}$, obtained by keeping only connected polymer clusters contained in the R-neighborhood of $\operatorname{supp} F$, and constants C_F such that

$$|\langle F \rangle_k - \langle F \rangle_{k,R}| \le C_F e^{-\zeta R} \|K_k\|_\zeta + \chi_{F,k}(R), \qquad \lim_{R\to\infty} \sup_k \chi_{F,k}(R) = 0. \tag{142.112}$$

   This cluster-tail estimate is part of the continuum-control package, not a consequence of gauge covariance alone.

3. Reflection-positivity control. Let $\mathcal{A}_{k,+}^{\mathrm{inv}}$ be the algebra of gauge-invariant cylinder observables supported in the positive-time half-lattice, and let Θ be time reflection with orientation reversal on links crossing reflected edges. For every finite list $F_1, \ldots, F_m \in \mathcal{A}_{k,+}^{\mathrm{inv}}$ and coefficients $c_i \in \mathbb{C}$,

$$\sum_{i,j=1}^{m} \bar{c}_i c_j \int \Theta F_i(A)\, F_j(A)\, \mathrm{d}\mu_k^{\mathrm{blk}}(A) \ge -\rho_k(F, c), \tag{142.113}$$

   with $\rho_k(F, c) \to 0$ for each fixed finite family. Exact reflection positivity is the special case $\rho_k = 0$.

4. Gauge-invariant reconstruction maps for a declared class of observables $\mathcal{W}$, such as finite Wilson-loop products, smeared small-loop field-strength representatives, or matter bilinears with their Wilson-line connectors. For each $O \in \mathcal{W}$, the reconstructed finite-scale observable $\mathrm{Rec}_{O,k}$ takes values in a locally convex distribution or cylinder-observable topology and satisfies a bound of the form

$$p(\mathrm{Rec}_{O,k} - \mathrm{Rec}_{O,*}) \leq C_{O,p}\varepsilon_k + \eta_{O,p,k}, \qquad \eta_{O,p,k} \longrightarrow 0, \tag{142.114}$$

for every seminorm p used in the continuum statement.

The first item is not a harmless rewriting. The logarithm of a blocked gauge-invariant measure can contain arbitrarily large Wilson loops. The locality estimate (142.111) is the assertion that those large connected contributions are summable in a norm strong enough to define a Wilsonian chart. In gauge theory this estimate is one of the main constructive burdens.

Consequences of the estimates. Once Definition 142.28 is proved in a model, every $O \in \mathcal{W}$ has the declared continuum limit by (142.114). Gauge invariance passes to the limit because it holds at finite regulator by path-blocking equivariance and because the reconstruction topology tests gauge-invariant cylinder data. The estimate (142.112) is the quasi-locality statement: distant connected polymer clusters have a uniformly vanishing effect on each bounded local gauge-invariant observable after the retained local Wilsonian coordinates have been removed.

Reflection positivity is also a closed-cone statement once the finite quadratic forms have been identified. For $F_1, \ldots, F_m \in \mathcal{A}^{\mathrm{inv}}_{k,+}$ and $c_i \in \mathbb{C}$, write

$$Q_k(F, c) = \sum_{i,j} \bar{c}_i c_j \int \Theta F_i \, F_j \, \mathrm{d}\mu_k^{\mathrm{blk}}.$$

The reconstruction estimate gives convergence of the finitely many correlators entering $Q_k(F, c)$, while (142.113) gives $Q_k(F, c) \geq -\rho_k(F, c)$. Taking $k \to \infty$ gives the limiting positive-time quadratic form $Q_*(F, c) \geq 0$. This is why the estimate package must include the reflection-positive observable algebra and the defect ρ_k; it is not enough to know that the blocked links transform covariantly.

Gauge-invariant source windows. The source-window layer in a gauge RG theorem is part of the datum, because the source variables select which continuum distributions are being reconstructed. In the lattice form of Definition 142.26, let

$$E = \mathrm{span}_{\mathbb{C}}\{O_1, \ldots, O_N\}$$

be a finite-dimensional space of gauge-invariant cylinder observables on $\mathcal{A}_k$. Typical basis elements are closed Wilson loops, products of small-loop field-strength representatives, or matter bilinears whose color indices are contracted by a declared Wilson-line connector. The path, representation, endpoint contraction, and smearing data are part of the observable label. For $z = (z_1, \ldots, z_N)$ in a fixed polydisc P_ρ, define

$$W^{\mathrm{inv}}_{k,E}(z) = \log \int_{\mathcal{A}_k} \exp\left(\sum_{a=1}^{N} z_a O_a(A) \right) \mathrm{d}\mu_k(A), \tag{142.115}$$

whenever the integral is nonzero and the logarithm branch has been fixed at $z = 0$. Since each O_a is invariant under $\mathcal{G}_k$, the source-deformed density in (142.115) is invariant pointwise and therefore descends to the orbit space or, equivalently, to the invariant observable algebra. An admissible source for a colored transport operator includes the endpoint color contractions, Wilson-line geometry, or asymptotic dressing that makes the observable gauge invariant; the uncontracted open link belongs to a gauge-fixed coordinate chart.

The endpoint contraction can be checked at the same finite-regulator level. Let $R : G \to U(V)$ be a finite-dimensional unitary representation and let $P : x \to y$ be an oriented lattice path with holonomy $U_P(A)$. If $\psi_y \in V$ and $\bar{\psi}_x \in V^*$ transform as

$$\psi_y \mapsto R(g_y)\psi_y, \qquad \bar{\psi}_x \mapsto \bar{\psi}_x R(g_x)^{-1},$$

then the transported bilinear

$$O_{P,R}(A, \bar{\psi}_x, \psi_y) = \bar{\psi}_x \, R(U_P(A)) \, \psi_y \tag{142.116}$$

is invariant, because

$$U_P(A^g) = g_x U_P(A) g_y^{-1}.$$

The same two endpoint vectors without the transporter transform by $\bar{\psi}_x R(g_x)^{-1} R(g_y)\psi_y$, so they do not define a source on the gauge-orbit space when $x \neq y$. The path P is also part of the observable label: replacing P by another path with the same endpoints inserts the Wilson loop around the closed contour $P'\bar{P}$. A source-window RG estimate must therefore specify the transporter geometry and its renormalized path class, or else prove a reconstruction estimate that controls the difference between the chosen paths.

Path-deformation ledger for transported sources. The preceding path dependence has an exact finite-regulator algebra. Let $P, P' : x \to y$ be two oriented paths and let $\bar{P} : y \to x$ be the reverse of P. Put

$$C_{P',P} := P'\bar{P}, \qquad U_{C_{P',P}}(A) = U_{P'}(A) U_P(A)^{-1}.$$

Then

$$U_{P'}(A) = U_{C_{P',P}}(A) \, U_P(A), \tag{142.117}$$

and the two transported sources differ by the endpoint-local loop insertion

$$O_{P',R} - O_{P,R} = \bar{\psi}_x \left(R(U_{C_{P',P}}) - \mathbf{1} \right) R(U_P)\psi_y. \tag{142.118}$$

The closed-loop holonomy in (142.118) transforms by conjugation at x, and the endpoint vector $\bar{\psi}_x$ transforms by the dual representation, so the whole difference is still gauge invariant. If $C_{P',P}$ is a small plaquette loop in a continuum scaling window, then $R(U_{C_{P',P}}) - \mathbf{1}$ is the finite-regulator representative of a local curvature insertion plus higher local Wilson-loop coordinates. Thus identifying P and P' in a continuum reconstruction is a theorem only after the source-window estimate supplies, in the declared seminorms, a bound of the form

$$p\Big(\mathrm{Rec}_{O_{P',R},k} - \mathrm{Rec}_{O_{P,R},k}\Big) \leq C_{P,P',p} \, \varepsilon_{C_{P',P},k} + \eta_{P,P',p,k}, \tag{142.119}$$

where $\varepsilon_{C_{P',P},k}$ is the local small-loop or curvature coordinate controlled by the gauge-invariant Wilsonian chart and $\eta_{P,P',p,k} \to 0$. Without such a bound, different connector paths are different source labels, not alternate notations for the same observable.

In the BV form the same statement is slightly sharper. A finite source window is a holomorphic family $S_k(z)$ with $S_k(0) = S_k$ satisfying the scale-k quantum master equation and equipped with its composite-operator source coordinates. The first source derivatives $\partial_{z_a} S_k(0)$ are quantum observables, meaning $Q_{S_k}\partial_{z_a} S_k(0) = 0$. The higher source derivatives of $S_k(z)$ are the contact and composite-operator coordinates needed for the source family itself to remain in the BV chart. Thus the distinction between regularizing the path-integral measure and regularizing composite operators is built into the RG source datum rather than added after correlators have been computed.

The gauge source window is useful only if it obeys the same analytic estimates as the scalar source windows above, now in the invariant or BV cohomological chart. A theorem-facing estimate has the form

$$W^{\mathrm{inv}}_{k,E}(z) = C^{\mathrm{inv}}_{k,E}(z) + \mathfrak{W}^{\mathrm{inv}}_E\big(g^{\mathrm{inv}}_{k,E}(z), K^{\mathrm{inv}}_{k,E}(z)\big) + r^{\mathrm{inv}}_{k,E}(z), \tag{142.120}$$

on a fixed polydisc, with all three terms defined in the gauge-invariant lattice chart or in a BV chart satisfying the quantum master equation. If the right side lies in a common Lipschitz neighborhood of the limiting source chart, then

$$\sup_{z\in P_\rho}\big|W^{\mathrm{inv}}_{k,E}(z) - W^{\mathrm{inv}}_{*,E}(z)\big| \le \delta^{\mathrm{inv}}_{C,E} + L^{\mathrm{inv}}_E\big(\delta^{\mathrm{inv}}_{g,E} + \delta^{\mathrm{inv}}_{K,E}\big) + \delta^{\mathrm{inv}}_{r,E}. \tag{142.121}$$

The Cauchy estimates then extract connected correlators of the gauge observables O_a. Equation (142.121) is the place where a finite-regulator gauge computation becomes a reconstruction statement. A finite list of Wilson-loop expectation values, or a beta function in a gauge-fixed coordinate chart, becomes reconstruction input only after the source radius, local coordinates, polymer tail, contact/source coordinates, and thermodynamic boundary tails have been controlled.

The companion script `calculation-checks/lattice_gauge_blocking_checks.py` includes the finite S_3 check behind this paragraph: class functions of the blocked closed loop give source polynomials constant on coarse gauge orbits, while a source attached to a single open link fails the same invariance test. It also checks (142.116) in the permutation representation: the Wilson-line transported endpoint bilinear is invariant under all independent endpoint gauge transformations, the untransported endpoint pairing is not, and changing the connecting path changes the observable for a configuration with nontrivial holonomy. It also verifies the exact loop-insertion identity (142.117)–(142.118) and the finite reconstruction error budget (142.119). The same check file also tests the finite locality-tail arithmetic, reflection positive Gram compression, and the reconstruction error budget in (142.114); these finite checks are not substitutes for the continuum estimates, but they keep the algebraic interfaces of the estimate package explicit.

Common-scale schedule for gauge reconstruction. The estimates above are not independent badges. A gauge-compatible continuum claim needs them on one directed schedule. Let $\mathfrak{A}_{\mathrm{gauge}}$ be a directed family of finite gauge observation windows. A window $\alpha \in \mathfrak{A}_{\mathrm{gauge}}$ consists of a finite set $\mathcal{W}_\alpha$ of gauge-invariant Wilson-loop, small-loop, transported-matter, or BV-cohomology source labels; a finite positive-time test family $\mathcal{F}_\alpha$; a seminorm p_α on the reconstructed observable window; a source polydisc radius $\rho_\alpha > 0$; and, when connector paths are to be identified, a finite set $\mathcal{P}_\alpha$ of path-deformation pairs (P, P'). The window remembers the representation, path, endpoint contraction, smearing, orientation, and contact/source-coordinate convention for every label.

For a scale k, a polymer truncation radius R, and a finite volume Ω, the gauge reconstruction error for α is recorded by the budget

$$\begin{aligned}\mathcal{E}^{\mathrm{gauge}}_{\alpha,k,R,\Omega} &= C_\alpha e^{-\zeta_\alpha R}\|K_k\|_\zeta + \chi_{\alpha,k}(R) + \delta^{\mathrm{vol}}_{\alpha,k,\Omega} + \delta^{\mathrm{src}}_{\alpha,k} \\ &\quad + \eta^{\mathrm{rec}}_{\alpha,k} + \sum_{(P,P')\in\mathcal{P}_\alpha} \big(C_{P,P',\alpha}\varepsilon_{C_{P',P},k} + \eta_{P,P',\alpha,k}\big).\end{aligned} \tag{142.122}$$

The first two terms are the quasi-local polymer tail from (142.112); the third is the finite volume or boundary-tail defect; the fourth is the holomorphic source-window error in (142.121); the fifth is the observable reconstruction defect in (142.114); and the last line is the connector-path identification budget from (142.119). Reflection positivity has its own finite Gram-window defect:

$$\mathcal{R}^{\mathrm{gauge}}_{\alpha,k} = \rho_k(\mathcal{F}_\alpha) + |\mathcal{F}_\alpha|\,\epsilon^{\mathrm{Gram}}_{\alpha,k}, \tag{142.123}$$

where $\epsilon^{\mathrm{Gram}}_{\alpha,k}$ denotes the entrywise error between the regulated and limiting positive-time Gram matrices in that window, or is replaced by the corresponding operator-norm error if that stronger estimate is available.

A theorem-level gauge continuum limit must provide a cofinal schedule for these two budgets. For a nested cofinal sequence $\alpha_1 \preceq \alpha_2 \preceq \cdots$, this means choosing

$$N \longmapsto (k_N, R_N, \Omega_N)$$

so that, for every fixed j,

$$\mathcal{E}^{\mathrm{gauge}}_{\alpha_j,k_N,R_N,\Omega_N} \longrightarrow 0, \qquad \mathcal{R}^{\mathrm{gauge}}_{\alpha_j,k_N} \longrightarrow 0 \qquad (N\to\infty,\ N\ge j). \tag{142.124}$$

Equivalently, after increasing the schedule if necessary, one may demand a diagonal bound such as

$$\mathcal{E}^{\mathrm{gauge}}_{\alpha_j,k_N,R_N,\Omega_N} + \mathcal{R}^{\mathrm{gauge}}_{\alpha_j,k_N} \le 2^{-N}, \qquad j \le N,$$

with constants and radii already fixed by the windows. This is the gauge-theory version of the common-scale requirement in Definition 142.39. Separate statements that the locality tail vanishes for one list of Wilson loops, the source Cauchy estimate holds on another source polydisc, and reflection positivity holds on a third positive-time family do not yet define a projective gauge observable germ. The theorem is the existence of one schedule controlling all windows in the directed family, followed by OS, Wightman, or BV/cohomological reconstruction in the topology declared by those windows.

Warning 142.29 (Finite gauge blocking is not a continuum Yang–Mills proof)**.** Construction 142.27 and the finite S_3 companion calculation prove exact gauge covariance and exact pushforward invariance at finite regulator. They do not by themselves prove the quasi-local polymer bound (142.111), reflection positivity (142.113), or reconstruction (142.114). A theorem that a gauge-blocked Wilsonian trajectory defines a continuum local QFT must supply those estimates in a specific regulator class and observable topology.

Definition 142.30 (RG reconstruction estimate)**.** Let $\mathcal{S}_n = \mathcal{S}((\mathbb{R}^D)^n)$ be the Schwartz space and let $\mathcal{S}'_n$ be its continuous dual. For a bounded set $B \subset \mathcal{S}_n$, write

$$p_B(T) = \sup_{f\in B} |\langle T, f\rangle|, \qquad T \in \mathcal{S}'_n.$$

Let $\mathcal{R} : \mathcal{U} \to \mathcal{B}$ be an RG map with fixed point V_*. An n-point reconstruction estimate consists of distributions $\mathcal{S}_{n,*} \in \mathcal{S}'_n$, maps

$$\mathrm{Rec}_{n,k} : \mathcal{U} \longrightarrow \mathcal{S}'_n, \qquad k \in \mathbb{Z}_{\geq 0}, \tag{142.125}$$

and constants $C_B < \infty$, $0 < \theta < 1$, and $\varepsilon_{B,k} \to 0$, such that every tuned initial point V in the declared stable manifold satisfies

$$p_B(\mathrm{Rec}_{n,k}(V) - \mathcal{S}_{n,*}) \leq C_B\, \theta^k \, \|V - V_*\|_{\mathcal{B}} + \varepsilon_{B,k} \tag{142.126}$$

for all bounded $B \subset \mathcal{S}_n$. The maps $\mathrm{Rec}_{n,k}$ include the lattice spacing, coordinate rescaling, field-strength normalization, source normalization, and possible Wilson-line or BV-observable representative.

Immediate consequences of a reconstruction estimate. Assume Definition 142.30 for every $n \geq 1$ and every bounded set $B \subset \mathcal{S}_n$. This assumption already contains strong-dual convergence of the renormalized n-point functions. Indeed, strong convergence in $\mathcal{S}'_n$ means convergence with respect to the seminorms p_B as B ranges over bounded subsets of $\mathcal{S}_n$, and (142.126) gives

$$p_B(\mathrm{Rec}_{n,k}(V) - \mathcal{S}_{n,*}) \longrightarrow 0$$

because $\theta^k \to 0$ and $\varepsilon_{B,k} \to 0$. Thus the distributional convergence is not an additional theorem beyond the estimate; it is the meaning of the estimate in the chosen topology.

The same distinction matters for properties carried to the limit. For symmetry and Euclidean covariance, let U denote a permutation or Euclidean transformation acting continuously on $\mathcal{S}_n$. If the finite-regulator distributions satisfy $\langle \mathrm{Rec}_{n,k}(V), f\rangle = \langle \mathrm{Rec}_{n,k}(V), Uf\rangle$, then passing to the limit in the two scalar sequences gives the same identity for $\mathcal{S}_{n,*}$.

For reflection positivity, take a finite family of positive-time test functions f_i and coefficients c_i. At finite regulator the corresponding quadratic expression has the form

$$Q_k(c, f) = \sum_{i,j} \bar{c}_i c_j \left\langle \mathrm{Rec}_{m_i+m_j,k}(V), \Theta f_i \otimes f_j \right\rangle \geq 0, \tag{142.127}$$

where Θ is Euclidean time reflection. Each term converges by the distributional convergence encoded in (142.126), hence $Q_k(c, f) \to Q_*(c, f)$. The cone $[0, \infty) \subset \mathbb{R}$ is closed, so $Q_*(c, f) \geq 0$. Thus the limiting Schwinger functions inherit reflection positivity in the declared test-function domain whenever the finite-regulator positivity statement is formulated as a finite positive-semidefinite quadratic form continuous in the seminorms p_B. This closed-cone passage does not provide the missing model-specific estimates; it only records what follows after those estimates have already been proved.

142.16 Ordinary Short-Range Scalar Reconstruction

The scalar benchmark in the previous sections is hierarchical. An ordinary short-range scalar lattice model has a different microscopic object: fields on $a_k\mathbb{Z}^D$, finite-range interactions, and block-spin maps whose range is geometric in the lattice. The purpose of this section is to record the reconstruction structure for that ordinary setting. It is the structure a proof of a short-range Wilson–Fisher fixed point would have to supply; it is not replaced by a hierarchical or tensor-network theorem unless a comparison map with reconstruction estimates is also proved.

Definition 142.31 (Short-range scalar block-spin structure)**.** Fix an integer scale factor $L \geq 2$, spacetime dimension D, and lattice spacings $a_k = L^{-k}a_0$. A short-range scalar block-spin structure consists of the following objects.

1. Periodic lattice regions $\Lambda_k \subset a_k\mathbb{Z}^D$, scalar configuration spaces $\mathbb{R}^{\Lambda_k}$, and finite Gibbs measures

$$\mathrm{d}\mu_k(\phi) = Z_k^{-1} \exp\left(- \sum_{\substack{X\subset\Lambda_k \\ \mathrm{diam}(X)\leq Ra_k}} U_{k,X}(\phi_X) \right) \prod_{x\in\Lambda_k} \mathrm{d}\phi_x. \tag{142.128}$$

   Here $R < \infty$ is fixed before the continuum limit, and the potentials are assumed measurable with enough coercivity to make all polynomial moments used below finite.

2. A block kernel $q : \{0, \ldots, L-1\}^D \to \mathbb{R}$ satisfying

$$\sum_{r\in\{0,\ldots,L-1\}^D} q(r) = 1, \tag{142.129}$$

   and a field scaling exponent Δ_ϕ. The blocked field on Λ_{k-1} is

$$(B_k\phi)(y) = L^{\Delta_\phi} \sum_{r\in\{0,\ldots,L-1\}^D} q(r)\, \phi(y + a_kr). \tag{142.130}$$

   Periodic representatives are used when $y + a_kr$ crosses the boundary. The normalization makes a constant microscopic field transform by the declared field-scaling factor L^{Δ_ϕ}.

3. A localization map which writes the pushforward $(B_k)_\#\mu_k$ in a Banach RG chart

$$(g_k, K_k) \in E_{\mathrm{loc}} \oplus \mathcal{K}.$$

   The finite-dimensional coordinates g_k record relevant and marginal local terms. The polymer activity K_k records the infinite-dimensional irrelevant tail in a norm controlling both spatial decay and large-field behavior.

The structure is short-range only before the block step. After integrating out fluctuations, the effective interaction is generally not finite range; the polymer norm and its contraction estimates are the mathematical replacement for the microscopic finite-range property.

Construction 142.32 (Block-spin cumulants)**.** Let $f \in C_c^\infty(\mathbb{R}^D)$. The normalized lattice field at spacing a_k is the random variable

$$\Phi_k(f) = a_k^D\, a_k^{-\Delta_\phi} \sum_{x\in\Lambda_k} f(x)\phi_x. \tag{142.131}$$

For labels $f_1, \ldots, f_n$, define the connected reconstructed distribution by the joint cumulant

$$\langle S_{n,k}, f_1 \otimes \cdots \otimes f_n\rangle = \kappa_{\mu_k}\big(\Phi_k(f_1), \ldots, \Phi_k(f_n)\big). \tag{142.132}$$

The cumulant is computed from

$$\log \mathbb{E}_{\mu_k} \exp\left(\sum_{i=1}^n t_i\Phi_k(f_i)\right)$$

by taking $\partial_{t_1} \cdots \partial_{t_n}$ at the origin. The normalization in (142.131) is fixed by the source pairing: if $x = Ly$, then a source coupled to a field of dimension Δ_ϕ scales with exponent $D - \Delta_\phi$, as in (142.196).

The finite-regulator identity behind this normalization is the adjoint source-blocking relation. For a coarse test function f, define the fine-lattice pullback $B_k^\dagger f$ on one block by

$$(B_k^\dagger f)(y + a_k r) = L^D q(r) f(y), \qquad r \in \{0, \dots, L-1\}^D. \tag{142.133}$$

Then, with $a_{k-1} = La_k$,

$$a_{k-1}^{D-\Delta_\phi} \sum_{y \in \Lambda_{k-1}} f(y)(B_k\phi)(y) = a_k^{D-\Delta_\phi} \sum_{y \in \Lambda_{k-1}} \sum_{r \in \{0,\dots,L-1\}^D} (B_k^\dagger f)(y + a_k r)\phi_{y+a_k r}. \tag{142.134}$$

Thus the source normalization, field-strength normalization, and block-spin normalization are one datum, not three independent conventions. A source-window RG estimate for Φ_k must use the same $B_k^\dagger$ that is adjoint to the blocking map appearing in the measure pushforward. If one changes the field normalization while keeping the same symbol for the source window, the reconstructed Schwinger distributions have been rescaled; the comparison then belongs to the normalization group in Definition 142.45, not to equality of un-normalized observable germs.

The ordinary short-range scalar reconstruction problem is to prove, for each n, convergence of $S_{n,k}$ in $\mathcal{S}'((\mathbb{R}^D)^n)$ or in a declared local distribution topology. A Wilsonian RG proof supplies this convergence through estimates in the RG chart:

$$p_B(S_{n,k} - S_{n,*}) \le C_{n,B}\big(\|g_k - g_*\|_{E_{\rm loc}} + \|K_k - K_*\|_{\mathcal{K}}\big) + \epsilon_{n,B,k}, \tag{142.135}$$

where $B \subset \mathcal{S}((\mathbb{R}^D)^n)$ is bounded and $\epsilon_{n,B,k} \to 0$ is the discretization and finite-volume error. If the RG trajectory is tuned so that

$$\|g_k - g_*\|_{E_{\rm loc}} + \|K_k - K_*\|_{\mathcal{K}} \le C_0\theta^k, \qquad 0 < \theta < 1, \tag{142.136}$$

then (142.135) is precisely a reconstruction estimate of the form (142.126). The point is that (142.136) is the hard RG estimate, not the vocabulary of fixed points or universality.

Finite source windows to cumulant distributions. The cumulant notation in (142.132) is useful only after the source-extension estimates have been connected to actual test-function windows. Fix a finite-dimensional test space

$$E = \operatorname{span}\{f_1, \dots, f_m\} \subset C_c^\infty(\mathbb{R}^D)$$

and write $J_z = \sum_{a=1}^m z_a f_a$. At scale k, define the finite-window connected source functional

$$W_{k,E}(z) = \log \mathbb{E}_{\mu_k} \exp\{\Phi_k(J_z)\}, \qquad z \in \mathbb{C}^m, \tag{142.137}$$

whenever the expectation is finite and holomorphic in the chosen polydisc. If

$$\beta = (\beta_1, \dots, \beta_m), \qquad |\beta| = \beta_1 + \cdots + \beta_m,$$

then

$$\partial_z^\beta W_{k,E}(0) = \kappa_{\mu_k}\big(\underbrace{\Phi_k(f_1), \dots, \Phi_k(f_1)}_{\beta_1 \text{ times}}, \dots, \underbrace{\Phi_k(f_m), \dots, \Phi_k(f_m)}_{\beta_m \text{ times}}\big). \tag{142.138}$$

This identity is just the definition of joint cumulants through the logarithm of the moment-generating function, but it fixes the exact derivative whose convergence is needed for the Schwinger distribution window.

Suppose now that $W_{*,E}$ is holomorphic on the same closed polydisc $P_\rho = \{|z_a| \le \rho_a\}$ and that

$$\sup_{z\in P_\rho} |W_{k,E}(z) - W_{*,E}(z)| \le \epsilon_{E,k}, \qquad \epsilon_{E,k} \longrightarrow 0. \tag{142.139}$$

The multidimensional Cauchy formula gives, for every multi-index β,

$$\left|\partial_z^\beta W_{k,E}(0) - \partial_z^\beta W_{*,E}(0)\right| \le \frac{\beta!}{\rho^\beta}\,\epsilon_{E,k}, \qquad \rho^\beta = \prod_a \rho_a^{\beta_a}. \tag{142.140}$$

Thus finite-source-window convergence in a complex neighborhood gives quantitative convergence of every cumulant whose test functions lie in E. If $E \subset F$, compatibility of the source windows means

$$W_{k,F}(z_E, 0) = W_{k,E}(z_E), \qquad W_{*,F}(z_E, 0) = W_{*,E}(z_E),$$

so the cumulants extracted from larger windows restrict to the smaller ones.

The passage from these finite windows to a distribution is a further continuity statement, not a formal consequence of (142.140). For each n, the RG construction must also provide an integer r_n and a constant C_n, independent of the finite test space E and of k after the stated scale threshold. Applied to any ordered n-tuple $(h_1, \ldots, h_n) \subset E$, with source coordinates $z_1, \ldots, z_n$ chosen in those directions, the required bound is

$$|\partial_{z_1} \cdots \partial_{z_n} W_{k,E}(0)| \le C_n\, q_{r_n}(h_1 \otimes \cdots \otimes h_n) \tag{142.141}$$

for the declared Schwartz seminorm q_{r_n} on $\mathcal{S}((\mathbb{R}^D)^n)$, and the same bound for the limiting window. Compatibility plus (142.141) is precisely the input of Lemma 142.48. It produces the limiting tempered distribution $S_{n,*}$; the Cauchy estimate (142.140) supplies the finite-window convergence rate. Local source counterterms are handled as additional polynomial source coordinates whose derivatives are distributions supported on collision diagonals. They are part of the source window, not an after-the-fact modification of separated cumulants.

Source majorants for the OS-II growth input. The preceding paragraph controls fixed cumulant windows. The corrected OS-II reconstruction theorem needs a uniform many-insertion growth estimate for the Schwinger hierarchy itself, not only convergence at each fixed n. The corresponding Wilsonian estimate is most naturally stated for the moment source functional

$$Z_{k,E}(z) = \mathbb{E}_{\mu_k} \exp\{\Phi_k(J_z)\}, \qquad W_{k,E}(z) = \log Z_{k,E}(z), \tag{142.142}$$

on the same finite test space E. Let

$$N_n = N_0 + C_{\mathrm{OS}} n$$

be the seminorm order allowed in the OS-II linear-growth condition, and let q_{1,N_n} be the corresponding one-variable Schwartz seminorm. A source-window estimate strong enough for OS-II has the following form. For every ordered n-tuple $h_1, \ldots, h_n$ in the test space, the functional $Z_{k,E}$, $E = \mathrm{span}\{h_1, \ldots, h_n\}$, is holomorphic on the polydisc

$$|z_i| \le \frac{\rho}{q_{1,N_n}(h_i)}, \qquad i = 1, \ldots, n,$$

with constants $\rho, A, B, \gamma > 0$, independent of k, n, and of the chosen tuple, such that

$$\sup_{P_\rho(h_1,\dots,h_n)} |Z_{k,E}(z)| \le A\, B^n\, (n!)^\gamma. \tag{142.143}$$

Cauchy's formula in the n independent source variables then gives

$$|S_{n,k}(h_1 \otimes \cdots \otimes h_n)| \le A \left(\frac{B}{\rho}\right)^n (n!)^\gamma \prod_{i=1}^n q_{1,N_n}(h_i). \tag{142.144}$$

For a general zero-diagonal test function F, let $\pi_{n,N_n}(F)$ be the projective tensor seminorm obtained by decomposing F into finite sums of simple tensors and taking the infimum of the corresponding products of one-variable q_{1,N_n}-seminorms. Linearity gives

$$|S_{n,k}(F)| \le A \left(\frac{B}{\rho}\right)^n (n!)^\gamma \pi_{n,N_n}(F). \tag{142.145}$$

Thus the OS-II bound (12.4) follows from the source majorant whenever the chosen Schwartz seminorm family satisfies a comparison estimate

$$\pi_{n,N_n}(F) \le C_\pi^n q_{n,N_0'+C_{\mathrm{OS}}'n}(F)$$

on the zero-diagonal test class. The constants in the OS-II growth condition are then $B_{\mathrm{OS}} = C_\pi B/\rho$, with the same factorial exponent γ. This is a stricter demand than fixed-n source convergence: if the available source radius shrinks with n, if the supremum in (142.143) has uncontrolled combinatorial growth, or if only connected cumulants are bounded without a summable partition estimate, the OS-II analytic input has not been obtained.

From connected cumulants to moments. The source functional most directly produced by a polymer or cluster RG construction is often $W_{k,E} = \log Z_{k,E}$, hence connected cumulants. The corrected OS-II growth hypothesis is a bound on Schwinger functions themselves. The passage from one to the other is the moment–cumulant partition sum, and its constants must be controlled uniformly in the number of insertions.

Lemma 142.33 (Cumulant partition bound for OS-II moments)**.** *Fix $n \ge 1$, test functions $h_1, \dots, h_n$, and the seminorm q_{1,N_n} used in the preceding paragraph. For each nonempty $B \subset \{1, \dots, n\}$, let $\kappa_B(h_B)$ be the connected cumulant with insertion set B, where $h_B = (h_i)_{i\in B}$. Assume that constants $A_{\mathrm{c}}, C_{\mathrm{c}}, \gamma_{\mathrm{c}}$, independent of n and of the chosen test functions, satisfy*

$$|\kappa_B(h_B)| \le A_{\mathrm{c}}\, C_{\mathrm{c}}^{|B|}\, (|B|!)^{\gamma_{\mathrm{c}}} \prod_{i\in B} q_{1,N_n}(h_i) \tag{142.146}$$

for every nonempty B. Let

$$M_n(h_1, \dots, h_n) = \sum_{\pi\in\Pi_n} \prod_{B\in\pi} \kappa_B(h_B)$$

be the corresponding Schwinger moment, with Π_n the set of set partitions of $\{1, \dots, n\}$. Then

$$|M_n(h_1, \dots, h_n)| \le \big(2C_{\mathrm{c}} \max(1, A_{\mathrm{c}})\big)^n (n!)^{\gamma_{\mathrm{c}}+1} \prod_{i=1}^n q_{1,N_n}(h_i). \tag{142.147}$$

Proof. The moment–cumulant identity is the finite identity obtained by expanding $\exp W$. Taking absolute values and applying (142.146) gives

$$|M_n(h_1,\dots,h_n)| \le C_{\mathrm{c}}^n \prod_{i=1}^n q_{1,N_n}(h_i) \sum_{\pi\in\Pi_n} A_{\mathrm{c}}^{|\pi|} \prod_{B\in\pi} (|B|!)^{\gamma_{\mathrm{c}}}.$$

For every partition π, one has $\prod_{B\in\pi} |B|! \le n!$, since the left hand side counts permutations internal to the blocks and is bounded by all permutations of the n labels. Also $A_{\mathrm{c}}^{|\pi|} \le \max(1, A_{\mathrm{c}})^n$. Finally, $|\Pi_n| \le 2^{n-1}n!$: every partition can be obtained by choosing a permutation of the n labels and then choosing cuts between consecutive labels, so the stated number is a surjective overcount. Combining these three bounds gives (142.147). $\square$

Consequently a connected-cumulant RG theorem can feed the corrected OS-II hypothesis only after the constants in (142.146) are obtained uniformly in the insertion number and with the declared seminorm order $N_n = N_0 + C_{\mathrm{OS}}n$. The estimate loses one factorial power when no sharper partition control is available. This loss is part of the theorem statement, not a matter of notation: if the connected bound carries constants depending on the number of clusters, on the source-window dimension, or on an n-dependent radius, then (142.147) does not supply the OS-II growth input.

Polymer derivative norm behind the connected input. In a polymer RG proof the connected estimate (142.146) should be produced before the moment–cumulant partition sum is used. Let $h_1,\dots,h_m$ be local test directions in a finite source window, and let K_i be the block support of the discretized source h_i at scale k. For $\emptyset \ne B \subset \{1,\dots,m\}$, write

$$D_B = \prod_{i\in B} \frac{\partial}{\partial z_i}\bigg|_{z=0}, \qquad K_B = \bigcup_{i\in B} K_i.$$

If the connected source functional has a cluster expansion

$$W_{k,E}(z) = \sum_{\mathcal{C}} w_{\mathcal{C}}(z),$$

then the model-specific source theorem must control the derivatives $D_B w_{\mathcal{C}}(0)$ as part of the source extension of the polymer activity bounds. A useful form of the required estimate is the anchored derivative norm

$$\mathcal{N}_{k,B}(h_B) = \sum_{\mathcal{C}\in\mathfrak{C}_k(B)} e^{\zeta\, \mathrm{diam}_k(\mathrm{supp}\,\mathcal{C}\cup K_B)} \left| D_B w_{\mathcal{C}}(0)\right|, \tag{142.148}$$

where $\mathfrak{C}_k(B)$ is the family of connected clusters whose source dependence can attach to every K_i, $i\in B$. For a strictly local source coupling this means that the support of the cluster meets each K_i; for a block-smeared source it means the corresponding enlarged block support. Source-local contact coordinates are included separately in the local source chart, so that (142.148) is the estimate for the declared nonlocal connected tail.

The polymer input strong enough for the connected OS-II bound is

$$\mathcal{N}_{k,B}(h_B) \le A_{\mathrm{p}}\, C_{\mathrm{p}}^{|B|}\, (|B|!)^{\gamma_{\mathrm{p}}} \prod_{i\in B} q_{1,N_{|B|}}(h_i), \tag{142.149}$$

with $A_{\mathrm{p}}, C_{\mathrm{p}}, \gamma_{\mathrm{p}}, \zeta$ independent of k, of the finite window E, and of $|B|$ except through the displayed factors. The connected cumulant is

$$\kappa_B(h_B) = \sum_{\mathcal{C}\in\mathfrak{C}_k(B)} D_B w_{\mathcal{C}}(0),$$

after the contact-source coordinates assigned to B have been separated. Since the exponential weight in (142.148) is at least one, (142.149) gives (142.146) with

$$A_{\mathrm{c}} = A_{\mathrm{p}}, \qquad C_{\mathrm{c}} = C_{\mathrm{p}}, \qquad \gamma_{\mathrm{c}} = \gamma_{\mathrm{p}}.$$

Keeping the exponential weight also records separated-cluster decay: if

$$\tau_k(K_B) = \inf\{\mathrm{diam}_k(Y) : Y \text{ is a connected block set meeting every } K_i,\ i \in B\},$$

then

$$|\kappa_B(h_B)| \le e^{-\zeta\tau_k(K_B)} A_{\mathrm{p}} C_{\mathrm{p}}^{|B|} (|B|!)^{\gamma_{\mathrm{p}}} \prod_{i\in B} q_{1,N_{|B|}}(h_i).$$

Thus the load-bearing model estimate is the uniform derivative cluster norm (142.149). A cluster expansion whose constants depend on the dimension of the source window, on an uncontrolled choice of source radius, or on the number of possible source attachments has not supplied the connected input needed by the corrected OS-II reconstruction theorem.

RG-chart control of a holomorphic source window. The hypothesis (142.139) is not supplied by knowing that the unsourced local coordinates converge. A Wilsonian proof must control the source-extended chart itself. For a fixed finite test space E and a fixed closed polydisc P_ρ, the source extension of the RG chart should give a decomposition of the connected source functional of the form

$$W_{k,E}(z) = C_{k,E}(z) + \mathfrak{W}_E\big(g_{k,E}(z), K_{k,E}(z)\big) + r_{k,E}(z), \qquad z \in P_\rho. \tag{142.150}$$

Here $C_{k,E}$ is the local normalizing coordinate, including source dependent vacuum and contact coordinates, $g_{k,E}$ are the retained local coordinates, $K_{k,E}$ is the source-decorated polymer tail, and $r_{k,E}$ is the declared sampling, boundary, and finite-step remainder. The map $\mathfrak{W}_E$ is the finite-window evaluation map of the RG chart. It is not assumed to be a universal function independent of the chosen chart; it is part of the reconstruction datum for this finite source window.

Suppose that all chart points occurring in (142.150) lie in a common tube $\mathcal{T}_E$ on which $\mathfrak{W}_E$ obeys

$$\big|\mathfrak{W}_E(g,K) - \mathfrak{W}_E(g',K')\big| \le L_E\big(\|g-g'\|_{E_{\mathrm{loc}}} + \|K-K'\|_{\mathcal{K}_E}\big). \tag{142.151}$$

If limiting source-chart data $(C_{*,E}, g_{*,E}, K_{*,E}, r_{*,E})$ are holomorphic on the same polydisc and

$$\delta^C_{E,k} := \sup_{P_\rho} |C_{k,E} - C_{*,E}|, \tag{142.152}$$

$$\delta^g_{E,k} := \sup_{P_\rho} \|g_{k,E} - g_{*,E}\|_{E_{\mathrm{loc}}}, \tag{142.153}$$

$$\delta^K_{E,k} := \sup_{P_\rho} \|K_{k,E} - K_{*,E}\|_{\mathcal{K}_E}, \tag{142.154}$$

$$\delta^r_{E,k} := \sup_{P_\rho} |r_{k,E} - r_{*,E}| \tag{142.155}$$

all tend to zero, then

$$\sup_{z\in P_\rho} |W_{k,E}(z) - W_{*,E}(z)| \le \delta^C_{E,k} + L_E(\delta^g_{E,k} + \delta^K_{E,k}) + \delta^r_{E,k}. \tag{142.156}$$

Inserting this bound into (142.140) gives the cumulant convergence rate for the finite window. The fixed polydisc is load-bearing: a bound on P_{ρ_k} with $\rho_k \downarrow 0$ does not give a uniform Cauchy estimate for derivatives. Thus source-radius control, local normalizing coordinates, source-decorated irrelevant tails, and finite-step remainders are all part of the Wilsonian reconstruction theorem; they cannot be recovered from an unsourced fixed-point statement.

Source-stable trajectory estimate. The source-extended chart also has its own stable and unstable directions. This is where local contact terms enter the RG theorem rather than being added after the continuum limit. For a finite test space E, write

$$g_{k,E}(z) - g_{*,E}(z) = u_{k,E}(z) + s_{k,E}(z)$$

according to the unstable/retained and stable/irrelevant splitting of the source-local coordinate space. The unstable part includes ordinary relevant couplings and any source-local or contact coordinates whose engineering or anomalous exponent makes them non-decaying in the source window. For a fixed polydisc P_ρ, a finite-depth RG estimate has the form

$$\sup_{P_\rho} \|s_{k+1,E}\| \le \theta_E \sup_{P_\rho} \|s_{k,E}\| + \varepsilon^s_{k,E}, \qquad 0 < \theta_E < 1, \tag{142.157}$$

$$\sup_{P_\rho} \|u_{k+1,E}\| \le \Lambda_E \sup_{P_\rho} \|u_{k,E}\| + \varepsilon^u_{k,E}, \qquad \Lambda_E > 1. \tag{142.158}$$

The first recursion gives

$$\sup_{P_\rho} \|s_{N,E}\| \le \theta_E^N \sup_{P_\rho} \|s_{0,E}\| + \sum_{j=0}^{N-1} \theta_E^{N-1-j} \varepsilon^s_{j,E}. \tag{142.159}$$

The second recursion gives the finite-depth amplification bound

$$\sup_{P_\rho} \|u_{N,E}\| \le \Lambda_E^N \sup_{P_\rho} \|u_{0,E}\| + \sum_{j=0}^{N-1} \Lambda_E^{N-1-j} \varepsilon^u_{j,E}. \tag{142.160}$$

Thus a source-local coordinate whose unstable component is not tuned to order Λ_E^{-N}, up to the accumulated source-local defects, can spoil the finite-window limit even if the unsourced scalar trajectory is on its critical surface.

Combining (142.159)–(142.160) with (142.156) gives the actual holomorphic source-window error bound

$$\epsilon^{\mathrm{src}}_{E,N} \le \delta^C_{E,N} + L_E\left(\sup_{P_\rho} \|u_{N,E}\| + \sup_{P_\rho} \|s_{N,E}\| + \delta^K_{E,N} \right) + \delta^r_{E,N}. \tag{142.161}$$

This is the source-window version of stable-manifold tuning. The source-local counterterms and collision-diagonal coordinates must either be retained and tuned in $u_{k,E}$, shown to contract in $s_{k,E}$, or bounded in the explicit remainder. If they are simply omitted from the chart, the Wilsonian RG estimate has not yet produced the Schwinger distribution window used in OS reconstruction.

Finite volume to infinite volume for a source window. The thermodynamic step at fixed lattice spacing is another estimate, not a notation change. At fixed lattice spacing a_k, let $\Omega \subset a_k\mathbb{Z}^D$ be a finite connected region and write $W_{k,\Omega,E}(z)$ for the connected source functional (142.137) computed with the finite-volume Gibbs measure on Ω and the declared local boundary convention. Let

$$K_{E,k} = \Omega \cap \bigcup_{a=1}^{m} \operatorname{supp} f_a$$

be the lattice source support, after the continuum test functions are restricted to $a_k\mathbb{Z}^D$, and let

$$R_\Omega = \operatorname{dist}_k(K_{E,k}, a_k\mathbb{Z}^D \setminus \Omega)$$

be the lattice distance from the source support to the boundary of Ω, in physical units or in lattice units according to the declared cluster norm. Suppose the source-window cluster expansion gives, on a fixed closed polydisc P_ρ, the boundary-tail estimate

$$\sup_{z\in P_\rho} |W_{k,\Omega',E}(z) - W_{k,\Omega,E}(z)| \le A_E\, \Xi(R_\Omega) \tag{142.162}$$

whenever $\Omega \subset \Omega'$ and both regions contain $K_{E,k}$, where $\Xi(R) \to 0$ as $R \to \infty$. In a finite-range or exponentially clustering polymer estimate one expects $\Xi(R) \le C\exp(-\zeta R)$; in a critical construction the available Ξ is whatever the RG polymer norm actually proves. Equation (142.162) is the statement that clusters touching the source window and clusters that feel the boundary have a summable connected bridge.

Lemma 142.34 (Polymer bridge criterion for source-window boundary tails)**.** *Work at a fixed scale k and a fixed finite source window E. Let $\Lambda_k = a_k\mathbb{Z}^D$ be the ambient lattice, let $K = K_{E,k}$ be the lattice source support, and let d_k be the block distance. Suppose the connected source functional in a finite region $\Omega \supset K$ has an absolutely convergent connected-cluster expansion on P_ρ,*

$$W_{k,\Omega,E}(z) = \sum_{\substack{\mathcal{C}\subset\Omega\\ \operatorname{supp}\mathcal{C}\cap K\neq\emptyset}} w_{\mathcal{C}}(z), \qquad z \in P_\rho, \tag{142.163}$$

where $\operatorname{supp}\mathcal{C}$ *is a finite connected block set. Assume that the cluster weights obey the bridge majorant*

$$\sum_{\substack{\mathcal{C}:\,\operatorname{supp}\mathcal{C}\cap K\neq\emptyset\\ b\in\operatorname{supp}\mathcal{C}}} \sup_{z\in P_\rho} |w_{\mathcal{C}}(z)| \le B_E\, e^{-\zeta d_k(b,K)} \tag{142.164}$$

for every block $b \in \Lambda_k$, with $B_E < \infty$ and $\zeta > 0$, uniformly in the finite volume. Then, whenever $\Omega \subset \Omega'$ and both regions contain K,

$$\sup_{z\in P_\rho} |W_{k,\Omega',E}(z) - W_{k,\Omega,E}(z)| \le B_E \sum_{b\in\Lambda_k\setminus\Omega} e^{-\zeta d_k(b,K)}. \tag{142.165}$$

In particular, if

$$R_\Omega = d_k(K, \Lambda_k \setminus \Omega)$$

and the source-centered shells obey

$$\#\{b \in \Lambda_k :\ d_k(b,K) = n\} \le C_E(1+n)^{D_E-1}, \qquad n \ge 0,$$

then (142.162) *holds with*

$$A_E\,\Xi(R) = B_E C_E \sum_{n\geq R} (1+n)^{D_E-1} e^{-\zeta n}. \tag{142.166}$$

The right side tends to zero as $R\to\infty$.

Proof. Subtract the two cluster expansions. The terms whose support lies in Ω cancel. Every remaining cluster has $\operatorname{supp}\mathcal{C}\cap K\neq\emptyset$ and contains at least one block $b\in\Lambda_k\setminus\Omega$. Absolute convergence permits the union bound

$$\begin{aligned}\sup_{z\in P_\rho}|W_{k,\Omega',E}(z)-W_{k,\Omega,E}(z)| &\leq \sum_{\substack{\mathcal{C}\subset\Omega'\\ \operatorname{supp}\mathcal{C}\cap K\neq\emptyset\\ \operatorname{supp}\mathcal{C}\not\subset\Omega}} \sup_{z\in P_\rho}|w_{\mathcal{C}}(z)| \\ &\leq \sum_{b\in\Lambda_k\setminus\Omega}\ \sum_{\substack{\mathcal{C}:\,\operatorname{supp}\mathcal{C}\cap K\neq\emptyset\\ b\in\operatorname{supp}\mathcal{C}}} \sup_{z\in P_\rho}|w_{\mathcal{C}}(z)|.\end{aligned}$$

The bridge majorant (142.164) gives (142.165). If $b\in\Lambda_k\setminus\Omega$, then $d_k(b,K)\geq R_\Omega$. Grouping the boundary sum by the distance $n=d_k(b,K)$ and using the shell-count bound gives (142.166). The final series is the tail of an exponentially weighted polynomial series, hence it converges and its tail tends to zero. □

The bridge majorant (142.164) is the model-specific cluster estimate that must be proved from the polymer norm and the finite range or summable covariance bounds. Once it is available, Lemma 142.34 turns it into the thermodynamic source-window bound used in the rest of this subsection.

For every multi-index β, Cauchy's formula on the same polydisc gives

$$\left|\partial_z^\beta W_{k,\Omega',E}(0)-\partial_z^\beta W_{k,\Omega,E}(0)\right| \leq \frac{\beta!}{\rho^\beta}\,A_E\,\Xi(R_\Omega). \tag{142.167}$$

Thus the finite-volume cumulant windows are Cauchy as the boundary recedes from the source support. Their limit is denoted

$$\partial_z^\beta W_{k,\infty,E}(0) := \lim_{\Omega\uparrow a_k\mathbb{Z}^D} \partial_z^\beta W_{k,\Omega,E}(0),$$

provided the directed family of regions is chosen so that $R_\Omega\to\infty$. The resulting window is independent of the chosen cofinal exhaustion whenever the same tail estimate controls any two exhaustions through a common larger region. This is the finite-volume part of item 1 in Definition 142.36. Without a bound of the form (142.162), a sequence of finite volumes may have plausible local numerical stability while failing to define the thermodynamic source window required by OS reconstruction.

The independence of the exhaustion is also part of the same estimate. Let $\{\Omega_i\}$ and $\{\widetilde{\Omega}_j\}$ be two directed exhaustions whose boundary distances from $K_{E,k}$ tend to infinity. For fixed i,j, choose a connected region $\Omega^\sharp_{ij}$ containing both Ω_i and $\widetilde{\Omega}_j$. Applying (142.162) twice gives

$$\sup_{z\in P_\rho}|W_{k,\Omega_i,E}(z)-W_{k,\widetilde{\Omega}_j,E}(z)| \leq A_E\Xi(R_{\Omega_i}) + A_E\Xi(R_{\widetilde{\Omega}_j}). \tag{142.168}$$

The right side tends to zero as $i, j \to \infty$, so the holomorphic limit on P_ρ is independent of the cofinal volume sequence. Cauchy's formula then yields the derivative comparison

$$\left|\partial_z^\beta W_{k,\Omega_i,E}(0) - \partial_z^\beta W_{k,\widetilde{\Omega}_j,E}(0)\right| \le \frac{\beta!}{\rho^\beta}\big(A_E \Xi(R_{\Omega_i}) + A_E \Xi(R_{\widetilde{\Omega}_j})\big). \tag{142.169}$$

The same bookkeeping fixes the joint thermodynamic and continuum limit used later in the RG-to-OS assembly package. Suppose that, for the same finite source window E, the RG-chart comparison to a limiting source functional $W_{*,E}$ gives an error $\epsilon_{E,k}^{\mathrm{RG}}$ on P_ρ, while the chosen finite volume Ω_k obeys the boundary distance $R_{\Omega_k} \to \infty$. Combining (142.156) with (142.162) gives

$$\sup_{z \in P_\rho} |W_{k,\Omega_k,E}(z) - W_{*,E}(z)| \le \epsilon_{E,k}^{\mathrm{RG}} + A_E \Xi(R_{\Omega_k}). \tag{142.170}$$

Consequently every extracted cumulant in the E-window satisfies

$$\left|\partial_z^\beta W_{k,\Omega_k,E}(0) - \partial_z^\beta W_{*,E}(0)\right| \le \frac{\beta!}{\rho^\beta}\left(\epsilon_{E,k}^{\mathrm{RG}} + A_E \Xi(R_{\Omega_k})\right). \tag{142.171}$$

Thus the finite-volume simulation or finite-volume constructive estimate may be used as thermodynamic Schwinger data only through a boundary-tail function and a scale schedule that makes the combined right side tend to zero for each fixed source window.

Adjoint source blocking and smooth-test error. The source normalization in (142.131) is not a convention that can be chosen independently at each scale. Let F be a real-valued test function on the coarse lattice Λ_{k-1}. The source paired with the blocked field is

$$a_{k-1}^{D-\Delta_\phi} \sum_{y \in \Lambda_{k-1}} F(y)(B_k\phi)(y).$$

Using $a_{k-1} = La_k$ and the definition (142.130), this expression is equal to

$$a_k^{D-\Delta_\phi} \sum_{y \in \Lambda_{k-1}} \sum_{r \in \{0,\dots,L-1\}^D} L^D q(r) F(y)\, \phi_{y+a_k r}. \tag{142.172}$$

Thus the adjoint source map associated with the normalized pairings is

$$(B_k^\dagger F)(y + a_k r) = L^D q(r) F(y), \qquad r \in \{0, \dots, L-1\}^D, \tag{142.173}$$

with periodic representatives at the boundary. Equivalently,

$$a_{k-1}^{D-\Delta_\phi} \sum_y F(y)(B_k\phi)(y) = a_k^{D-\Delta_\phi} \sum_x (B_k^\dagger F)(x)\phi_x. \tag{142.174}$$

The exponent D, rather than $D - \Delta_\phi$, in (142.173) is forced by the factor L^{Δ_ϕ} already present in the blocked field. This is the finite-regulator identity behind source-window extraction in an ordinary short-range scalar RG chart.

For comparison with continuum test functions, take the uniform kernel $q(r) = L^{-D}$ and let $f \in C_c^1(\mathbb{R}^D)$. Put $F(y) = f(y)$ on the coarse lattice and let Y_k be a finite set of coarse sites containing all blocks that meet the support of f. Then

$$a_k^D \sum_{y \in Y_k} \sum_{r \in \{0,\dots,L-1\}^D} \left|(B_k^\dagger F)(y + a_k r) - f(y + a_k r)\right| \le C_{D,L}\, \|\nabla f\|_\infty\, a_{k-1}\, \mathrm{Vol}_{k-1}(Y_k), \tag{142.175}$$

where

$$\mathrm{Vol}_{k-1}(Y_k) = a_{k-1}^D |Y_k|, \qquad C_{D,L} = L^{-(D+1)} \sum_{r\in\{0,\ldots,L-1\}^D} |r|.$$

Indeed, for the uniform kernel $B_k^\dagger F$ is constant on each block and equal to $f(y)$, while $|f(y) - f(y+a_k r)| \le a_k |r| \, \|\nabla f\|_\infty$. Multiplication by a_k^D and summation over y and r gives (142.175). Higher-order block kernels may improve this sampling error when their moments are matched to the chosen cell coordinates; without those moment conditions the exact identity (142.174), not pointwise approximation of smooth tests, is the invariant source statement.

This construction also fixes the role of the block kernel. A different kernel q, a different field-strength normalization, or a different localization map may give an equivalent continuum theory only after a comparison map with estimates in the sense of Definition 142.2 is supplied. Finite-range microscopic interactions alone do not identify the continuum normalization of the field.

Lemma 142.35 (Reflection-positive block-spin pullback)**.** *Let Λ_k be split by a time reflection θ into positive, negative, and fixed-time sites, and let $\mathcal{A}_{k,+}$ be the algebra of polynomials in the positive-time fine fields. Suppose the finite measure μ_k is reflection positive:*

$$\int_{\mathbb{R}^{\Lambda_k}} \overline{\theta P(\phi)}\, P(\phi)\, \mathrm{d}\mu_k(\phi) \ge 0, \qquad P \in \mathcal{A}_{k,+}.$$

Assume that the block-spin map B_k is reflection compatible in the following finite sense: every coarse positive-time field $\Phi_y = (B_k\phi)(y)$, $y^0 > 0$, is a real linear combination of fine fields in the positive-time half-lattice, and $(B_k\phi)(\theta y) = (B_k(\theta\phi))(y)$. Let $\nu_{k-1} := (B_k)_\#\mu_k$ be the blocked measure. Then ν_{k-1} is reflection positive for the coarse positive-time polynomial algebra.

Proof. Let F be a polynomial in coarse positive-time fields, and define its pullback

$$B_k^* F(\phi) = F(B_k\phi).$$

By the support assumption on the positive-time block stencils, $B_k^*F \in \mathcal{A}_{k,+}$. Reflection compatibility gives

$$\theta(B_k^*F) = B_k^*(\theta F),$$

because reflecting the fine configuration and then blocking is the same, on the reflected coarse lattice, as blocking and then reflecting. Therefore

$$\begin{aligned} \int \overline{\theta F(\Phi)}\, F(\Phi)\, \mathrm{d}\nu_{k-1}(\Phi) &= \int \overline{B_k^*(\theta F)(\phi)}\, B_k^*F(\phi)\, \mathrm{d}\mu_k(\phi) \\ &= \int \overline{\theta(B_k^*F)(\phi)}\, B_k^*F(\phi)\, \mathrm{d}\mu_k(\phi) \ge 0. \end{aligned}$$

Thus every finite coarse reflection-positivity Gram matrix is the compression of a fine reflection-positivity Gram form under the pullback B_k^*. The lemma is finite-regulator only. A continuum OS statement still requires the directed-family convergence and growth estimates described in Definition 142.47. □

Requirements for OS reconstruction. The preceding construction and lemma are finite pieces. A critical short-range scalar limit reaches a local QFT through a directed family of estimates in exactly the form required by Definition 12.2.

Definition 142.36 (Short-range scalar OS reconstruction requirements)**.** Fix a short-range scalar block-spin structure as in Definition 142.31 and a tuned trajectory $V_k = (g_k, K_k)$ in its RG chart. A short-range scalar OS reconstruction argument consists of the following additional objects and estimates.

1. An infinite-volume prescription for the cumulants $S_{n,k}$. Either the finite-volume limit is taken at fixed lattice spacing before $k \to \infty$, or a joint volume–continuum limit is specified, with estimates uniform enough to give the same limiting distributions on every compactly supported test window.

2. Distributional reconstruction estimates: for every n and every bounded set $B \subset \mathcal{S}((\mathbb{R}^D)^n)$,

$$p_B(S_{n,k} - S_{n,*}) \longrightarrow 0,$$

   together with a uniform temperedness bound of the form

$$|S_{n,k}(f)| \le C_n\, q_{n,r_n}(f), \qquad f \in \mathcal{S}((\mathbb{R}^D)^n),$$

   for a declared Schwartz seminorm q_{n,r_n}. This bound is the continuity estimate that turns a projective family of finite windows into a tempered distribution, as in Lemma 142.48.

3. Euclidean covariance, permutation symmetry, normalization $S_{0,k} = 1$, and Hermiticity at finite regulator, or regulator defects for these identities that vanish in the same distributional topology.

4. Reflection positivity in a directed positive-time test family. More precisely, for every finite positive-time polynomial test family $\mathcal{F} = \{F_1, \ldots, F_m\}$, the regulated Gram matrices

$$G_{k,\mathcal{F};ij} = S_k((\Theta F_i) F_j)$$

   are positive semidefinite, or obey a defect inequality whose defect tends to zero, and their entries converge to the limiting Gram matrix. If one uses quantitative entrywise error estimates for increasing families, the estimates must be compatible with the family size in the sense explained below (142.213).

5. Positive-time semigroup regularity on the OS quotient. This means that the positive-time translations defined from the limiting Schwinger hierarchy obey the semigroup law and strong continuity conditions (12.5)–(12.8). In an RG proof this is an estimate on translated positive-time test windows, additional to the finite Gram-form positivity estimates.

6. Corrected OS-II analytic regularity. A sufficient form is the uniform linear-growth estimate

$$|S^{\mathrm{red}}_{n,k}(F)| \le A\, B^n\, (n!)^\gamma\, q_{n,N_0 + C_{\mathrm{OS}} n}(F)$$

   for all sufficiently large k, with constants $A, B, \gamma, N_0, C_{\mathrm{OS}}$ independent of n and k. The same bound then passes to the limiting reduced hierarchy by distributional convergence. Equivalently, one may provide a different model-specific analytic theorem that yields the Lorentzian boundary-value package of Definition 12.8. Ordinary temperedness at each fixed n supplies fixed-n continuity; the OS-II item controls the many-variable analytic continuation uniformly in the insertion number. In a Wilsonian source construction, a usable route to this item is a moment-source majorant of the form (142.143), together with the projective-seminorm comparison following (142.145).

7. The ordered-insertion adjoint identity required in Theorem 12.16; for a single real scalar field this is the compatibility of Hermiticity with the positive-time multiplication convention, while for a labelled field family it is an identity of the declared label reflection.

Clustering estimates are added when the target claim includes uniqueness of the vacuum.

Positive-time translation continuity from finite windows. Item 5 of Definition 142.36 is a continuity estimate in the limiting OS Hilbert norm. That norm is not the Schwartz norm of a Euclidean test function; it is the limiting positive-time Gram norm. Thus strong continuity of the positive-time translation semigroup is proved by estimates on translated Gram windows.

Let F be a polynomial positive-time test vector whose Euclidean-time support has distance $d_F > 0$ from the reflection plane. For $0 \le t < d_F/2$, let $\tau_t F$ denote translation of every Euclidean-time argument of F forward by t. Suppose the regulated Schwinger hierarchy gives, uniformly for all sufficiently large k,

$$S_k(\Theta(\tau_t F - F)(\tau_t F - F)) \le \omega_F(t) + \varepsilon_{F,k}, \qquad \lim_{t\downarrow 0} \omega_F(t) = 0, \qquad \varepsilon_{F,k} \to 0. \tag{142.176}$$

Here the left side is a finite positive-time Gram-window entry, and the support restriction ensures that $\tau_t F - F$ still belongs to the positive-time test algebra. If the corresponding Gram entries converge to the limiting OS form, then

$$\|[\tau_t F] - [F]\|^2_{\mathcal{H}_{\mathrm{OS}}} = S_*(\Theta(\tau_t F - F)(\tau_t F - F)) \le \omega_F(t),$$

after taking $k \to \infty$. Therefore $t \mapsto [\tau_t F]$ is continuous at $t = 0$ on every such vector. Translation covariance gives $\tau_t \tau_s F = \tau_{t+s} F$ while the support remains positive-time; after passing to the OS quotient this supplies the semigroup law on the dense positive-time domain. Extending the semigroup from this domain to the OS Hilbert-space closure requires the same bound on a directed family of positive-time vectors whose classes are dense. A Wilsonian RG proof must therefore supply (142.176), or an equivalent model-specific equicontinuity estimate, in addition to finite reflection positivity.

Lemma 142.37 (Positive-time quotient semigroup criterion)**.** *Let P_∞ be the algebraic positive-time test space and let*

$$Q(F, G) = S_*((\Theta F)G)$$

be the limiting positive semidefinite OS form on P_∞. Put

$$\mathcal{N}_Q = \{F \in P_\infty \mid Q(F, F) = 0\}, \qquad \|[F]\|^2_{\mathrm{OS}} = Q(F, F).$$

Assume that for $0 \le t \le t_0$ the positive-time translations $\tau_t : P_\infty \to P_\infty$ satisfy $\tau_0 = 1$ and $\tau_t \tau_s = \tau_{t+s}$ whenever $s, t, s + t \in [0, t_0]$. Assume also the quotient-stability estimate

$$Q(\tau_t F, \tau_t F) \le C_t\, Q(F, F), \qquad C_t < \infty, \tag{142.177}$$

with $\sup_{0\le t\le t_0} C_t < \infty$, and the limiting Gram-continuity estimate

$$Q(\tau_t F - F, \tau_t F - F) \longrightarrow 0 \qquad (t \downarrow 0)$$

for every $F \in P_\infty$. Then

$$T_t[F] = [\tau_t F]$$

is a well-defined strongly continuous local semigroup on the OS Hilbert-space completion of $P_\infty/\mathcal{N}_Q$ for $0 \le t \le t_0$, with $\|T_t\| \le C_t^{1/2}$ on its initial domain of definition. If the same estimates hold on every compact positive-time interval, these local semigroups assemble to a strongly continuous semigroup for $t \ge 0$. If $C_t \le 1$, the corresponding semigroup is contractive.

Proof. The first load-bearing point is descent to the quotient. If $F \in \mathcal{N}_Q$, then (142.177) gives

$$Q(\tau_t F, \tau_t F) \le C_t Q(F, F) = 0,$$

so $\tau_t F \in \mathcal{N}_Q$. Hence the class $[\tau_t F]$ depends only on the class $[F]$. The same estimate gives

$$\|T_t[F]\|_{\mathrm{OS}}^2 = Q(\tau_t F, \tau_t F) \le C_t Q(F, F) = C_t \|[F]\|_{\mathrm{OS}}^2,$$

so T_t is bounded on the quotient norm and extends uniquely to the Hilbert completion.

The semigroup law is inherited from the algebraic identity $\tau_t \tau_s F = \tau_{t+s} F$ on the common positive-time domain and then extends by continuity. It remains to prove strong continuity on the completion. On the dense quotient $P_\infty/\mathcal{N}_Q$, the assumed Gram-continuity estimate is exactly

$$\|T_t[F] - [F]\|_{\mathrm{OS}}^2 = Q(\tau_t F - F, \tau_t F - F) \longrightarrow 0.$$

For a general Hilbert vector v, choose $[F]$ with $\|v - [F]\|_{\mathrm{OS}} < \alpha$. If $M = \sup_{0 \le t \le t_0} C_t^{1/2}$, then

$$\|T_t v - v\|_{\mathrm{OS}} \le (M + 1)\alpha + \|T_t[F] - [F]\|_{\mathrm{OS}}.$$

First choose α small and then t small. This proves strong continuity at $t = 0$, and the semigroup law gives strong continuity at every positive time in the interval. □

This lemma isolates an estimate that is logically prior to writing $[\tau_t F]$ as an OS Hilbert-space vector. The finite-window bound (142.176) supplies the continuity term after the regulator is removed. The quotient-stability bound (142.177) supplies invariance of the OS null space. In a model proof both estimates should be derived from the same directed Gram-window control.

Given Definition 142.36, the passage to a Wightman theory is the reconstruction stage following the RG estimates. The distributional estimates give tempered limiting Schwinger functions. The covariance, symmetry, Hermiticity, and normalization identities pass to the limit because they are continuous linear identities on the test-function spaces. The reflection-positive Gram forms pass to the limit by the closed cone argument following Definition 142.30, provided the directed finite-family estimates have actually been supplied. The positive-time semigroup regularity and the corrected OS-II growth package are then exactly the remaining hypotheses of Theorem 12.16. Applying that theorem constructs the Hilbert space, vacuum vector, translation representation, and operator-valued tempered distribution whose Euclidean boundary values reproduce the non-coincident limiting Schwinger functions.

These reconstruction requirements contain more information than the statement that (g_k, K_k) approaches a fixed point. Finite-regulator reflection positivity plus convergence of a few correlators supplies only the finite windows under control. OS reconstruction asks for the whole directed positive-time Gram family, the positive-time translation semigroup, and the OS-II analytic growth estimates. These are the model-specific burdens that remain for the ordinary short-range scalar Wilson–Fisher target.

Remark 142.38 (Current theorem status for the ordinary scalar target). For massive superrenormalizable scalar theories, constructive methods can produce Euclidean measures and hence Wightman theories after OS reconstruction. For an ordinary short-range three-dimensional critical scalar model, a theorem at the Wilsonian fixed-point level would have to construct Definition 142.31, prove a Banach-space fixed point or stable trajectory for the corresponding short-range block-spin RG, establish (142.135) for local fields and their source extensions, prove reflection-compatible blocking as in Lemma 142.35 or an equivalent positivity-preserving construction, and then supply the full OS reconstruction requirements of Definition 142.36. This is stronger than identifying a candidate fixed point in an epsilon expansion, in a hierarchical model, or in a finite projection truncation.

Proof dependency ledger for the ordinary short-range target. The assembly package below is reconstruction-facing; it is not the whole ordinary short-range scalar fixed-point theorem. The missing theorem has to close the following dependency chain in this order.

1. Construct the exact finite short-range block-spin map, including the microscopic Gibbs measures, reflection-compatible block kernel, source adjoint, finite-volume prescription, and localization map into the declared polymer coordinates.
2. Prove that the localized RG map is defined on a Banach polymer chart with uniformly bounded coordinate extraction, large-field regulators, finite-range or summable covariance tails, and irrelevant-activity contraction.
3. Build the critical trajectory or stable graph for the ordinary short-range map itself, including relevant-coordinate tuning and the nonsemisimple or marginal normal forms when those occur.
4. Extend the same trajectory to source windows: retained local source coordinates, connected polymer derivative norms, thermodynamic boundary tails, and Cauchy estimates must all use common source radii and compatible finite test windows.
5. Feed those estimates into the RG-to-OS package: cofinal distributional limits, directed reflection positivity, quotient-stable positive-time translations, OS-II growth, and one common scale schedule for every finite reconstruction demand.
6. Identify the target. Hierarchical, long-range, fermionic, functional-RG, tensor, or numerical fixed points count as ordinary short-range scalar evidence only after auxiliary-to-short-range transfer estimates compare the RG maps, observables, normalizations, and reconstruction topology.

A failure at any earlier layer is not repaired by a later finite identity. For example, a finite OS Gram-window estimate cannot supply the stable graph; a source Cauchy bound cannot supply reflection positivity; and a list of critical exponents from an auxiliary model cannot identify the ordinary short-range Wilson–Fisher QFT without the transfer estimates of Definition 142.40.

The ordinary short-range scalar RG-to-OS assembly package. The preceding estimates can be organized into one theorem-facing package. This is not an additional theorem about the three-dimensional Ising or Wilson–Fisher target; it is the precise list of estimates a model-specific proof must supply before the OS reconstruction theorem can be invoked.

Definition 142.39 (Short-range scalar RG-to-OS assembly package)**.** Fix a short-range scalar block-spin structure and source normalization as in Definitions 142.31 and 142.36. An RG-to-OS assembly package for a critical short-range scalar target consists of the following scale-indexed estimates.

1. A tuned RG trajectory (g_k, K_k) in a declared Banach polymer chart and a limiting source-extended chart $(C_{*,E}, g_{*,E}, K_{*,E}, r_{*,E})$ for every finite test space E, all defined on a fixed source polydisc P_{ρ_E}.

2. For every E, a source-window error budget

$$\begin{aligned}\epsilon^{\mathrm{src}}_{E,k} = \delta^{C}_{E,k} + L_E(\delta^{g}_{E,k} + \delta^{K}_{E,k}) + \delta^{r}_{E,k} \\ + A_E \Xi_E(R_{E,k}) + \sigma_{E,k},\end{aligned} \tag{142.178}$$

   with $\epsilon^{\mathrm{src}}_{E,k} \to 0$. The first line is the RG-chart error of (142.156); $A_E \Xi_E(R_{E,k})$ is the thermodynamic boundary tail of (142.162); and $\sigma_{E,k}$ is the remaining cofinal-window, sampling, or finite-step error at scale k.

3. Uniform distribution bounds: for each n there are r_n and C_n, independent of k and of the finite window E, such that the n-source derivatives extracted from $W_{k,E}$ satisfy (142.141). Consequently, for every multi-index β in the E-window,

$$\left|\partial_z^{\beta} W_{k,E}(0) - \partial_z^{\beta} W_{*,E}(0)\right| \le \frac{\beta!}{\rho_E^{\beta}}\, \epsilon^{\mathrm{src}}_{E,k}. \tag{142.179}$$

4. Cofinal compatibility: the controlled finite test spaces are cofinal in the Schwartz test space, their restriction maps commute with the source-window functionals, and the fixed-window Cauchy estimates have the form required by Lemma 142.49.

5. Directed OS positivity and time-regularity: the positive-time Gram windows satisfy the directed positivity assembly hypotheses of Lemma 142.51, the quotient stability and Gram-continuity estimates of Lemma 142.37, and the corrected OS-II growth package in Definition 142.36.

6. A common directed scale schedule. For every finite reconstruction demand

$$\mathcal{D} = (E, \beta, \mathcal{F}, F, t, H, n),$$

   consisting of a source window and multi-index, a finite positive-time Gram family, a translated positive-time vector, and an n-point test H used in the OS-II bound, there is $k_{\mathcal{D}}$ such that all estimates in the preceding items hold for $k \ge k_{\mathcal{D}}$ with the same constants assigned to $\mathcal{D}$. The assignment is directed: if $\mathcal{D}_1 \le \mathcal{D}_2$ means that the second demand contains the first by enlarging the test windows or increasing the insertion order, then the constants and thresholds restrict compatibly from $\mathcal{D}_2$ to $\mathcal{D}_1$.

When these estimates are supplied by a specific short-range scalar model, the logic is fixed. Equation (142.179) gives convergence of every finite source window. Cofinal compatibility and the uniform Schwartz bounds produce limiting tempered Schwinger distributions. Directed positivity, quotient-stable time translations, and OS-II growth provide the hypotheses of Theorem 12.16. The conclusion is then a Wightman QFT whose Euclidean Schwinger functions are the reconstructed limits. The unproved part for the ordinary critical scalar target is the model-specific construction of the estimates in Definition 142.39; the implication from those estimates to reconstruction is the functional-analytic assembly just described. The common-scale item prevents a frequent logical gap: source convergence, finite Gram positivity, translation equicontinuity, and OS-II growth must be available on the same cofinal regulator tail for the same reconstruction demand. Separate estimates along incompatible scale subsequences give separate finite statements; the OS reconstruction theorem uses their joint directed limit.

142.17 Transfer Estimates From Auxiliary Fixed-Point Models

The theorem-level fixed points known in hierarchical scalar models, fractional or long-range models, fermionic small-parameter models, and tensor-network RG are not automatically fixed points of the ordinary short-range scalar block-spin problem of Definition 142.31. Their use for the ordinary target is controlled by an auxiliary-to-target comparison, not by a shared list of exponents. This section records the estimate that such a comparison must contain.

Definition 142.40 (Auxiliary-to-short-range RG transfer estimates)**.** Let

$$(\mathcal{B}_{\mathrm{aux}}, \mathcal{R}_{\mathrm{aux}}, V_*^{\mathrm{aux}}) \qquad \text{and} \qquad (\mathcal{B}_{\mathrm{sr}}, \mathcal{R}_{\mathrm{sr}}, V_*^{\mathrm{sr}})$$

be an auxiliary RG system and an ordinary short-range target RG system, with Banach spaces, domains, fixed points, stable neighborhoods, source extensions, and reconstruction maps already specified. Transfer estimates from the auxiliary system to the short-range target consist of:

1. a map $\Phi : \mathcal{U}_{\mathrm{aux}} \to \mathcal{B}_{\mathrm{sr}}$, defined on an auxiliary neighborhood that contains the orbit under consideration;
2. a map $\Psi : \mathcal{O}_{\mathrm{aux}} \to \mathcal{O}_{\mathrm{sr}}$ between the corresponding locally convex observable-data spaces;
3. one-step RG defects

$$d_j(y_0) = \mathcal{R}_{\mathrm{sr}}(\Phi(y_j)) - \Phi(y_{j+1}), \qquad y_j = \mathcal{R}_{\mathrm{aux}}^j y_0, \tag{142.180}$$

   with explicit norm bounds $\|d_j(y_0)\|_{\mathcal{B}_{\mathrm{sr}}} \le \delta_j(y_0)$;
4. Lipschitz constants M_j for $\mathcal{R}_{\mathrm{sr}}$ on a tube in $\mathcal{B}_{\mathrm{sr}}$ containing both the true short-range orbit $\mathcal{R}_{\mathrm{sr}}^j \Phi(y_0)$ and the transferred auxiliary orbit $\Phi(y_j)$;
5. comparison of tuning maps for the unstable coordinates,

$$\tau_{\mathrm{sr}}(\Phi y) = A\, \tau_{\mathrm{aux}}(y) + r(y), \tag{142.181}$$

   where A is a specified linear map between unstable coordinate spaces and $r(y)$ is bounded in the target unstable norm;
6. observable comparison estimates

$$p\big(\Psi\ \mathrm{Rec}_{n,k}^{\mathrm{aux}}(y_0) - \mathrm{Rec}_{n,k}^{\mathrm{sr}}(\Phi y_0)\big) \le \varepsilon_{n,p,k}(y_0) \tag{142.182}$$

   for every declared observable seminorm p relevant to the claimed continuum statement.

The transfer estimates refine Definition 142.2 in the direction needed for ordinary short-range critical models. The finite RG-orbit estimate below is elementary as a recurrence, but it is not a decorative calculation: it is the point at which an auxiliary theorem either does or does not transfer to the ordinary short-range target. The model-specific work is to construct the comparison map, the common tube, the constants M_j, and the defects δ_j. Let

$$x_j = \mathcal{R}_{\mathrm{sr}}^j \Phi(y_0), \qquad z_j = x_j - \Phi(y_j).$$

Then $z_0 = 0$ and

$$z_{j+1} = \mathcal{R}_{\mathrm{sr}}(x_j) - \mathcal{R}_{\mathrm{sr}}(\Phi(y_j)) + d_j(y_0). \tag{142.183}$$

The Lipschitz estimate on the tube gives

$$\|z_{j+1}\|_{\mathcal{B}_{\mathrm{sr}}} \le M_j \|z_j\|_{\mathcal{B}_{\mathrm{sr}}} + \delta_j(y_0). \tag{142.184}$$

Iterating this scalar inequality yields

$$\|z_n\|_{\mathcal{B}_{\mathrm{sr}}} \le \sum_{j=0}^{n-1} \left(\prod_{\ell=j+1}^{n-1} M_\ell \right) \delta_j(y_0). \tag{142.185}$$

Thus an auxiliary fixed-point theorem becomes a controlled statement about the short-range target only when the one-step defects are summable after the target RG amplification factors are included.

On a stable subspace, suppose $M_j \le \theta < 1$ and $\delta_j(y_0) \le Cq^j$ with $0 < q < 1$. Then

$$\|z_n\| \le C \sum_{j=0}^{n-1} \theta^{n-1-j} q^j = \begin{cases} C \dfrac{\theta^n - q^n}{\theta - q}, & \theta \ne q, \\ Cn\theta^{n-1}, & \theta = q. \end{cases} \tag{142.186}$$

Both terms tend to zero when $\theta, q < 1$. This is the stable-direction part of the comparison problem.

Relevant directions have the opposite behavior. If a target unstable coordinate has linear eigenvalue $\lambda_a = L^{y_a}$, $y_a > 0$, and one-step comparison errors $e_{a,j}$, then the finite-depth bound is

$$|u_{a,N}| \le |\lambda_a|^N |u_{a,0}| + \sum_{j=0}^{N-1} |\lambda_a|^{N-1-j} |e_{a,j}|. \tag{142.187}$$

Consequently, if y lies on the auxiliary critical surface $\tau_{\mathrm{aux}}(y) = 0$, the target initial point Φy lies on the target critical surface only when the remainder $r(y)$ in (142.181) is itself tuned away, or is small to the finite-depth accuracy demanded by (142.187). This is why a comparison between a hierarchical or long-range theorem and an ordinary short-range scalar theorem must include the unstable tuning map, not only the stable contraction estimate.

Finally, the observable estimate (142.182) must be combined with (142.185). If $\mathrm{Rec}_{n,k}^{\mathrm{sr}}$ is locally Lipschitz in the RG chart with respect to a seminorm p, then the observable error is bounded by the explicit auxiliary-observable defect plus the Lipschitz image of the orbit error z_k. Only after both terms vanish in the chosen observable topology does an auxiliary theorem transfer to the ordinary short-range QFT claim. Without this transfer structure, hierarchical, long-range, tensor, and functional-RG fixed points should be read as theorem-level benchmarks or computational evidence in their own frameworks, not as a proof of the ordinary short-range Wilson–Fisher QFT.

Transfer to a projective observable germ. The comparison must be made window by window, because a continuum local-QFT claim is a projective statement about all reconstruction windows. Fix a finite observation window α in the directed family of the short-range target. Suppose the auxiliary theorem supplies a corresponding auxiliary window and an auxiliary limiting observable $O^{\mathrm{aux}}_{*,\alpha}$ such that, after its normalization,

$$p^{\mathrm{sr}}_{\alpha}\big(\Psi\ \mathrm{Rec}^{\mathrm{aux}}_{\alpha,k}(y_0) - \Psi O^{\mathrm{aux}}_{*,\alpha}\big) \le a_{\alpha,k}. \tag{142.188}$$

Assume further that the comparison of observable reconstructions has the finite-window defect

$$p^{\mathrm{sr}}_{\alpha}\big(\mathrm{Rec}^{\mathrm{sr}}_{\alpha,k}(\Phi y_0) - \Psi\ \mathrm{Rec}^{\mathrm{aux}}_{\alpha,k}(y_0)\big) \le \varepsilon_{\alpha,k}, \tag{142.189}$$

and that the short-range reconstruction map is Lipschitz on the target tube:

$$p^{\mathrm{sr}}_{\alpha}\big(\mathrm{Rec}^{\mathrm{sr}}_{\alpha,k}(x_0) - \mathrm{Rec}^{\mathrm{sr}}_{\alpha,k}(\Phi y_0)\big) \le L_{\alpha,k}\|x_k - \Phi(y_k)\|_{\mathcal{B}_{\mathrm{sr}}}. \tag{142.190}$$

Here x_0 is the actual short-range initial point whose window is being claimed; in the simplest transferred construction $x_0 = \Phi y_0$, but the separate notation is useful when the target microscopic regulator is only close to the transferred auxiliary initial condition. If the allowed normalization of the short-range window differs from the pushed-forward auxiliary normalization by at most $n_{\alpha,k}$, the triangle inequality and (142.185) give the finite projective-window transfer estimate

$$\begin{aligned} p^{\mathrm{sr}}_{\alpha}\big(g_{\mathrm{sr}}\,\mathrm{Rec}^{\mathrm{sr}}_{\alpha,k}(x_0) - \Psi O^{\mathrm{aux}}_{*,\alpha}\big) &\le n_{\alpha,k} + a_{\alpha,k} + \varepsilon_{\alpha,k} \\ &\quad + L_{\alpha,k}\sum_{j=0}^{k-1}\left(\prod_{\ell=j+1}^{k-1} M_\ell\right)\delta_j(y_0). \end{aligned} \tag{142.191}$$

Thus an auxiliary fixed point transfers to the ordinary short-range observable germ only after the right-hand side of (142.191) tends to zero for every window α in the directed family. The estimate separates four different analytic tasks: convergence of the auxiliary observable window, comparison of auxiliary and target reconstructions, control of the target orbit defect, and compatibility of the normalization group. A shared critical exponent controls at most one contribution to one family of windows; it does not provide the projective observable-germ transfer.

142.18 Source-Extended RG, Scaling Operators, And Contact Terms

A fixed interaction is not yet a QFT spectrum. Scaling operators are obtained by extending the RG map to sources and by reconstructing the resulting functional derivatives as distributions. This section records the minimal theorem-level structure, because otherwise the phrase "operator dimension" may mean only an eigenvalue of a finite list of couplings.

Let A be a set of source labels. For each $\alpha \in A$, let $\mathcal{J}_\alpha$ be a locally convex space of test sources on $\mathbb{R}^D$, for instance $C^\infty_c(\mathbb{R}^D)$ or $\mathcal{S}(\mathbb{R}^D)$. A regulated source-dependent generating functional has the form

$$Z_k(V;J) = \int \exp\left(-S_k(\phi;V) + \sum_{\alpha\in A}\langle J_\alpha, \mathcal{O}_{\alpha,k}(\phi)\rangle\right) \mathrm{d}\mu_k(\phi), \tag{142.192}$$

where $\langle J_\alpha, \mathcal{O}_{\alpha,k} \rangle$ denotes the pairing between a test source and a regulated insertion. In a gauge theory, the source direction must either couple to a gauge-invariant lattice observable, to a Wilson-line or Wilson-loop observable with its path data included, or to a class in the BV observable cohomology. A source coupled to a gauge-fixed colored field variable is not, by itself, a nonperturbative observable.

Definition 142.41 (Source-extended RG datum)**.** A source-extended RG datum near a fixed point V_* consists of:

1. a Banach RG chart $\mathcal{B}$, an RG map $\mathcal{R} : \mathcal{U} \to \mathcal{B}$, and a fixed point $\mathcal{R}(V_*) = V_*$;
2. a locally convex source space $\mathcal{J} = \bigoplus_{\alpha \in A} \mathcal{J}_\alpha$;
3. a map
$$\widehat{\mathcal{R}} : \mathcal{U} \times \mathcal{V}_J \longrightarrow \mathcal{B} \times \mathcal{J}, \qquad \widehat{\mathcal{R}}(V, J) = \big(\mathcal{R}(V),\, \mathcal{M}_V J + \mathcal{N}_V(J)\big), \tag{142.193}$$
where $\mathcal{V}_J$ is a neighborhood of $0 \in \mathcal{J}$, $\mathcal{M}_V$ is linear in J, and $\mathcal{N}_V(J) = O(J^2)$ in the declared source topology;
4. an exact finite-regulator identity
$$Z_k(V; J) = e^{A_k(V;J)} Z_{k-1}\Big(\widehat{\mathcal{R}}(V, J)\Big), \tag{142.194}$$
with $A_k(V; J)$ a local normalization functional in the sources;
5. reconstruction maps taking n source derivatives of $\log Z_k(V; J)$ at $J = 0$ to connected distributions on $(\mathbb{R}^D)^n$, or to distributions on configuration space away from collision diagonals.

The local functional $A_k(V; J)$ is part of the datum. Its source derivatives are precisely where contact terms generated by the RG step are recorded.

At a fixed point, the linear source map
$$\mathcal{M}_* = \mathcal{M}_{V_*} = D_J \widehat{\mathcal{R}}(V_*, 0) \tag{142.195}$$
contains the scaling data. If a source J_α couples to a local field whose scaling dimension is Δ_α, then the constant-source coordinate has RG exponent
$$y_\alpha = D - \Delta_\alpha. \tag{142.196}$$
This relation is fixed by the invariant pairing $\int J_\alpha(x) \mathcal{O}_\alpha(x)\, \mathrm{d}^D x$: under $x = Lx'$, a field with $\mathcal{O}_\alpha(Lx') = L^{-\Delta_\alpha} \mathcal{O}_\alpha(x')$ requires
$$J'_\alpha(x') = L^{D-\Delta_\alpha} J_\alpha(Lx'). \tag{142.197}$$
Thus the dimension is not assigned to a formal monomial alone; it is read from the source direction after redundant directions, null fields, and contact redefinitions have been quotiented as appropriate.

Definition 142.42 (Scaling source and scaling field)**.** Let $\mathcal{M}_*$ be the linearized source RG map. A scaling source direction is a nonzero equivalence class $[j_\alpha]$ in the source space modulo null source directions and source redefinitions whose functional derivatives vanish at separated points, such that

$$\mathcal{M}_*[j_\alpha] = L^{D-\Delta_\alpha}[j_\alpha]. \tag{142.198}$$

The corresponding scaling field is the distribution-valued functional derivative of the connected generating functional in the direction $[j_\alpha]$, reconstructed in the continuum limit. In a BV formulation, the equivalence class is taken in Q_{S_*}-cohomology of observables; in a lattice gauge formulation, it is taken among gauge-invariant source directions.

The quotient in Definition 142.42 is not a matter of taste. If two source directions differ by a local source counterterm, their separated-point connected correlators agree while their extensions across coincident points may differ. The following definition fixes the vocabulary used in the rest of the monograph.

Definition 142.43 (Contact term)**.** Let $n \geq 2$, and let

$$\mathfrak{D}_n = \bigcup_{1 \leq i < j \leq n} \{(x_1, \dots, x_n) \in (\mathbb{R}^D)^n : \; x_i = x_j\} \tag{142.199}$$

be the union of pairwise collision diagonals. A contact term in an n-point distribution is a distribution

$$C \in \mathcal{D}'((\mathbb{R}^D)^n)$$

whose support is contained in $\mathfrak{D}_n$. Equivalently, $\langle C, f \rangle = 0$ for every $f \in C_c^\infty((\mathbb{R}^D)^n)$ whose support is disjoint from $\mathfrak{D}_n$. Contact terms are not ordinary separated-point functions. In a source formalism they are generated by local functionals of the sources and their derivatives.

Let

$$\mathrm{Conf}_n(\mathbb{R}^D) = (\mathbb{R}^D)^n \setminus \mathfrak{D}_n \tag{142.200}$$

be the configuration space of ordered distinct points. For $f \in C_c^\infty(\mathrm{Conf}_n(\mathbb{R}^D))$, define the dilation of the test function by

$$(S_L f)(x_1, \dots, x_n) = L^{-nD} f(L^{-1}x_1, \dots, L^{-1}x_n). \tag{142.201}$$

This convention is chosen so that

$$\langle G, S_L f \rangle = \int G(Ly_1, \dots, Ly_n) f(y_1, \dots, y_n) \, \mathrm{d}^D y_1 \cdots \mathrm{d}^D y_n \tag{142.202}$$

whenever G is represented by an integrable function on the support of the test function.

Separated-point scaling from source-extended RG. The nontrivial step in a source-extended RG construction is proving the finite-scale identity below for actual source derivatives of the regulated theory. Once that identity is available with a vanishing error, its separated-point consequence is a distributional limit statement. Fix labels $\alpha_1, \dots, \alpha_n$ with source eigenvalues $L^{D-\Delta_{\alpha_i}}$. Suppose that the source-extended RG datum gives connected finite-regulator distributions

$$G_{k;\alpha_1 \dots \alpha_n} \in \mathcal{D}'(\mathrm{Conf}_n(\mathbb{R}^D))$$

which converge to

$$G_{*;\alpha_1 \dots \alpha_n} \in \mathcal{D}'(\mathrm{Conf}_n(\mathbb{R}^D))$$

in the usual distribution topology on every compact subset of $\mathrm{Conf}_n(\mathbb{R}^D)$. Assume moreover that for every $f \in C_c^\infty(\mathrm{Conf}_n(\mathbb{R}^D))$ the finite-scale RG identity implies

$$\left| \langle G_{k;\alpha_1\ldots\alpha_n}, S_L f\rangle - L^{-\sum_i \Delta_{\alpha_i}} \langle G_{k-1;\alpha_1\ldots\alpha_n}, f\rangle \right| \le \varepsilon_k(f), \tag{142.203}$$

with $\varepsilon_k(f) \to 0$. Then the limiting separated-point distribution is homogeneous under scale L:

$$\langle G_{*;\alpha_1\ldots\alpha_n}, S_L f\rangle = L^{-\sum_i \Delta_{\alpha_i}} \langle G_{*;\alpha_1\ldots\alpha_n}, f\rangle \tag{142.204}$$

for every $f \in C_c^\infty(\mathrm{Conf}_n(\mathbb{R}^D))$.

If $T_{*;\alpha_1\ldots\alpha_n} \in \mathcal{D}'((\mathbb{R}^D)^n)$ is any extension of $G_{*;\alpha_1\ldots\alpha_n}$ to all of $(\mathbb{R}^D)^n$, then the distribution

$$H_L(f) = \langle T_{*;\alpha_1\ldots\alpha_n}, S_L f\rangle - L^{-\sum_i \Delta_{\alpha_i}} \langle T_{*;\alpha_1\ldots\alpha_n}, f\rangle \tag{142.205}$$

is a contact term.

The verification is a support calculation for distributions, not a separate RG theorem. The dilation S_L maps $C_c^\infty(\mathrm{Conf}_n(\mathbb{R}^D))$ continuously to itself. By distributional convergence on configuration space,

$$\langle G_{k;\alpha_1\ldots\alpha_n}, S_L f\rangle \longrightarrow \langle G_{*;\alpha_1\ldots\alpha_n}, S_L f\rangle$$

and

$$\langle G_{k-1;\alpha_1\ldots\alpha_n}, f\rangle \longrightarrow \langle G_{*;\alpha_1\ldots\alpha_n}, f\rangle.$$

Taking $k \to \infty$ in (142.203) gives (142.204), because $\varepsilon_k(f) \to 0$.

For the last assertion, let $f \in C_c^\infty((\mathbb{R}^D)^n)$ have support disjoint from $\mathfrak{D}_n$. Then f and $S_L f$ are test functions on $\mathrm{Conf}_n(\mathbb{R}^D)$, and the extension $T_{*;\alpha_1\ldots\alpha_n}$ agrees with $G_{*;\alpha_1\ldots\alpha_n}$ on both of them. Therefore (142.204) gives $H_L(f) = 0$. A distribution that vanishes on every test function supported in the open set $(\mathbb{R}^D)^n \setminus \mathfrak{D}_n$ has support contained in $\mathfrak{D}_n$, by the definition of support of a distribution. Hence H_L is a contact term in the sense of Definition 142.43.

This is the logical order. Source eigenvalues determine candidate scaling dimensions. Reconstruction estimates make the source derivatives into distributions. The finite-scale RG identity then proves homogeneity at separated points. Extension across collision diagonals is an additional renormalization problem; different extensions differ by contact terms, and local source counterterms change precisely those contact terms. This is why anomalous dimensions, OPE coefficients at separated points, and contact terms must be kept as distinct pieces of data.

Remark 142.44 (Status of short-range scalar and gauge targets)*.* Constructive massive ϕ^4_3 and related superrenormalizable models give Wightman QFTs after their Euclidean constructions and OS reconstruction are completed. That achievement is logically distinct from constructing the critical Wilson–Fisher CFT as a non-Gaussian fixed point of a short-range block-spin map with stable manifold, operator spectrum, and reconstruction estimates of the form (142.126). Hierarchical scalar models, fractional long-range models, fermionic small-parameter models, and rigorous tensor RG supply theorem-level benchmarks for parts of this structure.

For gauge theories the corresponding theorem must be formulated through Definition 142.26. A lattice proof would construct the RG map on gauge-invariant measures and Wilson-line observables with reflection-positivity control. A continuum perturbative proof would construct the same flow in a regularized BV complex, prove the quantum master equation after each RG step, and identify the physical observables as cohomology classes before reconstruction. These are stronger requirements than the computation of beta functions for a finite list of local coefficients.

In four-dimensional scalar ϕ^4, perturbation theory supplies a formal renormalized coordinate system. Existing triviality results and expectations belong to particular regulator classes and limiting procedures. The existence of a UV-complete nonperturbative QFT whose short-distance expansion agrees with four-dimensional ϕ^4 perturbation theory to all orders remains outside the theorem-level results recorded here.

142.19 Relation To Universality Classes

In this monograph, the phrase *universality class* is not used as a synonym for "same symmetries and same dimension." It denotes a convergence statement in a declared topology. The minimal statement is the following.

Definition 142.45 (Wilsonian universality statement)**.** A Wilsonian universality statement consists of:

1. an index set I of microscopic regulators or bare finite-cutoff models;
2. for each $i \in I$, a tuned initial point V_i in a common Banach RG chart $(\mathcal{B}, \|\cdot\|)$, or in charts identified by specified coordinate maps;
3. an RG map $\mathcal{R} : \mathcal{U} \to \mathcal{B}$, a neighborhood $\mathcal{N} \subset \mathcal{U}$, and a fixed point $V_* \in \mathcal{N}$;
4. a topological vector space $\mathcal{O}$ of normalized long-distance observable data, for example finite lists of smeared Schwinger functions in a distribution topology;
5. reconstruction maps
$$\mathrm{Rec}_{i,n} : \mathcal{U} \to \mathcal{O}$$
giving the n-step long-distance observable data of the microscopic model i;
6. a normalization group G acting continuously on $\mathcal{O}$, encoding allowed metric factors, field normalizations, and coordinate rescalings.

This is a theorem-level universality statement if, for every $i \in I$, there are $g_i \in G$ and $O_* \in \mathcal{O}$ such that
$$\mathcal{R}^n(V_i) \in \mathcal{N} \quad (n \gg 1), \qquad \mathcal{R}^n(V_i) \longrightarrow V_* \quad \text{in } \mathcal{B},$$
and
$$g_i \, \mathrm{Rec}_{i,n}(V_i) \longrightarrow O_* \qquad \text{in } \mathcal{O}.$$
The common limit O_* is part of the assertion; without the reconstruction convergence, convergence of local couplings alone is not a QFT universality theorem.

Observable-germ formulation. For an actual QFT the reconstructed observable is rarely a single Banach-space coordinate. It is normally a compatible family of finite tests: finitely many smeared n-point functions, finite lists of Wilson loops, finite momentum windows, finite source derivatives, or finite spectral windows. Thus the topology in Definition 142.45 is most naturally given by a projective system.

Definition 142.46 (Observable-germ universality class)**.** An observable-germ universality structure is a Wilsonian universality statement together with the following refinement of $\mathcal{O}$.

1. A directed set $\mathfrak{A}$ of finite observation windows.
2. For each $\alpha \in \mathfrak{A}$, a Banach space $\mathcal{O}_\alpha$ with norm p_α, and for $\alpha \preceq \beta$ a continuous projection $\pi_{\alpha\beta} : \mathcal{O}_\beta \to \mathcal{O}_\alpha$ satisfying
$$\pi_{\alpha\gamma} = \pi_{\alpha\beta}\pi_{\beta\gamma}, \qquad \alpha \preceq \beta \preceq \gamma.$$
3. The projective-limit observable space
$$\mathcal{O}_{\mathrm{germ}} = \varprojlim_{\alpha\in\mathfrak{A}} \mathcal{O}_\alpha = \{(O_\alpha)_\alpha : \pi_{\alpha\beta}O_\beta = O_\alpha \text{ for } \alpha \preceq \beta\},$$
equipped with the seminorms $p_\alpha(O) = p_\alpha(O_\alpha)$.
4. Reconstruction maps
$$\mathrm{Rec}^\alpha_{i,n} : \mathcal{U} \longrightarrow \mathcal{O}_\alpha$$
compatible with the projections:
$$\pi_{\alpha\beta}\,\mathrm{Rec}^\beta_{i,n} = \mathrm{Rec}^\alpha_{i,n}\,.$$
5. A normalization group G acting by compatible continuous maps on all $\mathcal{O}_\alpha$.

The microscopic regulator i belongs to the observable-germ universality class represented by the normalized germ $O_* \in \mathcal{O}_{\mathrm{germ}}$ if there exists $g_i \in G$ such that, for every finite observation window α,
$$p_\alpha\big(g_i\ \mathrm{Rec}^\alpha_{i,n}(V_i) - (O_*)_\alpha\big) \longrightarrow 0. \tag{142.206}$$
The word *class* therefore refers to an equivalence class of normalized observable germs in this projective topology. Agreement of finitely many critical exponents, amplitude ratios, or correlation functions is a finite-window statement until the remaining windows are controlled.

The preceding definition deliberately uses observable windows rather than the phrase "the same theory." Equality of a few numerical quantities, or even of a large but finite list of reconstructed correlators, is not equality of local QFT data. The bridge to a local quantum field theory requires that the projective family contain enough test-function windows, positivity conditions, covariance identities, and growth bounds to feed one of the reconstruction frameworks developed in Chapters 12 and 2.

Definition 142.47 (Local-QFT-strength observable germ)**.** An observable-germ structure is *local-QFT-strength* for an Euclidean scalar or gauge-invariant observable sector if its directed family $\mathfrak{A}$ contains, as compatible subwindows, the following data.

1. For each finite list of observable labels $a_1, \dots, a_n$ and each finite-dimensional subspace $E \subset \mathcal{S}((\mathbb{R}^D)^n)$ of test functions, a window that records the values of a distribution $S_{a_1\dots a_n} \in \mathcal{S}'((\mathbb{R}^D)^n)$ on E. The projective limit over E recovers the full tempered distribution only after the compatibility and seminorm-bound conditions of Lemma 142.48 are supplied; finite pointwise or moment data alone are a smaller collection of tests.

2. Windows recording the algebraic identities required of the sector: permutation or graded permutation covariance, Euclidean covariance, reflection compatibility for the chosen time direction, and the local source-counterterm subspace whose derivatives are distributions supported on collision diagonals.
3. Windows recording the positivity forms used in reconstruction. In the OS route these are the finite reflection-positivity Gram matrices for test functions supported at positive Euclidean time. In a directly Lorentzian route they are the Wightman positivity forms on the polynomial test-field algebra.
4. The growth or regularity hypotheses needed by the chosen reconstruction theorem. For the OS-to-Wightman route this includes the corrected OS-II growth hypothesis used in Chapter 12; for the Wightman route it includes temperedness, the spectrum condition, locality, and the common invariant domain structure.
5. If vacuum uniqueness or particle data are part of the claim, windows for cluster properties or spectral projections in the declared observable topology.

The normalization group is restricted to transformations of the observable labels, coordinates, metric factors, and source normalizations that preserve these identities and positivity forms.

Projective distribution-window extension. The first item in Definition 142.47 contains a functional analytic obligation that is easy to hide if one speaks only of many finite windows. Fix n and write $X = (\mathbb{R}^D)^n$. For an integer $r \geq 0$, set

$$q_r(f) = \max_{|\alpha| \leq r} \sup_{x \in X} (1 + |x|)^r \, |\partial^\alpha f(x)|, \qquad f \in \mathcal{S}(X), \tag{142.207}$$

where α is a multi-index on X. These seminorms generate the Schwartz topology up to the usual harmless replacement by an equivalent countable family.

Lemma 142.48 (Projective finite windows define a distribution)**.** *Let $\mathcal{E}$ be a directed family of finite-dimensional subspaces of $\mathcal{S}(X)$, ordered by inclusion, and suppose that $E_\infty = \bigcup_{E \in \mathcal{E}} E$ is dense in $\mathcal{S}(X)$. For each $E \in \mathcal{E}$, let $S_E : E \to \mathbb{C}$ be linear. Assume:*

1. *whenever $E \subset F$, $S_F|_E = S_E$;*
2. *there exist $r \in \mathbb{Z}_{\geq 0}$ and $C < \infty$ such that*

$$|S_E(f)| \leq C \, q_r(f) \qquad (E \in \mathcal{E}, \; f \in E). \tag{142.208}$$

Then there is a unique tempered distribution $S \in \mathcal{S}'(X)$ satisfying $S|_E = S_E$ for every $E \in \mathcal{E}$. Moreover S obeys the same bound

$$|S(f)| \leq C \, q_r(f), \qquad f \in \mathcal{S}(X).$$

Proof. Compatibility first produces a single algebraic functional on E_∞. If $f \in E \cap F$, choose $H \in \mathcal{E}$ with $E \subset H$ and $F \subset H$. Then

$$S_E(f) = S_H(f) = S_F(f),$$

so $S_\infty(f) := S_E(f)$ for $f \in E$ is well defined on E_∞. Linearity follows after passing to a common upper window containing the finitely many vectors being combined. The bound (142.208) gives

$$|S_\infty(f)| \le Cq_r(f), \qquad f \in E_\infty.$$

Let $f \in \mathcal{S}(X)$. Choose $f_j \in E_\infty$ with $f_j \to f$ in the Schwartz topology. Then $q_r(f_j - f_k) \to 0$, hence

$$|S_\infty(f_j) - S_\infty(f_k)| \le Cq_r(f_j - f_k),$$

so $S_\infty(f_j)$ is Cauchy in $\mathbb{C}$. If $g_j \in E_\infty$ is another approximating sequence, then $q_r(f_j - g_j) \to 0$, so the two limits agree. Define

$$S(f) = \lim_{j\to\infty} S_\infty(f_j).$$

The definition is linear by applying the same construction to approximating sequences for finite linear combinations, and the estimate $|S(f)| \le Cq_r(f)$ follows by taking the limit of $|S_\infty(f_j)| \le Cq_r(f_j)$. Thus S is continuous on $\mathcal{S}(X)$, hence $S \in \mathcal{S}'(X)$, and it extends each S_E. If $T \in \mathcal{S}'(X)$ is another continuous extension, then $T - S$ vanishes on the dense subspace E_∞; continuity gives $T = S$. □

This lemma isolates the exact theorem-facing content of the phrase "distribution window." Compatibility supplies a single algebraic functional; the uniform Schwartz-seminorm bound supplies tempered continuity. In a genuine Wilsonian RG theorem the estimates must be produced for the Schwinger hierarchy and for the source derivatives that generate the desired local observables. After this distributional object exists, the finite reflection-positivity windows below test whether it is eligible for OS reconstruction.

Cofinal assembly from regulated finite windows. The previous lemma starts from limiting window functionals. An RG proof usually produces regulated window functionals $S_{k,N}$ at scale k, where N records how large a finite test window has been controlled. The following criterion is the diagonal step needed before the limiting functionals in Lemma 142.48 exist.

Lemma 142.49 (Cofinal finite-window assembly)**.** *Let*

$$E_1 \subset E_2 \subset \cdots \subset \mathcal{S}(X)$$

be finite-dimensional subspaces whose union is dense in $\mathcal{S}(X)$. Let $N_k \to \infty$, and suppose that for every k and every $N \le N_k$ there is a linear functional

$$S_{k,N} : E_N \to \mathbb{C}.$$

Assume:

1. *finite-scale compatibility: $S_{k,M}|_{E_N} = S_{k,N}$ whenever $N \le M \le N_k$;*
2. *a uniform seminorm bound: there exist r and C, independent of k and N, such that*

$$|S_{k,N}(f)| \le Cq_r(f), \qquad f \in E_N, \quad N \le N_k;$$

3. cofinal Cauchy control: for each fixed N,

$$\eta_{N,k} = \sup_{\ell \geq k} \sup_{\substack{f \in E_N \\ q_r(f) \leq 1}} |S_{k,N}(f) - S_{\ell,N}(f)| \longrightarrow 0 \tag{142.209}$$

as $k \to \infty$, with the supremum restricted to k, ℓ for which $N \leq N_k, N_\ell$.

Then there are compatible limiting functionals

$$S_N : E_N \to \mathbb{C}, \qquad S_M|_{E_N} = S_N \quad (N \leq M),$$

with $|S_N(f)| \leq C q_r(f)$. Hence Lemma 142.48 produces a unique tempered distribution $S \in \mathcal{S}'(X)$ extending all S_N. Moreover one may choose a strictly increasing scale subsequence k_j with $N_{k_j} \geq j$ and

$$\eta_{N,k_j} \leq 2^{-j}, \qquad 1 \leq N \leq j. \tag{142.210}$$

Along this subsequence every fixed finite window E_N converges to its limit at a quantified rate after $j \geq N$.

Proof. Fix N. Since $N_k \to \infty$, the functionals $S_{k,N}$ are defined for all sufficiently large k. The Cauchy control (142.209) says that $S_{k,N}$ is Cauchy in the operator seminorm

$$\|T\|_{E_N,r} = \sup_{\substack{f \in E_N \\ q_r(f) \leq 1}} |T(f)|.$$

The target space is finite dimensional, so this normed space of linear functionals is complete. Define S_N to be the limit of $S_{k,N}$ in that norm. The bound $|S_N(f)| \leq C q_r(f)$ follows by taking the limit of the uniform bound for $S_{k,N}$.

If $N \leq M$, choose k so large that $M \leq N_k$. Finite-scale compatibility gives

$$S_{k,M}|_{E_N} = S_{k,N}.$$

Taking $k \to \infty$ in the operator seminorms on E_M and E_N gives

$$S_M|_{E_N} = S_N.$$

Thus the limiting windows satisfy the hypotheses of Lemma 142.48, and the tempered distribution follows.

It remains to spell out the diagonal schedule. For a fixed j, the set $\{1, \ldots, j\}$ is finite. Since each $\eta_{N,k} \to 0$, and since $N_k \to \infty$, there exists k_j larger than k_{j-1} such that

$$N_{k_j} \geq j, \qquad \eta_{N,k_j} \leq 2^{-j} \quad (1 \leq N \leq j).$$

Choosing these k_j recursively gives (142.210). For fixed N and $j \geq N$, the definition of η_{N,k_j} bounds the distance from $S_{k_j,N}$ to the limiting functional S_N by 2^{-j} in the same operator seminorm. □

This lemma identifies a common hidden gap in RG reconstruction arguments. Controlling one finite window at each scale is insufficient: the number of controlled windows must be cofinal, the already-controlled windows must be Cauchy as the regulator is removed, and the seminorm bound must be uniform in the window. The lemma supplies the diagonal functional-analytic step. It does not supply the model-specific polymer or cluster estimates that prove the hypotheses.

Lemma 142.50 (Moving finite windows approximate fixed test functions)**.** *Assume the hypotheses of Lemma 142.49. Let $\Pi_N : \mathcal{S}(X) \to E_N$ be linear approximation maps such that, for each $f \in \mathcal{S}(X)$,*

$$q_r(\Pi_N f - f) \longrightarrow 0.$$

Let $S \in \mathcal{S}'(X)$ be the limiting distribution constructed in Lemma 142.49. Then, for every fixed $f \in \mathcal{S}(X)$,

$$S_{k,N_k}(\Pi_{N_k} f) \longrightarrow S(f) \qquad (k \to \infty). \tag{142.211}$$

Proof. The point is to avoid confusing a moving finite window with convergence on a fixed test function. Fix N, and take k so large that $N \le N_k$. By finite-scale compatibility,

$$S_{k,N_k}(\Pi_N f) = S_{k,N}(\Pi_N f).$$

Therefore

$$\begin{aligned}\big|S_{k,N_k}(\Pi_{N_k} f) - S(f)\big| \le{}& \big|S_{k,N_k}(\Pi_{N_k} f - \Pi_N f)\big| \\ &+ \big|S_{k,N}(\Pi_N f) - S_N(\Pi_N f)\big| + \big|S(\Pi_N f - f)\big|.\end{aligned}$$

The uniform seminorm bound gives

$$\big|S_{k,N_k}(\Pi_{N_k} f - \Pi_N f)\big| \le C q_r(\Pi_{N_k} f - \Pi_N f) \le C q_r(\Pi_{N_k} f - f) + C q_r(f - \Pi_N f).$$

The limiting distribution satisfies the same bound $|S(g)| \le C q_r(g)$, because it is the continuous extension of the compatible finite-window limits. Hence

$$|S(\Pi_N f - f)| \le C q_r(\Pi_N f - f).$$

For fixed N, the middle term tends to zero as $k \to \infty$, by the fixed-window convergence in Lemma 142.49. Taking the upper limit in k gives

$$\limsup_{k\to\infty} \big|S_{k,N_k}(\Pi_{N_k} f) - S(f)\big| \le 2C q_r(\Pi_N f - f).$$

Finally let $N \to \infty$. The assumed approximation property of Π_N gives (142.211). ☐

This lemma is the distributional diagonal step used when the RG construction controls only a scale-dependent finite test space. It still assumes the uniform seminorm bound and fixed-window Cauchy control from the preceding lemma. If the projection error $q_r(\Pi_N f - f)$ is not controlled in the same seminorm that bounds the finite functionals, or if N_k does not tend to infinity, the moving-window values do not define the continuum action of a tempered distribution on the fixed test function f.

Finite OS-positivity Gram-matrix bounds. The positivity windows in Definition 142.47 are not decorative. They are finite Gram matrices whose limits must be controlled before Osterwalder–Schrader reconstruction can be invoked. Fix a finite family $\mathcal{F} = \{F_1, \dots, F_m\}$ of polynomial Euclidean observable test vectors supported at positive Euclidean time, and let Θ be the Euclidean time reflection with the conjugation appropriate to the observable sector. A regulated Schwinger hierarchy gives the finite matrix

$$G_{k,\mathcal{F};ij} = S_k\big((\Theta F_i) F_j\big), \qquad 1 \le i, j \le m. \tag{142.212}$$

Reflection positivity at scale k is the assertion that

$$c^* G_{k,\mathcal{F}} c \geq 0 \qquad \text{for every } c \in \mathbb{C}^m.$$

If the window is part of a reconstruction-strength RG estimate, the entries of $G_{k,\mathcal{F}}$ converge to entries

$$G_{*,\mathcal{F};ij} = S_*\big((\Theta F_i) F_j\big).$$

For each fixed c, continuity of the finite quadratic form gives

$$c^* G_{*,\mathcal{F}} c = \lim_{k\to\infty} c^* G_{k,\mathcal{F}} c \geq 0.$$

Thus positivity passes to the limit for this finite family. The quantitative finite-window form is also useful. If $G_{k,\mathcal{F}}$ is Hermitian, $G_{k,\mathcal{F}} \geq \ell\, 1_m$, and the limiting-window error satisfies

$$|G_{*,\mathcal{F};ij} - G_{k,\mathcal{F};ij}| \leq \epsilon \qquad (1 \leq i, j \leq m),$$

then

$$c^* G_{*,\mathcal{F}} c \geq \big(\ell - m\epsilon\big) \|c\|_2^2. \tag{142.213}$$

Indeed,

$$|c^*(G_{*,\mathcal{F}} - G_{k,\mathcal{F}})c| \leq \epsilon \Big(\sum_{i=1}^m |c_i|\Big)^2 \leq m\epsilon\, \|c\|_2^2.$$

Equation (142.213) is a finite Gram-matrix lower bound, not an OS reconstruction theorem. For this entrywise form to give a positive lower bound on a family of size m, one needs $\epsilon < \ell/m$. Hence a directed-family OS theorem cannot be obtained by fixing an error tolerance independently of the number of test vectors: if $\mathcal{F}_N$ is an increasing family with $m_N = |\mathcal{F}_N|$, the estimate must supply $\epsilon_{N,k}$ and $\ell_{N,k}$ with $\ell_{N,k} - m_N \epsilon_{N,k} \geq 0$ in the limit being taken, or else use a stronger operator-norm estimate $\|G_{*,\mathcal{F}_N} - G_{k,\mathcal{F}_N}\|_{\ell^2\to\ell^2} \leq \epsilon^{\mathrm{op}}_{N,k}$ with $\ell_{N,k} - \epsilon^{\mathrm{op}}_{N,k} \geq 0$. Producing such family-size-compatible error control from RG estimates is a load-bearing part of the theorem. OS positivity for the continuum hierarchy requires this bound, or the corresponding limiting argument, for every finite positive-time test family in the directed observable germ. Agreement of separated two-point entries, critical exponents, or a finite list of amplitudes does not supply the missing Gram windows.

There is a closely related semidefinite version, which is often the form available in an RG proof with regulator defects. Suppose that the regulated window is not strictly bounded below but satisfies

$$c^* G_{k,\mathcal{F}} c \geq -\delta_{k,\mathcal{F}} \|c\|_2^2 \qquad (c \in \mathbb{C}^m)$$

and that the entrywise error from this regulated window to the candidate limit is at most $\epsilon_{k,\mathcal{F}}$. Then the same estimate gives

$$c^* G_{*,\mathcal{F}} c \geq -\big(\delta_{k,\mathcal{F}} + m\epsilon_{k,\mathcal{F}}\big) \|c\|_2^2. \tag{142.214}$$

For a fixed family $\mathcal{F}$, exact finite reflection positivity and entrywise convergence imply positivity of the limiting window by closedness of the finite positive cone. For a directed sequence of growing windows, a proof using the quantitative defect route must instead produce a common scale schedule such that

$$\delta_{k_N,\mathcal{F}_N} + |\mathcal{F}_N| \epsilon_{k_N,\mathcal{F}_N} \longrightarrow 0.$$

An operator-norm estimate replaces the factor $|\mathcal{F}_N|\epsilon$ by the corresponding operator-norm error. The distinction matters: exact reflection positivity is a finite-regulator structural property, while approximate positivity with defects is an estimate whose constants must scale with the observation window.

Lemma 142.51 (Directed OS-positive form assembly)**.** *Let*

$$P_1 \subset P_2 \subset \cdots$$

be finite-dimensional subspaces of the positive-time polynomial test algebra, with dense algebraic union P_∞ in the positive-time test topology used for OS reconstruction. Let $N_k \to \infty$. For every $N \le N_k$, suppose the regulated Schwinger hierarchy supplies a Hermitian sesquilinear form

$$Q_{k,N} : P_N \times P_N \longrightarrow \mathbb{C}$$

such that:

1. *$Q_{k,M}|_{P_N \times P_N} = Q_{k,N}$ whenever $N \le M \le N_k$;*
2. *$Q_{k,N}(F, F) \ge 0$ for every $F \in P_N$;*
3. *after choosing any norm $\|\cdot\|_N$ on P_N,*

$$\eta_{N,k} = \sup_{\ell \ge k} \sup_{\substack{\|F\|_N \le 1 \\ \|G\|_N \le 1}} |Q_{k,N}(F, G) - Q_{\ell,N}(F, G)| \longrightarrow 0 \tag{142.215}$$

   for each fixed N, with the supremum restricted to scales for which $N \le N_k, N_\ell$.

Then there is a unique compatible positive Hermitian form

$$Q_* : P_\infty \times P_\infty \longrightarrow \mathbb{C}$$

whose restriction to P_N is the limit of $Q_{k,N}$ for every fixed N. If, in addition, the limiting forms obey the continuity estimate required by the OS chapter on a dense positive-time family, then Q_* extends to the positive-time OS pre-Hilbert form. The lemma by itself does not supply strong continuity of the time-translation semigroup or the OS-II growth hypothesis.

Proof. For fixed N, the space of sesquilinear forms on P_N is finite dimensional and complete in the operator norm induced by $\|\cdot\|_N$. Condition (142.215) therefore gives a limit form $Q_{*,N}$ on P_N. Positivity passes to the limit because

$$Q_{*,N}(F, F) = \lim_{k \to \infty} Q_{k,N}(F, F) \ge 0$$

for each fixed $F \in P_N$. Hermiticity passes in the same way.

If $N \le M$, finite-scale compatibility gives

$$Q_{k,M}|_{P_N \times P_N} = Q_{k,N}$$

for all sufficiently large k. Passing to the finite-dimensional limits on P_M and P_N gives

$$Q_{*,M}|_{P_N \times P_N} = Q_{*,N}.$$

Thus one defines $Q_*(F,G) = Q_{*,N}(F,G)$ whenever $F, G \in P_N$; the preceding compatibility makes this independent of N. Positivity and Hermiticity on P_∞ follow by choosing a single P_N that contains the finitely many vectors involved. The final extension statement is exactly the continuity step in OS reconstruction: without a bound in the positive-time topology, a positive algebraic form on the dense union need not define a continuous form on the desired test completion. □

The quantitative entrywise estimate (142.213) is one way to prove the Cauchy and positivity inputs of Lemma 142.51. For a nested family with m_N basis vectors it must be used with a scale-dependent error schedule satisfying

$$\liminf_{k\to\infty}\bigl(\ell_{N,k} - m_N\epsilon_{N,k}\bigr) \geq 0 \qquad \text{for each fixed } N.$$

If the goal is a uniform lower bound on an increasing family, the right condition is correspondingly uniform in N; a fixed entrywise tolerance is not enough. This is the precise mathematical content behind the warning that finite OS Gram windows must be controlled as a directed family.

When universality reconstructs the same local QFT. Suppose a Wilsonian universality statement has a local-QFT-strength observable germ and that the normalized reconstructions of all microscopic regulators converge to a common germ O_*. The common germ then determines a common Schwinger or Wightman hierarchy in the sense of the chosen reconstruction framework. Applying the reconstruction theorem proved earlier in the monograph gives the corresponding Hilbert space, vacuum vector, fields or observable algebra, and spacetime symmetry representation. Thus the phrase "the regulators define the same local QFT" means: after the declared normalizations, their full local-QFT-strength observable germs converge to one reconstruction input, and the reconstructed presentations are identified by the uniqueness clause of that reconstruction theorem. Contact-term choices are part of the source-local extension data; they may change extensions across collision diagonals without changing the separated-point germ.

This paragraph is not an additional fixed-point theorem. It records the dependency chain that a model-specific universality theorem must establish: RG attraction in a Banach chart, convergence of the full projective observable germ, verification of OS or Wightman positivity and growth hypotheses, and then reconstruction. A calculation of critical exponents, a finite bootstrap table, a finite tensor-window comparison, or a lattice finite-size scaling plot supplies only the finite windows it actually controls.

The finite-window form is still useful because it is the object produced by simulations, rigorous finite-volume estimates, and perturbative calculations. If $\mathfrak{A}_0 \subset \mathfrak{A}$ is finite and, for each $\alpha \in \mathfrak{A}_0$,

$$p_\alpha\bigl(g_i\ \mathrm{Rec}^\alpha_{i,n}(V_i) - (O_*)_\alpha\bigr) \leq e_{\alpha,i,n}, \qquad p_\alpha\bigl(g_j\ \mathrm{Rec}^\alpha_{j,n}(V_j) - (O_*)_\alpha\bigr) \leq e_{\alpha,j,n}, \tag{142.216}$$

then the triangle inequality gives the finite-window estimate

$$p_\alpha\bigl(g_i\ \mathrm{Rec}^\alpha_{i,n}(V_i) - g_j\ \mathrm{Rec}^\alpha_{j,n}(V_j)\bigr) \leq e_{\alpha,i,n} + e_{\alpha,j,n}, \qquad \alpha \in \mathfrak{A}_0. \tag{142.217}$$

A finite-window estimate becomes substantially more informative when its error is expressed in RG coordinates. Fix a finite window $\alpha \in \mathfrak{A}$ and a scale n_0 after which two normalized microscopic data lie in a common stable chart at V_*. Write $u \in E_u$ for the relevant coordinate and $s \in E_s$ for the stable coordinate in that chart. Suppose that, after the allowed normalizations, the relevant mismatch is bounded by

$$\|u_i(n_0) - u_j(n_0)\| \leq \delta_u,$$

and that the stable mismatch d_ℓ after ℓ further RG steps obeys the finite recurrence

$$d_{\ell+1} \le \theta d_\ell + \eta_\ell, \qquad d_0 \le \delta_s, \qquad 0 \le \theta < 1. \tag{142.218}$$

Here η_ℓ is the one-step comparison defect: it may come from different microscopic blocking kernels, a finite auxiliary-to-target intertwining error, or a controlled truncation of the stable coordinate. Assume also that the reconstructed α-window is Lipschitz in the chart, with constants $C_{u,\alpha}$ and $C_{s,\alpha}$, and that the source-tail and normalization errors in this window at depth m are bounded by $\Xi_{\alpha,m}$. Then the finite observable-window bound is

$$\begin{aligned} p_\alpha\big(g_i \operatorname{Rec}^\alpha_{i,n_0+m}(V_i) - g_j \operatorname{Rec}^\alpha_{j,n_0+m}(V_j)\big) &\le C_{u,\alpha}\delta_u + C_{s,\alpha}\theta^m\delta_s \\ &\quad + C_{s,\alpha}\sum_{\ell=0}^{m-1}\theta^{m-1-\ell}\eta_\ell + \Xi_{\alpha,m}. \end{aligned} \tag{142.219}$$

This is the finite-scale form of a Wilsonian universality comparison. Its derivation is the iteration of (142.218), followed by the Lipschitz bound for the reconstruction map in the chosen window. Exact tuning means $\delta_u = 0$. A theorem-level universality result must prove constants for every window in a directed family and show that the right-hand side of (142.219) tends to zero along the claimed continuum or long-distance limit. Without that directed-window limit, (142.219) remains a precise finite observation bound.

The theorem-level burden is the passage from these finite bounds to (142.206) for the directed family of observation windows.

Quantifier order in the directed-window limit. The finite estimate (142.219) becomes a universality theorem only with the projective-limit quantifiers in the right order. For every window $\alpha \in \mathfrak{A}$ and every $\varepsilon > 0$, after the window-dependent constants $C_{u,\alpha}$, $C_{s,\alpha}$, the normalization convention, and the source-tail bound have been fixed, one must exhibit a depth $m_{\alpha,\varepsilon}$ such that for all $m \ge m_{\alpha,\varepsilon}$

$$C_{u,\alpha}\delta_u + C_{s,\alpha}\theta^m\delta_s + C_{s,\alpha}\sum_{\ell=0}^{m-1}\theta^{m-1-\ell}\eta_\ell + \Xi_{\alpha,m} < \varepsilon. \tag{142.220}$$

If exact relevant tuning has not been proved, the first term in (142.220) is a nondecaying obstruction for the window α. If the one-step defects do not have a summable tail, the convolution term has a positive error floor even when $\theta < 1$. If the source-tail and normalization errors are controlled only for a fixed finite collection of windows, the conclusion is exactly that finite collection, not the projective germ.

For a cofinal nested family α_N, the theorem must provide a schedule

$$N \longmapsto m_N$$

such that the estimates for α_N hold on compatible regulator tails and the right-hand side of (142.220) tends to zero for each fixed α_N. The constants may grow with N; the proof must show that the chosen depth and regulator tail outpace that growth. This is the same directed-family issue as in the OS Gram bounds above: a finite numerical window, or a family of windows chosen after the calculation, is not a substitute for a cofinal projective-limit estimate.

Remark 142.52 (Universality as an equivalence relation after reconstruction). Assume the data of Definition 142.45, and suppose the displayed convergence to a common O_* holds. Define $i \sim j$ if there exist $g_i, g_j \in G$ such that

$$g_i \operatorname{Rec}_{i,n}(V_i) - g_j \operatorname{Rec}_{j,n}(V_j) \longrightarrow 0 \qquad \text{in } \mathcal{O}.$$

Then $\sim$ is an equivalence relation on I. Reflexivity holds by taking the same normalization on both sides. Symmetry follows because $\mathcal{O}$ is a topological vector space: if a sequence of differences tends to zero, the sequence with the opposite sign also tends to zero.

For transitivity, suppose $i \sim j$ and $j \sim k$. Then there are normalizations $g_i, g_j, h_j, h_k \in G$ for which

$$g_i \operatorname{Rec}_{i,n}(V_i) - g_j \operatorname{Rec}_{j,n}(V_j) \to 0, \qquad h_j \operatorname{Rec}_{j,n}(V_j) - h_k \operatorname{Rec}_{k,n}(V_k) \to 0.$$

In the theorem-level situation above, each normalized sequence also converges to the same orbit representative O_* after some allowed normalization. Choose the normalizations $a_i, a_j, a_k \in G$ that appear in Definition 142.45. Then

$$a_i \operatorname{Rec}_{i,n}(V_i) \to O_*, \qquad a_k \operatorname{Rec}_{k,n}(V_k) \to O_*,$$

so

$$a_i \operatorname{Rec}_{i,n}(V_i) - a_k \operatorname{Rec}_{k,n}(V_k) \to 0.$$

Thus $i \sim k$. The proof uses the existence of a common reconstructed limit and therefore controls more than pairwise similarity of formal coupling lists.

The common-limit hypothesis is essential to the way this remark is used in the monograph. Pairwise finite-window comparisons with unrelated choices of normalization do not by themselves define a theorem-level universality relation: the normalization of j in the i-j comparison need not be compatible with the normalization of j in the j-k comparison, and agreement in one finite window does not control the remaining directed windows. The object that carries the equivalence relation is the reconstructed observable germ modulo the declared normalization group, not a list of matched exponents or a chain of pairwise plots.

Thus a universality class may be summarized by a triple

$$(\mathcal{R}, \mathcal{N}, V_*)$$

together with the observable topology, reconstruction maps, and normalization group of Definition 142.45. Symmetry and dimension may guide the choice of I and the list of relevant coordinates, but they do not by themselves define the class. The theorem is the attraction and reconstruction statement.

Correction-to-scaling data. The limiting reconstructed datum is only the first layer of a Wilsonian universality theorem. A sharper theorem also identifies the controlled approach to the limit. This matters because the amplitudes of irrelevant directions depend on the microscopic regulator, while the decay exponents and the reconstructed correction distributions are fixed by the RG chart and the fixed point.

Definition 142.53 (Correction-to-scaling datum)**.** Assume the data of Definition 142.45. A correction-to-scaling datum of order A consists of:

1. a locally convex topology on $\mathcal{O}$, specified by seminorms $\{p_\beta\}$;
2. a stable coordinate chart near V_* in which the tuned trajectories have stable coordinates $w_i(n) \in E_s$;
3. vectors $e_1, \dots, e_A \in E_s$ and positive numbers $\omega_1 \leq \cdots \leq \omega_A$ such that the linearized RG map sends
$$e_a \longmapsto L^{-\omega_a} e_a;$$
4. a number $\omega_{A+1} > \omega_A$, or another declared remainder rate, bounding the omitted stable directions;
5. constants $c_{i,a} \in \mathbb{C}$, depending on the microscopic regulator i, and remainders $\rho_i(n) \in E_s$ satisfying
$$w_i(n) = \sum_{a=1}^{A} c_{i,a} L^{-n\omega_a} e_a + \rho_i(n), \qquad \|\rho_i(n)\|_{E_s} \leq C_i\big(L^{-n\omega_{A+1}} + L^{-2n\omega_1}\big); \tag{142.221}$$
6. differentiability of the normalized reconstruction map at V_*, with first derivative
$$D\,\mathrm{Rec}_* : E_s \longrightarrow \mathcal{O}$$
and a quadratic remainder estimate in every seminorm p_β.

The associated correction distributions are

$$\mathcal{C}_a = D\,\mathrm{Rec}_*(e_a) \in \mathcal{O}.$$

Under these hypotheses the normalized reconstructed observables have the expansion

$$g_i\,\mathrm{Rec}_{i,n}(V_i) = O_* + \sum_{a=1}^{A} c_{i,a} L^{-n\omega_a} \mathcal{C}_a + \mathcal{E}_i(n), \tag{142.222}$$

where, for every seminorm p_β, there is a constant $C_{\beta,i}$ such that

$$p_\beta(\mathcal{E}_i(n)) \leq C_{\beta,i}\big(L^{-n\omega_{A+1}} + L^{-2n\omega_1}\big). \tag{142.223}$$

Indeed, write the normalized reconstruction map in the stable chart as

$$\mathrm{Rec}_*(V_* + w) = O_* + D\,\mathrm{Rec}_*(w) + Q(w), \qquad p_\beta(Q(w)) \leq C_\beta \|w\|_{E_s}^2$$

for w in a sufficiently small stable neighborhood. Substitution of (142.221) gives the linear correction terms and puts the stable-coordinate remainder together with $Q(w_i(n))$ into (142.223).

This is the precise content behind the common phrase "same universality class but different corrections to scaling." It is not a theorem about a model until the stable-coordinate expansion, the reconstruction derivative, and the seminorm estimates have all been proved in the chosen RG framework. The coefficients $c_{i,a}$ are microscopic coordinates. The exponents ω_a and correction distributions $\mathcal{C}_a$ are fixed-point data in the declared Wilsonian chart and observable topology.

Second-order reconstruction corrections. The linear correction ledger above is sufficient only when the quadratic reconstruction term is truly below the retained accuracy. Suppose, in the same stable chart, that the normalized reconstruction map has a second Frechet derivative and a cubic seminorm remainder,

$$\mathrm{Rec}_*(V_*+w)=O_*+D\,\mathrm{Rec}_*(w)+\frac{1}{2}D^2\,\mathrm{Rec}_*(w,w)+R_3(w),\qquad p_\beta(R_3(w))\le C_\beta\|w\|_{E_s}^3.$$

Substituting the stable-coordinate expansion gives the contact-free second-order correction terms

$$\frac{1}{2}\sum_{a,b=1}^{A}c_{i,a}c_{i,b}L^{-n(\omega_a+\omega_b)}\mathcal{C}_{ab}^{(2)},\qquad \mathcal{C}_{ab}^{(2)}:=D^2\,\mathrm{Rec}_*(e_a,e_b).\tag{142.224}$$

These terms are not optional bookkeeping if their exponents fall within the declared error window. If $2\omega_1<\omega_2$, the first subleading observable correction after the e_1 term is the nonlinear $\mathcal{C}_{11}^{(2)}$ contribution, not the next linear stable eigendirection. If $2\omega_1=\omega_2$, the coefficient at the common exponent is

$$c_{i,2}\mathcal{C}_2+\frac{1}{2}c_{i,1}^2\mathcal{C}_{11}^{(2)}.$$

Thus a fit that identifies the $L^{-2n\omega_1}$ amplitude with only the linear coordinate $c_{i,2}$ has silently assumed either vanishing quadratic reconstruction or a coordinate choice that removes it with a controlled normal-form argument. A theorem-level correction-to-scaling statement must declare which quadratic and higher nonlinear reconstruction terms are retained, and must put the rest into the same seminorm remainder estimate as the omitted stable coordinates.

Nonsemisimple stable blocks. The definition above is the semisimple case. If the stable linearization is not diagonalizable, the correction-to-scaling datum must record the Jordan chains; otherwise the theorem silently drops polynomial factors. Suppose a stable block has $\lambda_b=L^{-\omega_b}$, $\omega_b>0$, and a chain $e_{b,0},\dots,e_{b,m_b-1}$ with

$$D\mathcal{R}|_{V_*}e_{b,r}=\lambda_b e_{b,r}+\lambda_b e_{b,r-1},\qquad e_{b,-1}:=0.\tag{142.225}$$

Equivalently, on the block $D\mathcal{R}|_{V_*}=\lambda_b(1+N_b)$ with $N_b^{m_b}=0$. The exact iterate is

$$(D\mathcal{R}|_{V_*})^n e_{b,r}=L^{-n\omega_b}\sum_{q=0}^{r}\binom{n}{q}e_{b,r-q}.\tag{142.226}$$

Thus a stable-coordinate expansion with amplitudes $c_{i,b,r}$ gives

$$w_i(n)=\sum_b L^{-n\omega_b}\sum_{r=0}^{m_b-1}c_{i,b,r}\sum_{q=0}^{r}\binom{n}{q}e_{b,r-q}+\rho_i(n),\tag{142.227}$$

with a remainder bounded in the declared stable norm. Applying the linearized reconstruction map gives

$$g_i\,\mathrm{Rec}_{i,n}(V_i)=O_*+\sum_b L^{-n\omega_b}\sum_{r=0}^{m_b-1}c_{i,b,r}\sum_{q=0}^{r}\binom{n}{q}\mathcal{C}_{b,r-q}+\mathcal{E}_i(n),\qquad \mathcal{C}_{b,r}:=D\,\mathrm{Rec}_*(e_{b,r}).\tag{142.228}$$

The factor $n^{m_b-1}L^{-n\omega_b}$ is still decaying, but it is not a pure power law. In finite-volume or numerical RG comparisons, fitting corrections only by $L^{-n\omega_b}$ therefore tests a semisimplicity hypothesis about the stable block. A theorem-level correction-to-scaling statement must either prove semisimplicity in the chosen chart or include the binomial factors in (142.228), together with seminorm bounds for the nilpotent-chain remainder.

Marginally irrelevant normal forms. A zero linear exponent is even more delicate. Calling a coordinate "marginal" only records the linearized RG map. Logarithmic corrections come from a nonlinear normal form and from a remainder estimate in the same Banach chart. The basic one-dimensional mechanism is the following.

Lemma 142.54 (Marginally irrelevant reciprocal estimate)**.** *Let $m_n \in (0,\rho]$ be a scalar RG coordinate satisfying*

$$m_{n+1} = m_n - \beta m_n^2 + R_n, \qquad |R_n| \le c m_n^3, \tag{142.229}$$

with $\beta > 0$ and $(\beta + c\rho)\rho \le \frac{1}{2}$. Then $m_{n+1} > 0$ and

$$\left| \frac{1}{m_{n+1}} - \frac{1}{m_n} - \beta \right| \le 2(\beta^2 + c + \beta c\rho) m_n. \tag{142.230}$$

If also $c\rho < \beta$, then

$$\frac{1}{m_n} = \frac{1}{m_0} + \beta n + O\left(\sum_{j<n} m_j \right), \qquad m_j \le \frac{1}{m_0^{-1} + (\beta - c\rho) j}.$$

Hence the nonlinear normal form gives

$$m_n = \frac{1}{\beta n + O(\log n)}.$$

Proof. Write $R_n = m_n^3 \eta_n$, $|\eta_n| \le c$. Then

$$m_{n+1} = m_n(1 - \beta m_n + \eta_n m_n^2).$$

The denominator is at least $1 - (\beta + c\rho)\rho \ge \frac{1}{2}$, so $m_{n+1} > 0$. Moreover

$$\frac{1}{m_{n+1}} - \frac{1}{m_n} = \frac{\beta - \eta_n m_n}{1 - \beta m_n + \eta_n m_n^2},$$
$$\frac{1}{m_{n+1}} - \frac{1}{m_n} - \beta = \frac{\beta^2 m_n - \eta_n m_n - \beta \eta_n m_n^2}{1 - \beta m_n + \eta_n m_n^2}.$$

Taking absolute values gives (142.230). The last assertion follows by summing (142.230). For the displayed bound on m_j, use

$$m_{j+1} \le m_j - (\beta - c\rho) m_j^2$$

and invert. The resulting harmonic majorant has logarithmic partial sums. ☐

Thus a logarithmic correction in a Wilsonian theorem is not supplied by the word marginal. The theorem must identify the marginal coordinate, put its flow into a normal form such as (142.229), prove the sign of β, bound the cubic and irrelevant-tail remainders, and transport the resulting reciprocal estimate through the same reconstruction seminorms used for power-law corrections. An exactly marginal coordinate is the different case $\beta = 0$ together with a flat normal form or a symmetry/geometric argument that produces a genuine fixed-point manifold.

Open Problem 142.55 (Nonperturbative Wilsonian fixed points). Construct non-Gaussian Wilsonian fixed points in three and four dimensions as fixed points of explicit RG maps on Banach spaces of interactions, with stable manifolds, operator spectra, and reconstruction of the associated local QFT data. The open directions include: short-range scalar critical fixed points with distributional reconstruction; gauge-compatible fixed points in the lattice or BV sense of Definition 142.26; and estimates that identify the limiting local, extended, and cohomological observables rather than only the local coordinate flow.

Chapter 143

Relation Between Lattice And Continuum Local QFT

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter explains how finite-lattice data become continuum local QFT data. The passage requires scaling maps for observables, convergence of correlation functions as distributions, reflection positivity, and reconstruction or local-net comparison.

143.1 Scaling Maps

Let $a > 0$ be the lattice spacing and let $\Lambda_a = a\mathbb{Z}^d \cap V$ inside a finite region V. A lattice field $\phi_a(x)$ becomes a continuum distribution only after a scaling map is specified:

$$\Phi_a(f) = Z_a^{1/2} a^d \sum_{x \in \Lambda_a} f(x)\phi_a(x),$$

where $f \in C_c^\infty(V)$ and Z_a is the field normalization. Composite operators require a mixing matrix

$$\mathcal{O}_{A,a}^{\mathrm{ren}} = \sum_B Z_{AB}(a)\mathcal{O}_{B,a}.$$

The operator basis and normalization are part of the continuum-limit datum.

A useful way to remove a common normalization ambiguity is to use cell averages. Let $Q_a(x)$ be the half-open cube of side a centered at $x \in a\mathbb{Z}^d$, and define

$$(I_a f)(x) = a^{-d} \int_{Q_a(x)} f(u)\, d^d u. \tag{143.1}$$

The smeared lattice field is then

$$\Phi_a(f) = Z_a^{1/2} a^d \sum_{x \in a\mathbb{Z}^d} (I_a f)(x) \phi_a(x). \tag{143.2}$$

This is exactly the pairing of the lattice field with the piecewise-constant test function

$$f_a(u) = \sum_{x \in a\mathbb{Z}^d} (I_a f)(x) \mathbf{1}_{Q_a(x)}(u). \tag{143.3}$$

Cell averages approximate test functions. Let $K \subset \mathbb{R}^d$ be compact and let $f, h \in C_c^1(\mathbb{R}^d)$ have support contained in K. Then

$$\left| a^d \sum_{x \in a\mathbb{Z}^d} (I_a f)(x)(I_a h)(x) - \int_{\mathbb{R}^d} f(u) h(u)\, d^d u \right| \le C_K a \big(\|f\|_{C^1} \|h\|_{C^0} + \|f\|_{C^0} \|h\|_{C^1} \big), \tag{143.4}$$

where C_K depends only on a fixed compact enlargement of K. In particular $f_a \to f$ in L^2_{loc}. On each cell $Q_a(x)$,

$$|(I_a f)(x) - f(u)| \le c_d a \|f\|_{C^1}, \qquad |(I_a h)(x) - h(u)| \le c_d a \|h\|_{C^1}$$

for all $u \in Q_a(x)$, by the mean-value theorem and $\operatorname{diam} Q_a(x) = \sqrt{d}\, a$. Therefore

$$|(I_a f)(x)(I_a h)(x) - f(u)h(u)| \le c_d' a \big(\|f\|_{C^1} \|h\|_{C^0} + \|f\|_{C^0} \|h\|_{C^1} \big) + c_d'' a^2 \|f\|_{C^1} \|h\|_{C^1}.$$

Integrating this estimate over the cells meeting the compact enlargement of K gives (143.4), after increasing C_K.

Definition 143.1 (Scaling-limit datum)**.** A scaling-limit datum for a lattice regulator family consists of:

regulator spaces	Ω_a and probability states $\langle - \rangle_a$,
scaling trajectory	couplings and boundary conditions as functions of a,
test spaces	$\mathcal{D}_i$ for each intended continuum field or operator,
operator maps	$\mathcal{O}_{i,a}(f)$ for $f \in \mathcal{D}_i$,
normalizations	$Z_{ij}(a)$ and operator-mixing matrices,
topology	the seminorms in which all correlators converge.

Without these data the phrase "the continuum limit of a lattice operator" does not define a mathematical object.

143.2 Distributional Convergence

The n-point Schwinger distributions are

$$S_{n,a}(f_1, \ldots, f_n) = \langle \Phi_a(f_1) \cdots \Phi_a(f_n) \rangle_a .$$

A continuum Schwinger function S_n is obtained when

$$\lim_{a \to 0} S_{n,a}(f_1, \ldots, f_n) = S_n(f_1, \ldots, f_n)$$

for all test functions in the chosen class, with compatible infinite-volume and continuum limits. Pointwise lattice correlators are auxiliary data; the continuum field is distributional.

The next criterion is the practical form in which distributional convergence is often verified. Let $\mathcal{D}$ be a test-function space equipped with an increasing family of seminorms $p_1, p_2, \ldots$. For functions supported in a compact set K, a typical seminorm is

$$p_{K,r}(f) = \max_{|\alpha| \le r} \sup_{x \in K} |\partial^\alpha f(x)|.$$

Dense-test convergence plus uniform seminorm control. Let T_a be a family of n-linear functionals on $\mathcal{D}$, and let $D_0 \subset \mathcal{D}$ be dense in the seminorm used below. Assume there are a constant C and a continuous seminorm p such that

$$|T_a(f_1, \ldots, f_n)| \le C\, p(f_1) \cdots p(f_n) \tag{143.5}$$

for all sufficiently small a, and assume $T_a(g_1, \ldots, g_n)$ converges for all $g_i \in D_0$. Then there is a unique continuous n-linear functional T satisfying

$$\lim_{a \to 0} T_a(f_1, \ldots, f_n) = T(f_1, \ldots, f_n) \qquad (f_i \in \mathcal{D}). \tag{143.6}$$

For $g_i \in D_0$, define $T(g_1, \ldots, g_n)$ as the limit. The bound (143.5) passes to the limit on D_0, so T is uniformly continuous with respect to p on D_0^n. It therefore has a unique continuous extension to $\mathcal{D}^n$. For general $f_i \in \mathcal{D}$, choose $g_i \in D_0$ with

$$p(f_i - g_i) < \epsilon.$$

Multilinearity and (143.5) give, uniformly in a,

$$|T_a(f_1, \ldots, f_n) - T_a(g_1, \ldots, g_n)| \le C' \epsilon \prod_i (1 + p(f_i))$$

after replacing one entry at a time. The same estimate holds for T. Taking first $a \to 0$ on the dense tuple $g_1, \ldots, g_n$, and then $\epsilon \to 0$, proves (143.6).

This argument isolates the countability step after the uniform seminorm bound has been proved: convergence may be checked on a countable dense family of test functions. The hard constructive work is the bound (143.5), not the extension argument.

143.3 Random-Walk Representation of a Massive Lattice Covariance

The most concrete bridge from lattice locality to continuum estimates is the path expansion of a massive lattice Green function. Let $G = (V, E)$ be a finite undirected r-regular graph without self-loops, let A be its adjacency matrix, and let $m^2 > 0$. Define

$$K_m = (m^2 + r)I - A. \tag{143.7}$$

For vertices x, y, let $N_n(x, y)$ be the number of length-n nearest neighbor paths from x to y, equivalently $N_n(x, y) = (A^n)_{xy}$.

Finite-graph random-walk resolvent. The matrix K_m is positive definite and

$$(K_m^{-1})_{xy} = \sum_{n=0}^{\infty} \frac{N_n(x, y)}{(m^2 + r)^{n+1}}. \tag{143.8}$$

Equivalently, if $P = A/r$ is the simple-random-walk transition matrix and

$$\rho = \frac{r}{m^2 + r} < 1,$$

then

$$(K_m^{-1})_{xy} = \frac{1}{m^2 + r} \sum_{n=0}^{\infty} \rho^n P^n(x, y). \tag{143.9}$$

For any vector u,

$$u^* K_m u = m^2 \sum_x |u_x|^2 + \frac{1}{2} \sum_{x \sim y} |u_x - u_y|^2, \tag{143.10}$$

where each unoriented edge is counted once. Thus K_m is positive definite. Since the operator norm of A on $\ell^2(V)$ is at most r,

$$\left\| \frac{A}{m^2 + r} \right\| < 1.$$

The Neumann series converges absolutely in operator norm:

$$K_m^{-1} = \frac{1}{m^2 + r} \left(I - \frac{A}{m^2 + r} \right)^{-1} = \sum_{n=0}^{\infty} \frac{A^n}{(m^2 + r)^{n+1}}.$$

Taking the (x, y) matrix entry gives (143.8). Replacing A^n by $r^n P^n$ gives (143.9).

For a cubic lattice with spacing a, the free covariance is obtained from the same formula after the replacement

$$K_{m,a} = m^2 I - a^{-2} \sum_{\mu=1}^{d} (T_\mu + T_\mu^{-1} - 2I) = (m^2 + 2da^{-2})I - a^{-2} A. \tag{143.11}$$

The path expansion then weights an n-step path by

$$a^{-2n} \big(m^2 + 2da^{-2} \big)^{-(n+1)}$$

in the covariance matrix $K_{m,a}^{-1}$. In an interacting scalar construction the free path expansion is replaced by a random-walk or polymer expansion with local weights. The proof obligations are the same in structure as in the finite-graph resolvent calculation above: identify a positive reference operator, expand the perturbation in local objects, and prove a norm or polymer-sum bound that survives the intended limit.

143.4 Reflection Positivity And OS Reconstruction

Assume the lattice measures are reflection positive with respect to a hyperplane and that the scaling limit preserves reflection positivity:

$$\sum_{i,j} \bar{c}_i c_j \, S(F_i^{\Theta} F_j) \geq 0$$

for all finite linear combinations of positive-time test functionals. If the limit Schwinger functions also satisfy Euclidean covariance, symmetry, regularity, and the OS growth hypotheses, OS reconstruction produces a Hilbert space, vacuum, Hamiltonian, and Wightman distributions. Thus the lattice-to-continuum bridge is a theorem only after these hypotheses are verified for the limiting distributions.

Closedness of reflection positivity. Let S_a be reflection-positive Schwinger functionals on a common positive-time test algebra $\mathfrak{A}_+$. Suppose that, for every finite list $F_1, \ldots, F_N \in \mathfrak{A}_+$, the limits

$$\lim_{a \to 0} S_a(F_i^{\Theta} F_j) = S(F_i^{\Theta} F_j) \tag{143.12}$$

exist. Then the limiting functional S is reflection positive:

$$\sum_{i,j=1}^{N} \bar{c}_i c_j \, S(F_i^{\Theta} F_j) \geq 0 \tag{143.13}$$

for all $c_i \in \mathbb{C}$.

For each a, the matrix

$$M_a(F)_{ij} = S_a(F_i^{\Theta} F_j)$$

is positive semidefinite by reflection positivity. Hence

$$\sum_{i,j} \bar{c}_i c_j M_a(F)_{ij} \geq 0.$$

Taking the entrywise limit (143.12) gives (143.13). No compactness or reconstruction input is hidden here; the only point is that positivity of finite Gram matrices is a closed condition under entrywise convergence.

143.5 Local Algebras From Lattice Algebras

For a bounded continuum region O, let $O_a \subset \Lambda_a$ be the set of lattice sites or links whose cells lie in O. The lattice observable algebra $\mathcal{A}_a(O_a)$ is finite dimensional in spin systems and finite-regulator gauge systems after gauge constraints are imposed. A continuum local algebra is approached by embeddings or correlation-function limits

$$\mathcal{A}_a(O_a) \longrightarrow \mathcal{A}(O)$$

that preserve inclusion, locality, and the state in the scaling limit. The construction is delicate for gauge theories because Gauss-law constraints and center degrees of freedom affect the algebra assigned to a region with boundary.

For spin systems the algebraic limit can be stated directly. Let $\mathcal{H}_x$ be a finite-dimensional Hilbert space at each site and set

$$\mathcal{A}_a(X) = \bigotimes_{x\in X} \mathrm{End}(\mathcal{H}_x) \tag{143.14}$$

for a finite set $X \subset \Lambda_a$. If $X \subset Y$, the inclusion is

$$A \longmapsto A \otimes \mathbf{1}_{Y\setminus X}.$$

For disjoint X, Y, the images of $\mathcal{A}_a(X)$ and $\mathcal{A}_a(Y)$ commute. The quasi-local algebra at fixed a is the norm closure of the union over finite X.

Lemma 143.2 (Locality passes through state convergence for spin nets)**.** *Assume that for every bounded continuum region O and every sufficiently small a there is a finite set $O_a \subset \Lambda_a$, with isotony $O_1 \subset O_2 \Rightarrow O_{1,a} \subset O_{2,a}$. Suppose a collection of lattice observables $A_{i,a}(O_i) \in \mathcal{A}_a(O_{i,a})$ has limiting correlation functions in a state ω on the abstract algebra generated by the symbols $A_i(O_i)$. If O_1 and O_2 have positive separation, then for all sufficiently small a,*

$$[A_{1,a}(O_1), A_{2,a}(O_2)] = 0,$$

and the limiting GNS representation obeys

$$[\pi_\omega(A_1(O_1)), \pi_\omega(A_2(O_2))] = 0$$

on the dense domain generated by finite products of local symbols.

Proof. Positive separation of O_1 and O_2 implies $O_{1,a} \cap O_{2,a} = \varnothing$ for all sufficiently small a, after the cell approximation is chosen inside a fixed small thickening. The finite tensor-product construction then gives exact commutation at lattice spacing a. For any finite product B_a of additional local lattice observables whose correlations converge,

$$\omega\big(B[A_1(O_1), A_2(O_2)]\big) = \lim_{a\to 0} \omega_a\big(B_a[A_{1,a}(O_1), A_{2,a}(O_2)]\big) = 0.$$

Moreover, for every such B, set

$$C = [A_1(O_1), A_2(O_2)], \qquad C_a = [A_{1,a}(O_1), A_{2,a}(O_2)].$$

Then

$$\|\pi_\omega(C)\pi_\omega(B)\Omega_\omega\|^2 = \omega(B^*C^*CB) = \lim_{a\to 0} \omega_a(B_a^* C_a^* C_a B_a) = 0.$$

Thus the commutator annihilates the GNS dense domain generated by local symbols. Extension to bounded local von Neumann algebras, when they exist, is a further closure statement and requires the chosen topology of the scaling limit. □

Gauge theories are not obtained by the same tensor-factor argument after imposing Gauss constraints. The gauge-invariant algebra of a region need not factor over a boundary; electric center, magnetic center, and extended Hilbert-space prescriptions assign different boundary algebras. A continuum local-net claim for a lattice gauge scaling limit must therefore state which regional algebra is being scaled and how charged or line-operator sectors are represented.

143.6 Gauge-Invariant Operators

In lattice gauge theory, link variables are regulator coordinates. Continuum local gauge-invariant operators arise from small Wilson loops, covariant lattice differences, and matter bilinears after subtracting and mixing all operators with the same symmetries. For example, the continuum action density is represented by a plaquette combination

$$\mathcal{P}_a(x) = \frac{1}{a^4}\left(1 - \frac{1}{\dim R}\,\mathrm{Re}\,\mathrm{Tr}_R\, U_{\Box_x}\right) + \text{local mixings.}$$

The mixings include identity and lower-dimensional terms allowed by the regulator symmetries.

143.7 Universality As A Convergence Statement

Two lattice regulator families define the same continuum QFT when there are scaling maps for their observables such that all reconstructed local QFT data agree: Schwinger distributions, Wightman distributions or local nets, symmetry actions, stress tensor normalization, line or defect sectors when included, and background responses. Equality of critical exponents is a useful diagnostic but is not the full equivalence relation.

143.8 Continuum Limit Checklist

A lattice construction intended to define a continuum QFT must record:

regulator family	lattice actions, measures, boundary conditions,
scaling trajectory	couplings as functions of a,
operator maps	normalization and mixing,
limit topology	distributional, OS, Wightman, or local-net,
positivity	reflection positivity or replacement structure,
symmetries	continuum symmetry recovery and anomalies.

Open Problem 143.3 (Local nets from interacting lattice gauge limits). Construct continuum local algebras for interacting lattice gauge theory scaling limits, including Gauss-law center choices, charged sectors, extended operators, reflection positivity, and comparison with Wightman or OS reconstruction.

Chapter 144

Stochastic Quantization and Singular SPDE

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Stochastic quantization constructs Euclidean QFT data as the invariant law of a Markov process on fields. The auxiliary time of the process is not Lorentzian time and is not an extra physical dimension. Its purpose is to replace a formal functional integral by a dynamical construction whose stationary distribution can sometimes be proved to exist.

In singular dimensions the stochastic equation itself must be renormalized. The counterterms are local coordinates in the regulated stochastic drift and must be fixed before the cutoff is removed. The resulting invariant measure still has to be checked against the OS hypotheses before it becomes a Lorentzian QFT by reconstruction.

144.1 Finite-Dimensional Langevin Identity

Finite-dimensional invariant density. Let $S : \mathbb{R}^n \to \mathbb{R}$ be smooth and confining enough that

$$Z = \int_{\mathbb{R}^n} \mathrm{e}^{-S(x)}\,\mathrm{d}x < \infty.$$

The overdamped Langevin equation

$$\mathrm{d}X_t = -\nabla S(X_t)\,\mathrm{d}t + \sqrt{2}\,\mathrm{d}B_t \tag{144.1}$$

has generator

$$Lf = -\nabla S \cdot \nabla f + \Delta f.$$

For smooth compactly supported f, g,

$$\int (Lf) g \,\mathrm{e}^{-S} \mathrm{d}x = -\int \nabla f \cdot \nabla g \,\mathrm{e}^{-S} \mathrm{d}x. \tag{144.2}$$

Therefore L is symmetric in $L^2(\mathrm{e}^{-S}\mathrm{d}x)$, and the probability measure $Z^{-1}\mathrm{e}^{-S}\mathrm{d}x$ is invariant. The calculation is ordinary finite-dimensional integration by parts:

$$\int (-\partial_i S)(\partial_i f) g \,\mathrm{e}^{-S} \mathrm{d}x = \int \partial_i(\mathrm{e}^{-S})(\partial_i f) g \,\mathrm{d}x.$$

Adding the Laplacian contribution and integrating by parts once more,

$$\int \left[\partial_i(\mathrm{e}^{-S})(\partial_i f) g + (\partial_i^2 f) g \mathrm{e}^{-S}\right] \mathrm{d}x = -\int (\partial_i f)(\partial_i g) \mathrm{e}^{-S} \mathrm{d}x.$$

Summing over i gives (144.2). With $g = 1$, the right-hand side vanishes, so the adjoint generator annihilates $\mathrm{e}^{-S}\mathrm{d}x$. This is the infinitesimal invariant-density identity; actual stationarity of the stochastic process is the semigroup statement in Lemma 144.1.

Lemma 144.1 (Finite-cutoff reversibility from the gradient Langevin datum)**.** *Let*

$$\mathrm{d}\pi(x) = Z^{-1} \mathrm{e}^{-S(x)} \mathrm{d}x.$$

Assume that the symmetric operator

$$L_0 f = -\nabla S \cdot \nabla f + \Delta f, \qquad f \in C_c^\infty(\mathbb{R}^n),$$

is essentially self-adjoint as an operator in $L^2(\pi)$, and that its self-adjoint closure $\overline{L}$ generates a conservative Markov semigroup

$$P_t = \mathrm{e}^{t\overline{L}}, \qquad t \geq 0,$$

on $L^2(\pi)$. Then P_t is reversible with respect to π:

$$\int (P_t f) g \,\mathrm{d}\pi = \int f (P_t g) \,\mathrm{d}\pi, \qquad f, g \in L^2(\pi), \tag{144.3}$$

and π is invariant:

$$\int P_t f \,\mathrm{d}\pi = \int f \,\mathrm{d}\pi, \qquad f \in L^2(\pi) \cap L^1(\pi). \tag{144.4}$$

For $f, g \in C_c^\infty(\mathbb{R}^n)$, the Dirichlet form of the closure is the closure of

$$\mathcal{E}(f, g) = \int \nabla f \cdot \nabla g \,\mathrm{d}\pi.$$

Proof. Equation (144.2) says precisely that

$$\langle L_0 f, g \rangle_{L^2(\pi)} = -\mathcal{E}(f, g) = \langle f, L_0 g \rangle_{L^2(\pi)}$$

on the core $C_c^\infty(\mathbb{R}^n)$. Hence the self-adjoint closure $\overline{L}$ is nonpositive. By the spectral theorem, $e^{t\overline{L}}$ is a self-adjoint contraction on $L^2(\pi)$, which gives (144.3). Conservativeness is the statement $P_t 1 = 1$. Taking $g = 1$ in (144.3) gives

$$\int P_t f \, d\pi = \langle P_t f, 1\rangle = \langle f, P_t 1\rangle = \int f \, d\pi,$$

first for bounded L^2 functions and then for $L^1(\pi) \cap L^2(\pi)$ by truncation. The Dirichlet form statement is the definition of the closed quadratic form associated with the nonpositive self-adjoint operator $\overline{L}$, restricted to the displayed core where the integration-by-parts calculation identifies the form explicitly. □

The lemma records the finite-regulator theorem actually used below. The integration-by-parts identity proves the symmetric Dirichlet form on a core; the passage to a stationary Markov process also requires the finite-dimensional diffusion to be conservative and the generator closure to produce the semigroup. These hypotheses are elementary for the smooth compact cutoff systems used as finite regulators, but they are logically distinct from the singular infinite-dimensional limit.

144.2 Regularized Field Equation

Let M be a compact Euclidean spatial manifold, let C_Λ be a smooth ultraviolet cutoff covariance on M, and let ξ_Λ be white noise in stochastic time with spatial covariance chosen so that the linear equation has invariant Gaussian law μ_{C_Λ}. A regularized scalar Φ^4 Langevin equation has the form

$$\partial_\tau \phi_\Lambda = -C_\Lambda^{-1}\phi_\Lambda - \lambda_\Lambda \phi_\Lambda^3 + c_\Lambda \phi_\Lambda + \xi_\Lambda. \tag{144.5}$$

The drift is the negative L^2-gradient of the regulated action

$$S_\Lambda(\phi) = \frac{1}{2}(\phi, C_\Lambda^{-1}\phi) + \int_M \left[\frac{\lambda_\Lambda}{4}\phi^4 - \frac{c_\Lambda}{2}\phi^2\right] d^d x. \tag{144.6}$$

At finite Λ, the argument of the previous section applies on the finite-dimensional cutoff field space. Thus

$$Z_\Lambda^{-1} e^{-S_\Lambda(\phi)} D\phi$$

is invariant. The constructive question is whether the laws of ϕ_Λ, with tuned local coordinates, converge as $\Lambda \to \infty$.

144.3 Renormalized Products

For the Gaussian free field in spatial dimension $d \geq 2$, $\phi(x)$ is a distribution. Products in the drift are therefore defined through renormalized local functionals. If $\phi_\epsilon = \rho_\epsilon * \phi$ and

$$C_\epsilon = \mathbb{E}[\phi_\epsilon(x)^2],$$

then

$$:\phi_\epsilon^3: = \phi_\epsilon^3 - 3C_\epsilon \phi_\epsilon. \tag{144.7}$$

The coefficient 3 is not conventional: it counts the possible contractions of two of the three fields. The same convention gives

$$:\phi_\epsilon^4:= \phi_\epsilon^4 - 6C_\epsilon\phi_\epsilon^2 + 3C_\epsilon^2.$$

144.4 Stationary Stochastic Convolution and Wick Powers

The first analytic object in the Da Prato–Debussche construction is the stationary solution of the linear stochastic heat equation. We record the Fourier construction because it fixes the normalization of the noise and proves, in a Sobolev form, the existence of the Wick powers used later.

Let $\mathbb{T}^2 = \mathbb{R}^2/(2\pi\mathbb{Z})^2$, and let $\{e_k\}_{k\in\mathbb{Z}^2}$ be the orthonormal Fourier basis of $L^2(\mathbb{T}^2)$, normalized so that $-\Delta e_k = |k|^2 e_k$. The spacetime white noise in the stochastic quantization equation is normalized by

$$\mathbb{E}[\xi(\tau,x)\xi(\tau',y)] = 2\,\delta(\tau-\tau')\delta(x-y).$$

Equivalently, in Fourier coordinates,

$$\mathrm{d}X_k(\tau) = -(|k|^2+m^2)X_k(\tau)\mathrm{d}\tau + \sqrt{2}\,\mathrm{d}B_k(\tau), \qquad X_{-k} = \overline{X_k}, \tag{144.8}$$

where the complex Brownian motions are paired so that the reconstructed field is real.

Lemma 144.2 (Stationary covariance of the linear SPDE)**.** *The stationary solution of* (144.8) *satisfies*

$$\mathbb{E}[X_k\overline{X_\ell}] = \frac{\delta_{k\ell}}{|k|^2+m^2}. \tag{144.9}$$

Consequently $X(\tau,\cdot)$ has the massive Gaussian free-field law with covariance $(-\Delta+m^2)^{-1}$, and

$$\mathbb{E}\|X(\tau)\|^2_{H^{-s}(\mathbb{T}^2)} = \sum_{k\in\mathbb{Z}^2} \frac{(1+|k|^2)^{-s}}{|k|^2+m^2} < \infty \qquad (s>0). \tag{144.10}$$

Proof. For the real one-dimensional Ornstein–Uhlenbeck equation $\mathrm{d}Z_t = -aZ_t\mathrm{d}t + \sqrt{2}\,\mathrm{d}B_t$, $a>0$, the stationary solution is obtained by solving from time $-\infty$:

$$Z_t = \sqrt{2}\int_{-\infty}^t e^{-a(t-r)}\,\mathrm{d}B_r,$$

where the integral is well-defined in $L^2(\Omega)$ because $\int_0^\infty e^{-2au}\mathrm{d}u < \infty$. Ito isometry gives

$$\mathbb{E}|Z_t|^2 = 2\int_0^\infty e^{-2au}\,\mathrm{d}u = a^{-1}.$$

For the complex Fourier mode X_k one applies the same calculation to the paired real and imaginary coordinates, with the covariance convention in (144.8) chosen so that $\mathbb{E}[X_k\overline{X_\ell}]=0$ for $k\neq\ell$ and $\mathbb{E}|X_k|^2 = (|k|^2+m^2)^{-1}$. Taking $a=|k|^2+m^2$ gives (144.9).

For a finite Fourier cutoff N, Parseval gives

$$\mathbb{E}\|P_NX(\tau)\|^2_{H^{-s}} = \sum_{|k|\le N}\frac{(1+|k|^2)^{-s}}{|k|^2+m^2}.$$

The summands are nonnegative, so monotone convergence passes to the infinite sum. In two dimensions the large-$|k|$ summand is comparable to $|k|^{-2-2s}$, and the lattice count $\#\{k \in \mathbb{Z}^2 : R \le |k| < R+1\} = O(R)$ reduces convergence to $\sum_R R^{-1-2s} < \infty$, namely $s > 0$. Thus the stationary field is an H^{-s}-valued Gaussian random distribution for every $s > 0$, with covariance $(-\Delta + m^2)^{-1}$. ☐

Let P_N be the Fourier projection to $|k| \le N$, set $X_N = P_N X$, and write

$$C_N(x-y) = \mathbb{E}[X_N(x)X_N(y)].$$

The Wick powers are

$$:X_N^2 := X_N^2 - C_N(0), \qquad :X_N^3 := X_N^3 - 3C_N(0)X_N.$$

Lemma 144.3 (Two-dimensional massive-convolution bound)**.** *Let*

$$g(k) = \frac{1}{1+|k|^2}, \qquad L(k) = 1 + \log(2+|k|), \qquad k \in \mathbb{Z}^2.$$

For every integer $n \ge 1$ there is $C_n < \infty$ such that the n-fold lattice convolution satisfies

$$g^{*n}(q) \le C_n \frac{L(q)^{n-1}}{1+|q|^2}, \qquad q \in \mathbb{Z}^2. \tag{144.11}$$

Proof. The case $n = 1$ is the definition. The induction step is the elementary estimate

$$\sum_{p\in\mathbb{Z}^2} \frac{L(p)^a}{(1+|p|^2)(1+|q-p|^2)} \le C_a \frac{L(q)^{a+1}}{1+|q|^2}, \qquad a \ge 0. \tag{144.12}$$

For $|q| \le 4$ the left side is finite and the estimate is absorbed into the constant. Assume $|q| > 4$. Split the sum into three regions:

$$A = \{|p| \le |q|/2\}, \qquad B = \{|q-p| \le |q|/2\}, \qquad C = (A \cup B)^c.$$

On A, $1 + |q-p|^2 \ge c(1+|q|^2)$, and

$$\sum_{|p|\le|q|/2} \frac{L(p)^a}{1+|p|^2} \le C_a L(q)^{a+1},$$

because the two-dimensional shell of radius r contributes $\lesssim r^{-1}(1+\log r)^a$. This proves the desired bound on A. The region B is identical after replacing $r = q - p$: then $|p| \ge |q|/2$, $L(p) \le CL(q)$, and the remaining $\sum_{|r|\le|q|/2}(1+|r|^2)^{-1}$ contributes one additional logarithm. On C, both $|p|$ and $|q-p|$ are $\ge |q|/2$. Decompose C into dyadic annuli $|p| \sim 2^j|q|$ and $|q-p| \sim 2^k|q|$. The number of lattice points in a two-dimensional dyadic annulus of radius R is $O(R^2)$, while the summand is bounded by $CL(p)^a/(|p|^2|q-p|^2)$. Summing first over the smaller of the two annuli and then over the larger gives

$$\sum_{p\in C} \frac{L(p)^a}{(1+|p|^2)(1+|q-p|^2)} \le C_a \frac{L(q)^a}{1+|q|^2}.$$

Combining the three regions proves (144.12). Applying it with $a = n-1$ to $g * g^{*n}$ proves (144.11) by induction. ☐

Proposition 144.4 (Smeared Wick powers of the two-dimensional stochastic convolution)**.** *For every $n \geq 1$ and every $f \in C^\infty(\mathbb{T}^2)$, the random variables*

$$:X_N^n:(f) = \int_{\mathbb{T}^2} f(x) :X_N(x)^n: \, \mathrm{d}^2x$$

converge in $L^2(\Omega)$ as $N \to \infty$. Moreover, for every $s > 0$, the fields $:X_N^n:$ converge in $L^2(\Omega; H^{-s}(\mathbb{T}^2))$.

Proof. The Wick product covariance is the finite-dimensional Gaussian identity

$$\mathbb{E}[:X_N(x)^n::X_M(y)^n:] = n!\, C_{N,M}(x-y)^n, \qquad C_{N,M}(x-y) = \mathbb{E}[X_N(x)X_M(y)]. \tag{144.13}$$

This follows from the generating function $\exp(tX_N - \frac{1}{2}t^2 C_N(0))$ and differentiating n times in each variable. Hence

$$\mathbb{E}\left[:X_N^n:(f)\ :X_M^n:(f)\right] = n! \int_{\mathbb{T}^2\times\mathbb{T}^2} f(x)f(y)\, C_{N,M}(x-y)^n \, \mathrm{d}^2x \, \mathrm{d}^2y.$$

The massive two-dimensional covariance has the local form

$$C(x) = -\frac{1}{2\pi} \log|x| + O(1) \qquad (x \to 0),$$

and powers of $\log|x|$ are locally integrable in two dimensions:

$$\int_0^r \rho\, |\log\rho|^n \, \mathrm{d}\rho < \infty.$$

The kernels $C_{N,M}$ converge to C away from the diagonal, and the standard Fourier cutoff bounds are dominated by an integrable logarithmic majorant. Dominated convergence therefore proves the L^2-Cauchy property for every smeared Wick power.

For the Sobolev statement, use the dual norm

$$\|u\|_{H^{-s}}^2 = \sum_{q\in\mathbb{Z}^2} (1+|q|^2)^{-s} |\widehat{u}(q)|^2.$$

Applying (144.13) to Fourier test functions shows that

$$\mathbb{E}|\widehat{:X_N^n:}(q)|^2 = n! \sum_{\substack{k_1+\cdots+k_n=q\\ |k_i|\leq N}} \prod_{i=1}^n \frac{1}{|k_i|^2+m^2}. \tag{144.14}$$

The right side is bounded by $C_{n,m}L(q)^{n-1}(1+|q|^2)^{-1}$ by Lemma 144.3. Therefore

$$\sum_{q\in\mathbb{Z}^2} (1+|q|^2)^{-s} \mathbb{E}|\widehat{:X_N^n:}(q)|^2 \leq C_{n,m} \sum_{q\in\mathbb{Z}^2} \frac{L(q)^{n-1}}{(1+|q|^2)^{1+s}} < \infty$$

for every $s > 0$. For fixed q, the cutoff variances and mixed covariances converge by dominated convergence of the convolution sums. The same convolution bound dominates $\mathbb{E}|\widehat{:X_N^n:}(q) - \widehat{:X_M^n:}(q)|^2$, up to a harmless constant, so dominated convergence over q proves convergence in $L^2(\Omega; H^{-s})$. In particular the stochastic input needed by the Sobolev DPD fixed point below is available for any prescribed $0 < \kappa < 1/4$ after taking $s = \kappa$. $\square$

Proposition 144.5 (Smooth Fourier multiplier covariance convergence)**.** *Let $m^2 > 0$, and let*

$$C(z) = \sum_{k\in\mathbb{Z}^2} \frac{e^{ik\cdot z}}{|k|^2 + m^2}$$

be the massive covariance on $\mathbb{T}^2$, understood through the dyadic Fourier decomposition used below. For $\sigma \in \{A, B\}$, let $\mu^\sigma \in C_c^\infty(\mathbb{R}^2)$ be real, even, and satisfy $\mu^\sigma(0) = 1$. Define the cutoff Gaussian field on the same Gaussian probability space by

$$X_N^\sigma = \mu^\sigma(D/N)X,$$

so that the mixed and cutoff covariances are translation invariant kernels

$$C_N^{\sigma\infty}(z) = \sum_{k\in\mathbb{Z}^2} \frac{\mu^\sigma(k/N)}{|k|^2 + m^2} e^{ik\cdot z}, \qquad C_N^{\sigma\sigma}(z) = \sum_{k\in\mathbb{Z}^2} \frac{\mu^\sigma(k/N)^2}{|k|^2 + m^2} e^{ik\cdot z}.$$

Then, for every $1 \le p < \infty$,

$$C_N^{\sigma\infty} \longrightarrow C, \qquad C_N^{\sigma\sigma} \longrightarrow C \quad \text{in } L^p(\mathbb{T}^2). \tag{144.15}$$

Consequently the hypotheses of Lemma 144.6 hold for every finite Wick order n.

Proof. Choose a smooth radial dyadic partition of unity on frequency space,

$$\chi_{-1}(\xi) + \sum_{j\ge 0} \chi_j(\xi) = 1, \qquad \chi_j(\xi) = \chi(2^{-j}\xi),$$

where χ_{-1} is supported near the origin and χ is supported in an annulus. Let

$$a(k) = |k|^2 + m^2,$$

and let $\nu_N(k)$ denote any one of the three multipliers

$$1, \qquad \mu^\sigma(k/N), \qquad \mu^\sigma(k/N)^2.$$

For $j \ge 0$, set

$$K_{j,N}^\nu(z) = \sum_{k\in\mathbb{Z}^2} \chi_j(k) \frac{\nu_N(k)}{a(k)} e^{ik\cdot z}.$$

We first prove the uniform dyadic kernel bound

$$|K_{j,N}^\nu(z)| \le C_M \big(1 + 2^j d_{\mathbb{T}^2}(z, 0)\big)^{-M}, \qquad M \ge 0, \tag{144.16}$$

with a constant independent of j, N, ν. Indeed, put

$$q_{j,N}^\nu(\xi) = \chi_j(\xi) \frac{\nu_N(\xi)}{|\xi|^2 + m^2}.$$

On the support of χ_j, $|\xi| \simeq 2^j$. If $\nu_N(\xi) = \mu^\sigma(\xi/N)$ or $\mu^\sigma(\xi/N)^2$, the support of $q_{j,N}^\nu$ is empty unless $2^j \le CN$; on the nonempty support, derivatives of ν_N satisfy

$$|\partial^\alpha \nu_N(\xi)| \le C_\alpha N^{-|\alpha|} \le C_\alpha 2^{-j|\alpha|}.$$

Together with the corresponding derivative bounds for χ_j and $(|\xi|^2 + m^2)^{-1}$, this gives

$$|\partial^\alpha q^\nu_{j,N}(\xi)| \le C_\alpha \, 2^{-2j} 2^{-j|\alpha|}. \tag{144.17}$$

Let $\check{q}^\nu_{j,N}$ be the inverse Fourier transform on $\mathbb{R}^2$. Integrating by parts in the oscillatory integral and using (144.17) gives

$$|\check{q}^\nu_{j,N}(x)| \le C_M (1 + 2^j |x|)^{-M}.$$

Poisson summation identifies $K^\nu_{j,N}$ with the periodization of $\check{q}^\nu_{j,N}$. Summing over lattice translates gives (144.16) when $M > 2$; decreasing M if necessary gives the stated form for all $M \ge 0$. The low-frequency block $j = -1$ is bounded uniformly because it contains only finitely many lattice modes.

Summing (144.16) over j with $M > 2$ gives the logarithmic majorant

$$\left| \sum_{j \ge -1} K^\nu_{j,N}(z) \right| \le C\big(1 + |\log d_{\mathbb{T}^2}(z, 0)|\big), \tag{144.18}$$

where the right side is interpreted as a bounded function away from $z = 0$. The logarithmic singularity belongs to $L^p(\mathbb{T}^2)$ for every finite p, because in polar coordinates

$$\int_0^{1/2} r \, |\log r|^p \, \mathrm{d}r < \infty.$$

It remains to prove pointwise convergence away from the diagonal. Fix $z \ne 0$. For any fixed dyadic level j, the block $K^\nu_{j,N}$ is a finite sum, and the multiplier $\nu_N(k)$ tends to 1 for every fixed k. Hence

$$K^\nu_{j,N}(z) \longrightarrow K_{j,\infty}(z)$$

for each fixed j. The tail is uniform in N:

$$\sum_{j > J} |K^\nu_{j,N}(z)| \le C_M \sum_{j > J} (1 + 2^j d_{\mathbb{T}^2}(z, 0))^{-M} \le C_{M,z} \, 2^{-JM}.$$

Therefore the full dyadic sums converge pointwise for every $z \ne 0$. Together with the logarithmic majorant (144.18), dominated convergence gives (144.15). Taking $\nu_N = \mu^\sigma(k/N)$ gives the mixed covariance, while taking $\nu_N = \mu^\sigma(k/N)^2$ gives the cutoff covariance. Since this holds for $p = n$, and since a translation-invariant kernel $K(x-y)$ has $L^n(\mathbb{T}^2 \times \mathbb{T}^2)$-norm equal to the volume factor times its $L^n(\mathbb{T}^2)$-norm, the hypotheses of Lemma 144.6 hold for every finite Wick order n. ☐

Lemma 144.6 (Mixed-covariance criterion for common Wick limits)**.** *Let X be a centered Gaussian generalized field on $\mathbb{T}^2$, and let X^σ_N, $\sigma \in \{A, B\}$, be centered Gaussian cutoff fields on the same probability space. Write*

$$C(x, y) = \mathbb{E}[X(x)X(y)], \qquad C^{\sigma\sigma}_N(x, y) = \mathbb{E}[X^\sigma_N(x) X^\sigma_N(y)],$$

and

$$C^{\sigma\infty}_N(x, y) = \mathbb{E}[X^\sigma_N(x) X(y)].$$

Fix $n \ge 1$, and assume that these covariance kernels are represented by functions in $L^n(\mathbb{T}^2 \times \mathbb{T}^2)$ and that, for $\sigma = A, B$,

$$\|C^{\sigma\sigma}_N - C\|_{L^n(\mathbb{T}^2 \times \mathbb{T}^2)} + \|C^{\sigma\infty}_N - C\|_{L^n(\mathbb{T}^2 \times \mathbb{T}^2)} \longrightarrow 0. \tag{144.19}$$

Then, for every real $f \in C^\infty(\mathbb{T}^2)$,

$$:(X_N^\sigma)^n:(f) \longrightarrow :X^n:(f) \quad \textit{in } L^2(\Omega), \qquad \sigma = A, B, \tag{144.20}$$

where each Wick product is normal ordered with respect to the covariance of the Gaussian field appearing in it.

Proof. Let

$$Y_N^\sigma =:(X_N^\sigma)^n:(f), \qquad Y =:X^n:(f).$$

For two jointly Gaussian centered random variables U, V, Wick ordering with respect to the individual variances gives

$$\mathbb{E}\big[:U^n::V^n:\big] = n!\,\mathbb{E}[UV]^n.$$

This follows by differentiating the identity

$$\mathbb{E}\Big[e^{tU-\frac{1}{2}t^2\mathbb{E}[U^2]}e^{sV-\frac{1}{2}s^2\mathbb{E}[V^2]}\Big] = e^{ts\mathbb{E}[UV]}$$

n times in t and n times in s at the origin. Therefore

$$\mathbb{E}|Y_N^\sigma - Y|^2 = n! \int_{\mathbb{T}^2\times\mathbb{T}^2} f(x)f(y)\Big[\big(C_N^{\sigma\sigma}(x,y)\big)^n - 2\big(C_N^{\sigma\infty}(x,y)\big)^n + C(x,y)^n\Big]\,\mathrm{d}^2x\,\mathrm{d}^2y.$$

It remains to show that the two n-th powers converge in L^1 to C^n. If $a, b \in L^n(\mathbb{T}^2\times\mathbb{T}^2)$, then

$$|a^n - b^n| \le n|a-b|\big(|a|^{n-1} + |b|^{n-1}\big).$$

Holder's inequality gives

$$\|a^n - b^n\|_{L^1} \le n\|a-b\|_{L^n}\left(\|a\|_{L^n}^{n-1} + \|b\|_{L^n}^{n-1}\right).$$

The convergence assumption (144.19) implies that the L^n-norms of $C_N^{\sigma\sigma}$ and $C_N^{\sigma\infty}$ are bounded and that both kernels converge to C in L^n. Hence

$$\big(C_N^{\sigma\sigma}\big)^n \to C^n, \qquad \big(C_N^{\sigma\infty}\big)^n \to C^n \quad \text{in } L^1.$$

Since f is bounded, the displayed formula for $\mathbb{E}|Y_N^\sigma - Y|^2$ tends to zero. This proves (144.20). $\square$

Remark 144.7 (Common limits of finite Wick-coordinate vectors). Fix finitely many pairs

$$(n_j, f_j), \qquad 1 \le j \le r,$$

where $n_j \ge 1$ and $f_j \in C^\infty(\mathbb{T}^2)$. For one cutoff sequence X_N, set

$$\mathcal{X}_N = \big(:X_N^{n_1}:(f_1), \dots, :X_N^{n_r}:(f_r)\big) \in \mathbb{R}^r.$$

Then $\mathcal{X}_N$ converges in $L^2(\Omega;\mathbb{R}^r)$, hence in probability, to

$$\mathcal{X} = \big(:X^{n_1}:(f_1), \dots, :X^{n_r}:(f_r)\big).$$

More generally, suppose X_N^A and X_N^B are two cutoff approximations of the same massive Gaussian field on a common probability space, and suppose that, for every j and $\sigma \in \{A, B\}$,

$$:(X_N^\sigma)^{n_j}:(f_j) \longrightarrow :X^{n_j}:(f_j) \quad \text{in } L^2(\Omega). \tag{144.21}$$

Then the coordinate vectors

$$\mathcal{X}_N^\sigma = \big(:(X_N^\sigma)^{n_1}:(f_1), \dots, :(X_N^\sigma)^{n_r}:(f_r)\big)$$

satisfy

$$\mathcal{X}_N^\sigma \longrightarrow \mathcal{X} \quad \text{in } L^2(\Omega; \mathbb{R}^r) \quad \text{and in probability,} \qquad \sigma = A, B. \tag{144.22}$$

For every bounded continuous $F : \mathbb{R}^r \to \mathbb{C}$,

$$F(\mathcal{X}_N^\sigma) \longrightarrow F(\mathcal{X}) \quad \text{in probability.} \tag{144.23}$$

For the single Fourier cutoff sequence, each coordinate converges in $L^2(\Omega)$ by Proposition 144.4. Therefore

$$\mathbb{E}|\mathcal{X}_N - \mathcal{X}|^2_{\mathbb{R}^r} = \sum_{j=1}^r \mathbb{E}\left|:X_N^{n_j}:(f_j) - :X^{n_j}:(f_j)\right|^2 \longrightarrow 0.$$

The two-regulator statement is identical after replacing the preceding coordinate convergence by (144.21); a concrete covariance criterion for this hypothesis is Lemma 144.6. L^2-convergence implies convergence in probability by Chebyshev's inequality. Finally, if $\mathcal{X}_N^\sigma \to \mathcal{X}$ in probability and F is continuous, then $F(\mathcal{X}_N^\sigma) \to F(\mathcal{X})$ in probability because the inverse image of the complement of any small neighborhood of $F(\mathcal{X})$ is controlled by continuity of F at the realized value of $\mathcal{X}$; equivalently, every almost surely convergent subsequence has a further subsequence on which the conclusion follows pointwise.

Remark 144.8 (Convergence of the Wick quartic potential)*.* Let $\lambda \in \mathbb{R}$, and define the cutoff Wick quartic functional on the Gaussian probability space of Proposition 144.4 by

$$V_N = \frac{\lambda}{4} \int_{\mathbb{T}^2} :X_N(x)^4: \, \mathrm{d}^2 x = \frac{\lambda}{4} \, :X_N^4:(1).$$

Then there is an $L^2(\Omega)$ random variable

$$V = \frac{\lambda}{4} \, :X^4:(1)$$

such that $V_N \to V$ in $L^2(\Omega)$, and hence in probability.

More generally, suppose X_N^A and X_N^B are two cutoff approximations of the same massive Gaussian field for which the conclusion of Proposition 144.4 holds for $:(X_N^\sigma)^4:(1)$, $\sigma = A, B$, with the same limiting Wick functional $:X^4:(1)$. Set

$$V_N^\sigma = \frac{\lambda}{4} \, :(X_N^\sigma)^4:(1), \qquad V = \frac{\lambda}{4} \, :X^4:(1).$$

Then $V_N^A \to V$ and $V_N^B \to V$ in $L^2(\Omega)$. Consequently, if the exponential weights $e^{-V_N^\sigma}$ obey a uniform L^p bound for some $p > 1$ and if the cylinder coordinates are finite Wick-coordinate vectors satisfying Remark 144.7, then the bounded-cylinder comparison conclusion of Corollary 144.33 applies. The first statement is Proposition 144.4 with $n = 4$ and with the smooth test function $f \equiv 1$. Multiplication by the scalar $\lambda/4$ preserves L^2-convergence. The two cutoff approximations are handled separately by the same Wick-power convergence proposition; because both sequences have the same L^2 limit,

$$\|V_N^\sigma - V\|_{L^2(\Omega)} \longrightarrow 0, \qquad \sigma = A, B.$$

The last assertion follows from Corollary 144.33, since L^2-convergence implies convergence in probability of the potentials.

Proposition 144.9 (Path-space convergence of the two-dimensional enhanced noise)**.** *Let*

$$W_N^{(n)}(\tau) =: X_N(\tau)^n :, \qquad n = 1, 2, 3.$$

For every $T < \infty$, every $s > 0$, every $0 < \vartheta < \min\{s, 1\}$, and every integer $p \geq 1$ with $p\vartheta > 1$, there is a constant $C = C(T, s, \vartheta, p, n, m) < \infty$, independent of N, such that

$$\mathbb{E}\, \|W_N^{(n)}(\tau) - W_N^{(n)}(\sigma)\|_{H^{-s}}^{2p} \leq C|\tau - \sigma|^{p\vartheta} \qquad (0 \leq \sigma, \tau \leq T). \tag{144.24}$$

Consequently the triple

$$\mathbb{X}_N = (X_N, :X_N^2:, :X_N^3:)$$

converges in probability in

$$C([0, T]; H^{-s}(\mathbb{T}^2))^3$$

to a continuous enhanced noise $\mathbb{X} = (X, :X^2:, :X^3:)$.

Proof. Write $a_k = |k|^2 + m^2$. The stationary Ornstein–Uhlenbeck formula gives, for $\tau, \sigma \in \mathbb{R}$,

$$\mathbb{E}\Big[X_k(\tau)\overline{X_\ell(\sigma)}\Big] = \delta_{k\ell}\frac{e^{-a_k|\tau-\sigma|}}{a_k}. \tag{144.25}$$

Indeed, with $\tau \geq \sigma$,

$$X_k(\tau) = e^{-a_k(\tau-\sigma)}X_k(\sigma) + \sqrt{2}\int_\sigma^\tau e^{-a_k(\tau-r)}\,\mathrm{d}B_k(r),$$

and the stochastic integral is independent of $X_k(\sigma)$.

Let $\widehat{W}_{N,q}^{(n)}(\tau)$ denote the q-th Fourier coefficient of $W_N^{(n)}(\tau)$. Wick's theorem and (144.25) give

$$\mathbb{E}\Big[\widehat{W}_{N,q}^{(n)}(\tau)\overline{\widehat{W}_{N,q}^{(n)}(\sigma)}\Big] = n! \sum_{\substack{k_1+\cdots+k_n=q \\ |k_i|\leq N}} \prod_{i=1}^n \frac{e^{-a_{k_i}|\tau-\sigma|}}{a_{k_i}}. \tag{144.26}$$

Therefore

$$\begin{aligned} &\mathbb{E}\left|\widehat{W}_{N,q}^{(n)}(\tau) - \widehat{W}_{N,q}^{(n)}(\sigma)\right|^2 \\ &\qquad = 2n! \sum_{\substack{k_1+\cdots+k_n=q \\ |k_i|\leq N}} \prod_{i=1}^n \frac{1}{a_{k_i}}\left(1 - e^{-|\tau-\sigma|\sum_i a_{k_i}}\right). \end{aligned} \tag{144.27}$$

For $0 < \vartheta < 1$, $1 - e^{-r} \leq r^\vartheta$, and concavity gives $(\sum_i a_{k_i})^\vartheta \leq \sum_i a_{k_i}^\vartheta$. Hence the right side of (144.27) is bounded by

$$C_{n,\vartheta}|\tau - \sigma|^\vartheta \sum_{j=1}^n \sum_{k_1+\cdots+k_n=q} a_{k_j}^{-1+\vartheta} \prod_{i\neq j} a_{k_i}^{-1}.$$

Let $g_\vartheta(k) = (1 + |k|^2)^{-1+\vartheta}$. Repeating the three-region proof of Lemma 144.3, with the factor $(1 + |p|^2)^{-1}$ replaced once by $(1 + |p|^2)^{-1+\vartheta}$, gives

$$(g_\vartheta * g^{*(n-1)})(q) \leq C_{n,\vartheta}\,\frac{L(q)^n}{(1 + |q|^2)^{1-\vartheta}}. \tag{144.28}$$

The only changed part of the induction is the region in which the weakened factor is the small momentum: there $\sum_{|p|\le |q|/2}(1+|p|^2)^{-1+\vartheta}\le C_\vartheta(1+|q|^2)^{\vartheta}$, which changes $(1+|q|^2)^{-1}$ into $(1+|q|^2)^{-1+\vartheta}$. All other regions are bounded by the same or a smaller power, up to logarithms. Thus

$$\mathbb{E}\left|\widehat{W}^{(n)}_{N,q}(\tau)-\widehat{W}^{(n)}_{N,q}(\sigma)\right|^2\le C|\tau-\sigma|^{\vartheta}\frac{L(q)^n}{(1+|q|^2)^{1-\vartheta}}. \tag{144.29}$$

After multiplying by the H^{-s} weight and summing over q, the large-shell exponent is

$$1-2s-2(1-\vartheta)=-1-2s+2\vartheta.$$

This is strictly smaller than -1 because $\vartheta<s$. Hence

$$\mathbb{E}\,\|W^{(n)}_N(\tau)-W^{(n)}_N(\sigma)\|^2_{H^{-s}}\le C|\tau-\sigma|^{\vartheta}.$$

Each scalar Fourier coefficient of the increment lies in the n-th homogeneous Wiener chaos. Applying Lemma 144.51 to scalar Fourier coordinates and using Minkowski's inequality in $L^p(\Omega)$ for the series defining the squared H^{-s}-norm gives

$$\mathbb{E}\,\|W^{(n)}_N(\tau)-W^{(n)}_N(\sigma)\|^{2p}_{H^{-s}}\le C_{p,n}\left(\sum_q(1+|q|^2)^{-s}\mathbb{E}\left|\widehat{W}^{(n)}_{N,q}(\tau)-\widehat{W}^{(n)}_{N,q}(\sigma)\right|^2\right)^p,$$

which proves (144.24).

It remains to pass from equal-time convergence to path convergence. Fix $\epsilon,\eta>0$. By Proposition 144.4, for every finite time grid $\mathcal{G}\subset[0,T]$,

$$\max_{\tau\in\mathcal{G}}\|W^{(n)}_N(\tau)-W^{(n)}_M(\tau)\|_{H^{-s}}\longrightarrow 0\quad\text{in probability as } N,M\to\infty.$$

The uniform moment bound (144.24) and the Kolmogorov dyadic argument imply that, after choosing the mesh of $\mathcal{G}$ sufficiently small,

$$\sup_N\mathbb{P}\left(\sup_{|\tau-\sigma|\le\mathrm{mesh}(\mathcal{G})}\|W^{(n)}_N(\tau)-W^{(n)}_N(\sigma)\|_{H^{-s}}>\epsilon\right)<\eta.$$

The same estimate holds with M in place of N. The triangle inequality between a time and the nearest grid point then shows that $\{W^{(n)}_N\}_N$ is Cauchy in probability in $C([0,T];H^{-s})$. Its limit has continuous paths because this Banach space is complete. The finite-dimensional time marginals agree with the equal-time Wick-power limits, so the limiting process is precisely $:X^n:$. Applying the argument to $n=1,2,3$ proves the convergence of $\mathbb{X}_N$. □

Heat-kernel smoothing estimate. Let $A=\Delta-m^2$ on $\mathbb{T}^d$. The parabolic gain used below is the following Fourier estimate: for $r\in\mathbb{R}$, $\theta\ge 0$, and $t>0$,

$$\|e^{tA}u\|_{H^{r+2\theta}}\le C_\theta t^{-\theta}e^{-m^2t/2}\|u\|_{H^r}. \tag{144.30}$$

Consequently, if $F\in L^\infty([0,T];H^r)$, then

$$\left\|\int_0^t e^{(t-s)A}F(s)\,\mathrm{d}s\right\|_{H^{r+2\theta}}\le C_{\theta,T}\|F\|_{L^\infty([0,T];H^r)}\quad(0\le\theta<1). \tag{144.31}$$

Indeed, in Fourier coordinates,

$$\|e^{tA}u\|_{H^{r+2\theta}}^2 = \sum_k (1+|k|^2)^{r+2\theta} e^{-2t(|k|^2+m^2)} |\widehat{u}(k)|^2.$$

The elementary bound

$$(1+|k|^2)^{2\theta} e^{-t(|k|^2+m^2)} \le C_\theta t^{-2\theta} e^{-m^2 t/2}$$

gives (144.30). The Duhamel estimate follows by integrating $(t-s)^{-\theta}$ over $0<s<t$, which is finite exactly for $\theta<1$. The restriction $\theta<1$ is therefore not a stochastic effect; it is the endpoint singularity of the deterministic heat kernel in this L_t^∞ estimate. Sharper parabolic Besov–Holder versions distribute time regularity differently, but the fixed-point argument below only needs the displayed Sobolev form.

144.5 Da Prato–Debussche in Two Dimensions

On a two-dimensional torus, consider the stochastic quantization equation for the Wick-ordered measure

$$\partial_\tau \Phi = \Delta\Phi - m^2\Phi - \lambda :\Phi^3: +\xi. \tag{144.32}$$

Let X solve the stationary linear equation

$$\partial_\tau X = (\Delta - m^2)X + \xi. \tag{144.33}$$

The field $X(\tau,\cdot)$ has the massive Gaussian free-field law on the spatial torus and is almost surely a spatial distribution of regularity $-\kappa$ for every $\kappa>0$. Write

$$\Phi = X + Y.$$

Then the nonlinear equation for Y is

$$\partial_\tau Y = (\Delta - m^2)Y - \lambda\big(Y^3 + 3Y^2X + 3Y :X^2: + :X^3:\big). \tag{144.34}$$

In two dimensions the products in (144.34) are well-defined once $:X^2:$ and $:X^3:$ are constructed as Wick powers, because the unknown Y gains positive parabolic regularity from the heat operator.

144.5.1 Local Product Estimates and Mild Fixed Points

Lemma 144.10 (Sobolev products for the DPD fixed point)**.** *Let $0<\kappa<1/4$ and set $\beta = 1+2\kappa$. On $\mathbb{T}^2$, there is $C_\kappa<\infty$ such that*

$$\|uv\|_{H^\beta} \le C_\kappa \|u\|_{H^\beta}\|v\|_{H^\beta}, \tag{144.35}$$

$$\|uv\|_{H^{-\kappa}} \le C_\kappa \|u\|_{H^\beta}\|v\|_{H^{-\kappa}}, \tag{144.36}$$

for u,v in the indicated spaces. Consequently, if $\mathbb{X} = (X, X^{(2)}, X^{(3)}) \in C([0,T];H^{-\kappa})^3$ and

$$\mathcal{N}(Y,\mathbb{X}) = Y^3 + 3Y^2X + 3YX^{(2)} + X^{(3)}, \tag{144.37}$$

then $\mathcal{N}(Y,\mathbb{X}) \in C([0,T];H^{-\kappa})$ for every $Y \in C([0,T];H^\beta)$. We write

$$\|\mathbb{X}\|_{C_TH^{-\kappa}} = \max_{1\le j\le 3} \|X^{(j)}\|_{C([0,T];H^{-\kappa})}, \qquad X^{(1)} = X,$$

and for $\|Y\|_{C_TH^\beta}, \|Z\|_{C_TH^\beta} \le R$,

$$\|\mathcal{N}(Y,\mathbb{X}) - \mathcal{N}(Z,\mathbb{X})\|_{C_TH^{-\kappa}} \le C_{\kappa,R}\big(1+\|\mathbb{X}\|_{C_TH^{-\kappa}}\big)\|Y-Z\|_{C_TH^\beta}. \tag{144.38}$$

Proof. We recall the dyadic proof because this is the exact multiplication input in the fixed point. Let Δ_j be a Littlewood–Paley partition on the torus and $S_j = \sum_{i<j} \Delta_i$. Bony's decomposition writes

$$uv = u \prec v + u \circ v + u \succ v, \qquad u \prec v = \sum_j S_{j-1}u\, \Delta_j v,$$

with $u \circ v = \sum_{|i-j|\le 1} \Delta_i u\, \Delta_j v$. Bernstein's inequality in two dimensions gives

$$\|\Delta_j u\|_{L^\infty} \le C 2^{j(1-\beta)} \|u\|_{H^\beta} \qquad (\beta > 1), \tag{144.39}$$

and summing in j gives $H^\beta \hookrightarrow L^\infty$. The paraproduct estimates following from the almost-disjoint frequency supports are

$$\|u \prec v\|_{H^s} + \|u \succ v\|_{H^s} \le C\|u\|_{L^\infty}\|v\|_{H^s} + C\|v\|_{L^\infty}\|u\|_{H^s}, \tag{144.40}$$

and, for the resonant term,

$$\|u \circ v\|_{H^{s+t-1}} \le C\|u\|_{H^s}\|v\|_{H^t} \quad \text{when } s+t>1. \tag{144.41}$$

Indeed, $\Delta_\ell(u \prec v)$ only receives terms with $|j-\ell| \le O(1)$, so

$$2^{\ell s}\|\Delta_\ell(u \prec v)\|_{L^2} \le C\|u\|_{L^\infty} \sum_{|j-\ell|\le O(1)} 2^{js}\|\Delta_j v\|_{L^2},$$

and square summation in ℓ gives the first paraproduct bound; the bound for $u \succ v$ is identical. For $u \circ v$, the product $\Delta_i u\, \Delta_j v$ with $|i-j| \le 1$ has frequencies $\lesssim 2^j$. Bernstein and Cauchy–Schwarz give $\|\Delta_i u\, \Delta_j v\|_{L^2} \le C2^{j(1-s-t)}a_i b_j$, where $a_j = 2^{js}\|\Delta_j u\|_{L^2}$ and $b_j = 2^{jt}\|\Delta_j v\|_{L^2}$. Multiplication by the H^{s+t-1} weight cancels the factor $2^{j(1-s-t)}$, and the condition $s+t>1$ makes the finite-overlap high-frequency convolution summable. Taking $s=t=\beta$ gives the algebra estimate (144.35), since $2\beta - 1 > \beta$. Taking $s=\beta$ and $t=-\kappa$ gives $\beta-\kappa>1$, so the resonant term lands in $H^{\beta-\kappa-1}$. Because $\beta-\kappa-1 = \kappa > -\kappa$, this term is in $H^{-\kappa}$, and the two paraproduct terms are controlled by the L^∞ embedding of H^β. This proves (144.36).

The bounds on $\mathcal{N}$ follow by applying (144.35) and (144.36) term by term:

$$\|Y^3\|_{H^\beta} \le C\|Y\|_{H^\beta}^3, \quad \|Y^2X\|_{H^{-\kappa}} \le C\|Y\|_{H^\beta}^2\|X\|_{H^{-\kappa}},$$

and similarly for $YX^{(2)}$. For the Lipschitz estimate, use

$$Y^3 - Z^3 = (Y-Z)(Y^2+YZ+Z^2), \qquad Y^2X - Z^2X = (Y-Z)(Y+Z)X,$$

and the same two product estimates. This gives (144.38). $\square$

Proposition 144.11 (Besov–Holder product continuity for the DPD nonlinearity)**.** *Let* $0<\kappa<\alpha$*, and let*

$$\mathcal{C}^\gamma(\mathbb{T}^2) = B^\gamma_{\infty,\infty}(\mathbb{T}^2), \qquad \|u\|_{\mathcal{C}^\gamma} = \sup_{j\ge -1} 2^{j\gamma}\|\Delta_j u\|_{L^\infty}.$$

Here $(\Delta_j)_{j\ge-1}$ *is a fixed smooth dyadic partition of unity on the torus, with* Δ_{-1} *the low-frequency block. Then Bony's formula defines canonical continuous bilinear maps extending ordinary multiplication of smooth functions,*

$$\mathcal{C}^\alpha \times \mathcal{C}^{-\kappa} \longrightarrow \mathcal{C}^{-\kappa}, \qquad \mathcal{C}^\alpha \times \mathcal{C}^\alpha \longrightarrow \mathcal{C}^\alpha.$$

Consequently, for

$$\mathbb{X} = (X_1, X_2, X_3) \in C([0,T]; \mathcal{C}^{-\kappa})^3 \quad \textit{and} \quad Y \in C([0,T]; \mathcal{C}^{\alpha}),$$

the expression

$$\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X}) = Y^3 + 3Y^2 X_1 + 3Y X_2 + X_3$$

is a well-defined element of $C([0,T]; \mathcal{C}^{-\kappa})$. *Here*

$$\|\mathbb{X}\|_{C_T \mathcal{C}^{-\kappa}} = \max_{1 \le i \le 3} \|X_i\|_{C([0,T]; \mathcal{C}^{-\kappa})}.$$

The same convention is used for any other triple $\mathbb{Z} = (Z_1, Z_2, Z_3)$. *More precisely, for every* $R > 0$ *there is* $C_{\alpha,\kappa,R}$ *such that, whenever* $\mathbb{Z} = (Z_1, Z_2, Z_3)$ *and*

$$\|Y\|_{C_T \mathcal{C}^{\alpha}} + \|Z\|_{C_T \mathcal{C}^{\alpha}} + \|\mathbb{X}\|_{C_T \mathcal{C}^{-\kappa}} + \|\mathbb{Z}\|_{C_T \mathcal{C}^{-\kappa}} \le R,$$

one has

$$\begin{aligned} &\|\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X}) - \mathcal{N}_{\mathcal{C}}(Z, \mathbb{Z})\|_{C_T \mathcal{C}^{-\kappa}} \\ &\qquad \le C_{\alpha,\kappa,R} \left(\|Y - Z\|_{C_T \mathcal{C}^{\alpha}} + \max_{1 \le i \le 3} \|X_i - Z_i\|_{C_T \mathcal{C}^{-\kappa}} \right). \end{aligned} \tag{144.42}$$

Proof. It is enough to prove the two multiplication statements, since the continuity of $\mathcal{N}_{\mathcal{C}}$ then follows by expanding differences:

$$Y^3 - Z^3 = (Y - Z)(Y^2 + YZ + Z^2), \qquad Y^2 X_1 - Z^2 Z_1 = (Y^2 - Z^2) X_1 + Z^2 (X_1 - Z_1),$$

and similarly for $Y X_2 - Z Z_2$.

Use Bony's decomposition

$$fg = f \prec g + f \circ g + f \succ g, \qquad f \prec g = \sum_j S_{j-1} f \, \Delta_j g,$$

where $S_j = \sum_{i<j} \Delta_i$ and

$$f \circ g = \sum_{|i-j| \le 1} \Delta_i f \, \Delta_j g.$$

The frequency supports imply that $\Delta_\ell(f \prec g)$ receives only $|j - \ell| \le C_0$. Hence, for any $\beta \in \mathbb{R}$,

$$2^{\ell\beta} \|\Delta_\ell (f \prec g)\|_{L^\infty} \le C \|f\|_{L^\infty} \sup_{|j-\ell| \le C_0} 2^{j\beta} \|\Delta_j g\|_{L^\infty},$$

and therefore

$$\|f \prec g\|_{\mathcal{C}^\beta} \le C \|f\|_{L^\infty} \|g\|_{\mathcal{C}^\beta}. \tag{144.43}$$

If $\beta < 0$, then the low-frequency sum satisfies

$$\|S_{j-1} g\|_{L^\infty} \le C 2^{-j\beta} \|g\|_{\mathcal{C}^\beta},$$

because $\sum_{i<j} 2^{-i\beta} \le C 2^{-j\beta}$. Thus, for $\alpha > 0$ and $\beta < 0$,

$$\|g \prec f\|_{\mathcal{C}^{\alpha+\beta}} \le C \|g\|_{\mathcal{C}^\beta} \|f\|_{\mathcal{C}^\alpha}. \tag{144.44}$$

For the resonant term, the block $\Delta_\ell(f \circ g)$ receives only indices $i, j \geq \ell - C_1$ with $|i-j| \leq 1$. Therefore

$$2^{\ell(\alpha+\beta)} \|\Delta_\ell(f \circ g)\|_{L^\infty} \leq C \|f\|_{\mathcal{C}^\alpha} \|g\|_{\mathcal{C}^\beta} \sum_{i \geq \ell - C_1} 2^{(\ell-i)(\alpha+\beta)}.$$

The final geometric sum is bounded exactly when $\alpha + \beta > 0$, and then

$$\|f \circ g\|_{\mathcal{C}^{\alpha+\beta}} \leq C \|f\|_{\mathcal{C}^\alpha} \|g\|_{\mathcal{C}^\beta}. \tag{144.45}$$

Now take $\beta = -\kappa$. Since $\alpha - \kappa > 0$, (144.43), (144.44), and (144.45) give

$$\|fg\|_{\mathcal{C}^{-\kappa}} \leq C_{\alpha,\kappa} \|f\|_{\mathcal{C}^\alpha} \|g\|_{\mathcal{C}^{-\kappa}},$$

using the continuous embedding $\mathcal{C}^{\alpha-\kappa} \hookrightarrow \mathcal{C}^{-\kappa}$. Taking instead $f, g \in \mathcal{C}^\alpha$, the paraproduct terms are controlled by $\mathcal{C}^\alpha \hookrightarrow L^\infty$, and the resonant term belongs to $\mathcal{C}^{2\alpha}$, hence to $\mathcal{C}^\alpha$. This proves that $\mathcal{C}^\alpha$ is an algebra. The bilinear maps are therefore well-defined by the displayed paraproduct and resonant sums. On smooth inputs the dyadic partition is a partition of unity, so Bony's formula equals the ordinary pointwise product; on rough inputs the formula is the canonical product used in this Besov scale. If a sequence of smooth inputs converges in a slightly stronger Besov norm, the bilinear estimates show that its ordinary products converge to the same paraproduct value.

Applying these two bilinear estimates at each time t, taking suprema in time, and expanding the displayed differences gives (144.42). □

Proposition 144.12 (Besov heat smoothing on the torus)**.** *Let $m^2 > 0$, $0 < \theta < 1$, and $A = \Delta - m^2$ on $\mathbb{T}^2$. For every $\rho \in \mathbb{R}$ there is $C_{\rho,\theta,m} < \infty$ such that*

$$\|e^{tA} f\|_{\mathcal{C}^{\rho+2\theta}} \leq C_{\rho,\theta,m}\, t^{-\theta}\, \|f\|_{\mathcal{C}^\rho}, \qquad 0 < t \leq 1. \tag{144.46}$$

Consequently, if $F \in C([0,T]; \mathcal{C}^\rho)$ and $T \leq 1$, then

$$\left\| \int_0^t e^{(t-s)A} F(s)\, \mathrm{d}s \right\|_{C([0,T];\mathcal{C}^{\rho+2\theta})} \leq C_{\rho,\theta,m}\, T^{1-\theta} \|F\|_{C([0,T];\mathcal{C}^\rho)}.$$

Proof. Let $(\Delta_j)_{j \geq -1}$ be the dyadic partition used in Proposition 144.11. For $j \geq 0$, let $K_{j,t}$ be the convolution kernel on $\mathbb{T}^2$ of the multiplier

$$k \longmapsto \varphi(2^{-j} k) \exp(-t(|k|^2 + m^2)),$$

where φ is the annular cutoff defining Δ_j. The rescaled multiplier

$$\xi \longmapsto \varphi(\xi) \exp(-t(2^{2j}|\xi|^2 + m^2))$$

has derivatives of every fixed order bounded by

$$C_N (1 + t2^{2j})^N \exp(-c\, t2^{2j}),$$

hence by $C_N \exp(-c_N t 2^{2j})$. The standard integration-by-parts estimate for Fourier kernels with compactly supported smooth multipliers, applied after this rescaling and then periodized to $\mathbb{T}^2$, gives

$$\|K_{j,t}\|_{L^1(\mathbb{T}^2)} \leq C_N (1 + t2^{2j})^{-N} \leq C_\theta t^{-\theta} 2^{-2\theta j}, \qquad j \geq 0, \quad 0 < t \leq 1,$$

after choosing $N > \theta$. The low block Δ_{-1} has a smooth compactly supported multiplier, so its kernel has uniformly bounded L^1-norm and is absorbed by increasing the constant. Since Δ_j commutes with e^{tA}, Young's inequality gives

$$2^{j(\rho+2\theta)}\|\Delta_j e^{tA} f\|_{L^\infty} \le C_{\theta,m} t^{-\theta} 2^{j\rho}\|\Delta_j f\|_{L^\infty}.$$

Taking the supremum over $j \ge -1$ proves (144.46).

For the Duhamel term, apply (144.46) to $e^{(t-s)A}F(s)$ and integrate:

$$\left\|\int_0^t e^{(t-s)A}F(s)\,\mathrm{d}s\right\|_{\mathcal{C}^{\rho+2\theta}} \le C_{\rho,\theta,m}\|F\|_{C_T\mathcal{C}^\rho}\int_0^t (t-s)^{-\theta}\,\mathrm{d}s.$$

Since $\theta < 1$, the last integral is $t^{1-\theta}/(1-\theta)$, uniformly bounded by a constant times $T^{1-\theta}$. $\square$

Theorem 144.13 (Deterministic DPD local fixed point in Besov–Holder coordinates)**.** *Let $m^2 > 0$, $\lambda > 0$, and choose exponents*

$$0 < \kappa < \alpha < 2 - \kappa.$$

Let

$$\mathbb{X} = (X_1, X_2, X_3) \in C([0,T_0];\mathcal{C}^{-\kappa}(\mathbb{T}^2))^3, \qquad Y_0 \in \mathcal{C}^\alpha(\mathbb{T}^2).$$

Set

$$M_{\mathbb{X}} = \max_{1\le i\le 3}\|X_i\|_{C([0,T_0];\mathcal{C}^{-\kappa})}.$$

For another enhanced noise $\mathbb{Z} = (Z_1, Z_2, Z_3)$, the notation $\|\mathbb{Z}\|_{C_T\mathcal{C}^{-\kappa}}$ below always means the same maximum over the three components restricted to $[0,T]$. Then there is $T \in (0, T_0]$, depending only on

$$\alpha, \kappa, m, \lambda, \|Y_0\|_{\mathcal{C}^\alpha}, \quad \textit{and} \quad M_{\mathbb{X}},$$

such that the mild equation

$$Y(t) = e^{t(\Delta-m^2)}Y_0 - \lambda\int_0^t e^{(t-s)(\Delta-m^2)}\mathcal{N}_{\mathcal{C}}(Y(s), \mathbb{X}(s))\,\mathrm{d}s \tag{144.47}$$

has a unique solution $Y \in C([0,T];\mathcal{C}^\alpha)$. On every ball where

$$\|Y_0\|_{\mathcal{C}^\alpha} + \|Z_0\|_{\mathcal{C}^\alpha} + \|\mathbb{X}\|_{C_T\mathcal{C}^{-\kappa}} + \|\mathbb{Z}\|_{C_T\mathcal{C}^{-\kappa}} \le R,$$

and for T chosen depending only on $\alpha, \kappa, m, \lambda, R$, the solution map

$$(Y_0, \mathbb{X}) \longmapsto Y$$

is Lipschitz from

$$\mathcal{C}^\alpha \times \left(C_T\mathcal{C}^{-\kappa}\right)^3$$

to $C_T\mathcal{C}^\alpha$.

Proof. Put

$$\theta = \frac{\alpha+\kappa}{2}.$$

The hypothesis $\alpha < 2 - \kappa$ is exactly $\theta < 1$, which is the integrability condition for the Duhamel kernel. Let $A = \Delta - m^2$ and define, for $Y \in C_T\mathcal{C}^\alpha$,

$$(\Psi Y)(t) = e^{tA}Y_0 - \lambda \int_0^t e^{(t-s)A}\mathcal{N}_{\mathcal{C}}(Y(s), \mathbb{X}(s))\, \mathrm{d}s.$$

By Proposition 144.11, $\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X}) \in C_T\mathcal{C}^{-\kappa}$. Applying Proposition 144.12 with $\rho = -\kappa$ and $2\theta = \alpha + \kappa$ gives

$$\left\| \int_0^t e^{(t-s)A}\mathcal{N}_{\mathcal{C}}(Y(s), \mathbb{X}(s))\, \mathrm{d}s \right\|_{C_T\mathcal{C}^\alpha} \leq CT^{1-\theta}\|\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X})\|_{C_T\mathcal{C}^{-\kappa}}. \tag{144.48}$$

The heat semigroup is bounded on $\mathcal{C}^\alpha$. Choose

$$R_0 = 2C\|Y_0\|_{\mathcal{C}^\alpha} + 1.$$

For $\|Y\|_{C_T\mathcal{C}^\alpha} \leq R_0$, the product-continuity proposition gives

$$\|\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X})\|_{C_T\mathcal{C}^{-\kappa}} \leq C_{\alpha,\kappa,R_0+M_{\mathbb{X}}}.$$

Taking $T \leq T_0$ so that the right side of (144.48), multiplied by λ, is at most $R_0/2$, the map Ψ sends the closed ball

$$B_{R_0} = \{Y \in C_T\mathcal{C}^\alpha : \|Y\|_{C_T\mathcal{C}^\alpha} \leq R_0\}$$

to itself.

For $Y, Z \in B_{R_0}$, equations (144.42) and (144.48) give

$$\|\Psi Y - \Psi Z\|_{C_T\mathcal{C}^\alpha} \leq \lambda C_{\alpha,\kappa,m,R_0+M_{\mathbb{X}}}T^{1-\theta}\|Y - Z\|_{C_T\mathcal{C}^\alpha}.$$

Decreasing T if necessary makes the coefficient strictly smaller than one. Since $C_T\mathcal{C}^\alpha$ is complete, Banach's fixed-point theorem gives a unique fixed point in B_{R_0}. If another solution exists on the same interval with finite $C_T\mathcal{C}^\alpha$ norm, the same contraction argument on a smaller ball containing both solutions, possibly after partitioning the time interval into finitely many subintervals, forces equality.

For Lipschitz dependence, let Y and Z solve (144.47) with data $(Y_0, \mathbb{X})$ and $(Z_0, \mathbb{Z})$, all bounded by R. The semigroup bound, the Duhamel estimate, and (144.42) give

$$\begin{aligned}\|Y - Z\|_{C_T\mathcal{C}^\alpha} &\leq C\|Y_0 - Z_0\|_{\mathcal{C}^\alpha} \\ &\quad + \lambda C_{\alpha,\kappa,m,R}T^{1-\theta}\left(\|Y - Z\|_{C_T\mathcal{C}^\alpha} + \max_i \|X_i - Z_i\|_{C_T\mathcal{C}^{-\kappa}}\right).\end{aligned}$$

Choose T so the coefficient of $\|Y - Z\|_{C_T\mathcal{C}^\alpha}$ on the right is at most $1/2$, and absorb it to the left. This proves the stated Lipschitz bound. □

Theorem 144.14 (Deterministic DPD local fixed point in Sobolev coordinates). *Let* $0 < \kappa < 1/4$, $\beta = 1 + 2\kappa$, $m^2 > 0$, $\lambda > 0$, *and*

$$\mathbb{X} = (X, X^{(2)}, X^{(3)}) \in C([0, T_0]; H^{-\kappa}(\mathbb{T}^2))^3.$$

Set

$$M_{\mathbb{X}} = \max_{1 \leq j \leq 3} \|X^{(j)}\|_{C([0,T_0];H^{-\kappa})}, \qquad X^{(1)} = X.$$

For every $Y_0 \in H^\beta(\mathbb{T}^2)$ there is $T \in (0, T_0]$, depending only on $\|Y_0\|_{H^\beta}$, λ, m, κ, and $M_{\mathbb{X}}$, such that the mild equation

$$Y(t) = e^{t(\Delta - m^2)} Y_0 - \lambda \int_0^t e^{(t-s)(\Delta - m^2)} \mathcal{N}(Y(s), \mathbb{X}(s))\, \mathrm{d}s \tag{144.49}$$

has a unique solution $Y \in C([0,T]; H^\beta)$. The solution depends locally Lipschitz continuously on Y_0 and on $\mathbb{X}$ in these norms.

Proof. Let $C_T H^r = C([0,T]; H^r)$ and put $A = \Delta - m^2$. Define

$$(\Psi Y)(t) = e^{tA} Y_0 - \lambda \int_0^t e^{(t-s)A} \mathcal{N}(Y(s), \mathbb{X}(s))\, \mathrm{d}s.$$

The forcing belongs to $C_T H^{-\kappa}$ by Lemma 144.10. To estimate the Duhamel term in H^β, use the heat-kernel estimate (144.30) with

$$r = -\kappa, \qquad r + 2\theta = \beta, \qquad \theta = \frac{\beta + \kappa}{2} = \frac{1 + 3\kappa}{2}.$$

Since $\kappa < 1/4$, $\theta < 1$. Hence

$$\left\| \int_0^t e^{(t-s)A} F(s)\, \mathrm{d}s \right\|_{C_T H^\beta} \le C_{\kappa,m} T^{1-\theta} \|F\|_{C_T H^{-\kappa}}. \tag{144.50}$$

Choose $R = 2C\|Y_0\|_{H^\beta} + 1$, where C bounds the heat semigroup on H^β. Lemma 144.10 gives, for $\|Y\|_{C_T H^\beta} \le R$,

$$\|\mathcal{N}(Y, \mathbb{X})\|_{C_T H^{-\kappa}} \le C_{\kappa,R}\big(1 + \|\mathbb{X}\|_{C_T H^{-\kappa}}\big).$$

By (144.50), T can be chosen so small that Ψ maps the closed ball $B_R \subset C_T H^\beta$ into itself. For $Y, Z \in B_R$, equations (144.38) and (144.50) give

$$\|\Psi Y - \Psi Z\|_{C_T H^\beta} \le |\lambda| C_{\kappa,R,m} T^{1-\theta} \big(1 + \|\mathbb{X}\|_{C_T H^{-\kappa}}\big) \|Y - Z\|_{C_T H^\beta}.$$

Reducing T once more makes the coefficient < 1. Starting from any $Y_0^\sharp \in B_R$ and setting $Y_{n+1}^\sharp = \Psi Y_n^\sharp$, the differences obey

$$\|Y_{n+1}^\sharp - Y_n^\sharp\|_{C_T H^\beta} \le q^n \|Y_1^\sharp - Y_0^\sharp\|_{C_T H^\beta}, \qquad q < 1.$$

The resulting sequence is Cauchy in the complete space $C_T H^\beta$; its limit is a fixed point, and the same inequality applied to two fixed points forces equality. Applying the contraction estimate to two sets of data gives local Lipschitz dependence, after taking the smaller of the two local existence times. □

This theorem is deliberately weaker than the sharp Da Prato–Debussche theorem in Holder–Besov spaces, but it proves the exact deterministic logic: enhanced noise first makes every term in the nonlinearity meaningful, then heat smoothing supplies a positive time power, and the local solution is obtained by contraction. The remaining global and invariant-measure steps require estimates beyond this local theorem.

144.5.2 Energy Inequalities and Compactness of Smooth Approximations

Lemma 144.15 (Smooth enhanced-noise energy estimate)**.** *Let X_1, X_2, X_3 be smooth real functions on $[0,T] \times \mathbb{T}^2$, let $m^2 > 0$, $\lambda > 0$, and let Y be a smooth solution of*

$$\partial_t Y = (\Delta - m^2)Y - \lambda\big(Y^3 + 3Y^2 X_1 + 3Y X_2 + X_3\big). \tag{144.51}$$

Then, for a numerical constant C,

$$\begin{aligned}\frac{1}{2}\frac{d}{dt}\|Y(t)\|_{L^2}^2 + \|\nabla Y(t)\|_{L^2}^2 + m^2\|Y(t)\|_{L^2}^2 + \frac{\lambda}{4}\|Y(t)\|_{L^4}^4 \\ \leq C\lambda\left(\|X_1(t)\|_{L^4}^4 + \|X_2(t)\|_{L^2}^2 + \|X_3(t)\|_{L^{4/3}}^{4/3}\right).\end{aligned} \tag{144.52}$$

Consequently no finite-time blowup can occur in a smooth Galerkin approximation whose enhanced noise norms on the right-hand side stay integrable on compact stochastic-time intervals.

Proof. Multiply (144.51) by Y and integrate over the torus. Periodicity gives

$$\int_{\mathbb{T}^2} Y \Delta Y \, \mathrm{d}^2 x = -\|\nabla Y\|_{L^2}^2.$$

Thus

$$\begin{aligned}&\frac{1}{2}\frac{d}{dt}\|Y\|_{L^2}^2 + \|\nabla Y\|_{L^2}^2 + m^2\|Y\|_{L^2}^2 + \lambda\|Y\|_{L^4}^4 \\ &\qquad = -3\lambda\int Y^3 X_1 - 3\lambda\int Y^2 X_2 - \lambda\int Y X_3.\end{aligned}$$

Young's inequality with conjugate exponents $(4/3, 4)$, $(2, 2)$, and $(4, 4/3)$ gives pointwise bounds

$$\begin{aligned}3|Y|^3|X_1| &\leq \frac{1}{4}|Y|^4 + C|X_1|^4, \\ 3|Y|^2|X_2| &\leq \frac{1}{4}|Y|^4 + C|X_2|^2, \\ |Y||X_3| &\leq \frac{1}{4}|Y|^4 + C|X_3|^{4/3}.\end{aligned}$$

Substituting these three estimates into the energy identity and retaining the remaining positive $\lambda\|Y\|_{L^4}^4/4$ proves (144.52). Integrating the inequality in time bounds $\|Y(t)\|_{L^2}^2$, the accumulated H^1 norm, and the accumulated L^4 norm by the initial L^2 norm and the three enhanced noise norms. A smooth Galerkin solution can be continued as long as its finite-dimensional norm is finite; the displayed bound prevents blowup on intervals where the right-hand side is integrable. □

Proposition 144.16 (Closedness of the DPD energy inequality under approximation)**.** *Let $m^2 > 0$, $\lambda > 0$, and $T > 0$. For $n \geq 1$, let $(X_{1,n}, X_{2,n}, X_{3,n})$ be smooth real functions on $[0,T] \times \mathbb{T}^2$, and let Y_n be a smooth solution of (144.51) with X_i replaced by $X_{i,n}$. Assume*

$$\begin{aligned}X_{1,n} &\to X_1 \quad \text{in } L^4([0,T] \times \mathbb{T}^2), \\ X_{2,n} &\to X_2 \quad \text{in } L^2([0,T] \times \mathbb{T}^2), \\ X_{3,n} &\to X_3 \quad \text{in } L^{4/3}([0,T] \times \mathbb{T}^2),\end{aligned}$$

and suppose that $Y_n(0) \to Y_0$ strongly in $L^2(\mathbb{T}^2)$. Let Y be a function such that, after passing to a subsequence,

$$\begin{aligned} Y_n &\rightharpoonup Y && \text{weakly in } L^2([0,T];H^1(\mathbb{T}^2)),\\ Y_n &\rightharpoonup Y && \text{weakly in } L^4([0,T]\times\mathbb{T}^2),\\ Y_n(T) &\rightharpoonup Y(T) && \text{weakly in } L^2(\mathbb{T}^2). \end{aligned}$$

Then Y satisfies the integrated energy inequality

$$\begin{aligned} \frac{1}{2}\|Y(T)\|_{L^2}^2 &+ \int_0^T \left[\|\nabla Y(t)\|_{L^2}^2 + m^2\|Y(t)\|_{L^2}^2 + \frac{\lambda}{4}\|Y(t)\|_{L^4}^4\right] \mathrm{d}t \\ &\le \frac{1}{2}\|Y_0\|_{L^2}^2 + C\lambda \int_0^T \left[\|X_1(t)\|_{L^4}^4 + \|X_2(t)\|_{L^2}^2 + \|X_3(t)\|_{L^{4/3}}^{4/3}\right] \mathrm{d}t. \qquad (144.53) \end{aligned}$$

Proof. Integrating (144.52) for the n-th smooth solution gives

$$\begin{aligned} \frac{1}{2}\|Y_n(T)\|_{L^2}^2 &+ \int_0^T \left[\|\nabla Y_n(t)\|_{L^2}^2 + m^2\|Y_n(t)\|_{L^2}^2 + \frac{\lambda}{4}\|Y_n(t)\|_{L^4}^4\right] \mathrm{d}t \\ &\le \frac{1}{2}\|Y_n(0)\|_{L^2}^2 + C\lambda \int_0^T \left[\|X_{1,n}(t)\|_{L^4}^4 + \|X_{2,n}(t)\|_{L^2}^2 + \|X_{3,n}(t)\|_{L^{4/3}}^{4/3}\right] \mathrm{d}t. \qquad (144.54) \end{aligned}$$

The right hand side converges to the right hand side of (144.53): the initial data converge strongly in L^2, and convergence in L^p implies convergence of $\|X_{1,n}\|_{L^4}^4$, $\|X_{2,n}\|_{L^2}^2$, and $\|X_{3,n}\|_{L^{4/3}}^{4/3}$ by the elementary inequality

$$\big||a|^p - |b|^p\big| \le p\,|a-b|(|a|+|b|)^{p-1}, \qquad p \ge 1,$$

followed by Hölder's inequality.

The left hand side is lower semicontinuous under the assumed weak convergences. For the quadratic terms this is the lower semicontinuity of the norm in Hilbert space, applied in

$$L^2([0,T];H^1(\mathbb{T}^2)), \qquad L^2([0,T];L^2(\mathbb{T}^2)),$$

and also at the endpoint T. For the quartic term, the map

$$u \longmapsto \|u\|_{L^4([0,T]\times\mathbb{T}^2)}^4$$

is convex and norm-continuous on L^4, hence weakly lower semicontinuous. Taking the liminf of the left hand side of (144.54) and the limit of its right hand side proves (144.53). ☐

Proposition 144.17 (Energy compactness for smooth DPD remainders)**.** *Let $m^2 > 0$, $\lambda > 0$, $T > 0$, and set $Q_T = [0,T]\times\mathbb{T}^2$. For $n \ge 1$, let $(X_{1,n}, X_{2,n}, X_{3,n})$ be smooth real functions on Q_T, and let Y_n be a smooth solution of (144.51) with X_i replaced by $X_{i,n}$. Assume that*

$$M_T := \sup_n \left[\|Y_n(0)\|_{L^2(\mathbb{T}^2)} + \|X_{1,n}\|_{L^4(Q_T)} + \|X_{2,n}\|_{L^2(Q_T)} + \|X_{3,n}\|_{L^{4/3}(Q_T)}\right] < \infty.$$

Then there is a constant C_T, depending on T, m^2, λ, and M_T, but not on n, such that

$$\begin{aligned} \sup_n \Big[\|Y_n\|_{L^\infty([0,T];L^2)} &+ \|Y_n\|_{L^2([0,T];H^1)} + \|Y_n\|_{L^4(Q_T)} \\ &+ \|\partial_t Y_n\|_{L^{4/3}([0,T];H^{-1})}\Big] \le C_T. \qquad (144.55) \end{aligned}$$

Consequently, after passing to a subsequence, there is a function Y such that

$$\begin{aligned} Y_n &\rightharpoonup^* Y \quad \text{weakly-* in } L^\infty([0,T];L^2(\mathbb{T}^2)),\\ Y_n &\rightharpoonup Y \quad \text{weakly in } L^2([0,T];H^1(\mathbb{T}^2)),\\ Y_n &\rightharpoonup Y \quad \text{weakly in } L^4(Q_T), \end{aligned}$$

and, after a further subsequence if necessary,

$$Y_n(T) \rightharpoonup Y(T) \qquad \text{weakly in } L^2(\mathbb{T}^2),$$

where Y is represented by its weakly L^2-continuous time representative.

Proof. Apply (144.52) on every interval $[0,t]$, $0 \le t \le T$. Since the right hand side is bounded uniformly by the definition of M_T, the $L^\infty_t L^2_x$, $L^2_t H^1_x$, and $L^4_{t,x}$ parts of (144.55) follow.

It remains to prove the time-derivative bound. Let $\|v\|_{H^1(\mathbb{T}^2)} \le 1$. In two dimensions the Sobolev embedding $H^1(\mathbb{T}^2) \hookrightarrow L^4(\mathbb{T}^2)$ gives

$$\|f\|_{H^{-1}} \le C\|f\|_{L^{4/3}} \qquad \text{for } f \in L^{4/3}(\mathbb{T}^2).$$

Testing the smooth equation against v therefore gives, in the dual space H^{-1},

$$\begin{aligned} \|\partial_t Y_n\|_{H^{-1}} \le C\Big(&\|Y_n\|_{H^1} + \|Y_n\|_{L^2} + \|Y_n\|_{L^4}^3 + \|Y_n\|_{L^4}^2\|X_{1,n}\|_{L^4} \\ &+ \|Y_n\|_{L^4}\|X_{2,n}\|_{L^2} + \|X_{3,n}\|_{L^{4/3}}\Big). \end{aligned} \tag{144.56}$$

Here and below the spatial norms are taken on $\mathbb{T}^2$ at the fixed time under consideration. Taking the $L^{4/3}$-norm in time and using Hölder's inequality on Q_T gives

$$\begin{aligned} \|Y_n^3\|_{L^{4/3}(Q_T)} &= \|Y_n\|_{L^4(Q_T)}^3,\\ \|Y_n^2 X_{1,n}\|_{L^{4/3}(Q_T)} &\le \|Y_n\|_{L^4(Q_T)}^2\|X_{1,n}\|_{L^4(Q_T)},\\ \|Y_n X_{2,n}\|_{L^{4/3}(Q_T)} &\le \|Y_n\|_{L^4(Q_T)}\|X_{2,n}\|_{L^2(Q_T)}. \end{aligned}$$

The already established energy bounds and the definition of M_T now prove the $L^{4/3}_t H^{-1}_x$ estimate for $\partial_t Y_n$.

The compactness assertions are consequences of standard weak compactness, but we spell out the endpoint identification because it is the point needed in Proposition 144.16. The spaces $L^2([0,T];H^1)$ and $L^4(Q_T)$ are reflexive, while $L^\infty([0,T];L^2)$ is the dual of $L^1([0,T];L^2)$ because $L^2(\mathbb{T}^2)$ is separable. Banach–Alaoglu and a diagonal subsequence therefore give the displayed weak and weak-* convergences. The derivative bound passes to the same limit in $\mathcal{D}'((0,T);H^{-1})$, so the limit has an H^{-1}-valued absolutely continuous representative.

Let $D \subset H^1(\mathbb{T}^2)$ be countable and dense in L^2. For each $v \in D$, the scalar functions

$$a_{n,v}(t) := \langle Y_n(t), v\rangle_{L^2}$$

are bounded in $W^{1,4/3}([0,T])$: the $L^\infty_t L^2_x$ bound controls $a_{n,v}$, and the $L^{4/3}_t H^{-1}_x$ bound controls its derivative. The compact embedding $W^{1,4/3}([0,T]) \hookrightarrow C([0,T])$, together with the distributional convergence already obtained, implies

$$\langle Y_n(T), v\rangle_{L^2} \longrightarrow \langle Y(T), v\rangle \qquad (v \in D)$$

after a diagonal extraction. The sequence $Y_n(T)$ is bounded in L^2, so a further subsequence has a weak L^2 limit; the preceding identity on the dense set D identifies that limit with $Y(T)$. Hence $Y_n(T) \rightharpoonup Y(T)$ weakly in $L^2(\mathbb{T}^2)$. $\square$

Lemma 144.18 (Fourier Aubin–Lions compactness on the torus)**.** *Let (u_n) be a sequence such that*

$$\sup_n \Big[\|u_n\|_{L^2([0,T];H^1(\mathbb{T}^2))} + \|\partial_t u_n\|_{L^{4/3}([0,T];H^{-1}(\mathbb{T}^2))} \Big] < \infty.$$

Then a subsequence converges strongly in $L^2([0,T];L^2(\mathbb{T}^2))$.

Proof. Let P_M denote the Fourier projection onto modes $|k| \le M$. The high-frequency tail is uniformly small:

$$\|(1-P_M)u_n\|_{L^2_t L^2_x} \le (1+M^2)^{-1/2} \|u_n\|_{L^2_t H^1_x}.$$

It remains to prove compactness of $P_M u_n$ for fixed M. The range $E_M = P_M L^2(\mathbb{T}^2)$ is finite dimensional. On E_M all Hilbert norms are equivalent, and the hypotheses imply

$$\sup_n \Big[\|P_M u_n\|_{L^2([0,T];E_M)} + \|\partial_t P_M u_n\|_{L^{4/3}([0,T];E_M)} \Big] < \infty.$$

Since $[0,T]$ has finite measure, the first term also bounds $\|P_M u_n\|_{L^{4/3}([0,T];E_M)}$. Thus $P_M u_n$ is bounded in $W^{1,4/3}([0,T];E_M)$. For $s,t \in [0,T]$,

$$\|P_M u_n(t) - P_M u_n(s)\|_{E_M} \le |t-s|^{1/4} \, \|\partial_t P_M u_n\|_{L^{4/3}([0,T];E_M)},$$

so the family is equicontinuous. The $L^{4/3}$-bound also gives a uniform pointwise bound: for each n, choose t_n with

$$\|P_M u_n(t_n)\|_{E_M} \le T^{-3/4} \|P_M u_n\|_{L^{4/3}([0,T];E_M)},$$

and use the preceding Hölder estimate to bound $P_M u_n(t)$ for every t. Arzela–Ascoli in the finite-dimensional space E_M now gives a subsequence converging in $C([0,T];E_M)$, hence strongly in $L^2([0,T];E_M)$. Taking $M = 1,2,\dots$ and using a diagonal subsequence, the finite-mode parts converge for every M. The uniform tail estimate then shows that the same subsequence is Cauchy in $L^2([0,T];L^2(\mathbb{T}^2))$, proving the lemma. $\square$

Proposition 144.19 (Identification of the DPD distributional limit)**.** *Let the hypotheses of Proposition 144.17 hold, and in addition assume that, for some functions X_1, X_2, X_3,*

$$\begin{aligned} X_{1,n} &\to X_1 \quad \textit{strongly in } L^4(Q_T), \\ X_{2,n} &\to X_2 \quad \textit{strongly in } L^2(Q_T), \\ X_{3,n} &\to X_3 \quad \textit{strongly in } L^{4/3}(Q_T), \end{aligned}$$

and that $Y_n(0) \to Y_0$ strongly in $L^2(\mathbb{T}^2)$. Let Y be the subsequential limit supplied by Proposition 144.17. After passing to a subsequence, $Y_n \to Y$ strongly in $L^r(Q_T)$ for every $1 \le r < 4$. Moreover Y satisfies

$$\partial_t Y = \Delta Y - m^2 Y - \lambda\big(Y^3 + 3Y^2 X_1 + 3Y X_2 + X_3\big) \tag{144.57}$$

as an identity in $\mathcal{D}'((0,T)\times\mathbb{T}^2)$. Equivalently, for every $\varphi\in C^\infty([0,T]\times\mathbb{T}^2)$,

$$\begin{aligned}\langle Y(T),\varphi(T)\rangle - \langle Y_0,\varphi(0)\rangle - \int_0^T \langle Y(t),\partial_t\varphi(t)\rangle\,\mathrm{d}t \\ = \int_0^T \langle Y(t),\Delta\varphi(t) - m^2\varphi(t)\rangle\,\mathrm{d}t \\ - \lambda\int_{Q_T}\big(Y^3 + 3Y^2X_1 + 3YX_2 + X_3\big)\varphi\,\mathrm{d}t\,\mathrm{d}x. \end{aligned}\tag{144.58}$$

Proof. The compactness lemma applied to $u_n = Y_n$ gives, after passing to a subsequence,

$$Y_n \to Y \qquad \text{strongly in } L^2(Q_T).$$

The same sequence is bounded in $L^4(Q_T)$. Interpolation between L^2 convergence and the uniform L^4 bound gives strong convergence in $L^r(Q_T)$ for every $2\le r<4$, and finite measure gives strong convergence for $1\le r<2$ as well.

We next pass the nonlinearities. The cubic term satisfies

$$\|Y_n^3 - Y^3\|_{L^1} \le C\|Y_n - Y\|_{L^2}\big(\|Y_n\|_{L^4}^2 + \|Y\|_{L^4}^2\big) \longrightarrow 0.$$

For the Y^2X_1 term, choose the strong convergence $Y_n\to Y$ in $L^{8/3}(Q_T)$. Then

$$\|Y_n^2 - Y^2\|_{L^{4/3}} \le C\|Y_n - Y\|_{L^{8/3}}\big(\|Y_n\|_{L^{8/3}} + \|Y\|_{L^{8/3}}\big) \longrightarrow 0.$$

Hence, using Hölder's inequality and the strong L^4 convergence of $X_{1,n}$,

$$\begin{aligned}\|Y_n^2X_{1,n} - Y^2X_1\|_{L^1} &\le \|Y_n^2 - Y^2\|_{L^{4/3}}\|X_{1,n}\|_{L^4} \\ &\quad + \|Y^2\|_{L^{4/3}}\|X_{1,n} - X_1\|_{L^4} \longrightarrow 0.\end{aligned}$$

The mixed term with X_2 is simpler:

$$\|Y_nX_{2,n} - YX_2\|_{L^1} \le \|Y_n - Y\|_{L^2}\|X_{2,n}\|_{L^2} + \|Y\|_{L^2}\|X_{2,n} - X_2\|_{L^2} \longrightarrow 0.$$

Finally $X_{3,n}\to X_3$ in $L^{4/3}(Q_T)$, hence in $L^1(Q_T)$ because Q_T has finite measure.

For every smooth test function φ, the smooth equation for Y_n gives

$$\begin{aligned}\langle Y_n(T),\varphi(T)\rangle - \langle Y_n(0),\varphi(0)\rangle - \int_0^T\langle Y_n,\partial_t\varphi\rangle\,\mathrm{d}t \\ = \int_0^T\langle Y_n,\Delta\varphi - m^2\varphi\rangle\,\mathrm{d}t - \lambda\int_{Q_T}\big(Y_n^3 + 3Y_n^2X_{1,n} + 3Y_nX_{2,n} + X_{3,n}\big)\varphi\,\mathrm{d}t\,\mathrm{d}x.\end{aligned}$$

The initial term converges by the strong L^2 convergence of $Y_n(0)$. The terminal term converges by the weak L^2 convergence $Y_n(T)\rightharpoonup Y(T)$ from Proposition 144.17. The linear spacetime terms converge by the strong $L^2(Q_T)$ convergence of Y_n, and the nonlinear terms converge by the L^1 convergence just proved. Passing to the limit gives (144.58), which is precisely (144.57) in distributional form. □

Proposition 144.20 (Compatibility of the Besov local solution with smooth energy approximation)**.** *Let $m^2 > 0$, $\lambda > 0$, and*

$$0 < \kappa < \alpha < 2 - \kappa.$$

Let $T_0 > 0$, let

$$Y_{0,n} \in C^\infty(\mathbb{T}^2), \qquad Y_0 \in \mathcal{C}^\alpha(\mathbb{T}^2),$$

with $Y_{0,n} \to Y_0$ in $\mathcal{C}^\alpha$, and let

$$\mathbb{X}_n = (X_{1,n}, X_{2,n}, X_{3,n}) \in C^\infty([0, T_0] \times \mathbb{T}^2)^3$$

converge to $\mathbb{X} = (X_1, X_2, X_3)$ in

$$C([0, T_0]; \mathcal{C}^{-\kappa}(\mathbb{T}^2))^3.$$

Let Y_n be the smooth solution of

$$\partial_t Y_n = (\Delta - m^2)Y_n - \lambda\big(Y_n^3 + 3Y_n^2 X_{1,n} + 3Y_n X_{2,n} + X_{3,n}\big), \qquad Y_n(0) = Y_{0,n}.$$

Let Y be the Besov–Holder mild solution obtained from Theorem 144.13 for the data $(Y_0, \mathbb{X})$. Then there is a time $T \in (0, T_0]$, depending only on a bounded neighborhood of the convergent data, such that

$$Y_n \longrightarrow Y \qquad \text{in } C([0, T]; \mathcal{C}^\alpha). \tag{144.59}$$

Assume in addition that, on $Q_T = [0, T] \times \mathbb{T}^2$,

$$\begin{aligned} X_{1,n} &\to X_1 \quad \text{in } L^4(Q_T), \\ X_{2,n} &\to X_2 \quad \text{in } L^2(Q_T), \\ X_{3,n} &\to X_3 \quad \text{in } L^{4/3}(Q_T), \end{aligned}$$

and that

$$\sup_n \Big[\|Y_{0,n}\|_{L^2} + \|X_{1,n}\|_{L^4(Q_T)} + \|X_{2,n}\|_{L^2(Q_T)} + \|X_{3,n}\|_{L^{4/3}(Q_T)}\Big] < \infty.$$

Then Y is the energy-compactness limit of the same smooth approximations. More precisely, $Y \in L^2([0, T]; H^1) \cap L^4(Q_T)$ and for every $0 \le \tau \le T$,

$$\begin{aligned} &\frac{1}{2}\|Y(\tau)\|_{L^2}^2 + \int_0^\tau \left[\|\nabla Y(t)\|_{L^2}^2 + m^2\|Y(t)\|_{L^2}^2 + \frac{\lambda}{4}\|Y(t)\|_{L^4}^4\right] \mathrm{d}t \\ &\qquad \le \frac{1}{2}\|Y_0\|_{L^2}^2 + C\lambda \int_0^\tau \left[\|X_1(t)\|_{L^4}^4 + \|X_2(t)\|_{L^2}^2 + \|X_3(t)\|_{L^{4/3}}^{4/3}\right] \mathrm{d}t. \end{aligned} \tag{144.60}$$

Proof. Choose R so that, for all sufficiently large n,

$$\|Y_{0,n}\|_{\mathcal{C}^\alpha} + \|Y_0\|_{\mathcal{C}^\alpha} + \|\mathbb{X}_n\|_{C([0,T_0];\mathcal{C}^{-\kappa})} + \|\mathbb{X}\|_{C([0,T_0];\mathcal{C}^{-\kappa})} \le R.$$

The local Lipschitz part of Theorem 144.13 gives a common time $T \in (0, T_0]$ and a Lipschitz constant L_R on this ball. The smooth solution Y_n satisfies the Duhamel formula with ordinary products. Since Bony's product agrees with ordinary multiplication on smooth inputs, this is the same fixed-point equation as (144.47) for the data $(Y_{0,n}, \mathbb{X}_n)$. The uniqueness statement in Theorem 144.13 therefore identifies the smooth solution with the Besov fixed point on $[0, T]$. The Lipschitz estimate gives

$$\|Y_n - Y\|_{C([0,T];\mathcal{C}^\alpha)} \le L_R \left(\|Y_{0,n} - Y_0\|_{\mathcal{C}^\alpha} + \max_i \|X_{i,n} - X_i\|_{C([0,T];\mathcal{C}^{-\kappa})}\right),$$

which proves (144.59).

For the energy statement, fix $\tau \in [0,T]$. The additional hypotheses on $[0,\tau]$ are exactly the hypotheses of Proposition 144.17, so every subsequence of (Y_n) has a further subsequence converging weakly in

$$L^2([0,\tau];H^1), \qquad L^4([0,\tau]\times\mathbb{T}^2), \qquad \text{and at time } \tau \text{ in } L^2.$$

But the already proved convergence in $C([0,T];\mathcal{C}^\alpha)$ implies convergence in $C([0,T];L^2)$, because $\mathbb{T}^2$ has finite volume and $\mathcal{C}^\alpha \hookrightarrow L^\infty \hookrightarrow L^2$. Thus every such weak limit is the same function Y. In particular

$$Y \in L^2([0,\tau];H^1) \cap L^4([0,\tau]\times\mathbb{T}^2).$$

Applying Proposition 144.16 on $[0,\tau]$ gives (144.60). Since τ was arbitrary, the inequality holds for every $\tau \le T$. □

The logical role of this proposition is to identify the two approximation mechanisms on their common domain of validity. The Besov topology defines the canonical rough products and gives a unique local mild solution; the Lebesgue hypotheses are exactly those needed by the elementary energy inequality. For the Wick-enhanced stochastic convolution in two dimensions, the corresponding global theorem requires a rough energy-continuity estimate in which the Lebesgue pairings above are replaced by the appropriate paracontrolled or Besov energy pairings.

The rough Da Prato–Debussche global argument is therefore reduced to two precise analytic tasks. First, construct smooth approximations whose enhanced noises converge in the integrability spaces appearing in Proposition 144.16, or in Besov/paracontrolled spaces that imply those bounds after pairing with the energy solution. Proposition 144.19 then identifies the compactness limit as a distributional solution whenever the products are represented in these strong L^p spaces. In the full rough stochastic application, where the enhanced noise is controlled in Besov or paracontrolled coordinates rather than in ordinary Lebesgue spaces, the same role is played, at the elementary Besov level, by Proposition 144.11. The quartic term supplies the coercive bound, compactness extracts a weak energy limit, product continuity identifies the equation in the topology where the enhanced noise is built, and the closedness proposition passes the energy inequality to that rough limit.

144.5.3 Global Continuity, Invariant Laws, and Tightness

Lemma 144.21 (Global compact-continuity criterion for DPD solution maps)**.** *Fix $T > 0$, $0 < \kappa < 1$, and an exponent $\alpha \in (0, 2-\kappa)$ for which the local Besov fixed-point theorem applies. Let*

$$\mathfrak{D}_T := (\mathcal{C}^\alpha(\mathbb{T}^2) \cap L^2(\mathbb{T}^2)) \times C([0,T];\mathcal{C}^{-\kappa}(\mathbb{T}^2))^3$$

with its product topology, and write a datum as

$$D = (Y_0, \mathbb{X}_1, \mathbb{X}_2, \mathbb{X}_3).$$

For each D let Y_D be the maximal local DPD solution produced by Theorem 144.13, and denote its maximal existence time in $[0,T]$ by $\tau(D)$.

Let $K \subset \mathfrak{D}_T$ be compact. Assume the following two statements hold for every $D \in K$.

1. Blow-up alternative. *If $\tau(D) < T$, then*

$$\limsup_{t\uparrow\tau(D)} \|Y_D\|_{C([0,t];\mathcal{C}^\alpha)} = \infty.$$

2. Rough energy-to-Besov bound. *There is a finite constant $B_{K,T}$, depending on K and T but not on D, such that*

$$\sup_{0<s<\tau(D)} \|Y_D\|_{C([0,s];\mathcal{C}^\alpha)} \le B_{K,T}.$$

Then every $D \in K$ has a solution on the full interval $[0,T]$, and the solution map

$$\mathcal{S}_T : K \longrightarrow C([0,T];\mathcal{C}^\alpha), \qquad D \longmapsto Y_D,$$

is uniformly continuous. Consequently, if $D_N \to D$ in $\mathfrak{D}_T$, and if $\{D\} \cup \{D_N : N \ge N_0\}$ is contained in a compact set on which the two hypotheses above hold with a common constant, then

$$Y_{D_N} \longrightarrow Y_D \quad \textit{in } C([0,T];\mathcal{C}^\alpha).$$

Proof. The full-time existence statement is the contradiction between the two assumptions. If $\tau(D) < T$, the rough energy-to-Besov estimate gives a finite bound for $\|Y_D\|_{C([0,s];\mathcal{C}^\alpha)}$ as $s \uparrow \tau(D)$, whereas the blow-up alternative requires this quantity to be unbounded. Hence $\tau(D) = T$.

It remains to prove continuity with constants that are uniform on K. Compactness of K gives a finite noise bound

$$M_{K,T} := \sup_{D\in K} \sum_{j=1}^{3} \|\mathbb{X}_j\|_{C([0,T];\mathcal{C}^{-\kappa})} < \infty.$$

Inspecting the contraction estimate in Theorem 144.13, one obtains a time $\delta > 0$ and a constant $L < \infty$, depending only on $B_{K,T}$, $M_{K,T}$, T, and the fixed exponents, with the following property. If two solutions are known on a time interval beginning at t_0 and both remainders have $\mathcal{C}^\alpha$-norm at most $B_{K,T}$, then on $[t_0, t_0+\delta] \cap [0,T]$

$$\|Y_D - Y_{\widetilde{D}}\|_{C([t_0,t_0+\delta]\cap[0,T];\mathcal{C}^\alpha)} \le L\Big(\|Y_D(t_0) - Y_{\widetilde{D}}(t_0)\|_{\mathcal{C}^\alpha} + d_{\mathfrak{D}_T}(D,\widetilde{D})\Big),$$

where $d_{\mathfrak{D}_T}$ is any metric inducing the product topology on bounded subsets of $\mathfrak{D}_T$. The same δ works at every t_0 because the heat-kernel estimates depend only on the length of the interval, while the nonlinear estimates depend only on the preceding uniform bounds.

Choose an integer m with $m\delta \ge T$. Iterating the last estimate over the grid $0, \delta, 2\delta, \dots, m\delta$ gives, for D and $\widetilde{D}$ sufficiently close in K,

$$\|Y_D - Y_{\widetilde{D}}\|_{C([0,T];\mathcal{C}^\alpha)} \le C_{K,T}\, d_{\mathfrak{D}_T}(D,\widetilde{D})$$

with finite $C_{K,T}$. Thus $\mathcal{S}_T$ is continuous at each point of K, and compactness of K upgrades pointwise continuity to uniform continuity. The convergence statement is the preceding uniform-continuity claim applied to the compact set containing the tail of the sequence and its limit. □

This criterion separates a soft continuation argument from the genuinely hard stochastic estimate. Once the local Besov theory is known, global cutoff convergence on compact enhanced-noise sets is reduced to proving a rough energy-to-Besov a priori bound. The latter is precisely where the Wick-renormalized coercivity of the two-dimensional equation must enter.

Proposition 144.22 (Local rough-forcing bootstrap for the energy-to-Besov step)**.** *Keep the notation and exponents of Theorem 144.13, and put*

$$\theta = \frac{\alpha + \kappa}{2} \in (0,1), \qquad A = \Delta - m^2.$$

Let C_0 and C_1 be constants such that, for all $0 \le t \le 1$ and all intervals I of length at most 1,

$$\|e^{tA} f\|_{\mathcal{C}^\alpha} \le C_0 \|f\|_{\mathcal{C}^\alpha}, \qquad \left\| \int_{t_0}^t e^{(t-s)A} F(s)\, \mathrm{d}s \right\|_{C(I;\mathcal{C}^\alpha)} \le C_1 |I|^{1-\theta} \|F\|_{C(I;\mathcal{C}^{-\kappa})}. \tag{144.61}$$

Let $Y \in C([0,T];\mathcal{C}^\alpha)$ solve the Besov mild equation (144.47) on $[0,T]$. Choose a partition

$$0 = t_0 < t_1 < \cdots < t_M = T, \qquad I_\ell = [t_\ell, t_{\ell+1}], \qquad |I_\ell| \le \delta \le 1.$$

Assume that on every I_ℓ the renormalized DPD nonlinearity satisfies a local rough-forcing estimate

$$\|\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X})\|_{C(I_\ell;\mathcal{C}^{-\kappa})} \le A_\ell + \varepsilon \|Y\|_{C(I_\ell;\mathcal{C}^\alpha)} \tag{144.62}$$

with $A_\ell \ge 0$ and

$$|\lambda| C_1 \delta^{1-\theta} \varepsilon \le \frac{1}{2}. \tag{144.63}$$

Then, writing

$$D_0 = 2C_0 \|Y(0)\|_{\mathcal{C}^\alpha} + 2|\lambda| C_1 \delta^{1-\theta} A_0,$$

and recursively

$$D_\ell = 2C_0 D_{\ell-1} + 2|\lambda| C_1 \delta^{1-\theta} A_\ell, \qquad 1 \le \ell \le M-1,$$

one has

$$\|Y\|_{C(I_\ell;\mathcal{C}^\alpha)} \le D_\ell, \qquad 0 \le \ell \le M-1. \tag{144.64}$$

Equivalently,

$$\|Y\|_{C([0,T];\mathcal{C}^\alpha)} \le (2C_0)^M \|Y(0)\|_{\mathcal{C}^\alpha} + 2|\lambda| C_1 \delta^{1-\theta} \sum_{j=0}^{M-1} (2C_0)^{M-1-j} A_j. \tag{144.65}$$

In particular, if the numbers A_ℓ are bounded uniformly on a compact set of enhanced noises and initial conditions, and if the same δ, ε satisfy (144.63) throughout that compact set, then the rough energy-to-Besov hypothesis in Lemma 144.21 follows.

Proof. For $t \in I_\ell$, the mild equation restarted at time t_ℓ is

$$Y(t) = e^{(t-t_\ell)A} Y(t_\ell) - \lambda \int_{t_\ell}^t e^{(t-s)A} \mathcal{N}_{\mathcal{C}}(Y(s), \mathbb{X}(s))\, \mathrm{d}s. \tag{144.66}$$

Taking the $C(I_\ell;\mathcal{C}^\alpha)$ norm and using (144.61) gives

$$R_\ell \le C_0 \|Y(t_\ell)\|_{\mathcal{C}^\alpha} + |\lambda| C_1 \delta^{1-\theta} \|\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X})\|_{C(I_\ell;\mathcal{C}^{-\kappa})}, \qquad R_\ell := \|Y\|_{C(I_\ell;\mathcal{C}^\alpha)}.$$

Insert the rough-forcing estimate (144.62). The absorption condition (144.63) implies

$$R_\ell \le 2C_0 \|Y(t_\ell)\|_{\mathcal{C}^\alpha} + 2|\lambda| C_1 \delta^{1-\theta} A_\ell. \tag{144.67}$$

For $\ell = 0$ this is exactly $R_0 \le D_0$. If $\ell \ge 1$, then $\|Y(t_\ell)\|_{\mathcal{C}^\alpha} \le R_{\ell-1}$. Induction using (144.67) proves (144.64). Iterating the recursion for D_ℓ gives the explicit bound (144.65). The compact-set consequence follows by taking the supremum of the right hand side over the compact family. $\square$

Proposition 144.23 (Energy low-mode forcing estimate)**.** *Let $0 < \kappa < \alpha$ and put*

$$\theta = \frac{\alpha + \kappa}{2} < \frac{1}{4}.$$

Let $P_{\le R}$ be a smooth Fourier multiplier on $\mathbb{T}^2$ whose range is contained in the span of the modes $|k| \le R$, with $R \ge 1$. For an interval $I = [a, b]$ of length at most one and smooth fields Y, X_1, X_2, X_3 on $I \times \mathbb{T}^2$, define

$$\mathcal{N}(Y, \mathbb{X}) = Y^3 + 3Y^2 X_1 + 3Y X_2 + X_3$$

and

$$\begin{aligned} L_I(Y, \mathbb{X}) := \|Y\|^3_{L^4(I\times\mathbb{T}^2)} &+ 3\|Y\|^2_{L^4(I\times\mathbb{T}^2)}\|X_1\|_{L^4(I\times\mathbb{T}^2)} \\ &+ 3\|Y\|_{L^4(I\times\mathbb{T}^2)}\|X_2\|_{L^2(I\times\mathbb{T}^2)} + \|X_3\|_{L^{4/3}(I\times\mathbb{T}^2)}. \end{aligned}$$

Then there are constants $C_{\kappa,R}$ and $C_{\alpha,\kappa,R,m}$ such that

$$\|P_{\le R}\mathcal{N}(Y, \mathbb{X})\|_{L^{4/3}(I;\mathcal{C}^{-\kappa})} \le C_{\kappa,R} L_I(Y, \mathbb{X}) \tag{144.68}$$

and, with $A = \Delta - m^2$,

$$\left\| \int_a^t e^{(t-s)A} P_{\le R}\mathcal{N}(Y(s), \mathbb{X}(s))\, \mathrm{d}s \right\|_{C(I;\mathcal{C}^\alpha)} \le C_{\alpha,\kappa,R,m}|I|^{1/4-\theta} L_I(Y, \mathbb{X}). \tag{144.69}$$

Proof. The only finite-dimensional input is the low-mode embedding

$$\|P_{\le R} f\|_{\mathcal{C}^{-\kappa}} \le C_{\kappa,R}\|f\|_{L^{4/3}(\mathbb{T}^2)}. \tag{144.70}$$

Indeed, only dyadic blocks with $2^j \lesssim R$ can contribute. Bernstein's inequality on $\mathbb{T}^2$, with $p = 4/3$, gives

$$2^{-j\kappa}\|\Delta_j P_{\le R} f\|_{L^\infty} \le C 2^{j(3/2-\kappa)}\|f\|_{L^{4/3}},$$

and the supremum over the finitely many contributing j's is absorbed into $C_{\kappa,R}$.

Holder's inequality in spacetime gives the exact energy exponents

$$\begin{aligned} \|Y^3\|_{L^{4/3}(I\times\mathbb{T}^2)} &= \|Y\|^3_{L^4(I\times\mathbb{T}^2)}, \\ \|Y^2 X_1\|_{L^{4/3}(I\times\mathbb{T}^2)} &\le \|Y\|^2_{L^4(I\times\mathbb{T}^2)}\|X_1\|_{L^4(I\times\mathbb{T}^2)}, \\ \|Y X_2\|_{L^{4/3}(I\times\mathbb{T}^2)} &\le \|Y\|_{L^4(I\times\mathbb{T}^2)}\|X_2\|_{L^2(I\times\mathbb{T}^2)}. \end{aligned}$$

Together with (144.70), these estimates prove (144.68). Proposition 144.12, with $\rho = -\kappa$ and $\rho + 2\theta = \alpha$, gives

$$\|e^{(t-s)A}F(s)\|_{\mathcal{C}^\alpha} \le C_{\alpha,\kappa,m}(t-s)^{-\theta}\|F(s)\|_{\mathcal{C}^{-\kappa}}.$$

Applying this to $F = P_{\le R}\mathcal{N}(Y, \mathbb{X})$ and using Holder's inequality in time with conjugate exponents 4 and 4/3 gives

$$\int_a^t (t-s)^{-\theta}\|F(s)\|_{\mathcal{C}^{-\kappa}}\, \mathrm{d}s \le \left(\int_0^{|I|} r^{-4\theta}\, \mathrm{d}r\right)^{1/4} \|F\|_{L^{4/3}(I;\mathcal{C}^{-\kappa})}.$$

The time integral is finite exactly because $4\theta < 1$, and it contributes a constant times $|I|^{1/4-\theta}$. Inserting (144.68) proves (144.69). $\square$

Corollary 144.24 (Low–high form of the rough-forcing input)**.** *Keep the notation of Proposition 144.22 and assume also $\theta < 1/4$. Let $P_{\le R}$ be as in Proposition 144.23. Assume that the low-frequency Duhamel term is represented by an energy-compatible smooth approximation, so that (144.69) holds on the intervals below with the displayed $L^4, L^2, L^{4/3}$ norms. On every interval $I_\ell = [t_\ell, t_{\ell+1}]$, suppose the high-mode remainder satisfies*

$$\|(1 - P_{\le R})\mathcal{N}_{\mathcal{C}}(Y, \mathbb{X})\|_{C(I_\ell;\mathcal{C}^{-\kappa})} \le B_{\ell,R} + \varepsilon \|Y\|_{C(I_\ell;\mathcal{C}^\alpha)} \tag{144.71}$$

and that the absorption condition (144.63) holds. Then, writing

$$S_\ell = \|Y\|_{C(I_\ell;\mathcal{C}^\alpha)}$$

and using the quantity $L_{I_\ell}(Y, \mathbb{X})$ from Proposition 144.23, one has

$$\begin{aligned} S_\ell \le\ & 2C_0 \|Y(t_\ell)\|_{\mathcal{C}^\alpha} + 2|\lambda| C_{\alpha,\kappa,R,m} |I_\ell|^{1/4-\theta} L_{I_\ell}(Y, \mathbb{X}) \\ & + 2|\lambda| C_1 |I_\ell|^{1-\theta} B_{\ell,R}. \end{aligned} \tag{144.72}$$

Consequently, a uniform energy bound on the displayed $L^4, L^2, L^{4/3}$ norms and a high-mode residual of the form (144.71) give the same global compact-continuity input as the local estimate (144.62).

Proof. Restart the mild equation at t_ℓ, split the nonlinearity into $P_{\le R}\mathcal{N}_{\mathcal{C}}$ and $(1 - P_{\le R})\mathcal{N}_{\mathcal{C}}$, and estimate the low-frequency Duhamel term by Proposition 144.23, using the stated energy-compatible approximation. The high-frequency term is estimated by (144.61) and (144.71). Thus

$$\begin{aligned} S_\ell \le\ & C_0 \|Y(t_\ell)\|_{\mathcal{C}^\alpha} + |\lambda| C_{\alpha,\kappa,R,m} |I_\ell|^{1/4-\theta} L_{I_\ell}(Y, \mathbb{X}) \\ & + |\lambda| C_1 |I_\ell|^{1-\theta} \big(B_{\ell,R} + \varepsilon S_\ell\big). \end{aligned}$$

The absorption condition moves the last term to the left and gives (144.72). Iterating this single-step estimate over the partition is identical to the recursion in Proposition 144.22, with the low-mode energy contribution and $B_{\ell,R}$ replacing the single abstract A_ℓ. □

Proposition 144.25 (High-frequency tail criterion for global DPD continuity)**.** *Keep the notation of Lemma 144.21 and Corollary 144.24, and assume $\theta = (\alpha+\kappa)/2 < 1/4$. Let $K \subset \mathfrak{D}_T$ be compact, and suppose the Besov local blow-up alternative holds on K. Assume that there is a finite energy constant $E_{K,T}$ with the following property: for every $D \in K$, for the smooth energy-compatible approximants used to construct the DPD solution, and for every interval $I \subset [0, T]$ of length at most one, the low-frequency forcing quantity of Proposition 144.23* obeys

$$L_I(Y_D, \mathbb{X}_D) \le E_{K,T}. \tag{144.73}$$

Assume further that the high-frequency paracontrolled residual has a compact tail: there are nonnegative functions $b_K(R)$ and $\varepsilon_K(R)$, with

$$b_K(R) \longrightarrow 0, \qquad \varepsilon_K(R) \longrightarrow 0 \qquad (R \to \infty),$$

such that, for every $D \in K$, every partition interval $I_\ell \subset [0, T]$, and every $R \ge 1$,

$$\|(1 - P_{\le R})\mathcal{N}_{\mathcal{C}}(Y_D, \mathbb{X}_D)\|_{C(I_\ell;\mathcal{C}^{-\kappa})} \le b_K(R) + \varepsilon_K(R) \|Y_D\|_{C(I_\ell;\mathcal{C}^\alpha)}. \tag{144.74}$$

Then the rough energy-to-Besov hypothesis in Lemma 144.21 holds on K. Consequently every $D \in K$ has a DPD solution on $[0, T]$, and the solution map is uniformly continuous on K.

Proof. Choose R so large that

$$|\lambda|C_1\varepsilon_K(R) \le 1.$$

Then choose a partition mesh $0 < \delta \le 1$ with

$$|\lambda|C_1\delta^{1-\theta}\varepsilon_K(R) \le \frac{1}{2}. \tag{144.75}$$

For a partition with $|I_\ell| \le \delta$, Corollary 144.24, (144.73), and (144.74) give the single-step bound

$$\begin{aligned}\|Y_D\|_{C(I_\ell;\mathcal{C}^\alpha)} \le{}& 2C_0\|Y_D(t_\ell)\|_{\mathcal{C}^\alpha}\\ &+ 2|\lambda|C_{\alpha,\kappa,R,m}\delta^{1/4-\theta}E_{K,T} + 2|\lambda|C_1\delta^{1-\theta}b_K(R).\end{aligned}$$

This is exactly Proposition 144.22 with

$$A_\ell = \frac{C_{\alpha,\kappa,R,m}}{C_1}\delta^{-3/4}E_{K,T} + b_K(R),$$

or, more directly, with the displayed low-mode and high-mode contributions kept separate. Iterating over

$$M = \lceil T/\delta \rceil$$

intervals gives

$$\begin{aligned}\|Y_D\|_{C([0,T];\mathcal{C}^\alpha)} \le{}& (2C_0)^M \sup_{\widetilde{D}\in K}\|Y_{\widetilde{D}}(0)\|_{\mathcal{C}^\alpha}\\ &+ \sum_{j=0}^{M-1}(2C_0)^{M-1-j}\Big[2|\lambda|C_{\alpha,\kappa,R,m}\delta^{1/4-\theta}E_{K,T} + 2|\lambda|C_1\delta^{1-\theta}b_K(R)\Big].\end{aligned}$$

The right hand side is finite and independent of $D \in K$. This proves the rough energy-to-Besov bound on K. The global existence and uniform continuity conclusions now follow from Lemma 144.21. □

The preceding propositions sharpen the remaining analytic obligation. The energy estimate and finite-mode smoothing already control the low-frequency part of the DPD forcing from the same $L^4, L^2, L^{4/3}$ quantities used in Proposition 144.17. What is still missing is not another finite exponent identity, but a genuinely rough high-frequency estimate of the compact-tail form (144.74). This is the paracontrolled commutator/noise-tail step in the rough energy-to-Besov bound. Once that estimate is proved on compact enhanced-noise sets, Proposition 144.25 converts it into global Besov compact-continuity.

Lemma 144.26 (Passing invariance through a cutoff limit)**.** *Let E be a Polish space, let $P_t^{(n)}$ and P_t be Markov semigroups on bounded continuous functions on E, and let μ_n be an invariant probability measure for $P_t^{(n)}$. Suppose $\mu_n \Rightarrow \mu$ weakly and that, for every bounded continuous function f and every fixed $t \ge 0$,*

$$P_t^{(n)}f \longrightarrow P_t f \quad \text{uniformly on compact subsets of } E.$$

Assume also that $\{\mu_n\}$ is tight and that the convergence above is uniform on a compact set whose μ_n-mass is arbitrarily close to one, uniformly in n. Then μ is invariant for P_t:

$$\int_E P_t f\,\mathrm{d}\mu = \int_E f\,\mathrm{d}\mu.$$

Proof. Fix $f \in C_b(E)$, $t \geq 0$, and $\eta > 0$. Choose a compact set $K \subset E$ such that $\mu_n(K) \geq 1 - \eta$ for all sufficiently large n and such that the convergence $P_t^{(n)} f \to P_t f$ is uniform on this same K. The latter requirement is not implied by tightness alone; it is the high-probability compact-set convergence hypothesis in the statement. Since Markov semigroups are contractions on bounded functions,

$$\|P_t^{(n)} f\|_\infty \leq \|f\|_\infty, \qquad \|P_t f\|_\infty \leq \|f\|_\infty.$$

Therefore

$$\left| \int P_t^{(n)} f \, \mathrm{d}\mu_n - \int P_t f \, \mathrm{d}\mu_n \right| \leq \sup_{x \in K} |P_t^{(n)} f(x) - P_t f(x)| + 2\|f\|_\infty \eta,$$

which tends to at most $2\|f\|_\infty \eta$. Letting $\eta \downarrow 0$ gives

$$\int P_t^{(n)} f \, \mathrm{d}\mu_n - \int P_t f \, \mathrm{d}\mu_n \longrightarrow 0.$$

The limiting semigroup is assumed to map $C_b(E)$ to $C_b(E)$, so weak convergence of μ_n gives

$$\int P_t f \, \mathrm{d}\mu_n \longrightarrow \int P_t f \, \mathrm{d}\mu.$$

The cutoff invariance gives

$$\int P_t^{(n)} f \, \mathrm{d}\mu_n = \int f \, \mathrm{d}\mu_n,$$

and weak convergence also gives

$$\int f \, \mathrm{d}\mu_n \longrightarrow \int f \, \mathrm{d}\mu.$$

Combining the three limits yields

$$\int P_t f \, \mathrm{d}\mu = \int f \, \mathrm{d}\mu.$$

Since f and t were arbitrary, μ is invariant for the limiting Markov semigroup. $\square$

For singular SPDE, the hypotheses of Lemma 144.26 are not automatic. They require tightness of the stationary cutoff laws in the chosen field topology, convergence of the renormalized solution maps on high-probability compact sets of enhanced noises and initial data, and continuity of the limiting Markov semigroup on the same topology. This is the exact invariant-law step that sits between cutoff Langevin stationarity and a Euclidean measure for QFT.

Lemma 144.27 (Sobolev compactness criterion for cutoff-field tightness)**.** *Let $0 < \eta < \kappa$, $p > 0$, and let $\{\nu_N\}$ be Borel probability measures on $H^{-\kappa}(\mathbb{T}^2)$. Suppose that each ν_N is carried by $H^{-\eta}(\mathbb{T}^2)$ and that*

$$\sup_N \int \|\phi\|_{H^{-\eta}}^p \, \mathrm{d}\nu_N(\phi) \leq C < \infty. \tag{144.76}$$

Then $\{\nu_N\}$ is tight as a family of probability measures on $H^{-\kappa}(\mathbb{T}^2)$. More explicitly, for every $R > 0$ the set

$$K_R = \{\phi \in H^{-\eta}(\mathbb{T}^2) : \|\phi\|_{H^{-\eta}} \leq R\}$$

is compact in $H^{-\kappa}(\mathbb{T}^2)$, and

$$\nu_N(K_R^c) \leq CR^{-p}.$$

Proof. Write the Fourier coefficients of ϕ as $\widehat{\phi}(k)$, $k \in \mathbb{Z}^2$, and set $\langle k\rangle = (1+|k|^2)^{1/2}$. The Sobolev norms are

$$\|\phi\|_{H^{-\rho}}^2 = \sum_{k\in\mathbb{Z}^2} \langle k\rangle^{-2\rho}|\widehat{\phi}(k)|^2, \qquad \rho \geq 0. \tag{144.77}$$

Let P_M be the projection to Fourier modes $|k| \leq M$, and write $\langle M\rangle = (1+M^2)^{1/2}$. If $\phi \in K_R$, then

$$\begin{aligned}\|(1-P_M)\phi\|_{H^{-\kappa}}^2 &= \sum_{|k|>M} \langle k\rangle^{-2(\kappa-\eta)}\langle k\rangle^{-2\eta}|\widehat{\phi}(k)|^2 \\ &\leq \langle M\rangle^{-2(\kappa-\eta)}\|\phi\|_{H^{-\eta}}^2 \leq \langle M\rangle^{-2(\kappa-\eta)}R^2.\end{aligned}$$

Thus the high-frequency tail of K_R is uniformly small in $H^{-\kappa}$. The set $P_M K_R$ is bounded in a finite-dimensional space and is therefore totally bounded. Given $\varepsilon > 0$, choose M so that $\langle M\rangle^{-(\kappa-\eta)}R < \varepsilon/3$, cover $P_M K_R$ by finitely many $H^{-\kappa}$-balls of radius $\varepsilon/3$, and add the tail estimate. This proves that K_R is totally bounded in $H^{-\kappa}$.

It remains only to see that K_R is closed in $H^{-\kappa}$. If $\phi_n \in K_R$ and $\phi_n \to \phi$ in $H^{-\kappa}$, then each Fourier coefficient converges. Fatou's lemma gives

$$\|\phi\|_{H^{-\eta}}^2 = \sum_k \langle k\rangle^{-2\eta}|\widehat{\phi}(k)|^2 \leq \liminf_{n\to\infty} \sum_k \langle k\rangle^{-2\eta}|\widehat{\phi}_n(k)|^2 \leq R^2.$$

Therefore $\phi \in K_R$, so K_R is compact in $H^{-\kappa}$. Finally, Markov's inequality applied to (144.76) gives

$$\nu_N(K_R^c) = \nu_N\{\|\phi\|_{H^{-\eta}} > R\} \leq R^{-p}\int \|\phi\|_{H^{-\eta}}^p \,\mathrm{d}\nu_N \leq CR^{-p}.$$

Choosing R large proves tightness. □

Proposition 144.28 (Massive Gaussian cutoff tightness in negative Sobolev topology)**.** *Let $A = -\Delta$ on $\mathbb{T}^2$, and let $\{e_\alpha\}_{\alpha\in\mathcal{I}}$ be a real orthonormal eigenbasis of $L^2(\mathbb{T}^2)$, with $Ae_\alpha = \lambda_\alpha e_\alpha$, $\lambda_\alpha \geq 0$. Fix $m^2 > 0$, and for $N \geq 1$ set*

$$\mathcal{I}_N = \{\alpha \in \mathcal{I} : \lambda_\alpha \leq N^2\}.$$

Let γ_N be the centered Gaussian law of

$$\phi_N = \sum_{\alpha\in\mathcal{I}_N} g_\alpha(\lambda_\alpha + m^2)^{-1/2}e_\alpha,$$

where $\{g_\alpha\}$ are independent real standard Gaussian random variables. Then for every $\eta > 0$,

$$\sup_N \int \|\phi\|_{H^{-\eta}(\mathbb{T}^2)}^2 \,\mathrm{d}\gamma_N(\phi) < \infty.$$

Consequently, if $0 < \eta < \kappa$, the family $\{\gamma_N\}$ is tight as a family of probability measures on $H^{-\kappa}(\mathbb{T}^2)$.

Proof. By definition of the Hilbert Sobolev norm associated with the Laplacian,

$$\|\phi_N\|_{H^{-\eta}}^2 = \sum_{\alpha\in\mathcal{I}_N} (1+\lambda_\alpha)^{-\eta}|(\phi_N, e_\alpha)_{L^2}|^2.$$

Taking expectation and using $\mathbb{E}g_\alpha^2 = 1$ gives

$$\mathbb{E}\|\phi_N\|_{H^{-\eta}}^2 = \sum_{\alpha\in\mathcal{I}_N} (1+\lambda_\alpha)^{-\eta}(\lambda_\alpha + m^2)^{-1}. \tag{144.78}$$

There is a constant $c_m < \infty$ such that $(\lambda + m^2)^{-1} \le c_m(1+\lambda)^{-1}$ for all $\lambda \ge 0$. Thus the right hand side of (144.78) is bounded by

$$c_m \sum_{\alpha\in\mathcal{I}} (1+\lambda_\alpha)^{-1-\eta}.$$

For the flat two-torus $\mathbb{R}^2/(2\pi\mathbb{Z})^2$, the complex Fourier basis has eigenvalues $|k|^2$, $k \in \mathbb{Z}^2$. Passing from the complex basis to a real sine-cosine eigenbasis changes the counting by a bounded factor. It therefore suffices to prove convergence of

$$\sum_{k\in\mathbb{Z}^2} (1+|k|^2)^{-1-\eta}.$$

Write $\langle k\rangle = (1+|k|^2)^{1/2}$. Let $A_0 = \{k : \langle k\rangle < 2\}$ and, for $j \ge 1$,

$$A_j = \{k \in \mathbb{Z}^2 : 2^j \le \langle k\rangle < 2^{j+1}\}.$$

There is a universal constant C such that the cardinality of A_j is at most $C2^{2j}$, while each summand on A_j is at most $2^{-2(1+\eta)j}$. Hence

$$\sum_{k\in A_j} (1+|k|^2)^{-1-\eta} \le C2^{-2\eta j}.$$

The geometric series over j converges because $\eta > 0$. This proves the uniform second-moment bound. Since each γ_N is carried by the finite-dimensional space spanned by $\{e_\alpha : \alpha \in \mathcal{I}_N\}$, it is carried by $H^{-\eta}$. Lemma 144.27 with $p = 2$ now gives tightness in $H^{-\kappa}$. □

Lemma 144.29 (L^q-density criterion for interacting negative-Sobolev moments)**.** *Let $0 < \eta < \kappa$. For each N, let γ_N be a centered Gaussian probability measure carried by a finite-dimensional subspace of $H^{-\eta}(\mathbb{T}^2)$, and assume*

$$\sigma^2 := \sup_N \int \|\phi\|_{H^{-\eta}}^2 \, \mathrm{d}\gamma_N(\phi) < \infty.$$

Let $\mu_N = \rho_N\gamma_N$, where $\rho_N \ge 0$, $\int \rho_N \, \mathrm{d}\gamma_N = 1$, and, for some $q > 1$,

$$A_q := \sup_N \|\rho_N\|_{L^q(\gamma_N)} < \infty.$$

Then, for every $r < \infty$,

$$\sup_N \int \|\phi\|_{H^{-\eta}}^r \, \mathrm{d}\mu_N(\phi) < \infty.$$

Consequently $\{\mu_N\}$ is tight in $H^{-\kappa}(\mathbb{T}^2)$.

Proof. Let $a = q/(q-1)$. Holder's inequality gives

$$\int \|\phi\|_{H^{-\eta}}^r \, \mathrm{d}\mu_N(\phi) = \int \|\phi\|_{H^{-\eta}}^r \rho_N(\phi) \, \mathrm{d}\gamma_N(\phi) \le A_q \left(\int \|\phi\|_{H^{-\eta}}^{ar} \, \mathrm{d}\gamma_N(\phi) \right)^{1/a}. \tag{144.79}$$

It remains to bound the Gaussian moment uniformly. Since γ_N is a finite-dimensional centered Gaussian law on the Hilbert space $H^{-\eta}$, its covariance operator is a nonnegative symmetric operator of finite rank. Diagonalize this covariance in an $H^{-\eta}$-orthonormal basis:

$$\phi_N = \sum_i \lambda_{N,i}^{1/2} g_i e_{N,i}, \qquad \|\phi_N\|_{H^{-\eta}}^2 = \sum_i \lambda_{N,i} g_i^2,$$

where the g_i are independent standard real Gaussians and $\sum_i \lambda_{N,i} \le \sigma^2$. For an integer $m \ge 1$,

$$\begin{aligned} \mathbb{E}_{\gamma_N} \|\phi\|_{H^{-\eta}}^{2m} &= \sum_{i_1,\dots,i_m} \lambda_{N,i_1} \cdots \lambda_{N,i_m} \mathbb{E}(g_{i_1}^2 \cdots g_{i_m}^2) \\ &\le (2m-1)!! \left(\sum_i \lambda_{N,i} \right)^m \le (2m-1)!! \, \sigma^{2m}. \end{aligned}$$

Choose m with $2m \ge ar$. The elementary inequality $x^{ar} \le 1 + x^{2m}$ for $x \ge 0$ gives a uniform bound for the Gaussian moment in (144.79). Thus the $H^{-\eta}$ r-th moments under μ_N are uniformly bounded. Applying Lemma 144.27 with any positive r proves tightness in $H^{-\kappa}$. □

Remark 144.30 (Density route to Φ_2^4 stationary-law tightness). Let $\mu_{0,N}$ be the massive Gaussian cutoff law in Proposition 144.28, and let

$$\mathrm{d}\mu_N(\phi) = Z_N^{-1} \exp\left[-\frac{\lambda}{4} \int_{\mathbb{T}^2} :(P_N\phi)^4: \, \mathrm{d}^2 x \right] \mathrm{d}\mu_{0,N}(\phi)$$

be a finite-dimensional Wick-ordered Φ_2^4 cutoff measure. If there exists $q > 1$ such that the normalized densities

$$\rho_N(\phi) = Z_N^{-1} \exp\left[-\frac{\lambda}{4} \int_{\mathbb{T}^2} :(P_N\phi)^4: \, \mathrm{d}^2 x \right]$$

satisfy

$$\sup_N \|\rho_N\|_{L^q(\mu_{0,N})} < \infty,$$

then $\{\mu_N\}$ is tight in $H^{-\kappa}(\mathbb{T}^2)$ for every $\kappa > 0$. Choose any $0 < \eta < \kappa$. The Gaussian reference law has a uniform $H^{-\eta}$ second moment by Proposition 144.28. The assumed L^q density bound then gives a uniform interacting $H^{-\eta}$ moment by Lemma 144.29, and Lemma 144.27 turns that moment bound into tightness in $H^{-\kappa}$.

Lemma 144.31 (Nelson stability implies normalized L^q density bounds)**.** *Let $\mu_{0,N}$ be a finite-dimensional massive Gaussian cutoff law on $\mathbb{T}^2$, and set*

$$V_N(\phi) = \frac{\lambda}{4} \int_{\mathbb{T}^2} :(P_N\phi)^4: \, \mathrm{d}^2 x, \qquad \lambda > 0,$$

where Wick ordering is taken with respect to $\mu_{0,N}$. Suppose that the cutoff family satisfies the Nelson stability exponential estimate

$$\sup_N \int \exp[-pV_N(\phi)] \, \mathrm{d}\mu_{0,N}(\phi) < \infty \qquad \text{for every finite } p \ge 1. \tag{144.80}$$

Let

$$Z_N = \int e^{-V_N(\phi)}\, \mathrm{d}\mu_{0,N}(\phi), \qquad \rho_N = Z_N^{-1} e^{-V_N}.$$

Then, for every finite $q \geq 1$,

$$\sup_N \|\rho_N\|_{L^q(\mu_{0,N})} < \infty.$$

Consequently, for every $0 < \eta < \kappa$, the interacting cutoff measures $\mu_N = \rho_N \mu_{0,N}$ are tight in $H^{-\kappa}(\mathbb{T}^2)$, provided the Gaussian reference laws have the uniform $H^{-\eta}$ second-moment bound of Proposition 144.28.

Proof. The normalization cannot be allowed to hide a cutoff-dependent loss. Wick ordering gives

$$\int :(P_N\phi(x))^4:\, \mathrm{d}\mu_{0,N}(\phi) = 0 \qquad \text{for every } x,$$

and hence, by Fubini in the finite-dimensional cutoff space,

$$\int V_N(\phi)\, \mathrm{d}\mu_{0,N}(\phi) = 0.$$

Jensen's inequality for the convex function $u \mapsto e^{-u}$ gives

$$Z_N = \int e^{-V_N}\, \mathrm{d}\mu_{0,N} \geq \exp\left[-\int V_N\, \mathrm{d}\mu_{0,N}\right] = 1. \tag{144.81}$$

Therefore, for $q \geq 1$,

$$\|\rho_N\|^q_{L^q(\mu_{0,N})} = Z_N^{-q} \int e^{-qV_N}\, \mathrm{d}\mu_{0,N} \leq \int e^{-qV_N}\, \mathrm{d}\mu_{0,N}.$$

The right-hand side is bounded uniformly in N by (144.80) with $p = q$. This proves the normalized L^q density bound. The tightness conclusion is then exactly Remark 144.30, or, equivalently, Lemma 144.29 followed by Lemma 144.27. □

The preceding proposition proves the probabilistic consequence of Nelson stability without losing constants in the normalization. For cutoff families covered by Quoted Theorem 137.3, the hypothesis (144.80) is exactly the $P(\phi)_2$ stability and exponential-integrability estimate. For a sharp Fourier-Galerkin stochastic regulator, the same conclusion requires either a direct Nelson stability proof for that regulator or a comparison with a smooth ultraviolet regulator for which the stability theorem has already been established. This is a regulator-specific constructive estimate, not a formal property of Wick ordering alone.

Lemma 144.32 (Bounded-cylinder comparison from a common density limit)**.** *Let $(\Omega, \mathcal{F}, \gamma)$ be a probability space. For $\sigma \in \{A, B\}$ and $N \geq 1$, let*

$$X_N^\sigma : \Omega \to \mathbb{R}^r, \qquad W_N^\sigma : \Omega \to [0, \infty)$$

be measurable, and let $X : \Omega \to \mathbb{R}^r$, $W : \Omega \to [0, \infty)$ be measurable limits. Assume

$$X_N^\sigma \longrightarrow X \quad \textit{in } \gamma\textit{-probability}, \qquad W_N^\sigma \longrightarrow W \quad \textit{in } L^1(\gamma) \tag{144.82}$$

for $\sigma = A, B$. Assume also that there is $p > 1$ such that

$$\sup_{N,\sigma} \|W_N^\sigma\|_{L^p(\gamma)} < \infty. \tag{144.83}$$

Set

$$Z_N^\sigma = \int W_N^\sigma \,\mathrm{d}\gamma, \qquad Z = \int W \,\mathrm{d}\gamma,$$

and suppose $Z > 0$. Then, for every bounded continuous $F : \mathbb{R}^r \to \mathbb{C}$,

$$\lim_{N\to\infty} \frac{\int F(X_N^A) W_N^A \,\mathrm{d}\gamma}{Z_N^A} = \frac{\int F(X) W \,\mathrm{d}\gamma}{Z} = \lim_{N\to\infty} \frac{\int F(X_N^B) W_N^B \,\mathrm{d}\gamma}{Z_N^B}. \tag{144.84}$$

Proof. The L^1-convergence of W_N^σ gives

$$Z_N^\sigma \longrightarrow Z$$

for $\sigma = A, B$. Thus it is enough to prove convergence of the unnormalized numerators. Fix σ and write

$$\begin{aligned} &\int F(X_N^\sigma) W_N^\sigma \,\mathrm{d}\gamma - \int F(X) W \,\mathrm{d}\gamma \\ &= \int \big(F(X_N^\sigma) - F(X)\big) W_N^\sigma \,\mathrm{d}\gamma + \int F(X) \big(W_N^\sigma - W\big) \,\mathrm{d}\gamma. \end{aligned}$$

The second term tends to zero because F is bounded and $W_N^\sigma \to W$ in L^1. For the first term, the convergence $X_N^\sigma \to X$ in probability and continuity of F imply

$$F(X_N^\sigma) - F(X) \longrightarrow 0 \quad \text{in probability.}$$

The difference is bounded by $2\|F\|_\infty$, while (144.83) implies uniform integrability of $\{W_N^\sigma\}$ by Holder's inequality:

$$\int_E W_N^\sigma \,\mathrm{d}\gamma \le \|W_N^\sigma\|_{L^p(\gamma)} \gamma(E)^{1-1/p}.$$

Given $\varepsilon > 0$, choose $\delta > 0$ so small that the right-hand side is at most ε for every N, σ whenever $\gamma(E) < \delta$. On the event $\{|F(X_N^\sigma) - F(X)| \le \varepsilon\}$, the first term is bounded by $\varepsilon \int W_N^\sigma \mathrm{d}\gamma$, and the integrals of W_N^σ are uniformly bounded by the L^p hypothesis. On the complement, the uniform-integrability estimate applies because the complement has γ-probability tending to zero. Hence the first term tends to zero for each fixed regulator type σ. Applying this conclusion for $\sigma = A$ and for $\sigma = B$ gives the two unnormalized limits, and the normalized limits follow from $Z_N^\sigma \to Z > 0$. □

Corollary 144.33 (Bounded-cylinder comparison from a common potential)**.** *In the setting of Lemma 144.32, replace the L^1-convergence assumption on the densities by the following potential-level assumptions. Let*

$$V_N^\sigma : \Omega \to \mathbb{R}, \qquad V : \Omega \to \mathbb{R}, \qquad \sigma \in \{A, B\},$$

be measurable real-valued interaction functionals, put

$$W_N^\sigma = e^{-V_N^\sigma}, \qquad W = e^{-V},$$

and assume

$$X_N^\sigma \longrightarrow X, \qquad V_N^\sigma \longrightarrow V \quad \textit{in } \gamma\textit{-probability} \tag{144.85}$$

for $\sigma = A, B$. Assume further that, for some $p > 1$,

$$\sup_{N,\sigma} \|e^{-V_N^\sigma}\|_{L^p(\gamma)} < \infty, \qquad Z := \int e^{-V}\, \mathrm{d}\gamma > 0. \tag{144.86}$$

Then the normalized bounded cylinder expectations of the two regulators have the common limit

$$\lim_{N\to\infty} \frac{\int F(X_N^\sigma) e^{-V_N^\sigma}\, \mathrm{d}\gamma}{\int e^{-V_N^\sigma}\, \mathrm{d}\gamma} = \frac{\int F(X) e^{-V}\, \mathrm{d}\gamma}{\int e^{-V}\, \mathrm{d}\gamma}, \qquad \sigma = A, B, \tag{144.87}$$

for every bounded continuous $F : \mathbb{R}^r \to \mathbb{C}$.

Proof. It is enough to verify the density hypotheses of Lemma 144.32. Since the exponential map is continuous,

$$e^{-V_N^\sigma} \longrightarrow e^{-V} \quad \text{in } \gamma\text{-probability.}$$

We first record explicitly that the limiting weight belongs to L^p. From any subsequence of $e^{-V_N^\sigma}$ one may choose a further subsequence converging to e^{-V} almost surely. Fatou's lemma gives

$$\|e^{-V}\|_{L^p(\gamma)}^p \le \liminf_{k\to\infty} \|e^{-V_{N_k}^\sigma}\|_{L^p(\gamma)}^p \le \sup_{N,\sigma} \|e^{-V_N^\sigma}\|_{L^p(\gamma)}^p.$$

Thus the family

$$\{e^{-V}\} \cup \{e^{-V_N^\sigma} : N \ge 1,\ \sigma = A, B\}$$

is uniformly integrable. Indeed, for every measurable $E \subset \Omega$, Holder's inequality gives

$$\int_E e^{-V_N^\sigma}\, \mathrm{d}\gamma \le \|e^{-V_N^\sigma}\|_{L^p(\gamma)} \gamma(E)^{1-1/p}, \qquad \int_E e^{-V}\, \mathrm{d}\gamma \le \|e^{-V}\|_{L^p(\gamma)} \gamma(E)^{1-1/p}.$$

We now prove the L^1-convergence rather than citing Vitali's theorem. Fix $\varepsilon > 0$. By the preceding uniform-integrability estimate, choose $\delta > 0$ so that the integral of any member of the displayed family over a set of γ-measure less than δ is at most ε. Let

$$E_N^\sigma = \{|e^{-V_N^\sigma} - e^{-V}| > \varepsilon\}.$$

Convergence in probability gives $\gamma(E_N^\sigma) < \delta$ for all sufficiently large N. Then

$$\begin{aligned}\int |e^{-V_N^\sigma} - e^{-V}|\, \mathrm{d}\gamma &\le \varepsilon + \int_{E_N^\sigma} e^{-V_N^\sigma}\, \mathrm{d}\gamma + \int_{E_N^\sigma} e^{-V}\, \mathrm{d}\gamma \\ &\le 3\varepsilon\end{aligned}$$

for all sufficiently large N. Hence

$$e^{-V_N^\sigma} \longrightarrow e^{-V} \quad \text{in } L^1(\gamma), \qquad \sigma = A, B.$$

The hypotheses of Lemma 144.32 are now satisfied, and its conclusion is exactly (144.87). $\square$

Bounded Wick-cylinder comparison for stable quartic cutoffs. Let X_N^A and X_N^B be two cutoff approximations of the same massive two-dimensional Gaussian field on a common probability space $(\Omega, \mathcal{F}, \gamma)$. Fix $\lambda \in \mathbb{R}$ and define

$$V_N^\sigma = \frac{\lambda}{4} :(X_N^\sigma)^4: (1), \qquad \sigma \in \{A, B\}.$$

Assume that the finite Wick coordinates

$$:(X_N^\sigma)^{n_j}: (f_j), \qquad 1 \le j \le r,$$

converge in $L^2(\Omega)$, for both $\sigma = A, B$, to common limits $:X^{n_j}: (f_j)$, and that

$$V_N^\sigma \longrightarrow V := \frac{\lambda}{4} :X^4: (1) \quad \text{in } L^2(\Omega), \qquad \sigma = A, B. \tag{144.88}$$

Assume also that there is $p > 1$ such that

$$\sup_{N,\sigma} \left\| e^{-V_N^\sigma} \right\|_{L^p(\gamma)} < \infty. \tag{144.89}$$

Let

$$\mathcal{X}_N^\sigma = \big(:(X_N^\sigma)^{n_1}: (f_1), \dots, :(X_N^\sigma)^{n_r}: (f_r)\big), \qquad \mathcal{X} = \big(:X^{n_1}: (f_1), \dots, :X^{n_r}: (f_r)\big).$$

Then, for every bounded continuous $G : \mathbb{R}^r \to \mathbb{C}$,

$$\lim_{N\to\infty} \frac{\int G(\mathcal{X}_N^A) e^{-V_N^A} \, \mathrm{d}\gamma}{\int e^{-V_N^A} \, \mathrm{d}\gamma} = \frac{\int G(\mathcal{X}) e^{-V} \, \mathrm{d}\gamma}{\int e^{-V} \, \mathrm{d}\gamma} = \lim_{N\to\infty} \frac{\int G(\mathcal{X}_N^B) e^{-V_N^B} \, \mathrm{d}\gamma}{\int e^{-V_N^B} \, \mathrm{d}\gamma}. \tag{144.90}$$

Remark 144.7 gives

$$\mathcal{X}_N^\sigma \longrightarrow \mathcal{X} \quad \text{in probability}, \qquad \sigma = A, B.$$

The assumed L^2-convergence (144.88) gives

$$V_N^\sigma \longrightarrow V \quad \text{in probability}.$$

From every subsequence one may choose a further subsequence along which $V_N^\sigma \to V$ almost surely. Fatou's lemma and (144.89) imply

$$\int e^{-pV} \, \mathrm{d}\gamma \le \liminf_{k\to\infty} \int e^{-pV_{N_k}^\sigma} \, \mathrm{d}\gamma < \infty.$$

Thus $e^{-V} \in L^p(\gamma)$, while $e^{-V} > 0$ almost surely because V is real-valued and finite almost surely. Hence

$$0 < \int e^{-V} \, \mathrm{d}\gamma < \infty.$$

All hypotheses of Corollary 144.33 are satisfied, and its conclusion is precisely (144.90).

144.5.4 Regulators, Reflection Positivity, and the Φ^4_2 Assembly

Proposition 144.34 (Smooth regulator consequences of Nelson stability)**.** *Let γ be the massive Gaussian free-field law on $\mathbb{T}^2$. For $\sigma \in \{A, B\}$, let*

$$X^\sigma_N = \mu^\sigma(D/N)X$$

be smooth Fourier multiplier cutoffs as in Proposition 144.5, and let

$$V^\sigma_N = \frac{\lambda}{4}\int_{\mathbb{T}^2} :(X^\sigma_N(x))^4: \, \mathrm{d}^2x, \qquad \lambda > 0,$$

with Wick ordering taken with respect to the cutoff covariance of X^σ_N. Assume the Nelson stability input

$$\sup_{N,\sigma} \int \exp[-pV^\sigma_N] \, \mathrm{d}\gamma < \infty \qquad \textit{for every finite } p \geq 1. \tag{144.91}$$

Set

$$Z^\sigma_N = \int e^{-V^\sigma_N} \, \mathrm{d}\gamma, \qquad \rho^\sigma_N = (Z^\sigma_N)^{-1} e^{-V^\sigma_N}, \qquad \mathrm{d}\nu^\sigma_N = \rho^\sigma_N \, \mathrm{d}\gamma.$$

Then the following statements hold.

1. *For every finite $q \geq 1$,*
$$\sup_{N,\sigma} \|\rho^\sigma_N\|_{L^q(\gamma)} < \infty. \tag{144.92}$$
2. *For every $\kappa > 0$, the two families $\{\nu^A_N\}$ and $\{\nu^B_N\}$ are tight in $H^{-\kappa}(\mathbb{T}^2)$.*
3. *For every finite list of Wick coordinates $:(X^\sigma_N)^{n_j}:(f_j)$, $1 \leq j \leq r$, and every bounded continuous $G : \mathbb{R}^r \to \mathbb{C}$, the normalized expectations of G under the two cutoff families have the common continuum limit stated in (144.90).*

Proof. Wick centering gives

$$\int V^\sigma_N \, \mathrm{d}\gamma = 0.$$

Jensen's inequality therefore gives

$$Z^\sigma_N = \int e^{-V^\sigma_N} \, \mathrm{d}\gamma \geq \exp\left[-\int V^\sigma_N \, \mathrm{d}\gamma\right] = 1.$$

Consequently

$$\|\rho^\sigma_N\|^q_{L^q(\gamma)} = (Z^\sigma_N)^{-q} \int e^{-qV^\sigma_N} \, \mathrm{d}\gamma \leq \int e^{-qV^\sigma_N} \, \mathrm{d}\gamma,$$

and (144.92) follows from (144.91).

For tightness, choose $0 < \eta < \kappa$. The massive Gaussian field has finite $H^{-\eta}$-moments of every order: diagonalizing the covariance in Fourier modes gives

$$\mathbb{E}_\gamma \|X\|^2_{H^{-\eta}} = \sum_{k \in \mathbb{Z}^2} \frac{(1 + |k|^2)^{-\eta}}{|k|^2 + m^2} < \infty,$$

and the higher moments are bounded by the same Gaussian Hilbert-norm argument used in Lemma 144.29. Holder's inequality with the uniform L^q bound for ρ_N^σ gives

$$\sup_{N,\sigma} \int \|\phi\|_{H^{-\eta}}^r \, \mathrm{d}\nu_N^\sigma(\phi) < \infty \qquad (r < \infty).$$

The compact embedding $H^{-\eta} \hookrightarrow H^{-\kappa}$, quantified in Lemma 144.27, proves tightness in $H^{-\kappa}$.

It remains to prove the comparison statement. By Proposition 144.5 and Lemma 144.6, the finite Wick-coordinate vectors of the two smooth regulators have common L^2 limits. Applying the fourth Wick-power convergence statement with $f \equiv 1$ gives

$$V_N^\sigma \longrightarrow \frac{\lambda}{4} :X^4:(1) \quad \text{in } L^2(\gamma), \qquad \sigma = A, B.$$

The stability input (144.91) supplies the uniform L^p bound on $e^{-V_N^\sigma}$. Hence the bounded Wick-cylinder comparison (144.90) applies and gives the stated comparison. □

In the regulator-comparison problem, X_N^σ is the finite list of smeared field or Wick-polynomial coordinates entering a bounded positive-time cylinder observable, and W_N^σ is the finite-cutoff interaction density. Lemma 144.32 therefore proves the bounded-observable comparison once both regulators are constructed on a common Gaussian probability space and their Wick densities are shown to have the same L^1 limit. Corollary 144.33 gives the common route used in cutoff constructions: it is enough to prove that the renormalized interaction functionals converge in probability to the same limiting potential and that their exponential weights obey a uniform L^p stability estimate. In the Wick quartic case, the comparison (144.90) is obtained once the common Wick-coordinate limits and exponential-weight stability have been proved. For smooth Fourier multiplier regulators satisfying the Nelson stability input, Proposition 144.34 derives the normalized L^q density bounds, tightness, and bounded Wick-cylinder comparison in one statement. Unbounded polynomial observables still require the separate uniform-integrability argument in Remark 144.41.

Proposition 144.35 (Brascamp–Lieb covariance domination for convex cutoffs)**.** *Let H_N be a finite-dimensional real Hilbert space, let A_N be a positive self-adjoint operator on H_N, and let $S_N \in C^2(H_N)$ satisfy*

$$\nabla^2 S_N(\phi) \geq A_N \tag{144.93}$$

as quadratic forms on H_N, for every $\phi \in H_N$. Define

$$\mathrm{d}\nu_N(\phi) = Z_N^{-1} e^{-S_N(\phi)} \, \mathrm{d}\phi$$

where $\mathrm{d}\phi$ is Lebesgue measure in an orthonormal coordinate system and $Z_N = \int e^{-S_N(\phi)} \mathrm{d}\phi$. Then $Z_N < \infty$, the integration-by-parts identities used below hold for smooth functions of polynomial growth, and every linear functional $\ell_v(\phi) = (v, \phi)_{H_N}$ satisfies

$$\mathrm{Var}_{\nu_N}(\ell_v) \leq (v, A_N^{-1} v)_{H_N}. \tag{144.94}$$

Suppose in addition that L_N is a nonnegative self-adjoint operator with orthonormal eigenvectors $e_{N,\alpha}$ and eigenvalues $\lambda_{N,\alpha}$, that $A_N \geq L_N + m^2 \mathbf{1}$ for some $m^2 > 0$, and that ν_N is invariant under $\phi \mapsto -\phi$. Define

$$\|\phi\|_{H_N^{-\eta}}^2 = \sum_\alpha (1 + \lambda_{N,\alpha})^{-\eta} |(\phi, e_{N,\alpha})_{H_N}|^2. \tag{144.95}$$

Then, for every $\eta > 0$,

$$\int \|\phi\|^2_{H_N^{-\eta}} \,\mathrm{d}\nu_N(\phi) \le \sum_\alpha (1+\lambda_{N,\alpha})^{-\eta}(\lambda_{N,\alpha}+m^2)^{-1}. \tag{144.96}$$

Consequently, any cutoff family for which the right hand side of (144.96) is uniformly bounded and whose $H_N^{-\eta}$ spaces embed into a common $H^{-\eta}$ approximation scheme satisfies the moment hypothesis in Lemma 144.27.

Proof. Let $a_N > 0$ be the smallest eigenvalue of A_N. Taylor's formula gives

$$S_N(\phi) \ge S_N(0) + (\nabla S_N(0), \phi)_{H_N} + \frac{a_N}{2}\|\phi\|^2_{H_N} \ge \frac{a_N}{4}\|\phi\|^2_{H_N} - C_N$$

for a finite constant C_N. Hence e^{-S_N} has Gaussian decay. This proves $Z_N < \infty$ and justifies the integration by parts below after inserting radial cutoffs and sending their radii to infinity.

We first prove the covariance estimate. Write

$$\mathcal{L} = \Delta - \nabla S_N \cdot \nabla.$$

This operator is symmetric in $L^2(\nu_N)$ on smooth compactly supported functions, and

$$-\int f\,\mathcal{L}g\,\mathrm{d}\nu_N = \int (\nabla f, \nabla g)_{H_N}\,\mathrm{d}\nu_N. \tag{144.97}$$

Let f be a smooth centered test function. On the centered subspace of $L^2(\nu_N)$, let $u_\varepsilon = (\varepsilon - \mathcal{L})^{-1} f$, $\varepsilon > 0$, where the inverse is the Friedrichs resolvent of the closed Dirichlet form in (144.97). The resolvent satisfies

$$\varepsilon u_\varepsilon - \mathcal{L}u_\varepsilon = f. \tag{144.98}$$

Pairing (144.98) with f and using (144.97) gives

$$\int f^2\,\mathrm{d}\nu_N = \varepsilon \int f u_\varepsilon \,\mathrm{d}\nu_N + \int (\nabla f, \nabla u_\varepsilon)_{H_N}\,\mathrm{d}\nu_N. \tag{144.99}$$

The spectral calculus of the nonnegative operator $-\mathcal{L}$ on centered $L^2(\nu_N)$ gives $\varepsilon u_\varepsilon \to 0$ and $-\mathcal{L}u_\varepsilon \to f$ in $L^2(\nu_N)$. Hence the first term on the right of (144.99) vanishes as $\varepsilon \downarrow 0$.

For smooth compactly supported u, differentiating $\mathcal{L}u$ and integrating by parts gives the finite-dimensional Bochner identity

$$\int (\mathcal{L}u)^2\,\mathrm{d}\nu_N = \int \|\nabla^2 u\|^2_{\mathrm{HS}}\,\mathrm{d}\nu_N + \int (\nabla u, \nabla^2 S_N\,\nabla u)_{H_N}\,\mathrm{d}\nu_N. \tag{144.100}$$

Indeed, expanding $\int (\Delta u - \nabla S_N \cdot \nabla u)^2 e^{-S_N}\,\mathrm{d}\phi$, moving one derivative from each second-derivative term, and collecting the mixed terms leaves precisely the Hessian term displayed above. Applying (144.100) to resolvent approximants and using (144.93) yields

$$\int (\nabla u_\varepsilon, A_N \nabla u_\varepsilon)_{H_N}\,\mathrm{d}\nu_N \le \int (\mathcal{L}u_\varepsilon)^2\,\mathrm{d}\nu_N. \tag{144.101}$$

Taking $\varepsilon \downarrow 0$ gives

$$\limsup_{\varepsilon\downarrow 0} \int (\nabla u_\varepsilon, A_N \nabla u_\varepsilon)_{H_N}\,\mathrm{d}\nu_N \le \int f^2\,\mathrm{d}\nu_N. \tag{144.102}$$

Therefore

$$\begin{aligned}\int f^2\,\mathrm{d}\nu_N &= \lim_{\varepsilon\downarrow 0}\int(\nabla f,\nabla u_\varepsilon)_{H_N}\,\mathrm{d}\nu_N\\ &\le \left[\int(\nabla f,A_N^{-1}\nabla f)_{H_N}\,\mathrm{d}\nu_N\right]^{1/2}\left[\limsup_{\varepsilon\downarrow 0}\int(\nabla u_\varepsilon,A_N\nabla u_\varepsilon)_{H_N}\,\mathrm{d}\nu_N\right]^{1/2}\\ &\le \left[\int(\nabla f,A_N^{-1}\nabla f)_{H_N}\,\mathrm{d}\nu_N\right]^{1/2}\left[\int f^2\,\mathrm{d}\nu_N\right]^{1/2}.\end{aligned}$$

Dividing by $(\int f^2\,\mathrm{d}\nu_N)^{1/2}$, and then applying this estimate to $f-\int f\,\mathrm{d}\nu_N$, gives

$$\mathrm{Var}_{\nu_N}(f)\le\int(\nabla f,A_N^{-1}\nabla f)_{H_N}\,\mathrm{d}\nu_N. \tag{144.103}$$

Linear functions are obtained by multiplying ℓ_v by smooth radial cutoffs and sending the cut-off radius to infinity; the quadratic lower bound following from (144.93) supplies the needed dominated-convergence bounds. Since $\nabla\ell_v=v$, (144.94) follows.

For the negative-Sobolev moment, the symmetry $\phi\mapsto-\phi$ gives $\int(\phi,e_{N,\alpha})_{H_N}\mathrm{d}\nu_N=0$. Applying (144.94) with $v=e_{N,\alpha}$ and using $A_N\ge L_N+m^2\mathbf{1}$ gives

$$\int|(\phi,e_{N,\alpha})_{H_N}|^2\,\mathrm{d}\nu_N(\phi)\le(e_{N,\alpha},A_N^{-1}e_{N,\alpha})_{H_N}\le(\lambda_{N,\alpha}+m^2)^{-1}.$$

Multiplying by $(1+\lambda_{N,\alpha})^{-\eta}$ and summing over α proves (144.96). $\square$

Remark 144.36 (Closedness of OS reflection positivity under weak convergence). Let E be a Hausdorff locally convex real vector space of Euclidean fields, let $\Theta:E\to E$ be a continuous involution, and let $\mu_N\Rightarrow\mu$ be weak convergence of Borel probability measures on E. Let $\mathcal{A}_+$ be an algebra of bounded continuous cylinder functions on E such that

$$\Theta F(\phi)=F(\Theta\phi)$$

is again a bounded continuous cylinder function whenever $F\in\mathcal{A}_+$. If

$$\int_E\overline{F(\Theta\phi)}\,F(\phi)\,\mathrm{d}\mu_N(\phi)\ge 0\qquad(F\in\mathcal{A}_+,\ N\ge 1), \tag{144.104}$$

then

$$\int_E\overline{F(\Theta\phi)}\,F(\phi)\,\mathrm{d}\mu(\phi)\ge 0\qquad(F\in\mathcal{A}_+). \tag{144.105}$$

If F is an unbounded polynomial cylinder observable, the same conclusion holds provided the random variables

$$\overline{F(\Theta\phi)}\,F(\phi)$$

are uniformly integrable under $\{\mu_N\}$ and integrable under μ, and F is approximated by bounded continuous cylinder cutoffs in $\mathcal{A}_+$. For $F\in\mathcal{A}_+$, define

$$Q_F(\phi)=\overline{F(\Theta\phi)}\,F(\phi).$$

Continuity of Θ and bounded continuity of F imply that Q_F is a bounded continuous function on E. Weak convergence therefore gives

$$\int_E Q_F \, \mathrm{d}\mu = \lim_{N\to\infty} \int_E Q_F \, \mathrm{d}\mu_N.$$

Each term in the sequence on the right is nonnegative by (144.104); the limit is therefore nonnegative, giving (144.105).

For an unbounded polynomial cylinder observable, choose bounded continuous functions χ_R on the finite-dimensional cylinder coordinate space such that $\chi_R = 1$ on the radius-R ball, $\chi_R = 0$ outside the radius-$2R$ ball, and $0 \le \chi_R \le 1$. Set $F_R = \chi_R F$. The bounded part of this observation gives

$$\int_E \overline{F_R(\Theta\phi)}\, F_R(\phi) \, \mathrm{d}\mu \ge 0.$$

Uniform integrability of $\overline{F(\Theta\phi)}F(\phi)$ under $\{\mu_N\}$, together with integrability under μ, permits $R \to \infty$ in the cutoff quadratic form. Hence the unbounded polynomial cylinder inequality follows whenever the stated moment hypothesis is available. This final step is substantive: in constructive field theory it is exactly where uniform moment or exponential-integrability estimates for the cutoff measures enter.

Remark 144.37 (Fourier cutoffs and reflection-positive regulators). The Fourier-Galerkin cutoff used above is an analytically convenient way to construct the stochastic convolution and the local Da Prato–Debussche solution map. OS reflection positivity, however, is not a formal consequence of being a reflection-symmetric ultraviolet cutoff. It is a positivity property of the Euclidean regulator with respect to a chosen time reflection. Thus the reflection-positivity hypothesis in Theorem 144.44 must be read as a condition on the actual cutoff family used to define the Euclidean measures, or else one must prove a regulator-independence comparison between a reflection-positive cutoff family and the Fourier-Galerkin SPDE approximation. The theorem below deliberately keeps this point visible: Fourier cutoffs are used for the path-space stochastic estimates, while OS positivity remains a separate regulator property until such a comparison is proved.

Proposition 144.38 (Lattice scalar cutoffs as OS-positive Euclidean regulators)**.** *Let $\Lambda_{a,L}$ be a finite two-dimensional periodic lattice with spacing $a > 0$, side length L, and an involutive time reflection ϑ whose reflection plane is either a set of sites or a set of mid-links. Let*

$$\mathrm{d}\mu_{a,L}(\phi) = Z_{a,L}^{-1} e^{-S_{a,L}(\phi)} \prod_{x\in\Lambda_{a,L}} \mathrm{d}\phi_x$$

where

$$S_{a,L}(\phi) = \frac{1}{2}\sum_{\langle xy\rangle} c_{xy}\,(\phi_x - \phi_y)^2 + \sum_{x\in\Lambda_{a,L}} V_x(\phi_x).$$

Assume $c_{xy} = c_{\vartheta x,\vartheta y} > 0$, the nearest-neighbor graph is invariant under ϑ, $V_{\vartheta x} = V_x$, and the finite integral defining $Z_{a,L}$ exists. Let the reflected field be $(\vartheta\phi)_x = \phi_{\vartheta x}$. Then $\mu_{a,L}$ is OS reflection positive on bounded observables depending only on the chosen nonnegative-time half-lattice, including the reflection plane when present:

$$\int \overline{F(\vartheta\phi)}\, F(\phi) \, \mathrm{d}\mu_{a,L}(\phi) \ge 0.$$

In particular, a lattice Φ^4_2 cutoff with reflection-invariant local coordinates,

$$V_x(u) = a^2\left[\frac{m_{a,L}^2}{2}u^2 + \frac{\lambda}{4}u^4 + E_{a,L}\right], \qquad \lambda > 0,$$

and positive nearest-neighbor kinetic coefficients is reflection positive at each finite cutoff whenever the displayed finite-dimensional integral is finite.

Proof. This is the scalar lattice reflection-positivity mechanism of Proposition 138.2, specialized to the regulators used in the constructive scalar theory. We spell out the assignment because it is the point at which the sign of the regulator is used. Split the lattice into the positive half, the reflected negative half, and the reflection plane if the plane contains sites. Terms contained strictly in one half are assigned to S_+ and ϑS_+. Reflection-plane on-site terms, and one half of every square term adjacent to the plane, are split symmetrically. A link crossing a mid-plane contributes

$$\frac{1}{2}c_{x,\vartheta x}(\phi_x - \phi_{\vartheta x})^2 = \frac{1}{2}c_{x,\vartheta x}\phi_x^2 + \frac{1}{2}c_{x,\vartheta x}\phi_{\vartheta x}^2 - c_{x,\vartheta x}\phi_x\phi_{\vartheta x}.$$

The first two summands have already been assigned to the two halves. In the Boltzmann weight the remaining cross-plane factor is therefore

$$\exp(c_{x,\vartheta x}\phi_x\phi_{\vartheta x}) = \sum_{n=0}^{\infty}\frac{c_{x,\vartheta x}^n}{n!}\,\phi_x^n\phi_{\vartheta x}^n,$$

with nonnegative coefficients. Multiplying these expansions for all crossing links expresses the reflection quadratic form $\int \overline{F(\vartheta\phi)}F(\phi)\mathrm{d}\mu_{a,L}$ as a sum of nonnegative coefficients times absolute squares of half-lattice integrals. Hence the quadratic form is nonnegative. The local potential and local counterterm coordinates do not enter this sign argument except through reflection invariance, reality, and integrability, because they are assigned to the two halves before the cross-plane kernel is expanded. $\square$

Proposition 144.38 proves the finite-cutoff OS-positivity input for a concrete lattice Euclidean regulator. Identifying that lattice family with the Fourier-Galerkin family used in the stochastic convolution estimates above is a separate comparison theorem. After matching the relevant local coordinates, one must prove convergence of the lattice and Fourier-Galerkin Schwinger functions, or construct a single regulator whose Langevin estimates and OS positivity are both available. Such a theorem must supply analytic estimates beyond either weak convergence or stochastic stationarity.

Remark 144.39 (Regulator comparison criterion for OS-positive stochastic limits)*.* Let E be a Hausdorff locally convex real vector space of Euclidean fields, let $\Theta : E \to E$ be a continuous involution, and let $\{\mu_N^{\mathrm{F}}\}$ and $\{\mu_N^{\mathrm{L}}\}$ be two cutoff families of Borel probability measures on E. Think of μ_N^{F} as the Fourier-Galerkin stochastic cutoff family and μ_N^{L} as a lattice cutoff family, but assume only the following properties.

First, suppose that

$$\mu_N^{\mathrm{F}} \Rightarrow \mu \qquad \text{weakly on } E.$$

Second, let $\mathcal{A}_+$ be an algebra of bounded continuous cylinder observables supported in nonnegative Euclidean time, and assume finite-cutoff OS positivity for the lattice family:

$$\int_E \overline{F(\Theta\phi)}\,F(\phi)\,\mathrm{d}\mu_N^{\mathrm{L}}(\phi) \geq 0, \qquad F \in \mathcal{A}_+. \tag{144.106}$$

Third, assume comparison of bounded cylinder observables in the following literal sense: for every bounded continuous cylinder function G in the algebra generated by $\mathcal{A}_+$ and its reflected observables,

$$\int_E G(\phi)\,\mathrm{d}\mu_N^{\mathrm{F}}(\phi) - \int_E G(\phi)\,\mathrm{d}\mu_N^{\mathrm{L}}(\phi) \longrightarrow 0. \tag{144.107}$$

Then the Fourier-Galerkin limiting measure μ is OS reflection positive on $\mathcal{A}_+$:

$$\int_E \overline{F(\Theta\phi)}\,F(\phi)\,\mathrm{d}\mu(\phi) \geq 0, \qquad F \in \mathcal{A}_+. \tag{144.108}$$

Let now P be a polynomial cylinder observable in finitely many continuous linear coordinates. Assume that bounded continuous cutoffs P_R of P can be chosen in the comparison algebra and that

$$|P_R(\phi) - P(\phi)| \leq 2|P(\phi)|\,\mathbf{1}_{\{|P(\phi)|>R\}}, \qquad P_R(\phi) \to P(\phi)$$

pointwise. If the random variables $|P|^2$ are uniformly integrable with respect to both cutoff families $\{\mu_N^{\mathrm{F}}\}$, $\{\mu_N^{\mathrm{L}}\}$, and are integrable with respect to μ, then both cutoff limits exist and

$$\int_E P\,\mathrm{d}\mu = \lim_{N\to\infty} \int_E P\,\mathrm{d}\mu_N^{\mathrm{F}} = \lim_{N\to\infty} \int_E P\,\mathrm{d}\mu_N^{\mathrm{L}}$$

holds. If, in addition, F is a positive-time polynomial observable and $|\overline{F\circ\Theta}F|$ has the same uniform-integrability property, then the OS inequality also holds for F. For bounded $F \in \mathcal{A}_+$, set

$$Q_F(\phi) = \overline{F(\Theta\phi)}\,F(\phi).$$

The function Q_F is a bounded continuous cylinder observable in the comparison algebra. Weak convergence of μ_N^{F} gives

$$\int_E Q_F\,\mathrm{d}\mu = \lim_{N\to\infty} \int_E Q_F\,\mathrm{d}\mu_N^{\mathrm{F}}.$$

The comparison hypothesis (144.107) gives

$$\lim_{N\to\infty} \int_E Q_F\,\mathrm{d}\mu_N^{\mathrm{F}} = \lim_{N\to\infty} \int_E Q_F\,\mathrm{d}\mu_N^{\mathrm{L}}$$

because the Fourier limit exists and the difference tends to zero. Each lattice integral is nonnegative by (144.106); hence its limit inferior is nonnegative. This proves (144.108).

For a polynomial cylinder observable P, fix R. Since P_R is bounded and belongs to the comparison algebra,

$$\lim_{N\to\infty} \left[\int_E P_R\,\mathrm{d}\mu_N^{\mathrm{F}} - \int_E P_R\,\mathrm{d}\mu_N^{\mathrm{L}}\right] = 0,$$

and weak convergence of μ_N^{F} gives

$$\int_E P_R\,\mathrm{d}\mu = \lim_{N\to\infty} \int_E P_R\,\mathrm{d}\mu_N^{\mathrm{F}}.$$

Uniform integrability allows $R \to \infty$ uniformly in N:

$$\left|\int (P - P_R)\,\mathrm{d}\mu_N^{\mathrm{F}}\right| \leq 2\int |P|\,\mathbf{1}_{\{|P|>R\}}\mathrm{d}\mu_N^{\mathrm{F}},$$

$$\left|\int (P - P_R)\,\mathrm{d}\mu_N^{\mathrm{L}}\right| \leq 2\int |P|\,\mathbf{1}_{\{|P|>R\}}\mathrm{d}\mu_N^{\mathrm{L}}.$$

The two L^1-tails tend to zero uniformly in N, because uniform integrability of $|P|^2$ implies uniform integrability of $|P|$ by Cauchy's inequality. Dominated convergence gives $\int P_R \, d\mu \to \int P \, d\mu$. Taking first $N \to \infty$ at fixed R, then $R \to \infty$, proves equality of the polynomial Schwinger-function limits. Applying the same truncation argument to $P = Q_F = \overline{F \circ \Theta F}$, after using the bounded part for each truncated F_R, gives the polynomial OS inequality.

The analytic comparison (144.107) is a separate constructive estimate; the criterion records what such a comparison must deliver. In Φ^4_2, the comparison is a constructive statement about two renormalized cutoff families in the same finite-volume local-coordinate chart. It must identify the mass and vacuum coordinates, prove convergence of bounded smeared-field observables, and provide the uniform-integrability estimates needed to remove the bounded truncations. Once these estimates are proved, lattice reflection positivity from Proposition 144.38 transfers to the stochastic Fourier-Galerkin limit by the criterion above.

Proposition 144.40 (Finite-volume Φ^4_2 SPDE/constructive route identification)**.** *Work on a fixed finite two-dimensional torus, with massive Gaussian reference law γ. Let $\sigma \in \{\mathrm{spde}, \mathrm{cons}\}$ label two ultraviolet cutoff families in the same field normalization and Wick-ordering chart. Let*

$$\mathcal{X}^\sigma_N$$

be the finite vector of smeared fields and Wick-polynomial coordinates entering a bounded cylinder observable, and let

$$V^\sigma_N = \frac{\lambda}{4} \int_{\mathbb{T}^2} :(R^\sigma_N \phi)^4: \, d^2x, \qquad W^\sigma_N = e^{-V^\sigma_N}, \qquad \lambda > 0,$$

where R^σ_N is the cutoff operator in the two regulator families. Assume that, for every finite cylinder-coordinate list under consideration,

$$\mathcal{X}^\sigma_N \to \mathcal{X} \quad \text{in } \gamma\text{-probability}, \qquad W^\sigma_N \to W \quad \text{in } L^1(\gamma), \qquad \sigma \in \{\mathrm{spde}, \mathrm{cons}\},$$

and that $\{W^\sigma_N\}$ is bounded in $L^p(\gamma)$ for some $p > 1$, uniformly in N and σ. Suppose also that the constructive family is one of the finite-volume $P(\phi)_2$ ultraviolet regulators covered by Theorem 137.4, specialized to $P(q) = \lambda q^4/4$, and that the chosen finite-volume constructive regulator is reflection positive in the sense of Proposition 144.38.

Then the bounded Wick-cylinder Schwinger functions of the stochastic cutoff family and of the constructive $P(\phi)_2$ cutoff family have the same finite-volume ultraviolet limit:

$$\lim_{N\to\infty} \frac{\int G(\mathcal{X}^{\mathrm{spde}}_N) W^{\mathrm{spde}}_N \, d\gamma}{\int W^{\mathrm{spde}}_N \, d\gamma} = \lim_{N\to\infty} \frac{\int G(\mathcal{X}^{\mathrm{cons}}_N) W^{\mathrm{cons}}_N \, d\gamma}{\int W^{\mathrm{cons}}_N \, d\gamma}$$

for every bounded continuous G of the displayed finite coordinate vector. If the polynomial cylinder observables used in the OS quadratic forms satisfy the uniform-integrability hypothesis of Remark 144.39, then the same common limit holds for those polynomial observables and the stochastic finite-volume limit is OS reflection positive on the positive-time polynomial cylinder algebra.

Consequently, in the massive finite-volume theory, the stochastic quantization invariant-law route and the constructive $P(\phi)_2$ route feed the same local Schwinger hierarchy into the later OS reconstruction problem whenever the displayed common-density and polynomial-tail estimates have been proved. Passing from this finite-volume identification to the infinite-volume scalar QFT is exactly the separate cluster-expansion input in Quoted Theorem 137.8; no thermodynamic-limit estimate is obtained merely from stochastic stationarity.

Proof. For a bounded continuous cylinder function G, apply Lemma 144.32 with $X_N^\sigma = \mathcal{X}_N^\sigma$ and $W_N^\sigma = e^{-V_N^\sigma}$. The lemma gives equality of the two normalized limiting expectations. The constructive side is the finite-volume $P(\phi)_2$ ultraviolet limit of Theorem 137.4, because the hypothesis places the constructive cutoff in the same Wick chart and supplies the L^1 density limit and uniform L^p integrability used there.

For polynomial cylinder observables, use bounded truncations. The uniform-integrability hypothesis permits the truncation radius to be sent to infinity uniformly in the two cutoff families, exactly as in Remark 144.39. Since the constructive finite regulator is reflection positive by Proposition 144.38, the bounded OS quadratic forms are nonnegative before the limit; the polynomial truncation passage transfers the inequality to the common ultraviolet limit. Finally, the infinite-volume statement is only a restatement of Quoted Theorem 137.8: once the finite-volume Schwinger hierarchies have been identified in every local window, the large-volume OS output still requires the cluster norm estimate and its consequences. □

Remark 144.41 (Polynomial OS observables from exponential moments). Let E be a Hausdorff locally convex real vector space, and let $\mu_N \Rightarrow \mu$ be Borel probability measures on E. Let $\ell_1, \dots, \ell_r$ be continuous real linear functionals on E, and fix $q > 0$, $\alpha > 0$. Put

$$V(\phi) = 1 + \sum_{j=1}^{r} |\ell_j(\phi)|^q.$$

Assume

$$\sup_N \int_E e^{\alpha V(\phi)}\, \mathrm{d}\mu_N(\phi) < \infty, \qquad \int_E e^{\alpha V(\phi)}\, \mathrm{d}\mu(\phi) < \infty. \tag{144.109}$$

Then for every polynomial $P \in \mathbb{C}[u_1, \dots, u_r]$, the random variables

$$|P(\ell_1(\phi), \dots, \ell_r(\phi))|^2$$

are uniformly integrable with respect to $\{\mu_N\}$ and integrable with respect to μ. Hence the unbounded polynomial-cylinder step in Remark 144.36 follows for such P whenever the bounded-cylinder reflection-positivity inequality is available.

There is a constant $C_P < \infty$ such that, for all $u \in \mathbb{R}^r$,

$$|P(u)|^2 \le C_P \exp\left(\frac{\alpha}{2}\left[1 + \sum_{j=1}^{r} |u_j|^q\right]\right). \tag{144.110}$$

This is the elementary domination of polynomial growth by exponential growth: each monomial is bounded by a constant times $\exp[(\alpha/4r)|u_j|^q]$ in each variable appearing in it, and the finite sum of monomials is absorbed into C_P. Let

$$A(\phi) = \exp\Big(\frac{\alpha}{2} V(\phi)\Big).$$

If $|P(\ell(\phi))|^2 > R$, then $C_P A(\phi) > R$. Therefore

$$|P(\ell(\phi))|^2 \mathbf{1}_{\{|P(\ell(\phi))|^2 > R\}} \le C_P A(\phi)\, \mathbf{1}_{\{A(\phi) > R/C_P\}} \le \frac{C_P^2}{R} A(\phi)^2.$$

Integrating and using $A^2 = e^{\alpha V}$ gives

$$\sup_N \int |P(\ell(\phi))|^2 \mathbf{1}_{\{|P(\ell(\phi))|^2 > R\}} \, d\mu_N(\phi) \le \frac{C_P^2}{R} \sup_N \int e^{\alpha V} \, d\mu_N \longrightarrow 0.$$

This is uniform integrability. The same estimate with μ instead of μ_N gives integrability under the limiting measure. Applying Remark 144.36 to bounded truncations of $P(\ell_1, \ldots, \ell_r)$ proves the final claim.

Lemma 144.42 (Finite lattice quartic tails)**.** *Let Λ be a finite set and let μ be a finite-dimensional scalar lattice measure*

$$d\mu(\phi) = Z^{-1} e^{-S(\phi)} \prod_{x \in \Lambda} d\phi_x, \qquad S(\phi) = K(\phi) + \sum_{x \in \Lambda} V_x(\phi_x),$$

where $K(\phi) \ge 0$. Suppose that, for constants $a_x > 0$, $b_x \ge 0$, and $d_x \in \mathbb{R}$,

$$V_x(u) \ge a_x u^4 - b_x u^2 - d_x. \tag{144.111}$$

Then $Z < \infty$, and for every $0 < \varepsilon < 1$,

$$\int \exp\left(\varepsilon \sum_{x \in \Lambda} a_x \phi_x^4 \right) d\mu(\phi) < \infty. \tag{144.112}$$

Consequently every polynomial cylinder observable has finite moments at this finite cutoff. A uniform version of (144.112) along a continuum cutoff family is a separate estimate; if it is available for the smeared coordinates entering an OS polynomial cylinder observable, then Remark 144.41 supplies the uniform integrability needed to pass that observable to the limit.

Proof. Since $K \ge 0$, the density is bounded above by

$$\exp\left[-\sum_x a_x \phi_x^4 + \sum_x b_x \phi_x^2 + \sum_x d_x \right].$$

For $A_x = (1 - \varepsilon) a_x$, the elementary inequality

$$b_x u^2 \le \frac{A_x}{2} u^4 + \frac{b_x^2}{2A_x}$$

gives

$$-A_x u^4 + b_x u^2 \le -\frac{A_x}{2} u^4 + \frac{b_x^2}{2A_x}.$$

Therefore

$$e^{\varepsilon \sum_x a_x \phi_x^4} e^{-S(\phi)} \le \exp\left[\sum_x d_x + \sum_x \frac{b_x^2}{2(1-\varepsilon) a_x} \right] \prod_x \exp\left[-\frac{(1-\varepsilon) a_x}{2} \phi_x^4 \right].$$

The product on the right is integrable over $\mathbb{R}^\Lambda$. Taking $\varepsilon = 0$ in the same estimate proves $Z < \infty$, while $Z > 0$ because the density is positive on a set of positive Lebesgue measure. Dividing by Z proves (144.112). Polynomial moments follow because every power of $|u|$ is bounded by a constant times $e^{\delta u^4}$ for any fixed $\delta > 0$. The final sentence is exactly Remark 144.41 applied to the finite list of smeared cylinder coordinates. $\square$

Hypothesis 144.43 (Φ^4_2 stochastic-quantization assembly inputs on the torus)**.** Fix $m^2 > 0$, $\lambda > 0$, $0 < \kappa < 1/4$, and $\beta = 1 + 2\kappa$. Let P_N be a reflection-symmetric Fourier cutoff on $\mathbb{T}^2$. Let μ_N be the finite-dimensional Wick-ordered Gibbs measure

$$\mathrm{d}\mu_N(\phi) = Z_N^{-1} \exp\left[-\frac{\lambda}{4}\int_{\mathbb{T}^2} :(P_N\phi)^4:\ \mathrm{d}^2x\right] \mathrm{d}\mu_{0,N}(\phi),$$

where $\mu_{0,N}$ is the massive Gaussian law with covariance $P_N(-\Delta + m^2)^{-1}P_N$. Let $P_t^{(N)}$ be the Markov semigroup of the corresponding finite-dimensional stochastic quantization equation, and embed all laws in $H^{-\kappa}(\mathbb{T}^2)$. By Proposition 144.9, the enhanced Ornstein–Uhlenbeck fields

$$\mathbb{X}_N = (X_N, :X_N^2:, :X_N^3:)$$

converge in probability in $C([0,T]; H^{-\kappa})^3$, for every $T < \infty$, to a limit $\mathbb{X} = (X, :X^2:, :X^3:)$.

Assume the following three further analytic facts.

(a) For every $Y_0 \in H^\beta$, the local solution map of Theorem 144.14 extends globally in stochastic time, and the cutoff solution maps converge to it uniformly on compact subsets of the enhanced-noise/initial-data space. Lemma 144.21 reduces this assertion, in the Besov formulation, to a blow-up alternative plus a rough energy-to-Besov a priori bound on compact enhanced-noise sets.

(b) The stationary laws $\{\mu_N\}$ are tight in $H^{-\kappa}$, and every weak limit μ is carried by fields admitting the decomposition $\Phi = X + Y$ with Y given by the global DPD solution map. By Lemma 144.27, this tightness follows from a cutoff-uniform moment bound in $H^{-\eta}$ for some $0 < \eta < \kappa$; the interacting stationary cutoff family therefore requires an independent constructive estimate establishing that moment bound before the weak-convergence passage is invoked. The corresponding free massive Gaussian estimate is Proposition 144.28. Lemma 144.29 and Remark 144.30 gives one precise route: a cutoff-uniform L^q bound for the normalized Wick-ordered density with respect to the massive Gaussian reference law implies the required interacting negative-Sobolev moments. If the cutoff Wick quartic satisfies the Nelson stability estimate (144.80), then Lemma 144.31 proves this L^q density bound.

(c) Reflection positivity of the cutoff measures μ_N holds for bounded cylinder observables depending on positive Euclidean time, and the polynomial Wick observables used to identify Schwinger functions obey the uniform-integrability bounds needed for the truncation step in Remark 144.36. This is a property of the chosen Euclidean regulator and must be proved for the regulator used in the limiting construction. For the lattice scalar regulator of Proposition 144.38, the bounded-observable positivity statement is proved at finite cutoff, and Lemma 144.42 proves finite-cutoff polynomial integrability. Passing polynomial observables uniformly through the continuum limit requires the exponential moment criterion of Remark 144.41. Using lattice positivity in the present Fourier-Galerkin stochastic assembly requires the bounded-cylinder and uniform-integrability comparison hypotheses stated in Remark 144.39. A sufficient condition for the bounded-cylinder comparison part is the common L^1 density-limit criterion of Lemma 144.32; a still more primitive sufficient condition, stated in terms of convergence of the renormalized interaction potentials and a uniform L^p stability estimate for their exponential weights, is Corollary 144.33. For the two-dimensional Wick quartic interaction, the potential convergence part of this condition follows from Remark 144.8; the remaining regulator-specific input is the uniform exponential-weight stability. The common finite cylinder-coordinate convergence for smeared Wick polynomials is supplied by Remark 144.7. Equivalently, under these common Wick-limit hypotheses and the uniform L^p stability bound, the bounded Wick-cylinder comparison is precisely (144.90). The common Wick-limit hypothesis itself can be checked from mixed covariance convergence by Lemma 144.6; for smooth compactly supported Fourier multiplier cutoffs, that covariance convergence is proved by Proposition 144.5. If, in addition, those smooth regulators satisfy the Nelson stability input, the density bounds, tightness, and bounded Wick-cylinder comparison are collected in Proposition 144.34.

Theorem 144.44 (Φ^4_2 stochastic-quantization assembly on the torus)**.** *Under Hypothesis 144.43, every weak limit μ of $\{\mu_N\}$ is an invariant law of the limiting DPD Markov semigroup. Its Schwinger functions are the limits of the finite-cutoff Wick-ordered Schwinger functions, and μ satisfies OS reflection positivity for cylinder observables. If, in addition, the resulting Schwinger hierarchy satisfies the moment-continuity, positive-time semigroup, and corrected OS-II linear-growth hypotheses in Remark 144.101, then the hierarchy determines a two-dimensional Wightman theory by Theorem 12.16.*

Proof. At finite cutoff the Langevin generator is the gradient generator of the finite-dimensional action defining μ_N. The integration-by-parts identity (144.2), together with the finite-dimensional semigroup hypotheses recorded in Lemma 144.1, therefore gives

$$\int P_t^{(N)} F \,\mathrm{d}\mu_N = \int F \,\mathrm{d}\mu_N$$

for every bounded smooth cylinder function F. Thus the word "stationary" at finite cutoff means reversibility and invariance of the Markov semigroup in the cutoff Hilbert space, not only a formal adjoint calculation for the infinitesimal generator.

The stochastic input is Proposition 144.9, which strengthens the equal-time Wick-power construction of Proposition 144.4 to path-space convergence and fixes the Wick normalization. Given this enhanced noise, the products in the DPD nonlinearity are defined by Lemma 144.10, and Theorem 144.14 gives the local solution map. Hypothesis 144.43(a) is precisely the global rough-energy and compact-continuity upgrade of the smooth estimate Lemma 144.15; in the Besov topology this upgrade is organized by Lemma 144.21. Thus the limiting Markov semigroup P_t is well-defined on the support of every weak stationary limit in Hypothesis 144.43(b), and $P_t^{(N)} F \to P_t F$ uniformly on the high-probability compact sets supplied by Hypothesis 144.43(a),(b).

Lemma 144.26 now applies with $E = H^{-\kappa}$. Therefore

$$\int P_t F \,\mathrm{d}\mu = \int F \,\mathrm{d}\mu$$

for every bounded continuous cylinder observable F, and hence μ is invariant. The convergence of Schwinger functions follows by applying the same weak convergence to products of smeared fields and Wick powers after approximating the polynomial observables by bounded cylinder observables; the uniform moment bounds needed for this approximation are part of the tightness and rough-energy input in Hypothesis 144.43(b).

For OS positivity, let Θ be Euclidean time reflection and let F be a cylinder observable supported in positive Euclidean time. The finite-cutoff reflection-positivity assumption gives

$$\int \overline{\Theta F}\, F \,\mathrm{d}\mu_N \geq 0.$$

Remark 144.36 passes this inequality to the weak limit, so

$$\int \overline{\Theta F}\, F \,\mathrm{d}\mu \geq 0.$$

This is OS reflection positivity on the cylinder algebra. Once the remaining OS growth and regularity estimates are verified, the OS reconstruction theorem of Chapter 12 applies. □

The theorem separates the logical assembly from the analytic estimates. In the chapter we have proved the finite-dimensional Langevin identity, the Sobolev Wick-power construction, the path-space enhanced-noise convergence, the Sobolev DPD local solution map, the smooth enhanced-noise energy inequality, and the abstract invariant-law passage. The sharp global two-dimensional theorem still requires four further inputs: a rough energy-to-Besov bound strong enough, by Lemma 144.21, to give global compact-continuity of the DPD solution map; a cutoff-uniform negative-Sobolev moment strong enough to imply tightness by Lemma 144.27; for Wick Φ^4_2 this moment follows from the density criterion Remark 144.30 once the uniform Nelson-type L^q density bound is proved, and Lemma 144.31 proves that bound from the Nelson exponential stability estimate; uniform integrability; and either finite-cutoff OS positivity for the stochastic regulator itself or a regulator-comparison theorem relating it to the OS-positive lattice regulator of Proposition 144.38. The abstract form of the latter implication is Remark 144.39; the bounded cylinder comparison follows from Lemma 144.32 if the two regulators have a common L^1 interaction-density limit and identical limiting cylinder coordinates; by Corollary 144.33, the common L^1 density limit follows from convergence in probability of the renormalized interaction potentials plus a uniform L^p stability bound on the exponential weights. For the Wick quartic potential, the convergence in probability is supplied by Remark 144.8, so the remaining constructive estimate is the uniform L^p stability of the weights in the chosen regulator family. The matching convergence of finite Wick-coordinate cylinder vectors is Remark 144.7; combined with the stability estimate, these inputs give the bounded comparison statement (144.90). The common Wick-limit hypothesis is reduced to a covariance estimate by Lemma 144.6, and for smooth Fourier multiplier cutoffs the needed covariance estimate follows from Proposition 144.5. The uniform-integrability input can be supplied by the exponential cylinder-moment criterion in Remark 144.41; finite quartic tails at each lattice cutoff are proved by Lemma 144.42, while uniformity as the cutoff is removed remains part of the constructive estimate. These inputs are listed explicitly in Hypothesis 144.43.

Sharp two-dimensional DPD closure status. The classical two-dimensional Da Prato–Debussche construction packages a local pathwise solution, global extension from the dissipative quartic drift, and identification of the invariant law with the Wick-ordered Euclidean Φ^4_2 measure on a finite torus. In this chapter that package is used through the explicit ingredients above, rather than as an imported black box. The mild form of (144.34) is

$$Y(\tau) = e^{\tau(\Delta-m^2)}Y(0) - \lambda \int_0^\tau e^{(\tau-s)(\Delta-m^2)}\mathcal{N}(Y(s), \mathbb{X}(s))\,\mathrm{d}s,$$

where $\mathcal{N}$ is the cubic expression in (144.34). Parabolic Schauder estimates increase spatial regularity by two derivatives relative to the forcing; the Sobolev version is the heat-kernel estimate (144.30), while the sharp two-dimensional fixed point uses the corresponding parabolic Besov–Holder estimates. Proposition 144.4 constructs the Wick powers in a Sobolev topology; the sharper fixed-point input places $:X^2:$ and $:X^3:$ in negative Holder/Besov spaces of arbitrarily small negative regularity. Lemma 144.10 and Theorem 144.14 give a self-contained Sobolev version of the local fixed-point argument. The sharp proof upgrades these Sobolev exponents to the scale-invariant parabolic Besov–Holder spaces. Multiplying the equation by Y, integrating over space, and using the sign of λY^4 gives an energy inequality with random lower-order forcing; the local rough-forcing estimate (144.62) is the precise remaining estimate that turns this energy mechanism into the global compact-continuity input of Hypothesis 144.43. The invariant law is identified through finite-cutoff Langevin reversibility, tightness, and regulator comparison; at fixed volume this comparison is assembled explicitly in Proposition 144.40. Those steps have been reduced above to Nelson stability for the chosen Wick quartic cutoff family, common Wick-coordinate limits, uniform integrability of polynomial cylinders, and the OS-II growth conditions in Remark 144.101. Thus the remaining two-dimensional work is a finite list of constructive estimates, not a separate theorem imported under the name Da Prato–Debussche.

144.5.5 Why the Two-Dimensional Decomposition Fails in Three Dimensions

Remark 144.45 (Sobolev DPD closure and the three-dimensional obstruction)*.* The Sobolev fixed-point mechanism used above for Φ^4_2 cannot close the dynamic Φ^4_3 equation by replacing 2 with 3. More precisely, let X be the three-dimensional stationary stochastic convolution. Its spatial regularity is

$$X \in H^{-1/2-\kappa-\varepsilon}(\mathbb{T}^3) \quad \text{for every } \varepsilon > 0,$$

and the cubic Wick power has the formal Sobolev regularity

$$:X^3: \in H^{-3/2-3\kappa-\varepsilon}(\mathbb{T}^3) \quad \text{for every } \varepsilon > 0.$$

If the remainder Y is sought in H^β, then even the minimal Sobolev multiplier requirement for the product YX is

$$\beta > \frac{1}{2} + \kappa. \tag{144.113}$$

The Duhamel map from the cubic forcing $:X^3:$ to H^β would require

$$\theta = \frac{\beta + \frac{3}{2} + 3\kappa}{2} > 1. \tag{144.114}$$

But the heat-kernel Duhamel estimate (144.31) is locally integrable at the upper time endpoint only for $\theta < 1$. Therefore the two-dimensional Sobolev DPD argument has no three-dimensional analogue.

The covariance of the massive three-dimensional Gaussian field has short-distance singularity $\|x-y\|^{-1}$. Equivalently, the field has Sobolev regularity below $-1/2$, and the k-th Wick power has the additive formal regularity below $-k/2$. With the small loss parameter κ, this gives the displayed regularities for X and $:X^3:$.

For multiplication in three spatial dimensions, a distribution of regularity $-1/2-\kappa$ can be multiplied by a Sobolev function of regularity β only when the sum of regularities is positive; this gives (144.113). If the forcing is in $H^{-3/2-3\kappa-\varepsilon}$, reaching H^β by the heat equation requires, after letting $\varepsilon \downarrow 0$, gain

$$2\theta > \beta + \frac{3}{2} + 3\kappa.$$

Combining this with (144.113) gives

$$\theta > \frac{\frac{1}{2} + \kappa + \frac{3}{2} + 3\kappa}{2} = 1 + 2\kappa.$$

This contradicts the condition $\theta < 1$ needed for the time singularity $(t-s)^{-\theta}$ to be integrable. If one instead requires H^β to be an algebra, then $\beta > 3/2$, and the obstruction is even stronger: $\theta > 3/2 + \frac{3}{2}\kappa$. Thus the failure is structural, not an artifact of a nonoptimal exponent choice.

144.6 Regularity Structures and Φ^4_3

In three spatial dimensions the decomposition $\Phi = X + Y$ is not sufficient: X has regularity $-\frac{1}{2} - \kappa$, and the products generated by the cubic drift fall below the classical multiplication threshold. Regularity structures supply the missing local expansion calculus.

144.6.1 Models, Modelled Distributions, and Reconstruction

Definition 144.46 (Regularity structure)**.** A regularity structure is a triple (A, T, G), where $A \subset \mathbb{R}$ is a locally finite set of homogeneities bounded below, $T = \bigoplus_{\alpha \in A} T_\alpha$ is a graded model space, and G is a structure group acting on T such that for $\tau \in T_\alpha$,

$$\Gamma\tau - \tau \in \bigoplus_{\beta<\alpha} T_\beta \qquad (\Gamma \in G).$$

A model on spacetime assigns to every point z a linear map $\Pi_z : T \to \mathcal{D}'(\mathbb{R}^{1+d})$ and to every pair z, z' an element $\Gamma_{zz'} \in G$, satisfying

$$\Pi_z = \Pi_{z'}\Gamma_{z'z}, \qquad \Gamma_{zz'}\Gamma_{z'z''} = \Gamma_{zz''},$$

together with analytic bounds compatible with the homogeneities.

Definition 144.47 (Parabolic model and modelled-distribution norms)**.** Let $\mathfrak{s} = (2, 1, \dots, 1)$ be the parabolic scaling on $\mathbb{R}^{1+d}$, let $|\mathfrak{s}| = d + 2$, and set

$$\|(\tau, x)\|_{\mathfrak{s}} = |\tau|^{1/2} + |x_1| + \cdots + |x_d|.$$

For $0 < \delta \le 1$, $z \in \mathbb{R}^{1+d}$, and $\varphi \in C^r_c(\mathbb{R}^{1+d})$, define

$$\varphi^\delta_z(w) = \delta^{-|\mathfrak{s}|}\varphi\big(\delta^{-2}(w_0 - z_0), \delta^{-1}(w_1 - z_1), \dots, \delta^{-1}(w_d - z_d)\big).$$

Let $\mathcal{B}_r$ be the set of such test functions supported in the unit $\mathfrak{s}$-ball and satisfying $\|\varphi\|_{C^r} \le 1$. Fix a compact set K and $\gamma > 0$. The model seminorm below γ is finite when

$$\|\Pi\|_{K;\gamma} = \sup_{\substack{z\in K,\ \alpha<\gamma \\ \tau\in T_\alpha,\ \|\tau\|_\alpha=1 \\ \varphi\in\mathcal{B}_r,\ 0<\delta\le 1}} \delta^{-\alpha}\left|\langle \Pi_z\tau, \varphi^\delta_z\rangle\right| < \infty$$

and

$$\|\Gamma\|_{K;\gamma} = \sup_{\substack{z,z'\in K,\ 0<\|z-z'\|_{\mathfrak{s}}\le 1 \\ \beta<\alpha<\gamma,\ \tau\in T_\alpha,\ \|\tau\|_\alpha=1}} \frac{\|(\Gamma_{zz'}\tau)_\beta\|_\beta}{\|z-z'\|_{\mathfrak{s}}^{\alpha-\beta}} < \infty.$$

Here $(\cdot)_\beta$ denotes projection to T_β. A modelled distribution of regularity γ on K is a function

$$F : K \longrightarrow T_{<\gamma} := \bigoplus_{\alpha<\gamma} T_\alpha$$

with finite norm

$$\|F\|_{\gamma;K} = \sup_{z\in K,\ \alpha<\gamma} \|F_\alpha(z)\|_\alpha + \sup_{\substack{z,z'\in K,\ 0<\|z-z'\|_{\mathfrak{s}}\le 1\\ \alpha<\gamma}} \frac{\|F_\alpha(z) - (\Gamma_{zz'}F(z'))_\alpha\|_\alpha}{\|z-z'\|_{\mathfrak{s}}^{\gamma-\alpha}}.$$

Lemma 144.48 (Coherence of a modelled local germ)**.** *Let F be a modelled distribution in the sense of Definition 144.47, and set $\zeta_z = \Pi_z F(z)$. If $z, z' \in K$, $\|z-z'\|_{\mathfrak{s}} \le \delta \le 1$, and $\varphi \in \mathcal{B}_r$, then*

$$\left|\left\langle \zeta_z - \zeta_{z'}, \varphi_z^\delta \right\rangle\right| \le C_K \|\Pi\|_{K;\gamma} \|F\|_{\gamma;K}\, \delta^\gamma.$$

Proof. The model identity gives

$$\Pi_{z'}F(z') = \Pi_z \Gamma_{zz'} F(z'),$$

hence

$$\zeta_z - \zeta_{z'} = \Pi_z\big(F(z) - \Gamma_{zz'}F(z')\big).$$

Decompose the vector in parentheses into homogeneous components. For each $\alpha < \gamma$, the modelled-distribution norm gives

$$\|(F(z) - \Gamma_{zz'}F(z'))_\alpha\|_\alpha \le \|F\|_{\gamma;K} \|z-z'\|_{\mathfrak{s}}^{\gamma-\alpha}.$$

The model bound gives

$$\left|\left\langle \Pi_z(F(z) - \Gamma_{zz'}F(z'))_\alpha, \varphi_z^\delta \right\rangle\right| \le \|\Pi\|_{K;\gamma} \|F\|_{\gamma;K} \delta^\alpha \|z-z'\|_{\mathfrak{s}}^{\gamma-\alpha}.$$

Since $\|z-z'\|_{\mathfrak{s}} \le \delta$ and the set $\{\alpha \in A : \alpha < \gamma\}$ is finite on compact homogeneity windows, the sum over α is bounded by the displayed constant times δ^γ. □

Theorem 144.49 (Compact finite-sector reconstruction theorem)**.** *Assume that the set $A_{<\gamma} = \{\alpha \in A : \alpha < \gamma\}$ is finite, assume $0 < \gamma < |\mathfrak{s}|$, let*

$$r > \max\{-\min A_{<\gamma},\, \gamma\},$$

and let the model seminorms of Definition 144.47 be finite on a compact parabolic neighborhood of K. For every modelled distribution F of regularity $\gamma > 0$ on that neighborhood, there is a unique distribution $\mathcal{R}F$ on the interior of K such that, for every $\varphi \in \mathcal{B}_r$, $z \in K$, and $0 < \delta \le 1$ with $\operatorname{supp} \varphi_z^\delta \subset K$,

$$\left|\left\langle \mathcal{R}F - \Pi_z F(z), \varphi_z^\delta \right\rangle\right| \le C_K (1 + \|\Pi\|_{K;\gamma})(1 + \|\Gamma\|_{K;\gamma}) \|F\|_{\gamma;K}\, \delta^\gamma. \tag{144.115}$$

Proof. Choose a compactly supported parabolic multiresolution system of class C^r: scaling functions φ_y^0 at scale 1, wavelets ψ_y^n at scale 2^{-n}, $y \in \Lambda_n$, with vanishing moments against all parabolic polynomials of degree $< r$, finite overlap at each scale, and the expansion formula

$$\eta = \sum_{y\in\Lambda_0} \langle \eta, \varphi_y^0 \rangle \varphi_y^0 + \sum_{n\ge 0} \sum_{y\in\Lambda_n} \langle \eta, \psi_y^n \rangle \psi_y^n$$

for every test function η supported in the interior of K. The wavelets are L^2-normalized, so $\psi_y^n = 2^{n|\mathfrak{s}|/2} \psi_y^{2^{-n}}$ in the notation of Definition 144.47.

Define a distribution by prescribing its coefficients

$$\langle \mathcal{R}F, \varphi_y^0\rangle = \langle \Pi_y F(y), \varphi_y^0\rangle, \qquad \langle \mathcal{R}F, \psi_y^n\rangle = \langle \Pi_y F(y), \psi_y^n\rangle.$$

The coefficient estimate for ψ_y^n is

$$|\langle \Pi_y F(y), \psi_y^n\rangle| \le C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K} 2^{-n(\alpha_0+|\mathfrak{s}|/2)}, \qquad \alpha_0 = \min A_{<\gamma}.$$

For a C^r test function η, the wavelet moment cancellation gives

$$|\langle \eta, \psi_y^n\rangle| \le C_\eta 2^{-n(r+|\mathfrak{s}|/2)}.$$

Only $O(2^{n|\mathfrak{s}|})$ wavelets at scale 2^{-n} meet $\operatorname{supp}\eta$, hence the absolute value of the scale-n contribution is bounded by

$$C_\eta\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K} 2^{n|\mathfrak{s}|} 2^{-n(\alpha_0+|\mathfrak{s}|/2)} 2^{-n(r+|\mathfrak{s}|/2)} = C_\eta\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K} 2^{-n(\alpha_0+r)}.$$

The hypothesis $r > -\alpha_0$ makes the series converge. Thus $\mathcal{R}F$ is a well-defined distribution.

It remains to prove the local estimate. Fix z, δ, and φ_z^δ. Put $\ell_n = 2^{-n}$. The coefficient of $\mathcal{R}F - \Pi_z F(z)$ against a wavelet ψ_y^n equals

$$\langle \Pi_y F(y) - \Pi_z F(z), \psi_y^n\rangle.$$

If ψ_y^n meets the support of φ_z^δ, then $\|y-z\|_{\mathfrak{s}} \le C(\ell_n+\delta)$. Split the wavelet expansion into coarse scales $\ell_n \ge \delta$ and fine scales $\ell_n < \delta$.

At a coarse scale, $\|y-z\|_{\mathfrak{s}} \le C\ell_n$, so Lemma 144.48, tested at scale ℓ_n, gives

$$|\langle \Pi_y F(y) - \Pi_z F(z), \psi_y^n\rangle| \le C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\ell_n^{\gamma+|\mathfrak{s}|/2}.$$

The r vanishing moments of ψ_y^n and the C^r bound of φ_z^δ give

$$|\langle \varphi_z^\delta, \psi_y^n\rangle| \le C\,\delta^r \ell_n^{-r-|\mathfrak{s}|/2}.$$

Only a bounded number of coarse-scale wavelets meet the support of φ_z^δ. Therefore the coarse contribution is bounded by

$$C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\delta^\gamma,$$

because

$$\sum_{\ell_n \ge \delta} \delta^r \ell_n^{\gamma-r} \le C\delta^\gamma$$

when $r > \gamma$. The scale-one scaling functions are handled in the same coarse block except that no moment cancellation is needed: their coefficients are bounded and their pairing with φ_z^δ is $O(\delta^{|\mathfrak{s}|})$, which is $O(\delta^\gamma)$ under the hypothesis $\gamma < |\mathfrak{s}|$.

At a fine scale, write the modelled-distribution difference by homogeneity:

$$\langle \mathcal{R}F - \Pi_z F(z), \psi_y^n\rangle = \sum_{\alpha<\gamma} \left\langle \Pi_z\big(\Gamma_{zy}F(y) - F(z)\big)_\alpha, \psi_y^n\right\rangle.$$

For wavelets meeting the support of φ_z^δ, $\|y-z\|_{\mathfrak{s}} \le C\delta$. The α-component of the modelled-distribution difference is therefore bounded by

$$C\|F\|_{\gamma;K}\delta^{\gamma-\alpha}.$$

Testing the corresponding model component at wavelet scale ℓ_n gives

$$\big|\big\langle \Pi_z\big(\Gamma_{zy}F(y) - F(z)\big)_\alpha, \psi_y^n\big\rangle\big| \le C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\delta^{\gamma-\alpha}\ell_n^{\alpha+|\mathfrak{s}|/2}.$$

The wavelet moment estimate in the opposite scale regime gives

$$|\langle \varphi_z^\delta, \psi_y^n\rangle| \le C\,\delta^{-|\mathfrak{s}|-r}\ell_n^{r+|\mathfrak{s}|/2}.$$

There are $O((\delta/\ell_n)^{|\mathfrak{s}|})$ fine-scale wavelets meeting the support of φ_z^δ. The scale-n contribution of a fixed homogeneity α is thus bounded by

$$C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\delta^{\gamma-\alpha-r}\ell_n^{\alpha+r}.$$

Since $r > -\alpha$, the sum over $\ell_n < \delta$ is bounded by

$$C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\delta^{\gamma-\alpha-r}\delta^{\alpha+r} = C\|\Pi\|_{K;\gamma}\|F\|_{\gamma;K}\delta^{\gamma}.$$

There are only finitely many $\alpha < \gamma$, so summing the homogeneities proves (144.115).

For uniqueness, let U be the difference of two distributions satisfying (144.115). Choose a non-negative $\chi \in C_c^r$ with integral one. For any test function η with support in the interior of K,

$$\langle U, \eta\rangle = \lim_{\delta\downarrow 0}\int \eta(z)\langle U, \chi_z^\delta\rangle\,\mathrm{d}z.$$

The bound $|\langle U, \chi_z^\delta\rangle| \le C\delta^\gamma$ and $\gamma > 0$ force the limit to vanish. Hence $U = 0$. $\square$

Theorem 144.49 supplies the reconstruction component of the finite-sector theory used by the local Φ^4_3 regularity structure. The still-open part for dynamic Φ^4_3 is not the reconstruction step itself; it is the construction of the BPHZ-renormalized random model with uniform analytic bounds, the convergence of those models as the mollifier is removed, and the nonlinear fixed-point argument in the corresponding modelled-distribution spaces.

144.6.2 Random Model Convergence and Finite-Chaos Coordinates

Lemma 144.50 (Dyadic Cauchy criterion for random models)**.** *Fix a compact parabolic set K, a regularity threshold $\gamma > 0$, and a finite homogeneity set $A_{<\gamma}$. Choose the test regularity*

$$r > -\min A_{<\gamma}.$$

Let $Z_n = (\Pi^{(n)}, \Gamma^{(n)})$, $n \ge 1$, be random models on this finite sector. Define

$$N_n = 1 + \|\Pi^{(n)}\|_{K;\gamma} + \|\Gamma^{(n)}\|_{K;\gamma},$$

where the seminorms are those of Definition 144.47. Let $d_{K;\gamma}(Z, Z')$ denote the corresponding model distance, obtained by replacing Π and Γ in those seminorms by $\Pi - \Pi'$ and $\Gamma - \Gamma'$. Suppose that, for some $p \ge 1$, $\rho > 0$, and constants $C_N, C_D < \infty$,

$$\sup_{n\ge 1}\mathbb{E}N_n^p \le C_N, \qquad \mathbb{E}\,d_{K;\gamma}(Z_{n+1}, Z_n)^p \le C_D 2^{-p\rho n}. \tag{144.116}$$

Then there exists a random model

$$Z_\infty = (\Pi^{(\infty)}, \Gamma^{(\infty)})$$

on the same finite sector such that

$$d_{K;\gamma}(Z_n, Z_\infty) \longrightarrow 0 \quad \textit{in } L^p(\Omega) \textit{ and almost surely.}$$

More precisely,

$$(\mathbb{E}\, d_{K;\gamma}(Z_n, Z_\infty)^p)^{1/p} \le \frac{C_D^{1/p}}{1-2^{-\rho}}\, 2^{-\rho n}. \tag{144.117}$$

For every $0 < \rho' < \rho$, there is an almost surely finite random constant $C_{\rho'}(\omega)$ such that

$$d_{K;\gamma}(Z_n(\omega), Z_\infty(\omega)) \le C_{\rho'}(\omega) 2^{-\rho' n} \tag{144.118}$$

for all n. The limiting model satisfies

$$\mathbb{E}\big(1 + \|\Pi^{(\infty)}\|_{K;\gamma} + \|\Gamma^{(\infty)}\|_{K;\gamma}\big)^p \le C_N.$$

Proof. Put

$$D_n = d_{K;\gamma}(Z_{n+1}, Z_n).$$

Minkowski's inequality and (144.116) give, for $m > n$,

$$(\mathbb{E}\, d_{K;\gamma}(Z_m, Z_n)^p)^{1/p} \le \sum_{j=n}^{m-1} (\mathbb{E} D_j^p)^{1/p} \le C_D^{1/p} \sum_{j=n}^{m-1} 2^{-\rho j}.$$

The geometric series is Cauchy, so Z_n is Cauchy in L^p for the model distance. Letting $m \to \infty$ after constructing the limit below will give (144.117).

We now construct the pointwise limiting model on the event where $\sum_{n\ge 1} D_n < \infty$. This event has probability one, because

$$\mathbb{E} \sum_{n\ge 1} D_n \le C_D^{1/p} \sum_{n \ge 1} 2^{-\rho n} < \infty.$$

Fix ω in this event. For each $z \in K$, $\alpha < \gamma$, and $\tau \in T_\alpha$, the numbers

$$\Big\langle \Pi_z^{(n)} \tau, \varphi_z^\delta \Big\rangle$$

are Cauchy uniformly over $\varphi \in \mathcal{B}_r$ and $\delta \in (0,1]$ after multiplication by $\delta^{-\alpha}$. Since $r > -\min A_{<\gamma}$, the dyadic wavelet expansion used in the proof of Theorem 144.49 implies that this Cauchy property determines a unique distribution, denoted $\Pi_z^{(\infty)}\tau$, on the interior of K. The same distance bound gives Cauchy convergence of each finite-dimensional component $(\Gamma_{zz'}^{(n)}\tau)_\beta$; define its limit to be $(\Gamma_{zz'}^{(\infty)}\tau)_\beta$.

The algebraic model identities pass to the limit. For instance, at every finite cutoff,

$$\Pi_{z'}^{(n)}\tau = \Pi_z^{(n)} \Gamma_{zz'}^{(n)} \tau.$$

Pair this identity with an arbitrary C^r test function supported in the interior of K, expand the right-hand side into the finitely many homogeneous components of $\Gamma_{zz'}^{(n)}\tau$, and take $n \to \infty$. The distributional convergence of the Π-components and the finite-dimensional convergence of the Γ-components give

$$\Pi_{z'}^{(\infty)}\tau = \Pi_z^{(\infty)}\Gamma_{zz'}^{(\infty)}\tau.$$

The identities $\Gamma_{zz}^{(n)} = \mathbf{1}$ and $\Gamma_{zz'}^{(n)}\Gamma_{z'z''}^{(n)} = \Gamma_{zz''}^{(n)}$ are polynomial identities among finitely many matrix entries on $\bigoplus_{\alpha<\gamma} T_\alpha$, so their limits satisfy the same identities.

The analytic bounds also pass to the limit. For every fixed normalized test configuration and every fixed reexpansion component, the limiting value is the limit of the finite-cutoff values. Taking the supremum gives

$$1 + \|\Pi^{(\infty)}\|_{K;\gamma} + \|\Gamma^{(\infty)}\|_{K;\gamma} \le \liminf_{n\to\infty} N_n.$$

Fatou's lemma therefore gives the displayed L^p bound on the limiting model. The same telescoping estimate gives, on the probability-one event,

$$d_{K;\gamma}(Z_n, Z_\infty) \le \sum_{j=n}^{\infty} D_j.$$

Taking the L^p norm of this inequality proves (144.117).

It remains to prove the almost-sure rate. Let $0 < \rho' < \rho$. Markov's inequality gives

$$\mathbb{P}(D_n > 2^{-\rho' n}) \le C_D\, 2^{-p(\rho-\rho')n}.$$

The right-hand side is summable in n. Borel–Cantelli implies that $D_n \le 2^{-\rho' n}$ for all sufficiently large n, almost surely. The finitely many earlier terms are absorbed into $C_{\rho'}(\omega)$, and the tail bound

$$\sum_{j=n}^{\infty} 2^{-\rho' j} = \frac{2^{-\rho' n}}{1 - 2^{-\rho'}}$$

proves (144.118). □

Lemma 144.50 reduces the convergence of a renormalized random model to two explicit analytic estimates: a uniform moment bound for the model seminorm and a dyadic Cauchy moment estimate for successive cutoff scales. In a BPHZ construction these estimates are proved tree by tree, after the forest character has removed every divergent local subtree and after the remaining kernels have been bounded in the parabolic model norm. The lemma above proves what those estimates imply; it does not prove the estimates for the concrete dynamic Φ^4_3 trees.

Lemma 144.51 (Finite Wiener-chaos moment bound)**.** *Let H be a real Hilbert space and let $\xi : H \to L^2(\Omega)$ be an isonormal Gaussian process:*

$$\mathbb{E}\xi(h) = 0, \qquad \mathbb{E}\xi(h)\xi(k) = \langle h, k\rangle_H.$$

For $q \ge 1$ and $f \in H^{\odot q}$, let $I_q(f)$ denote the q-fold Wick multiple integral, normalized by

$$I_q(h^{\otimes q}) = \|h\|_H^q H_q\left(\frac{\xi(h)}{\|h\|_H}\right) \quad (h \neq 0),$$

where H_q is the probabilists' Hermite polynomial and extension to $H^{\odot q}$ is by polarization and completion. Set $I_0(c) = c$. Then

$$\mathbb{E}\, I_q(f) I_{q'}(g) = \delta_{qq'} q!\, \langle f, g\rangle_{H^{\otimes q}}. \tag{144.119}$$

For every integer $m \geq 1$ there is a finite constant $C_{q,m}$, depending only on q and m, such that

$$\mathbb{E}|I_q(f)|^{2m} \leq C_{q,m}\|f\|_{H^{\otimes q}}^{2m}. \tag{144.120}$$

Proof. The exponential definition of Wick ordering is

$$:\exp \xi(h) := \exp\left(\xi(h) - \frac{1}{2}\|h\|_H^2\right).$$

For $s, t \in \mathbb{R}$,

$$\begin{aligned}\mathbb{E}\big(:\exp t\xi(h)::\exp s\xi(k):\big) &= \exp\left(\frac{1}{2}\|th+sk\|_H^2 - \frac{1}{2}t^2\|h\|_H^2 - \frac{1}{2}s^2\|k\|_H^2\right) \\ &= \exp(ts\langle h,k\rangle_H).\end{aligned}$$

Comparing the coefficient of $t^q s^{q'}$ gives

$$\mathbb{E}\, I_q(h^{\otimes q}) I_{q'}(k^{\otimes q'}) = \delta_{qq'} q!\, \langle h,k\rangle_H^q.$$

Polarization gives (144.119) for finite sums of pure symmetric tensors, and completion gives the general case.

For the even moment, first take f to be a finite-rank symmetric tensor. The needed pairing formula is derived from the same generating function. For vectors $h_1, \ldots, h_N \in H$,

$$\mathbb{E}\prod_{\ell=1}^{N} :\exp t_\ell \xi(h_\ell) := \exp\left(\sum_{1\leq i<j\leq N} t_i t_j \langle h_i, h_j\rangle_H\right).$$

Expanding the right-hand side and comparing coefficients gives pairings only between distinct Wick blocks. By multilinearity, the product of $2m$ finite-rank Wick monomials therefore obeys

$$\mathbb{E}\, I_q(f)^{2m} = \sum_{\pi\in\mathcal{P}_{q,2m}} C_\pi(f, \ldots, f).$$

Here $\mathcal{P}_{q,2m}$ is the finite set of pairings of the $\{1, \ldots, 2m\} \times \{1, \ldots, q\}$ labels that pair no two labels in the same block $\{\ell\} \times \{1, \ldots, q\}$, and C_π is the complete tensor contraction prescribed by π. Every C_π is a composition of tensor permutations and Hilbert contractions. Tensor permutations are unitary and each Hilbert contraction has operator norm ≤ 1, hence

$$|C_\pi(f, \ldots, f)| \leq \|f\|_{H^{\otimes q}}^{2m}.$$

Therefore

$$\mathbb{E}|I_q(f)|^{2m} = \mathbb{E}I_q(f)^{2m} \leq |\mathcal{P}_{q,2m}|\, \|f\|_{H^{\otimes q}}^{2m}.$$

Take $C_{q,m} = |\mathcal{P}_{q,2m}|$ for finite-rank tensors. Approximate a general $f \in H^{\odot q}$ by finite-rank tensors in $H^{\otimes q}$. The isometry (144.119) gives convergence in $L^2(\Omega)$, hence a subsequence converges almost surely. Fatou's lemma applied to that subsequence gives the same $2m$-moment bound for the limit. This proves (144.120). $\square$

Kernel bounds imply stochastic coordinate moments. Let $\mathcal{A}$ be an index set and let $\sigma : \mathcal{A} \to (0, \infty)$ be a deterministic scale weight. Suppose that random variables $Y_n(a)$, $a \in \mathcal{A}$, have finite chaos expansions

$$Y_n(a) = \sum_{q=0}^{Q} I_q(f_{n,a,q}), \qquad f_{n,a,q} \in H^{\odot q},$$

and that, for constants $B_q, \widetilde{B}_q < \infty$,

$$\|f_{n,a,q}\|_{H^{\otimes q}} \le B_q \sigma(a), \qquad \|f_{n+1,a,q} - f_{n,a,q}\|_{H^{\otimes q}} \le \widetilde{B}_q 2^{-\rho n} \sigma(a).$$

Then, for every integer $m \ge 1$, there are finite constants $M_m, \widetilde{M}_m$, depending only on m, Q, and the displayed kernel constants, such that

$$\mathbb{E}|Y_n(a)|^{2m} \le M_m \sigma(a)^{2m}, \qquad \mathbb{E}|Y_{n+1}(a) - Y_n(a)|^{2m} \le \widetilde{M}_m 2^{-2m\rho n} \sigma(a)^{2m}.$$

Use the elementary convexity inequality

$$\left| \sum_{q=0}^{Q} x_q \right|^{2m} \le (Q+1)^{2m-1} \sum_{q=0}^{Q} |x_q|^{2m}.$$

Apply Lemma 144.51 to each chaos component. The deterministic $q = 0$ component is included with $C_{0,m} = 1$. This gives

$$M_m = (Q+1)^{2m-1} \sum_{q=0}^{Q} C_{q,m} B_q^{2m}$$

and the same expression with B_q replaced by $\widetilde{B}_q$ for $\widetilde{M}_m$. The factor $2^{-2m\rho n}$ comes from raising the dyadic kernel-difference estimate to the $2m$-th power.

The kernel-to-moment calculation above is the stochastic part of a BPHZ model estimate. A concrete tree calculation must still prove the deterministic kernel bounds for every tested model coordinate and must upgrade the resulting pointwise coordinate estimates to the full model seminorm by spatial and scale regularity estimates. Once those deterministic steps are done, Lemma 144.50 turns the coordinate estimates into convergence of the random model.

Proposition 144.52 (Dual-norm finite-chaos estimate)**.** *Let E be a separable Banach space with dual E'. For a Hilbert space H, write $H^{\odot q} \widehat{\otimes}_\pi E'$ for the projective tensor completion of the algebraic tensor product, with norm*

$$\|F\|_\pi = \inf \left\{ \sum_{j=1}^{N} \|f_j\|_{H^{\otimes q}} \|\ell_j\|_{E'} : F = \sum_{j=1}^{N} f_j \otimes \ell_j \right\},$$

where the infimum is over all finite representations; the completed norm is obtained by taking limits. If $F \in H^{\odot q} \widehat{\otimes}_\pi E'$, define the E'-valued chaos integral $I_q(F)$ by completion from

$$I_q\left(\sum_{j=1}^{N} f_j \otimes \ell_j \right) = \sum_{j=1}^{N} I_q(f_j) \ell_j.$$

Then, for every integer $m \geq 1$,

$$\| \|I_q(F)\|_{E'} \|_{L^{2m}(\Omega)} \leq C_{q,m} \|F\|_\pi, \tag{144.121}$$

where $C_{q,m}$ is any constant satisfying (144.120) and $C_{q,m} \geq 1$.

Consequently, suppose that E'-valued random variables $Y_n(a)$, $a \in \mathcal{A}$, have finite chaos expansions

$$Y_n(a) = \sum_{q=0}^{Q_0} I_q(F_{n,a,q}), \qquad F_{n,a,q} \in H^{\odot q} \widehat{\otimes}_\pi E',$$

and that deterministic weights $\sigma(a)$ and $\omega(a,b)$ obey

$$\|F_{n,a,q}\|_\pi \leq B_q \sigma(a), \qquad \|F_{n,b,q} - F_{n,a,q}\|_\pi \leq B_q^{\mathrm{ed}} \omega(a,b).$$

Then

$$\mathbb{E}\|Y_n(a)\|_{E'}^{2m} \leq M_m \sigma(a)^{2m}, \qquad \mathbb{E}\|Y_n(b) - Y_n(a)\|_{E'}^{2m} \leq M_m^{\mathrm{ed}} \omega(a,b)^{2m},$$

with

$$M_m = \left(\sum_{q=0}^{Q_0} C_{q,m} B_q \right)^{2m}, \qquad M_m^{\mathrm{ed}} = \left(\sum_{q=0}^{Q_0} C_{q,m} B_q^{\mathrm{ed}} \right)^{2m}.$$

The same conclusion holds with an additional factor $2^{-\rho n}$ in the projective-norm bounds for cutoff differences; the $2m$-th moments then carry the factor $2^{-2m\rho n}$.

Proof. First take $F = \sum_{j=1}^N f_j \otimes \ell_j$. The triangle inequality in E' and Minkowski's inequality in $L^{2m}(\Omega)$ give

$$\begin{aligned} \| \|I_q(F)\|_{E'} \|_{L^{2m}} &\leq \sum_{j=1}^N \| |I_q(f_j)| \, \|\ell_j\|_{E'} \|_{L^{2m}} \\ &\leq C_{q,m} \sum_{j=1}^N \|f_j\|_{H^{\otimes q}} \|\ell_j\|_{E'}. \end{aligned}$$

Taking the infimum over finite representations proves (144.121) on the algebraic tensor product. If $F^{(N)} \to F$ in the projective norm, the same inequality applied to $F^{(N)} - F^{(M)}$ shows that $I_q(F^{(N)})$ is Cauchy in $L^{2m}(\Omega; E')$; its limit is the stated completion, and the bound passes to the limit.

For a finite chaos expansion, apply (144.121) to each q and use Minkowski:

$$\| \|Y_n(a)\|_{E'} \|_{L^{2m}} \leq \sum_{q=0}^{Q_0} C_{q,m} \|F_{n,a,q}\|_\pi \leq \left(\sum_{q=0}^{Q_0} C_{q,m} B_q \right) \sigma(a).$$

Raising to the $2m$-th power gives the first estimate. Replacing $F_{n,a,q}$ by $F_{n,b,q} - F_{n,a,q}$ gives the edge estimate. Replacing that difference by a cutoff difference with projective-norm bound $2^{-\rho n} B_q \sigma(a)$, or by an edge cutoff difference with $2^{-\rho n} B_q^{\mathrm{ed}} \omega(a,b)$, gives the stated cutoff factor. $\square$

Apply Proposition 144.52 with

$$E = E_r := \{\varphi \in C^r(\mathbb{R}^{1+3}) : \operatorname{supp}\varphi \subset B_{\mathfrak{s}}(0,1)\}, \qquad \|\varphi\|_{E_r} = \|\varphi\|_{C^r}.$$

Then E_r' is the space in which a tested model coordinate acts before the supremum over $\varphi \in \mathcal{B}_r$ is taken. For a fixed physical parameter a, an E_r'-valued chaos expansion of the functional

$$\varphi \longmapsto \delta^{-|\tau|}\langle \Pi_z^{(n)}\tau, \varphi_z^\delta\rangle$$

has dual norm exactly

$$\sup_{\varphi\in\mathcal{B}_r} \delta^{-|\tau|}|\langle \Pi_z^{(n)}\tau, \varphi_z^\delta\rangle|.$$

Thus the correct route to the $Q_{n,\tau}^{\#}$ estimates is not to net the test-function ball. It is to prove projective tensor bounds for the E_r'-valued BPHZ kernels and then apply the dual-norm chaos estimate above.

Lemma 144.53 (Projective kernel estimate for dual-norm bounds)**.** *Let E be a separable Banach space, let H be a Hilbert space, and let (S,μ) be a σ-finite measure space. Fix $q \geq 0$. Suppose that $f : S \to H^{\odot q}$ is strongly measurable and that $\ell : S \to E'$ is strongly measurable, with*

$$\int_S \|f(s)\|_{H^{\otimes q}}\|\ell(s)\|_{E'}\,\mathrm{d}\mu(s) < \infty.$$

Then the Bochner integral

$$F = \int_S f(s)\otimes \ell(s)\,\mathrm{d}\mu(s)$$

defines an element of $H^{\odot q}\widehat{\otimes}_\pi E'$, and

$$\|F\|_\pi \leq \int_S \|f(s)\|_{H^{\otimes q}}\|\ell(s)\|_{E'}\,\mathrm{d}\mu(s). \tag{144.122}$$

Let X be a parameter set. Suppose $f_x : S \to H^{\odot q}$ and $\ell_x : S \to E'$ satisfy the preceding hypotheses for every $x \in X$. If deterministic functions $\Sigma : X \to [0,\infty)$ and $\Omega : X\times X \to [0,\infty)$ obey

$$\int_S \|f_x(s)\|\,\|\ell_x(s)\|\,\mathrm{d}\mu(s) \leq B\Sigma(x) \tag{144.123}$$

and

$$\begin{aligned}\int_S &\|f_x(s)-f_y(s)\|\,\|\ell_x(s)\|\,\mathrm{d}\mu(s)\\ &+\int_S \|f_y(s)\|\,\|\ell_x(s)-\ell_y(s)\|\,\mathrm{d}\mu(s) \leq B_{\mathrm{ed}}\Omega(x,y),\end{aligned} \tag{144.124}$$

then

$$\|F_x\|_\pi \leq B\Sigma(x), \qquad \|F_x - F_y\|_\pi \leq B_{\mathrm{ed}}\Omega(x,y),$$

where

$$F_x = \int_S f_x(s)\otimes \ell_x(s)\,\mathrm{d}\mu(s).$$

Proof. The algebraic tensor norm is a crossnorm:

$$\|u \otimes \lambda\|_\pi = \|u\|_{H^{\otimes q}} \|\lambda\|_{E'}.$$

Hence

$$\|f(s) \otimes \ell(s)\|_\pi = \|f(s)\|_{H^{\otimes q}} \|\ell(s)\|_{E'}.$$

The assumed integrability therefore makes $s \mapsto f(s) \otimes \ell(s)$ Bochner integrable as a map into $H^{\odot q} \widehat{\otimes}_\pi E'$. Approximate this map by simple functions G_N in $L^1(S; H^{\odot q} \widehat{\otimes}_\pi E')$. For a simple function $G_N = \sum_a \mathbf{1}_{S_a} u_a \otimes \lambda_a$,

$$\left\| \int_S G_N \, \mathrm{d}\mu \right\|_\pi \le \sum_a \mu(S_a) \|u_a\| \, \|\lambda_a\| = \int_S \|G_N(s)\|_\pi \, \mathrm{d}\mu(s).$$

Passing to the L^1 limit gives (144.122).

The base estimate is (144.122) applied to (f_x, ℓ_x). For the edge estimate write

$$F_x - F_y = \int_S (f_x(s) - f_y(s)) \otimes \ell_x(s) \, \mathrm{d}\mu(s) + \int_S f_y(s) \otimes (\ell_x(s) - \ell_y(s)) \, \mathrm{d}\mu(s).$$

Applying (144.122) to the two terms and using (144.124) proves the displayed bound. □

The criterion has a concrete meaning for tested model kernels. With

$$E_r = \{\varphi \in C^r(\mathbb{R}^{1+3}) : \operatorname{supp} \varphi \subset B_{\mathfrak{s}}(0,1)\},$$

the point-evaluation functional

$$\delta_u(\varphi) = \varphi(u)$$

has $\|\delta_u\|_{E_r'} \le 1$. If $0 < \theta \le \min\{r, 1\}$, then

$$\|\delta_u - \delta_v\|_{E_r'} = \sup_{\|\varphi\|_{C^r} \le 1} |\varphi(u) - \varphi(v)| \le C_r \|u - v\|_{\mathfrak{s}}^\theta. \tag{144.125}$$

The same bound holds for a finite sum of derivative evaluations $\partial^a \delta_u$ whenever $|a|_{\mathfrak{s}} + \theta \le r$, after replacing C_r by a constant depending on r and a. Thus a BPHZ-tested chaos kernel represented as

$$F_{x,q} = \int_S f_{x,q}(s) \otimes \delta_{u_x(s)} \, \mathrm{d}\mu(s)$$

is controlled by

$$\|F_{x,q}\|_\pi \le \int_S \|f_{x,q}(s)\|_{H^{\otimes q}} \, \mathrm{d}\mu(s),$$

and its parameter increments are controlled by the two visible mechanisms: variation of the Hilbert kernel $f_{x,q}$, and variation of the evaluation point $u_x(s)$ measured by (144.125). These are the deterministic estimates that the tree-by-tree BPHZ analysis must prove for the six Π-coordinates in the strict negative sector.

Lemma 144.54 (Dyadic parabolic convolution bound)**.** *Let* $(\mathbb{R}^D, \mathfrak{s})$ *be a parabolically scaled space with homogeneous dimension*

$$Q = |\mathfrak{s}|.$$

Assume the parabolic balls satisfy

$$|B_{\mathfrak{s}}(0,r)| \le V r^Q, \qquad 0<r\le 1.$$

Let $a,b>0$. For $i,j\ge 0$, let K_i, L_j be measurable kernels such that, for constants A, C_K, C_L,

$$\operatorname{supp} K_i, \operatorname{supp} L_i \subset B_{\mathfrak{s}}(0, A2^{-i}),$$

and

$$|K_i(x)| \le C_K 2^{(Q-a)i}, \qquad |L_i(x)| \le C_L 2^{(Q-b)i}.$$

Define the k-th output scale of the convolution by

$$M_k = \sum_{\min(i,j)=k} K_i * L_j.$$

Then the series defining M_k converges absolutely in L^∞,

$$\operatorname{supp} M_k \subset B_{\mathfrak{s}}(0, 2A2^{-k}),$$

and

$$\|M_k\|_{L^\infty} \le C\, C_K C_L\, 2^{(Q-a-b)k}, \tag{144.126}$$

where

$$C = VA^Q \left(\frac{1}{1-2^{-b}} + \frac{2^{-a}}{1-2^{-a}} \right).$$

Consequently

$$\|M_k\|_{L^1} \le C'\, C_K C_L\, 2^{-(a+b)k} \tag{144.127}$$

for a constant C' depending only on A, V, a, b, Q.

Proof. For fixed i,j, the convolution is supported in

$$B_{\mathfrak{s}}(0, A2^{-i}) + B_{\mathfrak{s}}(0, A2^{-j}) \subset B_{\mathfrak{s}}(0, 2A2^{-\min(i,j)}).$$

The pointwise bound follows by estimating the volume of the smaller support:

$$\begin{aligned} |(K_i * L_j)(x)| &\le C_K C_L 2^{(Q-a)i+(Q-b)j} \left| B_{\mathfrak{s}}\big(0, A2^{-\max(i,j)}\big) \right| \\ &\le VA^Q C_K C_L 2^{(Q-a)i+(Q-b)j-Q\max(i,j)}. \end{aligned}$$

Fix k. First take $i=k$ and $j=k+r$, $r\ge 0$. The preceding estimate gives

$$|(K_k * L_{k+r})(x)| \le VA^Q C_K C_L 2^{(Q-a-b)k} 2^{-br}.$$

Summing $r\ge 0$ gives the first geometric factor in C. Next take $j=k$ and $i=k+r$, $r\ge 1$; the term $r=0$ has already been counted. Then

$$|(K_{k+r} * L_k)(x)| \le VA^Q C_K C_L 2^{(Q-a-b)k} 2^{-ar}.$$

Summing $r\ge 1$ gives the second geometric factor. This proves absolute convergence in L^∞ and (144.126).

The support statement for M_k follows from the support statement for each summand with $\min(i,j)=k$. Multiplying the L^∞ estimate by

$$|B_{\mathfrak{s}}(0, 2A2^{-k})| \le V(2A)^Q 2^{-Qk}$$

gives (144.127). ∎

The exponents in Lemma 144.54 are the deterministic scale arithmetic behind many model-coordinate estimates. A kernel of order a has scale-i size $2^{(Q-a)i}$ and L^1-size 2^{-ai}. After convolution with an order-b kernel, the output scale $k=\min(i,j)$ has size $2^{(Q-a-b)k}$, which is exactly the size of an order-$(a+b)$ kernel. In a BPHZ proof, Taylor subtraction at divergent subgraphs supplies additional powers of the small scale; the proposition above is the unsubtracted convolution estimate to which those extra powers are attached.

Proposition 144.55 (Gaussian Wick-coordinate scale estimates)**.** *Let $Q=5$ and let $\mathfrak{s}=(2,1,1,1)$. Fix $0<\theta\le 1$, $r>\theta$, and $\kappa>0$. For*

$$x=(z,\delta),\qquad 0<\delta\le 1,$$

let

$$\mathsf{D}_\delta(t,x_1,x_2,x_3)=(\delta^2 t,\delta x_1,\delta x_2,\delta x_3),$$

write

$$\psi_x^\varphi(u)=\delta^{-Q}\varphi(\mathsf{D}_\delta^{-1}(u-z)),\qquad \varphi\in E_r,\quad \|\varphi\|_{C^r}\le 1. \tag{144.128}$$

First let ξ be white noise on $\mathbb{R}^{1+3}$, normalized by

$$\mathbb{E}\,\xi(f)\xi(g)=\int f(u)g(u)\,\mathrm{d}u.$$

Then

$$\left\|\delta^{Q/2+\kappa}\xi(\psi_x^\varphi)\right\|_{L^{2m}(\Omega)}\le C_{m,r}\delta^\kappa \tag{144.129}$$

uniformly in x and φ. If $x=(z,\delta)$ and $y=(z',\delta')$ have $\delta,\delta'\in[2^{-M-1},2^{-M}]$ and

$$\eta=2^M\|z-z'\|_{\mathfrak{s}}+2^M|\delta-\delta'|\le 1,$$

then

$$\left\|\delta^{Q/2+\kappa}\xi(\psi_x^\varphi)-\delta'^{Q/2+\kappa}\xi(\psi_y^\varphi)\right\|_{L^{2m}(\Omega)}\le C_{m,r,\kappa}\,2^{-\kappa M}\eta^\theta. \tag{144.130}$$

Next let X be a centered Gaussian field with covariance $C(u,v)$ such that, on the one-neighborhood of the compact region under consideration,

$$|C(u,v)|\le A\|u-v\|_{\mathfrak{s}}^{-1}. \tag{144.131}$$

For $k=1,2,3$, let $:X^k:$ be the Wick power defined by this covariance. Then

$$\left\|\delta^{k/2+k\kappa}\langle :X^k:,\psi_x^\varphi\rangle\right\|_{L^{2m}(\Omega)}\le C_{k,m,r,A}\delta^{k\kappa}. \tag{144.132}$$

If x,y lie in the same dyadic scale annulus as above, then

$$\left\|\delta^{k/2+k\kappa}\langle :X^k:,\psi_x^\varphi\rangle-\delta'^{k/2+k\kappa}\langle :X^k:,\psi_y^\varphi\rangle\right\|_{L^{2m}(\Omega)}\le C_{k,m,r,A,\kappa}\,2^{-k\kappa M}\eta^\theta. \tag{144.133}$$

Consequently, for the Gaussian coordinates

$$\Xi,\quad X,\quad X^2,\quad X^3$$

in the strict negative sector, the physical scale slack appearing in the negative-sector coordinate-control consequence is

$$\sigma_\Xi=\kappa,\qquad \sigma_{X^k}=k\kappa\quad(k=1,2,3),$$

before the remaining finite-net entropy is paid by taking a sufficiently high moment.

Proof. For white noise,

$$\|\psi_x^\varphi\|_{L^2}^2 = \delta^{-2Q} \int \left|\varphi(\mathsf{D}_\delta^{-1}(u-z))\right|^2 \,\mathrm{d}u = \delta^{-Q}\|\varphi\|_{L^2}^2 \le C_r \delta^{-Q}.$$

The Gaussian moment formula gives

$$\|\xi(\psi_x^\varphi)\|_{L^{2m}} \le C_m \|\psi_x^\varphi\|_{L^2},$$

and multiplication by $\delta^{Q/2+\kappa}$ proves (144.129).

For the edge estimate, compare the two rescaled test functions on the common parabolic ball of radius $C2^{-M}$ containing their supports. The C^r-bound and $r > \theta$ give

$$\left\|\delta^{Q/2+\kappa}\psi_x^\varphi - \delta'^{Q/2+\kappa}\psi_y^\varphi\right\|_{L^2} \le C_{r,\kappa} 2^{-\kappa M}\eta^\theta. \tag{144.134}$$

Indeed, in the scale 2^{-M} variables the normalized amplitudes are bounded, the displacement of the arguments is $\le C\eta$, and the prefactor $\delta^{Q/2+\kappa}\delta^{-Q}$ has L^2-size comparable to δ^κ. Applying the Gaussian moment formula to the difference proves (144.130).

For the Wick powers, Wick covariance gives, for every test function ψ,

$$\mathbb{E}\left|\langle : X^k :, \psi\rangle\right|^2 = k! \iint \psi(u)\psi(v) C(u,v)^k \,\mathrm{d}u\,\mathrm{d}v. \tag{144.135}$$

Because $k \le 3 < Q = 5$, the kernel $\|u-v\|_{\mathfrak{s}}^{-k}$ is locally integrable in parabolic dimension Q. Using (144.131) and changing variables

$$u = z + \mathsf{D}_\delta a, \qquad v = z + \mathsf{D}_\delta b,$$

one obtains

$$\begin{aligned}\iint |\psi_x^\varphi(u)|\,|\psi_x^\varphi(v)||C(u,v)|^k \,\mathrm{d}u\,\mathrm{d}v &\le A^k\delta^{-k} \iint_{B_{\mathfrak{s}}(0,1)^2} \frac{|\varphi(a)|\,|\varphi(b)|}{\|a-b\|_{\mathfrak{s}}^k}\,\mathrm{d}a\,\mathrm{d}b \\ &\le C_{k,r,A}\delta^{-k}.\end{aligned} \tag{144.136}$$

Thus the $L^2(\Omega)$-norm of $\delta^{k/2+k\kappa}\langle : X^k :, \psi_x^\varphi\rangle$ is bounded by $C\delta^{k\kappa}$. Lemma 144.51 upgrades this k-th chaos L^2-bound to L^{2m}, proving (144.132).

For the edge estimate, apply the same covariance identity to

$$\Psi_{x,y}^\varphi = \delta^{k/2+k\kappa}\psi_x^\varphi - \delta'^{k/2+k\kappa}\psi_y^\varphi.$$

In scale 2^{-M} variables, the two supports lie in a fixed parabolic ball, and the C^r-bound gives

$$|\Psi_{x,y}^\varphi(u)| \le C_{r,k,\kappa}\, 2^{M(Q-k/2-k\kappa)}\eta^\theta. \tag{144.137}$$

Changing variables as above and using local integrability of $\|a-b\|_{\mathfrak{s}}^{-k}$ gives

$$\mathbb{E}\left|\delta^{k/2+k\kappa}\langle : X^k :, \psi_x^\varphi\rangle - \delta'^{k/2+k\kappa}\langle : X^k :, \psi_y^\varphi\rangle\right|^2 \le C\, 2^{-2k\kappa M}\eta^{2\theta}.$$

The finite-chaos moment bound again upgrades this to L^{2m}, proving (144.133). The displayed values of σ_Ξ and σ_{X^k} are exactly the powers of $\delta \sim 2^{-M}$ in (144.129) and (144.132). $\square$

Proposition 144.56 (Dual-norm Gaussian Wick-coordinate estimates)**.** *Let the hypotheses and notation of Proposition 144.55 hold. Assume in addition that*

$$0 < \theta < r - \frac{Q}{2}.$$

Choose s with

$$\frac{Q}{2} + \theta < s < r.$$

Let E_r be the test-function space

$$E_r = \{\varphi \in C^r(\mathbb{R}^{1+3}) : \operatorname{supp}\varphi \subset B_{\mathfrak{s}}(0,1)\}, \qquad \|\varphi\|_{E_r} = \|\varphi\|_{C^r}.$$

Define the E_r'-valued random functionals

$$\mathcal{W}_x(\varphi) = \delta^{Q/2+\kappa}\xi(\psi_x^\varphi)$$

and, for $k = 1, 2, 3$,

$$\mathcal{X}_{k,x}(\varphi) = \delta^{k/2+k\kappa}\langle : X^k :, \psi_x^\varphi\rangle.$$

Then, for every integer $m \geq 1$,

$$\big\|\|\mathcal{W}_x\|_{E_r'}\big\|_{L^{2m}(\Omega)} \leq C\delta^\kappa, \qquad \big\|\|\mathcal{X}_{k,x}\|_{E_r'}\big\|_{L^{2m}(\Omega)} \leq C\delta^{k\kappa}. \tag{144.138}$$

If $x = (z, \delta)$, $y = (z', \delta')$, $\delta, \delta' \in [2^{-M-1}, 2^{-M}]$, and

$$\eta = 2^M\|z - z'\|_{\mathfrak{s}} + 2^M|\delta - \delta'| \leq 1,$$

then

$$\big\|\|\mathcal{W}_x - \mathcal{W}_y\|_{E_r'}\big\|_{L^{2m}(\Omega)} \leq C2^{-\kappa M}\eta^\theta, \tag{144.139}$$

and

$$\big\|\|\mathcal{X}_{k,x} - \mathcal{X}_{k,y}\|_{E_r'}\big\|_{L^{2m}(\Omega)} \leq C2^{-k\kappa M}\eta^\theta. \tag{144.140}$$

The constants depend on the compact region, the chosen wavelet system, r, s, θ, κ, m, and on the covariance constant A for the Wick powers, but not on x, y, δ, δ', or the particular test function.

Proof. Use a compactly supported parabolic wavelet system with regularity larger than r, as in the reconstruction proof. Write e_λ, $\lambda \in \Lambda_j$, for the L^2-normalized wavelets at unit-domain scale 2^{-j}, and include the finitely many scaling functions in a separate set Λ_{-1}. The system has finite overlap,

$$|\Lambda_j| \leq C2^{Qj} \qquad (j \geq 0),$$

and the coefficient estimate

$$\sum_{\lambda\in\Lambda_{-1}} |\langle\varphi, e_\lambda\rangle|^2 + \sum_{j\geq 0}\sum_{\lambda\in\Lambda_j} 2^{2sj}|\langle\varphi, e_\lambda\rangle|^2 \leq C\|\varphi\|_{C^r}^2 \tag{144.141}$$

for $0 < s < r$. For a distribution T supported in a fixed enlargement of the unit ball set

$$\|T\|_{-s,*}^2 = \sum_{\lambda\in\Lambda_{-1}} |\langle T, e_\lambda\rangle|^2 + \sum_{j\geq 0}\sum_{\lambda\in\Lambda_j} 2^{-2sj}|\langle T, e_\lambda\rangle|^2.$$

By Cauchy–Schwarz and (144.141),

$$\|T\|_{E'_r} = \sup_{\|\varphi\|_{C^r} \le 1} |T(\varphi)| \le C\|T\|_{-s,*}. \tag{144.142}$$

It is therefore enough to estimate the weighted wavelet coefficient norm.

For white noise, put $T = \mathcal{W}_x$. For every L^2-normalized unit-domain wavelet e_λ,

$$\mathbb{E}|\langle T, e_\lambda\rangle|^2 = \delta^{2\kappa}.$$

Consequently

$$\mathbb{E}\|T\|^2_{-s,*} \le C\delta^{2\kappa}\left(1 + \sum_{j\ge 0} 2^{Qj}2^{-2sj}\right) \le C\delta^{2\kappa}, \tag{144.143}$$

because $s > Q/2$.

For the edge estimate, the coefficient tested against a scale-j wavelet is the white-noise pairing with the difference

$$\delta^{Q/2+\kappa}\psi_x^{e_\lambda} - \delta'^{Q/2+\kappa}\psi_y^{e_\lambda}.$$

Rescale the common physical ball of radius $C2^{-M}$ to unit size. The unit-domain wavelet has C^θ-size $O(2^{j(Q/2+\theta)})$, while its L^2-size is one; translation and dilation of the outer parameter by η therefore give

$$\left\|\delta^{Q/2+\kappa}\psi_x^{e_\lambda} - \delta'^{Q/2+\kappa}\psi_y^{e_\lambda}\right\|_{L^2} \le C2^{-\kappa M}\min\{1, 2^{j\theta}\eta^\theta\}. \tag{144.144}$$

The finite set Λ_{-1} obeys the same bound with $j = 0$ after changing the constant. Hence

$$\mathbb{E}\|\mathcal{W}_x - \mathcal{W}_y\|^2_{-s,*} \le C2^{-2\kappa M}\sum_{j\ge 0} 2^{(Q-2s)j}\min\{1, 2^{j\theta}\eta^\theta\}^2.$$

Let J be chosen so that $2^{-J-1} < \eta \le 2^{-J}$. The part $j \le J$ is bounded by

$$C\eta^{2\theta}\sum_{j\le J} 2^{(Q-2s+2\theta)j} \le C\eta^{2\theta},$$

because $Q - 2s + 2\theta < 0$. The part $j > J$ is bounded by

$$C\sum_{j>J} 2^{(Q-2s)j} \le C2^{-(2s-Q)J} \le C\eta^{2\theta},$$

again because $2s - Q > 2\theta$. This proves the $L^2(\Omega)$ version of (144.139).

For the Wick powers, let $T = \mathcal{X}_{k,x}$. Wick covariance gives

$$\mathbb{E}|\langle T, e_\lambda\rangle|^2 \le C\delta^{2k\kappa}2^{(k-Q)j}, \qquad \lambda \in \Lambda_j, \quad j \ge 0. \tag{144.145}$$

Indeed, after the outer scale $u = z + \mathsf{D}_\delta a$ is removed, the coefficient is tested by the unit-domain wavelet e_λ, and

$$\iint |e_\lambda(a)|\,|e_\lambda(b)|\|a-b\|_{\mathfrak{s}}^{-k}\,\mathrm{d}a\,\mathrm{d}b \le C2^{(k-Q)j}.$$

The right-hand side follows from the support diameter $O(2^{-j})$, the L^∞-size $O(2^{Qj/2})$, and the local integrability of $\|a-b\|_{\mathfrak{s}}^{-k}$. Summing the weighted coefficients gives

$$\mathbb{E}\|T\|_{-s,*}^2 \le C\delta^{2k\kappa}\left(1+\sum_{j\ge 0} 2^{Qj}2^{-2sj}2^{(k-Q)j}\right) \le C\delta^{2k\kappa}, \tag{144.146}$$

because $s > Q/2 \ge k/2$ for $k \le 3$.

For x, y in the same dyadic annulus, apply the covariance identity to the difference of the two normalized test functions. The same rescaling used in (144.144) gives

$$\mathbb{E}\,|\langle \mathcal{X}_{k,x} - \mathcal{X}_{k,y}, e_\lambda\rangle|^2 \le C2^{-2k\kappa M}2^{(k-Q)j}\min\{1, 2^{j\theta}\eta^\theta\}^2. \tag{144.147}$$

Therefore

$$\mathbb{E}\|\mathcal{X}_{k,x} - \mathcal{X}_{k,y}\|_{-s,*}^2 \le C2^{-2k\kappa M}\sum_{j\ge 0} 2^{(k-2s)j}\min\{1, 2^{j\theta}\eta^\theta\}^2.$$

Since $k \le 3 < Q$ and $2s - Q > 2\theta$, the same split at $2^{-J} \simeq \eta$ bounds this sum by $C\eta^{2\theta}$. This proves the $L^2(\Omega)$ versions of (144.138), (144.139), and (144.140).

The random variables $\mathcal{W}_x$ and $\mathcal{W}_x - \mathcal{W}_y$ lie in the first Wiener chaos with values in the Hilbert space defined by $\|\cdot\|_{-s,*}$. The variables $\mathcal{X}_{k,x}$ and $\mathcal{X}_{k,x} - \mathcal{X}_{k,y}$ lie in the k-th Wiener chaos with values in the same Hilbert space. We use the Hilbert-valued form of the finite-chaos moment bound. For a finite wavelet truncation F in the q-th homogeneous chaos, let P_t be the Ornstein–Uhlenbeck semigroup. Then $P_tF = e^{-qt}F$, and Jensen's inequality gives

$$e^{-qt}\|F\|_{-s,*} = \|P_tF\|_{-s,*} \le P_t(\|F\|_{-s,*}).$$

The scalar hypercontractive estimate $\|P_tg\|_{L^{2m}} \le \|g\|_{L^2}$ when $e^{2t} \ge 2m-1$ therefore gives

$$\|\|F\|_{-s,*}\|_{L^{2m}} \le (2m-1)^{q/2}\|\|F\|_{-s,*}\|_{L^2}.$$

Passing from finite wavelet truncations to the limit by monotone convergence for the squared coefficient norm gives

$$\|\|F\|_{-s,*}\|_{L^{2m}} \le C_{k,m}\,\|\|F\|_{-s,*}\|_{L^2}$$

for every one of these Hilbert-valued chaos variables. Combining this with (144.142) proves the claimed L^{2m} dual-norm estimates. □

144.6.3 Multiscale Sector Estimates and Local Subtractions

Parabolic Taylor-subtraction gain. The local scale gain used below is an elementary L^1 estimate, so it is recorded as a calculation. Let K_i be a dyadic kernel on $(\mathbb{R}^D, \mathfrak{s})$ such that

$$\operatorname{supp} K_i \subset B_{\mathfrak{s}}(0, A2^{-i}), \qquad \|K_i\|_{L^1} \le C_K 2^{-ai},$$

with $a > 0$. Let $r > 0$, let F be a function on $B_{\mathfrak{s}}(0, A2^{-i})$, and let P be a polynomial such that

$$|F(h) - P(h)| \le H\|h\|_{\mathfrak{s}}^r \tag{144.148}$$

for all h in that ball. Then

$$\left|\int K_i(h)\big(F(h)-P(h)\big)\,\mathrm{d}h\right| \le C_K H A^r 2^{-(a+r)i}. \tag{144.149}$$

On the support of K_i, the remainder hypothesis gives

$$|F(h)-P(h)| \le HA^r 2^{-ri}.$$

Therefore

$$\begin{aligned}\left|\int K_i(h)\big(F(h)-P(h)\big)\,\mathrm{d}h\right| &\le HA^r 2^{-ri}\int |K_i(h)|\,\mathrm{d}h\\ &\le C_K H A^r 2^{-(a+r)i}.\end{aligned}$$

The extra factor 2^{-ri} is the gain produced by subtracting the local Taylor polynomial P; without the subtraction the L^1-size of the kernel would only give the scale 2^{-ai}.

The estimate (144.149) deliberately separates this elementary local gain from the harder BPHZ bookkeeping: one must still specify which polynomial is subtracted for each divergent subgraph, prove that the forest formula does not double count overlapping local parts, and combine the gain with the dyadic convolution bound in Lemma 144.54.

One-loop relative-scale estimate. The preceding local gain becomes a usable dyadic estimate only after the two relative-scale sectors are separated. Let $(\mathbb{R}^D,\mathfrak{s})$ be a parabolically scaled space with homogeneous dimension $Q=|\mathfrak{s}|$, and let $a,b,\theta>0$. Suppose that dyadic kernels K_i, L_j, $i,j\ge 0$, obey

$$\operatorname{supp} K_i \subset B_{\mathfrak{s}}(0,A2^{-i}), \qquad |K_i(h)| \le C_K 2^{(Q-a)i}, \qquad \|K_i\|_{L^1} \le C_K' 2^{-ai},$$

and

$$\operatorname{supp} L_j \subset B_{\mathfrak{s}}(0,A2^{-j}), \qquad |L_j(h)| \le C_L 2^{(Q-b)j}.$$

Assume also that, whenever $j\le i$ and $\|h\|_{\mathfrak{s}} \le A2^{-i}$,

$$|L_j(h)-L_j(0)| \le C_L' 2^{(Q-b)j}2^{-\theta(i-j)}. \tag{144.150}$$

Define

$$T_{i,j}^{\mathrm{loc}} = \int K_i(h)\big(L_j(h)-L_j(0)\big)\,\mathrm{d}h \quad (j\le i),$$

and

$$T_{i,j}^{\mathrm{off}} = \int K_i(h)L_j(h)\,\mathrm{d}h \quad (j>i).$$

Then the following two sector estimates hold:

$$|T_{i,j}^{\mathrm{loc}}| \le C_K' C_L'\, 2^{(Q-a-b)j}2^{-(a+\theta)(i-j)} \quad (j\le i), \tag{144.151}$$

and

$$|T_{i,j}^{\mathrm{off}}| \le C_K C_L V_A\, 2^{(Q-a-b)i}2^{-b(j-i)} \quad (j>i), \tag{144.152}$$

where

$$V_A = \sup_{0<\rho\le A} |B_{\mathfrak{s}}(0,\rho)|\,\rho^{-Q}.$$

These bounds are the explicit scale bookkeeping. In the local sector $j \le i$, the Holder-scale bound (144.150) applies on the support of K_i, and therefore

$$\begin{aligned}|T^{\mathrm{loc}}_{i,j}| &\le \|K_i\|_{L^1} C'_L 2^{(Q-b)j} 2^{-\theta(i-j)} \\ &\le C'_K C'_L 2^{-ai} 2^{(Q-b)j} 2^{-\theta(i-j)} \\ &= C'_K C'_L 2^{(Q-a-b)j} 2^{-(a+\theta)(i-j)}.\end{aligned}$$

This is (144.151). In the off-diagonal sector $j > i$, the integrand is supported where L_j is supported, so

$$\begin{aligned}|T^{\mathrm{off}}_{i,j}| &\le C_K C_L 2^{(Q-a)i+(Q-b)j} |B_{\mathfrak{s}}(0, A2^{-j})| \\ &\le C_K C_L V_A 2^{(Q-a)i+(Q-b)j-Qj} \\ &= C_K C_L V_A 2^{(Q-a-b)i} 2^{-b(j-i)}.\end{aligned}$$

This is (144.152). The estimate isolates the relative-scale summability gain; the nontrivial BPHZ content is the subsequent forest organization of all local subtractions, not this one-loop norm calculation.

For the one-loop dynamic Φ^4_3 contraction, $Q = 5$ and the heat and covariance kernels both have order 2, so $a = b = 2$. The base factor $2^{(Q-a-b)k} = 2^k$, where $k = \min(i, j)$, is the local mass-coordinate divergence. The estimates above show that the two relative-scale sectors have strictly positive gap exponents: $2 + \theta$ in the subtracted sector $j \le i$ and 2 in the off-diagonal sector $j > i$. Thus the relative scales are summable once the local coordinate has been separated.

Proposition 144.57 (Two-loop sunset gaps and nested forest cancellation)**.** *Let $(\mathbb{R}^D, \mathfrak{s})$ be a parabolically scaled space with homogeneous dimension $Q = |\mathfrak{s}|$, and assume*

$$|B_{\mathfrak{s}}(0, r)| \le V r^Q, \qquad 0 < r \le A.$$

Let $a, b, c \in (0, Q)$ satisfy

$$a + b + c = 2Q.$$

For $i, j, \ell \ge 0$, let K_i, L_j, M_ℓ be measurable kernels such that

$$\operatorname{supp} K_i \subset B_{\mathfrak{s}}(0, A2^{-i}), \quad \operatorname{supp} L_j \subset B_{\mathfrak{s}}(0, A2^{-j}), \quad \operatorname{supp} M_\ell \subset B_{\mathfrak{s}}(0, A2^{-\ell}),$$

and

$$|K_i(h)| \le C_K 2^{(Q-a)i}, \quad |L_j(h)| \le C_L 2^{(Q-b)j}, \quad |M_\ell(h)| \le C_M 2^{(Q-c)\ell}.$$

Define

$$S_{i,j,\ell} = \int K_i(h) L_j(h) M_\ell(h)\, \mathrm{d}h, \qquad n_* = \max(i, j, \ell),$$

and the non-negative relative gaps

$$r_K = n_* - i, \qquad r_L = n_* - j, \qquad r_M = n_* - \ell.$$

Then

$$|S_{i,j,\ell}| \le V A^Q C_K C_L C_M 2^{-(Q-a)r_K - (Q-b)r_L - (Q-c)r_M}. \tag{144.153}$$

Consequently, if

$$S_N = \sum_{\max(i,j,\ell) \le N} S_{i,j,\ell},$$

then

$$|S_{N+1} - S_N| \le VA^Q C_K C_L C_M \sum_{\nu \in \{K,L,M\}} \prod_{\mu \ne \nu} \frac{1}{1 - 2^{-\eta_\mu}}, \tag{144.154}$$

where

$$\eta_K = Q - a, \qquad \eta_L = Q - b, \qquad \eta_M = Q - c.$$

For dynamic Φ^4_3, $Q = 5$. The heat kernel in the retarded edge has order $a = 2$. Each stationary covariance edge has order 4: it is the time convolution of two order-2 heat edges, so Lemma 144.54 gives the order $2 + 2 = 4$ dyadic bound. Thus $b = c = 4$ and

$$\eta_K = 3, \qquad \eta_L = \eta_M = 1,$$

and the non-nested two-loop local sunset sectors obey

$$|S_{i,j,\ell}| \le C\, 2^{-3r_K - r_L - r_M}, \qquad |S_{N+1} - S_N| \le \frac{60}{7} C, \tag{144.155}$$

with $C = VA^5 C_K C_L C_M$.

In the same finite cutoff chart, write

$$G = \sum_{\ell \ge 0} G_\ell, \qquad C_{1,\ell} = G_\ell(0).$$

At fixed scales i, j, ℓ, the nested local coefficient in

$$X(z)^2 \int K_i(z - w) X(w)^3 \,\mathrm{d}w$$

is

$$6C_{1,\ell} \int K_i(h) G_j(h) \,\mathrm{d}h.$$

After the recursive one-loop forest subtraction

$$X(w)^3 \longmapsto X(w)^3 - 3C_{1,\ell} X(w),$$

the corresponding local coefficient from the subtracted term is

$$-6C_{1,\ell} \int K_i(h) G_j(h) \,\mathrm{d}h.$$

Therefore the renormalized nested two-loop local coefficient is zero for each triple (i, j, ℓ). The only new two-loop local coordinate left by the forest operation is the non-nested sunset coefficient bounded above.

Proof. The product $K_i L_j M_\ell$ is supported in the smallest of the three supports. Hence

$$\mathrm{supp}(K_i L_j M_\ell) \subset B_{\mathfrak{s}}(0, A 2^{-n_*}).$$

Therefore

$$\begin{aligned} |S_{i,j,\ell}| &\le C_K C_L C_M 2^{(Q-a)i + (Q-b)j + (Q-c)\ell} |B_{\mathfrak{s}}(0, A2^{-n_*})| \\ &\le VA^Q C_K C_L C_M 2^{(Q-a)i + (Q-b)j + (Q-c)\ell - Qn_*}. \end{aligned}$$

Substitute

$$i = n_* - r_K, \qquad j = n_* - r_L, \qquad \ell = n_* - r_M.$$

The coefficient of n_* is

$$(Q-a) + (Q-b) + (Q-c) - Q = 2Q - (a+b+c) = 0,$$

so the remaining factor is exactly the right-hand side of (144.153).

The increment $S_{N+1} - S_N$ is the sum over triples with $\max(i,j,\ell) = N+1$. Equivalently, at least one of the gaps r_K, r_L, r_M is zero. This shell is contained in the union of the three sets $r_\nu = 0$. Summing the geometric majorant from (144.153) over that union gives (144.154). For $(Q,a,b,c) = (5,2,4,4)$, this shell constant is

$$\frac{1}{(1-2^{-1})^2} + 2\,\frac{1}{(1-2^{-3})(1-2^{-1})} = \frac{60}{7}.$$

It remains to verify the nested cancellation. In

$$X(z)^2 X(w)^3$$

leave one of the three fields at w uncontracted, contract the two fields at z with the two remaining fields at w, and then Taylor-expand the uncontracted field at w to its local value at z. This is the non-nested sunset and gives $3 \cdot 2 = 6$ bridge pairings. For the nested coefficient, instead leave one of the two fields at z uncontracted, contract the other field at z with one of the three fields at w, and contract the two remaining fields at w with each other. This gives

$$2 \cdot 3 = 6$$

pairings and the coefficient

$$6C_{1,\ell} \int K_i(h) G_j(h)\,\mathrm{d}h.$$

The inner one-loop forest subtraction contributes

$$-3C_{1,\ell} X(w).$$

Multiplying by $X(z)^2$, leaving one of the two fields at z uncontracted, and contracting the other one with $X(w)$ gives

$$-3 \cdot 2\, C_{1,\ell} \int K_i(h) G_j(h)\,\mathrm{d}h.$$

This is the negative of the nested coefficient above. The cancellation is scale-wise because $C_{1,\ell} = G_\ell(0)$ was kept at fixed tadpole scale ℓ throughout the calculation. □

Theorem 144.58 (Multiscale sector summability for coordinate kernels)**.** *Let $R \geq 1$ and let $\eta_1, \ldots, \eta_R$ be positive real numbers. Here $\mathbb{N} = \{0,1,2,\ldots\}$. Set*

$$\eta_* = \min_{1 \leq h \leq R} \eta_h, \qquad G = \prod_{h=1}^{R} \frac{1}{1 - 2^{-\eta_h}},$$

and

$$\widetilde{G} = \sum_{h=1}^{R} \prod_{\substack{1 \leq k \leq R \\ k \neq h}} \frac{1}{1 - 2^{-\eta_k}}.$$

Let $\mathcal{H}$ be a real Hilbert space. Let $\mathcal{A}$ be an index set with a positive scale weight

$$\sigma : \mathcal{A} \to (0, \infty).$$

For $q = 0, \dots, Q$, $a \in \mathcal{A}$, and $\mathbf{r} = (r_1, \dots, r_R) \in \mathbb{N}^R$, let

$$f_{\mathbf{r},a,q} \in \mathcal{H}^{\odot q}$$

with $\mathcal{H}^{\odot 0} = \mathbb{R}$. Suppose that, for constants $B_q < \infty$,

$$\|f_{\mathbf{r},a,q}\|_{\mathcal{H}^{\otimes q}} \le B_q \sigma(a) \prod_{h=1}^{R} 2^{-\eta_h r_h} \tag{144.156}$$

for all displayed indices. Define the cutoff kernel

$$f_{n,a,q} = \sum_{\substack{\mathbf{r} \in \mathbb{N}^R \\ \max_h r_h \le n}} f_{\mathbf{r},a,q}.$$

Then the sum defining $f_{n,a,q}$ is absolutely convergent in $\mathcal{H}^{\otimes q}$, and

$$\|f_{n,a,q}\|_{\mathcal{H}^{\otimes q}} \le B_q G \sigma(a). \tag{144.157}$$

Moreover,

$$\|f_{n+1,a,q} - f_{n,a,q}\|_{\mathcal{H}^{\otimes q}} \le B_q \widetilde{G}\, 2^{-\eta_*(n+1)} \sigma(a) \le B_q \widetilde{G}\, 2^{-\eta_* n} \sigma(a). \tag{144.158}$$

Consequently, for any isonormal Gaussian process $\xi : \mathcal{H} \to L^2(\Omega)$, the random variables

$$Y_n(a) = \sum_{q=0}^{Q} I_q(f_{n,a,q})$$

satisfy the hypotheses of the kernel-to-moment calculation above with the replacement

$$B_q \mapsto B_q G, \qquad \widetilde{B}_q \mapsto B_q \widetilde{G}, \qquad \rho = \eta_*.$$

Proof. The triangle inequality and (144.156) give

$$\begin{aligned} \|f_{n,a,q}\|_{\mathcal{H}^{\otimes q}} &\le B_q \sigma(a) \sum_{\substack{\mathbf{r} \in \mathbb{N}^R \\ \max_h r_h \le n}} \prod_{h=1}^{R} 2^{-\eta_h r_h} \\ &\le B_q \sigma(a) \prod_{h=1}^{R} \sum_{r_h=0}^{\infty} 2^{-\eta_h r_h} = B_q G \sigma(a). \end{aligned}$$

This proves absolute convergence and (144.157).

The increment $f_{n+1,a,q} - f_{n,a,q}$ is the sum of those scale-gap assignments for which at least one r_h is equal to $n+1$ and no r_h is larger than $n+1$. This set is contained in the union, over

$h = 1, \dots, R$, of the sets with $r_h = n+1$. Therefore

$$\begin{aligned}\|f_{n+1,a,q} - f_{n,a,q}\|_{\mathcal{H}^{\otimes q}} &\le B_q \sigma(a) \sum_{h=1}^{R} 2^{-\eta_h(n+1)} \prod_{\substack{1\le k\le R\\ k\ne h}} \sum_{r_k=0}^{\infty} 2^{-\eta_k r_k} \\ &\le B_q \sigma(a)\, 2^{-\eta_*(n+1)} \sum_{h=1}^{R} \prod_{\substack{1\le k\le R\\ k\ne h}} \frac{1}{1-2^{-\eta_k}}.\end{aligned}$$

This is (144.158). The final assertion is obtained by comparing (144.157) and (144.158) with the deterministic kernel hypotheses of the kernel-to-moment calculation above. ☐

Theorem 144.58 is the multiscale summation step behind a BPHZ coordinate estimate. In an actual tree calculation, a sector decomposition rewrites relative scale assignments as non-negative gap variables r_h. Taylor subtraction and the forest formula must then prove positive deficits η_h for every gap variable. Once that has been done, the theorem above converts those deficits into uniform kernel bounds and dyadic cutoff-increment bounds for the finite chaos coordinates. The difficult part left for dynamic Φ^4_3 is therefore the derivation of (144.156) for each negative tree and each coordinate entering the model seminorm.

Theorem 144.59 (Dyadic-net upgrade from coordinates to a supremum)**.** *Let $(\mathcal{X}, d_{\mathcal{X}})$ be a compact metric space. Assume that there are finite sets $\mathcal{X}_\ell \subset \mathcal{X}$, $\ell \ge 0$, and maps*

$$\pi_\ell : \mathcal{X} \to \mathcal{X}_\ell$$

such that $\pi_\ell x \to x$ for every $x \in \mathcal{X}$, and such that the edge sets

$$\mathcal{E}_\ell = \{(\pi_\ell x, \pi_{\ell+1} x) : x \in \mathcal{X}\}$$

satisfy

$$|\mathcal{X}_0| \le C_0, \qquad |\mathcal{E}_\ell| \le C_1 2^{d\ell} \quad (\ell \ge 0)$$

for constants $C_0, C_1, d > 0$. Let $Y : \mathcal{X} \to L^p(\Omega)$ be a random field with almost surely continuous sample paths, where $p \ge 1$. Assume that there are constants $B_0, B, \varepsilon > 0$ such that

$$\mathbb{E}|Y(u)|^p \le B_0^p \quad (u \in \mathcal{X}_0),$$

and

$$\mathbb{E}|Y(v) - Y(u)|^p \le B^p 2^{-(d+\varepsilon)\ell} \quad ((u,v) \in \mathcal{E}_\ell). \tag{144.159}$$

Then

$$\Big\| \sup_{x\in\mathcal{X}} |Y(x)| \Big\|_{L^p(\Omega)} \le C_0^{1/p} B_0 + \frac{C_1^{1/p} B}{1 - 2^{-\varepsilon/p}}. \tag{144.160}$$

If $Y = Y_n$ depends on a cutoff index n and both B_0 and B in the two hypotheses are replaced by $2^{-\rho n} B_0$ and $2^{-\rho n} B$, then the right-hand side of (144.160) is multiplied by $2^{-\rho n}$.

Proof. For every $x \in \mathcal{X}$, continuity of the sample path and $\pi_\ell x \to x$ give

$$Y(x) = Y(\pi_0 x) + \sum_{\ell \ge 0} \big(Y(\pi_{\ell+1} x) - Y(\pi_\ell x) \big)$$

on the event of continuity. Taking the supremum over x gives the pointwise bound

$$\sup_{x\in\mathcal{X}} |Y(x)| \le \max_{u\in\mathcal{X}_0} |Y(u)| + \sum_{\ell\ge 0} \max_{(u,v)\in\mathcal{E}_\ell} |Y(v) - Y(u)|.$$

The L^p triangle inequality gives

$$\left\|\sup_{x\in\mathcal{X}} |Y(x)|\right\|_{L^p} \le \left\|\max_{u\in\mathcal{X}_0} |Y(u)|\right\|_{L^p} + \sum_{\ell\ge 0} \left\|\max_{(u,v)\in\mathcal{E}_\ell} |Y(v) - Y(u)|\right\|_{L^p}.$$

For the base net,

$$\left\|\max_{u\in\mathcal{X}_0} |Y(u)|\right\|_{L^p}^p \le \sum_{u\in\mathcal{X}_0} \mathbb{E}|Y(u)|^p \le C_0 B_0^p.$$

For each edge level, (144.159) gives

$$\begin{aligned}\left\|\max_{(u,v)\in\mathcal{E}_\ell} |Y(v) - Y(u)|\right\|_{L^p}^p &\le \sum_{(u,v)\in\mathcal{E}_\ell} \mathbb{E}|Y(v) - Y(u)|^p \\ &\le C_1 B^p 2^{-\varepsilon\ell}.\end{aligned}$$

Taking p-th roots and summing the geometric series gives (144.160). The cutoff-dependent statement uses the base and edge estimates with the additional factor $2^{-\rho n p}$. This factor is independent of the dyadic level ℓ, so it passes through the union bound, the p-th root, and the geometric series as the factor $2^{-\rho n}$ in the final supremum estimate. $\square$

Theorem 144.59 is the analytic bridge from pointwise model-coordinate estimates to compact model-seminorm estimates. In an application, $\mathcal{X}$ is a finite product of compact base-point, scale, test-function, and normalized-symbol parameter spaces after a finite regularity sector has been fixed. The integer d records the metric entropy of these parameters. The missing BPHZ estimates must therefore include not only a moment bound for each fixed coordinate, but also the increment bound (144.159) in the parameters that enter the model seminorm.

Corollary 144.60 (Scale-summed dyadic-net coordinate upgrade)**.** *Let $p \ge 1$. For every $m \in \mathbb{N} = \{0, 1, 2, \ldots\}$, let $(\mathcal{X}_m, d_m)$ be a compact metric space with finite nets $\mathcal{X}_{m,\ell}$, $\ell \ge 0$, projections*

$$\pi_{m,\ell} : \mathcal{X}_m \to \mathcal{X}_{m,\ell},$$

and edge sets

$$\mathcal{E}_{m,\ell} = \{(\pi_{m,\ell}x, \pi_{m,\ell+1}x) : x \in \mathcal{X}_m\}.$$

Assume

$$|\mathcal{X}_{m,0}| \le C_0 2^{Dm}, \qquad |\mathcal{E}_{m,\ell}| \le C_1 2^{Dm} 2^{d\ell} \quad (m, \ell \ge 0), \tag{144.161}$$

for constants $C_0, C_1, D, d \ge 0$. Let $Y_m : \mathcal{X}_m \to L^p(\Omega)$ have almost surely continuous sample paths. Suppose there are constants $B_0, B, \sigma, \varepsilon > 0$ such that

$$\mathbb{E}|Y_m(u)|^p \le B_0^p 2^{-p\sigma m} \quad (u \in \mathcal{X}_{m,0})$$

and

$$\mathbb{E}|Y_m(v) - Y_m(u)|^p \le B^p 2^{-p\sigma m} 2^{-(d+\varepsilon)\ell} \quad ((u, v) \in \mathcal{E}_{m,\ell}).$$

If

$$\sigma > \frac{D}{p}, \tag{144.162}$$

then

$$\left\| \sup_{m\geq 0} \sup_{x\in\mathcal{X}_m} |Y_m(x)| \right\|_{L^p(\Omega)} \leq \frac{C_0^{1/p} B_0 + C_1^{1/p} B(1-2^{-\varepsilon/p})^{-1}}{1-2^{-(\sigma-D/p)}}. \tag{144.163}$$

If $Y_m = Y_{n,m}$ depends on a cutoff index n and the two moment hypotheses are multiplied by $2^{-p\rho n}$, with $\rho > 0$, then the right-hand side of (144.163) is multiplied by $2^{-\rho n}$.

Proof. Fix m. Apply Theorem 144.59 to the compact space $\mathcal{X}_m$. The base entropy and edge entropy in (144.161) replace C_0 and C_1 by $C_0 2^{Dm}$ and $C_1 2^{Dm}$, while the coordinate moment constants are multiplied by $2^{-\sigma m}$. Hence

$$\left\| \sup_{x\in\mathcal{X}_m} |Y_m(x)| \right\|_{L^p} \leq \left(C_0^{1/p} B_0 + \frac{C_1^{1/p} B}{1-2^{-\varepsilon/p}} \right) 2^{-(\sigma-D/p)m}.$$

The L^p triangle inequality gives

$$\left\| \sup_{m\geq 0} \sup_{x\in\mathcal{X}_m} |Y_m(x)| \right\|_{L^p} \leq \sum_{m\geq 0} \left\| \sup_{x\in\mathcal{X}_m} |Y_m(x)| \right\|_{L^p}.$$

The geometric series in m converges exactly under (144.162) and gives (144.163). The cutoff-dependent statement follows by carrying the factor $2^{-\rho n}$ through the same inequalities. □

Corollary 144.61 (Shell-separated cutoff bridge)**.** *Use the entropy data of Corollary 144.60. Thus, for every m, the compact space $\mathcal{X}_m$ is equipped with finite nets $\mathcal{X}_{m,\ell}$, edge sets $\mathcal{E}_{m,\ell}$, and entropy constants C_0, C_1, D, d satisfying (144.161). Let*

$$Y_{n,m} : \mathcal{X}_m \to L^p(\Omega), \qquad n, m \geq 0,$$

have almost surely continuous sample paths. Suppose that, for constants $B_0, B, \sigma, \varepsilon, \rho > 0$,

$$\mathbb{E}|Y_{n,m}(u)|^p \leq B_0^p 2^{-p\sigma m} 2^{-p\rho(n-m)_+} \quad (u \in \mathcal{X}_{m,0}) \tag{144.164}$$

and

$$\mathbb{E}|Y_{n,m}(v) - Y_{n,m}(u)|^p \leq B^p 2^{-p\sigma m} 2^{-p\rho(n-m)_+} 2^{-(d+\varepsilon)\ell} \quad ((u,v) \in \mathcal{E}_{m,\ell}). \tag{144.165}$$

Assume

$$a := \sigma - \frac{D}{p} > 0$$

and choose

$$0 < \rho_* < \min\{\rho, a\}.$$

Define

$$H_{\rho_*,\rho,a} := \sup_{n\geq 0} 2^{\rho_* n} \sum_{m\geq 0} 2^{-am} 2^{-\rho(n-m)_+}. \tag{144.166}$$

Then $H_{\rho_*,\rho,a} < \infty$, and

$$\left\| \sup_{m\geq 0} \sup_{x\in\mathcal{X}_m} |Y_{n,m}(x)| \right\|_{L^p(\Omega)} \leq H_{\rho_*,\rho,a} \left(C_0^{1/p} B_0 + C_1^{1/p} B(1-2^{-\varepsilon/p})^{-1} \right) 2^{-\rho_* n}. \tag{144.167}$$

Proof. For fixed n, m, apply Theorem 144.59 to $\mathcal{X}_m$ with the base and edge constants multiplied by

$$2^{-\sigma m} 2^{-\rho(n-m)_+}.$$

The entropy factor 2^{Dm} is taken to the p-th root, so

$$\left\| \sup_{x \in \mathcal{X}_m} |Y_{n,m}(x)| \right\|_{L^p} \le \left(C_0^{1/p} B_0 + C_1^{1/p} B (1 - 2^{-\varepsilon/p})^{-1} \right) 2^{-am} 2^{-\rho(n-m)_+}.$$

The L^p triangle inequality over m gives the same constant times

$$S_n := \sum_{m \ge 0} 2^{-am} 2^{-\rho(n-m)_+}.$$

It remains to prove that $S_n \le H_{\rho_*,\rho,a} 2^{-\rho_* n}$ with a finite $H_{\rho_*,\rho,a}$.

Split the sum at $m = n$. For $0 \le m \le n$,

$$2^{-am} 2^{-\rho(n-m)} = 2^{-\rho_* n} 2^{-(a-\rho_*)m} 2^{-(\rho-\rho_*)(n-m)}.$$

Both $a - \rho_*$ and $\rho - \rho_*$ are positive. Therefore

$$\sum_{m=0}^{n} 2^{-am} 2^{-\rho(n-m)} \le 2^{-\rho_* n} \frac{1}{1 - 2^{-(a-\rho_*)}} \frac{1}{1 - 2^{-(\rho-\rho_*)}}.$$

For $m > n$,

$$\sum_{m > n} 2^{-am} = 2^{-a(n+1)} (1 - 2^{-a})^{-1} \le 2^{-\rho_* n} \frac{2^{-a}}{1 - 2^{-a}},$$

because $a > \rho_*$. These two estimates prove

$$H_{\rho_*,\rho,a} \le \frac{1}{(1 - 2^{-(a-\rho_*)})(1 - 2^{-(\rho-\rho_*)})} + \frac{2^{-a}}{1 - 2^{-a}} < \infty,$$

and hence (144.167). $\square$

Corollary 144.62 (Projective shell-separated coordinate criterion)**.** *Use the entropy data of Corollary 144.60. Let $p = 2\mathfrak{m}$ be an even integer. Let E be a separable Banach space, let H be a Hilbert space, and fix a finite chaos order Q_0. For $n, m \ge 0$, let*

$$Y_{n,m}(x) = \sum_{q=0}^{Q_0} I_q(F_{n,m,x,q}), \qquad F_{n,m,x,q} \in H^{\odot q} \widehat{\otimes}_\pi E', \qquad x \in \mathcal{X}_m,$$

be E'-valued random fields whose sample paths are almost surely continuous in the E'-norm. Suppose that there are constants

$$B_q,\ B_q^{\mathrm{ed}},\ \sigma,\ \varepsilon,\ \rho > 0$$

such that, for every base-net point $u \in \mathcal{X}_{m,0}$,

$$\|F_{n,m,u,q}\|_\pi \le B_q\, 2^{-\sigma m} 2^{-\rho(n-m)_+}, \tag{144.168}$$

and, for every edge $(u, v) \in \mathcal{E}_{m,\ell}$,

$$\|F_{n,m,v,q} - F_{n,m,u,q}\|_\pi \le B_q^{\mathrm{ed}}\, 2^{-\sigma m} 2^{-\rho(n-m)_+} 2^{-(d+\varepsilon)\ell/p}. \tag{144.169}$$

Set

$$B_\pi = \sum_{q=0}^{Q_0} C_{q,\mathfrak{m}} B_q, \qquad B_\pi^{\mathrm{ed}} = \sum_{q=0}^{Q_0} C_{q,\mathfrak{m}} B_q^{\mathrm{ed}},$$

where $C_{q,\mathfrak{m}}$ is the finite-chaos constant in (144.120). If

$$a := \sigma - \frac{D}{p} > 0, \qquad 0 < \rho_* < \min\{\rho, a\},$$

then

$$\begin{aligned} &\left\| \sup_{m\geq 0} \sup_{x\in\mathcal{X}_m} \|Y_{n,m}(x)\|_{E'} \right\|_{L^p(\Omega)} \\ &\qquad \leq H_{\rho_*,\rho,a} \left(C_0^{1/p} B_\pi + C_1^{1/p} B_\pi^{\mathrm{ed}} (1 - 2^{-\varepsilon/p})^{-1} \right) 2^{-\rho_* n}. \end{aligned} \tag{144.170}$$

In particular, an E_r'-valued BPHZ kernel estimate satisfying (144.168) and (144.169) gives the scale-summed cutoff-Cauchy estimate needed for the corresponding dualized model coordinate. If the kernels are written as Bochner integrals

$$F_{n,m,x,q} = \int_S f_{n,m,x,q}(s) \otimes \ell_{m,x}(s)\,\mathrm{d}\mu(s),$$

the displayed projective hypotheses are exactly the integral estimates obtained from Lemma 144.53.

Proof. Apply Proposition 144.52 to the base-net variables. The triangle inequality in $L^p(\Omega; E')$ gives

$$\big\|\|Y_{n,m}(u)\|_{E'}\big\|_{L^p} \leq B_\pi\, 2^{-\sigma m} 2^{-\rho(n-m)_+}.$$

For an edge $(u,v) \in \mathcal{E}_{m,\ell}$, apply the same proposition to

$$Y_{n,m}(v) - Y_{n,m}(u) = \sum_{q=0}^{Q_0} I_q(F_{n,m,v,q} - F_{n,m,u,q}).$$

Using (144.169) gives

$$\big\|\|Y_{n,m}(v) - Y_{n,m}(u)\|_{E'}\big\|_{L^p} \leq B_\pi^{\mathrm{ed}} 2^{-\sigma m} 2^{-\rho(n-m)_+} 2^{-(d+\varepsilon)\ell/p}.$$

Since

$$\big| \|Y_{n,m}(v)\|_{E'} - \|Y_{n,m}(u)\|_{E'} \big| \leq \|Y_{n,m}(v) - Y_{n,m}(u)\|_{E'},$$

the scalar random field

$$x \longmapsto \|Y_{n,m}(x)\|_{E'}$$

satisfies the base and edge moment hypotheses of Corollary 144.61 with the constants $B_0 = B_\pi$ and $B = B_\pi^{\mathrm{ed}}$. That corollary gives (144.170). The final sentence is the projective-kernel bound (144.122) applied to the displayed Bochner integral, and similarly to its edge difference. $\square$

The parameter m in Corollary 144.60 is the physical testing scale, $\delta \simeq 2^{-m}$, in a model seminorm. The exponent D is the entropy cost of resolving base points and test functions at that scale. The exponent σ is the regularity slack between the assigned homogeneity and the moment regularity proved for the stochastic coordinate. Thus the condition $\sigma > D/p$ is the precise high-moment requirement: by choosing p large enough, a positive regularity slack beats the scale entropy. Corollary 144.61 is the corresponding cutoff-Cauchy bridge for estimates whose ultraviolet gain is visible only after comparing the cutoff shell with the physical testing scale. It is the deterministic step used by scalar shell bounds such as (144.239): the factor $2^{-\rho(n-m)_+}$ becomes a summable $2^{-\rho_* n}$ cutoff rate whenever the physical-scale slack $a = \sigma - D/p$ and the shell gain ρ are both positive.

Hypothesis 144.63 (Finite-sector coordinate data)**.** Fix K, γ, $A_{<\gamma}$, and r as in Lemma 144.50. Let

$$Z_n = (\Pi^{(n)}, \Gamma^{(n)}), \qquad n \geq 1,$$

be random models on the finite sector, and define

$$N_n = 1 + \|\Pi^{(n)}\|_{K;\gamma} + \|\Gamma^{(n)}\|_{K;\gamma}.$$

Let $d_{K;\gamma}$ be the corresponding model distance. Let

$$I = \{1, \ldots, M\}$$

be a finite coordinate index set. For every $i \in I$, let $(\mathcal{X}_i, d_{\mathcal{X}_i})$ be a compact metric space with finite nets $\mathcal{X}_{i,\ell}$, projections

$$\pi_{i,\ell} : \mathcal{X}_i \to \mathcal{X}_{i,\ell},$$

with $\pi_{i,\ell} x \to x$ for every $x \in \mathcal{X}_i$, and edge sets

$$\mathcal{E}_{i,\ell} = \{(\pi_{i,\ell} x, \pi_{i,\ell+1} x) : x \in \mathcal{X}_i\}$$

such that

$$|\mathcal{X}_{i,0}| \leq C_{i,0}, \qquad |\mathcal{E}_{i,\ell}| \leq C_{i,1} 2^{D_i \ell}$$

for constants $C_{i,0}, C_{i,1}, D_i > 0$. Fix $p \geq 1$, $\rho > 0$, and $\varepsilon_i > 0$ for $i \in I$. Suppose there are real random fields

$$U_{n,i}, V_{n,i} : \mathcal{X}_i \to L^p(\Omega), \qquad n \geq 1, \quad i \in I,$$

with almost surely continuous sample paths, and a deterministic constant $A_{\mathrm{ctrl}} < \infty$, such that, almost surely,

$$N_n \leq A_{\mathrm{ctrl}} \left(1 + \sum_{i \in I} \sup_{x \in \mathcal{X}_i} |U_{n,i}(x)| \right), \tag{144.171}$$

and

$$d_{K;\gamma}(Z_{n+1}, Z_n) \leq A_{\mathrm{ctrl}} \sum_{i \in I} \sup_{x \in \mathcal{X}_i} |V_{n,i}(x)|. \tag{144.172}$$

For the uniform bound, assume

$$\mathbb{E}|U_{n,i}(u)|^p \leq B_{i,0}^p \quad (n \geq 1,\ u \in \mathcal{X}_{i,0}),$$

and

$$\mathbb{E}|U_{n,i}(v) - U_{n,i}(u)|^p \leq B_i^p 2^{-(D_i + \varepsilon_i)\ell} \quad (n \geq 1,\ (u,v) \in \mathcal{E}_{i,\ell}).$$

For the cutoff increment, assume

$$\mathbb{E}|V_{n,i}(u)|^p \leq \widetilde{B}_{i,0}^p 2^{-p\rho n} \quad (u \in \mathcal{X}_{i,0}),$$

and

$$\mathbb{E}|V_{n,i}(v) - V_{n,i}(u)|^p \leq \widetilde{B}_i^p 2^{-p\rho n} 2^{-(D_i + \varepsilon_i)\ell} \quad ((u,v) \in \mathcal{E}_{i,\ell}).$$

Define

$$S_i = C_{i,0}^{1/p} B_{i,0} + \frac{C_{i,1}^{1/p} B_i}{1 - 2^{-\varepsilon_i/p}}, \qquad \widetilde{S}_i = C_{i,0}^{1/p} \widetilde{B}_{i,0} + \frac{C_{i,1}^{1/p} \widetilde{B}_i}{1 - 2^{-\varepsilon_i/p}}.$$

144.6.4 Finite-Sector Model Convergence from Coordinate Estimates

Under Hypothesis 144.63,

$$\sup_{n\geq 1} \|N_n\|_{L^p(\Omega)} \leq A_{\mathrm{ctrl}} \left(1 + \sum_{i\in I} S_i\right),$$

and

$$\|d_{K;\gamma}(Z_{n+1}, Z_n)\|_{L^p(\Omega)} \leq A_{\mathrm{ctrl}} \left(\sum_{i\in I} \widetilde{S}_i\right) 2^{-\rho n}. \tag{144.173}$$

Consequently, Z_n satisfies (144.116) with

$$C_N = A_{\mathrm{ctrl}}^p \left(1 + \sum_{i\in I} S_i\right)^p, \qquad C_D = A_{\mathrm{ctrl}}^p \left(\sum_{i\in I} \widetilde{S}_i\right)^p.$$

Thus the limiting random model and the convergence estimates of Lemma 144.50 follow.

Apply Theorem 144.59 to each $U_{n,i}$. The hypotheses for $U_{n,i}$ give

$$\left\|\sup_{x\in\mathcal{X}_i} |U_{n,i}(x)|\right\|_{L^p} \leq S_i \quad (n \geq 1).$$

The L^p triangle inequality and (144.171) therefore give

$$\|N_n\|_{L^p} \leq A_{\mathrm{ctrl}} \left(1 + \sum_{i\in I} S_i\right).$$

Taking the supremum over n gives the uniform model-seminorm moment bound.

Apply the cutoff-dependent part of Theorem 144.59 to $V_{n,i}$. The base and edge bounds for $V_{n,i}$ give

$$\left\|\sup_{x\in\mathcal{X}_i} |V_{n,i}(x)|\right\|_{L^p} \leq \widetilde{S}_i 2^{-\rho n}.$$

Together with (144.172), this gives (144.173). Raising the two displayed L^p bounds to the p-th power gives the constants C_N and C_D in (144.116). The final assertion is exactly Lemma 144.50.

The finite-sector coordinate-control consequence fixes the logical boundary of the remaining BPHZ task. A finite-dimensional reexpansion component or a finite basis component of T_α is included by enlarging the finite index set I. The model construction for dynamic Φ^4_3 must therefore provide, for each negative tree and each coordinate chart entering the model seminorm, the two estimates appearing in the theorem: the uniform coordinate moment estimate and the dyadic cutoff increment estimate with enough excess exponent ε_i to dominate the metric entropy of the coordinate parameters.

For dynamic Φ^4_3, the symbols are generated by the noise Ξ, the abstract integration map $\mathcal{I}$, multiplication, and polynomials in the spacetime coordinates. Negative-homogeneity trees encode precisely the subdivergent stochastic diagrams. Renormalization acts on these trees before the reconstruction theorem is applied.

Lemma 144.64 (Finite negative-sector coordinates for dynamic Φ^4_3)**.** *Let $0 < \kappa < 1/14$, and set*

$$X = \mathcal{I}(\Xi), \qquad Y = \mathcal{I}(X^3), \qquad |X| = -\frac{1}{2} - \kappa, \qquad |Y| = \frac{1}{2} - 3\kappa.$$

Put

$$\gamma_- = \frac{1}{2} - 7\kappa > 0.$$

Among the monomials $X^a Y^b$ with $a + b \le 3$, the non-polynomial symbols of homogeneity $< \gamma_-$ are

$$X, \quad X^2, \quad X^3, \quad XY, \quad X^2 Y. \tag{144.174}$$

Together with the noise symbol Ξ and the constant symbol $\mathbf{1}$, these form the finite sector

$$\mathcal{T}_- = \{\mathbf{1}, \Xi, X, X^2, X^3, XY, X^2Y\}.$$

Their homogeneities are

τ	$\lvert\tau\rvert$
$\mathbf{1}$	0
Ξ	$-\frac{5}{2} - \kappa$
X	$-\frac{1}{2} - \kappa$
X^2	$-1 - 2\kappa$
X^3	$-\frac{3}{2} - 3\kappa$
XY	-4κ
X^2Y	$-\frac{1}{2} - 5\kappa.$

The excluded cubic monomial XY^2 has homogeneity

$$|XY^2| = \gamma_-,$$

and is therefore not part of the strict sector $T_{<\gamma_-}$.

Let $Z_n = (\Pi^{(n)}, \Gamma^{(n)})$ be cutoff models whose restriction to $\mathcal{T}_-$ is multiplicative and whose reexpansion of Y, modulo terms of homogeneity $\ge \gamma_-$, has the form

$$\Gamma^{(n)}_{zz'} Y = Y + c_n(z, z')\mathbf{1}. \tag{144.175}$$

Then, on $\mathcal{T}_-$, the only strict lower stochastic reexpansion coefficients are

$$\Gamma^{(n)}_{zz'}(XY) = XY + c_n(z, z')X, \qquad \Gamma^{(n)}_{zz'}(X^2Y) = X^2Y + c_n(z, z')X^2. \tag{144.176}$$

In particular, for a compact K, the model seminorm below γ_- is controlled by the following explicit coordinate fields:

$$P_{n,\tau}(z, \delta, \varphi) = \delta^{-|\tau|} \left| \langle \Pi^{(n)}_z \tau, \varphi^\delta_z \rangle \right|, \qquad \tau \in \{\Xi, X, X^2, X^3, XY, X^2Y\},$$

and

$$G_n(z, z') = \frac{|c_n(z, z')|}{\|z - z'\|_{\mathfrak{s}}^{|Y|}} \qquad (0 < \|z - z'\|_{\mathfrak{s}} \le 1).$$

More precisely, with the basis vectors above assigned norm one,

$$1 + \|\Pi^{(n)}\|_{K;\gamma_-} + \|\Gamma^{(n)}\|_{K;\gamma_-} \le A_- \left(1 + \sum_{\tau \in \mathcal{T}_- \setminus \{\mathbf{1}\}} \sup_{z,\delta,\varphi} P_{n,\tau}(z, \delta, \varphi) + \sup_{z,z'} G_n(z, z') \right) \tag{144.177}$$

for a numerical constant $A_- < \infty$ depending only on this finite basis. The same inequality holds for the model distance $d_{K;\gamma_-}(Z_{n+1}, Z_n)$ after replacing $P_{n,\tau}$ and G_n by the corresponding cutoff differences.

Proof. The homogeneity of $X^a Y^b$ is

$$a\left(-\frac{1}{2} - \kappa\right) + b\left(\frac{1}{2} - 3\kappa\right).$$

For $a + b \leq 3$, direct evaluation gives

$$\begin{array}{c|c}
X & -\frac{1}{2} - \kappa \\
X^2 & -1 - 2\kappa \\
X^3 & -\frac{3}{2} - 3\kappa \\
Y & \frac{1}{2} - 3\kappa \\
XY & -4\kappa \\
X^2Y & -\frac{1}{2} - 5\kappa \\
Y^2 & 1 - 6\kappa \\
XY^2 & \frac{1}{2} - 7\kappa \\
Y^3 & \frac{3}{2} - 9\kappa.
\end{array}$$

Since $0 < \kappa < 1/14$, the entries in (144.174) are strictly below γ_-, while Y, Y^2, and Y^3 are above γ_-, and XY^2 is exactly at γ_-. The strict truncation $T_{<\gamma_-}$ therefore contains the displayed non-polynomial monomials and not XY^2.

The symbol Y has homogeneity $|Y| = \frac{1}{2} - 3\kappa$, which lies in $(0, 1)$. Below γ_-, the only polynomial symbol with lower homogeneity than Y that can appear in its reexpansion is the constant symbol. This is the coefficient $c_n(z, z')$ in (144.175). The negative symbols Ξ, X, X^2, X^3 have no lower polynomial component in the sector $\mathcal{T}_-$. Multiplicativity of the model then gives

$$\Gamma^{(n)}_{zz'}(XY) = \Gamma^{(n)}_{zz'} X \, \Gamma^{(n)}_{zz'} Y = X(Y + c_n(z, z')\mathbf{1}),$$

and similarly

$$\Gamma^{(n)}_{zz'}(X^2 Y) = X^2(Y + c_n(z, z')\mathbf{1}).$$

This proves (144.176). The homogeneity gaps are

$$|XY| - |X| = |Y|, \qquad |X^2 Y| - |X^2| = |Y|.$$

Thus the normalized Γ-seminorms of these two strict lower components are both bounded by $\sup G_n$; all other strict lower components in this sector vanish.

For Π, the seminorm in Definition 144.47 is the supremum over unit vectors in a finite-dimensional graded space. In the chosen basis, the unit-vector supremum is bounded by a finite multiple of the sum of the basis-vector suprema. The constant symbol contributes the deterministic bound

$$|\langle 1, \varphi^\delta_z \rangle| \leq \|\varphi\|_{L^1} \leq C_r.$$

Combining this deterministic constant, the six non-polynomial Π coordinates, and the single c_n-coordinate proves (144.177). Applying the same finite-dimensional norm comparison to $\Pi^{(n+1)} - \Pi^{(n)}$ and to the coefficient $c_{n+1} - c_n$ gives the stated model-distance version. $\square$

Hypothesis 144.65 (Negative-sector scale-summed coordinate scheme)**.** Fix $0 < \kappa < 1/14$, set

$$\gamma_- = \frac{1}{2} - 7\kappa,$$

and let $K \subset \mathbb{R}^{1+3}$ be compact. Choose

$$r > \frac{5}{2} + \kappa.$$

Let $Z_n = (\Pi^{(n)}, \Gamma^{(n)})$, $n \geq 1$, be random cutoff models on the finite sector $\mathcal{T}_-$ of Lemma 144.64, with the same basis norms and with reexpansion coefficient $c_n(z, z')$ as in (144.175). Put

$$N_n^- = 1 + \|\Pi^{(n)}\|_{K;\gamma_-} + \|\Gamma^{(n)}\|_{K;\gamma_-}, \qquad D_n^- = d_{K;\gamma_-}(Z_{n+1}, Z_n).$$

For

$$\mathfrak{C}_\Pi = \{\Xi, X, X^2, X^3, XY, X^2Y\}, \qquad \mathfrak{C} = \mathfrak{C}_\Pi \sqcup \{\mathfrak{g}\},$$

define the physical coordinate functions

$$Q_{n,\tau}(z, \delta, \varphi) = \delta^{-|\tau|} \left| \langle \Pi_z^{(n)} \tau, \varphi_z^\delta \rangle \right|, \qquad \tau \in \mathfrak{C}_\Pi,$$

$$\Delta Q_{n,\tau}(z, \delta, \varphi) = \delta^{-|\tau|} \left| \langle (\Pi_z^{(n+1)} - \Pi_z^{(n)}) \tau, \varphi_z^\delta \rangle \right|,$$

for $z \in K$, $0 < \delta \leq 1$, $\varphi \in \mathcal{B}_r$, and

$$Q_{n,\mathfrak{g}}(z, z') = \frac{|c_n(z, z')|}{\|z - z'\|_{\mathfrak{s}}^{|Y|}}, \qquad \Delta Q_{n,\mathfrak{g}}(z, z') = \frac{|c_{n+1}(z, z') - c_n(z, z')|}{\|z - z'\|_{\mathfrak{s}}^{|Y|}},$$

for $z, z' \in K$ with $0 < \|z - z'\|_{\mathfrak{s}} \leq 1$. For every $i \in \mathfrak{C}$ and $m \geq 0$, let $(\mathcal{X}_{i,m}, d_{i,m})$ be a compact metric space with finite nets $\mathcal{X}_{i,m,\ell}$, projections

$$\pi_{i,m,\ell} : \mathcal{X}_{i,m} \to \mathcal{X}_{i,m,\ell},$$

and edge sets

$$\mathcal{E}_{i,m,\ell} = \{(\pi_{i,m,\ell} x, \pi_{i,m,\ell+1} x) : x \in \mathcal{X}_{i,m}\}.$$

Assume that there are constants $C_{i,0}, C_{i,1}, D_i, d_i > 0$ such that

$$|\mathcal{X}_{i,m,0}| \leq C_{i,0} 2^{D_i m}, \qquad |\mathcal{E}_{i,m,\ell}| \leq C_{i,1} 2^{D_i m} 2^{d_i \ell} \tag{144.178}$$

for all $m, \ell \geq 0$. Suppose further that there are real random fields

$$U_{n,i,m}, V_{n,i,m} : \mathcal{X}_{i,m} \to L^p(\Omega), \qquad n \geq 1, \quad i \in \mathfrak{C}, \quad m \geq 0,$$

with almost surely continuous sample paths, such that the coordinate domination inequalities

$$\sup Q_{n,i} \leq \sup_{m \geq 0} \sup_{x \in \mathcal{X}_{i,m}} |U_{n,i,m}(x)|, \qquad \sup \Delta Q_{n,i} \leq \sup_{m \geq 0} \sup_{x \in \mathcal{X}_{i,m}} |V_{n,i,m}(x)| \tag{144.179}$$

hold almost surely. In (144.179), the first supremum is over the displayed physical variables of $Q_{n,i}$, and the second supremum is over the displayed physical variables of $\Delta Q_{n,i}$.

Fix $p \geq 1$ and $\rho > 0$. For each $i \in \mathfrak{C}$, assume there are positive constants $B_{i,0}, B_i, \widetilde{B}_{i,0}, \widetilde{B}_i, \sigma_i$, and ε_i, with

$$\sigma_i > \frac{D_i}{p}, \tag{144.180}$$

such that, for every n, m, ℓ,

$$\mathbb{E}|U_{n,i,m}(u)|^p \leq B_{i,0}^p 2^{-p\sigma_i m} \quad (u \in \mathcal{X}_{i,m,0}),$$

$$\mathbb{E}|U_{n,i,m}(v) - U_{n,i,m}(u)|^p \leq B_i^p 2^{-p\sigma_i m} 2^{-(d_i+\varepsilon_i)\ell} \quad ((u,v) \in \mathcal{E}_{i,m,\ell}),$$

and

$$\mathbb{E}|V_{n,i,m}(u)|^p \leq \widetilde{B}_{i,0}^p 2^{-p\rho n} 2^{-p\sigma_i m} \quad (u \in \mathcal{X}_{i,m,0}),$$

$$\mathbb{E}|V_{n,i,m}(v) - V_{n,i,m}(u)|^p \leq \widetilde{B}_i^p 2^{-p\rho n} 2^{-p\sigma_i m} 2^{-(d_i+\varepsilon_i)\ell} \quad ((u,v) \in \mathcal{E}_{i,m,\ell}).$$

Define

$$S_i^{\mathrm{sc}} = \frac{C_{i,0}^{1/p} B_{i,0} + C_{i,1}^{1/p} B_i (1 - 2^{-\varepsilon_i/p})^{-1}}{1 - 2^{-(\sigma_i - D_i/p)}},$$

and

$$\widetilde{S}_i^{\mathrm{sc}} = \frac{C_{i,0}^{1/p} \widetilde{B}_{i,0} + C_{i,1}^{1/p} \widetilde{B}_i (1 - 2^{-\varepsilon_i/p})^{-1}}{1 - 2^{-(\sigma_i - D_i/p)}}.$$

Negative-sector model convergence from scale-summed coordinates. Under Hypothesis 144.65,

$$\sup_{n \geq 1} \|N_n^-\|_{L^p(\Omega)} \leq A_- \left(1 + \sum_{i \in \mathfrak{C}} S_i^{\mathrm{sc}}\right),$$

and

$$\|D_n^-\|_{L^p(\Omega)} \leq A_- \left(\sum_{i \in \mathfrak{C}} \widetilde{S}_i^{\mathrm{sc}}\right) 2^{-\rho n}. \tag{144.181}$$

Consequently $Z_n|_{\mathcal{T}_-}$ converges in L^p and almost surely, in the model distance $d_{K;\gamma_-}$, to a limiting random model on $\mathcal{T}_-$. More precisely,

$$\left(\mathbb{E}\, d_{K;\gamma_-}(Z_n, Z_\infty)^p\right)^{1/p} \leq \frac{A_- \sum_{i \in \mathfrak{C}} \widetilde{S}_i^{\mathrm{sc}}}{1 - 2^{-\rho}} 2^{-\rho n}.$$

For a fixed coordinate label i, the entropy hypothesis (144.178) and the four moment hypotheses are exactly the hypotheses of Corollary 144.60, first for $U_{n,i,m}$ and then for $V_{n,i,m}$. Hence

$$\left\| \sup_{m \geq 0} \sup_{x \in \mathcal{X}_{i,m}} |U_{n,i,m}(x)| \right\|_{L^p} \leq S_i^{\mathrm{sc}},$$

uniformly in n, and

$$\left\| \sup_{m \geq 0} \sup_{x \in \mathcal{X}_{i,m}} |V_{n,i,m}(x)| \right\|_{L^p} \leq \widetilde{S}_i^{\mathrm{sc}} 2^{-\rho n}.$$

Lemma 144.64 gives the finite-dimensional coordinate domination

$$N_n^- \le A_- \left(1 + \sum_{i\in\mathfrak{C}} \sup Q_{n,i}\right)$$

and the corresponding distance domination

$$D_n^- \le A_- \sum_{i\in\mathfrak{C}} \sup \Delta Q_{n,i}.$$

Insert (144.179) into these two inequalities and apply the L^p triangle inequality. This proves the two displayed bounds for N_n^- and D_n^-.

The hypotheses of Lemma 144.50 are therefore satisfied with

$$C_N = A_-^p \left(1 + \sum_{i\in\mathfrak{C}} S_i^{\mathrm{sc}}\right)^p, \qquad C_D = A_-^p \left(\sum_{i\in\mathfrak{C}} \widetilde{S}_i^{\mathrm{sc}}\right)^p.$$

Applying that theorem on the finite sector $\mathcal{T}_-$ gives the limiting model and the stated L^p tail estimate.

Proposition 144.66 (Physical parameter entropy for the strict negative sector)**.** *Let $K \subset \mathbb{R}^{1+3}$ be compact, fix $r > 0$, let*

$$\mathfrak{C}_\Pi = \{\Xi, X, X^2, X^3, XY, X^2Y\},$$

let $|Y| > 0$ be the exponent used to normalize the c_n-coordinate, let $\mathfrak{s} = (2,1,1,1)$, and let

$$Q = |\mathfrak{s}| = 5.$$

For $\lambda > 0$, write

$$\mathsf{D}_\lambda(t, x_1, x_2, x_3) = (\lambda^2 t, \lambda x_1, \lambda x_2, \lambda x_3).$$

For $\tau \in \mathfrak{C}_\Pi$, set

$$Q^{\#}_{n,\tau}(z,\delta) = \sup_{\varphi\in\mathcal{B}_r} \delta^{-|\tau|} \left|\langle \Pi_z^{(n)}\tau, \varphi_z^\delta\rangle\right|.$$

Then the supremum over $z \in K$ and $0 < \delta \le 1$ is the supremum over the dyadic-scale spaces

$$\mathcal{X}_{\Pi,m} = K \times [1/2, 1], \qquad (z,a) \longmapsto Q^{\#}_{n,\tau}(z, 2^{-m}a), \qquad m \ge 0.$$

Equip $\mathcal{X}_{\Pi,m}$ with

$$d_{\Pi,m}((z,a),(z',a')) = 2^m \|z - z'\|_{\mathfrak{s}} + |a - a'|.$$

There are finite nets and projections as in Corollary 144.60 for which

$$|\mathcal{X}_{\Pi,m,0}| \le C_{\Pi,0} 2^{Qm}, \qquad |\mathcal{E}_{\Pi,m,\ell}| \le C_{\Pi,1} 2^{Qm} 2^{(Q+1)\ell}. \tag{144.182}$$

For the Γ-coordinate, let

$$A_{\mathfrak{s}} = \{h \in \mathbb{R}^{1+3} : 1/2 \le \|h\|_{\mathfrak{s}} \le 1\},$$

and, for the reexpansion coefficient $c_n(z,z')$, set

$$Q_{n,\mathfrak{g}}(z,z') = \frac{|c_n(z,z')|}{\|z - z'\|_{\mathfrak{s}}^{|Y|}}.$$

For $m \geq 0$, define

$$\mathcal{X}_{\Gamma,m} = \{(z,h) \in K \times A_{\mathfrak{s}} : z + \mathsf{D}_{2^{-m}} h \in K\}.$$

The map

$$(z,h) \longmapsto Q_{n,\mathfrak{g}}(z, z + \mathsf{D}_{2^{-m}} h)$$

parametrizes the part of the Γ-seminorm with

$$2^{-(m+1)} \leq \|z - z'\|_{\mathfrak{s}} \leq 2^{-m}.$$

Equip $\mathcal{X}_{\Gamma,m}$ with

$$d_{\Gamma,m}((z,h),(z',h')) = 2^m \|z - z'\|_{\mathfrak{s}} + \|h - h'\|_{\mathfrak{s}}.$$

There are finite nets and projections for which

$$|\mathcal{X}_{\Gamma,m,0}| \leq C_{\Gamma,0} 2^{Qm}, \qquad |\mathcal{E}_{\Gamma,m,\ell}| \leq C_{\Gamma,1} 2^{Qm} 2^{2Q\ell}. \tag{144.183}$$

The constants in (144.182) and (144.183) depend on K and on the chosen parabolic norm, but not on m, ℓ, n, or the coordinate label τ.

Proof. First record the covering estimate used twice. Since K is compact, it is contained in a rectangular box

$$[-R,R] \times [-R,R]^3.$$

A grid with temporal mesh η^2 and spatial mesh η covers this box by at most $C_R \eta^{-5}$ parabolic balls of radius $C\eta$, for $0 < \eta \leq 1$. After changing the constant, every compact subset of $\mathbb{R}^{1+3}$ therefore has parabolic covering number at scale η bounded by $C_K \eta^{-Q}$. The interval $[1/2,1]$ has covering number $\leq C\eta^{-1}$ in the ordinary metric, and the annulus $A_{\mathfrak{s}}$ has covering number $\leq C\eta^{-Q}$ in $\|\cdot\|_{\mathfrak{s}}$.

For $\mathcal{X}_{\Pi,m}$, a ball of radius $2^{-\ell}$ in $d_{\Pi,m}$ requires resolution $2^{-m-\ell}$ in K and resolution $2^{-\ell}$ in $[1/2,1]$. Hence

$$N(\mathcal{X}_{\Pi,m}, d_{\Pi,m}; 2^{-\ell}) \leq C\, 2^{Qm} 2^{(Q+1)\ell}.$$

Choose a $2^{-\ell}$-net $\mathcal{X}_{\Pi,m,\ell}$ with this cardinality, increasing in ℓ after replacing it by the union of the previous nets if needed. Let $\pi_{\Pi,m,\ell}$ be any nearest-net projection. The base bound in (144.182) is the case $\ell = 0$, and the edge set

$$\mathcal{E}_{\Pi,m,\ell} = \{(\pi_{\Pi,m,\ell} x, \pi_{\Pi,m,\ell+1} x) : x \in \mathcal{X}_{\Pi,m}\}$$

has cardinality no larger than $|\mathcal{X}_{\Pi,m,\ell+1}|$. Absorbing the extra factor 2^{Q+1} into $C_{\Pi,1}$ gives the displayed edge estimate.

For $\mathcal{X}_{\Gamma,m}$, cover K by $O(2^{Q(m+\ell)})$ balls of radius $2^{-m-\ell}$ and $A_{\mathfrak{s}}$ by $O(2^{Q\ell})$ balls of radius $2^{-\ell}$. The product cover has $d_{\Gamma,m}$-radius $2^{-\ell}$, so

$$N(\mathcal{X}_{\Gamma,m}, d_{\Gamma,m}; 2^{-\ell}) \leq C\, 2^{Qm} 2^{2Q\ell}.$$

The subset condition $z + \mathsf{D}_{2^{-m}} h \in K$ only decreases the covering number. The same projection and edge-set construction proves (144.183).

It remains to check the parametrization. If $0 < \delta \leq 1$, choose $m \geq 0$ and $a \in [1/2,1]$ with $\delta = 2^{-m} a$. This gives the Π-coordinate decomposition. If $0 < \|z - z'\|_{\mathfrak{s}} \leq 1$, choose $m \geq 0$ so that

$$2^{-(m+1)} \leq \|z - z'\|_{\mathfrak{s}} \leq 2^{-m}$$

and set

$$h = \mathsf{D}_{2^m}(z' - z).$$

The parabolic norm is homogeneous under D_λ, hence $h \in A_{\mathfrak{s}}$ and $z' = z + \mathsf{D}_{2^{-m}}h$. This proves the Γ-coordinate decomposition. $\square$

Proposition 144.67 (Gaussian Π-coordinate input for scale-summed model convergence)**.** *Let $K \subset \mathbb{R}^{1+3}$ be compact, let*

$$Q = 5, \qquad 0 < \kappa < \frac{1}{14},$$

and choose r, θ with

$$0 < \theta < r - \frac{Q}{2}.$$

Let ξ be a centered Gaussian space-time white noise and

$$X = G * \xi$$

be the massive heat-convolution field used in Proposition 144.55. For

$$\mathfrak{C}_{\mathrm{G}} = \{\Xi, X, X^2, X^3\}$$

interpret X^k as the Wick power $: X^k :$, $k = 1, 2, 3$, and assign

$$|\Xi| = -\frac{Q}{2} - \kappa, \qquad |X^k| = -\frac{k}{2} - k\kappa.$$

For $m \geq 0$ and $a \in [1/2, 1]$ set

$$x = (z, 2^{-m}a)$$

and define the random fields on $\mathcal{X}_{\Pi,m} = K \times [1/2, 1]$ by

$$U_{\Xi,m}(z,a) = \|\mathcal{W}_x\|_{E_r'}, \qquad U_{X^k,m}(z,a) = \|\mathcal{X}_{k,x}\|_{E_r'}, \quad k = 1,2,3, \tag{144.184}$$

where $\mathcal{W}_x$ and $\mathcal{X}_{k,x}$ are the E_r'-valued functionals of Proposition 144.56. Equivalently,

$$U_{\Xi,m}(z,a) = \sup_{\varphi \in \mathcal{B}_r} (2^{-m}a)^{Q/2+\kappa} |\xi(\varphi_z^{2^{-m}a})|,$$

and

$$U_{X^k,m}(z,a) = \sup_{\varphi \in \mathcal{B}_r} (2^{-m}a)^{k/2+k\kappa} |\langle : X^k :, \varphi_z^{2^{-m}a} \rangle|.$$

Let $p = 2m_0$ be an even integer satisfying

$$p\kappa > Q, \qquad p\theta > Q + 1. \tag{144.185}$$

Then, after choosing the net system of Proposition 144.66, the fields $U_{\tau,m}$, $\tau \in \mathfrak{C}_{\mathrm{G}}$, have continuous modifications on each $\mathcal{X}_{\Pi,m}$ and satisfy the Π-coordinate hypotheses of the negative-sector coordinate-control consequence with

$$D_\tau = Q, \qquad d_\tau = Q + 1,$$

$$\sigma_\Xi = \kappa, \qquad \sigma_{X^k} = k\kappa, \qquad \varepsilon_\tau = p\theta - (Q+1) > 0. \tag{144.186}$$

More explicitly, there are constants $B_{\tau,0}, B_\tau < \infty$ such that, for every $m, \ell \geq 0$,

$$\mathbb{E}|U_{\tau,m}(u)|^p \leq B_{\tau,0}^p 2^{-p\sigma_\tau m} \qquad (u \in \mathcal{X}_{\Pi,m,0}) \tag{144.187}$$

and

$$\mathbb{E}|U_{\tau,m}(v) - U_{\tau,m}(u)|^p \leq B_\tau^p 2^{-p\sigma_\tau m} 2^{-(Q+1+\varepsilon_\tau)\ell} \qquad ((u,v) \in \mathcal{E}_{\Pi,m,\ell}). \tag{144.188}$$

Consequently the Gaussian coordinate labels Ξ, X, X^2, X^3 already feed into the scale-summed negative-sector model theorem without an additional stochastic supremum argument.

If a cutoff or mollifier sequence $(\xi_n, X_n, : X_n^2 :, : X_n^3 :)$ satisfies the same dual-norm bounds for the increments of the corresponding fields $U_{\tau,m}^{(n+1)} - U_{\tau,m}^{(n)}$, with an additional factor $2^{-\rho n}$ in L^p for some $\rho > 0$, then the associated cutoff-difference variables satisfy the V-hypotheses of the negative-sector coordinate-control consequence with the same $D_\tau, d_\tau, \sigma_\tau, \varepsilon_\tau$ and with that convergence rate ρ.

Proof. We first identify the scale-normalized physical coordinates with the dual-norm fields. For $\tau = \Xi$,

$$\delta^{-|\Xi|}|\langle \Pi_z \Xi, \varphi_z^\delta \rangle| = \delta^{Q/2+\kappa}|\xi(\varphi_z^\delta)|,$$

and this is $|\mathcal{W}_{(z,\delta)}(\varphi)|$. For $\tau = X^k$,

$$\delta^{-|X^k|}|\langle \Pi_z X^k, \varphi_z^\delta \rangle| = \delta^{k/2+k\kappa}|\langle : X^k :, \varphi_z^\delta \rangle|,$$

which is $|\mathcal{X}_{k,(z,\delta)}(\varphi)|$. Taking the supremum over $\mathcal{B}_r$, which is the unit ball of the same test space E_r with the support convention used in the dual-norm proposition, gives (144.184). This is the promised map from physical Π-coordinates to the abstract coordinate fields of the negative-sector coordinate-control consequence.

Set $\delta = 2^{-m}a$ with $a \in [1/2, 1]$. The factor a is bounded above and below by numerical constants, hence

$$\delta^{\sigma_\tau} \asymp 2^{-\sigma_\tau m}$$

for $\sigma_\Xi = \kappa$ and $\sigma_{X^k} = k\kappa$. Applying (144.138) and raising the L^p-bound to a p-th moment proves (144.187).

Let $(u,v) \in \mathcal{E}_{\Pi,m,\ell}$, say

$$u = (z,a), \qquad v = (z',a').$$

The nearest-net construction in Proposition 144.66 gives

$$2^m\|z - z'\|_{\mathfrak{s}} + |a - a'| \leq C_\Pi 2^{-\ell}. \tag{144.189}$$

With $x = (z, 2^{-m}a)$ and $y = (z', 2^{-m}a')$, the parameter η of Proposition 144.56 satisfies

$$\eta \leq C2^{-\ell}.$$

The edge estimates (144.139) and (144.140), together with

$$\big|\|A\|_{E_r'} - \|B\|_{E_r'}\big| \leq \|A - B\|_{E_r'},$$

therefore give

$$\|U_{\tau,m}(v) - U_{\tau,m}(u)\|_{L^p} \leq C_\tau 2^{-\sigma_\tau m} 2^{-\theta\ell}.$$

Raising to the p-th power yields

$$\mathbb{E}|U_{\tau,m}(v) - U_{\tau,m}(u)|^p \le C_\tau^p 2^{-p\sigma_\tau m} 2^{-p\theta\ell}.$$

Since $\varepsilon_\tau = p\theta - (Q+1)$, this is exactly (144.188).

The entropy dimensions are

$$D_\tau = Q, \qquad d_\tau = Q+1$$

by Proposition 144.66. The moment condition (144.185) implies

$$\sigma_\Xi = \kappa > \frac{Q}{p}, \qquad \sigma_{X^k} = k\kappa \ge \kappa > \frac{Q}{p},$$

and it also implies $\varepsilon_\tau > 0$. These are precisely the scale-slack and edge-slack inequalities required in the negative-sector coordinate-control consequence.

It remains only to justify the continuity hypothesis. The same edge estimate, before restriction to the dyadic edge set, holds for arbitrary $(z,a),(z',a') \in \mathcal{X}_{\Pi,m}$ with

$$d_{\Pi,m}((z,a),(z',a')) \le 1,$$

with $2^{-\ell}$ replaced by that metric distance. Since $\mathcal{X}_{\Pi,m}$ has metric covering dimension $Q+1$ uniformly in m, the Kolmogorov–Chentsov dyadic-net proof gives, for every

$$0 < \alpha < \theta - \frac{Q+1}{p},$$

a modification that is α-Holder continuous on $\mathcal{X}_{\Pi,m}$. This proves the required sample-path continuity.

For a cutoff sequence, apply the preceding Kolmogorov-net construction to

$$U_{\tau,m}^{(n+1)} - U_{\tau,m}^{(n)}$$

in place of $U_{\tau,m}$. The assumed extra factor $2^{-\rho n}$ is carried unchanged through the base estimate, the edge estimate, and the dyadic-net continuity argument, and hence gives the V-hypotheses of the scale-summed theorem. □

For the nonlinear Π-coordinates XY and X^2Y, and for the Γ-coordinate $c_n(z,z')$, the same assembly theorem applies but the analytic inputs are different. The XY and X^2Y coordinates require the concrete BPHZ kernel estimates for products involving $Y = \mathcal{I}(X^3)$. The Γ-coordinate has no test-function dual norm; it is a scalar finite-chaos estimate on $\mathcal{X}_{\Gamma,m}$, with entropy exponent $d_{\mathfrak{g}} = 10$ by Proposition 144.66. Thus the stochastic and entropy mechanism is now completely explicit, while the remaining Φ^4_3 work is the model-specific BPHZ kernel analysis for XY, X^2Y, and the reexpansion coefficient of Y.

Proposition 144.68 (Heat-integration reexpansion estimate)**.** *Let* $\mathfrak{s} = (2,1,1,1)$ *and* $Q = 5$. *Let*

$$-2 < \alpha < 0, \qquad 0 < \sigma, \qquad \beta = \alpha + 2, \qquad \gamma = \beta + \sigma,$$

and assume

$$0 < \beta < 1, \qquad 0 < \gamma < 1.$$

Fix $r > -\alpha - \sigma$. Let $K = \sum_{j\geq 0} K_j$ be a dyadic decomposition of a parabolic heat kernel, with the following properties. There are constants A, C_K and a number $\vartheta \in (\gamma, 1]$ such that, after enlarging A if necessary, $A \geq 1$ and

$$\operatorname{supp} K_j \subset B_{\mathfrak{s}}(0, A2^{-j}), \qquad |K_j(u)| \leq C_K 2^{(Q-2)j}, \qquad j \geq 0, \tag{144.190}$$

and, for every a, b with $\|a-b\|_{\mathfrak{s}} \leq A2^{-j}$, the translated kernel difference admits the test-function representation

$$K_j(a-\cdot) - K_j(b-\cdot) = C_K 2^{-2j}(2^j\|a-b\|_{\mathfrak{s}})^{\vartheta}\psi_{a,b,j}^{2^{-j}}, \tag{144.191}$$

where $\psi_{a,b,j} \in C_c^r$ is supported in a fixed $\mathfrak{s}$-ball and $\|\psi_{a,b,j}\|_{C^r} \leq 1$. The translated kernel itself has the analogous representation

$$K_j(a-\cdot) = C_K 2^{-2j}\psi_{a,j}^{2^{-j}}, \qquad \|\psi_{a,j}\|_{C^r} \leq 1. \tag{144.192}$$

Let T be a distribution on a fixed compact neighborhood U such that

$$\|T\|_{\alpha+\sigma;U,r} := \sup_{\substack{x\in U,\ 0<\lambda\leq 1\\ \varphi\in\mathcal{B}_r}} \lambda^{-(\alpha+\sigma)}|\langle T, \varphi_x^\lambda\rangle| < \infty. \tag{144.193}$$

For $a \in U$ whose unit parabolic neighborhood lies in U, define

$$(\mathcal{K}T)(a) = \sum_{j\geq 0}\langle T, K_j(a-\cdot)\rangle. \tag{144.194}$$

Then the increment series is absolutely convergent and is given by

$$\mathfrak{c}_T(a,b) = (\mathcal{K}T)(b) - (\mathcal{K}T)(a) = \sum_{j\geq 0}\langle T, K_j(b-\cdot) - K_j(a-\cdot)\rangle. \tag{144.195}$$

Moreover, whenever $0 < \|a-b\|_{\mathfrak{s}} \leq 1$,

$$|\mathfrak{c}_T(a,b)| \leq C\|T\|_{\alpha+\sigma;U,r}\|a-b\|_{\mathfrak{s}}^{\beta+\sigma}. \tag{144.196}$$

Consequently the coefficient normalized with the model homogeneity β has scale slack σ:

$$\frac{|\mathfrak{c}_T(a,b)|}{\|a-b\|_{\mathfrak{s}}^{\beta}} \leq C\|T\|_{\alpha+\sigma;U,r}\|a-b\|_{\mathfrak{s}}^{\sigma}. \tag{144.197}$$

If (a,b) and (a',b') satisfy

$$h = \|a-b\|_{\mathfrak{s}}, \qquad h' = \|a'-b'\|_{\mathfrak{s}}, \qquad h, h' \in [2^{-m-1}, 2^{-m}],$$

and

$$\eta = 2^m\big(\|a-a'\|_{\mathfrak{s}} + \|b-b'\|_{\mathfrak{s}}\big) \leq 1,$$

then, for every $0 < \theta \leq \gamma$,

$$\left|\frac{\mathfrak{c}_T(a,b)}{\|a-b\|_{\mathfrak{s}}^{\beta}} - \frac{\mathfrak{c}_T(a',b')}{\|a'-b'\|_{\mathfrak{s}}^{\beta}}\right| \leq C_\theta\|T\|_{\alpha+\sigma;U,r}2^{-\sigma m}\eta^{\theta}. \tag{144.198}$$

Proof. First prove the Schauder increment estimate for $\mathcal{K}T$. Set

$$M = \|T\|_{\alpha+\sigma;U,r}.$$

The representation (144.192) and the definition of M give

$$|\langle T, K_j(a-\cdot)\rangle| \le C_K 2^{-2j} M (2^{-j})^{\alpha+\sigma} = C_K M 2^{-\gamma j}. \tag{144.199}$$

This bound is summable for $j \to \infty$, since $\gamma > 0$. The possible large-scale additive ambiguity is the usual harmless constant in the parabolic Schauder estimate; it cancels in increments. Hence $\mathfrak{c}_T(a,b)$ is given by the absolutely convergent difference series in (144.195).

Let

$$h = \|a-b\|_{\mathfrak{s}}$$

and choose $J \ge 0$ so that

$$2^{-J-1} < h \le 2^{-J}.$$

For the fine scales $j > J$, use (144.199) separately at a and b:

$$\sum_{j>J} |\langle T, K_j(b-\cdot) - K_j(a-\cdot)\rangle| \le CM \sum_{j>J} 2^{-\gamma j} \le CMh^{\gamma}. \tag{144.200}$$

For the coarse scales $j \le J$, the kernel-difference representation (144.191) gives

$$\begin{aligned} |\langle T, K_j(b-\cdot) - K_j(a-\cdot)\rangle| &\le C_K 2^{-2j} (2^j h)^{\vartheta} M (2^{-j})^{\alpha+\sigma} \\ &= CMh^{\vartheta} 2^{(\vartheta-\gamma)j}. \end{aligned}$$

Since $\vartheta > \gamma$,

$$\sum_{j \le J} h^{\vartheta} 2^{(\vartheta-\gamma)j} \le Ch^{\vartheta} 2^{(\vartheta-\gamma)J} \le Ch^{\gamma}. \tag{144.201}$$

Combining (144.200) and (144.201) proves (144.196); dividing by h^{β} proves (144.197).

For the normalized edge estimate, write

$$F(a) = (\mathcal{K}T)(a).$$

The estimate just proved says

$$|F(x) - F(y)| \le CM\|x-y\|_{\mathfrak{s}}^{\gamma} \tag{144.202}$$

on the compact region under consideration. The assumptions on (a,b) and (a',b') imply $h' \simeq h \simeq 2^{-m}$ and

$$\|a-a'\|_{\mathfrak{s}} + \|b-b'\|_{\mathfrak{s}} \le C\eta h. \tag{144.203}$$

Therefore

$$\begin{aligned} |(F(b)-F(a)) - (F(b')-F(a'))| &\le CM\big(\|b-b'\|_{\mathfrak{s}}^{\gamma} + \|a-a'\|_{\mathfrak{s}}^{\gamma}\big) \\ &\le CMh^{\gamma}\eta^{\gamma}. \end{aligned}$$

Dividing by h^{β} gives $CMh^{\sigma}\eta^{\gamma}$. The remaining effect is the change of denominator:

$$|h^{-\beta} - h'^{-\beta}| \le C_{\beta} h^{-\beta} \frac{|h-h'|}{h} \le C_{\beta} h^{-\beta} \eta,$$

while $|F(b') - F(a')| \le CMh^{\gamma}$. This contribution is bounded by $CMh^{\sigma}\eta$. Since $0 < \eta \le 1$, $h \simeq 2^{-m}$, and $\theta \le \gamma < 1$, the sum of the two contributions is bounded by the right-hand side of (144.198). □

Apply Proposition 144.68 to the symbol $Y = \mathcal{I}(X^3)$ in dynamic Φ^4_3. Here

$$\alpha = |X^3| = -\frac{3}{2} - 3\kappa, \qquad \beta = |Y| = \alpha + 2 = \frac{1}{2} - 3\kappa.$$

The primitive Gaussian estimate for X^3 proved above gives the additional regularity slack

$$\sigma = 3\kappa, \qquad \alpha + \sigma = -\frac{3}{2}, \qquad \beta + \sigma = \frac{1}{2}.$$

Thus the constant reexpansion coefficient

$$c_n(z,z') = \big(\mathcal{K}\Pi_z^{(n)} X^3\big)(z') - \big(\mathcal{K}\Pi_z^{(n)} X^3\big)(z) \tag{144.204}$$

has the deterministic normalization

$$\frac{|c_n(z,z')|}{\|z-z'\|_{\mathfrak{s}}^{|Y|}} \le C\, \|\Pi_z^{(n)} X^3\|_{-3/2;U,r} \|z-z'\|_{\mathfrak{s}}^{3\kappa}. \tag{144.205}$$

Proposition 144.69 (Γ-coordinate input from heat integration of X^3)**.** *Let $K \subset \mathbb{R}^{1+3}$ be compact and let U be a compact neighborhood containing the unit parabolic neighborhoods of the points of K. Fix*

$$0 < \kappa < \frac{1}{14}, \qquad \beta = \frac{1}{2} - 3\kappa, \qquad \sigma_{\mathfrak{g}} = 3\kappa.$$

Let T_n, $n \ge 1$, be random distributions on U. Assume that the heat-kernel decomposition satisfies the hypotheses of Proposition 144.68 with

$$\alpha = -\frac{3}{2} - 3\kappa, \qquad \sigma = 3\kappa, \qquad \gamma = \beta + \sigma = \frac{1}{2}.$$

For $z, z' \in K$, define

$$c_n(z,z') = (\mathcal{K}T_n)(z') - (\mathcal{K}T_n)(z).$$

Choose $0 < \theta \le 1/2$ and an even integer p such that

$$3p\kappa > 5, \qquad p\theta > 10. \tag{144.206}$$

Suppose that, for some constants $B_{\mathfrak{g}}$, $\widetilde{B}_{\mathfrak{g}}$, and $\rho > 0$,

$$\sup_{n\ge1} \big\| \|T_n\|_{-3/2;U,r} \big\|_{L^p(\Omega)} \le B_{\mathfrak{g}}, \tag{144.207}$$

and

$$\big\| \|T_{n+1} - T_n\|_{-3/2;U,r} \big\|_{L^p(\Omega)} \le \widetilde{B}_{\mathfrak{g}} 2^{-\rho n}. \tag{144.208}$$

Here $\|\cdot\|_{-3/2;U,r}$ is the norm (144.193) with exponent $-3/2$.

For $m \ge 0$, let $\mathcal{X}_{\Gamma,m}$ be the physical Γ-coordinate parameter space of Proposition 144.66. For $(z,h) \in \mathcal{X}_{\Gamma,m}$, set

$$z_h = z + \mathsf{D}_{2^{-m}} h, \qquad U_{n,\mathfrak{g},m}(z,h) = \frac{|c_n(z,z_h)|}{\|z-z_h\|_{\mathfrak{s}}^{\beta}},$$

and

$$V_{n,\mathfrak{g},m}(z,h) = \frac{|(c_{n+1}-c_n)(z,z_h)|}{\|z-z_h\|_{\mathfrak{s}}^{\beta}}. \tag{144.209}$$

Then the $\mathfrak{g}$-coordinate hypotheses of the negative-sector coordinate-control consequence hold with

$$D_{\mathfrak{g}} = 5, \qquad d_{\mathfrak{g}} = 10, \qquad \sigma_{\mathfrak{g}} = 3\kappa, \qquad \varepsilon_{\mathfrak{g}} = p\theta - 10 > 0. \tag{144.210}$$

More explicitly, after choosing the nets of Proposition 144.66, there are constants C_0, C_1, independent of n, m, ℓ, such that

$$\mathbb{E}|U_{n,\mathfrak{g},m}(u)|^p \le C_0^p B_{\mathfrak{g}}^p 2^{-3p\kappa m} \qquad (u \in \mathcal{X}_{\Gamma,m,0}), \tag{144.211}$$

$$\mathbb{E}|U_{n,\mathfrak{g},m}(v) - U_{n,\mathfrak{g},m}(u)|^p \le C_1^p B_{\mathfrak{g}}^p 2^{-3p\kappa m} 2^{-(10+\varepsilon_{\mathfrak{g}})\ell} \qquad ((u,v) \in \mathcal{E}_{\Gamma,m,\ell}), \tag{144.212}$$

and the same two estimates hold for $V_{n,\mathfrak{g},m}$ with $B_{\mathfrak{g}}^p$ replaced by $\widetilde{B}_{\mathfrak{g}}^p 2^{-p\rho n}$.

For the primitive dynamic Φ^4_3 reexpansion coefficient, one takes

$$T_n = \Pi_z^{(n)} X^3,$$

which is independent of the base point z for this primitive Wick-cubic symbol. When T_n is the cutoff Wick cubic $: X_n^3 :$, the uniform bound (144.207) is the scale-summed X^3 consequence of Proposition 144.67 applied on the enlarged compact region U. The cutoff-Cauchy input (144.208) is the corresponding cutoff-increment estimate for the Wick cubic.

Proof. Let $(z,h) \in \mathcal{X}_{\Gamma,m}$ and put

$$z_h = z + \mathsf{D}_{2^{-m}} h, \qquad h_m = \|z - z_h\|_{\mathfrak{s}}.$$

Since $h \in A_{\mathfrak{s}}$, one has

$$2^{-m-1} \le h_m \le 2^{-m}. \tag{144.213}$$

Apply (144.197) with $T = T_n$, $\beta = 1/2 - 3\kappa$, and $\sigma = 3\kappa$. This gives

$$U_{n,\mathfrak{g},m}(z,h) \le C\|T_n\|_{-3/2;U,r} h_m^{3\kappa} \le C\|T_n\|_{-3/2;U,r} 2^{-3\kappa m}. \tag{144.214}$$

Taking L^p-norms and using (144.207) proves (144.211).

Let $u = (z,h)$ and $v = (z',h')$ be an edge in $\mathcal{E}_{\Gamma,m,\ell}$. The net construction gives

$$2^m \|z - z'\|_{\mathfrak{s}} + \|h - h'\|_{\mathfrak{s}} \le C 2^{-\ell}. \tag{144.215}$$

Set

$$a = z, \quad b = z + \mathsf{D}_{2^{-m}} h, \qquad a' = z', \quad b' = z' + \mathsf{D}_{2^{-m}} h'.$$

Then $a, b, a', b' \in U$, their separations are in $[2^{-m-1}, 2^{-m}]$, and the edge parameter

$$\eta = 2^m (\|a - a'\|_{\mathfrak{s}} + \|b - b'\|_{\mathfrak{s}})$$

is bounded by $C2^{-\ell}$. The normalized edge estimate (144.198) therefore gives

$$\left| \frac{c_n(a,b)}{\|a-b\|_{\mathfrak{s}}^{\beta}} - \frac{c_n(a',b')}{\|a'-b'\|_{\mathfrak{s}}^{\beta}} \right| \le C_\theta \|T_n\|_{-3/2;U,r} 2^{-3\kappa m} 2^{-\theta\ell}.$$

Since $\big||A| - |B|\big| \le |A - B|$, this implies

$$|U_{n,\mathfrak{g},m}(v) - U_{n,\mathfrak{g},m}(u)| \le C_\theta \|T_n\|_{-3/2;U,r} 2^{-3\kappa m} 2^{-\theta\ell}. \tag{144.216}$$

After taking the p-th moment, this is exactly (144.212), because

$$10 + \varepsilon_{\mathfrak{g}} = p\theta.$$

The same deterministic inequalities apply to $T_{n+1} - T_n$, and (144.208) supplies the additional factor $2^{-\rho n}$ in L^p. The entropy exponents

$$D_{\mathfrak{g}} = 5, \qquad d_{\mathfrak{g}} = 10$$

are those of Proposition 144.66. The conditions (144.206) say precisely that

$$\sigma_{\mathfrak{g}} = 3\kappa > \frac{D_{\mathfrak{g}}}{p}, \qquad \varepsilon_{\mathfrak{g}} = p\theta - d_{\mathfrak{g}} > 0.$$

Thus the scale-slack and edge-slack hypotheses in the negative-sector coordinate-control consequence hold. The deterministic Holder estimate (144.216) also gives continuous sample paths whenever the norm $\|T_n\|_{-3/2;U,r}$ is finite, which proves the required continuity on each compact coordinate space. $\square$

Hence the c_n-coordinate does not require an independent singular stochastic contraction: its model-convergence input is a heat-integration consequence of the X^3 coordinate estimates. What remains genuinely new in the strict negative sector is the BPHZ analysis of the nonlinear products XY and X^2Y, where multiplication with the integrated field introduces additional contraction sectors.

144.6.5 Nonlinear Negative Coordinates and Local Shell Bounds

Finite-cutoff Wick decomposition for nonlinear negative coordinates. Let X_ϵ be a smooth centered Gaussian field on spacetime, with covariance

$$G_\epsilon(a,b) = \mathbb{E}[X_\epsilon(a)X_\epsilon(b)],$$

and let $K_\epsilon(a,b)$ be a smooth retarded heat kernel with the same ultraviolet cutoff. Define

$$Y_\epsilon(a) = \int K_\epsilon(a,b) :X_\epsilon(b)^3: \,\mathrm{d}b.$$

The Wick product is always taken with respect to the joint Gaussian family $\{X_\epsilon(c)\}_c$. Then

$$\begin{aligned} X_\epsilon(a)Y_\epsilon(a) = &\int K_\epsilon(a,b) :X_\epsilon(a)X_\epsilon(b)^3: \,\mathrm{d}b \\ &+ 3\int K_\epsilon(a,b)G_\epsilon(a,b) :X_\epsilon(b)^2: \,\mathrm{d}b. \end{aligned} \tag{144.217}$$

Furthermore, if

$$C_{2,\epsilon}(a) = 2\int K_\epsilon(a,b)G_\epsilon(a,b)^2 \,\mathrm{d}b, \tag{144.218}$$

then the two-loop locally subtracted coordinate is

$$
\begin{aligned}
&{:}X_\epsilon(a)^2{:}\,Y_\epsilon(a) - 3C_{2,\epsilon}(a)X_\epsilon(a)\\
&= \int K_\epsilon(a,b)\,:X_\epsilon(a)^2X_\epsilon(b)^3:\,\mathrm{d}b\\
&\quad + 6\int K_\epsilon(a,b)G_\epsilon(a,b)\,:X_\epsilon(a)X_\epsilon(b)^2:\,\mathrm{d}b\\
&\quad + 6\int K_\epsilon(a,b)G_\epsilon(a,b)^2\big(X_\epsilon(b)-X_\epsilon(a)\big)\,\mathrm{d}b.
\end{aligned}
\tag{144.219}
$$

Thus XY has only fourth- and second-chaos pieces, while the BPHZ coordinate X^2Y has fifth-, third-, and locally subtracted first-chaos pieces. The last line of (144.219) is the exact place where the local Taylor-subtraction gain of (144.149) enters the multiscale estimate.

The verification is the two-variable Wick product identity. For two centered Gaussian variables A, B, with $C = \mathbb{E}[AB]$, the Wick product identity is

$$
{:}A^m{:}\,{:}B^n{:} = \sum_{r=0}^{\min(m,n)} \binom{m}{r}\binom{n}{r} r!\,C^r\ {:}A^{m-r}B^{n-r}{:}\,. \tag{144.220}
$$

This identity follows by comparing coefficients of $s^mt^n/(m!n!)$ in

$$
\exp\Big(sA - \frac{s^2}{2}\mathbb{E}[A^2]\Big)\exp\Big(tB - \frac{t^2}{2}\mathbb{E}[B^2]\Big) = e^{stC}\exp\Big(sA + tB - \frac{1}{2}\mathbb{E}[(sA+tB)^2]\Big).
$$

Apply (144.220) first with $(m,n) = (1,3)$, $A = X_\epsilon(a)$, $B = X_\epsilon(b)$. The terms $r = 0,1$ have coefficients 1 and 3, and integration against $K_\epsilon(a,b)$ gives (144.217).

Next apply the same identity with $(m,n) = (2,3)$. The coefficients are

$$
\binom{2}{0}\binom{3}{0}0! = 1, \qquad \binom{2}{1}\binom{3}{1}1! = 6, \qquad \binom{2}{2}\binom{3}{2}2! = 6.
$$

Therefore

$$
\begin{aligned}
{:}X_\epsilon(a)^2{:}\,Y_\epsilon(a) &= \int K_\epsilon(a,b)\,:X_\epsilon(a)^2X_\epsilon(b)^3:\,\mathrm{d}b\\
&\quad + 6\int K_\epsilon(a,b)G_\epsilon(a,b)\,:X_\epsilon(a)X_\epsilon(b)^2:\,\mathrm{d}b\\
&\quad + 6\int K_\epsilon(a,b)G_\epsilon(a,b)^2X_\epsilon(b)\,\mathrm{d}b.
\end{aligned}
$$

By (144.218),

$$
3C_{2,\epsilon}(a)X_\epsilon(a) = 6\int K_\epsilon(a,b)G_\epsilon(a,b)^2X_\epsilon(a)\,\mathrm{d}b.
$$

Subtracting this local part from the preceding identity proves (144.219).

The formal homogeneity bookkeeping is now tied to concrete finite-cutoff coordinates. The analytic estimates still to be proved for (144.217) and (144.219) are not generic Holder-product estimates: the sums of the classical regularities are borderline or negative. They are finite-chaos kernel estimates after Wick expansion and BPHZ local subtraction. The target regularity slacks are

$$
0 - |XY| = 4\kappa, \qquad \Big(-\frac{1}{2}\Big) - |X^2Y| = 5\kappa.
$$

Once the fifth-, fourth-, third-, second-, and locally subtracted first-chaos kernels in the two displayed decompositions are bounded with these slacks, the dual-norm finite-chaos estimate, physical-parameter entropy theorem, and negative-sector model convergence theorem above apply without further stochastic input.

Finite-chaos kernels for tested nonlinear coordinates. Let $\mathcal{H}$ be a real Hilbert space and let $\xi : \mathcal{H} \to L^2(\Omega)$ be an isonormal Gaussian process. Let

$$p_\epsilon(a) \in \mathcal{H}$$

be a smooth cutoff noise-to-field kernel and set

$$X_\epsilon(a) = I_1(p_\epsilon(a)), \qquad G_\epsilon(a,b) = \langle p_\epsilon(a), p_\epsilon(b)\rangle_{\mathcal{H}}.$$

Let $K_\epsilon(a,b)$ be the cutoff retarded heat kernel and let χ be a smooth compactly supported test density in the a-variable. Define

$$Y_\epsilon(a) = \int K_\epsilon(a,b) : X_\epsilon(b)^3 : \,\mathrm{d}b.$$

Write Sym_q for orthogonal symmetrization in $\mathcal{H}^{\otimes q}$. Assume that the Hilbert-valued integrands displayed below are Bochner integrable; for the smooth compactly supported cutoffs used here this follows from the L^1-integrability of $|K_\epsilon(a,b)|$, $|K_\epsilon(a,b)G_\epsilon(a,b)|$, and $|K_\epsilon(a,b)G_\epsilon(a,b)^2|$ against the relevant products of $\|p_\epsilon(a)\|_{\mathcal{H}}$, $\|p_\epsilon(b)\|_{\mathcal{H}}$, and $\|p_\epsilon(b) - p_\epsilon(a)\|_{\mathcal{H}}$. Define

$$\begin{aligned} F^\chi_{XY,4} &= \mathrm{Sym}_4 \int \chi(a) K_\epsilon(a,b)\, p_\epsilon(a) \otimes p_\epsilon(b)^{\otimes 3}\,\mathrm{d}a\,\mathrm{d}b, \\ F^\chi_{XY,2} &= 3\ \mathrm{Sym}_2 \int \chi(a) K_\epsilon(a,b) G_\epsilon(a,b)\, p_\epsilon(b)^{\otimes 2}\,\mathrm{d}a\,\mathrm{d}b. \end{aligned} \tag{144.221}$$

Then

$$\int \chi(a) X_\epsilon(a) Y_\epsilon(a)\,\mathrm{d}a = I_4(F^\chi_{XY,4}) + I_2(F^\chi_{XY,2}). \tag{144.222}$$

For the locally subtracted X^2Y coordinate, set

$$\begin{aligned} F^\chi_{X^2Y,5} &= \mathrm{Sym}_5 \int \chi(a) K_\epsilon(a,b)\, p_\epsilon(a)^{\otimes 2} \otimes p_\epsilon(b)^{\otimes 3}\,\mathrm{d}a\,\mathrm{d}b, \\ F^\chi_{X^2Y,3} &= 6\ \mathrm{Sym}_3 \int \chi(a) K_\epsilon(a,b) G_\epsilon(a,b)\, p_\epsilon(a) \otimes p_\epsilon(b)^{\otimes 2}\,\mathrm{d}a\,\mathrm{d}b, \\ F^\chi_{X^2Y,1} &= 6 \int \chi(a) K_\epsilon(a,b) G_\epsilon(a,b)^2 \big(p_\epsilon(b) - p_\epsilon(a)\big)\,\mathrm{d}a\,\mathrm{d}b. \end{aligned} \tag{144.223}$$

Then

$$\begin{aligned} &\int \chi(a) \big(: X_\epsilon(a)^2 : Y_\epsilon(a) - 3C_{2,\epsilon}(a) X_\epsilon(a)\big)\,\mathrm{d}a \\ &\qquad = I_5(F^\chi_{X^2Y,5}) + I_3(F^\chi_{X^2Y,3}) + I_1(F^\chi_{X^2Y,1}). \end{aligned} \tag{144.224}$$

The identities are finite-chaos bookkeeping. The identity

$$: X_\epsilon(a) X_\epsilon(b)^3 := I_4\big(\mathrm{Sym}_4\big(p_\epsilon(a) \otimes p_\epsilon(b)^{\otimes 3}\big)\big)$$

is the definition of the fourth Wick chaos associated to the vector family $p_\epsilon(\cdot)$. Likewise

$$:X_\epsilon(b)^2 := I_2(p_\epsilon(b)^{\otimes 2}).$$

Multiplying the pointwise identity (144.217) by $\chi(a)$, integrating in a, and using the linearity and continuity of finite multiple Wiener integrals gives (144.222) with the kernels in (144.221). The stated Bochner integrability assumption permits approximation of the Hilbert-valued integrals by simple functions. Passing to the Hilbert-space limit and using $\mathbb{E}[I_q(f)I_q(g)] = q!\langle f,g\rangle_{\mathcal{H}^{\otimes q}}$ justifies the interchange with I_q.

For X^2Y, the three Wick monomials in (144.219) are

$$:X_\epsilon(a)^2X_\epsilon(b)^3 := I_5\big(\mathrm{Sym}_5(p_\epsilon(a)^{\otimes 2}\otimes p_\epsilon(b)^{\otimes 3})\big)\,,$$
$$:X_\epsilon(a)X_\epsilon(b)^2 := I_3\big(\mathrm{Sym}_3(p_\epsilon(a)\otimes p_\epsilon(b)^{\otimes 2})\big)\,,$$

and

$$X_\epsilon(b) - X_\epsilon(a) = I_1(p_\epsilon(b) - p_\epsilon(a)).$$

Multiplying by $\chi(a)$, integrating, and again using linearity of I_q gives (144.224). The coefficient of the first-chaos kernel is precisely the local subtraction from (144.218); no additional contraction is hidden in $F^\chi_{X^2Y,1}$.

Proposition 144.70 (Covariance integral formulas for nonlinear chaos kernels)**.** *Use the notation and hypotheses of the preceding finite-chaos kernel calculation. Write*

$$G_{uv} = G_\epsilon(u,v), \qquad K_{ab} = K_\epsilon(a,b),$$

and let all integrals below run over two copies of the spacetime variables (a,b) and (a',b'). Then the Hilbert norms of the tested kernels are

$$\begin{aligned}\|F^\chi_{XY,4}\|^2_{\mathcal{H}^{\otimes 4}} &= \int \chi(a)\chi(a')K_{ab}K_{a'b'}\left(\frac{1}{4}G_{aa'}G^3_{bb'} + \frac{3}{4}G_{ab'}G_{ba'}G^2_{bb'}\right)\mathrm{d}a\,\mathrm{d}b\,\mathrm{d}a'\,\mathrm{d}b',\\ \|F^\chi_{XY,2}\|^2_{\mathcal{H}^{\otimes 2}} &= 9\int \chi(a)\chi(a')K_{ab}K_{a'b'}G_{ab}G_{a'b'}G^2_{bb'}\,\mathrm{d}a\,\mathrm{d}b\,\mathrm{d}a'\,\mathrm{d}b'.\end{aligned} \tag{144.225}$$

For the locally subtracted X^2Y coordinate,

$$\begin{aligned}\|F^\chi_{X^2Y,5}\|^2_{\mathcal{H}^{\otimes 5}} &= \int \chi(a)\chi(a')K_{ab}K_{a'b'}\Big(\frac{1}{10}G^2_{aa'}G^3_{bb'} + \frac{3}{5}G_{aa'}G_{ab'}G_{ba'}G^2_{bb'}\\ &\qquad\qquad + \frac{3}{10}G^2_{ab'}G^2_{ba'}G_{bb'}\Big)\,\mathrm{d}a\,\mathrm{d}b\,\mathrm{d}a'\,\mathrm{d}b',\\ \|F^\chi_{X^2Y,3}\|^2_{\mathcal{H}^{\otimes 3}} &= 36\int \chi(a)\chi(a')K_{ab}K_{a'b'}G_{ab}G_{a'b'}\left(\frac{1}{3}G_{aa'}G^2_{bb'} + \frac{2}{3}G_{ab'}G_{ba'}G_{bb'}\right)\mathrm{d}a\,\mathrm{d}b\,\mathrm{d}a'\,\mathrm{d}b',\\ \|F^\chi_{X^2Y,1}\|^2_{\mathcal{H}} &= 36\int \chi(a)\chi(a')K_{ab}K_{a'b'}G^2_{ab}G^2_{a'b'}\\ &\qquad\qquad \times\big(G_{bb'} - G_{ba'} - G_{ab'} + G_{aa'}\big)\,\mathrm{d}a\,\mathrm{d}b\,\mathrm{d}a'\,\mathrm{d}b'.\end{aligned} \tag{144.226}$$

Consequently, if

$$\begin{aligned}Z^\chi_{XY} &= \int \chi(a)X_\epsilon(a)Y_\epsilon(a)\,\mathrm{d}a,\\ Z^\chi_{X^2Y} &= \int \chi(a)\big(:X_\epsilon(a)^2:Y_\epsilon(a) - 3C_{2,\epsilon}(a)X_\epsilon(a)\big)\,\mathrm{d}a,\end{aligned}$$

then

$$\mathbb{E}\big[|Z^{\chi}_{XY}|^2\big] = 4!\,\|F^{\chi}_{XY,4}\|^2_{\mathcal{H}^{\otimes 4}} + 2!\,\|F^{\chi}_{XY,2}\|^2_{\mathcal{H}^{\otimes 2}},$$
$$\mathbb{E}\big[|Z^{\chi}_{X^2Y}|^2\big] = 5!\,\|F^{\chi}_{X^2Y,5}\|^2_{\mathcal{H}^{\otimes 5}} + 3!\,\|F^{\chi}_{X^2Y,3}\|^2_{\mathcal{H}^{\otimes 3}} + \|F^{\chi}_{X^2Y,1}\|^2_{\mathcal{H}}. \tag{144.227}$$

Proof. For $h_1,\dots,h_q,k_1,\dots,k_q \in \mathcal{H}$,

$$\big\langle \mathrm{Sym}_q(h_1\otimes\cdots\otimes h_q), \mathrm{Sym}_q(k_1\otimes\cdots\otimes k_q)\big\rangle = \frac{1}{q!}\sum_{\sigma\in S_q}\prod_{i=1}^{q}\langle h_i, k_{\sigma(i)}\rangle_{\mathcal{H}}. \tag{144.228}$$

This is the orthogonal projection formula for symmetrization: $\mathrm{Sym}_q^* = \mathrm{Sym}_q$ and $\mathrm{Sym}_q^2 = \mathrm{Sym}_q$.

Apply (144.228) first to $p(a)\otimes p(b)^{\otimes 3}$ and $p(a')\otimes p(b')^{\otimes 3}$. In a random permutation of the four right-hand factors, the single $p(a')$ occupies the single $p(a)$-slot with probability $1/4$, and one of the three $p(b)$-slots with probability $3/4$. This gives the two coefficients in the first line of (144.225). The second line follows because $p(b)^{\otimes 2}$ is already symmetric.

For $p(a)^{\otimes 2}\otimes p(b)^{\otimes 3}$, let k be the number of right-hand $p(a')$-factors landing in the two $p(a)$-slots. The hypergeometric weights are

$$\frac{\binom{2}{2}\binom{3}{0}}{\binom{5}{2}} = \frac{1}{10}, \qquad \frac{\binom{2}{1}\binom{3}{1}}{\binom{5}{2}} = \frac{3}{5}, \qquad \frac{\binom{2}{0}\binom{3}{2}}{\binom{5}{2}} = \frac{3}{10},$$

for $k = 2,1,0$, respectively. These are the three coefficients in $\|F^{\chi}_{X^2Y,5}\|^2$. The same count for $p(a)\otimes p(b)^{\otimes 2}$ gives weights $1/3$ and $2/3$, producing $\|F^{\chi}_{X^2Y,3}\|^2$.

Finally,

$$\langle p(b)-p(a), p(b')-p(a')\rangle_{\mathcal{H}} = G_{bb'} - G_{ba'} - G_{ab'} + G_{aa'},$$

which proves the first-chaos formula. The second-moment identities (144.227) follow from orthogonality of distinct homogeneous Wiener chaoses and the isometry $\mathbb{E}[I_q(f)I_q(g)] = q!\langle f,g\rangle_{\mathcal{H}^{\otimes q}}$. ☐

Proposition 144.71 (Logarithmic power-counting bound for tested XY covariance graphs)**.** *Let $Q=5$. Assign to a heat edge the singular exponent $3 = Q-2$ and to one covariance edge the singular exponent $1 = Q-4$. Consider the three four-vertex multigraphs on*

$$V = \{a,b,a',b'\}$$

which occur in the two XY covariance expressions (144.225):

$$\begin{aligned}
\mathcal{G}_{4,A}:&\quad (a,b)_3,\ (a',b')_3,\ (a,a')_1,\ 3(b,b')_1,\\
\mathcal{G}_{4,B}:&\quad (a,b)_3,\ (a',b')_3,\ (a,b')_1,\ (b,a')_1,\ 2(b,b')_1,\\
\mathcal{G}_{2}:&\quad (a,b)_3,\ (a,b)_1,\ (a',b')_3,\ (a',b')_1,\ 2(b,b')_1.
\end{aligned}$$

The subscript is the singular exponent of the corresponding dyadic kernel; parallel covariance edges are listed with multiplicity. Let

$$s_{\mathcal{G}}(W) = \sum_{\substack{e=(u,v)\in E(\mathcal{G})\\ u,v\in W}} s_e$$

for $W\subset V$, where s_e is the edge singular exponent. Then, for every graph $\mathcal{G}\in\{\mathcal{G}_{4,A},\mathcal{G}_{4,B},\mathcal{G}_2\}$,

$$\sum_{e\in E(\mathcal{G})} s_e = Q(|V|-2) = 10, \tag{144.229}$$

and every proper subset $W \subsetneq V$ with $|W| \geq 2$ obeys the strict subgraph inequality

$$s_{\mathcal{G}}(W) < Q(|W| - 1). \tag{144.230}$$

More precisely, the smallest deficit

$$\Delta_{\mathcal{G}}(W) = Q(|W| - 1) - s_{\mathcal{G}}(W)$$

over proper W is 2 for $\mathcal{G}_{4,A}$, 2 for $\mathcal{G}_{4,B}$, and 1 for $\mathcal{G}_2$.

Consequently the only possible scale loss in the scalar second-moment power counting for the tested XY kernels is an overall logarithm. After dyadic decomposition, all relative-scale sums are geometrically summable; if $2^{-M-1} < \delta \leq 2^{-M}$, the remaining overall-scale sum is bounded by $C(1 + M)$. Hence any scalar covariance integral associated with the three graphs above and tested by two L^1-normalized functions supported in parabolic balls of radius $O(\delta)$ satisfies a power bound

$$|I_\delta| \leq C_\eta \delta^{-\eta} \qquad (\eta > 0), \tag{144.231}$$

provided the dyadic heat and covariance blocks satisfy the support and size bounds used in Lemma 144.54.

Proof. The total singular exponent is $3 + 3 + 1 + 3 = 10$ for $\mathcal{G}_{4,A}$, $3 + 3 + 1 + 1 + 2 = 10$ for $\mathcal{G}_{4,B}$, and $(3 + 1) + (3 + 1) + 2 = 10$ for $\mathcal{G}_2$. This proves (144.229).

It remains to check proper subgraphs. For two-vertex subsets, the largest internal singular exponents are

$$\max_{|W|=2} s_{\mathcal{G}_{4,A}}(W) = 3, \qquad \max_{|W|=2} s_{\mathcal{G}_{4,B}}(W) = 3, \qquad \max_{|W|=2} s_{\mathcal{G}_2}(W) = 4.$$

The two fourth-chaos graphs therefore have two-vertex deficit at least 2, while the second-chaos graph has the smaller deficit 1, coming from the parallel heat-covariance pairs $\{a, b\}$ and $\{a', b'\}$. For three vertices, inspection of the three displayed edge lists gives the following maximal internal singular exponents:

$$\max_{|W|=3} s_{\mathcal{G}_{4,A}}(W) = 6, \qquad \max_{|W|=3} s_{\mathcal{G}_{4,B}}(W) = 6, \qquad \max_{|W|=3} s_{\mathcal{G}_2}(W) = 6.$$

Because $Q(|W| - 1) = 10$ when $|W| = 3$, these deficits are at least 4. Thus (144.230) holds, with the stated minimum deficits $2, 2, 1$.

Now decompose every heat and covariance factor into dyadic blocks. A relative-scale sector is obtained by choosing one overall scale n for a spanning cluster of all four vertices and non-negative gap variables recording how much smaller each proper connected subcluster is. The support and size assumptions give, in that sector, a factor

$$2^{-\sum_W \Delta_{\mathcal{G}}(W) r_W}$$

up to a constant depending only on the dyadic partition and on the finite graph. The strict inequalities just proved imply $\Delta_{\mathcal{G}}(W) \geq 1$ for every proper cluster which can occur in the sector decomposition, so Theorem 144.58 applies to the relative gap variables.

After those relative sums have been performed, the exponent of the remaining overall scale is zero, precisely because of (144.229) and because the two external test functions are L^1-normalized. Thus the contribution of all overall scales $0 \le n \le M + O(1)$ is $O(1 + M)$; larger scales are killed by the test-function support and the same proper-cluster estimates. Finally, for every $\eta > 0$,

$$1 + M \le C_\eta 2^{\eta M} \le C_\eta \delta^{-\eta}.$$

This proves (144.231). □

Proposition 144.72 (Scalar tested XY coordinate bound)**.** *Let the hypotheses of Proposition 144.71 hold uniformly for the cutoff heat and covariance blocks on a compact spacetime set. Let $\varphi \in C_c^r(\mathbb{R}^{1+3})$ be supported in the unit parabolic ball, let $\|\varphi\|_{C^r} \le 1$, and define the L^1-normalized test density*

$$\varphi_z^\delta(a) = \delta^{-Q} \varphi(\mathsf{D}_\delta^{-1}(a - z)), \qquad Q = 5.$$

For the finite-cutoff field, set

$$Z_{\epsilon,\delta,z}^{XY}(\varphi) = \int \varphi_z^\delta(a) X_\epsilon(a) Y_\epsilon(a) \, \mathrm{d}a. \tag{144.232}$$

Then, for every $\eta > 0$, there is a constant C_η, uniform for ϵ and for z in the chosen compact set, such that

$$\mathbb{E}\big|Z_{\epsilon,\delta,z}^{XY}(\varphi)\big|^2 \le C_\eta \delta^{-\eta}. \tag{144.233}$$

Consequently, for every even $p \ge 2$ and every

$$0 < \zeta_{XY} < 4\kappa,$$

there is a constant $C_{p,\zeta_{XY}}$ such that

$$\big\|\delta^{4\kappa} Z_{\epsilon,\delta,z}^{XY}(\varphi)\big\|_{L^p(\Omega)} \le C_{p,\zeta_{XY}} \delta^{4\kappa - \zeta_{XY}}. \tag{144.234}$$

This is the scalar tested base estimate for the XY coordinate. The full input required by Proposition 144.79 additionally requires the same multiscale estimate after dualizing the test-function variable and after taking differences in the parameters (z, δ).

Proof. Insert $\chi = \varphi_z^\delta$ in (144.225). The density φ_z^δ is L^1-normalized, and its support lies in a parabolic ball of radius $O(\delta)$. Each of the three scalar covariance graphs in (144.225) is therefore bounded by Proposition 144.71. The numerical coefficients $1/4$, $3/4$, and 9, and the chaos factors $4!$ and $2!$, are finite fixed constants. Thus (144.227) gives (144.233).

The random variable $Z_{\epsilon,\delta,z}^{XY}(\varphi)$ is the sum of a fourth-chaos and a second-chaos variable by (144.222). Applying Lemma 144.51 to these two homogeneous chaos components gives

$$\big\|Z_{\epsilon,\delta,z}^{XY}(\varphi)\big\|_{L^p} \le C_p \big\|Z_{\epsilon,\delta,z}^{XY}(\varphi)\big\|_{L^2}.$$

Choose $\eta = 2\zeta_{XY}$ in (144.233). Multiplication by the model normalization

$$\delta^{-|XY|} = \delta^{4\kappa}$$

then gives (144.234). □

Proposition 144.73 (Scalar tested XY parameter-edge bound)**.** *Keep the hypotheses of Proposition 144.72. Let $r \geq 1$, $0 < \theta \leq 1$, and let*

$$\mathcal{X}_{\Pi,m} = K \times [1/2, 1], \qquad d_{\Pi,m}((z,a),(z',a')) = 2^m \|z - z'\|_{\mathfrak{s}} + |a - a'|.$$

For $u = (z,a) \in \mathcal{X}_{\Pi,m}$, put

$$\delta_u = 2^{-m} a, \qquad \varphi_u(a_0) = \delta_u^{-Q} \varphi(\mathsf{D}_{\delta_u}^{-1}(a_0 - z)), \qquad \|\varphi\|_{C^r} \leq 1.$$

Define

$$Z^{XY}_{\epsilon,m,u}(\varphi) = \int \varphi_u(a_0) X_\epsilon(a_0) Y_\epsilon(a_0) \, \mathrm{d}a_0.$$

Then, whenever $d_{\Pi,m}(u,v) \leq 1$, for every even $p \geq 2$ and every $0 < \zeta_{XY} < 4\kappa$,

$$\left\|2^{-4\kappa m}\big(Z^{XY}_{\epsilon,m,v}(\varphi) - Z^{XY}_{\epsilon,m,u}(\varphi)\big)\right\|_{L^p(\Omega)} \leq C_{p,\zeta_{XY},\theta} 2^{-(4\kappa - \zeta_{XY})m} d_{\Pi,m}(u,v)^\theta. \tag{144.235}$$

The constant is uniform in the cutoff and in u, v with centers in the fixed compact set.

Proof. First record the deterministic variation of the transported test density. For $r \geq 1$, the map

$$(z,a) \longmapsto (2^{-m}a)^{-Q} \varphi(\mathsf{D}_{(2^{-m}a)^{-1}}(\,\cdot - z))$$

is Lipschitz from $\mathcal{X}_{\Pi,m}$ to L^1, uniformly in m and in $\|\varphi\|_{C^1} \leq 1$. Indeed, translation by z differentiates the test by $\nabla_{\mathfrak{s}}\varphi$ and produces the dimensionless factor $2^m\|z - z'\|_{\mathfrak{s}}$; differentiating in the scale parameter $a \in [1/2, 1]$ differentiates the map

$$a^{-Q} \varphi(\mathsf{D}_{a^{-1}} w)$$

on a compact interval. Therefore

$$\|\varphi_v - \varphi_u\|_{L^1} \leq C\, d_{\Pi,m}(u,v) \leq C\, d_{\Pi,m}(u,v)^\theta, \tag{144.236}$$

because $d_{\Pi,m}(u,v) \leq 1$. The supports of φ_u and φ_v lie in a common parabolic ball of radius $C2^{-m}$.

Set $\Delta\varphi = \varphi_v - \varphi_u$. By linearity,

$$Z^{XY}_{\epsilon,m,v}(\varphi) - Z^{XY}_{\epsilon,m,u}(\varphi) = \int \Delta\varphi(a_0) X_\epsilon(a_0) Y_\epsilon(a_0) \, \mathrm{d}a_0.$$

The covariance-graph estimate used in Proposition 144.72 is homogeneous in the two external test densities. Applying it to $\Delta\varphi$ in both slots, using (144.236), and taking $\delta = 2^{-m}$ gives, for every $\eta > 0$,

$$\mathbb{E}\left|Z^{XY}_{\epsilon,m,v}(\varphi) - Z^{XY}_{\epsilon,m,u}(\varphi)\right|^2 \leq C_\eta d_{\Pi,m}(u,v)^{2\theta} 2^{\eta m}. \tag{144.237}$$

The difference is again a sum of fourth- and second-chaos variables, so the finite-chaos moment bound gives its L^p-norm from the square root of (144.237). Choose $\eta = 2\zeta_{XY}$ and multiply by the model normalization $2^{-4\kappa m}$. This proves (144.235). $\square$

Proposition 144.74 (Scalar tested XY cutoff-shell gain)**.** *Keep the notation and graph hypotheses of Propositions 144.71 and 144.72. Let (X_n, Y_n) be a dyadic ultraviolet cutoff sequence, and write*

$$Z^{XY}_{n,m,u}(\varphi) = \int \varphi_u(a_0) X_n(a_0) Y_n(a_0)\, \mathrm{d}a_0$$

with φ_u as in Proposition 144.73. Assume the cutoff difference $Z^{XY}_{n+1,m,u} - Z^{XY}_{n,m,u}$ has the following admissible shell representation: after expanding the second moment by the finite-chaos formulas (144.222) and (144.225), every term is a finite linear combination of the three XY graph integrals in Proposition 144.71, with at least one heat or covariance edge replaced by a cutoff-shell block whose dyadic scale is $\geq n - c_0$. The shell block satisfies the same support and size bounds as the corresponding ordinary dyadic block, with constants independent of n.

Then, for every $\eta > 0$, every $0 < \rho < 1/2$, and every $u \in \mathcal{X}_{\Pi,m}$,

$$\mathbb{E}\left|Z^{XY}_{n+1,m,u}(\varphi) - Z^{XY}_{n,m,u}(\varphi)\right|^2 \leq C_{\eta,\rho}\, 2^{\eta m}\, 2^{-2\rho(n-m)_+}. \tag{144.238}$$

Consequently, for every even $p \geq 2$ and every

$$0 < \zeta_{XY} < 4\kappa,$$

$$\left\|2^{-4\kappa m}\big(Z^{XY}_{n+1,m,u}(\varphi) - Z^{XY}_{n,m,u}(\varphi)\big)\right\|_{L^p(\Omega)} \leq C_{p,\zeta_{XY},\rho} 2^{-(4\kappa-\zeta_{XY})m} 2^{-\rho(n-m)_+}. \tag{144.239}$$

The estimate is uniform for u with center in a fixed compact set.

Proof. Let $M = m + O(1)$ be the largest overall graph scale that can interact with two L^1-normalized test densities supported in parabolic balls of radius $O(2^{-m})$. The unconstrained graph estimate in Proposition 144.71 leaves only the overall-scale sum $0 \leq N \leq M + O(1)$, producing the logarithmic loss recorded there.

Now impose the shell condition from the cutoff increment. In the dyadic sector decomposition used in the proof of Proposition 144.71, the edge at scale $\geq n - c_0$ either lies at the overall scale or creates a proper subcluster whose relative-scale gap is at least $(n - M - C)_+$. The first alternative can occur only when $n \leq M + C$. In the second alternative, the sector carries the additional factor

$$2^{-\Delta r}$$

with $r \geq n - M - C$ and with $\Delta \geq 1$, because the smallest proper-subgraph deficit among the three XY graphs is 1. Therefore every sector with $n > M + C$ gains at least $2^{-(n-M-C)}$. Enlarging the constant absorbs the fixed C and gives, for every graph contribution,

$$|I^{\Delta XY}_{n,m}| \leq C_\eta 2^{\eta m} 2^{-(n-m)_+}.$$

Since $0 < \rho < 1/2$, the weaker bound

$$2^{-(n-m)_+} \leq C_\rho 2^{-2\rho(n-m)_+}$$

holds uniformly in m, n. Summing the finite list of graph terms in the admissible shell representation gives (144.238).

The cutoff difference is still a finite sum of homogeneous Wiener-chaos variables of orders 4 and 2. Lemma 144.51 therefore bounds its L^p-norm by a constant times the square root of (144.238). Choose $\eta = 2\zeta_{XY}$ and multiply by the model normalization $2^{-4\kappa m}$. This proves (144.239). $\square$

Proposition 144.75 (Scalar tested high-chaos X^2Y bound)**.** *Let $Q = 5$. Use the same dyadic heat and covariance block hypotheses as in Proposition 144.71. Consider the five four-vertex multigraphs on $V = \{a, b, a', b'\}$ which occur in the fifth- and third-chaos parts of (144.226):*

$$\begin{aligned}
\mathcal{H}_{5,A}: &\quad (a,b)_3,\ (a',b')_3,\ 2(a,a')_1,\ 3(b,b')_1,\\
\mathcal{H}_{5,B}: &\quad (a,b)_3,\ (a',b')_3,\ (a,a')_1,\ (a,b')_1,\ (b,a')_1,\ 2(b,b')_1,\\
\mathcal{H}_{5,C}: &\quad (a,b)_3,\ (a',b')_3,\ 2(a,b')_1,\ 2(b,a')_1,\ (b,b')_1,\\
\mathcal{H}_{3,A}: &\quad (a,b)_3,\ (a,b)_1,\ (a',b')_3,\ (a',b')_1,\ (a,a')_1,\ 2(b,b')_1,\\
\mathcal{H}_{3,B}: &\quad (a,b)_3,\ (a,b)_1,\ (a',b')_3,\ (a',b')_1,\ (a,b')_1,\ (b,a')_1,\ (b,b')_1.
\end{aligned}$$

The subscript again denotes the singular exponent of the edge. For every one of these graphs,

$$\sum_{e\in E(\mathcal{H})} s_e = Q(|V|-2)+1 = 11. \tag{144.240}$$

Every proper subset $W \subsetneq V$ with $|W| \geq 2$ obeys

$$s_{\mathcal{H}}(W) < Q(|W|-1).$$

The minimum proper-subgraph deficit is 2 for each fifth-chaos graph and 1 for each third-chaos graph.

Consequently, if χ_z^δ is an L^1-normalized test density supported in a parabolic ball of radius $O(\delta)$, then the scalar covariance integrals belonging to the fifth- and third-chaos X^2Y kernels obey

$$|I_\delta^{X^2Y,\geq 3}| \leq C\delta^{-1}, \qquad 0 < \delta \leq 1. \tag{144.241}$$

Equivalently, if

$$Z_{\epsilon,\delta,z}^{X^2Y,\geq 3}(\varphi) = I_5(F^{\chi_z^\delta}_{X^2Y,5}) + I_3(F^{\chi_z^\delta}_{X^2Y,3}),$$

then, uniformly in the cutoff and for z in a fixed compact set,

$$\mathbb{E}\left|Z_{\epsilon,\delta,z}^{X^2Y,\geq 3}(\varphi)\right|^2 \leq C\delta^{-1}. \tag{144.242}$$

For every even $p \geq 2$,

$$\left\|\delta^{1/2+5\kappa} Z_{\epsilon,\delta,z}^{X^2Y,\geq 3}(\varphi)\right\|_{L^p(\Omega)} \leq C_p\delta^{5\kappa}. \tag{144.243}$$

Proof. The edge lists give total degree $3+3+5 = 11$ for the three fifth-chaos graphs and $3+1+3+1+3 = 11$ for the two third-chaos graphs, which proves (144.240). For two-vertex subsets, the largest internal singular exponent is 3 in the fifth-chaos graphs and 4 in the third-chaos graphs. These give deficits 2 and 1, respectively, relative to $Q(|W|-1) = 5$. For three-vertex subsets, inspection of the displayed edge lists gives maximal internal singular exponent 6 in all five graphs, hence deficit 4 relative to $Q(|W|-1) = 10$. This proves the strict proper-subgraph inequalities and the stated minimum deficits.

The dyadic sector argument uses the same multiscale sector decomposition as the XY graph bound above. The strict proper-subgraph deficits make every relative-scale gap geometrically summable by the multiscale sector summability theorem. After the relative sums have been performed, the remaining overall scale has exponent one, because the total graph degree is $Q(|V|-2)+1$ rather than $Q(|V|-2)$. If $2^{-M-1} < \delta \le 2^{-M}$, the relevant overall scales therefore contribute

$$\sum_{0\le n\le M+O(1)} 2^n \le C2^M \le C\delta^{-1},$$

and scales larger than $M+O(1)$ are excluded by the test supports together with the same relative-cluster estimates. This proves (144.241).

Insert $\chi = \chi_z^\delta$ in the fifth- and third-chaos lines of (144.226). The fixed numerical coefficients and the chaos factors 5! and 3! are absorbed into C, and (144.227) gives (144.242). The variable $Z^{X^2Y,\ge 3}_{\epsilon,\delta,z}$ is a finite sum of homogeneous Wiener chaoses of orders 5 and 3; the finite-chaos moment estimate converts the L^2-bound to L^p. Multiplication by the model normalization $\delta^{1/2+5\kappa}$, corresponding to true target regularity $-1/2$ and assigned regularity $-1/2-5\kappa$, gives (144.243). $\square$

Proposition 144.76 (Scalar tested high-chaos X^2Y parameter-edge bound)**.** *Keep the hypotheses of Proposition 144.75. Let*

$$\mathcal{X}_{\Pi,m} = K\times[1/2,1], \qquad d_{\Pi,m}((z,a),(z',a')) = 2^m\|z-z'\|_{\mathfrak{s}} + |a-a'|,$$

and let

$$\varphi_u(a_0) = \delta_u^{-Q}\varphi(\mathsf{D}_{\delta_u}^{-1}(a_0-z)), \qquad \delta_u = 2^{-m}a, \qquad \|\varphi\|_{C^r}\le 1,$$

with $r\ge 1$. Define

$$Z^{X^2Y,\ge 3}_{\epsilon,m,u}(\varphi) = I_5(F^{\varphi_u}_{X^2Y,5}) + I_3(F^{\varphi_u}_{X^2Y,3}).$$

Then, whenever $d_{\Pi,m}(u,v)\le 1$,

$$\mathbb{E}\left|Z^{X^2Y,\ge 3}_{\epsilon,m,v}(\varphi) - Z^{X^2Y,\ge 3}_{\epsilon,m,u}(\varphi)\right|^2 \le C_\theta\, 2^m\, d_{\Pi,m}(u,v)^{2\theta}, \qquad 0<\theta\le 1. \tag{144.244}$$

Consequently, for every even $p\ge 2$,

$$\left\|2^{-(1/2+5\kappa)m}\big(Z^{X^2Y,\ge 3}_{\epsilon,m,v}(\varphi) - Z^{X^2Y,\ge 3}_{\epsilon,m,u}(\varphi)\big)\right\|_{L^p(\Omega)} \le C_{p,\theta}\, 2^{-5\kappa m} d_{\Pi,m}(u,v)^\theta. \tag{144.245}$$

Proof. The transported test-density estimate (144.236) is deterministic and applies here unchanged:

$$\|\varphi_v-\varphi_u\|_{L^1} \le Cd_{\Pi,m}(u,v)^\theta,$$

and the two supports lie in one parabolic ball of radius $C2^{-m}$. The graph estimate proved inside Proposition 144.75 is homogeneous in the two external test densities: replacing the L^1-normalized test in that proof by a signed test ψ supported in the same parabolic ball adds the factor $\|\psi\|^2_{L^1}$ to the covariance integral and changes no scale exponent. Applying this homogeneous form to $\psi=\varphi_v-\varphi_u$, with $\delta\simeq 2^{-m}$, gives (144.244). The difference is still a finite sum of homogeneous Wiener chaoses of orders 5 and 3. The finite-chaos moment estimate converts the square root of (144.244) to an L^p-bound. Multiplication by the model normalization $2^{-(1/2+5\kappa)m}$ leaves the scale factor $2^{-5\kappa m}$, proving (144.245). $\square$

Proposition 144.77 (Scalar tested high-chaos X^2Y cutoff-shell gain)**.** *Keep the notation and graph hypotheses of Proposition 144.75. Let*

$$Z^{X^2Y,\ge 3}_{n,m,u}(\varphi) = I_5(F^{\varphi_u}_{n,X^2Y,5}) + I_3(F^{\varphi_u}_{n,X^2Y,3})$$

be the high-chaos scalar tested coordinate at dyadic ultraviolet cutoff n. Assume the cutoff difference $Z^{X^2Y,\geq 3}_{n+1,m,u} - Z^{X^2Y,\geq 3}_{n,m,u}$ has the following admissible shell representation: after expanding the second moment by (144.224) and (144.226), every term is a finite linear combination of the five high-chaos graph integrals in Proposition 144.75, with at least one heat or covariance edge replaced by a cutoff-shell block whose dyadic scale is $\geq n - c_0$. The shell block satisfies the same support and size bounds as the corresponding ordinary dyadic block, with constants independent of n.

Then, for every $0 < \rho < 1/2$,

$$\mathbb{E}\left|Z^{X^2Y,\geq 3}_{n+1,m,u}(\varphi) - Z^{X^2Y,\geq 3}_{n,m,u}(\varphi)\right|^2 \leq C_\rho\, 2^m\, 2^{-2\rho(n-m)_+}. \tag{144.246}$$

Consequently, for every even $p \geq 2$,

$$\left\|2^{-(1/2+5\kappa)m}\big(Z^{X^2Y,\geq 3}_{n+1,m,u}(\varphi) - Z^{X^2Y,\geq 3}_{n,m,u}(\varphi)\big)\right\|_{L^p(\Omega)} \leq C_{p,\rho}\, 2^{-5\kappa m} 2^{-\rho(n-m)_+}. \tag{144.247}$$

Proof. Let $M = m + O(1)$ be the largest overall scale interacting with the two scale-2^{-m} test densities. Without the cutoff-shell constraint, Proposition 144.75 leaves the overall sum

$$\sum_{0\leq N\leq M+O(1)} 2^N = O(2^m).$$

Now impose the shell condition. If the shell edge is not at the overall scale, it lies inside a proper subcluster whose relative-scale gap is at least $(n-M-C)_+$. The smallest proper-subgraph deficit among the five high-chaos X^2Y graphs is 1, so that sector gains

$$2^{-(n-M-C)_+}.$$

If the shell edge is at the overall scale, then $n \leq M + C$, and the same bound is absorbed into the constant. Thus every graph contribution is bounded by

$$C2^m 2^{-(n-m)_+}.$$

Since $0 < \rho < 1/2$, this implies the weaker bound (144.246). The cutoff difference is a finite sum of homogeneous chaoses of orders 5 and 3, so the finite-chaos moment estimate and the normalization $2^{-(1/2+5\kappa)m}$ give (144.247). $\square$

Remark 144.78 (Scalar shell gain and projective cutoff input). Estimate (144.239) is a scale-separated scalar Cauchy estimate. It identifies where the ultraviolet shell gain enters the XY graph analysis. Proposition 144.75 supplies the parallel scalar base estimate for the fifth- and third-chaos pieces of X^2Y, while Propositions 144.76 and 144.77 supply the corresponding scalar edge and shell layers. The remaining X^2Y first-chaos component is different: its local subtraction produces covariance increments, treated below in Propositions 144.81 and 144.82. Corollary 144.61 then converts this scalar factor into a scale-summed cutoff rate whenever the normalization slack exceeds the parameter entropy. The projective cutoff-increment hypothesis (144.254) asks for a uniform factor $2^{-\rho n}$ in the full E'_r-dualized kernel norm. The scalar estimate gives the finite-coordinate shell mechanism; the dualized cutoff-increment estimate and its parameter-edge version supply the corresponding projective-kernel input needed by the Φ^4_3 model-convergence theorem.

Proposition 144.79 (Nonlinear Π-coordinate input from projective kernel bounds)**.** *Let $K \subset \mathbb{R}^{1+3}$ be compact and let*

$$\mathcal{X}_{\Pi,m} = K \times [1/2, 1], \qquad d_{\Pi,m}((z,a),(z',a')) = 2^m \|z - z'\|_{\mathfrak{s}} + |a - a'|$$

be the physical Π*-coordinate spaces of Proposition 144.66. Let*

$$E_r = \{\varphi \in C^r(\mathbb{R}^{1+3}) : \operatorname{supp}\varphi \subset B_{\mathfrak{s}}(0,1)\}, \qquad \|\varphi\|_{E_r} = \|\varphi\|_{C^r}.$$

Fix

$$0 < \kappa < \frac{1}{14}, \qquad 0 \le \zeta_{XY} < 4\kappa, \qquad 0 < \zeta_{X^2Y} < 5\kappa,$$

and set

$$\begin{gathered} |XY| = -4\kappa, \qquad |X^2Y| = -\frac{1}{2} - 5\kappa, \\ \sigma_{XY} = 4\kappa - \zeta_{XY}, \qquad \sigma_{X^2Y} = 5\kappa - \zeta_{X^2Y}. \end{gathered} \tag{144.248}$$

The loss ζ_{XY} is optional: it may be set to zero only after the concrete XY projective kernel estimate proves that the marginal overall-scale logarithm in Proposition 144.71 is absent or harmless in the chosen norm. The loss ζ_{X^2Y} is reserved for logarithmic factors in the locally subtracted first-chaos component of X^2Y.

For

$$\mathfrak{C}_{\mathrm{nl}} = \{XY, X^2Y\}, \qquad \mathcal{Q}_{XY} = \{4, 2\}, \qquad \mathcal{Q}_{X^2Y} = \{5, 3, 1\},$$

let $F_{n,\tau,q,m}(u) \in \mathcal{H}^{\odot q} \widehat{\otimes}_\pi E_r'$, where

$$n \ge 1, \qquad \tau \in \mathfrak{C}_{\mathrm{nl}}, \qquad q \in \mathcal{Q}_\tau, \qquad m \ge 0, \qquad u = (z,a) \in \mathcal{X}_{\Pi,m}.$$

Assume that the E_r'-valued chaos expansion

$$Y_{n,\tau,m}(u) = \sum_{q \in \mathcal{Q}_\tau} I_q(F_{n,\tau,q,m}(u)) \tag{144.249}$$

is the scale-normalized tested Π*-coordinate:*

$$Y_{n,\tau,m}(z,a)(\varphi) = (2^{-m}a)^{-|\tau|} \left\langle \Pi_z^{(n)}\tau, \varphi_z^{2^{-m}a} \right\rangle. \tag{144.250}$$

For X^2Y, the kernels are those of the locally subtracted coordinate (144.219); equivalently, after pairing with a test density, they reduce to (144.223). For XY, they reduce to (144.221).

Choose $0 < \theta \le 1$, an even integer $p = 2m_0$, and $\rho > 0$ such that

$$p\sigma_\tau > 5 \quad (\tau \in \mathfrak{C}_{\mathrm{nl}}), \qquad p\theta > 6. \tag{144.251}$$

Suppose that there are constants

$$B_{\tau,q,0},\ B_{\tau,q,1},\ \widetilde{B}_{\tau,q,0},\ \widetilde{B}_{\tau,q,1} < \infty$$

such that, for every n, m, τ, q and $u, v \in \mathcal{X}_{\Pi,m}$ with $d_{\Pi,m}(u,v) \le 1$,

$$\|F_{n,\tau,q,m}(u)\|_\pi \le B_{\tau,q,0} 2^{-\sigma_\tau m}, \tag{144.252}$$

$$\|F_{n,\tau,q,m}(v) - F_{n,\tau,q,m}(u)\|_\pi \le B_{\tau,q,1} 2^{-\sigma_\tau m} d_{\Pi,m}(u,v)^\theta, \tag{144.253}$$

and the cutoff increments obey

$$\|F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u)\|_\pi \le \widetilde{B}_{\tau,q,0} 2^{-\rho n} 2^{-\sigma_\tau m}, \tag{144.254}$$

$$\begin{aligned} &\|(F_{n+1,\tau,q,m}(v) - F_{n,\tau,q,m}(v)) - (F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u))\|_\pi \\ &\quad \le \widetilde{B}_{\tau,q,1} 2^{-\rho n} 2^{-\sigma_\tau m} d_{\Pi,m}(u,v)^\theta. \end{aligned} \tag{144.255}$$

Then the nonlinear coordinates XY and X^2Y satisfy the Π-coordinate hypotheses of the negative-sector coordinate-control consequence with

$$D_\tau = 5, \qquad d_\tau = 6, \qquad \varepsilon_\tau = p\theta - 6. \tag{144.256}$$

In particular, if

$$U_{n,\tau,m}(u) = \|Y_{n,\tau,m}(u)\|_{E'_r}$$

and $V_{n,\tau,m}$ is defined by replacing $Y_{n,\tau,m}$ with $Y_{n+1,\tau,m} - Y_{n,\tau,m}$, then, on the nets of Proposition 144.66,

$$\mathbb{E}|U_{n,\tau,m}(u)|^p \le A_{\tau,0}^p 2^{-p\sigma_\tau m}, \qquad \mathbb{E}|V_{n,\tau,m}(u)|^p \le \widetilde{A}_{\tau,0}^p 2^{-p\rho n} 2^{-p\sigma_\tau m},$$

and

$$\mathbb{E}|U_{n,\tau,m}(v) - U_{n,\tau,m}(u)|^p \le A_{\tau,1}^p 2^{-p\sigma_\tau m} 2^{-(6+\varepsilon_\tau)\ell},$$

$$\mathbb{E}|V_{n,\tau,m}(v) - V_{n,\tau,m}(u)|^p \le \widetilde{A}_{\tau,1}^p 2^{-p\rho n} 2^{-p\sigma_\tau m} 2^{-(6+\varepsilon_\tau)\ell}$$

for all $(u,v) \in \mathcal{E}_{\Pi,m,\ell}$. The constants are

$$A_{\tau,i} = \sum_{q\in\mathcal{Q}_\tau} C_{q,m_0} B_{\tau,q,i}, \qquad \widetilde{A}_{\tau,i} = \sum_{q\in\mathcal{Q}_\tau} C_{q,m_0} \widetilde{B}_{\tau,q,i}, \qquad i = 0,1, \tag{144.257}$$

where C_{q,m_0} is the finite-chaos constant in Proposition 144.52.

Proof. By (144.250),

$$\|Y_{n,\tau,m}(z,a)\|_{E'_r} = \sup_{\varphi\in\mathcal{B}_r} (2^{-m}a)^{-|\tau|} \left| \left\langle \Pi_z^{(n)}\tau, \varphi_z^{2^{-m}a} \right\rangle \right|.$$

Thus $U_{n,\tau,m}$ is exactly the physical Π-coordinate $Q^{\#}_{n,\tau}$ restricted to dyadic scale m, and the analogous statement holds for cutoff differences.

Apply Proposition 144.52 to (144.249). The projective base bound (144.252) gives

$$\|U_{n,\tau,m}(u)\|_{L^p(\Omega)} \le \sum_{q\in\mathcal{Q}_\tau} C_{q,m_0} B_{\tau,q,0} 2^{-\sigma_\tau m} = A_{\tau,0} 2^{-\sigma_\tau m}. \tag{144.258}$$

The cutoff base estimate follows in the same way from (144.254). For increments, use

$$\big| \|A\|_{E'_r} - \|B\|_{E'_r} \big| \le \|A - B\|_{E'_r}$$

and then apply the finite-chaos estimate to

$$Y_{n,\tau,m}(v) - Y_{n,\tau,m}(u) = \sum_{q\in\mathcal{Q}_\tau} I_q(F_{n,\tau,q,m}(v) - F_{n,\tau,q,m}(u)).$$

This proves

$$\|U_{n,\tau,m}(v) - U_{n,\tau,m}(u)\|_{L^p} \le A_{\tau,1} 2^{-\sigma_\tau m} d_{\Pi,m}(u,v)^\theta, \tag{144.259}$$

and the cutoff edge estimate follows from (144.255).

For an edge $(u,v) \in \mathcal{E}_{\Pi,m,\ell}$, the construction in Proposition 144.66 gives

$$d_{\Pi,m}(u,v) \le C2^{-\ell}.$$

Absorbing the fixed constant C^θ into $A_{\tau,1}$ and $\widetilde{A}_{\tau,1}$, and then raising the L^p-bounds to the p-th power, gives the displayed edge moments because

$$p\theta = 6 + \varepsilon_\tau.$$

The same entropy proposition gives $D_\tau = 5$ and $d_\tau = 6$. The conditions (144.251) are precisely

$$\sigma_\tau > \frac{D_\tau}{p}, \qquad \varepsilon_\tau > 0.$$

The required sample continuity follows from the same finite-net estimate and does not require an additional stochastic input. For fixed n, τ, m, choose nested $2^{-\ell}$-nets in $\mathcal{X}_{\Pi,m}$ as in Proposition 144.66. The edge family at level ℓ has cardinality at most

$$C2^{5m}2^{6\ell}.$$

By (144.259),

$$\sum_{\ell\ge 0} \mathbb{E} \sum_{(u,v)\in\mathcal{E}_{\Pi,m,\ell}} |U_{n,\tau,m}(v) - U_{n,\tau,m}(u)|^p \le C_{n,\tau,m} \sum_{\ell\ge 0} 2^{-(p\theta-6)\ell} < \infty.$$

Fubini therefore gives almost sure summability of the p-th powers of the dyadic edge increments. Since a summable nonnegative sequence tends to zero along the levels, the usual nearest-net telescoping sequence is almost surely Cauchy uniformly along every chain of nested approximants. This defines a continuous modification on the compact metric space $\mathcal{X}_{\Pi,m}$. Applying the identical dyadic-edge summability estimate to $V_{n,\tau,m}$, with the V-moment bounds in place of the U-moment bounds, gives the required continuous modification for the cutoff-difference field. Hence all hypotheses needed for the negative-sector coordinate-control consequence are satisfied for the nonlinear Π-coordinates. □

Corollary 144.80 (Shell-separated nonlinear Π-coordinate cutoff input)**.** *Keep the notation and hypotheses of Proposition 144.79 for the uniform base and parameter-edge bounds* (144.252) *and* (144.253)*. Replace the cutoff assumptions* (144.254) *and* (144.255) *by the shell-separated estimates*

$$\|F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u)\|_\pi \le \widehat{B}_{\tau,q,0} 2^{-\sigma_\tau m} 2^{-\rho_\tau (n-m)_+}, \tag{144.260}$$

and

$$\begin{aligned}\|(F_{n+1,\tau,q,m}(v) - F_{n,\tau,q,m}(v)) - (F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u))\|_\pi \\ \le \widehat{B}_{\tau,q,1} 2^{-\sigma_\tau m} 2^{-\rho_\tau (n-m)_+} d_{\Pi,m}(u,v)^\theta,\end{aligned} \tag{144.261}$$

for constants $\rho_\tau > 0$. Let $p = 2m_0$ be the chosen even moment order, and assume

$$p\sigma_\tau > 5, \qquad p\theta > 6.$$

For any

$$0 < \rho_\tau^* < \min\left\{\rho_\tau,\, \sigma_\tau - \frac{5}{p}\right\}, \tag{144.262}$$

there is a finite constant $\widehat{S}_\tau^{\mathrm{sh}}$ *such that the cutoff-difference field*

$$V_{n,\tau,m}(u) = \left\| \sum_{q\in\mathcal{Q}_\tau} I_q(F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u)) \right\|_{E'_\tau}$$

satisfies the scale-summed estimate

$$\left\| \sup_{m\geq 0} \sup_{u\in\mathcal{X}_{\Pi,m}} V_{n,\tau,m}(u) \right\|_{L^p(\Omega)} \leq \widehat{S}_\tau^{\mathrm{sh}}\, 2^{-\rho_\tau^* n}. \tag{144.263}$$

One may take

$$\begin{aligned} \widehat{S}_\tau^{\mathrm{sh}} &= H_{\rho_\tau^*,\rho_\tau,\sigma_\tau-5/p}\left(C_{\Pi,0}^{1/p}\widehat{A}_{\tau,0} + C_{\Pi,1}^{1/p}\widehat{A}_{\tau,1}(1-2^{-(p\theta-6)/p})^{-1}\right), \\ \widehat{A}_{\tau,i} &= \sum_{q\in\mathcal{Q}_\tau} C_{q,m_0}\widehat{B}_{\tau,q,i}, \qquad i=0,1. \end{aligned} \tag{144.264}$$

Proof. For the cutoff-difference chaos kernels, apply Proposition 144.52 exactly as in the proof of Proposition 144.79. The base estimate gives

$$\|V_{n,\tau,m}(u)\|_{L^p} \leq \widehat{A}_{\tau,0} 2^{-\sigma_\tau m} 2^{-\rho_\tau (n-m)_+}.$$

For an edge $(u,v)\in\mathcal{E}_{\Pi,m,\ell}$, use the norm inequality

$$|V_{n,\tau,m}(v) - V_{n,\tau,m}(u)| \leq \|\Delta_n Y_{\tau,m}(v) - \Delta_n Y_{\tau,m}(u)\|_{E'_\tau}$$

where

$$\Delta_n Y_{\tau,m}(u) = \sum_{q\in\mathcal{Q}_\tau} I_q(F_{n+1,\tau,q,m}(u) - F_{n,\tau,q,m}(u)).$$

The shell-separated edge hypothesis (144.261) and the finite-chaos estimate give

$$\|V_{n,\tau,m}(v) - V_{n,\tau,m}(u)\|_{L^p} \leq \widehat{A}_{\tau,1} 2^{-\sigma_\tau m} 2^{-\rho_\tau (n-m)_+} d_{\Pi,m}(u,v)^\theta.$$

On the dyadic edge set,

$$d_{\Pi,m}(u,v) \leq C 2^{-\ell}.$$

Absorb C^θ into $\widehat{A}_{\tau,1}$. Since the edge entropy is six, the edge moment has excess exponent

$$\varepsilon_\tau = p\theta - 6 > 0.$$

The entropy in the physical scale m is $D=5$, and the effective scale slack is

$$a_\tau = \sigma_\tau - \frac{5}{p} > 0.$$

Corollary 144.61, or equivalently the projective version Corollary 144.62 with $D=5$, $d=6$, $B_\pi = \widehat{A}_{\tau,0}$, and $B_\pi^{\mathrm{ed}} = \widehat{A}_{\tau,1}$, gives (144.263) with the constant (144.264). ☐

Proposition 144.81 (Scale bound for the locally subtracted first-chaos kernel)**.** *Let* $Q = 5$, $\mathfrak{s} = (2, 1, 1, 1)$, *and*

$$\mathsf{D}_\delta(t, x) = (\delta^2 t, \delta x).$$

Fix $0 < \theta \le 1$. *Let*

$$\chi_z^\delta(a) = \delta^{-Q}\chi(\mathsf{D}_\delta^{-1}(a - z)), \qquad 0 < \delta \le 1,$$

where χ *is supported in a fixed unit parabolic ball and* $\|\chi\|_{L^\infty} \le 1$*. For* $n \ge 0$*, let* $A_n(a, h)$ *be the shell packet of the local two-loop factor* $K(a, a+h)G(a, a+h)^2$*. Assume there are constants* R, A_0 *such that*

$$A_n(a, h) = 0 \quad \textit{unless } \|h\|_{\mathfrak{s}} \le R2^{-n}, \qquad \sup_a \int |A_n(a, h)|\,\mathrm{d}h \le A_0. \tag{144.265}$$

Let C_s*,* $s \ge 0$*, be dyadic covariance blocks of order* 4*. Assume that, whenever* h *and* h' *lie in the supports of* A_n *and* $A_{n'}$*, the double increment*

$$\begin{aligned}\Delta_{h,h'}C_s(a, a') = C_s(a+h, a'+h') &- C_s(a+h, a') \\ &- C_s(a, a'+h') + C_s(a, a')\end{aligned}$$

satisfies

$$\begin{aligned}|\Delta_{h,h'}C_s(a, a')| \le A_0\, 2^s\, 2^{-\theta(n-s)_+} &2^{-\theta(n'-s)_+} \\ &\times \sum_{\rho\in\{0,h\}}\sum_{\rho'\in\{0,h'\}} \mathbf{1}_{\{\|a+\rho-a'-\rho'\|_{\mathfrak{s}}\le R2^{-s}\}}.\end{aligned} \tag{144.266}$$

For a finite ultraviolet cutoff N*, define the scalar sector sum*

$$\begin{aligned}V_{\delta,N}^{(1)} = \sum_{0\le n,n',s\le N} \int \chi_z^\delta(a)\chi_z^\delta(a')A_n(a, h)A_{n'}(a', h') \\ \times \Delta_{h,h'}C_s(a, a')\,\mathrm{d}h\,\mathrm{d}h'\,\mathrm{d}a\,\mathrm{d}a'.\end{aligned} \tag{144.267}$$

Then there is a constant C*, independent of* z*,* δ*, and* N*, such that*

$$|V_{\delta,N}^{(1)}| \le C\,\delta^{-1}\big(1 + |\log_2 \delta|\big)^2. \tag{144.268}$$

Consequently, if $Z_{\delta,N}^{(1)}$ *is the first-chaos part of the tested locally subtracted* X^2Y *coordinate whose second moment is bounded by a finite sum of terms of the form* (144.267)*, then, for every* $\eta > 0$*,*

$$\Big\|\delta^{1/2+5\kappa} Z_{\delta,N}^{(1)}\Big\|_{L^2(\Omega)} \le C_\eta\, \delta^{5\kappa-\eta}. \tag{144.269}$$

Proof. For a fixed shift r, the test-function overlap obeys

$$\int |\chi_z^\delta(a)\chi_z^\delta(a')|\mathbf{1}_{\{\|a-a'-r\|_{\mathfrak{s}}\le R2^{-s}\}}\,\mathrm{d}a\,\mathrm{d}a' \le C_\chi \min\{1, \delta^{-Q}2^{-Qs}\}. \tag{144.270}$$

Indeed, if $2^{-s} \ge c\delta$, the left side is at most $\|\chi_z^\delta\|_{L^1}^2$. If $2^{-s} < c\delta$, then for each a the allowed a'-set has volume $O(2^{-Qs})$, while $\|\chi_z^\delta\|_{L^\infty} \le C\delta^{-Q}$ and $\|\chi_z^\delta\|_{L^1} \le C$.

Insert (144.266) into (144.267), use (144.265) for the h and h' integrals, and then use (144.270). This gives

$$|V_{\delta,N}^{(1)}| \le C\sum_{s=0}^N B_s(\delta)\left(\sum_{n=0}^N 2^{-\theta(n-s)_+}\right)^2,$$

where

$$B_s(\delta) = 2^s \min\{1, \delta^{-Q} 2^{-Qs}\}.$$

The local two-loop packets are shell-summable but not summable over all shells; this is exactly why the square of the shell count remains. Since

$$\sum_{n=0}^{N} 2^{-\theta(n-s)_+} \le (s+1) + \frac{1}{1-2^{-\theta}} \le C_\theta(1+s),$$

we have

$$|V^{(1)}_{\delta,N}| \le C \sum_{s \ge 0} B_s(\delta)(1+s)^2.$$

Choose $m \ge 0$ such that $2^{-m-1} < \delta \le 2^{-m}$. For $s \le m$, $B_s(\delta) \le 2^s$, hence

$$\sum_{s \le m} B_s(\delta)(1+s)^2 \le C 2^m (1+m)^2 \le C\delta^{-1}(1+|\log_2 \delta|)^2.$$

For $s > m$,

$$B_s(\delta) \le C 2^{Qm} 2^{-(Q-1)s}.$$

Because $Q - 1 = 4 > 0$,

$$\sum_{s > m} B_s(\delta)(1+s)^2 \le C 2^{Qm} 2^{-(Q-1)m}(1+m)^2 \le C\delta^{-1}(1+|\log_2 \delta|)^2.$$

This proves (144.268).

The first-chaos sector is a centered Gaussian variable, so its L^2-norm is the square root of its variance. Multiplying by $\delta^{1/2+5\kappa}$ gives

$$\left\| \delta^{1/2+5\kappa} Z^{(1)}_{\delta,N} \right\|_{L^2} \le C\delta^{5\kappa}(1+|\log_2 \delta|).$$

For every $\eta > 0$,

$$\sup_{0<\delta\le 1} \delta^\eta (1+|\log_2 \delta|) < \infty,$$

which gives (144.269). □

Proposition 144.82 (Cutoff-shell gain for the locally subtracted first-chaos kernel)**.** *Keep the hypotheses and notation of Proposition 144.81, and choose $m_\delta \ge 0$ by*

$$2^{-m_\delta - 1} < \delta \le 2^{-m_\delta}.$$

For $N \ge 0$, set

$$\Delta_N V^{(1)}_\delta = V^{(1)}_{\delta,N+1} - V^{(1)}_{\delta,N}.$$

Then, for every $0 < \rho < \theta/2$, there is a constant C_ρ, independent of z, δ, N, such that

$$|\Delta_N V^{(1)}_\delta| \le C_\rho\, \delta^{-1}(1+m_\delta)^2 2^{-2\rho(N-m_\delta)_+}. \tag{144.271}$$

Consequently, if the cutoff increment $Z^{(1)}_{\delta,N+1} - Z^{(1)}_{\delta,N}$ of the first-chaos part of the tested locally subtracted X^2Y coordinate has its second moment bounded by a fixed finite sum of terms of the form $\Delta_N V^{(1)}_\delta$, then for every $\eta > 0$ and every $0 < \rho < \theta/2$,

$$\left\| \delta^{1/2+5\kappa}\big(Z^{(1)}_{\delta,N+1} - Z^{(1)}_{\delta,N}\big) \right\|_{L^2(\Omega)} \le C_{\eta,\rho}\, \delta^{5\kappa-\eta} 2^{-\rho(N-m_\delta)_+}. \tag{144.272}$$

Proof. The proof keeps the shell location visible. Write

$$\alpha_{j,s} = 2^{-\theta(j-s)_+}, \qquad B_s(\delta) = 2^s \min\{1, \delta^{-Q} 2^{-Qs}\}.$$

The estimate in the proof of Proposition 144.81 gives the majorant

$$|V^{(1)}_{\delta,N}| \leq C \sum_{0\leq s\leq N} B_s(\delta) \left(\sum_{0\leq n\leq N} \alpha_{n,s} \right)^2 .$$

Subtracting the N-cutoff sum from the $N+1$-cutoff sum leaves exactly the sectors in which at least one of the three indices n, n', s is $N+1$. Hence

$$\begin{aligned} |\Delta_N V^{(1)}_\delta| \leq C\, B_{N+1}(\delta) \left(\sum_{0\leq j\leq N+1} \alpha_{j,N+1} \right)^2 \\ + C \sum_{0\leq s\leq N+1} B_s(\delta)\alpha_{N+1,s} \left(\sum_{0\leq j\leq N+1} \alpha_{j,s} \right) . \end{aligned} \tag{144.273}$$

The second line accounts for the two symmetric cases $n = N+1$ and $n' = N+1$, with the factor 2 absorbed into C.

Let $L = (N - m_\delta)_+$. If $N \leq m_\delta$, then the right side of (144.271) has no shell gain, and the total bound (144.268) already gives the claim. Assume from now on that $N > m_\delta$. The covariance-shell term in (144.273) has $s = N+1 > m_\delta$, so

$$B_{N+1}(\delta) \leq C 2^{m_\delta} 2^{-4(N-m_\delta)}.$$

Moreover $\sum_{j\leq N+1} \alpha_{j,N+1} \leq C(1+N)$. Since $2\rho < 4$, the polynomial factor is absorbed by weakening the exponential:

$$B_{N+1}(\delta) \left(\sum_{j\leq N+1} \alpha_{j,N+1} \right)^2 \leq C_\rho 2^{m_\delta}(1+m_\delta)^2 2^{-2\rho(N-m_\delta)}.$$

It remains to bound the local-shell line in (144.273). Use $\sum_{j\leq N+1} \alpha_{j,s} \leq C(1+s)$. For $s \leq m_\delta$,

$$\begin{aligned} \sum_{s\leq m_\delta} B_s(\delta)\alpha_{N+1,s}(1+s) &\leq C(1+m_\delta)2^{-\theta(N-m_\delta)} \sum_{s\leq m_\delta} 2^s \\ &\leq C 2^{m_\delta}(1+m_\delta)2^{-\theta(N-m_\delta)}. \end{aligned}$$

For $s > m_\delta$, write $s = m_\delta + t$. Then

$$B_s(\delta) \leq C 2^{m_\delta} 2^{-4t}.$$

The part $1 \leq t \leq N - m_\delta$ is bounded by

$$C 2^{m_\delta}(1+m_\delta) \sum_{1\leq t\leq N-m_\delta} (1+t)2^{-4t}2^{-\theta(N-m_\delta-t)} \leq C 2^{m_\delta}(1+m_\delta)2^{-\theta(N-m_\delta)},$$

because $4-\theta>0$. The tail $t>N-m_\delta$ has $\alpha_{N+1,s}=1$ and is bounded by

$$C2^{m_\delta}(1+m_\delta)\sum_{t>N-m_\delta}(1+t)2^{-4t}\le C2^{m_\delta}(1+m_\delta)2^{-4(N-m_\delta)}.$$

Since $2\rho<\theta\le 1<4$, the two local-shell estimates are bounded by

$$C_\rho 2^{m_\delta}(1+m_\delta)^2 2^{-2\rho(N-m_\delta)}.$$

Combining the covariance-shell and local-shell estimates, and using $2^{m_\delta}\simeq\delta^{-1}$, proves (144.271).

The first-chaos increment is Gaussian, so the L^2-norm is the square root of its variance. Multiplication by $\delta^{1/2+5\kappa}$ gives

$$C_\rho\delta^{5\kappa}(1+m_\delta)2^{-\rho(N-m_\delta)_+}.$$

The logarithm is absorbed as before: for every $\eta>0$,

$$(1+m_\delta)\le C_\eta\delta^{-\eta}.$$

This proves (144.272). $\square$

Proposition 144.83 (Parameter-edge bound for the locally subtracted first-chaos kernel)**.** *Keep the hypotheses and notation of Propositions 144.81 and 144.82. Let*

$$\mathcal{X}_{\Pi,m}=K\times[1/2,1],\qquad \mathrm{d}_{\Pi,m}((z,a),(z',a'))=2^m\|z-z'\|_{\mathfrak{s}}+|a-a'|,$$

where $K\subset\mathbb{R}^{1+3}$ is compact. For $\varphi\in C_c^1(B_{\mathfrak{s}}(0,1))$, $\|\varphi\|_{C^1}\le 1$, set

$$\varphi_u(x)=\delta_u^{-Q}\varphi(\mathsf{D}_{\delta_u}^{-1}(x-z)),\qquad u=(z,a),\qquad \delta_u=2^{-m}a.$$

Let $Z^{(1)}_{N,m,u}(\varphi)$ be the first-chaos scalar coordinate obtained from the locally subtracted X^2Y kernel by replacing the test density χ_z^δ in (144.267) by φ_u. More precisely, assume its second moment is bounded by a fixed finite sum of the sector integrals used in Proposition 144.81, with constants independent of m,N,u,φ, and assume the cutoff difference has the shell representation used in Proposition 144.82.

Then, whenever $\mathrm{d}_{\Pi,m}(u,v)\le 1$, for every $0<\vartheta\le 1$ there is a constant C_ϑ such that

$$\mathbb{E}\left|Z^{(1)}_{N,m,v}(\varphi)-Z^{(1)}_{N,m,u}(\varphi)\right|^2\le C_\vartheta\,2^m(1+m)^2\,\mathrm{d}_{\Pi,m}(u,v)^{2\vartheta}.\tag{144.274}$$

For every even $p\ge 2$ and every $\eta>0$,

$$\left\|2^{-(1/2+5\kappa)m}\big(Z^{(1)}_{N,m,v}(\varphi)-Z^{(1)}_{N,m,u}(\varphi)\big)\right\|_{L^p(\Omega)}\le C_{p,\eta,\vartheta}\,2^{-(5\kappa-\eta)m}\mathrm{d}_{\Pi,m}(u,v)^{\vartheta}.\tag{144.275}$$

Moreover, for every $0<\rho<\theta/2$, where θ is the covariance double-increment exponent in (144.266),

$$\begin{aligned}\Big\|2^{-(1/2+5\kappa)m}\big[(Z^{(1)}_{N+1,m,v}-Z^{(1)}_{N,m,v})-(Z^{(1)}_{N+1,m,u}-Z^{(1)}_{N,m,u})\big]\Big\|_{L^p(\Omega)}\\ \le C_{p,\eta,\vartheta,\rho}\,2^{-(5\kappa-\eta)m}2^{-\rho(N-m)_+}\mathrm{d}_{\Pi,m}(u,v)^{\vartheta}.\end{aligned}\tag{144.276}$$

Proof. The proof is the first-chaos analogue of the high-chaos edge estimate, but the local subtraction makes the overlap estimate worth recording explicitly. Put

$$d = d_{\Pi,m}(u,v), \qquad \psi = \varphi_v - \varphi_u.$$

The transported test map is Lipschitz from $\mathcal{X}_{\Pi,m}$ to both L^1 and the scale-normalized L^∞ norm. Differentiating in the base point produces the dimensionless factor $2^m\|z-z'\|_{\mathfrak{s}}$, and differentiating in $a \in [1/2,1]$ differentiates the compact family

$$a^{-Q}\varphi(\mathsf{D}_{a^{-1}}w).$$

Hence, because $d \le 1$ and $0 < \vartheta \le 1$,

$$\|\psi\|_{L^1} \le Cd^\vartheta, \qquad \|\psi\|_{L^\infty} \le C2^{Qm}d^\vartheta, \tag{144.277}$$

and the supports of φ_u, φ_v, and ψ lie in one parabolic ball of radius $C2^{-m}$.

Let r be any of the finitely many shifts $0, \pm h, \pm h'$, or $h-h'$, appearing in the four support indicators of the covariance double increment. For every $s \ge 0$,

$$\int |\psi(a)\psi(a')|\mathbf{1}_{\{\|a-a'-r\|_{\mathfrak{s}} \le R2^{-s}\}}\,\mathrm{d}a\,\mathrm{d}a' \le Cd^{2\vartheta}\min\{1, 2^{Qm}2^{-Qs}\}. \tag{144.278}$$

Indeed, the first bound is $\|\psi\|_{L^1}^2$. The second is obtained by integrating in a' over a parabolic ball of volume $O(2^{-Qs})$, using $\|\psi\|_{L^\infty}$ for the a'-factor and $\|\psi\|_{L^1}$ for the a-factor. Equation (144.277) then gives the displayed factor.

Now repeat the proof of Proposition 144.81 with χ_z^δ replaced by the signed density ψ and with $2^{-m}a$ in place of δ. The shell L^1 bounds on A_n and $A_{n'}$, the covariance double-increment estimate (144.266), and the signed overlap estimate (144.278) give

$$\mathbb{E}|Z^{(1)}_{N,m,v} - Z^{(1)}_{N,m,u}|^2 \le Cd^{2\vartheta}\sum_{s\ge 0} B_s(m)(1+s)^2,$$

where

$$B_s(m) = 2^s\min\{1, 2^{Qm}2^{-Qs}\}.$$

The same split at $s = m$ as before gives

$$\sum_{s\ge 0} B_s(m)(1+s)^2 \le C2^m(1+m)^2,$$

which proves (144.274).

For the cutoff edge, repeat the proof of Proposition 144.82 with the same signed density ψ. The decomposition into the covariance-shell term and the two local-shell terms is unchanged; every occurrence of the test overlap now carries the extra factor $d^{2\vartheta}$ from (144.278). Therefore

$$\mathbb{E}\left|(Z^{(1)}_{N+1,m,v} - Z^{(1)}_{N,m,v}) - (Z^{(1)}_{N+1,m,u} - Z^{(1)}_{N,m,u})\right|^2 \le C_{\rho,\vartheta}2^m(1+m)^2 2^{-2\rho(N-m)_+}d^{2\vartheta}.$$

The first-chaos variables are Gaussian, so their L^p-norms are bounded by a p-dependent constant times their L^2-norms. Multiplying by $2^{-(1/2+5\kappa)m}$ leaves

$$2^{-5\kappa m}(1+m)d^\vartheta$$

in the same-scale estimate and the additional $2^{-\rho(N-m)_+}$ in the cutoff-edge estimate. The logarithm is absorbed by $1+m \le C_\eta 2^{\eta m}$, giving (144.275) and (144.276). $\square$

Together with Proposition 144.75, this identifies the scalar base estimate for the whole locally subtracted X^2Y coordinate. The fifth- and third-chaos pieces have the sharp δ^{-1} variance dictated by target regularity $-1/2$; only the first-chaos covariance-increment sector consumes the logarithmic slack that is recorded in the projective X^2Y input. The cutoff increment of this first-chaos sector also has the scale-separated gain of Proposition 144.82; its logarithmic factor is harmless only after one chooses a positive slack ζ_{X^2Y} in the nonlinear Π-coordinate input. The same-scale and cutoff parameter-edge estimates in Proposition 144.83 show that the first-chaos scalar sector has the same physical-parameter continuity structure as the high-chaos sector, again with the logarithmic factor paid from ζ_{X^2Y}. What remains for the full nonlinear X^2Y Π-coordinate theorem is the E_r'-projective uniformization of these scalar estimates over the whole unit ball of tests.

Corollary 144.84 (Local KG^2 shell bound in dynamic Φ^4_3)**.** *Let $Q = 5$. Let K_i, $i \geq 0$, be dyadic heat-kernel pieces of order 2, and let G_j, $j \geq 0$, be dyadic covariance pieces of order 4. Thus, for a fixed parabolic ball constant R, with*

$$\operatorname{supp} K_i \subset B_{\mathfrak{s}}(0, R2^{-i}), \qquad \operatorname{supp} G_j \subset B_{\mathfrak{s}}(0, R2^{-j}),$$

and

$$|K_i(h)| \leq C_K 2^{(Q-2)i}, \qquad |G_j(h)| \leq C_G 2^{(Q-4)j}.$$

For $n \geq 0$, define the local two-loop shell packet

$$A_n(h) = \sum_{\max(i,j,\ell)=n} K_i(h) G_j(h) G_\ell(h).$$

Then

$$\int |A_n(h)| \,\mathrm{d}h \leq C \tag{144.279}$$

uniformly in n. The same estimate holds uniformly in a base point after translating the kernels, and hence supplies (144.265) for the first-chaos proposition.

Proof. For a single triple (i, j, ℓ), set

$$n_* = \max(i, j, \ell), \qquad r_K = n_* - i, \qquad r_G = n_* - j, \qquad r_{G'} = n_* - \ell.$$

The product is supported in a ball of radius $O(2^{-n_*})$. Therefore

$$\begin{aligned}\int |K_i(h) G_j(h) G_\ell(h)| \,\mathrm{d}h &\leq C\, 2^{(Q-2)i+(Q-4)j+(Q-4)\ell} 2^{-Qn_*} \\ &= C\, 2^{-3r_K - r_G - r_{G'}}.\end{aligned}$$

Here the coefficient of n_* vanishes because

$$(Q-2) + (Q-4) + (Q-4) - Q = 3 + 1 + 1 - 5 = 0.$$

Summing over the shell $\max(i, j, \ell) = n$ gives

$$\int |A_n(h)| \,\mathrm{d}h \leq C \sum_{\substack{r_K, r_G, r_{G'} \geq 0 \\ \min(r_K, r_G, r_{G'})=0}} 2^{-3r_K - r_G - r_{G'}} \leq C \left(1 + \frac{1}{1-2^{-3}}\right) \left(\frac{1}{1-2^{-1}}\right)^2.$$

This proves the uniform shell L^1 estimate. Translation of all kernels does not change either the support radius or the integral bound. $\square$

Corollary 144.85 (Covariance double increment for compact order-four blocks)**.** *Let $Q = 5$, $0 < \theta \le 1$, and let $\mathsf{D}_\lambda(t,x) = (\lambda^2 t, \lambda x)$. Suppose the dyadic covariance blocks have the rescaled form*

$$C_s(a,a') = 2^s c_s\big(\mathsf{D}_{2^s}(a-a')\big), \qquad s \ge 0,$$

where the functions c_s are supported in a fixed parabolic unit-scale ball and are bounded uniformly in C^2. Let h, h' satisfy

$$\|h\|_{\mathfrak{s}} \le R_1 2^{-n}, \qquad \|h'\|_{\mathfrak{s}} \le R_1 2^{-n'}.$$

Then there are constants A, R, depending only on R_1, θ, and the uniform block bounds, such that

$$\begin{aligned} |\Delta_{h,h'} C_s(a,a')| &\le A\, 2^s\, 2^{-\theta(n-s)_+} 2^{-\theta(n'-s)_+} \\ &\qquad \times \sum_{\rho \in \{0,h\}} \sum_{\rho' \in \{0,h'\}} \mathbf{1}_{\{\|a+\rho-a'-\rho'\|_{\mathfrak{s}} \le R2^{-s}\}}. \end{aligned} \tag{144.280}$$

In particular the covariance-block hypothesis (144.266) follows for compact dyadic order-four decompositions of the cutoff covariance.

Proof. Write

$$r = \mathsf{D}_{2^s}(a-a'), \qquad u = \mathsf{D}_{2^s} h, \qquad u' = \mathsf{D}_{2^s} h'.$$

Then

$$\begin{aligned} \Delta_{h,h'} C_s(a,a') = 2^s \{ & c_s(r+u-u') - c_s(r+u) \\ & - c_s(r-u') + c_s(r) \}. \end{aligned} \tag{144.281}$$

The uniform C^2 bound gives the scale-one finite-difference estimate

$$|c_s(r+u-u') - c_s(r+u) - c_s(r-u') + c_s(r)| \le C_\theta \min\{1, \|u\|_{\mathfrak{s}}\}^\theta \min\{1, \|u'\|_{\mathfrak{s}}\}^\theta. \tag{144.282}$$

Indeed, if $\|u\|_{\mathfrak{s}} \le 1$ and $\|u'\|_{\mathfrak{s}} \le 1$, the second-order integral form of the increment bounds the left side by $C\|u\|_{\mathfrak{s}}\|u'\|_{\mathfrak{s}}$, which is stronger than (144.282) because $\theta \le 1$. If only one increment is small, apply the first-order mean-value bound to the small increment and the triangle inequality in the other variable. If both increments are large, the uniform C^0 bound gives the estimate.

Since

$$\|u\|_{\mathfrak{s}} = 2^s \|h\|_{\mathfrak{s}} \le R_1 2^{s-n}, \qquad \|u'\|_{\mathfrak{s}} = 2^s \|h'\|_{\mathfrak{s}} \le R_1 2^{s-n'},$$

we have

$$\min\{1, \|u\|_{\mathfrak{s}}\}^\theta \le C_{R_1} 2^{-\theta(n-s)_+}, \qquad \min\{1, \|u'\|_{\mathfrak{s}}\}^\theta \le C_{R_1} 2^{-\theta(n'-s)_+}.$$

Combining these estimates with (144.281) gives the numerical factor in (144.280).

It remains only to record support. Each of the four terms in (144.281) vanishes unless the corresponding separation $a+\rho-a'-\rho'$, with $\rho \in \{0,h\}$ and $\rho' \in \{0,h'\}$, lies in a fixed parabolic ball of radius $O(2^{-s})$. If all four indicators in (144.280) vanish, then all four terms vanish. Otherwise the indicator sum is at least 1, and the previous numerical bound applies. Enlarging the support constant gives the displayed estimate. $\square$

144.7 BPHZ Renormalization of the Dynamic Equation

For the normalization

$$\partial_\tau \Phi = \Delta\Phi - m^2\Phi - \lambda\Phi^3 + \xi,$$

the parabolic dimension is $|\mathfrak{s}| = 5$. A mollified white noise ξ_ϵ is assigned homogeneity

$$|\Xi| = -\frac{5}{2} - \kappa,$$

where $\kappa > 0$ is chosen small. The heat integration map raises homogeneity by 2. Thus the stochastic convolution symbol $X = \mathcal{I}(\Xi)$ has

$$|X| = -\frac{1}{2} - \kappa, \qquad |X^2| = -1 - 2\kappa, \qquad |X^3| = -\frac{3}{2} - 3\kappa.$$

The one-loop subtraction is already forced by X^3. The first nonlinear response $\mathcal{I}(X^3)$ has homogeneity

$$|\mathcal{I}(X^3)| = \frac{1}{2} - 3\kappa,$$

and the product $X^2\mathcal{I}(X^3)$ has

$$|X^2\mathcal{I}(X^3)| = -\frac{1}{2} - 5\kappa.$$

The next remark records exactly which cubic drift monomials have negative homogeneity in the first nonlinear expansion. This finite drift-level bookkeeping determines the one-loop and two-loop local mass coordinates in the equation displayed below; the full regularity-structure construction then adds the model, reexpansion, and analytic-coordinate estimates for these symbols.

Remark 144.86 (Drift-level negative homogeneity bookkeeping). Let $0 < \kappa < 1/14$. Put

$$\alpha = -\frac{1}{2} - \kappa, \qquad \beta = \frac{1}{2} - 3\kappa.$$

Here α is the homogeneity of $X = \mathcal{I}(\Xi)$ and β is the homogeneity of the first nonlinear response $Y = \mathcal{I}(X^3)$. Among the four cubic monomials

$$X^3, \qquad X^2Y, \qquad XY^2, \qquad Y^3,$$

the monomials of negative homogeneity are exactly X^3 and X^2Y. Their homogeneities are

$$|X^3| = -\frac{3}{2} - 3\kappa, \qquad |X^2Y| = -\frac{1}{2} - 5\kappa.$$

The remaining two have positive homogeneity:

$$|XY^2| = \frac{1}{2} - 7\kappa > 0, \qquad |Y^3| = \frac{3}{2} - 9\kappa > 0.$$

Homogeneity is additive under multiplication and is raised by 2 under $\mathcal{I}$. Therefore

$$|Y| = |\mathcal{I}(X^3)| = 3\alpha + 2 = \frac{1}{2} - 3\kappa.$$

The four cubic monomials in the first nonlinear expansion have homogeneities

monomial	homogeneity
X^3	$3\alpha = -\frac{3}{2} - 3\kappa$
X^2Y	$2\alpha + \beta = -\frac{1}{2} - 5\kappa$
XY^2	$\alpha + 2\beta = \frac{1}{2} - 7\kappa$
Y^3	$3\beta = \frac{3}{2} - 9\kappa.$

The first two numbers are negative for every $\kappa > 0$. The inequality $\kappa < 1/14$ gives $1/2 - 7\kappa > 0$, and the weaker inequality $\kappa < 1/6$ gives $3/2 - 9\kappa > 0$. Hence the displayed list contains all and only the negative cubic drift monomials at this stage.

The coordinate attached to X^3 is the one-loop Wick contraction $C_{1,\epsilon}$. The coordinate attached to $X^2\mathcal{I}(X^3)$ is the two-loop local contraction $C_{2,\epsilon}$ after the nested one-loop subgraph has already been subtracted.

With these conventions, the renormalized cutoff equation in the BPHZ regularity-structure convention has the form

$$\partial_\tau \Phi_\epsilon = \Delta\Phi_\epsilon - m^2\Phi_\epsilon - \lambda\Phi_\epsilon^3 + \big(3\lambda C_{1,\epsilon} - 9\lambda^2 C_{2,\epsilon} + c_{\text{fin}}\big)\Phi_\epsilon + \xi_\epsilon. \tag{144.283}$$

Here $C_{1,\epsilon}$ is the one-loop contraction already visible in $:\Phi^3:$, $C_{2,\epsilon}$ is the two-loop local contraction arising from the negative tree with two cubic vertices, and c_{fin} is the finite mass coordinate. Different smooth mollifiers or subtraction schemes change $C_{1,\epsilon}$, $C_{2,\epsilon}$, and c_{fin} separately, but not the statement that only the local linear drift and vacuum-energy coordinates are needed in this superrenormalizable model.

Example 144.87 (Sharp spatial cutoff one-loop coordinate)**.** Work on $\mathbb{T}^3 = (\mathbb{R}/2\pi\mathbb{Z})^3$ with Fourier basis

$$e_n(x) = (2\pi)^{-3/2} e^{in\cdot x}, \qquad n \in \mathbb{Z}^3.$$

Let $m > 0$, and let X_M be the stationary solution of the linear equation

$$\partial_\tau X_M = (\Delta - m^2)X_M + \xi_M$$

obtained by projecting the noise to modes $|n|_\infty \le M$, with normalization

$$\mathbb{E}\,\xi(\tau,x)\xi(\tau',x') = 2\delta(\tau-\tau')\delta(x-x').$$

Then the one-loop local coordinate is

$$C_1(M) = \mathbb{E}X_M(\tau,x)^2 = (2\pi)^{-3} \sum_{\substack{n\in\mathbb{Z}^3\\ |n|_\infty \le M}} \frac{1}{|n|^2 + m^2}, \tag{144.284}$$

independent of (τ, x). There are constants $0 < c_m < C_m < \infty$ such that, for all $M \ge 1$,

$$C_1(M) \le C_m(1+M),$$

and, for all $M \ge \max(1, \lceil m \rceil)$,

$$C_1(M) \ge c_m M.$$

Consequently, for dyadic cutoffs $M_N = 2^N$,

$$0 \le C_1(M_{N+1}) - C_1(M_N) \le C_m' 2^N$$

with $C_m' < \infty$.

For a fixed Fourier mode n, the linear equation is the Ornstein–Uhlenbeck equation

$$dX_n = -(|n|^2 + m^2)X_n\, d\tau + \sqrt{2}\, dB_n(\tau),$$

with the real-field constraint $X_{-n} = \overline{X_n}$. The stationary variance is the ratio between the noise variance 2 and twice the damping rate:

$$\mathbb{E}|X_n|^2 = \frac{1}{|n|^2 + m^2}.$$

Since $|e_n(x)|^2 = (2\pi)^{-3}$, summing the retained modes gives (144.284).

Let

$$S_r = \{n \in \mathbb{Z}^3 : |n|_\infty = r\}.$$

For $r \geq 1$,

$$|S_r| = (2r+1)^3 - (2r-1)^3 = 24r^2 + 2.$$

If $n \in S_r$, then $r^2 \leq |n|^2 \leq 3r^2$. Hence

$$\sum_{n\in S_r} \frac{1}{|n|^2 + m^2} \leq \frac{24r^2 + 2}{r^2} \leq 26.$$

Adding the zero mode gives the upper bound $C_1(M) \leq C_m(1 + M)$.

For $r \geq \max(1, \lceil m \rceil)$, the same shell satisfies

$$|n|^2 + m^2 \leq 3r^2 + r^2 = 4r^2.$$

Therefore

$$\sum_{n\in S_r} \frac{1}{|n|^2 + m^2} \geq \frac{24r^2}{4r^2} = 6.$$

Summing these shell lower bounds from $\max(1, \lceil m \rceil)$ to M gives $C_1(M) \geq c_m M$ after adjusting c_m to cover the finite initial range. The dyadic increment bound follows from the upper shell estimate applied to $M_N < |n|_\infty \leq M_{N+1}$, whose shell radii are $M_N + 1, \ldots, M_{N+1}$.

Lemma 144.88 (Spatial Fourier cutoff two-loop coordinate)**.** *Use the notation of Example 144.87, and put*

$$a_n = |n|^2 + m^2, \qquad n \in \mathbb{Z}^3.$$

Let

$$K_M(t, x) = \mathbf{1}_{t>0}(2\pi)^{-3} \sum_{\substack{k\in\mathbb{Z}^3\\ |k|_\infty \leq M}} e^{-a_k t} e^{ik\cdot x}$$

be the retarded heat kernel with the same spatial cutoff, and let

$$G_M(t, x) = (2\pi)^{-3} \sum_{\substack{p\in\mathbb{Z}^3\\ |p|_\infty \leq M}} \frac{e^{-a_p|t|} e^{ip\cdot x}}{a_p}$$

be the stationary covariance. Define

$$C_2(M) = 2 \int_0^\infty \int_{\mathbb{T}^3} K_M(t, x) G_M(t, x)^2 \, \mathrm{d}x\, \mathrm{d}t. \tag{144.285}$$

Then

$$C_2(M) = 2(2\pi)^{-6} \sum_{\substack{p,q\in\mathbb{Z}^3 \\ |p|_\infty,|q|_\infty,|p+q|_\infty\le M}} \frac{1}{a_p a_q(a_p + a_q + a_{p+q})}. \tag{144.286}$$

There are constants $0 < c_m < C_m < \infty$, depending on m but not on M, such that

$$C_2(M) \le C_m\big(1 + \log(1 + M)\big) \qquad (M \ge 1),$$

and

$$C_2(M) \ge c_m \log M \qquad (M \ge 16).$$

Proof. Substituting the Fourier series for K_M and G_M into (144.285) gives

$$C_2(M) = 2(2\pi)^{-9} \sum_{\substack{k,p,q\in\mathbb{Z}^3 \\ |k|_\infty,|p|_\infty,|q|_\infty\le M}} \frac{1}{a_p a_q} \int_0^\infty e^{-(a_k+a_p+a_q)t}\,\mathrm{d}t \int_{\mathbb{T}^3} e^{i(k+p+q)\cdot x}\,\mathrm{d}x.$$

The spatial integral is $(2\pi)^3$ when $k + p + q = 0$ and is zero otherwise. Eliminating k gives (144.286).

For the upper bound, discard the restriction $|p + q|_\infty \le M$. Let

$$B_0 = \{n \in \mathbb{Z}^3 : |n|_\infty < 2\}, \qquad B_\ell = \{n \in \mathbb{Z}^3 : 2^\ell \le |n|_\infty < 2^{\ell+1}\} \quad (\ell \ge 1).$$

There is a constant $A < \infty$ such that

$$|B_\ell| \le A2^{3\ell} \qquad (\ell \ge 0).$$

For $\ell \ge 1$ this follows from

$$|B_\ell| \le |\{n : |n|_\infty < 2^{\ell+1}\}| = (2^{\ell+2} - 1)^3,$$

and B_0 is finite. There is also $b_m > 0$, for instance

$$b_m = \min(m^2, 1),$$

such that, for $n \in B_\ell$,

$$a_n \ge b_m 2^{2\ell} \qquad (\ell \ge 0).$$

If $p \in B_\ell$ and $q \in B_s$, then

$$a_p + a_q + a_{p+q} \ge a_p + a_q \ge b_m 2^{2\max(\ell,s)}.$$

Thus the contribution of the block $B_\ell \times B_s$ is bounded by

$$C_m \frac{2^{3\ell}2^{3s}}{2^{2\ell}2^{2s}2^{2\max(\ell,s)}} = C_m 2^{-|\ell-s|}.$$

If $|p|_\infty, |q|_\infty \le M$, then only $\ell, s \le L_M = \lceil \log_2(1 + M)\rceil$ occur. Hence

$$C_2(M) \le C_m \sum_{\ell=0}^{L_M} \sum_{s=0}^{L_M} 2^{-|\ell-s|} \le 3C_m(L_M + 1),$$

which is the stated upper bound after increasing C_m.

For the lower bound, write $N = \lfloor \log_2 M \rfloor$. For $2 \le \ell \le N-2$, let

$$P_\ell = \{n \in \mathbb{Z}^3 : 2^\ell \le n_i < 2^\ell + 2^{\ell-2},\ i = 1,2,3\}.$$

Then $|P_\ell| \ge 2^{3\ell-6}$. If $p, q \in P_\ell$, then

$$|p|_\infty,\ |q|_\infty,\ |p+q|_\infty \le 2^{\ell+2} \le M,$$

and

$$a_p,\ a_q,\ a_{p+q} \le A_m 2^{2\ell}$$

with $A_m < \infty$ independent of ℓ. The summands in (144.286) are therefore bounded below by $A_m^{-3} 2^{-6\ell}$ on $P_\ell \times P_\ell$. The contribution of this block is at least

$$2(2\pi)^{-6} |P_\ell|^2 A_m^{-3} 2^{-6\ell} \ge c_m.$$

Summing the disjoint lower-bound blocks for $\ell = 2, \dots, N-2$ gives $C_2(M) \ge c_m(N-3)$. Since there is an absolute constant $c_0 > 0$ with

$$N - 3 \ge c_0 \log M \qquad (M \ge 16),$$

the lower bound follows after decreasing c_m. $\square$

Proposition 144.89 (Dyadic shell bound for the two-loop coordinate)**.** *Let $C_2(M)$ be the sharp spatial Fourier-cutoff two-loop coordinate in Lemma 144.88, and set*

$$M_N = 2^N, \qquad N \in \mathbb{N}.$$

There is a constant $C_m^{\mathrm{shell}} < \infty$, depending on m but not on N, such that, for all $N \ge 2$,

$$0 \le C_2(M_{N+1}) - C_2(M_N) \le C_m^{\mathrm{shell}}.$$

Proof. Write

$$D_N = \{(p,q) \in \mathbb{Z}^3 \times \mathbb{Z}^3 : |p|_\infty, |q|_\infty, |p+q|_\infty \le 2^N\}.$$

The summand in (144.286) is non-negative, and $D_N \subset D_{N+1}$, so the increment is non-negative.

Use the dyadic annuli B_ℓ from the proof of Lemma 144.88. The same block estimate gives a constant $A_m < \infty$ such that, for every $\ell, s \ge 0$, the contribution of

$$(B_\ell \times B_s) \cap D_{N+1}$$

to $C_2(M_{N+1})$ is bounded by

$$A_m 2^{-|\ell - s|}.$$

If $(p,q) \in D_{N+1} \setminus D_N$ and

$$p \in B_\ell, \qquad q \in B_s,$$

then $\ell, s \le N+1$. Moreover, $\max(\ell, s) \ge N-1$. Indeed, if $\ell, s \le N-2$, then

$$|p|_\infty < 2^{N-1}, \qquad |q|_\infty < 2^{N-1},$$

hence $|p+q|_\infty < 2^N$, so $(p,q) \in D_N$, a contradiction. Therefore

$$\begin{aligned} C_2(M_{N+1}) - C_2(M_N) &\le A_m \sum_{\substack{0\le \ell,s\le N+1\\ \max(\ell,s)\ge N-1}} 2^{-|\ell-s|} \\ &\le A_m \sum_{t=N-1}^{N+1} \left(1 + 2\sum_{r=0}^{t-1} 2^{-(t-r)}\right) \\ &\le 9A_m. \end{aligned}$$

Thus $C_m^{\text{shell}} = 9A_m$ is admissible. □

Finite-cutoff local counterterm calculation. Let X_ϵ be the smooth stationary Gaussian solution of the linearized cutoff equation and write

$$G_\epsilon(z,w) = \mathbb{E}\big[X_\epsilon(z)X_\epsilon(w)\big].$$

Let K_ϵ denote the retarded heat kernel with the same ultraviolet mollification and define the local constants

$$C_{1,\epsilon} = G_\epsilon(z,z), \qquad C_{2,\epsilon} = 2\int K_\epsilon(z,w)G_\epsilon(z,w)^2\,\mathrm{d}w, \tag{144.287}$$

where translation invariance on the spacetime torus makes the right-hand sides independent of z. Consider the perturbative fixed-point expansion

$$\Phi_\epsilon = X_\epsilon - \lambda K_\epsilon(X_\epsilon^3) + O(\lambda^2),$$

and let $\mathcal{L}$ denote the projection that retains only the local linear part produced by Wick contractions and the zeroth Taylor coefficient of the remaining field at $w = z$. Then

$$\mathcal{L}\big[-\lambda X_\epsilon^3 + 3\lambda^2 X_\epsilon^2 K_\epsilon(X_\epsilon^3)\big] = \big(-3\lambda C_{1,\epsilon} + 9\lambda^2 C_{2,\epsilon}\big)X_\epsilon.$$

Consequently the counterterm inserted in the cutoff drift is the negative of this local singular part, namely

$$\big(3\lambda C_{1,\epsilon} - 9\lambda^2 C_{2,\epsilon}\big)\Phi_\epsilon,$$

up to the independent finite mass coordinate $c_{\text{fin}}\Phi_\epsilon$.

The one-loop term is the Wick contraction of two of the three fields in X_ϵ^3:

$$X_\epsilon(z)^3 = :X_\epsilon(z)^3: + 3G_\epsilon(z,z)X_\epsilon(z).$$

Thus

$$\mathcal{L}[-\lambda X_\epsilon^3] = -3\lambda C_{1,\epsilon}X_\epsilon.$$

For the two-loop term, expand the nonlinearity to first order in the nonlinear response:

$$-\lambda\Phi_\epsilon^3 = -\lambda X_\epsilon^3 + 3\lambda^2 X_\epsilon^2 K_\epsilon(X_\epsilon^3) + O(\lambda^3).$$

The coefficient 3 is the number of choices for the factor of Φ_ϵ in Φ_ϵ^3 that is replaced by $-\lambda K_\epsilon(X_\epsilon^3)$; the two minus signs give the positive sign in the displayed term. At a spacetime point z,

$$X_\epsilon(z)^2 K_\epsilon(X_\epsilon^3)(z) = \int K_\epsilon(z,w)X_\epsilon(z)^2 X_\epsilon(w)^3\,\mathrm{d}w.$$

Its local linear part is obtained by contracting four of the five Gaussian fields and replacing the remaining field at w by its zeroth Taylor term at z. There are two possible forms of such contractions.

First leave one of the three $X_\epsilon(w)$ factors uncontracted and contract the two $X_\epsilon(z)$ factors with the two remaining $X_\epsilon(w)$ factors. This gives $3 \cdot 2 = 6$ pairings and contributes

$$6 \int K_\epsilon(z,w) G_\epsilon(z,w)^2 \, \mathrm{d}w \; X_\epsilon(z) = 3C_{2,\epsilon} X_\epsilon(z).$$

Second leave one of the two $X_\epsilon(z)$ factors uncontracted, contract the other $X_\epsilon(z)$ with one of the three $X_\epsilon(w)$ factors, and contract the remaining two $X_\epsilon(w)$ factors with each other. This produces

$$6 \int K_\epsilon(z,w) G_\epsilon(z,w) G_\epsilon(w,w) \, \mathrm{d}w \; X_\epsilon(z).$$

This is the one-loop tadpole inserted into the inner cubic vertex. The finite-cutoff forest subtraction used here is the following recursive local operation: before extracting the new local part of a graph, replace every proper divergent subgraph by its already computed local counterterm. For the present tree this means replacing the inner $X_\epsilon(w)^3$ by its one-loop Wick-ordered cubic, so the displayed nested tadpole is removed before the two-loop coordinate is defined. Therefore the new two-loop local coordinate is the first contribution only, with the normalization in (144.287). Multiplying by the outer factor $3\lambda^2$ gives

$$\mathcal{L}[3\lambda^2 X_\epsilon^2 K_\epsilon(X_\epsilon^3)] = 9\lambda^2 C_{2,\epsilon} X_\epsilon.$$

Combining the one-loop and two-loop local parts proves the displayed formula. The finite coordinate c_{fin} is not fixed by singular subtraction; it labels the chosen renormalized mass coordinate.

Proposition 144.90 (Static-dynamic mass-coordinate translation)**.** *Fix a finite cutoff and write the Euclidean local density of Chapter 137 as*

$$g_4 \phi_\epsilon^4 + a_\epsilon \phi_\epsilon^2 + b_\epsilon.$$

Let the cutoff Langevin equation use the convention of (144.1)*, so that the drift is the negative L^2-gradient of the regulated action. If the same dynamics is written as*

$$\partial_\tau \Phi_\epsilon = \Delta \Phi_\epsilon - m^2 \Phi_\epsilon - \lambda_{\mathrm{dyn}} \Phi_\epsilon^3 + M_\epsilon \Phi_\epsilon + \xi_\epsilon,$$

then

$$\lambda_{\mathrm{dyn}} = 4g_4, \qquad M_\epsilon = -2a_\epsilon. \tag{144.288}$$

Consequently, relative to the Wick covariance $C_\epsilon(0)$ used in (137.27)*, the normal-ordered mass coordinate is*

$$\alpha_\epsilon = a_\epsilon + 6g_4 C_\epsilon(0) = -\frac{1}{2} M_\epsilon + \frac{3}{2} \lambda_{\mathrm{dyn}} C_\epsilon(0). \tag{144.289}$$

In the dynamic BPHZ chart

$$M_\epsilon = 3\lambda_{\mathrm{dyn}} C_{1,\epsilon} - 9\lambda_{\mathrm{dyn}}^2 C_{2,\epsilon} + c_{\mathrm{fin}}.$$

If the Wick covariance in the constructive chart is the same local covariance, $C_\epsilon(0) = C_{1,\epsilon}$, then the one-loop coordinate cancels in (144.289) *and*

$$\alpha_\epsilon^{\mathrm{dyn}} = \frac{9}{2} \lambda_{\mathrm{dyn}}^2 C_{2,\epsilon} - \frac{1}{2} c_{\mathrm{fin}}. \tag{144.290}$$

Thus the common-chart comparison with (137.33) is a comparison of normal-ordered mass coordinates, together with a chosen finite mass normalization, not a comparison of the raw a_ϵ and M_ϵ coefficients. The vacuum coordinate b_ϵ, or equivalently β_ϵ, remains a separate free-energy normalization because an additive constant in the action is invisible to the Langevin drift.

Proof. For the finite-cutoff local part

$$\int \left[g_4\phi_\epsilon^4 + a_\epsilon\phi_\epsilon^2 + b_\epsilon\right] \mathrm{d}^3x,$$

the variational derivative contributes

$$4g_4\Phi_\epsilon^3 + 2a_\epsilon\Phi_\epsilon.$$

The gradient Langevin drift is its negative, added to the Gaussian drift $\Delta\Phi_\epsilon - m^2\Phi_\epsilon$. Comparing the cubic and linear terms with the displayed dynamic equation gives (144.288). The first equality in (144.289) is precisely the coordinate conversion (137.27), with the Euclidean quartic coefficient renamed g_4. Substituting $g_4 = \lambda_{\mathrm{dyn}}/4$ and $a_\epsilon = -M_\epsilon/2$ gives the second equality. Finally substituting the BPHZ expression for M_ϵ and identifying $C_\epsilon(0)$ with $C_{1,\epsilon}$ cancels the one-loop term and leaves (144.290). The constant term b_ϵ drops out of the variational derivative, so it cannot be recovered from the drift comparison. □

Theorem 144.91 (Abstract local fixed point in modelled distributions)**.** *Let $0 < T \leq 1$. Let E_T be a Banach space of modelled distributions on the parabolic time slab $[0,T] \times \mathbb{T}^3$, let F_T be a Banach space of modelled distributional forcing terms on the same slab, and assume the following data and estimates.*

(i) A zero-initial-time abstract heat integration operator $\mathcal{K}_T : F_T \to E_T$ satisfies, for constants $A > 0$ and $\theta > 0$,

$$\|\mathcal{K}_T H\|_{E_T} \leq AT^\theta \|H\|_{F_T}. \tag{144.291}$$

The power T^θ encodes the positive time gain obtained after the singular local model has been fixed.

(ii) A reconstructed stochastic convolution $X_T \in E_T$ and an initial-data lift $P_T u_0 \in E_T$ are given. Put

$$R_0 = \|P_T u_0 + X_T\|_{E_T}.$$

(iii) The cubic product is a locally Lipschitz map $E_T \to F_T$: for a constant $B > 0$,

$$\|U^3\|_{F_T} \leq B\|U\|_{E_T}^3,$$

and

$$\|U^3 - V^3\|_{F_T} \leq B(\|U\|_{E_T}^2 + \|V\|_{E_T}^2)\|U - V\|_{E_T}. \tag{144.292}$$

(iv) The local linear term is bounded as a map $E_T \to F_T$:

$$\|U\|_{F_T} \leq D\|U\|_{E_T}$$

for a constant $D > 0$.

Fix real parameters λ and M. Define

$$\Psi_T(U) = P_T u_0 + X_T + \mathcal{K}_T\big(-\lambda U^3 + MU\big). \tag{144.293}$$

Let $R = 2R_0$. If

$$AT^\theta\big(B|\lambda|R^3 + D|M|R\big) \le \frac{R}{2}, \tag{144.294}$$

$$AT^\theta\big(2B|\lambda|R^2 + D|M|\big) < 1, \tag{144.295}$$

then Ψ_T has a unique fixed point in the closed ball

$$\mathbb{B}_R = \{U \in E_T : \|U\|_{E_T} \le R\}.$$

The fixed point depends Lipschitz-continuously on $P_T u_0 + X_T$ as long as the same constants and the same ball are used.

Proof. For $U \in \mathbb{B}_R$, the Schauder estimate (144.291), the cubic bound, and the linear bound give

$$\begin{aligned}\|\Psi_T(U)\|_{E_T} &\le R_0 + AT^\theta\big(|\lambda|\|U^3\|_{F_T} + |M|\|U\|_{F_T}\big)\\ &\le \frac{R}{2} + AT^\theta\big(B|\lambda|R^3 + D|M|R\big) \le R.\end{aligned}$$

Thus Ψ_T maps $\mathbb{B}_R$ into itself. For $U, V \in \mathbb{B}_R$, the Lipschitz estimate (144.292) gives

$$\begin{aligned}\|\Psi_T(U) - \Psi_T(V)\|_{E_T} &\le AT^\theta\left(|\lambda|\|U^3 - V^3\|_{F_T} + |M|\|U - V\|_{F_T}\right)\\ &\le AT^\theta\big(2B|\lambda|R^2 + D|M|\big)\|U - V\|_{E_T}.\end{aligned}$$

Condition (144.295) makes this Lipschitz constant strictly smaller than one; call it q. Choose $U_0 \in \mathbb{B}_R$ and set $U_{n+1} = \Psi_T(U_n)$. Since $\Psi_T(\mathbb{B}_R) \subset \mathbb{B}_R$,

$$\|U_{n+1} - U_n\|_{E_T} \le q^n\|U_1 - U_0\|_{E_T}.$$

For $m > n$,

$$\|U_m - U_n\|_{E_T} \le \sum_{j=n}^{m-1} q^j\|U_1 - U_0\|_{E_T} \le \frac{q^n}{1-q}\|U_1 - U_0\|_{E_T}.$$

The space E_T is complete, so U_n converges to some $U_* \in \mathbb{B}_R$. Continuity of Ψ_T gives $\Psi_T(U_*) = U_*$. If V_* is another fixed point in $\mathbb{B}_R$, then

$$\|U_* - V_*\|_{E_T} \le q\|U_* - V_*\|_{E_T},$$

and $q < 1$ forces $U_* = V_*$.

For dependence on the inhomogeneous term, let $Y = P_T u_0 + X_T$ and $\widetilde{Y} = \widetilde{P}_T\widetilde{u}_0 + \widetilde{X}_T$, and suppose the two corresponding fixed points $U, \widetilde{U}$ lie in the same ball $\mathbb{B}_R$. The same estimate gives

$$\|U - \widetilde{U}\|_{E_T} \le \|Y - \widetilde{Y}\|_{E_T} + q\|U - \widetilde{U}\|_{E_T}, \qquad q = AT^\theta(2B|\lambda|R^2 + D|M|) < 1.$$

Therefore

$$\|U - \widetilde{U}\|_{E_T} \le \frac{1}{1-q}\|Y - \widetilde{Y}\|_{E_T}.$$

□

In the dynamic Φ^4_3 application, E_T is a weighted modelled-distribution space whose lowest components encode the stochastic convolution and whose positive components encode the unknown remainder. The space F_T is the corresponding forcing space after subtracting the singular local parts of the cubic. The operator $\mathcal{K}_T$ is the abstract heat integration map, and

$$M = 3\lambda C_{1,\epsilon} - 9\lambda^2 C_{2,\epsilon} + c_{\mathrm{fin}}$$

in the finite-cutoff equation before passing to the renormalized model. The theorem proves the fixed-point step once the model bounds, product bounds, and Schauder bound have been established. It does not prove convergence of the BPHZ-renormalized models; that remains a separate stochastic estimate.

Proposition 144.92 (Fixed-point-sector comparison criterion). *Let E_T, F_T, R, $0 < q < 1$, and $\mathbb{B}_R \subset E_T$ be fixed. For $n \in \mathbb{N} \cup \{\infty\}$, suppose*

$$\Psi_n : \mathbb{B}_R \to \mathbb{B}_R$$

is a contraction with Lipschitz constant at most q. Let U_n be its unique fixed point in $\mathbb{B}_R$. If

$$\epsilon_n := \sup_{U \in \mathbb{B}_R} \|\Psi_n(U) - \Psi_\infty(U)\|_{E_T} \longrightarrow 0, \tag{144.296}$$

then

$$\|U_n - U_\infty\|_{E_T} \le \frac{\epsilon_n}{1-q}. \tag{144.297}$$

In the modelled Φ^4_3 chart, a sufficient way to produce (144.296) is the following common-space comparison. Write

$$\Psi_n(U) = Y_n + \mathcal{K}_n\big(-\lambda\, \mathcal{P}_{3,n}(U) + M_n \mathcal{L}_n U\big), \qquad Y_n = P_T^{(n)} u_0^{(n)} + X_T^{(n)},$$

and similarly for Ψ_∞. Suppose on $\mathbb{B}_R$

$$\|\mathcal{P}_{3,\infty}(U)\|_{F_T} \le BR^3, \qquad \|\mathcal{L}_\infty U\|_{F_T} \le DR,$$

and suppose the comparison estimates

$$\begin{aligned} \|Y_n - Y_\infty\|_{E_T} &\le \delta_{Y,n}, \\ \sup_{\|H\|_{F_T} \le H_R} \|(\mathcal{K}_n - \mathcal{K}_\infty)H\|_{E_T} &\le \delta_{K,n} H_R, \\ \sup_{\|U\|_{E_T} \le R} \|\mathcal{P}_{3,n}(U) - \mathcal{P}_{3,\infty}(U)\|_{F_T} &\le \delta_{P,n} R^3, \\ \sup_{\|U\|_{E_T} \le R} \|\mathcal{L}_n U - \mathcal{L}_\infty U\|_{F_T} &\le \delta_{L,n} R \end{aligned}$$

hold with

$$H_R = |\lambda| BR^3 + |M_\infty| DR.$$

If $\|\mathcal{K}_n H\|_{E_T} \le AT^\theta \|H\|_{F_T}$ and $|M_n - M_\infty| \le \delta_{M,n}$, then

$$\epsilon_n \le \delta_{Y,n} + \delta_{K,n} H_R + AT^\theta\big(|\lambda|\delta_{P,n} R^3 + |M_\infty|\delta_{L,n} R + D\delta_{M,n} R + \delta_{M,n}\delta_{L,n} R\big). \tag{144.298}$$

Proof. The fixed-point comparison is an a posteriori contraction estimate:

$$\begin{aligned}\|U_n - U_\infty\|_{E_T} &= \|\Psi_n(U_n) - \Psi_\infty(U_\infty)\|_{E_T} \\ &\le \|\Psi_n(U_n) - \Psi_\infty(U_n)\|_{E_T} + \|\Psi_\infty(U_n) - \Psi_\infty(U_\infty)\|_{E_T} \\ &\le \epsilon_n + q\|U_n - U_\infty\|_{E_T}.\end{aligned}$$

Moving the second term to the left gives (144.297).

For the displayed modelled-SPDE budget, add and subtract the terms obtained by successively replacing Y_n, $\mathcal{K}_n$, $\mathcal{P}_{3,n}$, $\mathcal{L}_n$, and M_n by their limiting counterparts. The $\mathcal{K}_n - \mathcal{K}_\infty$ term is tested on the limiting forcing $-\lambda\mathcal{P}_{3,\infty}(U) + M_\infty\mathcal{L}_\infty U$, whose norm is bounded by H_R. The remaining terms are controlled by the common Schauder bound for $\mathcal{K}_n$ and the product, linear, and mass-coordinate comparison estimates. The mass-linear part must be expanded as a product:

$$\begin{aligned}M_n\mathcal{L}_n U - M_\infty\mathcal{L}_\infty U = M_\infty(\mathcal{L}_n - \mathcal{L}_\infty)U &+ (M_n - M_\infty)\mathcal{L}_\infty U \\ &+ (M_n - M_\infty)(\mathcal{L}_n - \mathcal{L}_\infty)U.\end{aligned}$$

Hence its F_T-norm is bounded on $\mathbb{B}_R$ by

$$|M_\infty|\delta_{L,n}R + D\delta_{M,n}R + \delta_{M,n}\delta_{L,n}R.$$

Taking the supremum over $U \in \mathbb{B}_R$ gives (144.298). □

For dynamic Φ^4_3, this proposition is the fixed-point-sector layer following random-model convergence. The negative-sector model estimates control Y_n and the singular model coordinates. Schauder, multiplication, and reexpansion estimates control the comparison errors $\delta_{K,n}$, $\delta_{P,n}$, and $\delta_{L,n}$. The renormalized mass coordinate supplies $\delta_{M,n}$; the product $M_n\mathcal{L}_n$ also pays the mixed error $\delta_{M,n}\delta_{L,n}R$ when both coordinates vary at once. Once these quantities tend to zero while the contraction constant q stays below one on a common ball, the renormalized modelled solutions converge in E_T. This still leaves the invariant-law and OS-comparison layers as separate analytic steps.

Lemma 144.93 (Coupled stationary-law comparison after SPDE convergence)**.** *Let (E, d) be a Polish metric space, and let P_t be a Markov semigroup on E. For a fixed $t \ge 0$, suppose $U_n(0), U_n(t), U_*(0), U_*(t)$ are E-valued random variables on one probability space such that:*

(i) $U_n(0)$ and $U_n(t)$ have the same law μ_n;

(ii) $U_*(0)$ has law μ_*, and

$$\mathbb{E}[f(U_*(t))] = \int_E P_t f \,\mathrm{d}\mu_*$$

for every bounded Lipschitz $f : E \to \mathbb{C}$;

(iii) for some $\delta_n, \varepsilon_{n,t} \ge 0$ and $a_t < \infty$,

$$\mathbb{E}\, d(U_n(0), U_*(0)) \le \delta_n, \qquad \mathbb{E}\, d(U_n(t), U_*(t)) \le a_t\delta_n + \varepsilon_{n,t}. \tag{144.299}$$

Then every bounded Lipschitz f obeys

$$\left|\int_E f \,\mathrm{d}\mu_n - \int_E f \,\mathrm{d}\mu_*\right| \le \mathrm{Lip}(f)\,\delta_n, \tag{144.300}$$

and

$$\left|\int_E P_t f \,\mathrm{d}\mu_* - \int_E f \,\mathrm{d}\mu_*\right| \le \mathrm{Lip}(f)\big((a_t+1)\delta_n + \varepsilon_{n,t}\big). \tag{144.301}$$

If, for each fixed t, the quantity $(a_t+1)\delta_n+\varepsilon_{n,t}$ tends to zero along the comparison sequence, then μ_* is invariant for P_t in the sense of equality of probability measures.

Proof. For (144.300), write the two integrals as expectations of $f(U_n(0))$ and $f(U_*(0))$, and apply the Lipschitz bound:

$$|\mathbb{E}f(U_n(0)) - \mathbb{E}f(U_*(0))| \le \mathrm{Lip}(f)\,\mathbb{E}d(U_n(0), U_*(0)).$$

For the invariance defect, use the representation of P_t in (ii), insert the stationary cutoff variables, and use (i):

$$\begin{aligned}\left|\int_E P_t f \,\mathrm{d}\mu_* - \int_E f \,\mathrm{d}\mu_*\right| &= |\mathbb{E}f(U_*(t)) - \mathbb{E}f(U_*(0))| \\ &\le |\mathbb{E}f(U_*(t)) - \mathbb{E}f(U_n(t))| \\ &\quad + |\mathbb{E}f(U_n(t)) - \mathbb{E}f(U_n(0))| \\ &\quad + |\mathbb{E}f(U_n(0)) - \mathbb{E}f(U_*(0))| \\ &\le \mathrm{Lip}(f)\big(\mathbb{E}d(U_*(t), U_n(t)) + \mathbb{E}d(U_n(0), U_*(0))\big),\end{aligned}$$

because the middle term vanishes by stationarity of U_n. Substituting (144.299) gives (144.301). If the right side tends to zero for every bounded Lipschitz f, then $\int P_t f \,\mathrm{d}\mu_* = \int f \,\mathrm{d}\mu_*$ for every bounded Lipschitz f. Bounded Lipschitz functions separate probability measures on a Polish metric space, so $P_t^*\mu_* = \mu_*$. ☐

Lemma 144.94 (Polynomial stationarity by truncation)**.** *Keep the hypotheses and notation of Lemma 144.93. Let $\mathcal{O} : E \to \mathbb{C}$ be a measurable cylinder observable. Suppose there are bounded Lipschitz functions $\mathcal{O}_R : E \to \mathbb{C}$, $R \ge 1$, such that*

$$T_R(t) := \mathbb{E}|\mathcal{O}(U_*(t)) - \mathcal{O}_R(U_*(t))|, \qquad T_R(0) := \mathbb{E}|\mathcal{O}(U_*(0)) - \mathcal{O}_R(U_*(0))|$$

tend to zero as $R \to \infty$. Then

$$\begin{aligned}|\mathbb{E}\mathcal{O}(U_*(t)) - \mathbb{E}\mathcal{O}(U_*(0))| &\le T_R(t) + T_R(0) \\ &\quad + \mathrm{Lip}(\mathcal{O}_R)\big((a_t+1)\delta_n + \varepsilon_{n,t}\big).\end{aligned} \tag{144.302}$$

Consequently, if for each fixed R the comparison defect $(a_t+1)\delta_n+\varepsilon_{n,t}$ tends to zero and the tails $T_R(t)+T_R(0)$ tend to zero, then

$$\mathbb{E}\mathcal{O}(U_*(t)) = \mathbb{E}\mathcal{O}(U_*(0)).$$

For polynomial cylinder observables this reduces stationarity to tail estimates: the truncations $\mathcal{O}_R$ must converge in L^1 at times 0 and t.

Proof. Insert $\mathcal{O}_R$ and use the triangle inequality:

$$\begin{aligned}|\mathbb{E}\mathcal{O}(U_*(t)) - \mathbb{E}\mathcal{O}(U_*(0))| &\le T_R(t) + T_R(0) \\ &\quad + |\mathbb{E}\mathcal{O}_R(U_*(t)) - \mathbb{E}\mathcal{O}_R(U_*(0))|\,.\end{aligned}$$

The last term is controlled by Lemma 144.93, applied to the bounded Lipschitz test $\mathcal{O}_R$. This proves (144.302). Taking $n \to \infty$ at fixed R, then $R \to \infty$, proves the equality. ☐

In the renormalized Φ^4_3 problem, Lemma 144.93 is the invariant-law layer following the fixed-point-sector comparison. A stationary cutoff solution started from μ_n supplies $U_n(0)$ and $U_n(t)$. The random-model and fixed-point estimates must then be strengthened to a coupling of the time-zero and time-t fields in the topology E used for the Markov process. This proves invariance of a limiting SPDE law only for bounded Lipschitz tests on E. Lemma 144.94 records the additional truncation step needed before an unbounded polynomial cylinder observable can be treated as stationary. The polynomial Schwinger moments, reflection positivity, and corrected OS-II growth needed for QFT reconstruction still come from the hierarchy comparison in Construction 144.102.

Proposition 144.95 (Finite-window OS assembly defect budget)**.** *Let*

$$\mathcal{W} = \{F_1, \dots, F_M\}$$

be a finite family of positive-time polynomial cylinder observables. Let Θ denote physical Euclidean time reflection. For a cutoff stationary SPDE law μ_N, define the finite OS Gram matrix

$$G^{(N)}_{ij} = \int \overline{F_i(\Theta\Phi)}\, F_j(\Phi)\, \mathrm{d}\mu_N(\Phi), \qquad 1 \le i, j \le M,$$

and let G_{ij} be the corresponding entries of a candidate limiting Schwinger hierarchy. Suppose that, for this window, the cutoff Gram form has a lower OS defect

$$\sum_{i,j=1}^{M} \overline{c_i} c_j G^{(N)}_{ij} \ge -\delta_{\mathcal{W},N} \sum_{i=1}^{M} |c_i|^2 \tag{144.303}$$

for every $c \in \mathbb{C}^M$, and that the limiting entries are controlled entrywise by

$$\max_{1 \le i,j \le M} |G_{ij} - G^{(N)}_{ij}| \le \varepsilon_{\mathcal{W},N}. \tag{144.304}$$

Then the limiting window obeys

$$\sum_{i,j=1}^{M} \overline{c_i} c_j G_{ij} \ge -\big(\delta_{\mathcal{W},N} + M\varepsilon_{\mathcal{W},N}\big) \sum_{i=1}^{M} |c_i|^2. \tag{144.305}$$

Consequently, a directed family of finite positive-time windows gives polynomial OS positivity for the limiting hierarchy if one can choose a cutoff $N(\mathcal{W})$ for each window such that

$$\delta_{\mathcal{W},N(\mathcal{W})} + |\mathcal{W}|\varepsilon_{\mathcal{W},N(\mathcal{W})} \longrightarrow 0$$

along the directed window net.

Now let H_{ij} be the OS Gram entries of a constructive Euclidean hierarchy in the same field-normalization and local-counterterm chart. If

$$\max_{i,j} |G_{ij} - H_{ij}| \le \eta_{\mathcal{W}},$$

then

$$\left| \sum_{i,j=1}^{M} \overline{c_i} c_j (G_{ij} - H_{ij}) \right| \le M\eta_{\mathcal{W}} \sum_{i=1}^{M} |c_i|^2. \tag{144.306}$$

Thus equality of all finite-window entries identifies the positive-time pre-Hilbert inner products and their null spaces. If the comparison is first obtained with finite-window defects, the same directed-window schedule must send $M\eta_{\mathcal{W}}$ to zero before one may identify the OS quotients.

Finally, suppose the constructive hierarchy satisfies a corrected OS-II growth estimate

$$|S_n^{\mathrm{cons}}(F)| \le AB^n (n!)^\gamma q_{n,N_0+C_{\mathrm{OS}}n}(F),$$

and the SPDE/constructive difference satisfies, for the same or a dominated seminorm family,

$$|S_n^{\mathrm{spde}}(F) - S_n^{\mathrm{cons}}(F)| \le A_\Delta B_\Delta^n (n!)^{\gamma_\Delta} q_{n,N_\Delta+C_\Delta n}(F).$$

Then S_n^{spde} satisfies a corrected OS-II estimate with constants obtained by replacing A by $A+A_\Delta$, B by $\max\{B, B_\Delta\}$, γ by $\max\{\gamma,\gamma_\Delta\}$, and the linear seminorm order by a common dominating order. In particular, if the hierarchy comparison error tends to zero in the stated seminorms, the OS-II growth package transfers from the constructive hierarchy to the SPDE hierarchy.

Proof. Subtract the cutoff Gram form from the limiting Gram form:

$$\sum_{i,j} \overline{c_i} c_j G_{ij} = \sum_{i,j} \overline{c_i} c_j G_{ij}^{(N)} + \sum_{i,j} \overline{c_i} c_j (G_{ij} - G_{ij}^{(N)}).$$

The first term is bounded from below by (144.303). The second satisfies

$$\left| \sum_{i,j} \overline{c_i} c_j (G_{ij} - G_{ij}^{(N)}) \right| \le \varepsilon_{\mathcal{W},N} \left(\sum_i |c_i| \right)^2 \le M\varepsilon_{\mathcal{W},N} \sum_i |c_i|^2,$$

by Cauchy's inequality. This proves (144.305). If the directed-window schedule drives the displayed defect to zero, every finite positive-time polynomial OS quadratic form is nonnegative in the limit, which is exactly polynomial OS positivity on the directed cylinder algebra.

The constructive comparison estimate (144.306) is the same calculation with $G-H$ in place of $G-G^{(N)}$. When every finite-window entry is equal, the Gram matrices are equal, so the positive-time inner products and null spaces are equal before completion. With defects, the factor M is the price of entrywise control; a growing OS window therefore requires a schedule strong enough to make $M\eta_{\mathcal{W}}$ vanish, or else an operator-norm comparison replacing the entrywise bound.

For the growth statement, use the triangle inequality and dominate the two Schwartz seminorms by one member of the increasing seminorm family. Since

$$B^n (n!)^\gamma, \quad B_\Delta^n (n!)^{\gamma_\Delta} \le \max\{B, B_\Delta\}^n (n!)^{\max\{\gamma,\gamma_\Delta\}},$$

the displayed constants give the asserted OS-II bound for S_n^{spde}. If the difference term tends to zero in the relevant seminorms, the constructive constants alone control the limiting SPDE hierarchy. ◻

Proposition 144.96 (Finite-rate assembly schedule for dynamic Φ_3^4)**.** *Let*

$$\mathcal{W}_k = \{F_{k,1}, \dots, F_{k,m_k}\}, \qquad k = 1, 2, \dots,$$

be a directed sequence of finite positive-time polynomial OS windows. Suppose that the model estimates, fixed-point-sector comparison, stationary-law coupling, and polynomial truncation have been assembled into the entrywise window bound

$$\max_{i,j\le m_k} |G^{\mathrm{spde}}_{k,ij} - G^{(n)}_{k,ij}| \le C_k e_n + T_{k,R}. \tag{144.307}$$

Here $G^{(n)}$ is the cutoff OS Gram matrix, G^{spde} is the limiting stationary-SPDE Gram matrix, e_n is the projective model/fixed-point defect, C_k is the finite-window amplification constant, and $T_{k,R}$ is the polynomial-tail truncation error. Assume also that the cutoff window has lower OS defect $\delta_{k,n}$, and that the constructive hierarchy is entrywise comparable to the limiting SPDE hierarchy:

$$\max_{i,j\le m_k} |G^{\mathrm{spde}}_{k,ij} - H^{\mathrm{cons}}_{k,ij}| \le \eta_k. \tag{144.308}$$

Then for every cutoff and truncation schedule $n = n(k)$, $R = R(k)$,

$$\begin{aligned}\sum_{i,j\le m_k} \overline{c_i} c_j H^{\mathrm{cons}}_{k,ij} \ge -\Delta_k \sum_{i\le m_k} |c_i|^2,\\ \Delta_k := \delta_{k,n(k)} + m_k\big(C_k e_{n(k)} + T_{k,R(k)} + \eta_k\big).\end{aligned} \tag{144.309}$$

If $\Delta_k \to 0$, the directed union has the same positive-time OS pre-Hilbert form as the constructive hierarchy. The OS-II growth constants transfer whenever the truncation and comparison errors are dominated by a common OS-II seminorm envelope.

For example, if $m_k \le 2^{\alpha k}$ and $C_k \le 2^{\beta k}$, choose

$$e_{n(k)} \le 2^{-(\alpha+\beta+3)k}, \qquad T_{k,R(k)} \le 2^{-(\alpha+3)k}, \qquad \eta_k \le 2^{-(\alpha+3)k}, \qquad \delta_{k,n(k)} \le 2^{-k}.$$

Then

$$\Delta_k \le 2^{-k} + 2^{-3k} + 2^{-3k} + 2^{-3k} \le 4\,2^{-k}.$$

Proof. Apply Proposition 144.95 to the k-th window with $\varepsilon_{\mathcal{W}_{k,n,R}} = C_k e_n + T_{k,R}$. This gives a limiting SPDE lower defect $\delta_{k,n} + m_k(C_k e_n + T_{k,R})$. Comparing the SPDE Gram matrix with the constructive Gram matrix by (144.308) adds at most $m_k \eta_k \sum_i |c_i|^2$ to the lower defect, proving (144.309). The sample schedule is the displayed arithmetic: the model/fixed-point error must beat both the window cardinality m_k and the window amplification C_k, while truncation and hierarchy-comparison errors only pay the window-cardinality loss. The directed-union and OS-II statements are the corresponding conclusions of Proposition 144.95 applied along the schedule. □

Proposition 144.97 (Cross-route phase-cell/SPDE assembly budget)**.** *Work in one finite-volume chart: the same field normalization, Wick-ordering convention, renormalized mass coordinate, and local counterterm normalization are used for the phase-cell construction of Chapter 137 and for the dynamic Φ^4_3 SPDE construction. For a positive-time polynomial OS window*

$$\mathcal{W}_k = \{F_{k,1}, \dots, F_{k,m_k}\}$$

let $G^{\mathrm{spde}}_{k,ij}$ be the limiting stationary-SPDE Gram entries, $G^{(n)}_{k,ij}$ a cutoff SPDE Gram matrix, $H^{(J)}_{k,ij}$ the corresponding phase-cell regulator at constructive scale J, and $H^{\mathrm{cons}}_{k,ij}$ the limiting constructive

Gram matrix. Suppose that

$$\max_{i,j\le m_k} |G^{\mathrm{spde}}_{k,ij} - G^{(n)}_{k,ij}| \le C^{\mathrm{spde}}_k e_n + T_{k,R}, \tag{144.310}$$

$$\max_{i,j\le m_k} |G^{(n)}_{k,ij} - H^{(J)}_{k,ij}| \le \chi_{k,n,J}, \tag{144.311}$$

$$\max_{i,j\le m_k} |H^{(J)}_{k,ij} - H^{\mathrm{cons}}_{k,ij}| \le D_k\, \mathcal{E}^{\mathrm{constr}}_J. \tag{144.312}$$

Here e_n is the projective model/fixed-point SPDE defect, $T_{k,R}$ is the polynomial truncation tail, $\chi_{k,n,J}$ is the finite-chart comparison error between the stochastic and phase-cell regulators, and $\mathcal{E}^{\mathrm{constr}}_J$ is the constructive phase-cell defect bounded in (137.52). If the phase-cell window has lower OS defect

$$\sum_{i,j\le m_k} \overline{c_i} c_j H^{(J)}_{k,ij} \ge -\delta_{k,n,J} \sum_{i\le m_k} |c_i|^2, \tag{144.313}$$

then the limiting SPDE Gram matrix satisfies

$$\sum_{i,j\le m_k} \overline{c_i} c_j G^{\mathrm{spde}}_{k,ij} \ge -\Xi_{k,n,J,R} \sum_{i\le m_k} |c_i|^2, \tag{144.314}$$

where

$$\Xi_{k,n,J,R} = \delta_{k,n,J} + m_k\big(C^{\mathrm{spde}}_k e_n + T_{k,R} + \chi_{k,n,J}\big). \tag{144.315}$$

Moreover

$$\max_{i,j\le m_k} |G^{\mathrm{spde}}_{k,ij} - H^{\mathrm{cons}}_{k,ij}| \le C^{\mathrm{spde}}_k e_n + T_{k,R} + \chi_{k,n,J} + D_k \mathcal{E}^{\mathrm{constr}}_J. \tag{144.316}$$

Consequently, if there is a directed schedule $(n(k), J(k), R(k))$ for which

$$\Xi_{k,n(k),J(k),R(k)} \to 0, \qquad m_k\big(C^{\mathrm{spde}}_k e_{n(k)} + T_{k,R(k)} + \chi_{k,n(k),J(k)} + D_k \mathcal{E}^{\mathrm{constr}}_{J(k)}\big) \to 0,$$

then the directed SPDE hierarchy and the constructive hierarchy have the same positive-time OS pre-Hilbert form. The corrected OS-II growth package transfers from the constructive hierarchy whenever the entrywise comparison errors are dominated by a common OS-II seminorm envelope.

For instance, if

$$m_k \le 2^{\alpha k}, \qquad C^{\mathrm{spde}}_k \le 2^{\beta k}, \qquad D_k \le 2^{\gamma k},$$

then the sample choices

$$e_{n(k)} \le 2^{-(\alpha+\beta+4)k}, \qquad T_{k,R(k)} \le 2^{-(\alpha+4)k},$$
$$\chi_{k,n(k),J(k)} \le 2^{-(\alpha+4)k}, \qquad \mathcal{E}^{\mathrm{constr}}_{J(k)} \le 2^{-(\alpha+\gamma+4)k},$$
$$\delta_{k,n(k),J(k)} \le 2^{-k}$$

make the combined finite-window defect at most $2\,2^{-k}$.

Proof. By the triangle inequality,

$$|G^{\mathrm{spde}}_{k,ij} - H^{(J)}_{k,ij}| \le C^{\mathrm{spde}}_k e_n + T_{k,R} + \chi_{k,n,J}.$$

Substituting this estimate into the quadratic form and using $(\sum_i |c_i|)^2 \le m_k \sum_i |c_i|^2$, exactly as in Proposition 144.95, gives (144.314) and (144.315). Adding (144.312) to the same triangle estimate proves (144.316).

If the directed schedule sends the two displayed defects to zero, every finite positive-time polynomial OS quadratic form in the SPDE hierarchy is the limit of the corresponding constructive form, and the finite-window comparison identifies the null spaces before completion. The OS-II growth statement follows from the growth-transfer part of Proposition 144.95.

For the sample rate schedule, multiply each entrywise error by the worst window factor m_k. The model/fixed-point contribution is bounded by

$$2^{\alpha k}2^{\beta k}2^{-(\alpha+\beta+4)k} = 2^{-4k},$$

the truncation and finite-chart comparison terms by 2^{-4k}, and the phase-cell tail by

$$2^{\alpha k}2^{\gamma k}2^{-(\alpha+\gamma+4)k} = 2^{-4k}.$$

Together with the lower OS defect 2^{-k}, this is $2^{-k} + 4\,2^{-4k} \le 2\,2^{-k}$ for $k \ge 1$. □

Proposition 144.98 (Directed OS pre-Hilbert comparison)**.** *Let*

$$V_1 \subset V_2 \subset \cdots, \qquad V_k = \operatorname{span}\{F_{k,1}, \ldots, F_{k,m_k}\},$$

be an increasing exhaustion of the positive-time polynomial cylinder algebra $\mathfrak{A}_+^{\mathrm{poly}} = \bigcup_k V_k$. Let G^{spde} and H^{cons} be the sesquilinear OS Gram forms determined by the limiting stationary-SPDE hierarchy and by the constructive Euclidean hierarchy, respectively. Suppose that the schedules of Proposition 144.97 provide numbers $\Xi_k \to 0$ and $E_k \to 0$ such that, on V_k,

$$G^{\mathrm{spde}}(v,v) \ge -\Xi_k \|c(v)\|_{\ell^2}^2, \tag{144.317}$$

$$|G^{\mathrm{spde}}(v,w) - H^{\mathrm{cons}}(v,w)| \le E_k \|c(v)\|_{\ell^1} \|c(w)\|_{\ell^1}. \tag{144.318}$$

Here $c(v)$ denotes the coefficient vector of v in the listed window; when $v \in V_r \subset V_k$, the vector is padded by zeroes. Assume also that H^{cons} is OS positive on $\mathfrak{A}_+^{\mathrm{poly}}$. Then G^{spde} is OS positive on $\mathfrak{A}_+^{\mathrm{poly}}$, the two forms agree on the algebraic cylinder algebra, and the identity map descends to an isometric isomorphism

$$\mathfrak{A}_+^{\mathrm{poly}}/\mathcal{N}_{\mathrm{spde}} \cong \mathfrak{A}_+^{\mathrm{poly}}/\mathcal{N}_{\mathrm{cons}}, \qquad \mathcal{N}_\bullet := \{v : \langle v,v\rangle_\bullet = 0\}.$$

After completion, the OS Hilbert spaces generated by these positive-time cylinder vectors are canonically unitarily identified. This conclusion uses only the finite-window route-comparison estimates. It does not prove the model estimates, the finite-chart comparison, OS-II growth, Euclidean covariance, locality, or domain statements needed for the final Wightman field presentation; those remain the analytic inputs named in Theorem 144.99.

Proof. Fix $v \in \mathfrak{A}_+^{\mathrm{poly}}$. Choose r with $v \in V_r$. For every $k \ge r$, (144.317) gives

$$G^{\mathrm{spde}}(v,v) \ge -\Xi_k \|c(v)\|_{\ell^2}^2.$$

Letting $k \to \infty$ proves $G^{\mathrm{spde}}(v,v) \ge 0$. Thus the stationary-SPDE hierarchy has a positive algebraic OS form once the directed defects vanish.

For $v, w \in \mathfrak{A}_+^{\mathrm{poly}}$, choose r with $v, w \in V_r$. The same padding argument and (144.318) give, for all $k \geq r$,

$$|G^{\mathrm{spde}}(v, w) - H^{\mathrm{cons}}(v, w)| \leq E_k \|c(v)\|_{\ell^1} \|c(w)\|_{\ell^1}.$$

Letting $k \to \infty$ gives equality of the two sesquilinear forms on the directed union. Hence v has zero SPDE norm if and only if it has zero constructive norm; the null spaces are equal. The identity map on $\mathfrak{A}_+^{\mathrm{poly}}$ therefore descends to an isometry of the quotient pre-Hilbert spaces, and an isometry between dense pre-Hilbert spaces extends uniquely to a unitary between their Hilbert completions. □

Quoted Theorem 144.99 (Renormalized dynamic Φ^4_3 theorem package)**.** *Let the spatial manifold be a finite three-dimensional torus, let $\xi_\epsilon = \rho_\epsilon * \xi$ be a smooth space-time mollification of white noise, and fix the normalization of* (144.283)*. In the BPHZ regularity-structure chart there are local constants $C_{1,\epsilon}$, $C_{2,\epsilon}$, and a finite mass coordinate c_{fin}, such that the following statements hold.*

(i) For each fixed $\epsilon > 0$ and smooth initial field, the cutoff equation (144.283) *has a unique smooth local solution. The solution map is Markovian and depends continuously on the initial field and on the smooth noise.*

(ii) After enhancing the mollified noise by its BPHZ-renormalized negative trees, the cutoff solutions converge in probability, on compact stochastic-time intervals before explosion and in negative spatial Holder or Besov topologies, to a limit independent of the mollifier up to finite local coordinate changes.

(iii) The positive quartic drift, together with the renormalized mass coordinate, gives global solutions and invariant probability measures for the limiting Markov process in the massive phase. Starting the cutoff equation in its finite-cutoff Gibbs law gives stationary solutions, and every limiting stationary law is invariant for the limiting Markov semigroup.

(iv) In a common finite-volume regulator and renormalization chart, this invariant law has the same Schwinger moments as the constructive Φ^4_3 Euclidean measure with the same renormalized mass coordinate. Equivalently, after the field and mass normalizations are matched, the SPDE stationary construction and the constructive Euclidean construction determine the same OS input hierarchy.

This renormalized Φ^4_3 SPDE theorem is a quoted theorem-boundary for the regularity-structures construction, not a proof completed here. The quoted source lineage is Hairer's regularity-structures construction and the Hairer–Mourrat–Weber treatments of dynamic Φ^4_3 renormalization. The four clauses are logically distinct. Local cutoff well-posedness is an ordinary smooth parabolic theorem. Renormalized convergence is the singular SPDE theorem: one first builds the canonical model from the mollified noise; its negative tree components diverge as $\epsilon \downarrow 0$; the BPHZ character subtracts the expectations of all divergent negative subtrees, producing a renormalized model satisfying uniform analytic bounds; compactness and Kolmogorov estimates then give convergence of the model.

After the renormalized model has been constructed, the local fixed-point step has the form proved in Theorem 144.91. The missing analytic input is the verification, for the actual BPHZ model, of the Schauder, product, and small-time estimates used in that theorem. Reconstructing the fixed point then gives the distribution-valued solution by Theorem 144.49. The explicit local term in (144.283) is the image, in the concrete equation, of the BPHZ action on the negative trees. Invariant measures are identified by finite-cutoff stationarity, tightness, and convergence of stationary solutions. Identification with the constructive Euclidean Φ^4_3 measure is still another step: both constructions must be placed in the same finite-volume cutoff chart, the mass and field coordinates must be matched, and equality of the limiting Schwinger moments must be proved. Each sentence in this paragraph names a theorem-level estimate; none is to be treated as proved merely by being quoted.

The proof boundary has narrowed. For the Φ^4_2 equation, the construction of the stochastic convolution and its Wick powers, the path-space enhanced-noise convergence, the Sobolev and Besov local DPD maps, the smooth energy estimate, the compactness and closedness steps for smooth approximants, the regulator comparison criteria, and the abstract SPDE-to-OS reconstruction criterion have been proved above. The remaining two-dimensional work is not a generic appeal to the Da Prato–Debussche theorem. It consists of specific constructive estimates: the local rough-forcing estimate in (144.62), Nelson stability for the chosen Wick quartic cutoff family, and the moment-continuity, positive-time semigroup regularity, and corrected OS-II growth estimates needed by Remark 144.101.

For dynamic Φ^4_3, the self-contained proof boundary is still larger. The finite negative sector, its homogeneity bookkeeping, its reexpansion coordinates, and the scale-summed criterion that would imply convergence of that sector have been proved in Lemma 144.64 and the negative-sector coordinate-control consequence. What remains is to prove, for the actual BPHZ-renormalized model, the coordinate estimates required by that scale-summed criterion for

$$\Xi, \quad X, \quad X^2, \quad X^3, \quad XY, \quad X^2Y, \quad \text{and} \quad c_n(z,z'),$$

including both uniform model-seminorm moments and dyadic cutoff-increment moments with enough scale and parameter slack. One must then extend the negative-sector convergence to the full modelled-distribution space used by the fixed point, prove the Schauder and multiplication estimates for the concrete model, identify the BPHZ counterterms with the local constants in (144.283), and compare the stationary SPDE law with the Euclidean constructive measure. [1] The cited works identify deeper analytic machinery that remains to be reconstructed in this monograph; citation supplies orientation, while the proof obligations remain the estimates just listed.

Open Problem 144.100 (Remaining self-contained singular-SPDE proof stack). Complete the proof stack left open by the preceding analysis. The two-dimensional part requires: a proof of the rough-forcing estimate (144.62) for the Wick-enhanced Φ^4_2 stochastic convolution; a direct Nelson stability theorem, or a fully controlled comparison with a regulator for which Nelson stability has been proved, for the cutoff family used in the stochastic assembly; and the OS reconstruction inputs listed in Remark 144.101.

The three-dimensional part requires: construction of the BPHZ-renormalized dynamic Φ^4_3 model; proof of the coordinate moment and cutoff-Cauchy estimates in the negative-sector coordinate-control consequence; extension of those estimates from the strict negative sector to the full sector used in the fixed-point problem; verification that the concrete BPHZ model satisfies the Schauder and product estimates required by Theorem 144.91; derivation of the local counterterms $C_{1,\epsilon}$,

[1] See G. Da Prato and A. Debussche, "Strong solutions to the stochastic quantization equations," *Ann. Probab.* 31 (2003); M. Hairer, "A theory of regularity structures," *Invent. Math.* 198 (2014); and the Hairer–Mourrat–Weber regularity-structures treatment of Φ^4_3 renormalization. For recent singular-SPDE work in gauge contexts, see A. Chandra, I. Chevyrev, M. Hairer, and H. Shen, "Stochastic quantisation of Yang–Mills," Invent. Math. **230** (2022) 1025–1096.

$C_{2,\epsilon}$, and c_{fin} from the BPHZ character in the convention of (144.283); invariant-law construction and comparison with the constructive Euclidean Φ^4_3 measure; and the SPDE-to-OS reconstruction inputs for the resulting Schwinger hierarchy. Until these arguments are supplied, the remaining quoted theorem boundary is a documented proof boundary rather than an authority claim.

144.8 Paracontrolled and RG Routes

Regularity structures are not the only analytic language for singular SPDE. Paracontrolled distributions decompose products using Bony's paraproduct

$$fg = f \prec g + f \circ g + f \succ g,$$

and control the resonant product $f \circ g$ by enhancing the noise with the few ill-defined resonant objects needed by the equation. For Φ^4_3, this route uses the same local counterterm content as (144.283), expressed in Fourier/Besov language rather than in a tree Hopf algebra.

Kupiainen-style RG treats the stochastic convolution and nonlinear response by scale integration. It is closer in form to the constructive RG of Chapter 142. The common structure is that no finite truncation of diagrams is being trusted by itself: the theorem estimates the infinite irrelevant tail in a norm and shows convergence of the renormalized limit.

144.9 Invariant Measure and OS Data

If the renormalized Markov process exists and is ergodic with invariant measure μ, the Euclidean Schwinger functions are

$$S_n(f_1, \dots, f_n) = \int \Phi(f_1) \cdots \Phi(f_n) \, \mathrm{d}\mu(\Phi). \tag{144.319}$$

A complete QFT construction must verify:

$$\begin{array}{rl} \text{Euclidean covariance,} & \text{reflection positivity,} \\ \text{regularity and OS growth bounds,} & \text{clustering or phase decomposition.} \end{array}$$

Stochastic quantization is especially powerful because it gives a dynamic construction of the measure and a precise algebraic account of stochastic counterterms. Reflection positivity, however, is a property of the Euclidean field measure under physical time reflection; it is not automatic from Markov positivity in the auxiliary stochastic time.

Remark 144.101 (SPDE invariant law as an OS reconstruction input). Let $E = \mathcal{S}'(\mathbb{R}^d)$ be the real tempered-distribution space, equipped with its Borel σ-algebra, and let μ be a probability measure on E. For $f \in \mathcal{S}(\mathbb{R}^d)$ write $\Phi(f)(\varphi) = \varphi(f)$. Suppose that the following conditions hold.

(i) For every $n \geq 0$, the multilinear functional initially defined on finite tensor sums by

$$S_n\left(\sum_a c_a f_{a,1} \otimes \cdots \otimes f_{a,n}\right) = \sum_a c_a \int_E \Phi(f_{a,1}) \cdots \Phi(f_{a,n}) \, \mathrm{d}\mu(\Phi)$$

is well-defined and obeys a Schwartz-seminorm estimate

$$|S_n(F)| \le C_n\, q_{n,N_n}(F), \qquad F \in \mathcal{S}((\mathbb{R}^d)^n), \tag{144.320}$$

after extending from finite tensor sums. Here $q_{n,N}$ is any fixed increasing defining family of Schwartz seminorms on $\mathcal{S}((\mathbb{R}^d)^n)$. Equivalently, μ has enough polynomial cylinder moments, with enough seminorm continuity, to make each S_n a tempered Euclidean distribution.

(ii) The hierarchy $\{S_n\}$ is normalized, Euclidean covariant, permutation symmetric, and Hermitian in the sense of Definition 12.2. In a scalar real theory these conditions follow from $S_0 = 1$, invariance of μ under the Euclidean group action on E, and reality of the field coordinates; for labelled or graded fields the label reflection and Koszul signs must be part of the declared field presentation.

(iii) Let Θ denote physical Euclidean time reflection. For every polynomial cylinder observable

$$F(\Phi) = \sum_a c_a\, \Phi(f_{a,1}) \cdots \Phi(f_{a,r_a})$$

whose test functions are supported in the positive-time half-space,

$$\int_E \overline{F(\Theta\Phi)}\, F(\Phi)\, \mathrm{d}\mu(\Phi) \ge 0. \tag{144.321}$$

If this inequality is first proved only for bounded cylinder functions, then the passage to polynomial cylinders must be justified by the uniform integrability or truncation estimates appropriate to the cutoff limit.

(iv) The positive-time translation operators on the OS quotient satisfy the semigroup law, symmetry, and strong-continuity hypotheses (12.5)–(12.8).

(v) The translation-reduced hierarchy satisfies the corrected OS-II linear-growth estimate (12.4); explicitly, for some $A, B, \gamma > 0$ and integers N_0, C_{OS},

$$|S_n^{\mathrm{red}}(F)| \le A\, B^n\, (n!)^\gamma\, q_{n,N_0 + C_{\mathrm{OS}} n}(F)$$

on the zero-diagonal reduced Schwartz test space of Chapter 12.

Then the Schwinger hierarchy obtained from μ satisfies the hypotheses of Theorem 12.16. Consequently it reconstructs Lorentzian Wightman field data whose Euclidean time-ordered boundary values recover the Schwinger functions at noncoincident Euclidean configurations. If the hierarchy is clustering in the sense of Corollary 12.19, the reconstructed vacuum is unique; without clustering one obtains the corresponding phase-decomposed Wightman presentation. Condition (i) is the distributional regularity step. Finite tensor sums are dense in the Schwartz tensor product, and the estimate (144.320) makes the cylinder moment functional continuous for the Schwartz topology. Thus each S_n extends uniquely to a tempered distribution on $(\mathbb{R}^d)^n$.

Condition (ii) gives normalization, Euclidean covariance, permutation symmetry, and Hermiticity. Condition (iii) is exactly OS reflection positivity on the positive-time polynomial cylinder algebra; the warning in the second sentence records the point used repeatedly above, namely that polynomial OS positivity cannot be read off from bounded-cylinder positivity without a tail estimate. Conditions (iv) and (v) are the corrected analytic inputs emphasized in Chapter 12:

reflection positivity constructs the Hilbert space and positive Hamiltonian, while the OS-II semigroup and linear-growth package supplies the many-variable Fourier–Laplace continuation with tempered Lorentzian boundary values.

All hypotheses of Theorem 12.16 are therefore present. Applying that theorem gives

$$(\mathcal{H}_{\mathrm{OS}}, \Omega_{\mathrm{OS}}, U, \mathcal{D}_{\mathrm{OS}}, \{\widehat{\Phi}_\alpha\})$$

and the Wightman distributions obtained as boundary values of the analytic continuations of the S_n. The clustering statement is precisely Corollary 12.19.

In stochastic quantization the preceding remark is a checklist, not an automatic corollary of stationarity. The Markov invariant law supplies a candidate μ. The constructive proof must still establish moment continuity, physical-time reflection positivity, the OS-II positive-time semigroup regularity, and the corrected linear-growth estimate. For Φ^4_2 and Φ^4_3, these conditions should ultimately be verified by comparing the SPDE invariant law with the corresponding constructive Euclidean measure in a common renormalization chart, because the constructive measure is where reflection positivity and OS growth are naturally controlled. Proposition 144.95 is the finite-window bookkeeping for this comparison: it records the exact loss incurred when cutoff OS positivity, polynomial truncation, and hierarchy comparison are known only with window-dependent defects.

Construction 144.102 (Common Schwinger-hierarchy comparison)**.** Let

$$E = \mathcal{S}'(\mathbb{R}^d)$$

with its cylinder σ-algebra. Let μ_{spde} be a candidate stationary law produced by a renormalized stochastic quantization construction, and let μ_{cons} be a constructive Euclidean measure in the same finite-volume, field-normalization, mass-coordinate, and local-counterterm chart. For $f \in \mathcal{S}(\mathbb{R}^d)$, write

$$\Phi(f)(\varphi) = \varphi(f).$$

The comparison datum needed for OS reconstruction is the equality of Schwinger hierarchies, not equality of auxiliary stochastic processes. A precise sufficient datum is the following.

(i) For each n, both moment functionals

$$S_n^{\mathrm{spde}}(f_1, \dots, f_n) = \int_E \prod_{j=1}^n \Phi(f_j)\, \mathrm{d}\mu_{\mathrm{spde}}(\Phi), \qquad S_n^{\mathrm{cons}}(f_1, \dots, f_n) = \int_E \prod_{j=1}^n \Phi(f_j)\, \mathrm{d}\mu_{\mathrm{cons}}(\Phi)$$

extend continuously to $\mathcal{S}((\mathbb{R}^d)^n)$, with declared Schwartz seminorm bounds

$$|S_n^\bullet(F)| \le C_n^\bullet q_{n,N_n^\bullet}(F), \qquad \bullet \in \{\mathrm{spde}, \mathrm{cons}\}.$$

(ii) There is a dense linear subspace $\mathcal{D} \subset \mathcal{S}(\mathbb{R}^d)$ such that

$$S_n^{\mathrm{spde}}(f_1, \dots, f_n) = S_n^{\mathrm{cons}}(f_1, \dots, f_n), \qquad f_j \in \mathcal{D},$$

for every n. In applications $\mathcal{D}$ is often generated by the test functions used by the two regulator families, after matching the field and mass coordinates.

(iii) The constructive hierarchy $S^{\mathrm{cons}}_\bullet$ satisfies the OS normalization, Euclidean covariance, symmetry, Hermiticity, polynomial reflection positivity, positive-time semigroup regularity, corrected OS-II linear growth, and any declared clustering or phase-decomposition hypothesis.

Then the SPDE hierarchy and the constructive hierarchy coincide as tempered Schwinger distributions. Indeed, finite sums of tensors $f_1 \otimes \cdots \otimes f_n$ with $f_j \in \mathcal{D}$ are dense in $\mathcal{S}((\mathbb{R}^d)^n)$. The difference

$$S^{\mathrm{spde}}_n - S^{\mathrm{cons}}_n$$

is continuous by (i) and vanishes on that dense tensor subspace by (ii), hence vanishes on all of $\mathcal{S}((\mathbb{R}^d)^n)$. Every OS quadratic form is a finite linear combination of these distributions evaluated on reflected positive-time tensor products. Reflection positivity, covariance, symmetry, Hermiticity, the semigroup regularity inputs, the corrected OS-II growth bound, and clustering therefore transfer from $S^{\mathrm{cons}}_\bullet$ to $S^{\mathrm{spde}}_\bullet$ with the same constants after replacing the seminorm family by a common dominating family.

Consequently the OS reconstruction of the SPDE hierarchy is canonically identified with the OS reconstruction of the constructive hierarchy: the positive-time polynomial pre-Hilbert inner products are identical, the null spaces are identical, and the completed Hilbert spaces and reconstructed Wightman distributions agree under the induced unitary identification. If the comparison is first proved only for bounded cylinder functions, the bounded-to-polynomial passage must use the uniform-integrability and truncation criteria proved above; bounded-cylinder equality by itself supplies only the bounded part of the comparison datum. Equality of probability laws is a stronger route to the same conclusion when a moment-determinacy theorem is available, but OS reconstruction uses the Schwinger hierarchy itself as its input.

Remark 144.103 (Gauge theories and BV compatibility). For gauge theories, stochastic quantization must be reconciled with gauge symmetry, gauge fixing, and the BV master equation. A stochastic evolution for gauge potentials before quotienting is not by itself a construction of a gauge-invariant local QFT. The constructive target is a measure or observable theory for gauge-invariant fields, or a gauge-fixed/BV construction whose quantum master equation and positivity replacement are controlled. Two- and three-dimensional Yang–Mills SPDE programs provide important laboratories; four-dimensional Yang–Mills remains a separate open problem.

Open Problem 144.104 (SPDE-to-Wightman construction). Starting from a renormalized singular SPDE construction of an interacting Euclidean field, prove the inputs of Remark 144.101, identify the resulting Wightman distributions, and compare the stochastic counterterms with Wilsonian local coordinates in a common renormalization chart.

- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Hamiltonian numerical methods are regulator frameworks for QFT. This chapter formulates Hamiltonian truncation, light-front discretization, and benchmark scripts as controlled approximations with explicitly declared Hilbert spaces, cutoffs, counterterms, and convergence tests.

Definition 145.1 (Hamiltonian truncation regulator specification)**.** A Hamiltonian truncation regulator specification is a tuple

$$\mathfrak{H}_{\mathrm{trunc}} = \big(\mathcal{H}, \mathcal{Q}_H, \{\mathcal{H}_\Lambda, P_\Lambda\}_{\Lambda \in I}, \mathcal{B}_\Lambda, \{\mathcal{O}_a, c_a(\Lambda)\}_{a \in \mathcal{A}_{\mathrm{ct}}}, \mathcal{O}_{\mathrm{obs}}, \mathcal{E}_{\mathrm{sys}}\big)$$

with the following entries.

(i) $\mathcal{H}$ is the target Hilbert space and $\mathcal{Q}_H$ is a lower-bounded closed quadratic form on a dense form domain $\mathrm{Dom}\,\mathcal{Q}_H$. When the limiting Hamiltonian is known as a self-adjoint operator H, $\mathcal{Q}_H$ is its associated form.

(ii) I is a directed cutoff set. For each $\Lambda \in I$, $\mathcal{H}_\Lambda \subset \mathrm{Dom}\,\mathcal{Q}_H$ is a finite-dimensional trial space and P_Λ is the Hilbert-space projection onto $\mathcal{H}_\Lambda$. The specification states whether the intended density statement is strong, form-norm, graph-norm, or another declared topology.

(iii) $\mathcal{B}_\Lambda$ is the ordered computational basis used to build finite matrices. The basis choice includes inner-product conventions, quantum-number sectors, symmetry projections, and normalization of finite volume states.

(iv) $\mathcal{O}_a$ are local counterterm or improvement operators admitted by the regulator, and $c_a(\Lambda)$ are their cutoff-dependent coordinates in a declared scheme. The finite Hamiltonian matrix is

$$H_\Lambda^{\text{ren}} = P_\Lambda H P_\Lambda + \sum_{a\in\mathcal{A}_{\text{ct}}} c_a(\Lambda) P_\Lambda \mathcal{O}_a P_\Lambda$$

when the formal operator expression is meaningful; otherwise the same formula denotes the finite quadratic form specified in the basis $\mathcal{B}_\Lambda$.

(v) $\mathcal{O}_{\text{obs}}$ is the list of finite-regulator observables to be extracted from H_Λ^{ren}, together with their normalization and symmetry-sector labels.

(vi) $\mathcal{E}_{\text{sys}}$ is the systematic-error model: cutoff extrapolation ansatz, finite-volume correction model, counterterm-fitting prescription, residual-bound tolerance, and benchmark scripts used to check finite-matrix algebra.

This records a regulator family. A continuum or infinite-volume claim requires an additional convergence theorem or controlled approximation that states the topology, the limiting quadratic form or observable, and an error bound.

145.1 Projected Hamiltonian Regulator

The elementary version of Definition 145.1 starts with a known self-adjoint Hamiltonian H on $\mathcal{H}$, bounded below. Choose finite-dimensional subspaces

$$\mathcal{H}_\Lambda \subset \mathcal{H}, \qquad P_\Lambda : \mathcal{H} \to \mathcal{H}_\Lambda,$$

with $P_\Lambda \to I$ strongly. The projected Hamiltonian is

$$H_\Lambda = P_\Lambda H P_\Lambda$$

on $\mathcal{H}_\Lambda$. If H is defined by a QFT regulator, H_Λ must be supplemented by local counterterms:

$$H_\Lambda^{\text{ren}} = P_\Lambda H P_\Lambda + \sum_a c_a(\Lambda) P_\Lambda \mathcal{O}_a P_\Lambda.$$

The pair $(\mathcal{H}_\Lambda, H_\Lambda^{\text{ren}})$ is the numerical regulator.

145.2 Rayleigh–Ritz Bound

Lemma 145.2 (Rayleigh–Ritz bound at fixed Hamiltonian)**.** *Let H be a self-adjoint operator on $\mathcal{H}$, bounded below, and suppose that*

$$E_0 \le E_1 \le \cdots \le E_n$$

are isolated eigenvalues below the bottom of the essential spectrum, counted with multiplicity. Let $\mathcal{Q}_H$ be the closed quadratic form of H. For a finite-dimensional subspace $\mathcal{H}_\Lambda \subset \operatorname{Dom}\mathcal{Q}_H$, define

$$E_n(\Lambda) = \min_{\substack{W\subset\mathcal{H}_\Lambda \\ \dim W = n+1}} \max_{\substack{\psi\in W \\ \|\psi\|=1}} \mathcal{Q}_H(\psi,\psi).$$

Then $E_n(\Lambda) \geq E_n$. If $\{\mathcal{H}_\Lambda\}$ is an increasing net and, for some orthonormal eigenbasis $\varphi_0, \ldots, \varphi_n$ of the first $n+1$ eigenspaces, there are $\eta_j^\Lambda \in \mathcal{H}_\Lambda$ with

$$\eta_j^\Lambda \to \varphi_j \quad \textit{in the form norm} \quad \|\psi\|_{\mathcal{Q}}^2 = \|\psi\|^2 + \mathcal{Q}_H(\psi,\psi) - c\|\psi\|^2$$

for a constant $c < \inf \operatorname{spec} H$, then $E_n(\Lambda) \downarrow E_n$.

Proof. The min–max characterization of the n-th discrete eigenvalue gives

$$E_n = \inf_{\substack{W \subset \operatorname{Dom} \mathcal{Q}_H \\ \dim W = n+1}} \sup_{\substack{\psi \in W \\ \|\psi\|=1}} \mathcal{Q}_H(\psi,\psi).$$

The variational problem defining $E_n(\Lambda)$ restricts the same infimum to the smaller family of subspaces contained in $\mathcal{H}_\Lambda$, hence $E_n(\Lambda) \geq E_n$. By the approximation hypothesis, Gram–Schmidt in the ordinary Hilbert norm produces an $(n+1)$-dimensional subspace $W_\Lambda \subset \mathcal{H}_\Lambda$ whose unit sphere converges in form norm to the unit sphere of $\operatorname{span}\{\varphi_0, \ldots, \varphi_n\}$. The Gram–Schmidt coefficients are rational functions of inner products whose limiting denominators are nonzero, so the form-norm convergence is preserved. The supremum of $\mathcal{Q}_H$ on that unit sphere therefore converges to E_n. The upper bound $E_n(\Lambda) \leq \sup_{\psi \in W_\Lambda, \|\psi\|=1} \mathcal{Q}_H(\psi,\psi)$ gives $\limsup_\Lambda E_n(\Lambda) \leq E_n$. Together with the lower bound this proves convergence. Monotonic decrease follows because increasing $\mathcal{H}_\Lambda$ enlarges the family of trial subspaces. ☐

This proposition concerns a fixed self-adjoint operator H. It does not assert monotonicity for a family H_Λ^{ren} whose counterterms change with Λ, nor for a sequence of finite matrices obtained from different regulators. Those comparisons require their own cutoff-error estimates.

Proposition 145.3 (Gap-stable Ritz counting for a fixed Hamiltonian)**.** *Let H and $\mathcal{Q}_H$ be as in Lemma 145.2. Let $\{\mathcal{H}_\Lambda\}$ be an increasing net of finite-dimensional subspaces of* $\operatorname{Dom} \mathcal{Q}_H$ *which is dense in the form norm. Let*

$$E_0 \leq E_1 \leq \cdots$$

be the discrete eigenvalues of H below the bottom of the essential spectrum, counted with multiplicity, and let

$$E_0(\Lambda) \leq E_1(\Lambda) \leq \cdots \leq E_{\dim \mathcal{H}_\Lambda - 1}(\Lambda)$$

be the Ritz eigenvalues obtained by restricting $\mathcal{Q}_H$ to $\mathcal{H}_\Lambda$. Suppose $a < b < \inf \operatorname{spec}_{\mathrm{ess}} H$ and that $a, b \notin \operatorname{spec} H$. Define

$$N_H(c) = \#\{j : E_j < c\}, \qquad c \in \{a, b\},$$

and $m = N_H(b) - N_H(a)$. Then, for all sufficiently large Λ, exactly m Ritz eigenvalues lie in the interval (a,b).

Proof. Since b lies below the essential spectrum and is not an eigenvalue, there are only finitely many eigenvalues below b. Put

$$M = N_H(b), \qquad r = N_H(a).$$

For each $j < M$, the form-norm density of $\bigcup_\Lambda \mathcal{H}_\Lambda$ implies the approximation hypothesis in Lemma 145.2 for the first $j+1$ eigenspaces; hence

$$E_j(\Lambda) \downarrow E_j. \tag{145.1}$$

If $j < r$, then $E_j < a$, and (145.1) gives

$$E_j(\Lambda) < a$$

for all sufficiently large Λ. If $r \le j < M$, then

$$a < E_j < b.$$

The lower inequality $E_j(\Lambda) \ge E_j > a$ follows from Lemma 145.2; convergence gives

$$E_j(\Lambda) < b$$

for all sufficiently large Λ. Thus, eventually, at least $M - r = m$ Ritz values lie in (a, b), namely those with labels

$$r, \ldots, M - 1.$$

It remains to exclude extra Ritz values below b. If $E_M(\Lambda) < b$ for some Λ, then the min–max definition of $E_M(\Lambda)$ supplies an $(M+1)$-dimensional subspace of $\operatorname{Dom} \mathcal{Q}_H$ on whose unit sphere the quadratic form is strictly less than b. Applying the min–max characterization in the full form domain would give $E_M < b$, contradicting $M = N_H(b)$. Therefore no Ritz value with label $j \ge M$ can lie below b. Combining the two statements gives exactly m Ritz values in (a, b) for all sufficiently large Λ. □

The proposition is a theorem about Galerkin approximation to one fixed self-adjoint Hamiltonian and one fixed quadratic form. Its hypotheses are visible: a lower-bounded self-adjoint operator, an isolated finite spectral window, and form-norm density of the trial spaces. It does not justify a counterterm-dependent truncation unless one has first proved that the renormalized finite matrices converge to a fixed limiting quadratic form in a sense strong enough to replace the form-norm density assumption.

145.3 Truncated Conformal Space

For a two-dimensional QFT built as a relevant deformation of a CFT, choose the CFT Hilbert space on a circle and keep states satisfying

$$L_0 + \bar{L}_0 - \frac{c}{12} \le E_{\mathrm{cut}} \frac{L}{2\pi}.$$

The Hamiltonian matrix elements are

$$\langle i|H|j\rangle = \frac{2\pi}{L}\left(\Delta_i - \frac{c}{12}\right)\delta_{ij} + \sum_a \lambda_a \left(\frac{L}{2\pi}\right)^{1-\Delta_a} \langle i|\mathcal{O}_a(1)|j\rangle.$$

High-energy states generate cutoff dependence. The local Hamiltonian counterterms are determined by matching low-energy observables as E_{cut} is varied.

145.4 Exactly Solvable TCSA Benchmark: Ising Energy Deformation

A useful benchmark must distinguish the finite Hamiltonian matrix from the continuum theory it approximates. The thermal deformation of the two dimensional Ising CFT is special because the deformed theory is a free massive Majorana fermion. On a circle of circumference L, in the Neveu–Schwarz sector, positive modes are labelled by

$$r \in \mathbb{Z}_{\geq 0} + \frac{1}{2}, \qquad p_r = \frac{2\pi r}{L}.$$

For each r, the finite-mode Hamiltonian reduces to the real symmetric Bogoliubov block

$$H_r = \begin{pmatrix} -p_r & m \\ m & p_r \end{pmatrix},$$

where m is the Majorana mass induced by the energy-operator coupling in a fixed normalization. The corresponding finite truncation with N modes is the direct sum

$$H_N = \bigoplus_{r=1/2}^{N-1/2} H_r.$$

Remark 145.4 (Finite-mode Majorana benchmark). The eigenvalues of H_N are

$$\left\{ \pm\sqrt{p_r^2 + m^2} \;:\; r = \frac{1}{2}, \frac{3}{2}, \ldots, N - \frac{1}{2} \right\}.$$

For a fixed mode r,

$$\det(H_r - \lambda I) = (-p_r - \lambda)(p_r - \lambda) - m^2 = \lambda^2 - (p_r^2 + m^2).$$

Thus the two eigenvalues of H_r are $\lambda = \pm\sqrt{p_r^2 + m^2}$. The matrix H_N is a direct sum of the blocks H_r, so its characteristic polynomial is the product of the block characteristic polynomials. The benchmark is therefore exact at every finite cutoff N; any numerical deviation from these values measures an implementation or diagonalization error rather than a truncation effect.

The script

`qft_scripts/tcsa_ising_energy_benchmark.py`

diagonalizes H_N and checks Remark 145.4. Its role is narrow and rigorous: it is a public finite-matrix benchmark for Hamiltonian-truncation conventions before nonintegrable perturbations, counterterm fitting, and cutoff extrapolation are introduced. The magnetic-field Ising TCSA problem and the E_8 mass-spectrum computation require additional sectors and perturbing operators.

145.5 Sine-Gordon Zero-Mode Truncation As A Vertex Benchmark

The sine-Gordon model is a useful Hamiltonian-truncation test because the perturbing operator is a pair of vertex operators. A full finite-volume sine-Gordon TCSA computation requires the compact-boson Hilbert space with oscillator descendants, winding sectors, vertex-operator normal ordering, topological-charge choices, cutoff counterterms, and an extrapolation scheme. Before those ingredients are assembled, there is a small finite benchmark that checks the zero-mode vertex selection rule without pretending to compute the complete QFT spectrum.

Let θ be a 2π-periodic coordinate and let

$$\mathcal{H}_0 = L^2(S^1, \mathrm{d}\theta/2\pi), \qquad |n\rangle(\theta) = e^{\mathrm{i}n\theta}, \qquad n \in \mathbb{Z}.$$

The zero-mode coordinate is related to the sine-Gordon field by $\theta = \beta q$, where q is the spatial zero mode of ϕ. All normalization factors depending on L, the compactification radius, and β are absorbed below into two positive finite-regulator coordinates: $\kappa > 0$, the coefficient of the zero-mode kinetic energy, and $g \in \mathbb{R}$, the coefficient of the vertex perturbation. For $N \in \mathbb{Z}_{\geq 0}$, let

$$P_N : \mathcal{H}_0 \to \operatorname{span}\{|n\rangle : -N \leq n \leq N\}$$

be the Fourier cutoff. The finite matrix is

$$H_N^{\mathrm{SG},0} = P_N \left(-\kappa \frac{\mathrm{d}^2}{\mathrm{d}\theta^2} + g\cos\theta \right) P_N. \tag{145.2}$$

In the ordered basis $|-N\rangle, \ldots, |N\rangle$,

$$\left(H_N^{\mathrm{SG},0}\right)_{nm} = \kappa n^2 \delta_{nm} + \frac{g}{2}\left(\delta_{n,m+1} + \delta_{n,m-1}\right), \qquad -N \leq n, m \leq N. \tag{145.3}$$

Remark 145.5 (Benchmark scope). The matrix (145.3) checks three finite facts that are sensitive to conventions. First, $\cos\theta = (e^{\mathrm{i}\theta} + e^{-\mathrm{i}\theta})/2$ shifts the compact momentum by ± 1 and has no diagonal zero-mode matrix element. Second, the projected finite matrix is Hermitian. Third, if $N \geq 1$, ordinary finite-dimensional perturbation theory around the nondegenerate state $|0\rangle$ gives the second-order ground-state shift

$$\Delta E_0^{(2)} = \sum_{n \neq 0} \frac{|\langle n|\, g\cos\theta\, |0\rangle|^2}{0 - \kappa n^2} = -\frac{g^2}{2\kappa}. \tag{145.4}$$

Only $n = \pm 1$ contributes. None of these finite identities asserts the existence or accuracy of a full sine-Gordon TCSA spectrum. The full two-dimensional calculation must add oscillator states and all regulator data listed at the beginning of this section.

The companion script

`qft_scripts/sine_gordon_zero_mode_truncation.py`

builds (145.3), diagonalizes it at a declared finite N, checks Hermiticity and reflection symmetry $n \mapsto -n$, and reports the perturbative coefficient (145.4). The calculation check

`calculation-checks/hamiltonian_truncation_dlcq_checks.py`

verifies the $\Delta n = \pm 1$ selection rule, the zero-coupling spectrum, finite Hermiticity, and the second-order shift directly from the finite matrix elements.

145.6 Sine-Gordon TCSA Vertex Assembly

The zero-mode benchmark checks only the compact momentum shift. A genuine TCSA matrix for the sine-Gordon perturbation also needs the oscillator descendants of the compact boson. This section records the finite algebraic object that must be assembled before any discussion of spectra, counterterms, or extrapolation can begin.

Fix a compact free-boson radius coordinate $R > 0$. The finite regulator uses integer momentum and winding labels

$$n \in \{-N_{\text{mom}}, \dots, N_{\text{mom}}\}, \qquad w \in \{-N_{\text{wind}}, \dots, N_{\text{wind}}\},$$

left and right oscillator occupation numbers

$$\mathbf{m} = (m_1, \dots, m_M), \qquad \bar{\mathbf{m}} = (\bar{m}_1, \dots, \bar{m}_M), \qquad m_r, \bar{m}_r \in \mathbb{Z}_{\geq 0},$$

and the total oscillator-level cutoff

$$|\mathbf{m}|_{\text{osc}} + |\bar{\mathbf{m}}|_{\text{osc}} = \sum_{r=1}^{M} r(m_r + \bar{m}_r) \leq L_{\text{osc}}.$$

The finite basis vector is denoted $|n, w; \mathbf{m}, \bar{\mathbf{m}}\rangle$. In the convention used by the companion script, its dimensionless free cylinder energy and spin are

$$E_0(n, w; \mathbf{m}, \bar{\mathbf{m}}) = \frac{1}{2}\left(\frac{n}{R}\right)^2 + \frac{1}{2}(wR)^2 + |\mathbf{m}|_{\text{osc}} + |\bar{\mathbf{m}}|_{\text{osc}}, \tag{145.5}$$

$$S(n, w; \mathbf{m}, \bar{\mathbf{m}}) = nw + |\mathbf{m}|_{\text{osc}} - |\bar{\mathbf{m}}|_{\text{osc}}. \tag{145.6}$$

The additive Casimir energy is irrelevant for the finite vertex-normalization check and has been omitted. If the calculation is performed in the spatial momentum-zero sector, one keeps $S = 0$; equivalently, the spatial integral of a spin-zero perturbing operator kills matrix elements whose bra and ket spins differ.

Let $b_r, \bar{b}_r$ be normalized oscillator annihilation operators, $[b_r, b_s^\dagger] = [\bar{b}_r, \bar{b}_s^\dagger] = \delta_{rs}$. For a real finite vertex charge coordinate α, define the normal-ordered oscillator factor

$$\mathcal{E}_r(\alpha) = \exp\!\left(\frac{\alpha}{\sqrt{r}} b_r^\dagger\right) \exp\!\left(-\frac{\alpha}{\sqrt{r}} b_r\right), \qquad \bar{\mathcal{E}}_r(\alpha) = \exp\!\left(\frac{\alpha}{\sqrt{r}} \bar{b}_r^\dagger\right) \exp\!\left(-\frac{\alpha}{\sqrt{r}} \bar{b}_r\right). \tag{145.7}$$

The finite matrix element of $\mathcal{E}_r(\alpha)$ between normalized number states is the finite sum

$$\langle a|\mathcal{E}_r(\alpha)|b\rangle = \sum_{\ell=0}^{b} \mathbf{1}_{a-b+\ell\geq 0} \, \frac{(-s)^\ell}{\ell!} \sqrt{\frac{b!}{(b-\ell)!}} \, \frac{s^{a-b+\ell}}{(a-b+\ell)!} \sqrt{\frac{a!}{(b-\ell)!}}, \qquad s = \frac{\alpha}{\sqrt{r}}. \tag{145.8}$$

The formula is an exact finite matrix element of the normal-ordered exponential. The sum is finite because the annihilation exponential can remove at most b quanta, and the subsequent creation exponential must create exactly $a - b + \ell$ quanta.

The finite local vertex shifting the compact momentum by $\varepsilon = \pm 1$ has the matrix element

$$\begin{aligned} &\langle n', w'; \mathbf{a}, \bar{\mathbf{a}}|\, V_\varepsilon(0)\, |n, w; \mathbf{b}, \bar{\mathbf{b}}\rangle \\ &\quad = \delta_{n', n+\varepsilon}\, \delta_{w', w} \prod_{r=1}^{M} \langle a_r|\mathcal{E}_r(\varepsilon\alpha)|b_r\rangle \prod_{r=1}^{M} \langle \bar{a}_r|\bar{\mathcal{E}}_r(\varepsilon\alpha)|\bar{b}_r\rangle. \end{aligned} \tag{145.9}$$

The spatially integrated sine-Gordon perturbation in this finite convention is

$$V_{\mathrm{SG}}^{\mathrm{fin}} = \frac{1}{2}\,\Pi_{\Delta S=0}\left(V_+(0) + V_-(0)\right), \tag{145.10}$$

where $\Pi_{\Delta S=0}$ means that the matrix element is set to zero unless the spin coordinate (145.6) is the same on the bra and ket. The finite TCSA matrix assembled by the script is

$$H_{\mathrm{SG}}^{\mathrm{fin}} = E_0 + \lambda V_{\mathrm{SG}}^{\mathrm{fin}}. \tag{145.11}$$

Remark 145.6 (What this finite construction verifies). Equations (145.5)–(145.11) verify the finite matrix-assembly problem for the compact-boson vertex operator. For example, between oscillator vacua one recovers $\langle n+1, w; 0, 0|V_{\mathrm{SG}}^{\mathrm{fin}}|n, w; 0, 0\rangle = 1/2$. Between a vacuum ket and a bra with one left and one right oscillator in the first mode, the integrated matrix element is $\alpha^2/2$, while a bra with only one left oscillator has zero integrated matrix element because the spin changes. The winding label is preserved. These are finite algebraic checks. A continuum sine-Gordon spectrum also requires the physical normalization connecting α to the usual coupling β, the choice of radius and topological sectors, relevant counterterms generated by the cutoff, and a controlled $L_{\mathrm{osc}}, N_{\mathrm{mom}}, M \to \infty$ extrapolation.

The companion script

```
qft_scripts/sine_gordon_tcsa_vertex.py
```

constructs the basis above, assembles (145.10), checks Hermiticity, verifies spin and winding selection, and diagonalizes the resulting finite matrix for a declared cutoff. The calculation-check harness verifies the displayed oscillator-vacuum, one-oscillator, and two-oscillator matrix elements directly from (145.8).

145.7 Nonintegrable Scalar ϕ^4 Truncation

The previous benchmark is exactly solvable. It is useful for checking mode normalizations, but it does not test the matrix assembly problem that appears in a genuinely interacting truncation. The simplest finite QFT benchmark is the massive scalar field on a spatial circle, with the quartic interaction normal ordered relative to the massive free basis. This is still only a finite regulator; the continuum two-dimensional ϕ^4 theory requires the counterterm and cutoff analysis developed in the constructive chapters.

Construction 145.7 (Finite normal-ordered scalar truncation)**.** Fix $L > 0$, $m > 0$, a Fourier cutoff $N \in \mathbb{Z}_{\geq 0}$, a particle cutoff $P_{\max}$, a free-energy cutoff E_{cut}, and an integer total momentum label P_{tot}. For

$$r \in \{-N, -N+1, \dots, N\}, \qquad k_r = \frac{2\pi r}{L}, \qquad \omega_r = \sqrt{m^2 + k_r^2},$$

let $a_r, a_r^\dagger$ be finite-mode creation and annihilation operators with $[a_r, a_s^\dagger] = \delta_{rs}$. The truncated basis is the finite set of occupation vectors $\mathbf{n} = (n_{-N}, \dots, n_N)$ satisfying

$$\sum_{|r|\leq N} n_r \leq P_{\max}, \qquad \sum_{|r|\leq N} r n_r = P_{\mathrm{tot}}, \qquad \sum_{|r|\leq N} \omega_r n_r \leq E_{\mathrm{cut}}. \tag{145.12}$$

The corresponding normalized Fock vector is

$$|\mathbf{n}\rangle = \prod_{|\mathbf{r}|\leq \mathbf{N}} \frac{(\mathbf{a}_\mathbf{r}^\dagger)^{\mathbf{n}_\mathbf{r}}}{\sqrt{\mathbf{n}_\mathbf{r}!}}|\mathbf{0}\rangle.$$

The free Hamiltonian matrix is diagonal:

$$(H_0)_{\mathbf{nm}} = \delta_{\mathbf{nm}} \sum_{|r|\leq N} \omega_r n_r.$$

Define the finite free field at time zero by

$$\phi_N(x) = \sum_{|r|\leq N} \frac{1}{\sqrt{2L\omega_r}} \left(a_r e^{\mathrm{i}k_r x} + a_r^\dagger e^{-\mathrm{i}k_r x} \right),$$

and normal order with respect to the free vacuum. The finite interaction matrix is

$$V_N = P_\Lambda \int_0^L :\phi_N(x)^4: \,\mathrm{d}x\, P_\Lambda, \tag{145.13}$$

where P_Λ is the orthogonal projection onto the span of (145.12). Equivalently,

$$\int_0^L :\phi_N(x)^4: \,\mathrm{d}x = \sum_{\substack{s_i=\pm 1,\ |r_i|\leq N \\ \sum_i s_i r_i = 0}} L \prod_{i=1}^4 \frac{1}{\sqrt{2L\omega_{r_i}}} :B_{s_1,r_1} B_{s_2,r_2} B_{s_3,r_3} B_{s_4,r_4}:, \tag{145.14}$$

with $B_{+1,r} = a_r$ and $B_{-1,r} = a_r^\dagger$. The Kronecker condition in (145.14) is precisely the integral over the circle. The finite benchmark Hamiltonian is

$$H_\Lambda^{(\phi^4)} = H_0 + \frac{\lambda}{4!} V_N. \tag{145.15}$$

No continuum statement is attached to (145.15) unless a counterterm scheme and a cutoff-removal theorem or controlled approximation have also been stated.

The matrix $H_\Lambda^{(\phi^4)}$ is Hermitian at each finite cutoff. The field $\phi_N(x)$ is self-adjoint on the finite Fock space generated by the retained modes, normal ordering preserves the adjoint of the polynomial, and P_Λ is an orthogonal projection. In the explicit sum (145.14), taking the adjoint changes each s_i to $-s_i$ and reverses the operator order before normal ordering; the coefficient is real and the constraint $\sum_i s_i r_i = 0$ is invariant. Thus the restricted matrix is equal to its adjoint. This finite Hermiticity is a minimal consistency check; it does not estimate the dependence on N, $P_{\max}$, or E_{cut}.

A useful normalization check comes from retaining only the zero mode. If $N = 0$, then $\omega_0 = m$ and

$$\int_0^L :\phi_0(x)^4: \,\mathrm{d}x = \frac{1}{4Lm^2} :(a_0 + a_0^\dagger)^4: .$$

The vacuum diagonal entry is zero. In the two-particle zero-mode state $|2\rangle = (a_0^\dagger)^2|0\rangle/\sqrt{2}$, the only diagonal monomial is $6(a_0^\dagger)^2 a_0^2$, hence

$$\langle 2| \int_0^L :\phi_0(x)^4: \,\mathrm{d}x |2\rangle = \frac{6}{4Lm^2} \langle 2|(a_0^\dagger)^2 a_0^2|2\rangle = \frac{3}{Lm^2}. \tag{145.16}$$

This is an elementary finite-regulator identity, but it is convention sensitive: changing the field normalization, the 4! convention, or the normal-ordering prescription changes the displayed number.

The script

```
qft_scripts/phi4_hamiltonian_truncation.py
```

implements Construction 145.7. Its smoke mode builds a small total-momentum-zero matrix, checks Hermiticity, and prints the lowest finite eigenvalues. The calculation check

```
calculation-checks/hamiltonian_truncation_dlcq_checks.py
```

verifies the momentum-sector condition, the free-energy cutoff condition, the zero-coupling reduction to H_0, and the zero-mode identity (145.16). These checks are not a substitute for the constructive ϕ_2^4 continuum theorem; they verify the finite matrix that a reader can diagonalize before studying cutoff renormalization.

145.8 Ising TCSA And TFFSA With Spin Deformation

The two-dimensional Ising field theory with both thermal and magnetic deformations is the basic test case in which Hamiltonian truncation is useful and conceptually delicate. Start from the critical Ising CFT on a spatial circle of circumference L. Let $H_{\mathrm{CFT}}(L)$ be the self-adjoint Hamiltonian generated by cylinder time translations,

$$H_{\mathrm{CFT}}(L) = \frac{2\pi}{L}\left(L_0 + \bar{L}_0 - \frac{c}{12}\right), \qquad c = \frac{1}{2}.$$

Let ε be the energy operator of scaling dimension $\Delta_\varepsilon = 1$, and let σ be the spin operator of scaling dimension $\Delta_\sigma = 1/8$. A TCSA regulator for the two-coupling Ising family is the finite matrix

$$H_{\mathrm{TCSA}}(L; E_{\mathrm{cut}}) = P_{E_{\mathrm{cut}}}\left[H_{\mathrm{CFT}}(L) + \tau\int_0^L \varepsilon_{\mathrm{cyl}}(0,x)\,\mathrm{d}x + h\int_0^L \sigma_{\mathrm{cyl}}(0,x)\,\mathrm{d}x\right]P_{E_{\mathrm{cut}}} + H_{\mathrm{ct}}(E_{\mathrm{cut}}). \tag{145.17}$$

Here $P_{E_{\mathrm{cut}}}$ projects onto CFT states satisfying $(2\pi/L)(L_0 + \bar{L}_0 - c/12) \le E_{\mathrm{cut}}$. The symbol $\mathcal{O}_{\mathrm{cyl}}$ means the cylinder field obtained from the plane field by the conformal map. After fixing a plane normalization, the finite-volume matrix elements contain the factors $(2\pi/L)^{\Delta_a}$ dictated by the state-operator correspondence. The couplings have engineering dimensions

$$[\tau] = 1, \qquad [h] = \frac{15}{8}.$$

The counterterm matrix $H_{\mathrm{ct}}(E_{\mathrm{cut}})$ is part of the regulator. It is determined by a declared matching prescription; omitting it is a choice of truncation scheme, not a theorem that no high-energy effects exist.

The same physical family admits a second truncation. Treat the thermal deformation exactly. For $\tau \neq 0$, the unperturbed theory is the free massive Majorana theory with mass m proportional to τ in the chosen normalization. The magnetic perturbation is then

$$H_{\mathrm{IFT}}(L) = H_{\mathrm{Maj}}(m, L) + h\int_0^L \sigma(0,x)\,\mathrm{d}x. \tag{145.18}$$

Truncating (145.18) in the finite-volume fermion Fock space is the truncated free-fermion-space approach. Its advantage is not a new definition of the continuum theory; rather, it moves the relevant thermal deformation from the perturbation into the basis. This can reduce cutoff sensitivity when the low-energy states are better approximated by massive fermion states than by a small number of conformal states.

We now spell out the finite matrix. Let $\mathfrak{s}$ denote a fermion spin-structure sector on the circle, with allowed momenta

$$p_n = \frac{2\pi n}{L}, \qquad n \in Q_{\mathfrak{s}},$$

where $Q_{\mathfrak{s}}$ is either $\mathbb{Z} + \frac{1}{2}$ or $\mathbb{Z}$, depending on the sector. A finite-volume rapidity θ_n is defined by

$$p_n = m \sinh \theta_n, \qquad \omega_n = m \cosh \theta_n.$$

For a finite set $I = \{n_1, \ldots, n_k\} \subset Q_{\mathfrak{s}}$, write

$$|I\rangle_{\mathfrak{s}} = a^\dagger_{n_1} \cdots a^\dagger_{n_k} |0\rangle_{\mathfrak{s}}, \qquad E^{(0)}_I(L) = E^{\mathrm{vac}}_{\mathfrak{s}}(L) + \sum_{n\in I} \omega_n, \qquad P_I = \sum_{n \in I} p_n.$$

The TFFSA cutoff is an energy cutoff in this massive basis:

$$\mathcal{H}_{\mathrm{FF}}(L, E_{\mathrm{cut}}) = \mathrm{span}\{|I\rangle_{\mathfrak{s}} : E^{(0)}_I(L) \le E_{\mathrm{cut}}\}.$$

The diagonal part of $H_{\mathrm{Maj}}(m, L)$ is exact in this basis. The nontrivial matrix is the spin perturbation.

Definition 145.8 (TFFSA spin matrix element)**.** For two finite-volume fermion states I, J, the connected infinite-volume asymptotic spin matrix element is

$$V^{\mathrm{conn}}_{IJ} = hL\, \delta_{P_I,P_J}\, \frac{F^\sigma_{\mathrm{conn}}(\{\theta_i : i \in I\} \mid \{\theta_j : j \in J\})}{\sqrt{\rho_I \rho_J}}, \qquad \rho_I = \prod_{i\in I} mL \cosh\theta_i. \tag{145.19}$$

Here F^σ_{conn} is the crossed spin-field form factor derived in Chapter 76, and ρ_I is the free Bethe-state density of states. The full finite-volume matrix element also contains disconnected contraction terms when I and J share rapidities, and exponentially small finite-size corrections of order e^{-mL} in a massive theory. A numerical TFFSA scheme must specify whether it uses exact finite-volume Ising form factors, the asymptotic formula (145.19), or a hybrid prescription.

This definition makes the status of the computation explicit. At fixed (L, E_{cut}), after all matrix elements have been declared, TFFSA is ordinary finite-dimensional spectral theory. The physical assertions concern the removal or extrapolation of the cutoff and, if (145.19) is used, the large-mL control of the finite-volume form-factor approximation.

Definition 145.9 (Zero-momentum connected TFFSA block)**.** Fix $m > 0$, $L > 0$, an integer $N_{\mathrm{pair}} \ge 0$, a spin-field normalization $\bar{\sigma}$, and a magnetic coupling h. For

$$r_n = n + \frac{1}{2}, \qquad p_n = \frac{2\pi r_n}{L}, \qquad p_n = m \sinh\theta_n, \qquad \omega_n = m\cosh\theta_n, \quad n = 0, \ldots, N_{\mathrm{pair}} - 1,$$

let

$$|0\rangle, \qquad |n\rangle := |\theta_n, -\theta_n\rangle, \quad n = 0, \ldots, N_{\mathrm{pair}} - 1,$$

be the finite zero-total-momentum basis consisting of the vacuum and two-particle pairs. Set

$$\rho_n = (mL\cosh\theta_n)^2.$$

The connected-block TFFSA matrix is the Hermitian $(N_{\mathrm{pair}}+1)\times(N_{\mathrm{pair}}+1)$ matrix

$$H_{ij} = E_i^{(0)}\delta_{ij} + hL\,V_{ij},$$

where $E_0^{(0)} = 0$, $E_n^{(0)} = 2\omega_n$ for $n \geq 1$, and

$$V_{ii} = \bar{\sigma}.$$

For $i < j$, V_{ij} is defined by the crossed connected form factor

$$V_{ij} = \frac{F^{\sigma}_{\mathrm{conn}}(\{\theta_a + \mathrm{i}\pi : a \in I_i\} \mid \{\theta_b : b \in I_j\})}{\sqrt{\rho_i\rho_j}}, \qquad V_{ji} = \overline{V_{ij}}, \tag{145.20}$$

with $\rho_0 = 1$ and $I_0 = \varnothing$. The diagonal convention $V_{ii} = \bar{\sigma}$ keeps only the disconnected vacuum-expectation contribution. The omitted diagonal connected finite parts are singular crossed limits and require a separate diagonal finite-volume prescription.

Remark 145.10 (Connected TFFSA block)*.* The matrix in Definition 145.9 is Hermitian. If $h = 0$, its eigenvalues are

$$0, \quad 2\omega_0, \quad 2\omega_1, \quad \ldots, \quad 2\omega_{N_{\mathrm{pair}}-1}.$$

The diagonal entries $E_i^{(0)} + hL\bar{\sigma}$ are real. For $i < j$ the lower-triangular entry is defined to be $\overline{V_{ij}}$, hence

$$H_{ji} = hL\,\overline{V_{ij}} = \overline{hL\,V_{ij}} = \overline{H_{ij}}$$

for real h and L. Thus $H^\dagger = H$. At $h = 0$, all off-diagonal entries vanish and the matrix is diagonal with the displayed free finite-volume energies.

The script

`qft_scripts/tffsa_ising_spin_connected.py`

implements Definition 145.9. It checks Hermiticity in smoke mode and prints the finite eigenvalues together with the corresponding free energies. The purpose is to make the form-factor normalization, density factors, and diagonal convention executable. It is not a claim that the small connected block is the full magnetic-Ising spectrum.

Lemma 145.11 (Finite TFFSA spectral-flow derivative)**.** *Let*

$$H(h) = H_0 + hW, \qquad H_0 = H_0^\dagger, \quad W = W^\dagger, \tag{145.21}$$

be a finite Hermitian matrix family, with $h \in \mathbb{R}$. Suppose $\lambda_*(h_*)$ is a simple eigenvalue of $H(h_*)$, and let u_* be a normalized eigenvector. If

$$g = \operatorname{dist}\bigl(\lambda_*(h_*), \operatorname{spec} H(h_*) \setminus \{\lambda_*(h_*)\}\bigr) > 0, \tag{145.22}$$

then for $|h - h_*|\|W\| < g/2$ there is a unique eigenvalue branch $\lambda_*(h)$ near $\lambda_*(h_*)$, counted with its normalized eigenvector $u(h)$ after fixing a differentiable phase. Its derivative at $h = h_*$ is

$$\frac{\mathrm{d}\lambda_*}{\mathrm{d}h}(h_*) = u_*^\dagger W u_*. \tag{145.23}$$

If all eigenvalues of $H(h_*)$ are simple and $\lambda_a'(h_*) = u_a^\dagger W u_a$, then

$$\sum_a \lambda_a'(h_*) = \operatorname{tr} W. \tag{145.24}$$

Proof. Choose a positively oriented circle C centered at $\lambda_*(h_*)$ with radius smaller than $g/2$. For $z \in C$,

$$\|(h-h_*)W(H(h_*)-z)^{-1}\| \le |h-h_*|\|W\|\,\|(H(h_*)-z)^{-1}\| < 1,$$

when $|h-h_*|\|W\| < g/2$. Thus the resolvent identity and the Neumann series give a well-defined resolvent $(H(h)-z)^{-1}$ on C, analytic in h. The Riesz projection

$$P(h) = \frac{1}{2\pi \mathrm{i}} \oint_C (z-H(h))^{-1}\,\mathrm{d}z$$

therefore has rank one for h in this neighborhood and depends differentiably on h. Taking $u(h) = P(h)u_*/\|P(h)u_*\|$, with the phase chosen so that $u_*^\dagger u(h)$ is positive real near h_*, gives a differentiable normalized eigenvector for the unique eigenvalue branch inside C.

Differentiate

$$H(h)u(h) = \lambda_*(h)u(h)$$

at $h = h_*$. Since $H'(h) = W$,

$$Wu_* + H(h_*)u'(h_*) = \lambda_*'(h_*)u_* + \lambda_*(h_*)u'(h_*).$$

Taking the inner product with u_*, and using $u_*^\dagger H(h_*) = \lambda_*(h_*)u_*^\dagger$, cancels the terms containing $u'(h_*)$ and gives (145.23). If all eigenvalues are simple, their normalized eigenvectors form an orthonormal basis, so

$$\sum_a \lambda_a'(h_*) = \sum_a u_a^\dagger W u_a = \operatorname{tr} W.$$

$\square$

For the connected Ising TFFSA block, (145.21) is exactly the finite matrix

$$H(h) = H_0 + hL\,V.$$

The companion script

`qft_scripts/tffsa_ising_spectral_flow.py`

diagonalizes this finite block on a small grid of h-values and checks (145.23) against centered finite differences at a point where the finite spectrum is separated. This is a useful nonintegrable benchmark because it checks the actual finite spectral flow generated by spin-field form factors. It remains a finite-matrix check: comparison with the continuum magnetic-Ising spectrum requires the cutoff, finite-volume, diagonal-form-factor, and counterterm estimates described around (145.19).

145.8.1 Exact E_8 Target Data For Magnetic-Ising Benchmarks

The magnetic Ising ray $\tau = 0$, $h \neq 0$, is the standard case in which Hamiltonian truncation is compared with exact integrable-QFT target data. The target data are not obtained by diagonalizing a finite truncation. They come from the continuum factorized-scattering description of the integrable massive theory. In the numerical chapter we use only the part of that description needed for a reproducible benchmark: the dimensionless mass ratios

$$\rho_a = \frac{m_a}{m_1}, \qquad a = 1, \ldots, 8,$$

where m_1 sets the overall mass scale determined by the normalization of the magnetic coupling h. The eight ratios are

$$\begin{aligned}
&\rho_1 = 1, && \rho_2 = 2\cos\frac{\pi}{5}, && \rho_3 = 2\cos\frac{\pi}{30}, \\
&\rho_4 = 2\rho_2\cos\frac{7\pi}{30}, && \rho_5 = 2\rho_2\cos\frac{2\pi}{15}, && \rho_6 = 2\rho_2\cos\frac{\pi}{30}, \\
&\rho_7 = 4\rho_2\cos\frac{\pi}{5}\cos\frac{7\pi}{30}, && \rho_8 = 4\rho_2\cos\frac{\pi}{5}\cos\frac{2\pi}{15}.
\end{aligned} \tag{145.25}$$

Numerically this is approximately

$$\begin{gathered}
1, \quad 1.6180339887, \quad 1.9890437907, \quad 2.4048671724, \\
2.9562952015, \quad 3.2183404585, \quad 3.8911568233, \quad 4.7833861168.
\end{gathered}$$

There is a finite algebraic check for the convention used in (145.25). Let A_{E_8} be the adjacency matrix of the E_8 Dynkin graph with edges

$$(0,1), (1,2), (2,3), (3,4), (4,5), (5,6), (2,7).$$

The largest eigenvalue is

$$\lambda_{\max}(A_{E_8}) = 2\cos\frac{\pi}{30}.$$

If v is the positive Perron-Frobenius eigenvector and is normalized by $\min_i v_i = 1$, then the unordered component ratios of v are precisely the eight numbers in (145.25). For the node labeling above the normalized vector is

$$(v_0, \ldots, v_7) = (\rho_2, \rho_6, \rho_8, \rho_7, \rho_5, \rho_3, \rho_1, \rho_4).$$

The eigenvector equations $A_{E_8} v = \lambda_{\max} v$ reduce the statement to elementary trigonometric identities such as

$$v_5 + v_7 = \lambda_{\max} v_6, \qquad v_1 + v_3 + v_7 = \lambda_{\max} v_2,$$

after substituting $\lambda_{\max} = 2\cos(\pi/30)$ and the ratios above. This check fixes the table and its ordering; it does not replace the continuum integrable-QFT derivation that the magnetic-Ising scattering theory has this E_8 particle content.

The companion script

`qft_scripts/e8_ising_mass_ratios.py`

prints (145.25) and verifies the Perron–Frobenius check. In a TCSA or TFFSA comparison the observable being compared should be a set of finite-volume energy gaps $\Delta E_a(L, E_{\mathrm{cut}})$, divided by the lightest extracted gap, and then extrapolated in L and E_{cut} with a declared systematic model. Agreement with (145.25) is a target-data comparison only after those regulator coordinates have been specified.

Lemma 145.12 (Feshbach–Schur reduction with resolvent control)**.** *In a finite regulated Hilbert space, let $H = H^\dagger$ be a Hermitian matrix and let $\mathcal{H} = P\mathcal{H} \oplus Q\mathcal{H}$, where P is an orthogonal projection and $Q = 1 - P$. Suppose E is not an eigenvalue of the finite matrix $QHQ : Q\mathcal{H} \to Q\mathcal{H}$. Then E is an eigenvalue of H with $P\psi \neq 0$ only if*

$$\left[PHP - PHQ(QHQ - E)^{-1}QHP\right] P\psi = E\,P\psi. \tag{145.26}$$

Conversely, if $u \in P\mathcal{H}$ *satisfies* (145.26)*, then*

$$\psi = u - (QHQ - E)^{-1}QHPu$$

is an eigenvector of H *with eigenvalue* E*. Moreover, if*

$$d(E) = \operatorname{dist}(E, \operatorname{spec}(QHQ)) > 0,$$

then the eliminated component obeys the finite-cutoff estimate

$$\|Q\psi\| \le d(E)^{-1} \, \|QHP\,P\psi\|. \tag{145.27}$$

Proof. Write the eigenvalue equation $H\psi = E\psi$ as two block equations:

$$(PHP - E)P\psi + PHQ\,Q\psi = 0, \qquad QHP\,P\psi + (QHQ - E)Q\psi = 0.$$

Since E is in the resolvent set of QHQ, the second equation gives

$$Q\psi = -(QHQ - E)^{-1}QHP\,P\psi.$$

Substituting this into the first equation gives (145.26). This proves that any eigenvector with nonzero P-projection gives a vector in the kernel of the energy-dependent effective operator on $P\mathcal{H}$. Conversely, suppose $u \in P\mathcal{H}$ obeys the Schur-complement equation and define

$$\psi = u - (QHQ - E)^{-1}QHPu.$$

Then $P\psi = u$ and the second block equation is satisfied by construction, because $(QHQ - E)(QHQ - E)^{-1} = Q$ on $Q\mathcal{H}$. Substituting the Schur-complement equation into the first block equation gives zero there as well. Hence $H\psi = E\psi$.

Since QHQ is a finite Hermitian matrix, the spectral theorem gives

$$\|(QHQ - E)^{-1}\| = d(E)^{-1}.$$

Applying this to the explicit formula for $Q\psi$ gives (145.27). This estimate is the part of the finite-dimensional identity that survives as useful information in truncation theory: a high-energy block can be eliminated only together with control of the resolvent distance and the coupling QHP. □

Equation (145.26) is the precise operator identity behind cutoff counterterms in TCSA and TFFSA. In practice one expands the Q-space resolvent at high energy and replaces its low-energy action by local or quasilocal operators allowed by the symmetries. For the Ising spin perturbation this expansion is governed by the short- distance operator product of σ with itself; for the free-fermion basis it is equivalently encoded in the high-rapidity behavior of the spin form factors. A claimed numerical spectrum is therefore meaningful only after the truncation scheme states the cutoff, the finite-volume form-factor prescription, the symmetry sector, the counterterm coordinates, and the extrapolation model.

145.9 Finite-Matrix Spectral Bounds

Every Hamiltonian-truncation or DLCQ computation ultimately diagonalizes a finite Hermitian matrix. This elementary fact is useful only if the finite linear-algebra output is verified separately from the continuum claim. We therefore record the minimal residual bound used by the companion scripts.

Definition 145.13 (Residual bound for a finite truncation)**.** Let $A = A^\dagger$ be a finite Hermitian matrix on a finite-dimensional Hilbert space V. A residual bound for a proposed eigenpair is a triple

$$(\lambda, u, \rho), \qquad \|u\| = 1, \qquad \rho = \|(A - \lambda)u\|. \tag{145.28}$$

It is a bound for the finite matrix A only. The number λ becomes a QFT energy or invariant mass only after the regulator label, counterterm prescription, symmetry sector, finite-volume convention, and continuum-extrapolation hypothesis have also been supplied.

Spectral meaning of a finite residual. Let $A = A^\dagger$ be a finite Hermitian matrix, let $\|u\| = 1$, and set $\rho = \|(A - \lambda)u\|$. Then

$$\operatorname{dist}(\lambda, \operatorname{spec} A) \le \rho. \tag{145.29}$$

More generally, let $S \subset \operatorname{spec} A$ and let P_S be the orthogonal spectral projection onto the span of eigenvectors whose eigenvalues lie in S. If

$$g = \operatorname{dist}\big(\lambda, \operatorname{spec} A \setminus S\big) > 0, \tag{145.30}$$

then

$$\|(1 - P_S)u\| \le \frac{\rho}{g}. \tag{145.31}$$

Choose an orthonormal eigenbasis e_a of A,

$$Ae_a = E_a e_a, \qquad u = \sum_a c_a e_a, \qquad \sum_a |c_a|^2 = 1.$$

Then

$$\rho^2 = \|(A - \lambda)u\|^2 = \sum_a |c_a|^2 |E_a - \lambda|^2. \tag{145.32}$$

If every eigenvalue obeyed $|E_a - \lambda| > \rho$, the right hand side of (145.32) would be strictly larger than ρ^2, a contradiction. This proves (145.29). For the projection bound, split the sum into $E_a \in S$ and $E_a \notin S$. On the complement, $|E_a - \lambda| \ge g$, hence

$$\rho^2 \ge g^2 \sum_{E_a \notin S} |c_a|^2 = g^2 \|(1 - P_S)u\|^2.$$

Taking square roots gives (145.31).

The first inequality says that a small residual forces the existence of some finite-matrix eigenvalue near λ. The second says that, when a target spectral cluster is separated from the rest of the finite spectrum, the approximate eigenvector has quantitatively small leakage out of that cluster. These statements do not estimate the distance between different cutoffs. Cutoff comparison belongs to the Feshbach identity above, to counterterm matching, and to the extrapolation bounds below.

For a Hermitian block decomposition $V = PV \oplus QV$, the same finite linear algebra gives a practical diagnostic for a truncation counterterm. At a chosen low-energy value E, the omitted-space correction is exactly

$$\Sigma_P(E) = PHQ(QHQ - E)^{-1}QHP. \tag{145.33}$$

Approximating $\Sigma_P(E)$ by a low-dimensional local counterterm is a separate approximation; the identity itself is exact only before this replacement is made. A controlled truncation must therefore state a norm, an energy window, and a bound on

$$\Sigma_P(E) - \Sigma_P^{\mathrm{ct}}(E) \tag{145.34}$$

in that window.

The companion check

`calculation-checks/hamiltonian_truncation_dlcq_checks.py`

verifies the finite residual bound (145.29), the projector leakage estimate (145.31), the Feshbach determinant identity behind (145.26), the Ising-energy Bogoliubov benchmark, the connected Ising TFFSA block normalization, the finite Ising TFFSA spectral-flow derivative identity, the E_8 magnetic-Ising target-ratio Perron–Frobenius check, the finite large-N QCD DLCQ quadratic-form identity, and the exact-intercept cases of the finite large-K extrapolation diagnostic.

145.10 Krylov Data as Finite Spectral Evidence

Large truncation matrices are rarely diagonalized by forming a complete eigenbasis. The usual numerical output is a Krylov subspace calculation: Lanczos vectors, a tridiagonal compression, residuals, and sometimes a spectral density with respect to a chosen seed vector. These objects have exact finite-matrix meanings. They become evidence for a QFT spectrum only after the finite regulator, symmetry sector, seed overlap, counterterms, and continuum extrapolation are separately controlled.

Definition 145.14 (Krylov spectral data)**.** Let $A = A^\dagger$ be a finite Hermitian matrix on a finite-dimensional Hilbert space V, and let $v \in V$ be a normalized seed vector. For $m \geq 1$, the m-th Krylov subspace is

$$\mathcal{K}_m(A, v) = \operatorname{span}\{v, Av, \dots, A^{m-1}v\}.$$

A Krylov spectral datum consists of an orthonormal basis

$$V_m = (q_0, \dots, q_{m-1}) \quad \text{of} \quad \mathcal{K}_m(A, v), \qquad q_0 = v,$$

the compression

$$T_m = V_m^\dagger A V_m,$$

and the residual matrix

$$R_m = AV_m - V_m T_m.$$

When the basis is the exact Lanczos basis before breakdown, T_m is tridiagonal and

$$AV_m = V_m T_m + \beta_m q_m e_m^\dagger, \tag{145.35}$$

where $q_m \perp \mathcal{K}_m(A, v)$, $\|q_m\| = 1$, e_m is the last coordinate vector in $\mathbb{C}^m$, and $\beta_m \geq 0$. Breakdown means $\beta_m = 0$, in which case $\mathcal{K}_m(A, v)$ is already an invariant subspace for A.

Suppose $T_m y = \theta y$, $\|y\| = 1$, and set $u = V_m y$. Multiplying (145.35) by y gives the exact finite residual identity

$$(A - \theta)u = \beta_m\, y_m\, q_m, \qquad \|(A - \theta)u\| = \beta_m |y_m|. \tag{145.36}$$

Thus a reported Lanczos Ritz value is accompanied by a finite-matrix residual bound of the kind defined in Definition 145.13. Its content is finite and sectorwise: the regulated matrix in the declared sector has spectrum within $\beta_m|y_m|$ of θ, and the approximate eigenvector leakage into a separated finite spectral cluster is bounded by (145.31). A continuum QFT spectral claim then requires the regulator and extrapolation data specified in Definition 145.1.

The same Krylov data carry finite spectral-measure information. Let

$$\mu_v = \sum_a |\langle e_a, v\rangle|^2 \delta_{E_a}$$

be the finite spectral measure of A in the seed state, where $\{e_a\}$ is an orthonormal eigenbasis of A, $Ae_a = E_a e_a$. If θ_r are the eigenvalues of T_m and $s^{(r)}$ are normalized eigenvectors of T_m, define

$$w_r = |\langle e_1, s^{(r)}\rangle|^2, \qquad \mu_{v,m}^{\mathrm{Krylov}} = \sum_{r=1}^{m} w_r \delta_{\theta_r}.$$

For every polynomial p of degree at most $2m - 1$,

$$\int p(\lambda)\, \mathrm{d}\mu_v(\lambda) = \sum_{r=1}^{m} w_r p(\theta_r). \tag{145.37}$$

To see the mechanism, first note that if $\deg b \le m - 1$, then

$$b(A)v = V_m b(T_m) e_1.$$

Let $\pi_m(\lambda) = \det(\lambda I - T_m)$. The Lanczos recurrence implies that $\pi_m(A)v$ is orthogonal to $\mathcal{K}_m(A, v)$, while $\pi_m(T_m) = 0$. Any polynomial p with $\deg p \le 2m - 1$ decomposes as $p = a\pi_m + b$ with $\deg a, \deg b \le m - 1$. Since $a(A)v \in \mathcal{K}_m(A, v)$,

$$\langle v, p(A)v\rangle = \langle v, b(A)v\rangle = e_1^\dagger b(T_m) e_1 = e_1^\dagger p(T_m) e_1,$$

and diagonalizing T_m gives (145.37). The finite Krylov measure is therefore an exact quadrature rule for the seed spectral measure, not a complete list of all finite eigenvalues unless the chosen seeds have overlap with the relevant spectral subspaces.

Symmetry sectors must be part of the same finite spectral datum. If a finite group or compact group acts by unitary matrices commuting with A, and P_α is the exact projector onto a declared irreducible sector, then the Krylov calculation for that sector is the calculation for the finite matrix

$$A_\alpha = P_\alpha A P_\alpha \quad \text{on} \quad P_\alpha V.$$

A seed v with $P_\alpha v = 0$ contains no spectral information about that sector, and a single nonzero seed can miss degenerate eigenvectors orthogonal to its cyclic subspace. A numerical claim about absence of states in a finite window must therefore use either full diagonalization in the sector, a block-Krylov seed family with a rank check for the target subspace, or an independent variational lower bound. Without such sector coverage, Lanczos data are reliable spectral evidence for the cyclic subspace generated by the stated seed, not for the whole Hilbert space.

145.11 Variational Ansatz Bounds

Tensor-network, DMRG, MERA, and neural-state computations enter QFT as finite-regulator variational methods. The ansatz may be sophisticated, but the first mathematical object is still a finite Hilbert space, a finite Hermitian operator, and a family of trial vectors. The following finite bounds are the common core behind those methods.

Definition 145.15 (Finite variational ansatz)**.** A finite variational ansatz for a regulated Hamiltonian consists of

$$(V, A, \Theta, \Psi, \mathcal{S}, \mathcal{E}_{\text{samp}}).$$

Here V is a finite-dimensional Hilbert space, $A = A^\dagger$ is the finite Hamiltonian or invariant-mass matrix in a declared sector, Θ is the parameter space, and

$$\Psi : \Theta \to V \setminus \{0\}$$

is the trial-vector map. The entry $\mathcal{S}$ records exact constraints imposed on the ansatz, such as gauge invariance, global charge, momentum, parity, tensor-network bond dimension, locality of tensor contractions, or a neural architecture. The entry $\mathcal{E}_{\text{samp}}$ records the sampling law and estimator if the Rayleigh quotient is estimated stochastically rather than contracted exactly.

For $\psi \neq 0$, write

$$E_\psi = \frac{\langle \psi, A\psi \rangle}{\langle \psi, \psi \rangle}, \qquad r_\psi = (A - E_\psi)\psi, \qquad \Delta_\psi^2 = \frac{\|r_\psi\|^2}{\|\psi\|^2}.$$

The number Δ_ψ^2 is the energy variance in the trial state:

$$\Delta_\psi^2 = \frac{\langle \psi, A^2\psi \rangle}{\langle \psi, \psi \rangle} - E_\psi^2.$$

Consequently

$$\operatorname{dist}(E_\psi, \operatorname{spec} A) \leq \Delta_\psi. \tag{145.38}$$

This is exactly the residual bound (145.29) applied to $\psi/\|\psi\|$. If $S \subset \operatorname{spec} A$ is a separated finite spectral cluster and

$$g = \operatorname{dist}(E_\psi, \operatorname{spec} A \setminus S) > 0,$$

then

$$\|(1 - P_S)\psi\| \leq \frac{\Delta_\psi}{g}\,\|\psi\|. \tag{145.39}$$

Thus variance is a finite-matrix eigenstate diagnostic. It measures spectral concentration of the vector already produced by the ansatz; it does not by itself measure the expressive power of the ansatz family.

The Rayleigh quotient supplies a different bound when an exact lower spectral edge is available. Let

$$E_0 < E_1$$

be the lowest two distinct eigenvalues of A, and let P_0 be the ground-space projection. Expanding a normalized vector in an eigenbasis gives

$$E_\psi - E_0 = \sum_a |\langle e_a, \psi \rangle|^2 (E_a - E_0) \geq (E_1 - E_0)\|(1 - P_0)\psi\|^2.$$

Therefore

$$\|(1 - P_0)\psi\|^2 \le \frac{E_\psi - E_0}{E_1 - E_0}. \tag{145.40}$$

This bound is useful only after E_0 and a finite gap are known by another method, or after a rigorous lower bound replaces the exact ground energy. The variational upper bound $E_\psi \ge E_0$ alone is insufficient to bound distance to the ground-state subspace.

For a smooth normalized ansatz $\psi(\theta)$, the differential of the Rayleigh quotient exposes the precise meaning of a variational optimum. If $\|\psi(\theta)\| = 1$ and $\xi \in T_\theta\Theta$, put $\dot\psi_\xi = d\psi_\theta(\xi)$. Differentiating $\langle\psi, A\psi\rangle$ and using $\mathrm{Re}\langle\dot\psi_\xi, \psi\rangle = 0$ gives

$$dE_\theta(\xi) = 2\ \mathrm{Re}\langle\dot\psi_\xi, (A - E_\theta)\psi(\theta)\rangle. \tag{145.41}$$

A stationary variational parameter therefore makes the residual orthogonal to the tangent space of the ansatz manifold. An eigenvector error bound is stronger: it requires the residual norm $\|(A-E_\theta)\psi(\theta)\|$ to be small, or a separate argument that the tangent directions cover the missing finite directions.

For neural-state and Monte Carlo variational calculations one also needs the finite estimator identity. Choose an orthonormal computational basis $\{|x\rangle\}_{x\in X}$ and assume $\psi_x = \langle x|\psi\rangle \ne 0$ on the sampled support. Define

$$p_\psi(x) = \frac{|\psi_x|^2}{\sum_y |\psi_y|^2}, \qquad E_{\mathrm{loc}}(x) = \frac{(A\psi)_x}{\psi_x}.$$

Then

$$E_\psi = \sum_x p_\psi(x) E_{\mathrm{loc}}(x), \tag{145.42}$$

and

$$\Delta_\psi^2 = \sum_x p_\psi(x) |E_{\mathrm{loc}}(x) - E_\psi|^2. \tag{145.43}$$

The second identity uses Hermiticity of A:

$$\sum_x p_\psi(x)|E_{\mathrm{loc}}(x) - E_\psi|^2 = \frac{\|(A - E_\psi)\psi\|^2}{\|\psi\|^2}.$$

Sampling estimates of (145.42) and (145.43) require the Markov-chain or independent-sample error analysis of Section 141.12; optimization bias, autocorrelation, and architecture bias are additional entries of $\mathcal{E}_{\mathrm{samp}}$, not properties of the finite identities.

For a sampled variational calculation, the local-energy time series has its own finite error coordinate. Let $X_0, \dots, X_{N-1}$ be a stationary finite Markov chain with invariant distribution p_ψ, and let

$$F_t = \mathrm{Re}\, E_{\mathrm{loc}}(X_t), \qquad \mu = \mathbb{E} F_t.$$

Define

$$\gamma_t = \mathrm{Cov}(F_0, F_t), \qquad \gamma_0 > 0, \qquad \rho_t = \gamma_t/\gamma_0.$$

For

$$\overline{F}_N = \frac{1}{N}\sum_{t=0}^{N-1} F_t,$$

stationarity gives the exact finite identity

$$\mathrm{Var}(\overline{F}_N) = \frac{\gamma_0}{N}\left[1 + 2\sum_{t=1}^{N-1}\left(1 - \frac{t}{N}\right)\rho_t\right]. \tag{145.44}$$

Indeed,

$$\mathrm{Var}(\overline{F}_N) = \frac{1}{N^2}\sum_{r,s=0}^{N-1}\mathrm{Cov}(F_r, F_s) = \frac{1}{N^2}\left(N\gamma_0 + 2\sum_{t=1}^{N-1}(N-t)\gamma_t\right),$$

because there are $N - t$ ordered pairs at separation t in each direction. Thus the finite variance-inflation coordinate is

$$I_N = 1 + 2\sum_{t=1}^{N-1}\left(1 - \frac{t}{N}\right)\rho_t, \qquad N_{\mathrm{eff}} = N/I_N.$$

For neural-state and VMC energy estimates, (145.44) is the object reported by an error bar after a window or blocking prescription has been declared. Thermalization, slow-mode monitoring, truncation of the autocorrelation window, independent-chain comparison, and the same analysis for score–local-energy force coordinates remain part of the sampling-error datum, not consequences of the local-energy identity.

The force used in a smooth neural-state or variational-Monte-Carlo optimization is an equally finite identity. Let $\theta = (\theta^a)$ be real local coordinates on a patch of Θ, and assume $\psi_x(\theta) \neq 0$ on the sampled support. Define the score coordinate

$$\mathsf{s}_a(x;\theta) = \partial_a \log\psi_x(\theta).$$

Put $p_\theta = p_{\psi(\theta)}$ and $E_{\mathrm{loc}}(x;\theta) = ((A\psi(\theta))_x)/\psi_x(\theta)$. Without normalizing the vector $\psi(\theta)$, differentiation of the Rayleigh quotient gives

$$\partial_a E_\theta = 2\ \mathrm{Re}\,\frac{\langle\partial_a\psi, (A - E_\theta)\psi\rangle}{\langle\psi,\psi\rangle}.$$

In the computational basis this becomes the score–local-energy covariance identity

$$\partial_a E_\theta = 2\ \mathrm{Re}\sum_x p_\theta(x)\Big(\overline{\mathsf{s}_a(x;\theta)} - \sum_y p_\theta(y)\overline{\mathsf{s}_a(y;\theta)}\Big)\big(E_{\mathrm{loc}}(x;\theta) - E_\theta\big). \tag{145.45}$$

The centering of the score does not change the value because $\sum_x p_\theta(x)(E_{\mathrm{loc}}(x;\theta) - E_\theta) = 0$. Equation (145.45) is what a stochastic force estimator estimates after a sampling law has been declared. It is not an optimizer theorem: a small empirical force may indicate a tangent-space stationary point while the residual norm, the energy variance, the integrated autocorrelation time of the Markov chain, or the ansatz bias remains large. For QFT applications the finite force is therefore reported together with (145.43), sector constraints, and the regulator extrapolation data of Section 145.16.

Tensor-network terminology fits this definition by specifying Ψ. A finite matrix-product state on a spin chain of length L, physical local dimension d, and bond dimension χ is a vector whose amplitudes are finite contractions of matrices

$$\psi_{i_1\ldots i_L} = \mathrm{Tr}\Big(A_1^{i_1}A_2^{i_2}\cdots A_L^{i_L}\Big), \qquad A_\ell^i \in \mathrm{Mat}_{\chi_{\ell-1}\times\chi_\ell}(\mathbb{C}).$$

For an infinite translation-invariant MPS, a transfer-operator spectrum can estimate a correlation length, but a QFT continuum claim still requires a sequence of finite regulators, a scaling map for operators, and convergence of the corresponding Schwinger or Wightman data. Bond dimension, discarded weight, transfer-operator gap, local-energy variance, and Krylov residuals are finite evidence coordinates. The continuum claim is the additional statement that those coordinates control the regulator limit in a declared topology.

Finite transfer-operator correlation length. The most common tensor-network continuum diagnostic is the transfer-operator gap. Here is the finite statement in the form needed for QFT use. For a translation-invariant infinite MPS with tensors A^i, define the finite transfer operator

$$\mathbb{E}(X) = \sum_i A^i X (A^i)^\dagger$$

on $\mathrm{Mat}_{\chi\times\chi}(\mathbb{C})$. Assume, for this finite ansatz, that $\mathbb{E}$ has a simple eigenvalue $\lambda_0 = 1$, positive left and right eigenvectors ℓ, r normalized by $\ell(r) = 1$, and remaining eigenvalues λ_α with $|\lambda_\alpha| < 1$. A local lattice operator O is represented by the insertion map

$$\mathbb{E}_O(X) = \sum_{i,j} O_{ij} A^i X (A^j)^\dagger.$$

The connected two-point function at lattice separation $n \geq 1$ is

$$C_O(n) = \ell(\mathbb{E}_O \mathbb{E}^n \mathbb{E}_O r) - \ell(\mathbb{E}_O r)^2. \tag{145.46}$$

If $\mathbb{E}$ is diagonalizable on the subspace complementary to the fixed vector, then

$$C_O(n) = \sum_\alpha A_\alpha(O) \lambda_\alpha^n, \tag{145.47}$$

where the coefficients are products of the left and right spectral projections of $\mathbb{E}_O$. Thus a single isolated contributing eigenvalue with $\lambda_\alpha > 0$ gives a finite lattice correlation length

$$\xi_\alpha^{\mathrm{lat}} = -\frac{1}{\log \lambda_\alpha}.$$

If the lattice spacing is a, the corresponding finite effective mass is

$$m_\alpha(a) = -\frac{1}{a} \log \lambda_\alpha. \tag{145.48}$$

This is a finite transfer-operator identity, not yet a continuum QFT statement. To interpret $m_\alpha(a)$ as a physical mass one needs a sequence of regulator data $(a, \chi(a), A^i(a), O_a)$, a normalization of the operator O_a, and estimates of the form

$$\lambda_\alpha(a) = \exp[-am + O(a^{1+\delta})], \qquad Z_O(a)^2 A_\alpha(O_a) \longrightarrow A_{\mathrm{phys}}, \tag{145.49}$$

together with convergence of the corresponding multipoint Schwinger or Wightman distributions. Excited transfer modes are not nuisances in this language; they are visible finite terms in (145.47). If

$$C_O(n) = A_1 e^{-am_1 n} + A_2 e^{-am_2 n}, \qquad m_2 > m_1, \quad A_1, A_2 > 0,$$

then the finite effective mass

$$m_{\text{eff}}(a,n) = -\frac{1}{a}\log\frac{C_O(n+1)}{C_O(n)}$$

lies between m_1 and m_2 and approaches m_1 only after the second transfer mode is suppressed. A finite transfer gap therefore tells one which exponential appears in the finite ansatz; it does not, by itself, prove the continuum operator map, reflection positivity, locality, or cutoff-removal estimate needed for QFT.

Calculation check. The companion check

`calculation-checks/hamiltonian_truncation_dlcq_checks.py`

also verifies the finite variational identities (145.38)– (145.45): energy variance as residual norm, spectral distance bounded by variance, ground-projection leakage from a known finite gap, the tangent-gradient formula, the local-energy Monte Carlo identities, the Markov-chain variance-inflation formula (145.44), and the score-force identity in a finite basis. It also checks the finite transfer-operator spectral expansion (145.47), the single-mode effective-mass identity (145.48), the two-mode contamination bound for $m_{\text{eff}}(a,n)$, and the elementary logarithmic remainder bound implicit in (145.49).

145.12 Light-Front Kinematics And Constraints

Light-front Hamiltonian methods use a null hyperplane as the time slice. In the mostly-plus convention, choose one spatial direction x^1 and set

$$x^{\pm} = \frac{x^0 \pm x^1}{\sqrt{2}}, \qquad p^{\pm} = \frac{p^0 \pm p^1}{\sqrt{2}}. \tag{145.50}$$

For D-dimensional Minkowski space,

$$\mathrm{d}s^2 = -2\,\mathrm{d}x^+\mathrm{d}x^- + \mathrm{d}x_\perp^2, \qquad p\cdot x = -p^-x^+ - p^+x^- + p_\perp\cdot x_\perp, \tag{145.51}$$

and x^+ is the evolution parameter. The generator conjugate to x^+ is P^-; the longitudinal momentum P^+ and transverse momenta $P_\perp$ label superselection sectors for the finite light-front Hamiltonians used below. These identities are kinematic; they do not define an interacting QFT until the constraint and zero-mode sectors have also been specified.

Definition 145.16 (Light-front Hamiltonian regulator specification)**.** A light-front Hamiltonian regulator specification is a Hamiltonian truncation regulator specification $\mathfrak{H}_{\text{trunc}}$ together with the following additional structure.

(i) A null-coordinate chart (145.50), the sign convention (145.51), and a declared evolution parameter x^+.

(ii) A positive-longitudinal nonzero-mode sector, with one-particle labels carrying $p^+ > 0$ and whatever transverse, spin, flavor, color, and statistics labels are kept by the regulator.

(iii) A zero-mode and constraint sector

$$\mathcal{Z}_\Lambda, \qquad \mathcal{C}_{\Lambda,\alpha} = 0, \qquad \mathcal{G}_{\Lambda,\mathrm{res}},$$

recording the $p^+ = 0$ modes, finite global Gauss-law constraints, residual gauge transformations, and any additional compact or topological degrees of freedom. Eliminating, quantizing, or imposing these variables are different regulator choices and must be part of the regulator specification.

(iv) A finite physical Hilbert space

$$\mathcal{H}_\Lambda^{\mathrm{phys}} \subset \mathcal{H}_\Lambda^{p^+>0} \otimes \mathcal{H}_{\mathcal{Z},\Lambda}$$

obtained after the stated constraint prescription, together with commuting finite operators P_Λ^+ and $P_{\perp,\Lambda}$ on the physical sector.

(v) A finite self-adjoint light-front Hamiltonian P_Λ^- on $\mathcal{H}_\Lambda^{\mathrm{phys}}$, commuting with the retained translation generators on the finite physical sector. In a simultaneous $P^+ = p^+ > 0$, $P_\perp = p_\perp$ sector, the finite invariant-mass operator is

$$M_\Lambda^2 = 2p^+ P_\Lambda^- - p_\perp^2. \tag{145.52}$$

Outside a fixed momentum sector the same formula is read as a joint functional calculus expression on the common spectral representation of the commuting momenta and P_Λ^-.

(vi) A continuum diagnostic specifying how p^+-cutoffs, harmonic resolution, transverse cutoffs, counterterms, principal-value prescriptions, and zero-mode constraints are taken to their limiting values.

One-particle measure. The free massive representation fixes the basic measure behind the positive-p^+ Fock construction. For a test function F on momentum space and $m > 0$,

$$\int_{\mathbb{R}^D} \mathrm{d}^D p\, \theta(p^0)\delta(p^2 + m^2) F(p) = \int_{p^+>0} \frac{\mathrm{d}p^+\, \mathrm{d}^{D-2}p_\perp}{2p^+}\, F\left(p^+, \frac{m^2 + p_\perp^2}{2p^+}, p_\perp\right). \tag{145.53}$$

Indeed,

$$p^2 + m^2 = -2p^+p^- + p_\perp^2 + m^2,$$

so the p^--integration localizes at

$$p^- = \frac{m^2 + p_\perp^2}{2p^+} \tag{145.54}$$

with Jacobian $|\partial(p^2 + m^2)/\partial p^-| = 2p^+$. The positive-energy condition selects $p^+ > 0$ on the massive shell. The massless boundary $p^+ = 0$, and the constrained zero modes of gauge theories, are not included in this one-particle measure; they are entries of $\mathcal{Z}_\Lambda$ and $\mathcal{C}_{\Lambda,\alpha}$ in Definition 145.16.

Spectral interpretation. At fixed p^+ and $p_\perp$, M_Λ^2 in (145.52) and P_Λ^- have the same finite eigenvectors, and their eigenvalues are related by

$$M^2 = 2p^+ P^- - p_\perp^2.$$

This is the finite-sector reason light-front calculations often diagonalize P^- while reporting invariant masses. A gauge-theory light-front calculation is therefore specified only after the nonzero-mode Hamiltonian, zero-mode/constraint prescription, and residual gauge data have all been declared in the same regulator scheme.

145.13 DLCQ Regulator

DLCQ is the compact positive-longitudinal-momentum specialization of Definition 145.16. It compactifies

$$x^- \sim x^- + 2\pi R$$

so that

$$p^+ = \frac{n}{R}, \qquad n \in \mathbb{Z}_{\geq 0}.$$

The total longitudinal momentum is

$$P^+ = \frac{K}{R},$$

where K is the harmonic resolution. The finite DLCQ Hilbert space at fixed K consists of partitions of K among partons, with transverse and internal cutoffs added as needed. Zero modes with $n = 0$ are constrained variables or additional degrees of freedom depending on the theory; their treatment is part of the regulator.

Definition 145.17 (DLCQ regulator specification)**.** A DLCQ regulator specification is a Hamiltonian truncation regulator specification together with the following light-front entries.

(i) The spatial light-front coordinate is compactified as $x^- \sim x^- + 2\pi R$, and the total longitudinal momentum sector is fixed by $P^+ = K/R$ with harmonic resolution $K \in \mathbb{Z}_{>0}$.

(ii) The finite basis consists of all declared parton partitions $K = n_1 + \cdots + n_N$, with $n_i > 0$, together with the transverse, internal, gauge, and statistics labels kept by the regulator.

(iii) The zero-mode sector is specified as part of the regulator: constrained variables, eliminated modes, residual global constraints, and additional zero-mode degrees of freedom are all recorded before diagonalization.

(iv) The finite operator is the light-front Hamiltonian P_K^-, or equivalently the invariant mass operator $M_K^2 = 2P^+P_K^- - P_\perp^2$, with counterterms and principal-value prescriptions stated in the same regulator scheme.

(v) The continuum diagnostic specifies the ordered finite labels followed as $K \to \infty$, the extrapolation variable, and the remainder model used to interpret finite-K data.

145.14 Scalar ϕ^4 DLCQ Warmup

Before the large-N gauge-theory example, it is useful to record a nonintegrable scalar light-front matrix whose finite definition is completely explicit. This is a warmup for DLCQ, not a definition of the continuum ϕ_2^4 theory. The $p^+ = 0$ mode is omitted in the construction below; in light-front scalar theory that omission is a regulator choice and is precisely where vacuum and symmetry-breaking information can hide. A continuum claim therefore needs a zero-mode prescription and a counterterm/extrapolation theorem in addition to the finite matrix.

Construction 145.18 (Finite scalar DLCQ matrix)**.** Fix a harmonic resolution $K \in \mathbb{Z}_{>0}$, a mass $m > 0$, and a finite coupling coordinate g. The finite bosonic basis consists of occupation vectors

$$\mathbf{N} = (N_1, \ldots, N_K) \in \mathbb{Z}_{\geq 0}^K, \qquad \sum_{n=1}^{K} nN_n = K. \tag{145.55}$$

The parton with label n carries longitudinal momentum $p_n^+ = n/R$, and the total sector has $P^+ = K/R$. The free invariant mass is

$$M_{0,K}^2(\mathbf{N}) = Km^2 \sum_{n=1}^{K} \frac{N_n}{n}. \tag{145.56}$$

This is the finite-sector form of

$$M^2 = 2P^+P^-, \qquad P_0^- = \sum_{n=1}^{K} \frac{m^2}{2p_n^+} N_n,$$

with zero transverse momentum.

Let $a_n, a_n^\dagger$ be bosonic creation and annihilation operators with $[a_n, a_m^\dagger] = \delta_{nm}$. The dimensionless normal-ordered quartic operator Q_K is

$$Q_K = \sum_{\substack{\epsilon_i = \pm 1,\ 1 \le n_i \le K \\ \sum_i \epsilon_i n_i = 0}} \frac{:B_{\epsilon_1,n_1}B_{\epsilon_2,n_2}B_{\epsilon_3,n_3}B_{\epsilon_4,n_4}:}{\sqrt{n_1 n_2 n_3 n_4}}, \qquad B_{+1,n} = a_n, \quad B_{-1,n} = a_n^\dagger. \tag{145.57}$$

The Kronecker condition is longitudinal momentum conservation. If one uses the field normalization

$$\phi(x^-) = \sum_{n>0} \frac{a_n e^{-inx^-/R} + a_n^\dagger e^{inx^-/R}}{\sqrt{4\pi n}}, \qquad x^- \sim x^- + 2\pi R,$$

then $g = \lambda/(96\pi)$ for the interaction $\lambda \int :\phi^4:/4!$ when written in invariant-mass units. The chapter treats g as the finite regulator coordinate, because a cutoff-dependent coupling and possible zero-mode counterterms are part of a continuum scheme.

The finite DLCQ invariant-mass matrix is

$$M_K^2 = M_{0,K}^2 + gK\, P_K Q_K P_K, \tag{145.58}$$

where P_K is the projection onto the finite partition basis (145.55). Optional particle-number cutoffs may be added as further finite-regulator coordinates, but they must then be removed or extrapolated separately from the harmonic resolution.

The matrix (145.58) is Hermitian. The coefficient in (145.57) is real, and taking the adjoint sends every ordered monomial with signs ϵ_i to the corresponding monomial with signs $-\epsilon_i$. The constraint $\sum_i \epsilon_i n_i = 0$ is invariant under this sign change, and normal ordering restores the displayed ordered form. Since P_K is an orthogonal projection onto a fixed total-resolution sector, the projected finite matrix is Hermitian.

A small matrix element fixes the convention. At $K = 3$, the states

$$|1,1,1\rangle = \frac{(a_1^\dagger)^3}{\sqrt{3!}}|0\rangle, \qquad |3\rangle = a_3^\dagger|0\rangle$$

both lie in the same harmonic-resolution sector. The only term in Q_K that connects them is the ordered family with one $a_3^\dagger$ and three a_1's, together with its four possible positions in the quartic product. Thus

$$\langle 3|Q_3|1,1,1\rangle = \frac{4}{\sqrt{3}}\sqrt{3!} = 4\sqrt{2}. \tag{145.59}$$

For the three-particle state itself, the two-creation two-annihilation normal-ordered term with all momenta equal to one gives

$$\langle 1,1,1|Q_3|1,1,1\rangle = 6\,\langle 1,1,1|(a_1^\dagger)^2 a_1^2|1,1,1\rangle = 36. \tag{145.60}$$

These finite identities are not physical mass predictions; they are normalization checks for the regulator matrix.

The script

```
qft_scripts/phi4_dlcq.py
```

implements Construction 145.18. Its smoke mode builds a small positive-p^+ matrix, checks finite Hermiticity, and prints the lowest finite invariant masses. The companion calculation check

```
calculation-checks/hamiltonian_truncation_dlcq_checks.py
```

verifies total harmonic resolution, zero-coupling reduction to (145.56), Hermiticity, and the two convention-sensitive matrix elements (145.59) and (145.60).

145.15 Large-N Two-Dimensional QCD: A Finite DLCQ Matrix

The standard large-N two-dimensional QCD meson equation involves the principal-value operator

$$(\mathcal{K}\phi)(x) = \mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y, \qquad 0<x<1,$$

together with endpoint mass terms

$$\frac{m_1^2}{x}\phi(x) + \frac{m_2^2}{1-x}\phi(x).$$

This section records a finite regulator, not a continuum theorem. Fix a harmonic resolution $K \geq 3$ and grid points $x_n = n/K$, $n = 1,\dots,K-1$. For $\gamma > 0$, define the real symmetric matrix

$$(M_K^2)_{nm} = \delta_{nm}\left[\frac{m_1^2}{x_n} + \frac{m_2^2}{1-x_n} + \gamma K \sum_{\substack{j=1\\ j\neq n}}^{K-1} \frac{1}{(n-j)^2}\right] - (1-\delta_{nm})\frac{\gamma K}{(n-m)^2}.$$

The normalization of γ depends on the convention for g^2N/π. The finite object above is sufficient to illustrate harmonic resolution, positivity, and extrapolation obligations.

Finite principal-value quadratic form. For $m_1^2, m_2^2, \gamma > 0$ and any $v = (v_1,\dots,v_{K-1}) \in \mathbb{R}^{K-1}$,

$$v^T M_K^2 v = \sum_{n=1}^{K-1}\left(\frac{m_1^2}{x_n} + \frac{m_2^2}{1-x_n}\right)v_n^2 + \gamma K \sum_{1\leq n<m\leq K-1} \frac{(v_n-v_m)^2}{(n-m)^2}. \tag{145.61}$$

In particular M_K^2 is positive definite.

Substitute the definition of M_K^2 into $v^T M_K^2 v$. The mass terms give the first displayed sum. The off-diagonal kernel gives

$$\gamma K \sum_{n=1}^{K-1} \sum_{\substack{m=1 \\ m \neq n}}^{K-1} \frac{v_n^2 - v_n v_m}{(n-m)^2}.$$

Pair the term (n, m) with (m, n). For each unordered pair $\{n, m\}$,

$$\frac{v_n^2 - v_n v_m}{(n-m)^2} + \frac{v_m^2 - v_m v_n}{(m-n)^2} = \frac{(v_n - v_m)^2}{(n-m)^2}.$$

This gives the stated quadratic form. Since $0 < x_n < 1$, the mass coefficients are positive; hence $v^T M_K^2 v > 0$ for $v \neq 0$. The calculation is a finite-regulator algebra check: it proves positivity of the displayed matrix. Positivity and self-adjointness of the continuum principal-value operator require a separate continuum-domain construction.

The script

```
qft_scripts/thooft_dlcq.py
```

constructs this matrix and diagonalizes it at finite K. A continuum claim would require an analysis of the $K \to \infty$ limit, endpoint behavior, zero modes, normalization of γ, and comparison with a Lorentz-covariant reconstruction. The script therefore prints finite eigenvalues and a quadratic-form positivity check rather than presenting the numbers as physical meson masses.

145.16 Finite-Regulator Extrapolation

The output of a lattice, Hamiltonian-truncation, or DLCQ script is a number attached to a regulator. A continuum claim is a separate mathematical statement about a limiting procedure. This section records the minimal finite-dimensional facts used in the companion scripts and explains what an extrapolation hypothesis must contain.

Definition 145.19 (Finite-regulator observable record)**.** A finite-regulator observable record consists of:

$$\big(I, \preceq;\ X_i,\ A_i,\ \sigma_i,\ \mathcal{E}_i\big).$$

Here $(I, \preceq)$ is a directed set of regulator labels, X_i is the finite object being computed at label i, $A_i \in \mathbb{R}$ is the finite observable extracted from X_i, $\sigma_i \geq 0$ is the statistical standard error if A_i is estimated by a random algorithm, and $\mathcal{E}_i$ is the declared systematic error model. For deterministic TCSA or DLCQ diagonalization one has $\sigma_i = 0$, but $\mathcal{E}_i$ is not zero: it contains cutoff, finite-volume, counterterm, endpoint, or zero-mode errors. For a Markov-chain computation, A_i itself is an estimator and σ_i must include autocorrelation.

Remark 145.20 (Interpolation ambiguity of finite cutoff data)*.* Let $K_1, \ldots, K_N$ be distinct positive regulator values and let $A_1, \ldots, A_N \in \mathbb{R}$ be finite outputs. For every proposed continuum value $A_\infty \in \mathbb{R}$, there is a polynomial $p(t)$ of degree at most N such that

$$p(0) = A_\infty, \qquad p(K_j^{-1}) = A_j, \quad j = 1, \ldots, N.$$

Consequently finitely many cutoff values, by themselves, cannot prove a continuum limit or its value. The $N+1$ points

$$0, \quad K_1^{-1}, \ldots, K_N^{-1}$$

are distinct. Lagrange interpolation gives a unique polynomial of degree at most N taking the prescribed values $A_\infty, A_1, \ldots, A_N$ at those points. Since A_∞ was arbitrary, the same finite data are compatible with arbitrarily many candidate limits unless additional information is supplied. The obstruction is the missing analytic ansatz, monotonicity estimate, remainder bound, or convergence theorem that would restrict the allowed interpolating functions near $K^{-1} = 0$.

Definition 145.21 (Power-law cutoff expansion with a remainder bound)**.** Let K be a positive regulator parameter tending to infinity. A deterministic sequence A_K has an m-term power-law cutoff expansion with base exponent $\omega > 0$ and controlled remainder if there are real numbers $A_\infty, c_1, \ldots, c_m$, a constant C, and K_0 such that

$$\left| A_K - A_\infty - \sum_{a=1}^{m} c_a K^{-a\omega} \right| \le C K^{-(m+1)\omega}, \qquad K \ge K_0. \tag{145.62}$$

The same definition applies to a subsequence, for example $K, Ks_1, \ldots, Ks_m$, provided these are admissible regulator labels and the displayed bound holds on that subsequence. In a TCSA computation the exponent ω and the counterterm coordinates should be derived from the high-energy tail or OPE; in a DLCQ computation they should be derived from endpoint and zero-mode analysis. A fit without (145.62) is a diagnostic, not a theorem.

For a two-cutoff Richardson extrapolant, the leading correction cancels only under a stated asymptotic expansion with a controlled remainder. Assume

$$A_K = A_\infty + cK^{-\omega} + r_K, \qquad |r_K| \le CK^{-\eta}, \qquad \eta > \omega > 0,$$

for $K \ge K_0$. Define

$$R_K = \frac{2^\omega A_{2K} - A_K}{2^\omega - 1}. \tag{145.63}$$

Then

$$|R_K - A_\infty| \le \frac{2^\omega 2^{-\eta} + 1}{2^\omega - 1} CK^{-\eta}. \tag{145.64}$$

Substitute the assumed expansion into (145.63):

$$2^\omega A_{2K} - A_K = (2^\omega - 1)A_\infty + 2^\omega c(2K)^{-\omega} - cK^{-\omega} + 2^\omega r_{2K} - r_K.$$

The two terms proportional to c cancel because $2^\omega (2K)^{-\omega} = K^{-\omega}$. Dividing by $2^\omega - 1$ gives

$$R_K - A_\infty = \frac{2^\omega r_{2K} - r_K}{2^\omega - 1}.$$

Using $|r_{2K}| \le C(2K)^{-\eta}$ gives (145.64).

Integer-power extrapolation with explicit weights. Let $s_0, \ldots, s_m$ be distinct positive real numbers and suppose A_K satisfies (145.62) on the subsequence $s_j K$, $j = 0, \ldots, m$. Let $w_0, \ldots, w_m$ be the unique solution of

$$\sum_{j=0}^{m} w_j = 1, \qquad \sum_{j=0}^{m} w_j s_j^{-a\omega} = 0, \quad a = 1, \ldots, m. \tag{145.65}$$

Then the extrapolated value

$$R_K^{(m)} = \sum_{j=0}^{m} w_j A_{s_j K}$$

satisfies

$$|R_K^{(m)} - A_\infty| \le C K^{-(m+1)\omega} \sum_{j=0}^{m} |w_j| \, s_j^{-(m+1)\omega}. \tag{145.66}$$

Set $q_j = s_j^{-\omega}$. The numbers $q_0, \dots, q_m$ are distinct, so the Vandermonde matrix $(q_j^a)_{0 \le a,j \le m}$ is invertible. Hence (145.65) has a unique solution. Insert (145.62) into $R_K^{(m)}$. The coefficient of A_∞ is $\sum_j w_j = 1$. For $a = 1, \dots, m$, the coefficient of $c_a K^{-a\omega}$ is $\sum_j w_j s_j^{-a\omega} = 0$. The remaining error is bounded by the triangle inequality:

$$\left| \sum_{j=0}^{m} w_j r_{s_j K} \right| \le \sum_{j=0}^{m} |w_j| \, C (s_j K)^{-(m+1)\omega}.$$

This is (145.66). The finite algebra is exact, but its use in a continuum claim is only as good as the expansion and remainder estimate in Definition 145.21. The weights cancel declared integer powers; the QFT problem separately supplies the evidence that these powers are the correct cutoff expansion.

Large-K diagnostic for the finite 't Hooft matrices. For the finite matrices M_K^2 whose quadratic form is displayed in (145.61), write their eigenvalues in nondecreasing order as

$$\lambda_0(K) \le \lambda_1(K) \le \cdots \le \lambda_{K-2}(K).$$

For a fixed label ℓ, the numerical sequence

$$A_K = \lambda_\ell(K)$$

is a finite-regulator sequence in the sense of Definition 145.19. Keeping the label ℓ fixed is only a diagnostic convention until one proves that the corresponding continuum state is isolated and that nearby finite-K levels do not interchange in a way that changes the limiting object. Choose distinct resolutions $K_1 < \cdots < K_N$, a base exponent $\omega > 0$, and an integer $p < N$. Set

$$q_r = K_r^{-\omega}, \qquad X_{ra} = q_r^a, \qquad r = 1, \dots, N, \quad a = 0, \dots, p.$$

The least-squares polynomial fit is

$$\widehat{c} = (X^T X)^{-1} X^T A, \qquad A = (A_{K_1}, \dots, A_{K_N})^T, \tag{145.67}$$

provided X has full column rank. The reported continuum diagnostic is $\widehat{c}_0$, the fitted intercept at $q = 0$.

Finite large-K fit with an explicit remainder amplifier. Assume that the finite data used in (145.67) have the form

$$A_{K_r} = A_\infty + \sum_{a=1}^{p} c_a K_r^{-a\omega} + \rho_r, \qquad r = 1, \dots, N, \tag{145.68}$$

with X of full column rank. Let

$$B = (X^T X)^{-1} X^T.$$

Then the fitted intercept satisfies

$$|\widehat{c}_0 - A_\infty| \le \left(\sum_{r=1}^{N} |B_{0r}| \right) \max_{1 \le r \le N} |\rho_r|. \tag{145.69}$$

In particular, if all ρ_r vanish, the fit recovers A_∞ exactly, independently of the overdetermination $N > p + 1$.

Let

$$c = (A_\infty, c_1, \dots, c_p)^T, \qquad \rho = (\rho_1, \dots, \rho_N)^T.$$

Equation (145.68) is the vector identity

$$A = Xc + \rho.$$

Since X has full column rank, $BX = I_{p+1}$. Hence

$$\widehat{c} = BA = B(Xc + \rho) = c + B\rho.$$

Taking the zeroth component gives

$$\widehat{c}_0 - A_\infty = \sum_{r=1}^{N} B_{0r} \rho_r.$$

The triangle inequality gives (145.69). If $\rho = 0$, then $\widehat{c} = c$ and the intercept is exact.

The companion script

`qft_scripts/thooft_dlcq_extrapolation.py`

implements this finite procedure for the matrices M_K^2: it prints the finite eigenvalues, the fitted intercepts, the residuals, the condition number of X, and the factor $\sum_r |B_{0r}|$ appearing in (145.69). These quantities measure how a chosen finite data set responds to a chosen ansatz. They do not prove that the large-K limit of the large-N QCD meson equation exists or that the selected exponent ω is correct. Those conclusions require separate endpoint and zero-mode estimates producing a bound of the form (145.68).

The companion calculation

`calculation-checks/numerical_extrapolation_checks.py`

verifies the algebra in (145.63)–(145.66) with exact rational arithmetic. It does not verify that a particular QFT observable obeys (145.62); that remains a problem-specific analytic estimate.

The companion calculation

`calculation-checks/hamiltonian_truncation_dlcq_checks.py`

also verifies the exact-intercept and constant-sequence cases of the finite large-K fit calculation above.

Correlated fits and window stability. Production lattice, tensor-network, and Hamiltonian-truncation data are rarely independent scalar data. A continuum extrapolation specification at a chosen fit window $W = \{i_1, \ldots, i_N\}$ therefore contains

$$A = (A_{i_1}, \ldots, A_{i_N})^T, \qquad \Sigma_W, \qquad f_0, \ldots, f_p, \qquad R_1, \ldots, R_N.$$

Here A_i are the finite-regulator outputs, Σ_W is the covariance matrix of their statistical errors on the window, $f_a(i)$ are the declared fit functions with $f_0(i) = 1$, and R_r is a deterministic bound or declared systematic envelope for the part of A_{i_r} not represented by the chosen fit functions. Put

$$X_{ra} = f_a(i_r), \qquad X \in \mathrm{Mat}_{N\times(p+1)}(\mathbb{R}).$$

Assume in this paragraph that Σ_W is positive definite and that X has full column rank. If an estimated covariance matrix is singular, the shrinkage, projection, or diagonal approximation used to replace it is a new part of the fit specification, not an invisible numerical detail.

The correlated least-squares coordinate is

$$\widehat{c} = (X^T \Sigma_W^{-1} X)^{-1} X^T \Sigma_W^{-1} A. \tag{145.70}$$

Writing

$$G = X^T \Sigma_W^{-1} X, \qquad B = G^{-1} X^T \Sigma_W^{-1},$$

one has $BX = I_{p+1}$. If the data on the window decompose as

$$A = Xc + \rho + \epsilon, \qquad \mathbb{E}\epsilon = 0, \qquad \mathbb{E}(\epsilon\epsilon^T) = \Sigma_W, \tag{145.71}$$

then

$$\widehat{c} - c = B\rho + B\epsilon. \tag{145.72}$$

Thus the intercept $\widehat{A}_\infty = \widehat{c}_0$ has the exact finite error decomposition

$$\widehat{A}_\infty - A_\infty = \sum_{r=1}^{N} B_{0r}\rho_r + \sum_{r=1}^{N} B_{0r}\epsilon_r.$$

If $|\rho_r| \le R_r$, the deterministic fit-window systematic coordinate is

$$S_W = \sum_{r=1}^{N} |B_{0r}| R_r. \tag{145.73}$$

The stochastic variance of the intercept is

$$\sigma^2_{\infty,W} = e_0^T B \Sigma_W B^T e_0 = e_0^T G^{-1} e_0, \tag{145.74}$$

where $e_0 = (1, 0, \ldots, 0)^T$. The second equality follows from

$$B\Sigma_W B^T = G^{-1} X^T \Sigma_W^{-1} \Sigma_W \Sigma_W^{-1} X G^{-1} = G^{-1}.$$

The correlated residual

$$\chi^2_W = (A - X\widehat{c})^T \Sigma_W^{-1} (A - X\widehat{c}) \tag{145.75}$$

is a finite diagnostic for the chosen window and model. Its probabilistic interpretation requires the sampling law of the estimator, the covariance estimator, and the treatment of autocorrelation described in Section 141.12.

A window-stability analysis is the finite collection

$$\mathcal{W} = \{(W_\alpha, X_\alpha, \Sigma_\alpha, R_\alpha)\}_{\alpha \in A}$$

together with the resulting coordinates

$$\widehat{A}_{\infty,\alpha}, \qquad \sigma_{\infty,\alpha}, \qquad S_\alpha, \qquad \chi^2_\alpha.$$

Agreement of these coordinates across windows is evidence about the chosen finite-regulator family only after the windows use the same physical observable, the same renormalization convention, and compatible operator normalizations. The analytic estimate producing the envelopes R_α remains the source of continuum control. For tensor-network and neural-state calculations the window label must also record bond dimension or architecture, optimizer termination criterion, local-energy variance or discarded weight, and any symmetry projection used to select the finite sector. Otherwise a stable sequence of numbers may be comparing different finite problems rather than a single regulated QFT observable.

The reader-facing implementation

```
qft_scripts/finite_regulator_extrapolation.py
```

takes this paragraph literally. Its input data consist of regulator labels, finite observable values, an optional covariance matrix, nonnegative remainder envelopes, and half-open fit windows. For each window it constructs

$$X_{ra} = K_r^{-a\omega}, \qquad B = (X^T \Sigma_W^{-1} X)^{-1} X^T \Sigma_W^{-1},$$

then reports $\widehat{A}_{\infty,W}$, the propagated statistical error $(e_0^T G^{-1} e_0)^{1/2}$, the deterministic coordinate $\sum_r |B_{0r}| R_r$, the correlated residual, the condition number, and the spread of fitted intercepts across the declared windows. Supplying the identity matrix as a covariance, or using diagonal errors, is part of the finite fit specification and is printed as such. The script therefore checks the bookkeeping of a proposed extrapolation. The cutoff exponent, counterterm scheme, and remainder estimate are mathematical inputs whose justification comes from the regulated theory, not from the fit output alone.

145.17 Light-Front Hamiltonian

The light-front Hamiltonian convention used in this chapter is the regulator specification of Definition 145.16. The finite numerical sections above use its DLCQ specialization; the analytic large-N QCD construction in Chapter 53 and the Chern–Simons–matter light-cone construction in Chapter 95 use the same coordinate convention, but with model-specific constraint equations instead of a universal finite-matrix recipe.

145.18 Cross-Method Benchmark Comparisons

Lattice Monte Carlo, Hamiltonian truncation, TCSA/TFFSA, and DLCQ produce different finite mathematical objects. A numerical agreement between their outputs is meaningful only after a common QFT observable and a common normalization have been specified. The comparison itself is therefore part of the regulated calculation.

Definition 145.22 (Cross-method benchmark specification)**.** A cross-method benchmark specification consists of the following information.

1. A target QFT observable Q. Examples are a dimensionless mass ratio, a finite-volume energy gap in units of the physical mass, a matrix element normalized by a declared two-point function, or a Euclidean distribution paired with a specified test function.
2. A finite set of methods $m \in \mathcal{M}$. For each method one specifies the finite regulator object X_m: for Euclidean lattice Monte Carlo this includes lattice spacing, finite volume, boundary conditions, action, update kernel, and measured estimator; for Hamiltonian truncation it includes the finite Hilbert space, Hamiltonian matrix, counterterm coordinates, symmetry sector, and extraction map; for DLCQ it includes harmonic resolution, zero-mode prescription, constraint sector, and finite invariant-mass matrix.
3. A normalization map
$$N_m : X_m \longrightarrow \mathbb{R}^r$$
which converts the method-specific finite output to the same coordinate system for Q. Field-strength conventions, finite-volume units, operator normalizations, and sector labels are part of N_m.
4. Statistical error coordinates s_m, deterministic finite-regulator envelopes R_m, and a scheme-matching coordinate b_m measuring any residual mismatch between the method's finite observable and the declared target observable.
5. A limiting or extrapolation hypothesis, when a continuum statement is claimed, stating that
$$N_m(X_m) = Q + \epsilon_m, \qquad |\epsilon_m| \leq s_m + R_m + b_m$$
in the declared norm or componentwise in $\mathbb{R}^r$.

The comparison check between two methods is then finite arithmetic. If two methods m, n are claimed to compute the same coordinate of Q, their finite outputs must satisfy

$$|N_m(X_m) - N_n(X_n)| \leq s_m + s_n + R_m + R_n + b_m + b_n \tag{145.76}$$

for the claimed error coordinates. Failure of (145.76) means that at least one of the finite estimates, error models, normalization maps, or target identifications is wrong. Satisfaction of (145.76) supplies a finite compatibility check conditional on the stated extrapolation hypotheses. The continuum statement is the separate proof that the hypotheses and envelopes follow from the regulated QFT.

The main finite objects in the present numerical layer are as follows.

Euclidean lattice Monte Carlo.
The finite object is a positive measure, a Markov kernel, and sampled correlators. The usual spectral coordinate is a transfer-matrix gap extracted from a correlator matrix or effective mass. The continuum burden is reflection positivity, volume control, autocorrelation analysis, continuum scaling, and operator matching.

Hamiltonian truncation/TCSA/TFFSA.
The finite object is a sector of a Hilbert space together with a projected Hamiltonian matrix. The usual spectral coordinates are Ritz eigenvalues, residual bounds, and finite matrix elements. The continuum burden is counterterm determination, cutoff convergence, finite-volume control, and operator normalization.

DLCQ/light-front truncation.
The finite object is a fixed harmonic-resolution physical sector together with a finite M^2 matrix. The usual spectral coordinate is an ordered invariant-mass eigenvalue at fixed K. The continuum burden is zero-mode constraints, endpoint behavior, large-K estimates, and Lorentz-covariant reconstruction.

Definition 145.23 (Benchmark manifest)**.** A benchmark manifest is a finite, machine-readable representative of Definition 145.22. It consists of:

1. the target observable label Q, the dimension r of its reported coordinate vector, and the norm in which the comparison is to be made;
2. for each method m, a regulator description, a normalization identifier, the coordinate vector $x_m \in \mathbb{R}^r$, the componentwise statistical error σ_m, regulator envelope ρ_m, and matching error β_m;
3. optional covariance data for the statistical part, with the convention that covariance data never replace the declared deterministic envelopes ρ_m, β_m;
4. provenance data: script name or analysis notebook, input dataset, random seed where relevant, regulator parameters, and any hash or version identifier needed to reproduce the finite number x_m.

The declared componentwise error vector is

$$e_m = \sigma_m + \rho_m + \beta_m. \tag{145.77}$$

The manifest is consistent at the finite-regulator level when, for every pair of methods m, n,

$$|x_m - x_n|_{\text{comp}} \leq e_m + e_n, \tag{145.78}$$

where the absolute value and inequality are componentwise. The script `qft_scripts/benchmark_manifest_consistency.py` implements exactly (145.78) for JSON manifests. A passing manifest verifies only that the finite reported coordinates are mutually compatible with the declared error envelopes and normalization identifiers. It does not verify that the envelopes are correct, that the regulator limits exist, that the methods compute the same continuum QFT observable, or that the target observable is nonperturbatively constructed.

This manifest discipline is intentionally stricter than a table of numerical values. If a lattice correlator fit and a Hamiltonian-truncation diagonalization report the same mass ratio but use different finite-volume normalizations, the mismatch belongs in β_m or in a failed normalization identifier before any comparison is made. If two finite coordinates disagree beyond (145.78), the failure has a definite meaning: at least one coordinate, uncertainty model, normalization map, or target identification is not the one recorded in the manifest. If the manifest passes, the continuum conclusion still begins only after the separate estimates on $\sigma_m, \rho_m, \beta_m$ are proved or justified in the relevant regulator framework.

The companion scripts instantiate this comparison at finite regulator. The Euclidean side contains finite Ising, scalar ϕ^4, $\mathbb{Z}_2$, $SU(2)$, and $SU(3)$ samplers, plus autocorrelation, static-potential, Wilson-flow, smearing, topological-charge, HMC/RHMC, and glueball-GEVP diagnostics. The Hamiltonian side contains exactly solvable Ising thermal truncation, compact-boson sine-Gordon vertex assembly, nonintegrable scalar ϕ^4 truncation, connected Ising TFFSA blocks, spectral-flow diagnostics, and the exact E_8 target table. The light-front side contains scalar ϕ^4 DLCQ, the large-N two-dimensional QCD matrix, and a large-K extrapolation diagnostic. The generic finite-regulator extrapolation script records the common window/covariance/remainder-envelope data used by all three classes of methods, while the benchmark-manifest script records pairwise compatibility of normalized outputs across methods.

Public Finite-Regulator Check Index

The companion-script layer is part of the mathematical presentation only when each script is read through a finite verification check. A smoke run by itself is an implementation regression; it is not a QFT result. The finite check attached to a script is the tuple

$$\mathcal{C}_{\text{num}} = \big(\mathcal{D}_{\text{fin}}, F_{\text{fin}}, \mathcal{I}_{\text{check}}, \mathcal{S}_{\text{scope}}\big),$$

where $\mathcal{D}_{\text{fin}}$ is the declared finite regulator specification, F_{fin} is the finite output map computed by the script, $\mathcal{I}_{\text{check}}$ is the list of algebraic, spectral, measure, or statistical identities checked against the chapter, and $\mathcal{S}_{\text{scope}}$ is the boundary between the finite assertion and any continuum or infinite-volume assertion. The smoke harness checks that the implementation still produces its declared finite output. The corresponding calculation-check scripts, when present, check the identities in $\mathcal{I}_{\text{check}}$. Neither layer replaces the estimates needed to pass from $\mathcal{D}_{\text{fin}}$ to a continuum QFT observable.

The public scripts currently have the following finite-check meanings.

Spin and scalar Metropolis.
The Ising and scalar ϕ^4 Metropolis scripts compute finite periodic lattice expectations for explicitly declared Boltzmann weights. Their check is invariance of the finite target measure under the displayed single-site Metropolis kernels, together with local energy or action-difference identities. They do not prove Onsager scaling, constructive ϕ^4_2, a critical surface, or an Ising CFT limit.

Compact gauge samplers.
The finite $\mathbb{Z}_2$, $SU(2)$ Metropolis, $SU(2)$ heat-bath and overrelaxation, and $SU(3)$ HDF5 sampler scripts compute finite compact link-integrals and Wilson-loop estimators. Their checks are gauge invariance of the measured finite observables, Haar measure preservation, detailed

balance or conditional heat-bath invariance, and the declared data coordinate convention. They do not prove continuum Yang–Mills, mass gaps, confinement, topological sector sampling, or a production continuum extrapolation.

Flow, smearing, topology, and static-potential analysis.

The Wilson flow, APE smearing, clover topology diagnostic, static potential, static-source GEVP, and glueball GEVP scripts compute finite analysis functionals of saved lattice data. Their checks are finite group projection, covariance of smearing, the declared clover diagnostic, nonlinear jackknife and bootstrap propagation for Wilson-loop ratios, exact static-source matrix spectral identities, and finite generalized eigenvalue residual control. They do not define a continuum topological charge, a continuum static potential, or a physical glueball spectrum without the continuum estimates of Chapters 140 and 143.

HMC, RHMC, and Markov-chain error analysis.

The HMC and RHMC smoke module and the autocorrelation and resampling script compute finite algorithmic diagnostics: HMC reversibility defects, Hamiltonian changes, positive-matrix spectral edges, rational pseudofermion actions, solver residuals, autocorrelations, block errors, and jackknife and bootstrap coordinates. Their checks are the finite symplectic and reversibility identities, determinant or rational-determinant bookkeeping, and finite time-series formulae. They do not prove ergodic sampling of a large production ensemble or a continuum-determinant limit.

Hamiltonian truncation and TCSA/TFFSA matrices.

The Ising energy benchmark, sine-Gordon zero-mode, sine-Gordon oscillator vertex, scalar ϕ^4 truncation, connected Ising TFFSA, TFFSA spectral-flow, and E_8 target-data scripts compute finite matrices or exact finite target data. Their checks are finite Hermiticity, selection rules, normal-ordering conventions, residual or spectral-flow identities, and the Perron–Frobenius convention check for the E_8 target table. They do not prove cutoff-extrapolated spectra. For the sine-Gordon, nonintegrable ϕ^4, and magnetic-Ising TCSA/TFFSA E_8 comparisons, the counterterm, finite-volume, and cutoff-error data specified above remain separate hypotheses.

DLCQ and light-front finite matrices.

The scalar ϕ^4 DLCQ, large-N two-dimensional QCD DLCQ, and large-K extrapolation scripts compute finite matrices at harmonic resolution K, together with diagnostics at fixed spectral label. Their checks are positive longitudinal partition bookkeeping, finite principal value or normal ordered matrix identities, positivity of the finite quadratic form in the declared model, and finite least squares amplification for a declared large-K ansatz. They do not prove the $K \to \infty$ continuum spectrum without zero-mode, endpoint, constraint, and remainder estimates.

Extrapolation, manifests, and cluster wrappers.

The finite-regulator extrapolation, benchmark-manifest, and cluster-grid scripts compute finite bookkeeping checks: correlated-window intercepts with declared covariance and remainder envelopes, componentwise benchmark-manifest compatibility, and deterministic grid-to-task assignment for cluster sweeps. They do not create a cutoff ansatz, validate a systematic error model, or promote a small cluster run to a continuum QFT calculation.

This index is deliberately redundant with the comments printed by the scripts and with `qft_scripts/README.md`, where exact filenames and smoke commands are listed. Its role in the monograph is to make the finite mathematical object visible before the reader interprets any number produced by a public script.

For the magnetic Ising theory, the present public scripts deliberately stop at finite checks: the TFFSA connected-block matrix fixes the spin-field normalization convention, the spectral-flow script checks finite Hellmann–Feynman slopes, and the E_8 script fixes the continuum target mass-ratio table. A full comparison between a finite TCSA/TFFSA spectrum, Euclidean lattice correlators, and the exact E_8 masses still requires a declared finite-volume convention, cutoff counterterms, extrapolation envelopes, and comparison estimates in the sense of Definition 145.22.

145.19 Benchmark Protocol

A benchmark for any truncation method should specify:

$$\text{regulated Hilbert space}, \qquad \text{operator basis}, \qquad \text{counterterm coordinates},$$
$$\text{observables used for matching}, \qquad \text{extrapolation model}, \qquad \text{independent checks}.$$

Independent checks include Ward identities, known finite-volume limits, reflection positivity where applicable, spectral sum rules, and comparison with Euclidean lattice or exact integrable data in overlapping regimes.

The public companion-script policy is recorded in `planning/14_code_policy.md`. The script smoke harness

```
tools/run_qft_scripts_smoke.sh
```

runs the finite lattice, Hamiltonian-truncation, TCSA/TFFSA, DLCQ, finite-extrapolation, and benchmark-manifest smoke examples. Passing that harness verifies only the finite computations and internal consistency checks just described.

Open Problem 145.24 (Controlled QFT truncation)*.* Develop Hamiltonian truncation and DLCQ schemes with computable error bounds for interacting QFT observables, including counterterm determination, constraint preservation, zero-mode treatment, continuum extrapolation, and public benchmark scripts.

Chapter 146

Lattice Fermions And Chiral Symmetry

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Fermions on a lattice require two separate pieces of structure. The variables integrated in the Euclidean functional integral are generators of a finite Grassmann algebra, so the finite-cutoff integral is a Berezin functional rather than a Borel measure. The fields reconstructed after Osterwalder–Schrader positivity are operator-valued distributions satisfying graded locality. The purpose of this chapter is to state the finite algebraic regulator precisely, to identify where chiral symmetry is lost or modified at nonzero lattice spacing, and to record the reflection-positive fermion constructions that can serve as honest nonperturbative cutoffs.

146.1 Finite Lattice Grassmann Integral

Let $\Lambda \subset a\mathbb{Z}^D$ be a finite lattice with a chosen ordering of the pairs (x, α), where $x \in \Lambda$ and $\alpha = 1, \ldots, N_s$ is a spinor, flavor, and internal index. The fermionic field variables are odd generators

$$\psi_\alpha(x), \qquad \bar{\psi}_\alpha(x)$$

of the complex Grassmann algebra $\bigwedge(\mathbb{C}^{2N_s|\Lambda|})$. They are not points of a configuration space. A lattice fermion action quadratic in the fields is specified by a finite matrix D with entries

$$D_{xy}^{\alpha\beta} : \mathbb{C}^{N_s|\Lambda|} \longrightarrow \mathbb{C}^{N_s|\Lambda|},$$

and is written

$$S_D(\bar\psi, \psi) = \sum_{x,y\in\Lambda} \bar\psi_\alpha(x) D_{xy}^{\alpha\beta} \psi_\beta(y).$$

The Berezin functional is normalized by

$$\int \prod_{(x,\alpha)} d\bar\psi_\alpha(x) d\psi_\alpha(x) \prod_{(x,\alpha)} \bar\psi_\alpha(x)\psi_\alpha(x) = 1.$$

Changing this ordering changes both numerator and denominator by the same sign in normalized correlation functions, but a fixed ordering must be chosen before signs in reflection positivity or anomalies are meaningful.

Finite Berezin Gaussian identities. Let D be an invertible $N \times N$ complex matrix and write

$$S_D = \sum_{i,j=1}^{N} \bar\psi_i D_{ij} \psi_j.$$

With the Berezin ordering fixed above,

$$Z_D = \int \prod_i d\bar\psi_i \, d\psi_i \, e^{-S_D} = \det D.$$

For every i, j,

$$\frac{1}{Z_D} \int \prod_k d\bar\psi_k \, d\psi_k \, \bar\psi_j \psi_i \, e^{-S_D} = (D^{-1})_{ij}.$$

More generally, for equal numbers of ψ's and $\bar\psi$'s, the normalized expectation is the determinant of the matrix of two-point functions, with the sign fixed by the displayed order of the insertions.

Introduce independent odd sources $\eta_i, \bar\eta_i$. Completing the square is an identity in the finite Grassmann algebra:

$$-\bar\psi D\psi + \bar\eta\psi + \bar\psi\eta = -(\bar\psi - \bar\eta D^{-1}) D (\psi - D^{-1}\eta) + \bar\eta D^{-1}\eta.$$

Berezin translation invariance gives

$$\int d\bar\psi \, d\psi \, e^{-\bar\psi D\psi + \bar\eta\psi + \bar\psi\eta} = \det D \, e^{\bar\eta D^{-1}\eta}.$$

Differentiating with respect to η_i and $\bar\eta_j$, using left Grassmann derivatives in the fixed order, gives the two-point identity. Higher identities follow by differentiating the same generating functional; the exponential is quadratic in sources, so the coefficient of a monomial is the corresponding determinant.

146.2 Naive Dirac Operator And Doublers

Let γ_μ, $\mu = 1, \dots, D$, be Hermitian Euclidean gamma matrices,

$$\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}\mathbf{1}.$$

On a periodic lattice, the naive massive Dirac operator is

$$D_{\text{naive}}(p) = m\mathbf{1} + \frac{\mathrm{i}}{a}\sum_{\mu=1}^{D} \gamma_\mu \sin(ap_\mu), \qquad p_\mu \in (-\pi/a, \pi/a].$$

For $m \neq 0$ it is invertible and

$$D_{\text{naive}}(p)^{-1} = \frac{m\mathbf{1} - \frac{\mathrm{i}}{a}\sum_\mu \gamma_\mu \sin(ap_\mu)}{m^2 + a^{-2}\sum_\mu \sin^2(ap_\mu)}. \tag{146.1}$$

The massless symbol vanishes at every corner of the Brillouin zone:

$$p_\mu = \frac{\pi}{a}\epsilon_\mu, \qquad \epsilon_\mu \in \{0, 1\}.$$

The existence of these 2^D zeros is the elementary doubling phenomenon. The next proposition is a precise finite-dimensional version of the topological obstruction in the translation-invariant nearest-continuum setting.

Proposition 146.1 (Brillouin-torus index cancellation)**.** *Let $f = (f_1, \dots, f_D) : \mathbb{T}^D \to \mathbb{R}^D$ be a smooth periodic map whose zeros are isolated and nondegenerate. Consider the massless translation-invariant Dirac symbol*

$$D_f(p) = \mathrm{i}\sum_{\mu=1}^{D} \gamma_\mu f_\mu(p).$$

The chirality sign of a zero p_* is

$$\chi(p_*) = \operatorname{sign}\det\left(\frac{\partial f_\mu}{\partial p_\nu}(p_*)\right).$$

Then

$$\sum_{f(p_*)=0} \chi(p_*) = 0.$$

For $f_\mu(p) = a^{-1}\sin(ap_\mu)$, the zero at the corner $\epsilon \in \{0, 1\}^D$ has

$$\chi_\epsilon = (-1)^{\epsilon_1 + \cdots + \epsilon_D},$$

so the 2^D naive species split equally between the two chirality signs.

Proof. For a regular value $y \in \mathbb{R}^D$ of f, define

$$I(y) = \sum_{f(p)=y} \operatorname{sign}\det\left(\frac{\partial f_\mu}{\partial p_\nu}(p)\right).$$

The set of regular values is open and dense by Sard's theorem. On a connected component of regular values, $I(y)$ is locally constant: if $y(s)$ is a small path of regular values and $f(p_0) = y(0)$, the inverse function theorem gives a unique smooth branch $p(s)$ with $f(p(s)) = y(s)$, and the sign of the nonzero Jacobian determinant cannot change along the branch. No signed zero can appear or disappear while the value remains regular.

Since $f(\mathbb{T}^D)$ is compact, choose y_∞ outside the image. Then $I(y_\infty) = 0$. Connect 0 to y_∞ by a piecewise smooth path and perturb the path, keeping its endpoints fixed, so that it meets the critical-value set only at isolated crossing parameters. At such a crossing, the standard local normal form for a birth–death critical point creates or annihilates a pair of simple preimages with opposite Jacobian signs; hence the signed count does not change. Therefore $I(0) = I(y_\infty) = 0$. This is the degree-zero statement for a map from the torus to $\mathbb{R}^D$.

For the naive symbol,

$$\frac{\partial f_\mu}{\partial p_\nu} = \delta_{\mu\nu} \cos(ap_\mu),$$

and at $p_\mu = \pi\epsilon_\mu/a$ the determinant is $(-1)^{\epsilon_1+\cdots+\epsilon_D}$. □

Remark 146.2. The proposition proves the topological core of doubling for symbols of the form $D_f = \mathrm{i}\gamma \cdot f$. The full Nielsen–Ninomiya theorem allows a broader class of local, translation-invariant, chirally symmetric lattice Dirac operators. Its proof is the same degree-theoretic obstruction after one constructs the appropriate normalized vector field on the Brillouin torus. The hypotheses matter: dropping exact lattice chiral symmetry, ultralocality, or the finite-component Dirac symbol changes the conclusion.

146.3 Wilson Fermions

Wilson's construction changes the massless symbol by adding a spin-scalar lattice Laplacian:

$$D_W(p) = m\mathbf{1} + \frac{\mathrm{i}}{a}\sum_{\mu=1}^{D} \gamma_\mu \sin(ap_\mu) + \frac{r}{a}\sum_{\mu=1}^{D}(1 - \cos(ap_\mu))\mathbf{1}, \qquad r > 0. \tag{146.2}$$

In position space, with gauge links $U_\mu(x)$ in a unitary representation of the gauge group,

$$\begin{aligned}(D_W\psi)(x) &= (m + rDa^{-1})\psi(x) \\ &\quad - \frac{1}{2a}\sum_{\mu}\Big[(r - \gamma_\mu)U_\mu(x)\psi(x + a\hat{\mu}) + (r + \gamma_\mu)U_\mu(x - a\hat{\mu})^{-1}\psi(x - a\hat{\mu})\Big].\end{aligned} \tag{146.3}$$

The Wilson term is gauge covariant and local at fixed a. It is not chirally symmetric: when D is even and $\gamma_5 = \mathrm{i}^{D/2}\gamma_1 \cdots \gamma_D$, the scalar Wilson term does not anticommute with γ_5.

Wilson lifting of the naive species. Let $p = p_\epsilon + k$, where

$$(p_\epsilon)_\mu = \frac{\pi}{a}\epsilon_\mu, \qquad \epsilon_\mu \in \{0, 1\},$$

and ak_μ is small. Put

$$n_\epsilon = \epsilon_1 + \cdots + \epsilon_D.$$

Then the Wilson symbol has the expansion

$$D_W(p_\epsilon + k) = \left(m + \frac{2rn_\epsilon}{a}\right)\mathbf{1} + \mathrm{i}\sum_\mu (-1)^{\epsilon_\mu}\gamma_\mu k_\mu + O(a|k|^2).$$

Thus the physical corner $n_\epsilon = 0$ has mass m, while every doubler corner has mass $m + 2rn_\epsilon/a$, which diverges in lattice units as $a \to 0$ when m is held in the scaling window.

For $p_\mu = \pi\epsilon_\mu/a + k_\mu$,

$$\sin(ap_\mu) = (-1)^{\epsilon_\mu} ak_\mu + O(a^3|k_\mu|^3),$$

and

$$1 - \cos(ap_\mu) = 1 - (-1)^{\epsilon_\mu}\cos(ak_\mu) = 2\epsilon_\mu + O(a^2k_\mu^2).$$

Substitution in (146.2) gives the displayed expansion. The term $2rn_\epsilon/a$ is present exactly at corners with $n_\epsilon > 0$. Thus the Wilson term distinguishes the physical corner from the doubler corners by a regulator-scale mass shift while preserving the linear Dirac behavior of the physical corner.

146.4 Mid-link Reflection Positivity

Reflection positivity for fermions is a statement about an antilinear anti-automorphism of the Grassmann algebra and about the sign of the factor coupling the two halves of the lattice. It is not automatic from positivity of a determinant. We record the finite algebraic mechanism because this is where many informal discussions lose the distinction between a Berezin functional and a measure.

Let the reflection plane be the mid-link plane

$$x_0 = \frac{a}{2}.$$

Let

$$\Lambda_+ = \{x \in \Lambda : x_0 \geq a\}, \qquad \Lambda_- = \{x \in \Lambda : x_0 \leq 0\},$$

and let $\vartheta(t, \mathbf{x}) = (a - t, \mathbf{x})$. Choose the Euclidean time gamma matrix so that $\gamma_0^\dagger = \gamma_0$ and $\gamma_0^2 = \mathbf{1}$. The reflection Θ is defined on positive-time generators by

$$\Theta\big(\psi_\alpha(x)\big) = (\gamma_0)_\beta{}^\alpha\bar{\psi}_\beta(\vartheta x), \qquad \Theta\big(\bar{\psi}_\alpha(x)\big) = (\gamma_0)_\alpha{}^\beta\psi_\beta(\vartheta x),$$

extended antilinearly and with reversed order,

$$\Theta(AB) = \Theta(B)\Theta(A).$$

Figure 146.1 records the midlink reflection used in the lattice-fermion reflection-positivity argument and the induced exchange of fermion and antifermion variables under Θ.

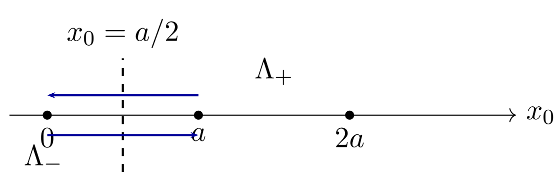

Figure 146.1: The mid-link reflection plane lies between neighboring time slices. The crossing hopping terms are the only terms that do not belong entirely to one half of the lattice.

Definition 146.3 (Fermionic reflection-positive crossing factor)**.** Let $\mathcal{A}_+$ be the Grassmann algebra generated by positive-time variables. A crossing factor is reflection-positive if it can be written, with a fixed ordering of the odd generators $F_1, \dots, F_M \in \mathcal{A}_+$, as

$$B_\times = \prod_{j=1}^{M} \bigl(1 + c_j \Theta(F_j) F_j\bigr), \qquad c_j \geq 0.$$

Proposition 146.4 (Finite Grassmann reflection-positivity criterion)**.** *Suppose a finite fermion functional has the form*

$$\langle A \rangle = \frac{1}{Z} \int d\mu_-\, d\mu_+\, \Theta(e^{-S_+})\, e^{-S_+}\, B_\times\, A,$$

where $S_+ \in \mathcal{A}_+$, $B_\times$ is a reflection-positive crossing factor in the sense of Definition 146.3, and $Z = \langle 1 \rangle > 0$. Then

$$\langle \Theta(O) O \rangle \geq 0$$

for every $O \in \mathcal{A}_+$.

Proof. Set

$$\Psi = e^{-S_+} O.$$

Because the F_j have a fixed order, expanding the crossing factor gives

$$B_\times = \sum_{I \subset \{1,\dots,M\}} c_I\, \Theta(F_I) F_I, \qquad c_I = \prod_{j \in I} c_j \geq 0,$$

where the ordered monomial F_I includes the sign convention needed to put $\Theta(F_I)F_I$ in reflected-positive order. The factorization of the Berezin volume into negative and positive halves and the anti-linear reflection convention give

$$\int d\mu_-\, d\mu_+\, \Theta(\Psi)\, B_\times\, \Psi = \sum_I c_I \int d\mu_-\, d\mu_+\, \Theta(F_I \Psi)\, F_I \Psi.$$

To see the sign and positivity explicitly, choose the ordered monomial basis $\{e_A\}$ of $\mathcal{A}_+$ normalized so that

$$\int d\mu_-\, d\mu_+\, \Theta(e_A) e_B = \delta_{AB}.$$

This normalization is exactly the finite Grassmann analogue of choosing an orthonormal basis in the positive-time algebra; it is fixed once the order of the generators and of their reflected partners has been fixed. Write

$$F_I \Psi = \sum_A z_{I,A} e_A.$$

Anti-linearity of Θ gives

$$\int d\mu_-\, d\mu_+\, \Theta(F_I \Psi)\, F_I \Psi = \sum_A |z_{I,A}|^2.$$

All possible signs from moving negative-time reflected generators past positive-time generators have already been absorbed into the definition of the ordered monomial F_I; no further indefinite form appears. Since each $c_I \geq 0$, the finite sum is nonnegative. Division by the positive normalization Z preserves the inequality. □

Proposition 146.5 (Free nearest-neighbor fermion: only the mid-link cut)**.** *For the free nearest-neighbor Dirac action with Hermitian Euclidean gamma matrices and reflection $x_0 \mapsto a - x_0$, the hopping terms crossing the plane $x_0 = a/2$ can be written as a reflection-positive crossing factor. The site reflection $x_0 \mapsto -x_0$ and the diagonal reflection generated by $e_0 + e_1$ fail already on one-fermion two-point tests for generic spinors.*

Proof. For the mid-link reflection, the only cross-plane nearest-neighbor terms are the links between $x_0 = 0$ and $x_0 = a$. In a basis diagonalizing the spin reflection pairing, the cross-plane part of the Boltzmann factor is a finite product of factors

$$1 + c\,\Theta(\chi_j)\chi_j, \qquad c > 0,$$

where each χ_j is one of the positive-time boundary Grassmann generators or its reflected spinor linear combination. Nilpotence makes the exponential of each bilinear equal to $1 + c\Theta(\chi_j)\chi_j$. Thus Definition 146.3 applies, and Proposition 146.4 proves reflection positivity.

The failure of the other cuts can be seen without a general theorem. For a one-particle positive-side test $O = \zeta^\alpha \psi_\alpha(x)$, the reflected two-point function is obtained from (146.1). For a site reflection in the time direction, the odd part of the $\sin p_0$ numerator integrates to zero and the remaining term contains

$$m\,\zeta^\dagger \gamma_0 \zeta \int_{-\pi/a}^{\pi/a} \frac{\cos(2p_0 x_0)\,\mathrm{d}p_0}{m^2 + a^{-2}\sin^2(ap_0) + B(\mathbf{p})},$$

where $B(\mathbf{p}) \geq 0$ is independent of p_0. The Hermitian form $\zeta^\dagger\gamma_0\zeta$ is indefinite, so the expression cannot be nonnegative for all spinors. For the diagonal reflection, the analogous test produces the indefinite Hermitian form $\zeta^\dagger(\gamma_0 + \gamma_1)\zeta$ after the symmetric momentum integral. Hence neither reflection gives OS positivity on the one-fermion subspace. $\square$

Wilson mid-link positivity at $r = 1$. For the gauge-covariant Wilson operator (146.3) with $r = 1$, unitary gauge links, and the mid-link time reflection, the cross-plane Wilson hopping term is a reflection-positive crossing factor after diagonalizing the positive semidefinite projectors

$$P_\pm = \frac{1}{2}(1 \pm \gamma_0).$$

The time-direction part of the Wilson action contains the cross-plane terms

$$-\frac{1}{a}\bar\psi(0,\mathbf{x})P_+ U_0(0,\mathbf{x})\psi(a,\mathbf{x}) - \frac{1}{a}\bar\psi(a,\mathbf{x})P_- U_0(0,\mathbf{x})^{-1}\psi(0,\mathbf{x}),$$

with all spin, color, and spatial indices suppressed. Reflection sends the second term to the first, with the unitary link reflected to its inverse. Choose orthonormal bases of the ranges of P_+ and P_-. In these bases the two crossing bilinears are a finite sum of terms

$$c_j\,\Theta(F_j)F_j, \qquad c_j = a^{-1} > 0,$$

where the link matrix is absorbed into the positive-side linear combination F_j. Nilpotence again turns the exponential of each bilinear into $1 + c_j\Theta(F_j)F_j$. Hence Definition 146.3 and Proposition 146.4 apply.

146.5 Staggered Fermions And A Reflection-positive Thirring Coupling

In two dimensions choose $\gamma_0 = \sigma_3$, $\gamma_1 = \sigma_1$. The staggered one-component field $\eta(x), \bar{\eta}(x)$ has kinetic matrix

$$M(x, x + a\hat{\mu}) = \frac{1}{2a}\eta_\mu(x), \qquad M(x, x - a\hat{\mu}) = -\frac{1}{2a}\eta_\mu(x - a\hat{\mu}),$$

with

$$\eta_0(x) = 1, \qquad \eta_1(x) = (-1)^{x_0/a}.$$

The action is

$$S_{\text{stag}} = \sum_{x,y} \bar{\eta}(x)M(x,y)\eta(y) + m\sum_x \bar{\eta}(x)\eta(x).$$

The mid-link reflection acts by

$$\Theta(\eta(x)) = (-1)^{x_1/a}\bar{\eta}(\vartheta x), \qquad \Theta(\bar{\eta}(x)) = (-1)^{x_1/a}\eta(\vartheta x),$$

with order reversal.

Proposition 146.6 (Staggered Thirring reflection positivity)**.** *Add the nearest-neighbor four-fermion interaction*

$$\Delta S = U\sum_{x,\mu} \bar{\eta}(x)\eta(x + a\hat{\mu})\bar{\eta}(x + a\hat{\mu})\eta(x).$$

For $U \geq 0$, the two-dimensional staggered fermion functional with action $S_{\text{stag}} + \Delta S$ is reflection positive for the mid-link time reflection.

Proof. The free staggered kinetic and mass terms have the mid-link crossing form already described for the nearest-neighbor fermion functional: all terms strictly on the positive half-lattice are placed in S_+, their reflected partners are placed in $\Theta(S_+)$, and the hopping terms crossing the reflection plane have a positive crossing-factor expansion.

It remains to check the quartic interaction at the reflection plane. Links entirely inside one half again belong to S_+ or to $\Theta(S_+)$. The only interaction terms crossing the plane are, for x on the positive boundary,

$$U\,\bar{\eta}(\vartheta x)\eta(x)\bar{\eta}(x)\eta(\vartheta x).$$

Using the displayed reflection rule and the order reversal, this monomial is the reflected-positive bilinear in the even positive-side generator $F_x = \eta(x)\bar{\eta}(x)$. More explicitly, with the fixed ordering of the positive generators,

$$e^{-\Delta S_\times} = \prod_{x \in P_+} \left(1 + U\,\Theta(\eta(x)\bar{\eta}(x))\,\eta(x)\bar{\eta}(x)\right),$$

because the square of each Grassmann quartic monomial vanishes. The different boundary links involve distinct Grassmann generators, so the finite product expands into a sum $\sum_I U^{|I|}\Theta(F_I)F_I$ with nonnegative coefficients precisely when $U \geq 0$. The full Boltzmann factor is therefore in the form required by Definition 146.3, and the finite reflection-positivity criterion, Proposition 146.4, applies. $\square$

146.6 Ginsparg–Wilson Relation

The Wilson term removes doublers by breaking the naive chiral symmetry. Ginsparg–Wilson fermions replace the naive anticommutation relation by a finite-cutoff identity. A lattice Dirac operator D satisfies the Ginsparg–Wilson relation with lattice spacing a if

$$\gamma_5 D + D\gamma_5 = aD\gamma_5 D. \tag{146.4}$$

Assume also γ_5-Hermiticity,

$$D^\dagger = \gamma_5 D\gamma_5.$$

Lemma 146.7 (Exact lattice chiral symmetry and the finite Berezinian)**.** *Let D satisfy* (146.4) *and γ_5-Hermiticity. The finite action*

$$S = \bar\psi D\psi$$

is invariant under the infinitesimal transformation

$$\delta\psi = \varepsilon\,\gamma_5(1-aD)\psi, \qquad \delta\bar\psi = \varepsilon\,\bar\psi\gamma_5.$$

If the finite spinor space has $\operatorname{Tr}\gamma_5 = 0$, the Berezin measure transforms by

$$d\bar\psi'\,d\psi' = \exp\Big(-2\varepsilon\ \operatorname{Tr}\gamma_5\left(1-\frac{a}{2}D\right) + O(\varepsilon^2)\Big)\,d\bar\psi\,d\psi.$$

The integer

$$\operatorname{index}(D) = \operatorname{Tr}\gamma_5\left(1-\frac{a}{2}D\right) \tag{146.5}$$

is the finite-cutoff index associated with the Ginsparg–Wilson operator.

Proof. The variation of the action is

$$\begin{aligned}\delta S &= \varepsilon\,\bar\psi\gamma_5 D\psi + \varepsilon\,\bar\psi D\gamma_5(1-aD)\psi\\ &= \varepsilon\,\bar\psi\big(\gamma_5 D + D\gamma_5 - aD\gamma_5 D\big)\psi = 0.\end{aligned}$$

For odd variables, the Berezin measure transforms with the inverse determinant. Therefore

$$d\psi' = \det\big(1+\varepsilon\gamma_5(1-aD)\big)^{-1}d\psi, \qquad d\bar\psi' = \det(1+\varepsilon\gamma_5)^{-1}d\bar\psi.$$

Taking logarithms gives

$$\log J = -\varepsilon\operatorname{Tr}\gamma_5(1-aD) - \varepsilon\operatorname{Tr}\gamma_5 + O(\varepsilon^2).$$

When $\operatorname{Tr}\gamma_5 = 0$, this becomes

$$\log J = \varepsilon a\ \operatorname{Tr}\gamma_5 D = -2\varepsilon\operatorname{Tr}\gamma_5\left(1-\frac{a}{2}D\right),$$

which is the displayed formula.

The integrality of the trace follows from a finite spectral argument. Define

$$\widehat{\gamma}_5 = \gamma_5(1-aD).$$

γ_5-Hermiticity gives

$$\widehat{\gamma}_5^\dagger = (1 - aD^\dagger)\gamma_5 = (1 - a\gamma_5 D\gamma_5)\gamma_5 = \gamma_5(1 - aD) = \widehat{\gamma}_5.$$

Multiplying the Ginsparg–Wilson relation by γ_5 on the left gives

$$D + \gamma_5 D\gamma_5 = a\gamma_5 D\gamma_5 D,$$

and therefore

$$\widehat{\gamma}_5^2 = (1 - a\gamma_5 D\gamma_5)(1 - aD) = 1.$$

Thus $\widehat{\gamma}_5$ is a Hermitian involution on the finite spinor space. Its eigenvalues are ± 1, so $\operatorname{Tr}\widehat{\gamma}_5 = \dim E_+ - \dim E_-$. Since $\operatorname{Tr}\gamma_5 = 0$, the finite spinor space is even-dimensional, and $\dim E_+ - \dim E_-$ is even. Finally,

$$\operatorname{Tr}\gamma_5\left(1 - \frac{a}{2}D\right) = \frac{1}{2}\operatorname{Tr}(\gamma_5 + \widehat{\gamma}_5) = \frac{1}{2}\operatorname{Tr}\widehat{\gamma}_5 \in \mathbb{Z}.$$

□

146.7 Overlap Operator

Let D_W be the Wilson operator with a negative mass parameter in the usual overlap window, and define the Hermitian kernel

$$H_W = \gamma_5(D_W - m_0/a).$$

Assume H_W has no zero eigenvalues. Let

$$\epsilon(H_W) = \operatorname{sign}(H_W) = H_W(H_W^2)^{-1/2}.$$

The overlap operator is

$$D_{\text{ov}} = \frac{1}{a}\left(\mathbf{1} + \gamma_5\epsilon(H_W)\right). \tag{146.6}$$

Overlap operator satisfies Ginsparg–Wilson. If $H_W = H_W^\dagger$ has no zero modes, then D_{ov} satisfies

$$\gamma_5 D_{\text{ov}} + D_{\text{ov}}\gamma_5 = aD_{\text{ov}}\gamma_5 D_{\text{ov}}.$$

Put

$$V = \gamma_5\epsilon(H_W).$$

Since $\epsilon(H_W)^\dagger = \epsilon(H_W)$ and $\epsilon(H_W)^2 = \mathbf{1}$, one has

$$V^\dagger = \epsilon(H_W)\gamma_5, \qquad V^\dagger V = \mathbf{1}.$$

Moreover $V^\dagger = \gamma_5 V\gamma_5$. Thus

$$D_{\text{ov}} = \frac{1}{a}(1 + V), \qquad D_{\text{ov}}^\dagger = \gamma_5 D_{\text{ov}}\gamma_5.$$

Unitarity of V gives

$$D_{\text{ov}} + D_{\text{ov}}^\dagger = \frac{1}{a}(2 + V + V^\dagger) = aD_{\text{ov}}^\dagger D_{\text{ov}}.$$

Multiplying this identity on the left by γ_5 and using $D_{\text{ov}}^\dagger = \gamma_5 D_{\text{ov}}\gamma_5$ gives the Ginsparg–Wilson relation.

Overlap index as spectral asymmetry. For the overlap operator,

$$\mathrm{index}(D_{\mathrm{ov}}) = -\frac{1}{2}\,\mathrm{Tr}\,\epsilon(H_W).$$

Using (146.6),

$$\gamma_5\left(1-\frac{a}{2}D_{\mathrm{ov}}\right) = \gamma_5\left(1-\frac{1}{2}(1+\gamma_5\epsilon(H_W))\right) = \frac{1}{2}\gamma_5 - \frac{1}{2}\epsilon(H_W).$$

The finite spinor-lattice trace of γ_5 vanishes, hence

$$\mathrm{Tr}\,\gamma_5\left(1-\frac{a}{2}D_{\mathrm{ov}}\right) = -\frac{1}{2}\,\mathrm{Tr}\,\epsilon(H_W).$$

The left-hand side is the Ginsparg–Wilson lattice index written as a finite trace, so the equality identifies the index with the spectral asymmetry of the Hermitian Wilson kernel H_W.

146.8 Domain-wall Fermions And The Overlap Limit

Domain-wall fermions realize the same chiral mechanism by adding a finite fifth lattice direction $s = 1, \dots, L_s$ with a mass profile whose sign changes across the wall. The low-energy modes are localized near opposite walls and have opposite chirality. At finite L_s their overlap gives a residual mass. In the limit $L_s \to \infty$, after integrating out the bulk fifth-dimensional modes, the effective four-dimensional operator is the overlap operator (146.6). Thus domain-wall fermions and overlap fermions should not be viewed as two unrelated solutions: one is a local higher-dimensional regulator whose infinite-wall limit produces the four-dimensional Ginsparg–Wilson operator.

The price paid by overlap fermions is that D_{ov} is not ultralocal. Locality means exponential decay of the kernel,

$$\|D_{\mathrm{ov}}(x,y)\| \le Ce^{-c|x-y|/a}.$$

This is a theorem only under hypotheses excluding near-zero modes of H_W, for instance an admissibility condition on the gauge plaquettes or a spectral-gap estimate in the gauge ensemble. Without such an estimate, the formula (146.6) still defines a finite matrix when H_W is invertible, but it does not by itself prove locality of the regulator.

146.9 Continuum Requirements

A lattice fermion construction used as a nonperturbative QFT regulator must specify the following data.

finite Grassmann algebra and Berezin ordering,

Dirac operator, gauge covariance, spin structure, and boundary conditions,

reflection positivity or a replacement Hilbert-space construction,

chiral symmetry, anomaly, and index convention,

locality estimates uniform enough for a scaling limit,

operator regularization and renormalization separate from the cutoff action.

For chiral gauge theories, the fermion determinant or Pfaffian is a section of a determinant line over the finite lattice gauge-field space. A nonperturbative definition requires a gauge-invariant, local, and reflection-compatible choice of phase. Anomaly cancellation is the local cohomological condition that makes such a choice possible perturbatively; it is not by itself a complete nonperturbative construction of the interacting continuum theory.

Open Problem 146.8 (Chiral gauge lattice)*.* Construct four-dimensional interacting chiral gauge theories on the lattice with locality, reflection positivity or an equivalent reconstruction route, exact gauge invariance, anomaly cancellation, and a continuum limit with the desired local operator algebra.

Part XII

Quantum Field Theory in Curved Spacetime and Background Fields

Chapter 147

Locally Covariant QFT and Hadamard States

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Curved-spacetime QFT is a background-field problem. The Lorentzian metric, orientation, time orientation, spin structure, background gauge bundle, and external sources are held fixed, while the quantum observables are assigned locally and covariantly to each background. The absence of a preferred translation-invariant vacuum is replaced by a condition on states: their short-distance singularity must have the same positive-frequency geometric form as the Minkowski vacuum when examined in a sufficiently small convex normal neighborhood.

This chapter fixes the functorial language and then constructs the free Klein–Gordon example in detail. The example is important because the time-slice axiom, causal propagation, commutation relations, and Hadamard subtraction are visible in one model without using a perturbative expansion.

147.1 Control Levels In Curved-Spacetime QFT

The chapters in this volume use four different levels of control. They are kept separate because the hypotheses that prove a fixed-background free-field statement are not the hypotheses that prove an interacting backreaction statement. The control-level matrix is:

Fixed-background free theory. Input data are a globally hyperbolic background, a linear hyperbolic operator, a CCR or CAR algebra, and a Hadamard state class. The controlled outputs are propagation, commutators, the two-point singularity, Wick powers, and the point-split stress tensor after finite local choices; see Chapters 147–155.

Perturbative interacting theory. Input data are the free Hadamard algebra, a local interaction, time-ordered products, causal factorization, and a renormalization prescription. The controlled outputs are relative S-matrices, interacting fields order by order, local counterterm freedom, and finite-order stress-tensor source terms; see Chapter 156.

Conditional semiclassical theory. Input data are an interacting or free stress tensor in a fixed scheme, an admissible state, gravitational EFT coordinates, and stability and response assumptions. The controlled outputs are the semiclassical Einstein equation, retarded metric response, noise kernel, Einstein–Langevin covariance, and validity windows; see Chapter 157.

Nonperturbative interacting curved QFT. Input data would be a genuine locally covariant interacting theory with controlled states and composite fields on the relevant background class. The controlled outputs would be state-independent structural claims beyond perturbation theory and exact horizon, cosmological, or interacting thermal statements. In this volume those claims appear only as open problems or as explicitly marked conditional statements.

Moving from one row to the next is a mathematical and physical strengthening: perturbative locality does not by itself give a nonperturbative state space, and a finite stress-tensor calculation does not by itself solve the semiclassical Einstein equation. The later chapters therefore state their state class, renormalization scheme, and response assumptions at the point where those assumptions first become load bearing.

147.2 Spacetimes And Causal Embeddings

Let M be a smooth D-manifold with Lorentzian metric g of mostly-plus signature. A tangent vector $v \in T_xM$ is causal when $g_x(v,v) \le 0$, timelike when $g_x(v,v) < 0$, and null when $g_x(v,v) = 0$ and $v \neq 0$. A time orientation is a continuous choice of future cone in the causal cone at every point. For a subset $S \subset M$, write $J^{\pm}_M(S)$ for the causal future and causal past of S.

Definition 147.1 (Globally hyperbolic spacetime)**.** An oriented and time-oriented Lorentzian manifold (M, g) is globally hyperbolic when it has no closed causal curve and when

$$J^+_M(p) \cap J^-_M(q)$$

is compact for every $p, q \in M$. A Cauchy surface is a subset $\Sigma \subset M$ intersected exactly once by every inextendible timelike curve. For globally hyperbolic M, smooth spacelike Cauchy surfaces exist, and M is diffeomorphic to $\mathbb{R} \times \Sigma$.

The compactness condition is the analytic input behind finite propagation statements. If $K \subset M$ is compact, then

$$J^+_M(K) \cap J^-_M(K')$$

is compact for every compact $K' \subset M$. This property is used below when a solution is cut off between two Cauchy surfaces.

Definition 147.2 (Causally convex subset)**.** An open subset $O \subset M$ is causally convex when every causal curve in M whose endpoints lie in O is entirely contained in O.

Causal convexity is the condition that lets a field equation be restricted to a subspacetime without importing causal propagation from the complement.

Definition 147.3 (Background category)**.** Let **Loc** be the category defined as follows.

An object is an oriented, time-oriented, globally hyperbolic Lorentzian manifold (M, g), possibly equipped with fixed background bundles and smooth background sources. A morphism

$$\chi : (M, g) \longrightarrow (N, h)$$

is a smooth embedding with open causally convex image such that

$$\chi^* h = g$$

and such that χ preserves the declared orientation, time orientation, and background bundle/source data. A morphism $\chi : M \to N$ is a Cauchy morphism when $\chi(M)$ contains a Cauchy surface of N.

Composition of morphisms is ordinary composition of embeddings. The image of a composite is causally convex: if a causal curve in the final spacetime has endpoints in the composite image, causal convexity of the second image first keeps the curve in the intermediate image, and causal convexity of the first image then keeps its pullback in the original image. Thus the above data form a category.

147.3 Algebra-Valued Functors

Let $\mathbf{Alg}_*$ denote a category of unital complex $*$-algebras. Its morphisms are unit-preserving injective $*$-homomorphisms. In analytic versions one uses locally convex topological $*$-algebras and continuous morphisms; the algebraic definition is enough for the functorial axioms in this chapter.

Definition 147.4 (Locally covariant QFT)**.** A locally covariant QFT is a covariant functor

$$\mathfrak{A} : \mathbf{Loc} \longrightarrow \mathbf{Alg}_*$$

with the following additional properties.

(i) If $\chi : M \to N$ is a Cauchy morphism, then

$$\mathfrak{A}(\chi) : \mathfrak{A}(M) \longrightarrow \mathfrak{A}(N)$$

is an isomorphism. This is the time-slice axiom.

(ii) If $\chi_i : M_i \to N$, $i = 1, 2$, have causally disjoint images, then

$$[\, \mathfrak{A}(\chi_1)(A_1), \mathfrak{A}(\chi_2)(A_2) \,] = 0$$

for all $A_i \in \mathfrak{A}(M_i)$. This is Einstein causality.

The injectivity of morphisms in $\mathbf{Alg}_*$ records isotony: an admissible spacetime inclusion identifies the algebra of the smaller background with a subalgebra of the larger one.

Definition 147.5 (Kinematic local algebra)**.** Let $O \subset M$ be open, causally convex, and globally hyperbolic with the induced metric and orientations. Let $\iota_{M;O} : O \hookrightarrow M$ be the inclusion morphism in **Loc**. The kinematic algebra of O inside M is

$$\mathfrak{A}^{\mathrm{kin}}(M;O) = \mathfrak{A}(\iota_{M;O})(\mathfrak{A}(O)) \subset \mathfrak{A}(M).$$

Remark 147.6 (Local net associated to a locally covariant theory). For each fixed M, the assignment

$$O \longmapsto \mathfrak{A}^{\mathrm{kin}}(M;O)$$

on causally convex globally hyperbolic open subsets is isotone and satisfies Einstein causality.

If $O_1 \subset O_2$, the inclusion factors as

$$O_1 \xrightarrow{\iota_{O_2;O_1}} O_2 \xrightarrow{\iota_{M;O_2}} M.$$

Functoriality gives

$$\mathfrak{A}(\iota_{M;O_1}) = \mathfrak{A}(\iota_{M;O_2}) \circ \mathfrak{A}(\iota_{O_2;O_1}),$$

so the image for O_1 is contained in the image for O_2. If O_1 and O_2 are causally disjoint in M, the two inclusion morphisms into M satisfy the hypothesis of Einstein causality in Definition 147.4, and the commutator of the two image algebras vanishes.

Locally covariant fields are defined by naturality. Let $\mathbf{Test}_E$ be the functor assigning to M the vector space $\Gamma_c(M, E_M)$ of compactly supported smooth sections of a natural bundle E_M, and to a morphism $\chi : M \to N$ the pushforward $\chi_* : \Gamma_c(M, E_M) \to \Gamma_c(N, E_N)$.

Definition 147.7 (Locally covariant field)**.** A locally covariant field of type E is a natural transformation

$$\Phi : \mathbf{Test}_E \Longrightarrow \mathfrak{A}.$$

Equivalently, for every M and every $f \in \Gamma_c(M, E_M)$ there is an element $\Phi_M(f) \in \mathfrak{A}(M)$, and every morphism $\chi : M \to N$ satisfies

$$\mathfrak{A}(\chi)\Phi_M(f) = \Phi_N(\chi_* f). \tag{147.1}$$

The condition is a commutative square:

$$\begin{tikzcd}
\Gamma_c(M, E_M) \arrow[r, "\Phi_M"] \arrow[d, "\chi_*"'] & \mathfrak{A}(M) \arrow[d, "\mathfrak{A}(\chi)"] \\
\Gamma_c(N, E_N) \arrow[r, "\Phi_N"'] & \mathfrak{A}(N).
\end{tikzcd}$$

147.4 States As Contravariant Data

A state on a unital $*$-algebra $\mathcal{A}$ is a linear functional $\omega : \mathcal{A} \to \mathbb{C}$ satisfying

$$\omega(\mathbf{1}) = 1, \qquad \omega(A^*A) \geq 0 \quad \text{for all } A \in \mathcal{A}.$$

Every morphism $\alpha : \mathcal{A} \to \mathcal{B}$ pulls states on $\mathcal{B}$ back to states on $\mathcal{A}$ by composition:

$$\alpha^*\omega = \omega \circ \alpha.$$

Thus a state assignment for a locally covariant theory is contravariant.

Definition 147.8 (Locally covariant state space)**.** A locally covariant state space for $\mathfrak{A}$ is a choice of subsets

$$\mathcal{S}(M) \subset \{\text{states on } \mathfrak{A}(M)\}$$

such that for every morphism $\chi : M \to N$,

$$\omega \in \mathcal{S}(N) \quad \Longrightarrow \quad \omega \circ \mathfrak{A}(\chi) \in \mathcal{S}(M).$$

Hadamard states provide the state spaces used for free scalar fields on curved backgrounds. Their definition is local in spacetime and stable under restriction to causally convex subregions.

147.5 The Free Klein–Gordon Functor

Fix real constants $m^2 \geq 0$ and $\xi \in \mathbb{R}$. For every $(M, g) \in \mathbf{Loc}$, define the real differential operator

$$P_M = -\nabla^\mu \nabla_\mu + m^2 + \xi R[g]$$

on $C^\infty(M, \mathbb{R})$. It is formally self-adjoint with respect to the pairing

$$(f, h)_M = \int_M f h \, \mathrm{d}\,\mathrm{vol}_g \, .$$

Global hyperbolicity gives unique retarded and advanced Green operators

$$E_M^{\mathrm{ret}}, E_M^{\mathrm{adv}} : C_c^\infty(M) \longrightarrow C^\infty(M)$$

with

$$\begin{aligned} P_M E_M^{\mathrm{ret}} f &= f, \qquad & P_M E_M^{\mathrm{adv}} f &= f, \\ E_M^{\mathrm{ret}} P_M f &= f, \qquad & E_M^{\mathrm{adv}} P_M f &= f, \end{aligned}$$

and support restrictions

$$\operatorname{supp} E_M^{\mathrm{ret}} f \subset J_M^+(\operatorname{supp} f), \qquad \operatorname{supp} E_M^{\mathrm{adv}} f \subset J_M^-(\operatorname{supp} f).$$

The causal propagator is

$$E_M = E_M^{\mathrm{ret}} - E_M^{\mathrm{adv}}.$$

Lemma 147.9 (Kernel of the causal propagator)**.** *For $f \in C_c^\infty(M)$,*

$$E_M f = 0 \quad \Longleftrightarrow \quad f = P_M h \textit{ for some } h \in C_c^\infty(M).$$

Proof. If $f = P_M h$ with compactly supported h, then

$$E_M f = E_M P_M h = h - h = 0,$$

using the defining identities for retarded and advanced Green operators.

Conversely assume $E_M f = 0$. Then

$$u := E_M^{\mathrm{ret}} f = E_M^{\mathrm{adv}} f.$$

The equality is an equality of smooth solutions, because both Green operators send compactly supported test functions to smooth functions and their difference is $E_M f$. The retarded representative satisfies

$$P_M u = f,$$

and the same identity holds for the advanced representative. The retarded expression has support in $J_M^+(\operatorname{supp} f)$, and the advanced expression has support in $J_M^-(\operatorname{supp} f)$. Thus

$$\operatorname{supp} u \subset J_M^+(\operatorname{supp} f) \cap J_M^-(\operatorname{supp} f),$$

which is compact by global hyperbolicity: the causal diamond of a compact set with itself is compact in a globally hyperbolic spacetime. Hence $u \in C_c^\infty(M)$, and $f = P_M u$ lies in $P_M C_c^\infty(M)$. $\square$

Define the real vector space of smeared solutions by

$$\mathcal{V}(M) = C_c^\infty(M, \mathbb{R}) / P_M C_c^\infty(M, \mathbb{R}), \qquad [f]_M \text{ for the class of } f.$$

Define

$$\sigma_M([f]_M, [h]_M) = \int_M f \, E_M h \, \mathrm{d}\,\mathrm{vol}_g \,. \tag{147.2}$$

This is well-defined because $E_M P_M = 0$ on compactly supported test functions and because P_M is formally self-adjoint. It is antisymmetric:

$$\int_M f \, E_M h \, \mathrm{d}\,\mathrm{vol}_g = -\int_M h \, E_M f \, \mathrm{d}\,\mathrm{vol}_g,$$

which follows by applying formal self-adjointness to retarded and advanced Green operators and using

$$(E_M^{\mathrm{ret}})^* = E_M^{\mathrm{adv}}.$$

Lemma 147.9 implies that σ_M is nondegenerate on $\mathcal{V}(M)$.

Definition 147.10 (CCR algebra of the scalar field)**.** The algebra $\mathfrak{A}_{\mathrm{KG}}(M)$ is the unital $*$-algebra generated by symbols $\Phi_M([f]_M)$, linear in $[f]_M$, with relations

$$\Phi_M([f]_M)^* = \Phi_M([f]_M), \qquad [\Phi_M([f]_M), \Phi_M([h]_M)] = \mathrm{i}\, \sigma_M([f]_M, [h]_M)\mathbf{1}.$$

The quotient by $P_M C_c^\infty(M)$ is the equation of motion:

$$\Phi_M(P_M h) = 0.$$

The commutator is determined by the causal propagator and therefore by the hyperbolic equation, not by a choice of state.

Proposition 147.11 (Functoriality of the free scalar field)**.** *For every morphism $\chi : M \to N$, the pushforward of test functions induces a symplectic linear map*

$$\mathcal{V}(\chi) : \mathcal{V}(M) \longrightarrow \mathcal{V}(N), \qquad [f]_M \longmapsto [\chi_* f]_N.$$

Consequently there is an injective ∗-homomorphism

$$\mathfrak{A}_{\mathrm{KG}}(\chi) : \mathfrak{A}_{\mathrm{KG}}(M) \to \mathfrak{A}_{\mathrm{KG}}(N)$$

defined by

$$\mathfrak{A}_{\mathrm{KG}}(\chi)\Phi_M([f]_M) = \Phi_N([\chi_* f]_N).$$

Proof. The embedding is isometric and preserves background scalar data, so

$$P_N \chi_* f = \chi_* P_M f.$$

Therefore χ_* maps $P_M C_c^\infty(M)$ into $P_N C_c^\infty(N)$, giving a map on quotients. Causal convexity gives compatibility of causal propagators:

$$E_N \chi_* f = \chi_* E_M f. \tag{147.3}$$

Indeed, both sides solve $P_N u = \chi_* f$ in $\chi(M)$, both vanish outside the same retarded-minus-advanced causal support determined by $\chi(\operatorname{supp} f)$, and uniqueness of retarded and advanced solutions gives equality. The volume form is preserved by χ, hence

$$\sigma_N([\chi_* f]_N, [\chi_* h]_N) = \int_N \chi_* f \, E_N \chi_* h \, \mathrm{d}\,\mathrm{vol}_h = \int_M f \, E_M h \, \mathrm{d}\,\mathrm{vol}_g = \sigma_M([f]_M, [h]_M).$$

The universal property of the CCR algebra then gives a ∗-homomorphism preserving the defining commutator. Injectivity follows from injectivity of the induced symplectic map; if $[\chi_* f]_N = 0$, then $E_N \chi_* f = 0$, so $\chi_* E_M f = 0$, hence $E_M f = 0$ and $[f]_M = 0$ by Lemma 147.9. □

Proposition 147.12 (Time-slice property for the free scalar)**.** *If $\chi : M \to N$ is a Cauchy morphism, then*

$$\mathfrak{A}_{\mathrm{KG}}(\chi) : \mathfrak{A}_{\mathrm{KG}}(M) \to \mathfrak{A}_{\mathrm{KG}}(N)$$

is an isomorphism.

Proof. It suffices to prove that $\mathcal{V}(\chi) : \mathcal{V}(M) \to \mathcal{V}(N)$ is surjective, since Proposition 147.11 already gives injectivity and the CCR algebra is generated by the smeared fields.

Let $f \in C_c^\infty(N)$ and set $u = E_N f$. Choose two smooth spacelike Cauchy surfaces Σ_- and Σ_+ contained in $\chi(M)$ such that Σ_+ lies to the future of Σ_- and the compact set

$$J_N(\operatorname{supp} f) \cap J_N^+(\Sigma_-) \cap J_N^-(\Sigma_+)$$

contains the part of u between the two surfaces. Choose a smooth function $\eta : N \to [0,1]$ that is 0 to the past of Σ_-, is 1 to the future of Σ_+, and whose derivative is supported in $\chi(M)$. Define

$$g = P_N(\eta u).$$

Since $P_N u = 0$, the support of g lies where derivatives of η are nonzero, hence $g \in C_c^\infty(\chi(M))$. Set

$$w = \eta u.$$

The section w vanishes to the past of Σ_- and satisfies $P_N w = g$, so uniqueness of the retarded Green solution gives

$$E_N^{\mathrm{ret}} g = w.$$

The section $w - u = (\eta - 1)u$ vanishes to the future of Σ_+ and also satisfies $P_N(w-u) = g$, so uniqueness of the advanced Green solution gives

$$E_N^{\mathrm{adv}} g = w - u.$$

Therefore

$$E_N g = E_N^{\mathrm{ret}} g - E_N^{\mathrm{adv}} g = w - (w-u) = u = E_N f.$$

Thus $E_N(g-f) = 0$. By Lemma 147.9, $g - f = P_N k$ for some $k \in C_c^\infty(N)$. Thus $[f]_N = [g]_N$. Since $\operatorname{supp} g \subset \chi(M)$, there is $\widetilde{g} \in C_c^\infty(M)$ with $g = \chi_* \widetilde{g}$, and $[f]_N = \mathcal{V}(\chi)[\widetilde{g}]_M$. □

147.6 Quasifree States

A state ω on $\mathfrak{A}_{\mathrm{KG}}(M)$ has n-point distributions

$$\omega_n(f_1, \ldots, f_n) = \omega(\Phi_M([f_1]) \cdots \Phi_M([f_n])) .$$

It is quasifree with vanishing one-point function when all odd n-point distributions vanish and all even n-point distributions are sums over pairings:

$$\omega_{2n}(f_1, \ldots, f_{2n}) = \sum_{\text{pairings } P} \prod_{\{i,j\} \in P} \omega_2(f_i, f_j).$$

The two-point distribution $\omega_2 \in \mathcal{D}'(M \times M)$ must satisfy

$$P_{M,x}\omega_2 = 0, \qquad P_{M,y}\omega_2 = 0,$$

$$\omega_2(f,h) - \omega_2(h,f) = \mathrm{i}\,\sigma_M([f],[h]),$$

and positivity:

$$\omega_2(\bar{f}, f) \geq 0 \quad \text{for all } f \in C_c^\infty(M, \mathbb{C}).$$

Conversely, a bidistribution with these properties defines a quasifree state on the CCR algebra.

147.7 Hadamard Form

Let x and y lie in a convex normal neighborhood $U \subset M$. Let

$$\sigma(x,y)$$

be Synge's world function: one half of the signed squared geodesic distance from x to y. Let T be any smooth time function on U, and set

$$\sigma_\epsilon(x,y) = \sigma(x,y) + \mathrm{i}\epsilon\big(T(x) - T(y)\big) + \epsilon^2, \qquad \epsilon > 0.$$

The limit $\epsilon \downarrow 0$ is taken in the distributional sense.

In four spacetime dimensions, the local Hadamard singular distribution for P_M has the form

$$H_{\epsilon,\mu}(x,y) = \frac{1}{8\pi^2}\left[\frac{U(x,y)}{\sigma_\epsilon(x,y)} + V(x,y)\log\bigl(\mu^2\sigma_\epsilon(x,y)\bigr)\right], \tag{147.4}$$

where $\mu > 0$ is a length inverse. The coefficient U is

$$U(x,y) = \Delta(x,y)^{1/2},$$

with Δ the van Vleck determinant. It is characterized by the transport equation

$$2\sigma^{;\mu}\nabla_\mu U + (\Box_g\sigma - D)U = 0, \qquad U(x,x) = 1.$$

The function V is locally determined by g, m, ξ through the requirement that $P_{M,x}H_{\epsilon,\mu}(x,y)$ have no singular part away from the diagonal. Equivalently, expanding

$$V(x,y) \sim \sum_{n\geq 0} V_n(x,y)\sigma(x,y)^n$$

gives transport equations along the geodesic from y to x, with initial data fixed recursively by P_M and the previous coefficients. The smooth part of a state is not included in $H_{\epsilon,\mu}$.

Definition 147.13 (Hadamard quasifree state)**.** A quasifree state ω of the Klein–Gordon field is Hadamard when, in every convex normal neighborhood,

$$\omega_2(x,y) - H_{\epsilon,\mu}(x,y)$$

has a smooth distributional limit as $\epsilon \downarrow 0$. The resulting smooth function is denoted $W_\omega(x,y)$.

Changing the time function T in σ_ϵ changes only the boundary-value prescription used to define the same positive-frequency singularity. Changing μ changes the subtraction by

$$\frac{1}{8\pi^2}V(x,y)\log(\mu'^2/\mu^2),$$

which is smooth near the diagonal because V is smooth.

Remark 147.14 (State-independent singular part)*.* Let ω and ω' be Hadamard quasifree states for the same operator P_M on the same globally hyperbolic spacetime. Then

$$\omega_2 - \omega_2' \in C^\infty(M \times M).$$

On each convex normal neighborhood, Definition 147.13 gives

$$\omega_2 = H_{\epsilon,\mu} + W_\omega, \qquad \omega_2' = H_{\epsilon,\mu} + W_{\omega'}$$

after taking the distributional boundary value. The same $H_{\epsilon,\mu}$ appears because U and V are fixed by (M,g), m, and ξ. Therefore

$$\omega_2 - \omega_2' = W_\omega - W_{\omega'}$$

is smooth on that neighborhood. Smoothness is local on $M \times M$, so the difference is smooth globally.

147.8 Microlocal Form And Wick Products

The local formula above is equivalent to the microlocal Hadamard condition developed in Chapter 155:

$$\mathrm{WF}(\omega_2) = \{(x, k_x; y, -k_y) : (x, k_x) \sim (y, k_y),\ k_x \in \overline{V}_+^*\}.$$

Here $(x, k_x) \sim (y, k_y)$ means that x and y are connected by a null geodesic and that k_y is the parallel transport of k_x. This condition is the curved-spacetime replacement for positive energy support.

For a Hadamard state, define the Wick square by point splitting:

$$:\phi^2:_H (f) = \int_M f(x) \lim_{y\to x} (\phi(x)\phi(y) - H_{\epsilon,\mu}(x, y)\mathbf{1})\, \mathrm{d}\,\mathrm{vol}_g(x).$$

Remark 147.14 implies that the subtraction removes the state-independent singularity. The remaining freedom is finite and local. In four dimensions,

$$:\phi^2:' = :\phi^2: + c_1 m^2 + c_2 R$$

for constants c_1, c_2, once covariance, scaling dimension, and the field equation are imposed. Stress-tensor point splitting in the next chapter is the same construction with the bidifferential operator dictated by the classical stress tensor.

147.9 Renormalization Freedom Of The Stress Tensor

The stress tensor is obtained by applying a bidifferential operator $D_{\mu\nu}(x, y)$ to the subtracted two-point expression and then taking the diagonal limit:

$$\langle T_{\mu\nu}(x)\rangle_\omega = \lim_{y\to x} D_{\mu\nu}(x, y)\big(\omega_2(x, y) - H_{\epsilon,\mu}(x, y)\big) + C_{\mu\nu}[g](x).$$

The tensor $C_{\mu\nu}[g]$ is local and covariant in the background. In four dimensions, conservation and engineering dimension restrict it to a linear combination of metric variations of

$$\int \sqrt{|g|}, \qquad \int \sqrt{|g|}R, \qquad \int \sqrt{|g|}R^2, \qquad \int \sqrt{|g|}R_{\mu\nu}R^{\mu\nu}, \qquad \int \sqrt{|g|}R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma},$$

with constants specifying the finite local curvature coordinates of the renormalized theory. This statement is a covariance and conservation classification of finite local terms; the explicit point-splitting construction and the trace-anomaly consequences are developed in Chapters 148 and 149.

Open Problem 147.15 (Interacting curved-spacetime QFT). Construct interacting locally covariant QFTs with nonperturbative control of state spaces, composite operators, stress tensors, and background dependence. The construction should compare perturbative algebraic QFT, constructive methods, lattice methods on discretized backgrounds, and Hamiltonian approaches in examples where more than one construction exists.

Chapter 148

Point Splitting and Stress Tensor Renormalization

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The previous chapter introduced Hadamard states as the admissible short-distance class for free fields on curved backgrounds. Point splitting uses the state-independent singular part of a Hadamard two-point function to define composite local fields.

148.1 Local Hadamard Subtraction Datum

Throughout this chapter the scalar operator is the one fixed in Chapter 147,

$$P_M = -\nabla^\mu \nabla_\mu + m^2 + \xi R[g], \qquad m^2 \geq 0, \qquad \xi \in \mathbb{R}. \tag{148.1}$$

Let $\mathcal{U} \subset M$ be a geodesically convex normal neighborhood. For $x, y \in \mathcal{U}$, let $\sigma(x, y)$ be Synge's world function: one half of the signed squared geodesic distance from x to y. Choose a smooth time function T on $\mathcal{U}$ and put

$$\sigma_\epsilon(x, y) = \sigma(x, y) + \mathrm{i}\epsilon\big(T(x) - T(y)\big) + \epsilon^2, \qquad \epsilon > 0. \tag{148.2}$$

The limit $\epsilon \downarrow 0$ is always distributional.

Definition 148.1 (Hadamard subtraction)**.** In four dimensions, a Hadamard subtraction for P_M on $\mathcal{U}$ is the distributional boundary value

$$H_{\epsilon,\mu}(x,y) = \frac{1}{8\pi^2}\left[\frac{U_H(x,y)}{\sigma_\epsilon(x,y)} + V_H(x,y)\log\bigl(\mu^2\sigma_\epsilon(x,y)\bigr)\right], \qquad \mu > 0, \tag{148.3}$$

where $U_H = \Delta^{1/2}$, Δ is the van Vleck determinant, and V_H is a smooth representative of the Hadamard coefficient whose jet at the diagonal is determined recursively by P_M. Different smooth representatives with the same jet, and additional smooth local biscalars added to the subtraction, change only the finite local subtraction datum; they are not part of the state.

The word "determined" in Definition 148.1 means a local transport construction of the jet of V_H at the diagonal. It is not a global Green-function prescription. To spell out the local object, write

$$V_H(x,y) \sim \sum_{j\geq 0} v_j(x,y)\sigma(x,y)^j \tag{148.4}$$

as an asymptotic expansion of smooth biscalars in a normal neighborhood. For each integer $N \geq 0$, the partial sum

$$V_H^{[N]}(x,y) = \sum_{j=0}^{N} v_j(x,y)\sigma(x,y)^j \tag{148.5}$$

is chosen so that

$$P_{M,x}\left[\frac{U_H(x,y)}{\sigma(x,y)} + V_H^{[N]}(x,y)\log\bigl(\mu^2\sigma(x,y)\bigr)\right] \tag{148.6}$$

has no negative powers of σ and no logarithmic terms through the order fixed by N. Expanding (148.6) in powers of σ gives ordinary differential equations along the unique geodesic from y to x. Since the coefficient multiplying the unknown diagonal value at the j-th step is nonzero, the transport equation fixes v_j from lower coefficients. A smooth V_H with this prescribed infinite jet exists by Borel's lemma. Replacing this representative by another one with the same jet changes $H_{\epsilon,\mu}$ by a smooth biscalar, because the difference is flat at the diagonal before multiplication by $\log\sigma$; adding any allowed smooth local biscalar is precisely a finite renormalization choice.

Lemma 148.2 (Leading Hadamard transport equation)**.** *The coefficient U_H in (148.3) is fixed by*

$$2\sigma^{;\mu}\nabla_\mu U_H + (\Box_g\sigma - 4)U_H = 0, \qquad U_H(x,x) = 1. \tag{148.7}$$

Proof. The calculation is local and may be performed for $x \neq y$, before taking the distributional boundary value. The defining identities of Synge's function in a normal neighborhood are

$$\sigma^{;\mu}\sigma_{;\mu} = 2\sigma, \qquad \Box_g\sigma = 4 + O(\sigma). \tag{148.8}$$

For a smooth biscalar U,

$$\nabla_\mu(\sigma^{-1}) = -\sigma_{;\mu}\sigma^{-2}, \qquad \Box_g(\sigma^{-1}) = -(\Box_g\sigma)\sigma^{-2} + 2\sigma^{;\mu}\sigma_{;\mu}\sigma^{-3}.$$

Using $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$, this becomes

$$\Box_g(\sigma^{-1}) = (4 - \Box_g\sigma)\sigma^{-2}.$$

Hence the most singular term in $-\Box_{g,x}(U/\sigma)$ is

$$\frac{2\sigma^{;\mu}\nabla_\mu U + (\Box_g\sigma - 4)U}{\sigma^2}.$$

The zeroth-order part $m^2+\xi R$ of P_M contributes only σ^{-1} singularities, so the σ^{-2} coefficient must vanish. This is exactly (148.7). The initial value $U_H(x,x) = 1$ gives the flat-space normalization and uniquely solves the transport equation along the geodesic from y to x; the solution is $\Delta^{1/2}$. $\square$

Lemma 148.3 (First logarithmic Hadamard coefficient). *Let $V_H = v_0 + O(\sigma)$. With the operator convention* (148.1)*, the first coefficient is fixed by*

$$2\sigma^{;\mu}\nabla_\mu v_0 + (\Box_g\sigma - 2)v_0 = P_{M,x}U_H. \tag{148.9}$$

In particular,

$$v_0(x,x) = \frac{1}{2}\left(m^2 + \left(\xi - \frac{1}{6}\right)R[g](x)\right). \tag{148.10}$$

Proof. After Lemma 148.2, the σ^{-2} coefficient in $P_{M,x}(U_H/\sigma)$ vanishes. The next singular term is therefore

$$\frac{P_{M,x}U_H}{\sigma}. \tag{148.11}$$

For a smooth biscalar v,

$$\nabla_\mu \log\sigma = \frac{\sigma_{;\mu}}{\sigma}, \qquad \Box_g \log\sigma = \frac{\Box_g\sigma - 2}{\sigma}, \tag{148.12}$$

where the second identity uses $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$. Hence

$$P_{M,x}\big(v\log\sigma\big) = (P_{M,x}v)\log\sigma - \frac{2\sigma^{;\mu}\nabla_\mu v + (\Box_g\sigma - 2)v}{\sigma}. \tag{148.13}$$

The zeroth-order part of P_M multiplies $v\log\sigma$ and contributes only the displayed logarithmic term, not a negative power of σ. Canceling the coefficient of σ^{-1} between (148.11) and (148.13) gives (148.9). Taking the coincidence limit, $\sigma^{;\mu} = 0$ and $\Box_g\sigma = 4$. Also

$$U_H(x,x) = 1, \qquad \Box_{g,x}U_H(x,y)|_{y=x} = \frac{1}{6}R[g](x), \tag{148.14}$$

which follows from the normal-coordinate expansion of $\Delta^{1/2}$. Therefore

$$P_{M,x}U_H(x,y)|_{y=x} = m^2 + \xi R - \frac{1}{6}R,$$

and (148.10) follows. $\square$

Proposition 148.4 (Hadamard logarithmic recursion). *Let*

$$V_H(x,y) \sim \sum_{j\geq 0} v_j(x,y)\sigma(x,y)^j$$

be the local Hadamard logarithmic coefficient in four dimensions. After U_H has been fixed by (148.7)*, the coefficients v_j are determined recursively along the geodesic from y to x by*

$$\big(2\sigma^{;\mu}\nabla_\mu + \Box_g\sigma - 2\big)v_0 = P_{M,x}U_H, \tag{148.15}$$

and, for $j \ge 0$,

$$\big(2\sigma^{;\mu}\nabla_\mu + \Box_g\sigma + 2j\big)v_{j+1} = \frac{1}{j+1}\,P_{M,x}v_j. \tag{148.16}$$

At coincidence this gives

$$v_{j+1}(x,x) = \frac{1}{2(j+1)(j+2)}\,P_{M,x}v_j(x,y)\big|_{y=x}. \tag{148.17}$$

The recursion fixes the complete diagonal jet of V_H. Choosing a smooth representative with that jet is a Borel-extension choice and changes the parametrix only by a smooth biscalar flat at the diagonal, hence only by a finite local subtraction in point-split composite fields.

Proof. Write $s = \sigma(x,y)$ and compute away from the diagonal. For a smooth biscalar v,

$$P_{M,x}(v\,s^k\log s) = \big(P_{M,x}(v\,s^k)\big)\log s - s^{k-1}\big(2\sigma^{;\mu}\nabla_\mu v + (\Box_g\sigma + 4k-2)v\big). \tag{148.18}$$

This follows by applying the product rule and $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$, exactly as in the proof of Lemma 148.3. The zeroth-order part $m^2 + \xi R$ contributes to the logarithmic term $(P_{M,x}(v\,s^k))\log s$, but not to the displayed nonlogarithmic coefficient.

The σ^{-1} nonlogarithmic singularity in

$$P_{M,x}\left(\frac{U_H}{s} + v_0\log s\right)$$

is $P_{M,x}U_H$ minus the $k=0$ coefficient in (148.18); setting it to zero gives (148.15). For $j \ge 0$, inspect the coefficient of $s^j\log s$ in

$$P_{M,x}\left(\sum_{\ell\ge 0} v_\ell s^\ell\right).$$

The term $P_{M,x}(v_j s^j)$ contributes $s^j P_{M,x}v_j$, while the lower-derivative part of $P_{M,x}(v_{j+1}s^{j+1})$ contributes

$$-(j+1)s^j\big(2\sigma^{;\mu}\nabla_\mu v_{j+1} + (\Box_g\sigma + 2j)v_{j+1}\big).$$

Vanishing of the coefficient of $s^j\log s$ gives (148.16). At coincidence $\sigma^{;\mu} = 0$ and $\Box_g\sigma = 4$, so (148.16) gives (148.17). The transport operator has nonzero coincidence coefficient at each step, so the value at $x = y$ and then all transverse derivatives are fixed recursively by differentiating the transport equation. Borel's lemma supplies a smooth biscalar with the prescribed infinite jet, and two such choices differ by a smooth biscalar flat at the diagonal. □

Changing the time function in (148.2) changes only the boundary-value prescription for the same local positive frequency singularity. Changing μ changes the subtraction by the smooth local biscalar

$$\frac{1}{8\pi^2}V_H(x,y)\log(\mu'^2/\mu^2). \tag{148.19}$$

Thus the singular part is state-independent, while the scale and smooth local terms are renormalization coordinates.

148.2 Wick Square

Definition 148.5 (Wick square by point splitting)**.** Let ω be a Hadamard state of the real Klein–Gordon field. Let $H(x,y)$ denote the locally covariant Hadamard parametrix, containing the singular U/σ_ϵ and $V\log\sigma_\epsilon$ terms. The point-split Wick square in state ω is the distribution defined by

$$\omega\big(:\Phi^2:(f)\big) = \int_M f(x) \lim_{y\to x}\big(\omega_2(x,y) - H(x,y)\big)\, d\mathrm{vol}_g(x).$$

Remark 148.6 (State dependence and subtraction dependence)*.* Fix a normal convex neighborhood in which the Hadamard parametrix H is defined. If ω and ω' are Hadamard states of the same Klein–Gordon field, then

$$W_{\omega,\omega'}(x,y) = \omega_2(x,y) - \omega_2'(x,y)$$

is smooth near the diagonal, and the corresponding Wick-square expectation values obey

$$\omega\big(:\Phi^2:_H(f)\big) - \omega'\big(:\Phi^2:_H(f)\big) = \int_M f(x)\, W_{\omega,\omega'}(x,x)\, d\mathrm{vol}_g(x).$$

If $H' = H + S$, where $S(x,y)$ is a smooth symmetric locally constructed biscalar, then

$$:\Phi^2:_{H'}(f) =:\Phi^2:_H(f) - \int_M f(x)S(x,x)\, d\mathrm{vol}_g(x)\,\mathbf{1}$$

as a relation between expectation values in every Hadamard state.

The defining property of a Hadamard two-point function is that, in each normal convex neighborhood, its singular part is the universal local parametrix H, while the remainder is smooth. Thus

$$\omega_2 = H + R_\omega, \qquad \omega_2' = H + R_{\omega'}$$

with R_ω and $R_{\omega'}$ smooth near the diagonal. Their difference $W_{\omega,\omega'} = R_\omega - R_{\omega'}$ is smooth, so the diagonal value $W_{\omega,\omega'}(x,x)$ is an ordinary smooth function. Subtracting the two point-splitting definitions gives the first displayed formula. For the second formula,

$$\omega_2 - H' = \omega_2 - H - S.$$

Taking the diagonal limit and smearing with f subtracts $\int f(x)S(x,x)d\mathrm{vol}_g(x)$, independent of the state. A state-independent scalar multiple of every expectation value is represented by the same scalar multiple of the identity field.

For higher Wick powers, one subtracts the parametrix in every contraction. The result is an operator-valued distribution in perturbative algebraic QFT and a quadratic form in representations where the required domains are available.

The subtraction has finite local freedom. For the Wick square in four dimensions,

$$:\Phi^2: \mapsto\, :\Phi^2: + c_1 R + c_2 m^2$$

with constants c_1, c_2, subject to the chosen covariance and scaling conditions.

148.3 Stress-Tensor Prescription and Local Freedom

The stress tensor has a sharper renormalization problem than the Wick square because a choice of finite local terms must also respect conservation and background covariance.

Definition 148.7 (Wald-type stress-tensor renormalization conditions)**.** For the scalar theory with operator P_M in (148.1), an expectation-value stress-tensor renormalization is an assignment

$$(M, g; m^2, \xi, \omega) \longmapsto \omega(T^{\text{ren}}_{\mu\nu}) \in \mathcal{D}'(M, S^2T^*M)$$

for every globally hyperbolic spacetime (M, g) and every Hadamard state ω. In this chapter the renormalization conditions are the following.

1. *Local covariance.* If $\chi : (M, g) \to (N, h)$ is an orientation- and time-orientation-preserving isometric embedding with causally convex image, and if ω_N is a Hadamard state on N, then the expectation value in the pulled-back state $\chi^*\omega_N$ equals the pullback of the expectation value on N.
2. *State dependence only through the smooth remainder.* For any two Hadamard states ω, ω', the difference $\omega(T^{\text{ren}}_{\mu\nu}) - \omega'(T^{\text{ren}}_{\mu\nu})$ is obtained by applying a fixed local bidifferential operator to the smooth biscalar $\omega_2 - \omega'_2$ and then restricting to the diagonal.
3. *Conservation.* The distributional divergence vanishes,
$$\nabla^\mu \omega(T^{\text{ren}}_{\mu\nu}) = 0, \tag{148.20}$$
for all Hadamard states in the declared state class.
4. *Metric dimension and almost homogeneous scaling.* In local formulae we assign engineering dimensions
$$[\nabla] = 1, \qquad [m] = 1, \qquad [R_{\mu\nu\rho\sigma}] = 2, \qquad [g_{\mu\nu}] = 0. \tag{148.21}$$
The state-independent local terms in $T^{\text{ren}}_{\mu\nu}$ have total dimension four. A change of the Hadamard length scale is allowed to produce only local logarithmic terms of the same dimension; this is the curved-space form of the trace-anomaly ambiguity.
5. *Flat normalization.* On Minkowski spacetime the massless vacuum expectation value is zero after the finite cosmological term is set to zero.

These are renormalization conditions on expectation values. A stronger operator-valued statement additionally requires a common domain or an algebraic definition of the composite field; that extra domain problem is not hidden in the word "stress tensor".

Definition 148.8 (Point-split stress-tensor prescription)**.** A point-split realization of Definition 148.7 for the scalar operator (148.1) assigns to every globally hyperbolic background (M, g), every Hadamard state ω, and every test tensor $f^{\mu\nu} \in C^\infty_c(M, S^2TM)$ a number $\omega(T(f))$. The prescription is required to satisfy the following conditions.

1. It is obtained locally from
$$\lim_{y \to x} \mathcal{D}_{\mu\nu}(x, y)\big(\omega_2(x, y) - H_{\epsilon,\mu}(x, y)\big) + C_{\mu\nu}[g](x), \tag{148.22}$$
where $\mathcal{D}_{\mu\nu}$ is the bidifferential operator obtained by polarizing the classical Hilbert stress tensor and $C_{\mu\nu}[g]$ is a state-independent local curvature tensor.

2. It is locally covariant: if $\chi : (M, g) \to (N, h)$ is an admissible isometric embedding in the locally covariant category and ω_N is a Hadamard state on N, then the pullback state on M has stress-tensor expectation equal to the pullback of the N-expectation.
3. Its dependence on the state is exactly through the smooth biscalar $\omega_2 - H_{\epsilon,\mu}$. Equivalently, for two Hadamard states ω, ω', the difference $\omega(T_{\mu\nu}) - \omega'(T_{\mu\nu})$ is obtained by applying $\mathcal{D}_{\mu\nu}$ to $\omega_2 - \omega_2'$ and then taking the diagonal limit.
4. It is conserved after the finite local tensor has been fixed:
$$\nabla^\mu \omega(T_{\mu\nu}) = 0 \tag{148.23}$$
for all Hadamard states in the declared state space.
5. It has engineering dimension four under constant rescaling of the metric and fields in the sense of (148.21), and it is normalized so that the Minkowski vacuum stress tensor vanishes when $m = 0$ and the finite cosmological term is set to zero.

Proposition 148.9 (Finite local freedom of the scalar stress tensor)**.** *Let $T_{\mu\nu}$ and $T'_{\mu\nu}$ be two prescriptions satisfying Definition 148.8. In four dimensions their difference is state-independent and has the form*
$$T'_{\mu\nu} - T_{\mu\nu} = a_0 m^4 g_{\mu\nu} + a_1 m^2 G_{\mu\nu} + a_2 I_{\mu\nu} + a_3 J_{\mu\nu}, \tag{148.24}$$
with real constants a_i. Here
$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu}, \tag{148.25}$$
and
$$I_{\mu\nu} = \frac{1}{\sqrt{|g|}} \frac{\delta}{\delta g^{\mu\nu}} \int \sqrt{|g|}\, R^2 \,\mathrm{d}^4x, \qquad J_{\mu\nu} = \frac{1}{\sqrt{|g|}} \frac{\delta}{\delta g^{\mu\nu}} \int \sqrt{|g|}\, R_{\alpha\beta} R^{\alpha\beta} \,\mathrm{d}^4x, \tag{148.26}$$
with compactly supported metric variations and boundary terms discarded.

Proof. Set $D_{\mu\nu} := T'_{\mu\nu} - T_{\mu\nu}$. The state-dependence clause in Definition 148.8 implies that for any two Hadamard states ω, ω',
$$\omega(D_{\mu\nu}) - \omega'(D_{\mu\nu}) = 0.$$
Thus $D_{\mu\nu}$ is a state-independent local covariant tensor constructed from $g_{\mu\nu}$, the constant mass parameter m, and curvature. The conservation clause gives $\nabla^\mu D_{\mu\nu} = 0$. The engineering dimension clause says that every monomial in $D_{\mu\nu}$ has total dimension four, counting m as dimension one, $g_{\mu\nu}$ as dimension zero, and each curvature tensor as dimension two.

The dimension-four local covariant candidates split by powers of m. The only m^4 tensor with two covariant indices and no derivatives is $m^4 g_{\mu\nu}$, and it is conserved because m is constant and $\nabla g = 0$. At order m^2 the possible curvature tensors are $m^2 R_{\mu\nu}$ and $m^2 R g_{\mu\nu}$. Their divergence is
$$\nabla^\mu (\alpha R_{\mu\nu} + \beta R g_{\mu\nu}) = \left(\frac{\alpha}{2} + \beta\right) \nabla_\nu R,$$
using the contracted Bianchi identity. Conservation therefore forces $\beta = -\alpha/2$, giving the Einstein tensor $G_{\mu\nu}$.

It remains to classify the curvature-squared part. In four dimensions the scalar local curvature densities of dimension four are spanned, modulo total derivatives, by

$$R^2, \qquad R_{\alpha\beta}R^{\alpha\beta}, \qquad R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta}.$$

Their metric Euler derivatives are symmetric conserved tensors because the corresponding integrated counterterms are diffeomorphism invariant. The dimensionless parameter ξ in the scalar stress tensor can change the constants multiplying these local tensors but cannot create a new dimension-four covariant tensor. The four-dimensional Gauss–Bonnet combination

$$E_4 = R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta} - 4R_{\alpha\beta}R^{\alpha\beta} + R^2$$

has vanishing metric variation on compactly supported variations in the interior, since its integral is topological. Hence the Euler derivative of $R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta}$ is a linear combination of the Euler derivatives of R^2 and $R_{\alpha\beta}R^{\alpha\beta}$. These two remaining Euler derivatives are precisely $I_{\mu\nu}$ and $J_{\mu\nu}$ in (148.26).

No further independent local covariant conserved tensor of this dimension is available inside the stated finite local freedom: terms with explicit derivatives, such as $\nabla_\mu\nabla_\nu R$, $g_{\mu\nu}\Box R$, and $\Box R_{\mu\nu}$, occur exactly in the Euler derivatives just described; total derivative scalar counterterms give boundary contributions under compactly supported metric variations; and tensors with more curvatures or more derivatives have dimension larger than four. Therefore $D_{\mu\nu}$ has the displayed four-parameter form. $\Box$

Proposition 148.10 (Curvature-squared Euler tensors)**.** *With the convention of* (148.26)*, the two independent curvature-squared Euler tensors are*

$$\begin{aligned} I_{\mu\nu} &= 2RR_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R^2 + 2g_{\mu\nu}\Box_g R - 2\nabla_\mu\nabla_\nu R, \\ J_{\mu\nu} &= 2R_{\mu\alpha\nu\beta}R^{\alpha\beta} - \frac{1}{2}g_{\mu\nu}R_{\alpha\beta}R^{\alpha\beta} + \nabla_\mu\nabla_\nu R - \Box_g R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}\Box_g R. \end{aligned} \tag{148.27}$$

They are conserved,

$$\nabla^\mu I_{\mu\nu} = 0, \qquad \nabla^\mu J_{\mu\nu} = 0, \tag{148.28}$$

and in four dimensions their traces are

$$g^{\mu\nu}I_{\mu\nu} = 6\Box_g R, \qquad g^{\mu\nu}J_{\mu\nu} = -2\Box_g R. \tag{148.29}$$

Proof. For the R^2 functional, use

$$\delta\sqrt{|g|} = -\frac{1}{2}\sqrt{|g|}\, g_{\mu\nu}\delta g^{\mu\nu}, \qquad \delta R = R_{\mu\nu}\delta g^{\mu\nu} + g_{\mu\nu}\Box_g\delta g^{\mu\nu} - \nabla_\mu\nabla_\nu\delta g^{\mu\nu}. \tag{148.30}$$

After two integrations by parts with compactly supported metric variation,

$$\delta\int\sqrt{|g|}R^2 = \int\sqrt{|g|}\left(2RR_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R^2 + 2g_{\mu\nu}\Box_g R - 2\nabla_\mu\nabla_\nu R\right)\delta g^{\mu\nu},$$

which is the first line of (148.27). For $\int\sqrt{|g|}R_{\alpha\beta}R^{\alpha\beta}$, the variation starts from

$$\delta\Big(\sqrt{|g|}R_{\alpha\beta}R^{\alpha\beta}\Big) = \sqrt{|g|}\left(-\frac{1}{2}g_{\mu\nu}R_{\alpha\beta}R^{\alpha\beta} + 2R_{\mu\alpha}R_\nu{}^\alpha\right)\delta g^{\mu\nu} + 2\sqrt{|g|}R^{\mu\nu}\delta R_{\mu\nu},$$

using

$$\delta R_{\mu\nu} = \frac{1}{2} g_{\mu\alpha} g_{\nu\beta} \Box_g \delta g^{\alpha\beta} + \frac{1}{2} g_{\alpha\beta} \nabla_\mu \nabla_\nu \delta g^{\alpha\beta} - \frac{1}{2} g_{\mu\alpha} \nabla_\beta \nabla_\nu \delta g^{\alpha\beta} - \frac{1}{2} g_{\nu\alpha} \nabla_\beta \nabla_\mu \delta g^{\alpha\beta}, \tag{148.31}$$

commuting covariant derivatives where needed, gives the second line. These are ordinary variational identities for compactly supported variations; no field equation is used.

Conservation follows from diffeomorphism invariance of the two functionals. For a compactly supported infinitesimal diffeomorphism generated by ζ^μ,

$$\delta_\zeta g^{\mu\nu} = -\nabla^\mu \zeta^\nu - \nabla^\nu \zeta^\mu.$$

If $E_{\mu\nu}$ denotes either variational derivative, then

$$0 = \delta_\zeta \mathcal{F} = -2 \int \sqrt{|g|}\, E_{\mu\nu} \nabla^\mu \zeta^\nu = 2 \int \sqrt{|g|}\, (\nabla^\mu E_{\mu\nu}) \zeta^\nu,$$

so $\nabla^\mu E_{\mu\nu} = 0$ distributionally, hence smoothly. Taking the trace of the two displayed formulas and using $g^{\mu\nu} \Box_g R_{\mu\nu} = \Box_g R$ gives

$$g^{\mu\nu} I_{\mu\nu} = (2 - \tfrac{D}{2}) R^2 + (2D - 2) \Box_g R, \qquad g^{\mu\nu} J_{\mu\nu} = (2 - \tfrac{D}{2}) R_{\alpha\beta} R^{\alpha\beta} - \frac{D}{2} \Box_g R.$$

Setting $D = 4$ gives (148.29). $\square$

148.4 Stress Tensor by Bidifferential Operator

For the classical scalar action

$$S[\phi] = -\frac{1}{2} \int_M \big(\nabla_\mu \phi \nabla^\mu \phi + m^2 \phi^2 + \xi R \phi^2 \big)\, d\mathrm{vol}_g$$

in mostly-plus Lorentzian convention, the stress tensor is obtained by metric variation. Quantum mechanically, define a bidifferential operator $\mathcal{D}_{\mu\nu}(x, y)$ by polarizing the classical quadratic expression in two field arguments. Then

$$\omega(T_{\mu\nu}(x)) = \lim_{y \to x} \mathcal{D}_{\mu\nu}(x, y) \big(\omega_2(x, y) - H(x, y) \big) + C_{\mu\nu}(x).$$

The local tensor $C_{\mu\nu}$ is the finite renormalization freedom classified in Proposition 148.9.

148.5 Worked Flat-Space Computation

We now compute a simple case explicitly. Let (M, η) be four-dimensional Minkowski spacetime with $\eta = \mathrm{diag}(-1, 1, 1, 1)$, and take the massless minimally coupled free scalar. The vacuum two-point distribution is

$$W_0(x, x') = \lim_{\epsilon \downarrow 0} \frac{1}{4\pi^2} \frac{1}{|\mathbf{x} - \mathbf{x}'|^2 - (t - t' - \mathrm{i}\epsilon)^2}.$$

In flat space the local Hadamard parametrix with the same $i\epsilon$ prescription is $H_0 = W_0$. Therefore the renormalized vacuum stress tensor obtained by point splitting is zero:

$$\langle T_{\mu\nu}\rangle_{0,\mathrm{ren}} = \lim_{x'\to x} \mathcal{D}_{\mu\nu}(x,x')\big(W_0(x,x') - H_0(x,x')\big) = 0,$$

if the finite flat-space cosmological-constant counterterm is set to zero. This is the explicit subtraction of the state-independent short-distance singularity.

For the thermal KMS state at inverse temperature β with respect to the inertial time t, the difference from the vacuum two-point function is smooth:

$$\Delta W_\beta(x,x') = W_\beta(x,x') - W_0(x,x')$$

$$= \int \frac{d^3k}{(2\pi)^3}\,\frac{n_\beta(\omega)}{2\omega}\left(e^{-\mathrm{i}\omega(t-t')+\mathrm{i}\mathbf{k}\cdot(\mathbf{x}-\mathbf{x}')} + e^{+\mathrm{i}\omega(t-t')-\mathrm{i}\mathbf{k}\cdot(\mathbf{x}-\mathbf{x}')}\right), \qquad \omega = |\mathbf{k}|,$$

where $n_\beta(\omega) = (e^{\beta\omega}-1)^{-1}$. Since ΔW_β is smooth, the point-split stress tensor is obtained by applying the polarized classical expression directly to this remainder. For the massless minimal tensor

$$T_{00} = \frac{1}{2}\big((\partial_t\phi)^2 + |\nabla\phi|^2\big),$$

the bidifferential operator is

$$\mathcal{D}_{00} = \frac{1}{2}\left(\partial_t\partial_{t'} + \sum_{i=1}^{3}\partial_i\partial_{i'}\right).$$

On either plane wave in ΔW_β,

$$\mathcal{D}_{00}e^{-\mathrm{i}\omega(t-t')+\mathrm{i}\mathbf{k}\cdot(\mathbf{x}-\mathbf{x}')} = \omega^2 e^{-\mathrm{i}\omega(t-t')+\mathrm{i}\mathbf{k}\cdot(\mathbf{x}-\mathbf{x}')}.$$

Taking the diagonal limit gives

$$\rho_\beta = \langle T_{00}\rangle_{\beta,\mathrm{ren}} = \int \frac{d^3k}{(2\pi)^3}\,\omega\, n_\beta(\omega) = \frac{1}{2\pi^2}\int_0^\infty \frac{k^3\,dk}{e^{\beta k}-1}.$$

The change of variables $x = \beta k$ and the expansion $(e^x-1)^{-1} = \sum_{n\ge1} e^{-nx}$ give

$$\int_0^\infty \frac{x^3\,dx}{e^x-1} = \sum_{n\ge1}\int_0^\infty x^3 e^{-nx}\,dx = 6\sum_{n\ge1}\frac{1}{n^4} = \frac{\pi^4}{15}.$$

Thus

$$\rho_\beta = \frac{\pi^2}{30\beta^4}.$$

For the spatial components,

$$T_{ij} = \partial_i\phi\,\partial_j\phi + \frac{1}{2}\delta_{ij}\big((\partial_t\phi)^2 - |\nabla\phi|^2\big),$$

so

$$\mathcal{D}_{ij} = \partial_i\partial_{j'} + \frac{1}{2}\delta_{ij}\left(\partial_t\partial_{t'} - \sum_{\ell=1}^{3}\partial_\ell\partial_{\ell'}\right).$$

For massless modes the second term vanishes on shell because $\omega^2 = |\mathbf{k}|^2$. Rotational invariance of the momentum integral gives

$$\int d\Omega\, k_i k_j = \frac{4\pi}{3}\delta_{ij} k^2,$$

and therefore

$$\langle T_{ij}\rangle_{\beta,\text{ren}} = \frac{1}{3}\rho_\beta\, \delta_{ij}.$$

The point-split computation thus yields

$$\langle T_{\mu\nu}\rangle_{\beta,\text{ren}} = \frac{\pi^2}{90\beta^4}\begin{pmatrix} 3 & 0 & 0 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\end{pmatrix}_{\mu\nu},$$

in the inertial frame. Its trace is $-\rho_\beta + 3p_\beta = 0$, as required for the massless conformal equation of state in flat spacetime.

148.6 Constant-Curvature Diagnostic

A de Sitter-invariant Hadamard state of a free scalar has a stress-tensor expectation value constrained by symmetry to the form

$$\langle T_{\mu\nu}\rangle_{\text{dS}} = C\, g_{\mu\nu}.$$

For the massless conformally coupled real scalar in four dimensions, the state-dependent classical trace vanishes. With the trace-anomaly convention of Chapter 149, the real scalar has $a = 1/360$, $c = 1/120$, and

$$\langle T^\mu{}_\mu\rangle = \frac{1}{16\pi^2}\left(cW_{\mu\nu\rho\sigma}W^{\mu\nu\rho\sigma} - aE_4 + b\Box R\right).$$

On four-dimensional de Sitter with Hubble parameter H,

$$W_{\mu\nu\rho\sigma} = 0, \qquad \Box R = 0, \qquad R = 12H^2,$$

$$R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} = 24H^4, \quad R_{\mu\nu}R^{\mu\nu} = 36H^4, \quad E_4 = 24H^4.$$

Consequently

$$4C = \langle T^\mu{}_\mu\rangle = -\frac{H^4}{240\pi^2}, \qquad C = -\frac{H^4}{960\pi^2}.$$

This calculation isolates the part fixed by local covariance, de Sitter invariance, and the anomaly normalization. Massive fields, and schemes that allow additional dimension-four metric counterterms, shift C by finite local terms; the point-splitting prescription must state that choice.

148.7 Conservation and Trace

Definition 148.11 (Conserved stress tensor)**.** Within a locally covariant point-splitting scheme, a renormalized stress tensor is called conserved when its finite local curvature terms have been chosen so that

$$\nabla^\mu \omega(T_{\mu\nu}) = 0$$

for all Hadamard states in the declared class.

The trace has the form

$$\omega(T^{\mu}{}_{\mu}) = m^2\,\omega(:\Phi^2:) + (\xi - \xi_c)\,\omega(\Box :\Phi^2:) + \mathcal{A}[g, m, \xi],$$

where $\xi_c = (D-2)/(4D-4)$ and $\mathcal{A}$ is a local curvature scalar determined up to the same finite renormalization freedom. In the massless conformally coupled case, the state-dependent classical trace terms vanish and the remaining local term is the trace anomaly.

148.8 Relation to Flat-Space Composite Operators

Point splitting is an operator-definition scheme. It differs from defining a regularized composite operator by inserting a classical functional into a regulated path integral and then renormalizing. The two schemes can be compared by finite local counterterms when both are defined on the same background and state class. This comparison is the curved-background version of the operator-coordinate changes developed in the renormalization volume.

Open Problem 148.12 (Interacting stress tensors beyond formal perturbation). Construct stress tensors for interacting curved-spacetime QFTs with nonperturbative control of domains, local covariance, conservation, trace anomalies, and state dependence. A solution should identify the exact relation between locally covariant composite fields and flat-space renormalized operator schemes.

Chapter 149

Trace Anomalies and Background Variations

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The preceding chapter defined renormalized stress tensors on curved backgrounds by locally covariant point splitting. The present chapter studies the trace of that stress tensor. The trace anomaly is a local response of the renormalized source functional to a Weyl variation of the background metric. It is part of the same curved-background QFT datum as the stress tensor, its contact terms, and its finite curvature counterterms.

149.1 Metric Source Convention

Let M be a closed smooth D-manifold and let g be a Riemannian metric. Write

$$\mathcal{W}[g, \lambda]$$

for the renormalized Euclidean effective action, including all declared background sources λ besides the metric. In a path-integral regularization this is $-\log Z[g, \lambda]$, after local counterterms have been fixed. The stress-tensor expectation value is defined by

$$\delta_g \mathcal{W}[g, \lambda] = -\frac{1}{2} \int_M d^D x \sqrt{g}\, \langle T^{\mu\nu}(x) \rangle_{g,\lambda}\, \delta g_{\mu\nu}(x). \tag{149.1}$$

Equivalently,

$$\langle T^{\mu\nu}(x)\rangle_{g,\lambda} = -\frac{2}{\sqrt{g}}\frac{\delta \mathcal{W}}{\delta g_{\mu\nu}(x)}.$$

For a local Weyl parameter $\sigma \in C^\infty(M)$,

$$\delta_\sigma g_{\mu\nu} = 2\sigma g_{\mu\nu}.$$

Substituting this variation into (149.1) gives

$$\delta_\sigma \mathcal{W}[g,\lambda] = -\int_M d^D x\,\sqrt{g}\,\sigma(x)\,\langle T^\mu{}_\mu(x)\rangle_{g,\lambda}. \tag{149.2}$$

Definition 149.1 (Trace-anomaly density)**.** For a theory whose classical curved-background action is Weyl invariant after the assigned transformations of all sources λ, the renormalized trace-anomaly density $\mathcal{A}[g,\lambda]$ is the local scalar density coefficient defined by

$$\langle T^\mu{}_\mu(x)\rangle_{g,\lambda} = \mathcal{A}[g,\lambda](x)$$

in the vacuum or state-independent part of the Weyl response. Thus

$$\delta_\sigma \mathcal{W}[g,\lambda] = -\int_M d^D x\,\sqrt{g}\,\sigma\,\mathcal{A}[g,\lambda]. \tag{149.3}$$

If the theory has mass parameters, relevant couplings, or fields assigned nontrivial Weyl transformations, the trace Ward identity contains additional operator terms such as $\beta^i\mathcal{O}_i$, masses times composite operators, and improvement terms. This chapter isolates the purely local curvature part which remains in a conformal theory or in the state-independent part of a locally covariant stress tensor.

149.2 Wess–Zumino Consistency

Let

$$\mathbf{A}_\sigma[g,\lambda] := \int_M d^D x\,\sqrt{g}\,\sigma\,\mathcal{A}[g,\lambda].$$

The Weyl transformations form an abelian Lie algebra:

$$[\delta_{\sigma_1},\delta_{\sigma_2}]g_{\mu\nu} = 0$$

when the source transformations are also abelian. Since $\mathcal{W}[g,\lambda]$ is a functional, the commutator of its two Weyl variations must vanish.

Remark 149.2 (Wess–Zumino consistency)*.* Assume the Weyl variation of $\mathcal{W}$ is local and has the form (149.3). Then

$$\delta_{\sigma_1}\mathbf{A}_{\sigma_2} - \delta_{\sigma_2}\mathbf{A}_{\sigma_1} = 0. \tag{149.4}$$

If a finite local counterterm $B[g,\lambda]$ is added to $\mathcal{W}$, then

$$\mathbf{A}_\sigma \longmapsto \mathbf{A}_\sigma - \delta_\sigma B. \tag{149.5}$$

Therefore the intrinsic trace anomaly is a class in local Weyl cohomology: local solutions of (149.4) modulo local Weyl variations of counterterms.

The Weyl transformations are abelian on the metric-source space under the present hypotheses:

$$[\delta_{\sigma_1}, \delta_{\sigma_2}] = 0.$$

Using $\delta_\sigma \mathcal{W} = -\mathbf{A}_\sigma$,

$$0 = [\delta_{\sigma_1}, \delta_{\sigma_2}]\mathcal{W} = -\delta_{\sigma_1}\mathbf{A}_{\sigma_2} + \delta_{\sigma_2}\mathbf{A}_{\sigma_1}.$$

This is (149.4). If $\mathcal{W}' = \mathcal{W} + B$, then

$$-\mathbf{A}'_\sigma = \delta_\sigma \mathcal{W}' = -\mathbf{A}_\sigma + \delta_\sigma B,$$

which gives (149.5).

The consistency condition is a local cohomological statement only after locality has been supplied. In perturbation theory, locality follows from the locality of counterterms. For free fields on curved backgrounds, it follows from the local Hadamard parametrix or, equivalently, from local heat-kernel coefficients. In a nonperturbative locally covariant QFT, locality is an additional structural property of the background dependence.

149.3 Curvature Variations under Weyl Rescaling

The classification in low dimensions uses a few explicit Weyl variations.

Weyl variation of the R^2 counterterm. On a D-dimensional Riemannian manifold,

$$\delta_\sigma \sqrt{g} = D\sigma\sqrt{g}, \tag{149.6}$$

$$\delta_\sigma R = -2\sigma R - 2(D-1)\nabla^2\sigma, \tag{149.7}$$

where $\nabla^2 = \nabla_\mu \nabla^\mu$. In $D = 4$, these imply

$$\delta_\sigma \int_M d^4x\, \sqrt{g}\, R^2 = -12 \int_M d^4x\, \sqrt{g}\, \sigma\, \nabla^2 R \tag{149.8}$$

on a closed manifold. The variation of the volume form follows from $\delta\sqrt{g} = \frac{1}{2}\sqrt{g}\, g^{\mu\nu}\delta g_{\mu\nu}$. The standard variation of the scalar curvature under a metric variation $h_{\mu\nu}$ is

$$\delta R = -R^{\mu\nu}h_{\mu\nu} + \nabla^\mu\nabla^\nu h_{\mu\nu} - \nabla^2(g^{\mu\nu}h_{\mu\nu}).$$

Putting $h_{\mu\nu} = 2\sigma g_{\mu\nu}$ gives (149.7). In $D = 4$,

$$\delta_\sigma(\sqrt{g}\, R^2) = 4\sigma\sqrt{g}\, R^2 + 2\sqrt{g}\, R(-2\sigma R - 6\nabla^2\sigma) = -12\sqrt{g}\, R\nabla^2\sigma.$$

Integrating by parts twice gives (149.8).

Equation (149.8) is the concrete reason why the coefficient of $\nabla^2 R$ in four dimensions is a scheme coordinate. Adding $\kappa(16\pi^2)^{-1}\int \sqrt{g}\, R^2$ shifts the coefficient b in the convention below by 12κ.

149.4 Two-Dimensional Anomaly

In two dimensions, the local parity-even scalar of Weyl weight two is the Ricci scalar. The trace anomaly of a unitary two-dimensional conformal field theory is written

$$\langle T^\mu{}_\mu \rangle_g = -\frac{c}{24\pi} R. \tag{149.9}$$

The coefficient c is the Virasoro central charge when the stress tensor is normalized by

$$\langle T(z)T(0) \rangle = \frac{c}{2z^4}$$

on the flat complex plane.

Let $\hat{g}_{\mu\nu} = e^{2\tau} g_{\mu\nu}$. The functional

$$S^{(2)}_{\mathrm{WZ}}[\tau; g] = -\frac{c}{24\pi} \int_M d^2x \sqrt{g} \left(\tau R + (\nabla\tau)^2 \right)$$

satisfies

$$S^{(2)}_{\mathrm{WZ}}[\tau + \sigma; g] - S^{(2)}_{\mathrm{WZ}}[\tau; g] = -\frac{c}{24\pi} \int_M d^2x \sqrt{\hat{g}}\, \sigma\, R[\hat{g}] + O(\sigma^2)$$

for infinitesimal σ. Hence it integrates the anomaly (149.9). In two dimensions,

$$\sqrt{\hat{g}}\, R[\hat{g}] = \sqrt{g}\, (R - 2\nabla^2\tau).$$

Varying $S^{(2)}_{\mathrm{WZ}}$ with respect to τ gives

$$\delta_\sigma S^{(2)}_{\mathrm{WZ}} = -\frac{c}{24\pi} \int_M \sqrt{g}\, \sigma (R - 2\nabla^2\tau) = -\frac{c}{24\pi} \int_M \sqrt{\hat{g}}\, \sigma R[\hat{g}],$$

after integrating by parts in the $(\nabla\tau)^2$ term.

149.5 Four-Dimensional Parity-Even Anomaly

In four dimensions define

$$E_4 = R_{\mu\nu\rho\sigma} R^{\mu\nu\rho\sigma} - 4R_{\mu\nu} R^{\mu\nu} + R^2$$

and

$$W^2 = W_{\mu\nu\rho\sigma} W^{\mu\nu\rho\sigma} = R_{\mu\nu\rho\sigma} R^{\mu\nu\rho\sigma} - 2R_{\mu\nu} R^{\mu\nu} + \frac{1}{3} R^2.$$

For a parity-even four-dimensional conformal theory on a closed manifold, the metric trace anomaly has the form

$$\langle T^\mu{}_\mu \rangle_g = \frac{1}{16\pi^2} \left(c\, W^2 - a\, E_4 + b\, \nabla^2 R \right) \tag{149.10}$$

plus terms involving other background fields when such sources are present.

Remark 149.3 (Four-dimensional cohomology representatives). Modulo local Weyl variations of dimension-four metric counterterms and total derivatives, the parity-even metric anomaly on a closed four-manifold has the two nontrivial representatives E_4 and W^2. The term $\nabla^2 R$ is shifted by the local counterterm $\int \sqrt{g}\, R^2$.

The dimension-four parity-even scalar curvature basis is spanned by

$$R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}, \qquad R_{\mu\nu}R^{\mu\nu}, \qquad R^2, \qquad \nabla^2 R.$$

The two combinations E_4 and W^2 displayed above are linearly independent. The integral of E_4 is topological on a closed four-manifold, so its Weyl variation is a total derivative and satisfies Wess–Zumino consistency. The density $\sqrt{g}\,W^2$ is pointwise Weyl invariant in four dimensions, so it also satisfies consistency. The $\nabla^2 R$ term is the Weyl variation of the R^2 counterterm by (149.8). These three directions span the basis modulo a choice of representative, leaving E_4 and W^2 as the nontrivial local cohomology classes in this sector.

If background gauge fields are present, further type-B terms appear. For a dimensionless background gauge field A, the density $\mathrm{tr}_{\mathcal{R}}\, F_{\mu\nu}F^{\mu\nu}$ has Weyl weight four, so its coefficient is constrained by the flavor current two-point normalization and by the choice of current-source convention. Parity-odd terms and manifolds with boundary require a separate orientation and boundary classification.

149.6 Heat-Kernel Derivation for Free Conformal Fields

The following computation gives a controlled derivation of the free-field entries in (149.10). Let P be a positive Laplace-type operator on a vector bundle $E \to M$, written

$$P = -(g^{\mu\nu}\nabla_\mu\nabla_\nu + \mathcal{E}).$$

Let $\Omega_{\mu\nu} = [\nabla_\mu, \nabla_\nu]$. On a closed four-manifold, the local heat-kernel expansion is

$$\mathrm{Tr}\, e^{-sP} \sim \frac{1}{(4\pi s)^2}\sum_{n\geq 0} s^n \int_M d^4x\,\sqrt{g}\,\mathrm{tr}_E\, a_{2n}(P).$$

The coefficient needed for the logarithmic Weyl response is

$$\begin{aligned}\mathrm{tr}_E\, a_4(P) = \mathrm{tr}_E \Bigg[&\frac{1}{360}\left(5R^2 - 2R_{\mu\nu}R^{\mu\nu} + 2R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}\right)\mathbf{1} \\ &+\frac{1}{6}R\mathcal{E} + \frac{1}{2}\mathcal{E}^2 + \frac{1}{12}\Omega_{\mu\nu}\Omega^{\mu\nu}\Bigg] + \nabla_\mu J^\mu. \end{aligned} \tag{149.11}$$

The divergent logarithmic term in $\frac{1}{2}\log\det P$ is proportional to $\int \mathrm{tr}\, a_4(P)$. For Grassmann fields and gauge fields one includes the corresponding minus signs, square-root factors, and ghost determinants.

For a real conformally coupled scalar in four dimensions,

$$P_\phi = -\nabla^2 + \frac{1}{6}R = -(\nabla^2 + \mathcal{E}), \qquad \mathcal{E} = -\frac{1}{6}R,$$

and $\Omega_{\mu\nu} = 0$. The non-derivative part of $\mathrm{tr}\, a_4(P_\phi)$ is

$$\frac{1}{180}\left(R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - R_{\mu\nu}R^{\mu\nu}\right).$$

Equivalently,

$$a_{\text{scalar}} = \frac{1}{360}, \qquad c_{\text{scalar}} = \frac{1}{120}.$$

Substituting $\mathcal{E} = -R/6$ and $\Omega_{\mu\nu} = 0$ into (149.11) gives the R^2 coefficient

$$\frac{5}{360} - \frac{1}{36} + \frac{1}{72} = 0.$$

The remaining terms are

$$\frac{2}{360} R^2_{\mu\nu\rho\sigma} - \frac{2}{360} R^2_{\mu\nu} = \frac{1}{180}(R^2_{\mu\nu\rho\sigma} - R^2_{\mu\nu}).$$

Using

$$cW^2 - aE_4 = (c-a)R^2_{\mu\nu\rho\sigma} + (-2c+4a)R^2_{\mu\nu} + \left(\frac{c}{3} - a\right) R^2$$

with $a = 1/360$, $c = 1/120$, gives the same curvature combination.

For the remaining free conformal fields, the same heat-kernel formula is applied to the squared Dirac operator and to the gauge-fixed Maxwell complex. The fermion sign and the vector ghost subtraction are part of the determinant calculation:

$$\mathcal{W}_{\text{Dirac}} = -\frac{1}{2} \log\det P_{\mathcal{D}}, \qquad \mathcal{W}_{\text{Maxwell}} = \frac{1}{2} \log\det P_1 - \log\det P_0.$$

Here

$$P_{\mathcal{D}} = \mathcal{D}^2 = -\nabla^2 + \frac{1}{4} R,$$

while P_1 is the Hodge Laplacian on one-forms and P_0 the scalar ghost Laplacian. Gamma-matrix traces in the spin bundle and the one-form/ghost bundle traces reduce the logarithmic terms to the following table:

free conformal field	a	c
real scalar	$\frac{1}{360}$	$\frac{1}{120}$
Weyl fermion	$\frac{11}{720}$	$\frac{1}{40}$
Dirac fermion	$\frac{11}{360}$	$\frac{1}{20}$
Maxwell vector	$\frac{31}{180}$	$\frac{1}{10}$

The Weyl fermion entries are half the Dirac entries. The vector entries include the Faddeev-Popov ghost determinant and refer to the gauge-invariant stress tensor rather than the unconstrained one-form determinant alone.

149.7 Example: N=4 Yang-Mills

Consider free four-dimensional $\mathcal{N} = 4$ Yang-Mills fields in the adjoint representation of a compact gauge group G, with

$$\dim G = d_G.$$

Per generator of G, the field content is one Maxwell vector, four Weyl fermions, and six real conformal scalars. Therefore

$$a_{\mathcal{N}=4}/d_G = \frac{31}{180} + 4\frac{11}{720} + 6\frac{1}{360} = \frac{1}{4},$$

and

$$c_{\mathcal{N}=4}/d_G = \frac{1}{10} + 4\frac{1}{40} + 6\frac{1}{120} = \frac{1}{4}.$$

Thus

$$a_{\mathcal{N}=4} = c_{\mathcal{N}=4} = \frac{1}{4}\dim G$$

in the free normalization. Supersymmetry and current multiplet arguments protect this equality in the interacting conformal theory once the theory and stress-tensor multiplet have been constructed with a compatible renormalization scheme.

149.8 Contact Terms and Local Covariance

The anomaly is a statement about coincident stress-tensor insertions as well as one-point functions. Functional differentiation of (149.3) gives

$$g_{\mu\nu}(x)\,\langle T^{\mu\nu}(x)T^{\rho\sigma}(y)\rangle_{\text{conn}} = \frac{2}{\sqrt{g}(y)}\frac{\delta}{\delta g_{\rho\sigma}(y)}\mathcal{A}[g](x) + \text{index-variation contact terms.}$$

At separated points in a flat conformal theory the trace vanishes. The curvature anomaly records the contact distribution obtained by varying through curved backgrounds and then returning to flat space. This is why the same coefficient c controls both the W^2 anomaly and the normalization of the separated stress-tensor two-point function, whereas a first appears in genuinely three-stress-tensor contact data.

In the locally covariant language, the assignment

$$(M, g, \lambda) \longmapsto \mathcal{W}[g, \lambda]$$

should be replaced by a functorial algebra of observables, a class of Hadamard states, and locally covariant composite fields. The anomaly is then the obstruction to choosing the stress tensor so that it is simultaneously conserved, locally covariant, and Weyl covariant with the declared finite renormalization freedom.

149.9 Status of the Curved-Background Theorem

For free scalar, spinor, and gauge fields, the heat-kernel and point-splitting constructions give theorem-level anomaly formulas once the operator domain, gauge fixing, ghost determinant, and finite local counterterms are fixed. In perturbative algebraic QFT, the anomaly appears in the local covariance and scaling behavior of time-ordered products. For a general nonperturbative interacting QFT, the following ingredients are required:

(i) a locally covariant curved-background QFT object replacing $\mathcal{W}[g, \lambda]$;

(ii) stress-tensor insertions as locally covariant composite fields;

(iii) a contact-term prescription for multiple metric variations;

(iv) a proof that Weyl variation is local modulo allowed counterterms;

(v) compatibility with gauge and gravitational anomaly lines for other background fields;

(vi) a rule identifying which finite curvature counterterms are part of the chosen renormalization scheme.

Open Problem 149.4 (Trace anomaly from nonperturbative QFT data). Formulate trace anomalies directly from nonperturbative local QFT data on curved backgrounds. The construction should identify the algebraic, functorial, or analytic object replacing $\mathcal{W}[g, \lambda]$, define stress-tensor contact terms, prove locality of Weyl variation, and recover the local Weyl cohomology class without importing a perturbative regulator as part of the definition.

Chapter 150

The Unruh Effect and Wedge Modular Theory

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The Unruh effect is the thermal character of the Minkowski vacuum when observables are restricted to a Rindler wedge and time evolution is generated by Lorentz boosts. The precise local-QFT theorem is the Bisognano–Wichmann theorem; the accelerated-detector calculation is a concrete consequence in free-field examples.

150.1 Rindler Wedges and Boost Flow

In $\mathbb{M}^D$, define the right Rindler wedge

$$W_R = \{x \in \mathbb{M}^D : x^1 > |x^0|\}.$$

The boost preserving W_R is

$$x^0(\eta) = x^0 \cosh\eta + x^1 \sinh\eta, \qquad x^1(\eta) = x^1 \cosh\eta + x^0 \sinh\eta.$$

Let K be the self-adjoint generator of this boost representation,

$$U(\eta) = \exp(\mathrm{i}\eta K).$$

For a uniformly accelerated observer with proper acceleration a, the Rindler time parameter is $\eta = a\tau$, where τ is proper time.

150.2 KMS Statement

Let $\mathcal{A}(W_R)$ be the von Neumann algebra generated by observables localized in W_R. The vacuum state restricted to $\mathcal{A}(W_R)$ is KMS at inverse temperature 2π with respect to boost time if, for $A, B \in \mathcal{A}(W_R)$, the function

$$F_{A,B}(\eta) = \langle \Omega, A\, U(\eta) B\, U(\eta)^{-1} \Omega \rangle$$

extends to the strip $0 < \operatorname{Im} \eta < 2\pi$ and satisfies the KMS boundary relation

$$F_{A,B}(\eta + 2\pi \mathrm{i}) = \langle \Omega, U(\eta) B\, U(\eta)^{-1} A \Omega \rangle.$$

In proper time, the temperature is therefore

$$T_{\text{Unruh}} = \frac{a}{2\pi}.$$

150.3 Complex Boost Geometry

The factor 2π in the preceding definition is fixed by the complexified boost geometry. This subsection records the elementary geometry because it is the part of the Unruh effect that is often hidden behind a detector calculation.

Let Λ_η denote the boost in the (x^0, x^1)-plane:

$$(\Lambda_\eta x)^0 = x^0 \cosh \eta + x^1 \sinh \eta, \qquad (\Lambda_\eta x)^1 = x^1 \cosh \eta + x^0 \sinh \eta,$$

with transverse coordinates fixed. For complex $\eta = t + \mathrm{i}s$, write $\operatorname{Im} \Lambda_\eta x$ for the imaginary part of the complex vector $\Lambda_\eta x$.

Imaginary part of a complex boost. If $y \in W_R$ and $\eta = t + \mathrm{i}s$, then

$$\operatorname{Im}(\Lambda_\eta y)^0 = \sin s\, (\Lambda_t y)^1,$$
$$\operatorname{Im}(\Lambda_\eta y)^1 = \sin s\, (\Lambda_t y)^0.$$

Consequently $\operatorname{Im} \Lambda_\eta y$ is future timelike for $0 < s < \pi$, past timelike for $\pi < s < 2\pi$, and

$$\Lambda_{t+\mathrm{i}\pi} y = -\Lambda_t y$$

in the $(0,1)$-plane. In particular $\Lambda_{t+\mathrm{i}\pi} W_R$ is the left wedge

$$W_L = \{x \in \mathbb{M}^D : x^1 < -|x^0|\}.$$

Every point of W_R is spacelike separated from every point of W_L. These are elementary hyperbolic-function identities, recorded here because they fix the tube domain used in the KMS strip. The formulas follow from

$$\cosh(t + \mathrm{i}s) = \cosh t \cos s + \mathrm{i} \sinh t \sin s, \qquad \sinh(t + \mathrm{i}s) = \sinh t \cos s + \mathrm{i} \cosh t \sin s.$$

Since $y \in W_R$, also $\Lambda_t y \in W_R$, so $(\Lambda_t y)^1 > |(\Lambda_t y)^0|$. The vector $((\Lambda_t y)^1, (\Lambda_t y)^0, 0, \ldots, 0)$ is therefore future timelike in the mostly-plus convention. Multiplication by $\sin s$ gives the future/past alternatives.

At $s = \pi$, $\cosh(t + \mathrm{i}\pi) = -\cosh t$ and $\sinh(t + \mathrm{i}\pi) = -\sinh t$, hence the stated left-wedge image. If $x \in W_R$ and $\ell \in W_L$, then

$$x^1 - \ell^1 > |x^0| + |\ell^0| \geq |x^0 - \ell^0|.$$

Thus $x - \ell$ is spacelike.

150.4 Bisognano–Wichmann Boundary and the Local Model

Remark 150.1 (Bisognano–Wichmann theorem boundary). The Bisognano–Wichmann theorem in wedge-modular form is a structural theorem about the standard pair $(\mathcal{A}(W_R), \Omega)$, where $\mathcal{A}(W_R)$ is the right-wedge algebra and Ω is the vacuum vector. Under the Wightman or Haag–Kastler hypotheses of positivity, Poincare covariance, locality, spectrum condition, and wedge cyclicity and separatingness of the vacuum, its conclusion is that the Tomita–Takesaki modular automorphism group of $(\mathcal{A}(W_R), \Omega)$ is the Lorentz boost flow preserving W_R. With the boost convention $U(\eta) = \exp(\mathrm{i}\eta K)$, this is equivalently the KMS condition at inverse boost temperature 2π.

The full theorem is kept here as an external AQFT theorem boundary. Its proof requires Tomita–Takesaki modular theory, the analytic continuation supplied by the spectrum condition, covariance under complexified boosts, and wedge locality at imaginary boost angle $\mathrm{i}\pi$. The self-contained theorem in this chapter is the free massive scalar model calculation below: it proves the same strip analyticity and KMS boundary relation directly for the polynomial wedge algebra, with every analytic domain and ordering step visible.

150.5 Free Scalar Wedge KMS

We now prove the wedge KMS property for the free scalar polynomial algebra. The result is a complete model calculation with all orderings and analytic domains visible; the full Bisognano–Wichmann theorem requires the additional net-theoretic hypotheses stated later in this chapter.

Definition 150.2 (Free scalar two-point distribution)**.** For $m > 0$, the massive scalar vacuum two-point distribution on $\mathbb{M}^D$ is

$$\Delta_+^{(m)}(z) = \int_{\mathbb{R}^{D-1}} \frac{\mathrm{d}^{D-1}\mathbf{p}}{(2\pi)^{D-1} 2E_{\mathbf{p}}} \, e^{-\mathrm{i}E_{\mathbf{p}} z^0 + \mathrm{i}\mathbf{p}\cdot\mathbf{z}}, \qquad E_{\mathbf{p}} = \sqrt{|\mathbf{p}|^2 + m^2}.$$

For test functions $f, g \in C_c^\infty(\mathbb{M}^D)$,

$$\langle \Omega, \phi(f)\phi(g)\Omega \rangle = \iint f(x)g(y)\Delta_+^{(m)}(x - y) \, \mathrm{d}x \, \mathrm{d}y.$$

The distribution $\Delta_+^{(m)}(z)$ is the boundary value of a holomorphic function in the past tube

$$\mathcal{T}_- = \{z \in \mathbb{C}^D : \operatorname{Im} z \in V_-\},$$

where V_- is the open past timelike cone. Indeed, if $\operatorname{Im} z = u \in V_-$, then

$$E_{\mathbf{p}} u^0 - \mathbf{p} \cdot \mathbf{u} \le -c_u E_{\mathbf{p}}$$

for some $c_u > 0$ on every compact subcone of V_-, and the defining mass-shell integral is absolutely convergent after the usual polynomial bounds from differentiating in z.

Theorem 150.3 (Free scalar wedge KMS)**.** *Let $f, g \in C_c^\infty(W_R)$. Let the boost automorphism act on smeared fields by*

$$\alpha_\eta(\phi(g)) = \phi(g_\eta), \qquad g_\eta(x) = g(\Lambda_{-\eta} x).$$

Then

$$F_{f,g}(\eta) = \langle \Omega, \phi(f) \alpha_\eta(\phi(g)) \Omega \rangle$$

is the lower boundary value of a function holomorphic in the strip

$$0 < \operatorname{Im} \eta < 2\pi,$$

continuous as a distributional boundary value on the two edges, and its upper boundary satisfies

$$F_{f,g}(\eta + 2\pi \mathrm{i}) = \langle \Omega, \alpha_\eta(\phi(g)) \phi(f) \Omega \rangle. \tag{150.1}$$

Proof. For real η, change variables in g_η to write

$$F_{f,g}(\eta) = \iint f(x) g(y) \Delta_+^{(m)}(x - \Lambda_\eta y) \, \mathrm{d}x \, \mathrm{d}y. \tag{150.2}$$

For $0 < \operatorname{Im} \eta < \pi$, the complex-boost geometry above implies that

$$\operatorname{Im}(x - \Lambda_\eta y) = -\operatorname{Im} \Lambda_\eta y \in V_-$$

for all $x, y \in W_R$. Since the supports of f and g are compact subsets of W_R, the image stays in a compact subcone of the past tube on compact sub-strips. Thus

$$F^{(1)}_{f,g}(\eta) = \iint f(x) g(y) \Delta_+^{(m)}(x - \Lambda_\eta y) \, \mathrm{d}x \, \mathrm{d}y$$

is holomorphic for $0 < \operatorname{Im} \eta < \pi$.

For $\pi < \operatorname{Im} \eta < 2\pi$, the same geometry says that $\operatorname{Im} \Lambda_\eta y \in V_-$. Hence

$$F^{(2)}_{f,g}(\eta) = \iint f(x) g(y) \Delta_+^{(m)}(\Lambda_\eta y - x) \, \mathrm{d}x \, \mathrm{d}y$$

is holomorphic on the upper half of the strip.

It remains to glue the two holomorphic functions across $\operatorname{Im} \eta = \pi$. At $\eta = t + \mathrm{i}\pi$, the point $\Lambda_\eta y$ lies in W_L. The complex-boost geometry above therefore makes x and $\Lambda_\eta y$ spacelike separated. The free scalar commutator is

$$[\phi(x), \phi(y)] = \mathrm{i} \Delta_m(x - y) \mathbf{1},$$

where Δ_m is the difference of the retarded and advanced fundamental solutions of $\Box - m^2$. Hyperbolic finite propagation gives $\Delta_m(z) = 0$ for spacelike z. Therefore the two boundary values

$$\Delta_+^{(m)}(x - \Lambda_{t+\mathrm{i}\pi} y) \quad \text{and} \quad \Delta_+^{(m)}(\Lambda_{t+\mathrm{i}\pi} y - x)$$

agree after smearing with $f(x)g(y)$. The edge-of-the-wedge gluing in this one-complex-variable strip is the following elementary distributional fact: if two holomorphic functions on adjacent strips have the same distributional boundary value on the common real line, they define a holomorphic function on the union. Applying it here gives a holomorphic $F_{f,g}$ on $0 < \operatorname{Im}\eta < 2\pi$.

The lower boundary is (150.2). The upper boundary is obtained from $F^{(2)}$ because $\Lambda_{\eta+2\pi\mathrm{i}} = \Lambda_\eta$:

$$\lim_{s\uparrow 2\pi} F^{(2)}_{f,g}(t+\mathrm{i}s) = \iint f(x)g(y)\Delta_+^{(m)}(\Lambda_t y - x)\,\mathrm{d}x\,\mathrm{d}y = \langle \Omega, \alpha_t(\phi(g))\phi(f)\Omega\rangle.$$

This is (150.1). □

Polynomial wedge algebra. Let $\mathcal{P}(W_R)$ be the unital $*$-algebra generated by the smeared free fields $\phi(f)$, $f \in C_c^\infty(W_R)$, modulo the free field equation and canonical commutation relations. The vacuum state restricted to $\mathcal{P}(W_R)$ is KMS at inverse boost temperature 2π with respect to α_η. The analytic input remains Theorem 150.3; the passage from fields to polynomials is Wick expansion: every vacuum n-point function of the free scalar field is a finite sum of products of two-point functions by Wick's theorem. If a polynomial B is boosted by complex η, each two-point factor connecting a field in A to a field in B is one of the strip-holomorphic functions proved in Theorem 150.3. Pairings entirely inside A or entirely inside B are independent of η or are invariant under the common boost. Products and finite sums preserve holomorphy in the strip. The boundary relation follows term by term from (150.1); the reordering at the upper edge is legitimate because the free commutator has already supplied the spacelike gluing at imaginary boost time π. This is exactly the KMS condition for all polynomial elements.

150.6 Worldline Specialization

For a uniformly accelerated trajectory in $D = 2$,

$$x^0(\tau) = a^{-1}\sinh(a\tau), \qquad x^1(\tau) = a^{-1}\cosh(a\tau),$$

the invariant separation between two points is

$$-(x(\tau) - x(0))^2 = \frac{4}{a^2}\sinh^2\!\left(\frac{a(\tau - \mathrm{i}0)}{2}\right).$$

The Wightman function along the trajectory is therefore a function of $\sinh^2(a(\tau - \mathrm{i}0)/2)$. Since

$$\sinh\!\left(\frac{a(\tau + \mathrm{i}2\pi/a)}{2}\right) = -\sinh\!\left(\frac{a\tau}{2}\right),$$

the two-point function has imaginary proper-time periodicity $\beta = 2\pi/a$ with the KMS ordering prescription. This verifies the two-point form of the free-field wedge KMS theorem on a single orbit.

150.7 Detector Response

An Unruh–DeWitt detector with energy gap $E > 0$ coupled linearly to the field has transition rate proportional to

$$\dot{P}(E) = \int_{-\infty}^{\infty} d\tau \, e^{-\mathrm{i}E\tau} W(x(\tau), x(0)).$$

The KMS condition implies detailed balance

$$\dot{P}(-E) = e^{\beta E} \dot{P}(E), \qquad \beta = \frac{2\pi}{a}.$$

Thus the detector response is thermal at temperature $a/(2\pi)$ when the coupling is weak, the detector is operated for a long time, and switching effects have been separated from the stationary rate.

Detailed balance from the KMS boundary relation. Let $G(\tau)$ be a tempered distribution which is the stationary two-point function sampled by a detector along a time-translation orbit, and suppose that it has the KMS boundary relation at inverse temperature β in the following convention:

$$G(\tau - \mathrm{i}\beta) = G(-\tau)$$

as boundary values of one holomorphic function in the strip $-\beta < \operatorname{Im} \tau < 0$. If the stationary transition rate

$$\dot{P}(E) = \int_{-\infty}^{\infty} e^{-\mathrm{i}E\tau} G(\tau) \, \mathrm{d}\tau$$

exists as the Fourier transform of this tempered distribution at $\pm E$, $E > 0$, and if the contour shift is justified by inserting a Schwartz switching function and then taking the stationary limit, then

$$\dot{P}(-E) = e^{\beta E} \dot{P}(E).$$

With a Schwartz switching function, all integrals below are ordinary absolutely convergent contour integrals; the stated distributional formula is the limit after the switching function is removed. Start from

$$\dot{P}(-E) = \int e^{\mathrm{i}E\tau} G(\tau) \, \mathrm{d}\tau = \int e^{-\mathrm{i}E\tau} G(-\tau) \, \mathrm{d}\tau.$$

Use the KMS boundary relation $G(-\tau) = G(\tau - \mathrm{i}\beta)$:

$$\dot{P}(-E) = \int_{\mathbb{R}} e^{-\mathrm{i}E\tau} G(\tau - \mathrm{i}\beta) \, \mathrm{d}\tau.$$

Shift the contour to $u = \tau - \mathrm{i}\beta$, so $\tau = u + \mathrm{i}\beta$. The exponential becomes

$$e^{-\mathrm{i}E(u+\mathrm{i}\beta)} = e^{\beta E} e^{-\mathrm{i}Eu}.$$

Holomorphy in the strip gives

$$\dot{P}(-E) = e^{\beta E} \int_{\mathbb{R}} e^{-\mathrm{i}Eu} G(u) \, \mathrm{d}u = e^{\beta E} \dot{P}(E).$$

Open Problem 150.4 (Interacting wedge thermality in examples). Develop explicit interacting examples where the wedge algebra, modular flow, and detector response can be computed or bounded beyond formal perturbation theory. The target is to connect the abstract Bisognano–Wichmann theorem with concrete nonperturbative correlation functions and operational detector limits.

Chapter 151

The Hawking Effect

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The Hawking effect is a statement about quantum fields on a fixed spacetime whose causal structure contains a future black-hole horizon. Its invariant content is not that a preferred global particle basis exists. Rather, under regularity at the future horizon and suitable propagation to future null infinity, late outgoing observables have a thermal occupation factor with temperature fixed by the surface gravity. This chapter separates four ingredients which are often compressed into one slogan: horizon regularity, exponential ray tracing, Bogoliubov mixing of wave packets, and propagation through the exterior geometry.

151.1 Stationary Horizons and Surface Gravity

Let (M, g) be a smooth Lorentzian spacetime and let χ be a Killing field. A null hypersurface $\mathcal{H}$ is a Killing horizon for χ if χ is tangent to $\mathcal{H}$, nonzero on the open horizon, and null on $\mathcal{H}$. On $\mathcal{H}$, the acceleration of the horizon generators is necessarily proportional to χ:

$$\chi^\nu \nabla_\nu \chi^\mu = \kappa \chi^\mu. \tag{151.1}$$

The proportionality factor κ is the surface gravity in the normalization of χ. For an asymptotically flat stationary black hole the normalization is fixed by requiring that χ approach a unit time translation at infinity.

Lemma 151.1 (Rindler normal form of a nonextremal horizon)**.** *Suppose $\mathcal{H}$ is a nonextremal Killing horizon, $\kappa > 0$. In a neighborhood of a horizon cross-section, the two-dimensional metric* *in the normal directions can be written, up to terms smooth in ρ^2, as*

$$ds_\perp^2 = -\kappa^2\rho^2\,dt^2 + d\rho^2.$$

Equivalently, the coordinates

$$U = -\rho e^{-\kappa t}, \qquad V = \rho e^{\kappa t}$$

are regular null coordinates through the future horizon $U = 0$, and $\chi = \partial_t$.

Proof. Choose a smooth cross-section $\Sigma \subset \mathcal{H}$. In a neighborhood of Σ one may use Gaussian null coordinates

$$(v, r, y^A), \qquad \mathcal{H} = \{r = 0\}, \qquad \chi = \partial_v,$$

where y^A are coordinates on Σ, v is the Killing parameter along the generators, and r is an affine parameter on null geodesics transverse to the horizon. The metric has the form

$$g = 2\,dv\,dr - 2\kappa r\,dv^2 + 2r h_A(r,y)\,dv\,dy^A + \gamma_{AB}(r,y)\,dy^A dy^B.$$

The coefficient of $r\,dv^2$ is fixed by (151.1): on $r = 0$, $\nabla_\chi \chi = \kappa\chi$, and nonextremality means $\kappa > 0$. Thus the normal two-dimensional part, at fixed y, is

$$ds_\perp^2 = 2\,dv\,dr - 2\kappa r\,dv^2 + O(r^2 dv^2) + O(r\,dv\,dy).$$

Put

$$r = \frac{\kappa}{2}\rho^2, \qquad t = v - \frac{1}{2\kappa}\log r = v - \frac{1}{\kappa}\log\rho + \text{constant}.$$

Then

$$dv = dt + \frac{dr}{2\kappa r} = dt + \frac{d\rho}{\kappa\rho},$$

and the leading normal metric becomes

$$\begin{aligned} 2\,dv\,dr - 2\kappa r\,dv^2 &= 2\left(dt + \frac{d\rho}{\kappa\rho}\right)\kappa\rho\,d\rho - \kappa^2\rho^2\left(dt + \frac{d\rho}{\kappa\rho}\right)^2 \\ &= -\kappa^2\rho^2 dt^2 + d\rho^2. \end{aligned}$$

The omitted coefficients are smooth functions of $r = \kappa\rho^2/2$ and of y, so the correction terms are smooth in ρ^2 in the Killing-adapted chart. Finally define

$$U = -\rho e^{-\kappa t}, \qquad V = \rho e^{\kappa t}.$$

Then $UV = -\rho^2$ and

$$-\kappa^2\rho^2 dt^2 + d\rho^2 = -\,dU\,dV,$$

up to the conventional factor used in writing a symmetric null product. Thus U, V extend smoothly through $U = 0$, the future horizon, and $\partial_t = \partial_v = \chi$. $\square$

For Schwarzschild of mass M in units $G = \hbar = c = k_B = 1$,

$$ds^2 = -\left(1 - \frac{2M}{r}\right)dt^2 + \left(1 - \frac{2M}{r}\right)^{-1} dr^2 + r^2 d\Omega_2^2.$$

Writing $r = 2M + \rho^2/(8M) + O(\rho^4/M^3)$ gives

$$ds_\perp^2 = -\left(\frac{\rho}{4M}\right)^2 dt^2 + d\rho^2 + O(\rho^4),$$

so

$$\kappa_{\text{Schw}} = \frac{1}{4M}, \qquad T_{\text{Schw}} = \frac{1}{8\pi M}.$$

151.2 Euclidean Regularity

Analytically continue the stationary time by $t = -\mathrm{i}\tau$. The normal metric becomes

$$ds_E^2 \simeq \kappa^2 \rho^2 d\tau^2 + d\rho^2.$$

This is the flat metric in polar coordinates if and only if the angular coordinate $\kappa\tau$ has period 2π. The Euclidean regularity argument therefore fixes

$$\beta_H = \frac{2\pi}{\kappa}, \qquad T_H = \frac{\kappa}{2\pi}.$$

Remark 151.2 (What Euclidean regularity proves). Assume a Euclidean QFT has been constructed on the smooth Euclidean black-hole section, the analytic continuation to stationary Lorentzian correlators exists, and the Euclidean time circle is the continuation of the normalized Killing time. Then the analytically continued stationary correlation functions satisfy the KMS periodicity at inverse temperature $\beta_H = 2\pi/\kappa$. This statement does not by itself prove existence of an interacting Lorentzian Hadamard state on a collapse spacetime.

Smoothness at $\rho = 0$ identifies $\kappa\tau$ as an angle. Hence the Euclidean Schwinger functions are periodic under $\tau \mapsto \tau + 2\pi/\kappa$, with the usual ordering around the Euclidean circle. Under the assumed Osterwalder-Schrader or analytic-continuation reconstruction for the stationary problem, Euclidean periodicity becomes the KMS boundary relation for Lorentzian Killing-time correlation functions. The final sentence records an implication that is not part of the argument: Euclidean smoothness constructs a stationary thermal object, whereas collapse requires a state empty on $\mathcal{I}^-$, regular at the future horizon, and propagated through a time-dependent geometry.

151.3 Exponential Ray Tracing in Collapse

The collapse derivation begins with the geometry of late outgoing null rays. Let v be advanced time on past null infinity $\mathcal{I}^-$, and let u be retarded time on future null infinity $\mathcal{I}^+$. Let v_0 label the last escaping ray: rays with $v < v_0$ reach $\mathcal{I}^+$, while rays with $v > v_0$ fall through the future horizon.

Universal late-time ray tracing. Assume the collapse spacetime settles at late retarded time to a stationary nonextremal black-hole exterior with future-horizon Kruskal coordinate

$$U = -C_H e^{-\kappa u}$$

near $\mathcal{I}^+$, with $C_H > 0$, and assume the past-null coordinate v is a smooth affine parameter through the last escaping ray with

$$U = A(v - v_0) + O((v - v_0)^2), \qquad A > 0.$$

Then for $v < v_0$,

$$v_0 - v = Ce^{-\kappa u} + O(e^{-2\kappa u}), \qquad C = \frac{C_H}{A} > 0,$$

or equivalently

$$u(v) = -\frac{1}{\kappa}\log\frac{v_0 - v}{C} + O(v_0 - v).$$

For an escaping ray close to the horizon, $U < 0$. Put $s = v_0 - v > 0$. The smoothness assumption at the last escaping ray gives

$$U = -As + O(s^2),$$

with $A > 0$. The horizon coordinate relation gives the same U as

$$-C_H e^{-\kappa u} = -As + O(s^2).$$

Multiplying by $-1/A$ gives

$$s - \frac{C_H}{A}e^{-\kappa u} = O(s^2).$$

For sufficiently late u, s is small and the inverse-function theorem applied to $s \mapsto s + O(s^2)$ yields

$$s = \frac{C_H}{A}e^{-\kappa u} + O(e^{-2\kappa u}).$$

Taking the logarithm of $s = Ce^{-\kappa u}(1 + O(e^{-\kappa u}))$, with $C = C_H/A$, gives

$$u = -\frac{1}{\kappa}\log\frac{s}{C} + O(s),$$

which is the stated inverse expansion.

The constants A, C_H, C are nonuniversal; the exponential rate κ is fixed by the regularity of the horizon coordinate.

151.4 Bogoliubov Coefficients from Mode Tracing

We carry out the coefficient calculation for a massless scalar field in the geometric-optics approximation. Angular variables and the exterior potential are suppressed in this section; they reappear as greybody factors below. Normalize right-moving modes on a null line by

$$f^{\text{in}}_{\omega'}(v) = \frac{1}{\sqrt{4\pi\omega'}}e^{-\mathrm{i}\omega' v}, \qquad p^{\text{out}}_{\omega}(u) = \frac{1}{\sqrt{4\pi\omega}}e^{-\mathrm{i}\omega u}, \qquad \omega, \omega' > 0.$$

Tracing p^{out}_{ω} backwards to $\mathcal{I}^-$ gives, near the singular late-time part responsible for particle creation,

$$p_\omega(v) = \frac{1}{\sqrt{4\pi\omega}}\left(\frac{v_0 - v}{C}\right)^{\mathrm{i}\omega/\kappa}\theta(v_0 - v) + \text{terms smooth across } v = v_0. \tag{151.2}$$

The smooth terms have rapidly decaying Fourier transforms at large ω' and do not determine the universal thermal ratio.

Use the Klein-Gordon product on a null line,

$$(f, g)_{\mathcal{I}^-} = -\mathrm{i}\int_{-\infty}^{\infty} f(v)\overleftrightarrow{\partial_v}\,\overline{g(v)}\,dv.$$

The expansion

$$p_\omega = \int_0^\infty d\omega' \left(\alpha_{\omega\omega'} f^{\rm in}_{\omega'} + \beta_{\omega\omega'} \overline{f^{\rm in}_{\omega'}} \right)$$

has

$$\alpha_{\omega\omega'} = (f^{\rm in}_{\omega'}, p_\omega)_{\mathcal{I}^-}, \qquad \beta_{\omega\omega'} = -(\overline{f^{\rm in}_{\omega'}}, p_\omega)_{\mathcal{I}^-}.$$

Putting $x = v_0 - v$ and $a = \omega/\kappa$, the needed oscillatory boundary values are

$$\int_0^\infty x^{\mathrm{i}a} e^{-\mathrm{i}\omega' x}\, dx = e^{-\mathrm{i}\pi/2} e^{\pi a/2} \Gamma(1+\mathrm{i}a)(\omega')^{-1-\mathrm{i}a},$$

$$\int_0^\infty x^{\mathrm{i}a} e^{+\mathrm{i}\omega' x}\, dx = e^{+\mathrm{i}\pi/2} e^{-\pi a/2} \Gamma(1+\mathrm{i}a)(\omega')^{-1-\mathrm{i}a}.$$

Equivalently, since $\Gamma(1+\mathrm{i}a) = \mathrm{i}a\,\Gamma(\mathrm{i}a)$, the singular coefficients can be written

$$\alpha_{\omega\omega'} = A_{\omega\omega'}\, e^{+\pi\omega/(2\kappa)} \Gamma(\mathrm{i}\omega/\kappa)(\omega')^{-\mathrm{i}\omega/\kappa},$$

$$\beta_{\omega\omega'} = -A'_{\omega\omega'}\, e^{-\pi\omega/(2\kappa)} \Gamma(\mathrm{i}\omega/\kappa)(\omega')^{-\mathrm{i}\omega/\kappa},$$

where $A_{\omega\omega'}$ and $A'_{\omega\omega'}$ differ only by phases and have common modulus

$$|A_{\omega\omega'}| = \frac{1}{2\pi\kappa} \sqrt{\frac{\omega}{\omega'}}.$$

Therefore

$$\frac{|\alpha_{\omega\omega'}|^2}{|\beta_{\omega\omega'}|^2} = e^{2\pi\omega/\kappa}.$$

Using

$$|\Gamma(\mathrm{i}a)|^2 = \frac{\pi}{a \sinh(\pi a)}$$

gives the explicit negative-frequency density

$$|\beta_{\omega\omega'}|^2 = \frac{1}{2\pi\kappa\, \omega'} \frac{1}{e^{2\pi\omega/\kappa} - 1}. \tag{151.3}$$

Equation (151.3) is not yet a finite particle number. The factor $1/\omega'$ is the density remnant of an idealized stationary late-time limit. Finite observables are wave-packet observables.

151.5 Wave Packets and the Planck Factor

Fix a frequency resolution $\varepsilon > 0$. For integers $j \geq 0$ and $n \in \mathbb{Z}$, define outgoing packets

$$p^{\rm out}_{jn} = \frac{1}{\sqrt{\varepsilon}} \int_{j\varepsilon}^{(j+1)\varepsilon} d\omega\, e^{2\pi \mathrm{i} n\omega/\varepsilon} p^{\rm out}_\omega. \tag{151.4}$$

The integer j labels a frequency bin and n labels retarded-time localization, with center approximately $u_n = 2\pi n/\varepsilon$.

Controlled Approximation 151.3 (Late-time packet occupation)**.** In the stationary late-time approximation determined by the exponential ray-tracing relation above, the number of incoming-vacuum quanta in the outgoing packet (j,n) is

$$\langle N_{jn}\rangle = \frac{1}{\varepsilon}\int_{j\varepsilon}^{(j+1)\varepsilon} \frac{d\omega}{e^{\beta_H\omega}-1} + o(1) \qquad (n\to+\infty), \tag{151.5}$$

where $\beta_H = 2\pi/\kappa$. If the bin is narrow compared with the scale on which the Planck factor varies, this is

$$\langle N_{jn}\rangle = \frac{1}{e^{\beta_H\omega_j}-1} + O(\varepsilon\,\partial_\omega n_\omega), \qquad \omega_j = (j+\tfrac{1}{2})\varepsilon.$$

The packet Bogoliubov coefficient is

$$\beta_{jn,\omega'} = \frac{1}{\sqrt{\varepsilon}}\int_{j\varepsilon}^{(j+1)\varepsilon} d\omega\, e^{2\pi\mathrm{i}n\omega/\varepsilon}\beta_{\omega\omega'}.$$

The packet number is

$$\langle N_{jn}\rangle = \int_0^\infty d\omega'\,|\beta_{jn,\omega'}|^2.$$

Inserting the singular coefficient gives a double integral over ω_1, ω_2 and the ω'-factor

$$\int_0^\infty \frac{d\omega'}{\omega'}(\omega')^{\mathrm{i}(\omega_2-\omega_1)/\kappa}.$$

With a large finite affine-time regulator this is the Fourier transform of a long interval in $\log\omega'$. In the infinite stationary limit it is the distribution

$$2\pi\kappa\,\delta(\omega_1-\omega_2). \tag{151.6}$$

The phase $e^{2\pi\mathrm{i}n(\omega_1-\omega_2)/\varepsilon}$ then drops out, and the remaining diagonal coefficient is exactly the Planck factor in (151.3). Nonstationary corrections from the $O(e^{-2\kappa u})$ part of the ray-tracing map and from the smooth part of the traced mode give the $o(1)$ term for packets moved to late retarded time.

The exact bin average in (151.5) can be written without approximation:

$$\frac{1}{\varepsilon}\int_{\omega_-}^{\omega_+}\frac{d\omega}{e^{\beta_H\omega}-1} = \frac{1}{\beta_H\varepsilon}\log\frac{1-e^{-\beta_H\omega_+}}{1-e^{-\beta_H\omega_-}}, \qquad \omega_\pm = j\varepsilon, (j+1)\varepsilon.$$

151.6 Two-Dimensional Flux and the Moving-Mirror Model

For a two-dimensional conformal scalar, the same exponential map determines the stress-tensor flux. Let $p(u)$ denote the incoming null coordinate of the ray reaching $\mathcal{I}^+$ at retarded time u:

$$v = p(u) = v_0 - Ce^{-\kappa u}.$$

For a CFT of central charge c in the incoming vacuum, the chiral stress tensor transforms under the reparametrization $v = p(u)$ as

$$\langle T_{uu}\rangle = -\frac{c}{24\pi}\{p,u\}, \qquad \{p,u\} = \frac{p'''}{p'} - \frac{3}{2}\left(\frac{p''}{p'}\right)^2. \tag{151.7}$$

For the exponential map,

$$\{v_0 - Ce^{-\kappa u}, u\} = -\frac{\kappa^2}{2},$$

and hence

$$\langle T_{uu} \rangle = \frac{c\,\kappa^2}{48\pi} = \frac{\pi c}{12\beta_H^2}. \tag{151.8}$$

The last equality is the thermal energy flux of one chiral CFT sector:

$$\int_0^\infty \frac{d\omega}{2\pi} \frac{\omega}{e^{\beta_H \omega} - 1} = \frac{\pi}{12\beta_H^2}$$

for $c = 1$. The moving-mirror model realizes this calculation in flat space by choosing a mirror trajectory whose ray-tracing function $p(u)$ has the same late exponential form. It is a useful model of the kinematics of Hawking radiation, not a derivation of quantum gravity.

151.7 Trans-Planckian Precursor Frequencies

The same tracing relation also shows the trans-Planckian domain of the geometric-optics derivation. A packet observed at retarded time u with frequency ω has precursor frequency on $\mathcal{I}^-$ of order

$$\omega_{\text{in}} \sim \omega \frac{du}{dv} = \frac{\omega}{\kappa(v_0 - v)} \sim \frac{\omega}{\kappa C} e^{\kappa u}.$$

For any fixed microscopic scale Λ_{micro}, sufficiently late packets have $\omega_{\text{in}} > \Lambda_{\text{micro}}$. Thus the fixed-background continuum derivation is a conditional theorem inside the assumed QFT on the assumed smooth geometry. Robustness under modified short-distance physics is a separate statement requiring a specified microscopic model and a controlled limit.

151.8 Boulware, Hartle–Hawking, and Unruh States

In a stationary eternal black-hole exterior, three quasifree scalar states serve as reference points.

(i) The Boulware state is positive-frequency with respect to the static Killing time at infinity. It is empty for static observers at infinity but is singular at the horizon.

(ii) The Hartle–Hawking state is regular on both future and past horizons of the bifurcate extension and is KMS at inverse temperature β_H with respect to the exterior Killing time.

(iii) The Unruh state is regular on the future horizon and empty on past null infinity. It is the fixed-background state appropriate to collapse and gives outgoing flux on $\mathcal{I}^+$.

These names denote state-selection properties, not extra axioms. In a given model, each state must be constructed as a positive Hadamard two-point function or by another equivalent locally covariant construction.

151.9 Greybody Factors and Four-Dimensional Flux

In an asymptotically flat black-hole spacetime, propagation from the near-horizon region to infinity includes scattering by the exterior curvature potential. For a scalar field on Schwarzschild, write the mode as

$$\phi_{\omega\ell m} = \frac{1}{r}\psi_{\omega\ell}(r_*)Y_{\ell m}(\theta,\varphi)e^{-\mathrm{i}\omega t}, \qquad \frac{dr_*}{dr} = \left(1 - \frac{2M}{r}\right)^{-1}.$$

The radial equation is

$$\left[-\frac{d^2}{dr_*^2} + V_\ell(r)\right]\psi_{\omega\ell} = \omega^2\psi_{\omega\ell}, \qquad V_\ell(r) = \left(1 - \frac{2M}{r}\right)\left(\frac{\ell(\ell+1)}{r^2} + \frac{2M}{r^3}\right).$$

Let $\Gamma_\ell(\omega)$ be the transmission probability through this one-dimensional scattering problem, normalized by unit incoming flux from the horizon. The number and energy fluxes at infinity are

$$\frac{dN}{dt\,d\omega} = \sum_{\ell,m}\frac{\Gamma_\ell(\omega)}{2\pi(e^{\beta_H\omega}-1)},$$

$$\frac{dE}{dt\,d\omega} = \sum_{\ell,m}\frac{\omega\,\Gamma_\ell(\omega)}{2\pi(e^{\beta_H\omega}-1)}.$$

The Planck factor is horizon kinematics; $\Gamma_\ell(\omega)$ is ordinary hyperbolic propagation through the exterior. Fermions replace the Bose-Einstein denominator by $e^{\beta_H\omega}+1$, and gauge fields require the corresponding physical-polarization and ghost-free Hilbert-space construction.

151.10 Back-Reaction Boundary

Fixed-background QFT treats g as prescribed. Semiclassical gravity asks instead for

$$G_{\mu\nu}[g] + \Lambda g_{\mu\nu} = 8\pi G\,\langle T_{\mu\nu}\rangle_{\mathrm{ren}}[g,\omega],$$

where ω is the chosen Hadamard state and the stress tensor includes the finite local curvature counterterms discussed earlier in this volume. In an adiabatic Schwarzschild approximation, energy conservation suggests an ODE

$$\frac{dM}{du} = -L(M), \qquad L(M) = \sum_{\ell,m}\int_0^\infty \frac{d\omega}{2\pi}\,\frac{\omega\,\Gamma_\ell(\omega;M)}{e^{8\pi M\omega}-1},$$

for a scalar contribution. This equation is not a theorem about the full evaporating geometry. It assumes slow variation on the scale M, ignores stress-tensor fluctuations except through their mean, and presupposes that the state remains close to an Unruh-type Hadamard state on each instantaneous exterior.

151.11 QFT Boundary

A theorem-level Hawking effect for an interacting local QFT on black-hole backgrounds requires all of the following data:

(i) a precise class of globally hyperbolic collapse spacetimes with controlled late approach to a nonextremal stationary exterior;

(ii) construction of a Hadamard state empty on $\mathcal{I}^-$ and regular at the future horizon;

(iii) a local and covariant stress-tensor renormalization scheme;

(iv) propagation estimates connecting near-horizon data to $\mathcal{I}^+$;

(v) control of the limits defining late-time wave-packet observables;

(vi) a statement separating the universal horizon factor from model-dependent greybody and interaction effects.

Without these hypotheses, the phrase "black holes radiate thermally" is not a mathematical theorem. With these hypotheses supplied, the fixed-background calculation above shows where the temperature and Planck factor enter.

Open Problem 151.4 (Interacting Hawking theorem). Prove a Hawking radiation theorem for an interacting local QFT on a class of black-hole backgrounds, including Hadamard state construction, KMS or near-horizon analyticity, renormalized stress tensor, greybody propagation, late-time wave-packet limits, and the precise sense in which the emitted flux is thermal.

Chapter 152

Background Gauge Fields and Index Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Background gauge fields are not auxiliary decorations. They are sources for global currents, they specify the bundles in which charged fields take values, and for chiral fermions they determine both zero-mode selection rules and anomaly lines. This chapter develops the index-theoretic part of that structure with explicit conventions. The analytic input is the index of a coupled Dirac operator; the QFT input is the Berezin integral over its zero modes and the determinant line of its nonzero modes. The source traces for the heat-kernel/index-theory line used here are Seeley, Gilkey, and Atiyah–Singer [54, 55, 56]; the derivations below keep the local Clifford and Chern-Weil conventions explicit because these are the conventions later used in anomaly formulae.

152.1 Spinors, Bundles, and Curvature Conventions

Let M^{2n} be a closed oriented Riemannian spin manifold. The complex spinor bundle splits into chiral pieces

$$S = S^+ \oplus S^-.$$

Let $E \to M$ be a Hermitian vector bundle with unitary connection ∇^E. In the characteristic-class formulas of this chapter the curvature $F_E = (\nabla^E)^2$ is skew-Hermitian, so

$$\mathrm{ch}(E) = \mathrm{tr}_E \exp\left(\frac{\mathrm{i}F_E}{2\pi}\right)$$

is a real even cohomology class. If a physics convention uses Hermitian generators and Hermitian curvature F_{phys}, then

$$F_E = -\mathrm{i}F_{\mathrm{phys}}$$

in this formula. All traces in $\mathrm{ch}(E)$ are traces in the fermion representation, not necessarily the trace used in the Yang-Mills kinetic term.

The coupled Dirac operator is

$$D_A : \Gamma(S \otimes E) \longrightarrow \Gamma(S \otimes E), \qquad D_A = \gamma^\mu \nabla_\mu^{S\otimes E}.$$

With respect to chirality,

$$D_A = \begin{pmatrix} 0 & D_A^- \\ D_A^+ & 0 \end{pmatrix}, \qquad D_A^+ : \Gamma(S^+ \otimes E) \to \Gamma(S^- \otimes E).$$

The analytic index is

$$\mathrm{Ind}(D_A^+) = \dim\ker D_A^+ - \dim\ker D_A^-. \tag{152.1}$$

Because M is compact and D_A^+ is elliptic, this is a finite integer.

152.2 McKean–Singer Supertrace

Let Γ denote the chirality operator, acting by $+1$ on S^+ and by -1 on S^-. The heat operator $e^{-tD_A^2}$ is trace class for $t > 0$.

Proposition 152.1 (McKean–Singer identity)**.** *For every $t > 0$,*

$$\mathrm{Str}\ e^{-tD_A^2} := \mathrm{Tr}\Big(\Gamma e^{-tD_A^2}\Big) = \mathrm{Ind}(D_A^+). \tag{152.2}$$

Proof. Because M is compact and D_A is elliptic and self-adjoint, D_A^2 has discrete spectrum with finite-dimensional eigenspaces and $e^{-tD_A^2}$ is trace class for $t > 0$. The chirality operator anticommutes with D_A, so D_A exchanges $S^+ \otimes E$ and $S^- \otimes E$. The nonzero spectrum of D_A^2 on $S^+ \otimes E$ is paired with the nonzero spectrum on $S^- \otimes E$. Indeed, if $\psi_+ \in \Gamma(S^+ \otimes E)$ satisfies

$$D_A^- D_A^+ \psi_+ = \lambda \psi_+, \qquad \lambda > 0,$$

then $D_A^+\psi_+ \neq 0$ and

$$D_A^+ D_A^- (D_A^+ \psi_+) = \lambda (D_A^+ \psi_+).$$

The inverse map on the λ-eigenspace is $\lambda^{-1} D_A^-$, so the pairing preserves multiplicities. Hence the positive eigenvalue contributions to

$$\mathrm{Tr}_{S^+}\, e^{-tD_A^- D_A^+} - \mathrm{Tr}_{S^-}\, e^{-tD_A^+ D_A^-}$$

cancel term by term, with absolute convergence supplied by the heat trace. The zero eigenspaces are precisely $\ker D_A^+$ and $\ker D_A^-$. Their contribution is independent of t and equals

$$\dim\ker D_A^+ - \dim\ker D_A^- = \mathrm{Ind}(D_A^+).$$

□

This proof is finite-dimensional after elliptic spectral theory supplies the discrete spectrum and heat-kernel trace class property. It is the analytic bridge between zero-mode counting and local curvature densities.

152.3 Lichnerowicz Formula and Heat-Kernel Scaling

The local index theorem is a statement about the short-time asymptotics of the heat kernel of D_A^2. We spell out the conventions because the same heat-kernel coefficients also enter point-splitting stress tensors and trace anomalies.

Let $c(e^a) = \gamma^a$ denote Clifford multiplication by an orthonormal coframe. We use

$$\gamma^{ab} := \frac{1}{2}[\gamma^a, \gamma^b], \qquad F^E = \frac{1}{2}F^E_{ab} e^a \wedge e^b.$$

The curvature of the spin connection is

$$[\nabla^S_a, \nabla^S_b] = \frac{1}{4}R_{abcd}\gamma^{cd}.$$

Lemma 152.2 (Lichnerowicz formula)**.** *For the coupled Dirac operator $D_A = \gamma^a \nabla_a^{S\otimes E}$,*

$$D_A^2 = (\nabla^{S\otimes E})^* \nabla^{S\otimes E} + \frac{1}{4}\mathrm{Scal} + \frac{1}{2}\gamma^{ab}F^E_{ab}. \tag{152.3}$$

Proof. At a chosen point p, take an oriented orthonormal frame whose Levi-Civita connection coefficients vanish at p. Write ∇ for the coupled connection on $S \otimes E$. Since the antisymmetric part of $\gamma^a\gamma^b$ is γ^{ab},

$$\begin{aligned} D_A^2 &= \gamma^a\gamma^b \nabla_a\nabla_b \\ &= g^{ab}\nabla_a\nabla_b + \gamma^{ab}\nabla_a\nabla_b \\ &= g^{ab}\nabla_a\nabla_b + \frac{1}{2}\gamma^{ab}[\nabla_a, \nabla_b]. \end{aligned}$$

Restoring the Christoffel term away from the chosen normal frame gives the connection Laplacian $(\nabla^{S\otimes E})^*\nabla^{S\otimes E}$ in the sign convention of this chapter. The curvature of the coupled connection is

$$[\nabla_a, \nabla_b] = \frac{1}{4}R_{abcd}\gamma^{cd} + F^E_{ab}.$$

The E-bundle curvature therefore contributes

$$\frac{1}{2}\gamma^{ab}F^E_{ab}.$$

The spin-curvature contribution is

$$\frac{1}{2}\gamma^{ab}\frac{1}{4}R_{abcd}\gamma^{cd}.$$

It remains to evaluate the Clifford contraction. With $\gamma^{abcd} := \gamma^{[a}\gamma^{b}\gamma^{c}\gamma^{d]}$, the Clifford relations give

$$\gamma^{ab}\gamma^{cd} = \gamma^{abcd} + g^{bc}\gamma^{ad} - g^{ac}\gamma^{bd} - g^{bd}\gamma^{ac} + g^{ad}\gamma^{bc} + g^{ac}g^{bd} - g^{ad}g^{bc}.$$

The coefficient of γ^{abcd} is the total antisymmetrization of R_{abcd}, hence vanishes by the first Bianchi identity $R_{[abc]d} = 0$. The terms with one remaining γ^{pq} reduce to Ricci contractions, for example $R_{abcd}g^{bc}\gamma^{ad}$, and vanish because the Ricci tensor is symmetric while γ^{ad} is antisymmetric. The scalar terms give

$$R_{abcd}(g^{ac}g^{bd} - g^{ad}g^{bc}) = 2\,\mathrm{Scal}$$

with the curvature and Clifford conventions stated above. Thus the spin-curvature piece is

$$\frac{1}{8}\,R_{abcd}\gamma^{ab}\gamma^{cd} = \frac{1}{4}\mathrm{Scal}.$$

Combining the connection Laplacian, spin curvature, and bundle curvature gives (152.3). □

Definition 152.3 (Laplace-type operator and heat coefficients)**.** A Laplace-type operator on a Hermitian vector bundle $V \to M^d$ is written in the form

$$P = -(g^{\mu\nu}\nabla_\mu\nabla_\nu + \mathcal{E}), \tag{152.4}$$

where ∇ is a connection on V and $\mathcal{E} \in \Gamma(\mathrm{End}\,V)$. Its curvature is $\Omega_{\mu\nu} = [\nabla_\mu, \nabla_\nu]$. The local heat coefficients $a_{2r}(P;x)$ are defined by

$$\mathrm{Tr}\big(fe^{-tP}\big) \sim (4\pi t)^{-d/2}\sum_{r\geq 0} t^r \int_M f(x)\,\mathrm{tr}_V a_{2r}(P;x)\,d\mathrm{vol}_g \tag{152.5}$$

for every test function f.

Quoted Theorem 152.4 (First Seeley–DeWitt coefficients)**.** Source trace. *The displayed normalization follows the Seeley–DeWitt/Gilkey heat-kernel convention [54, 55]. For the convention* (152.4)*,*

$$a_0 = \mathbf{1}_V, \qquad a_2 = \mathcal{E} + \frac{1}{6}\mathrm{Scal}\,\mathbf{1}_V, \tag{152.6}$$

and

$$\begin{aligned} a_4 = \frac{1}{360}\Big[&\big(5\mathrm{Scal}^2 - 2\mathrm{Ric}_{\mu\nu}\mathrm{Ric}^{\mu\nu} + 2R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}\big)\,\mathbf{1}_V \\ &+ 60\mathrm{Scal}\,\mathcal{E} + 180\mathcal{E}^2 + 30\Omega_{\mu\nu}\Omega^{\mu\nu} \\ &+ 12\nabla^2\mathrm{Scal}\,\mathbf{1}_V + 60\nabla^2\mathcal{E}\Big]. \end{aligned} \tag{152.7}$$

On a closed manifold the last line integrates to zero after taking a trace.

Parametrix origin. Work in a normal convex neighborhood and write Synge's world function as $\sigma(x, y)$. The heat kernel parametrix has the form

$$K_t(x, y) \sim (4\pi t)^{-d/2} e^{-\sigma(x,y)/2t} \Delta(x, y)^{1/2} \sum_{r \geq 0} t^r b_r(x, y), \qquad b_0(x, x) = \mathbf{1}_V, \tag{152.8}$$

where Δ is the van Vleck determinant and b_r is parallel transported in the bundle indices at leading order. Inserting (152.8) into $(\partial_t + P_x)K_t = 0$ and comparing powers of t gives the transport recursion

$$(\sigma^{;\mu}\nabla_\mu + r)b_r = -\Delta^{-1/2} P_x\Big(\Delta^{1/2} b_{r-1}\Big), \qquad r \geq 1. \tag{152.9}$$

The coincidence limits needed below are

$$[\sigma^{;\mu}] = 0, \qquad [\sigma^{;\mu}{}_\nu] = \delta^\mu{}_\nu, \qquad [\nabla_\mu \nabla_\nu \Delta^{1/2}] = \frac{1}{6}\mathrm{Ric}_{\mu\nu}, \tag{152.10}$$

with brackets denoting $y \to x$. Setting $r = 1$ in (152.9) immediately gives

$$[b_1] = \mathcal{E} + \frac{1}{6}\mathrm{Scal}\,\mathbf{1}_V.$$

For $r = 2$, differentiate the transport equation twice, use (152.10), the commutator $[\nabla_\mu, \nabla_\nu] = \Omega_{\mu\nu}$, and commute covariant derivatives until all third and fourth derivatives of σ and $\Delta^{1/2}$ are expressed in curvature. The resulting coincidence limit is precisely (152.7). No field equation is used; the calculation is the universal local recursion for a Laplace-type operator.

152.4 Local Index Theorem

Let R denote the Riemannian curvature two-form of TM. The $\widehat{A}$-class is

$$\widehat{A}(TM) = \det{}^{1/2}\left(\frac{R/4\pi}{\sinh(R/4\pi)}\right) = 1 - \frac{p_1(TM)}{24} + \frac{7p_1(TM)^2 - 4p_2(TM)}{5760} + \cdots.$$

The theorem below is the heat-kernel/Getzler route to the local Atiyah–Singer index formula [56, 55]; its proof is included to fix the curvature and chirality normalization used by the anomaly polynomial later in the chapter.

Theorem 152.5 (Local index density by Getzler rescaling)**.** *For the chiral Dirac operator coupled to E,*

$$\mathrm{Ind}(D_A^+) = \int_M \Big[\widehat{A}(TM)\,\mathrm{ch}(E)\Big]_{2n}. \tag{152.11}$$

Equivalently, the local heat-kernel density of the supertrace has

$$\lim_{t \to 0^+} \mathrm{str}\, K_t(x, x)\, \mathrm{dvol}_g = \Big[\widehat{A}(TM)\,\mathrm{ch}(E)\Big]_{2n}.$$

Proof. The McKean–Singer identity reduces the index to the small-t limit of the local supertrace. Fix $p \in M$. Choose geodesic normal coordinates, synchronous orthonormal frame, and radial gauges for S and E. In these coordinates the Taylor expansions of the two connections begin with their curvatures:

$$\nabla_a^S = \partial_a + \frac{1}{4} R_{abcd}(p) x^b \gamma^{cd} + O(|x|^2), \qquad \nabla_a^E = \partial_a + \frac{1}{2} F_{ab}^E(p) x^b + O(|x|^2). \tag{152.12}$$

Rescale $x = t^{1/2} y$. Under Getzler scaling the differential operator keeps the terms whose combined degree in $t^{1/2}$, derivatives, and Clifford variables can contribute to the top Clifford degree $2n$; all higher Taylor coefficients are suppressed by positive powers of $t^{1/2}$ in the diagonal heat kernel. Lemma 152.2 then gives the constant-curvature model operator

$$H_p = -\sum_a \left(\partial_{y^a} + \frac{1}{4} R_{ab}(p) y^b \right)^2 + \frac{1}{2} \gamma^{ab} F_{ab}^E(p), \tag{152.13}$$

where $R_{ab}(p)$ is viewed as the skew endomorphism of T_pM with matrix entries $R_{abcd}(p)\gamma^{cd}$ in the Clifford factor. The ordinary scalar-curvature term in (152.3) has Clifford degree 0, hence cannot by itself contribute to the supertrace in dimension $2n$; the missing gravitational contribution is instead produced by the harmonic-oscillator determinant in H_p.

The heat kernel of (152.13) is the Mehler kernel for a constant magnetic oscillator, tensored with the finite endomorphism exponential $\exp(-\frac{1}{2}\gamma^{ab}F_{ab}^E)$. Diagonalizing the skew curvature into two-planes gives the pointwise supertrace

$$\lim_{t\to 0^+} \operatorname{str} K_t(p,p)\, d\mathrm{vol}_g(p) = \left[\det{}^{1/2}\left(\frac{R/4\pi}{\sinh(R/4\pi)} \right) \operatorname{tr}_E \exp\left(\frac{\mathrm{i}F_E}{2\pi} \right) \right]_{2n}. \tag{152.14}$$

The determinant factor is the product over the curvature two-planes of the Mehler ratio

$$\frac{u/2}{\sinh(u/2)},$$

with u the corresponding Chern-Weil curvature variable. The Clifford supertrace extracts exactly the top exterior degree; lower Clifford degree terms vanish because str_S is zero away from degree $2n$. Equation (152.14) is precisely $\left[\widehat{A}(TM)\operatorname{ch}(E)\right]_{2n}$. Integrating over M and using (152.2) proves (152.11). $\square$

This theorem is a theorem of differential geometry, not an axiom of QFT. The derivation above identifies which part is analytic heat-kernel control and which part is local Clifford/Chern-Weil algebra. The QFT consequences below are then zero-mode selection rules, anomaly polynomials, determinant lines, and inflow.

In four dimensions the formula becomes

$$\operatorname{Ind}(D_A^+) = \int_M \left[\operatorname{ch}_2(E) - \frac{\operatorname{rank}(E)}{24} p_1(TM) \right]. \tag{152.15}$$

For an $SU(N)$ bundle E_R associated to a representation R,

$$c_1(E_R) = 0, \qquad \int_M \operatorname{ch}_2(E_R) = T_\Delta(R)\, k. \tag{152.16}$$

Here $k \in \mathbb{Z}$ is the instanton number in the fundamental bundle and $T_\Delta(R)$ is the quadratic index in the monograph's trace-delta normalization

$$\mathrm{tr}_R(t_R^a t_R^b) = T_\Delta(R)\delta^{ab}, \qquad T_\Delta(\Box) = 1.$$

Thus $T_\Delta(\mathrm{adj}) = 2N$. This is the same normalization compatible with the Yang-Mills kinetic term

$$\frac{1}{4g^2}\int \mathrm{tr}_\Delta(F_{\mu\nu}F^{\mu\nu}).$$

152.5 Four-Dimensional Examples

On a spin four-manifold with $p_1(TM) = 0$, a unit $SU(N)$ instanton gives

$$\mathrm{Ind}(D_\Box^+) = 1, \qquad \mathrm{Ind}(D_{\mathrm{adj}}^+) = 2N.$$

For $SU(2)$, the fundamental Weyl fermion has one complex zero mode in the orientation convention of (152.16), and an adjoint Weyl fermion has four complex zero modes. Reversing the orientation of the gauge instanton reverses the sign of the index and swaps the chirality of the zero modes.

For an Abelian line bundle L^q of charge q,

$$\mathrm{ch}(L^q) = e^{qx}, \qquad x = c_1(L).$$

On T^4 with $p_1(TT^4) = 0$, take integral two-forms a, b with

$$\int_{T^4} a \wedge b = 1, \qquad a \wedge a = b \wedge b = 0,$$

and $x = m_1 a + m_2 b$. Then

$$\mathrm{Ind}(D_{L^q}^+) = \int_{T^4} \frac{1}{2} q^2 x^2 = q^2 m_1 m_2. \tag{152.17}$$

This example is useful because it is completely Abelian: the index is the intersection pairing of magnetic fluxes through complementary two-tori.

152.6 Zero Modes and Berezin Selection Rules

Let ψ be a left-handed Weyl fermion valued in E. Decompose it in an orthonormal eigenbasis of the coupled Dirac operator. If $\{\zeta_1, \ldots, \zeta_m\}$ is a basis of $\ker D_A^+$, then the Grassmann field has zero-mode coordinates

$$\psi_0(x) = \sum_{i=1}^m \eta_i \zeta_i(x), \qquad \eta_i \eta_j = -\eta_j \eta_i.$$

Finite-dimensional zero-mode rule. After nonzero modes have been paired, the zero-mode part of a fermionic path integral is

$$\int d\eta_m \cdots d\eta_1\, \mathcal{O}(\eta_1, \ldots, \eta_m).$$

It vanishes unless the insertion $\mathcal{O}$ contains the top monomial $\eta_1 \cdots \eta_m$. Therefore a background with m unpaired Weyl zero modes requires m corresponding fermion insertions for a nonzero correlator. Berezin integration is the linear functional fixed by

$$\int d\eta\, 1 = 0, \qquad \int d\eta\, \eta = 1.$$

For m generators it extracts the coefficient of $\eta_1 \cdots \eta_m$ in the declared order. All lower-degree monomials are annihilated by at least one of the integrations.

For a vectorlike Dirac fermion in representation R, written in two-component language as left-handed fields in R and $\overline{R}$, a charge-k instanton produces $T_\Delta(R)k$ zero modes in each of the two conjugate chiral variables, with chirality determined by the instanton orientation. The resulting finite-dimensional Berezin integral is the precise origin of the fermion-number selection rule usually encoded by the 't Hooft vertex.

152.7 Anomaly Polynomial and Descent

For a chiral fermion in $2n$ dimensions, the anomaly polynomial is the $(2n+2)$-form

$$I_{2n+2} = \left[\widehat{A}(TM)\,\mathrm{ch}(E)\right]_{2n+2}. \tag{152.18}$$

Choose a Chern-Simons form I_{2n+1} satisfying

$$dI_{2n+1} = I_{2n+2}.$$

For an infinitesimal background gauge transformation with parameter α,

$$\delta_\alpha I_{2n+1} = dI_{2n}^{(1)}(\alpha).$$

The local anomalous variation of the Euclidean effective action is

$$\delta_\alpha W[A, g] = 2\pi \mathrm{i} \int_M I_{2n}^{(1)}(\alpha), \tag{152.19}$$

with an overall sign changed if the opposite chirality convention is chosen. The sign is not independent data; it is fixed by the orientation of D_A^+, the definition of $W = -\log Z$, and the chirality assignment of the fermion.

In four-dimensional QFT, the relevant six-form is

$$I_6 = \mathrm{ch}_3(E) - \frac{p_1(TM)}{24}\,\mathrm{ch}_1(E). \tag{152.20}$$

The first term gives cubic gauge anomalies. The second gives the mixed gauge-gravitational anomaly for a $U(1)$ background. For a semisimple group in a traceless representation, $\mathrm{ch}_1(E) = 0$, so the mixed term is absent. A background symmetry can be gauged only after the total anomaly line has been trivialized; cancellation of the local polynomial is necessary but does not by itself eliminate global anomalies.

152.8 Determinant Line and Families

As the metric and background connection vary, the chiral fermion determinant is not naturally a complex number. It is a section of the determinant line

$$\operatorname{Det} D = \bigwedge^{\max} \ker D_A^+ \otimes \left(\bigwedge^{\max} \ker D_A^-\right)^*$$

over background-field space. The local anomaly is the curvature of this line with its natural connection. Global anomalies are its holonomies around loops. Thus a well-defined background-field partition function requires a trivialization of the determinant line together with the vanishing of the local curvature obstruction. The source traces for the determinant-line and eta-holonomy formulation used in the next chapter are Bismut–Freed and Dai–Freed [60, 61].

The next chapter develops the eta-invariant formula for these holonomies. The present chapter supplies the local and zero-mode input: the index counts the imbalance of chiral zero modes, while the family of such indices organizes the determinant line.

Open Problem 152.6 (Index-theoretic anomaly line in interacting QFT)*.* Extend the determinant-line and index-theoretic description from free chiral fermions coupled to backgrounds to interacting continuum QFTs with composite currents, contact terms, and extended operators, while retaining an explicit comparison with local anomaly descent and global anomaly holonomy.

Chapter 153

Eta Invariants and Global Anomalies

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Chapter 152 treated the local index density and the curvature of the determinant line. This chapter develops the complementary holonomy problem. A local anomaly is detected by infinitesimal motion in background-field space; a global anomaly is detected by transporting the fermion functional integral around a closed loop of backgrounds. For free fermions the transport is computed by eta invariants of Dirac operators on the associated mapping tori. The source traces for the global-analysis inputs are the APS spectral asymmetry papers, the Bismut–Freed holonomy theorem, Dai–Freed determinant lines, and Witten's $SU(2)$ anomaly [57, 58, 59, 60, 61, 62].

153.1 Self-Adjoint Dirac Operators and Eta Functions

Let Y be a closed oriented Riemannian spin manifold of odd dimension $2n+1$. Let $E \to Y$ be a Hermitian vector bundle with unitary connection ∇^E. The coupled Dirac operator

$$B_Y : C^\infty(Y, S_Y \otimes E) \longrightarrow C^\infty(Y, S_Y \otimes E)$$

is self-adjoint on $L^2(Y, S_Y \otimes E)$ when the Clifford action is chosen skew-Hermitian in Euclidean signature. Its spectrum is real, discrete, and has finite-dimensional eigenspaces. The eta function is initially defined by

$$\eta_{B_Y}(s) = \sum_{\lambda \in \mathrm{Spec}(B_Y)\setminus\{0\}} \mathrm{sign}(\lambda)|\lambda|^{-s}, \qquad \mathrm{Re}\, s \gg 1. \tag{153.1}$$

For a Dirac-type operator the heat-kernel expansion gives a meromorphic continuation to $s \in \mathbb{C}$, regular at $s = 0$. We define

$$h(B_Y) = \dim\ker B_Y, \qquad \xi(B_Y) = \frac{\eta_{B_Y}(0) + h(B_Y)}{2}. \tag{153.2}$$

The real number $\xi(B_Y)$ depends on the metric and connection, but $\exp(2\pi i\xi(B_Y))$ is the natural phase variable: when eigenvalues cross through zero, ξ changes by an integer.

Remark 153.1 (Integer jump at a simple crossing). Let B_t, $t \in (-\varepsilon, \varepsilon)$, be a smooth one-parameter family of self-adjoint Dirac-type operators. Suppose exactly one simple eigenvalue $\lambda(t)$ crosses zero, with $\lambda(t) < 0$ for $t < 0$ and $\lambda(t) > 0$ for $t > 0$, and all other eigenvalues stay away from zero. Then the contribution of this eigenvalue to $\xi(B_t)$ jumps by $+1$. A crossing in the opposite direction gives a jump by -1. Away from the crossing the eigenvalue contributes $\mathrm{sign}(\lambda)/2$ to $(\eta(0) + h)/2$. Just before the crossing this contribution is $-1/2$, at the crossing it is $1/2$ because $h = 1$, and just after the crossing it is $1/2$. Thus the one-sided jump from $t < 0$ to $t > 0$ is $+1$. If the eigenvalue crosses from positive to negative, the contribution changes from $+1/2$ before the crossing to $-1/2$ after the crossing, again with $h = 1$ at the crossing instant, so the one-sided jump is -1.

Definition 153.2 (Spectral flow)**.** For a smooth path B_t, $0 \le t \le 1$, whose endpoints are invertible, the spectral flow $\mathrm{sf}(B_t)$ is the signed number of eigenvalues crossing zero from negative to positive, counted with multiplicity. If the endpoints have kernels, one fixes a small perturbation or uses the APS convention below; the resulting quantity is well-defined modulo the endpoint-kernel bookkeeping appearing in ξ.

Remark 153.1 is the elementary reason that global anomalies are naturally phases rather than real-valued functions of $\eta(0)$ alone. The smooth part of ξ is local; the integer jumps record spectral flow.

153.2 The APS Boundary Formula

Let X be a compact oriented Riemannian spin manifold of even dimension $2n+2$, with boundary $\partial X = Y$. Assume that, on a collar $(-\epsilon, 0] \times Y$, the metric and the connection have product form. Let u be the inward normal coordinate. In this collar the chiral Dirac operator has the form

$$D_X^+ = c(\nu)\big(\partial_u + B_Y\big) \quad \text{up to the standard chiral identification,} \tag{153.3}$$

where ν is the outward unit normal and B_Y is the self-adjoint tangential Dirac operator on Y.

The APS boundary condition keeps the boundary values of spinors in the negative spectral subspace of B_Y:

$$P_{\ge 0}\big(\psi|_Y\big) = 0, \tag{153.4}$$

where $P_{\ge 0}$ is the orthogonal projection onto the span of eigenvectors with eigenvalue ≥ 0. Including the zero eigenspace in $P_{\ge 0}$ is the convention paired with the reduced invariant $\xi = (\eta + h)/2$.

Half-cylinder sign check. The sign in (153.4) is fixed by the product collar, not by an arbitrary convention. Replace the collar by the infinite inward cylinder $(-\infty, 0] \times Y$ with the same model operator

$$c(\nu)(\partial_u + B_Y).$$

If $B_Y \phi_\lambda = \lambda\phi_\lambda$ and $\psi(u, y) = f_\lambda(u)\phi_\lambda(y)$, the equation $(\partial_u + B_Y)\psi = 0$ becomes

$$\frac{df_\lambda}{du} + \lambda f_\lambda = 0, \qquad f_\lambda(u) = e^{-\lambda u} f_\lambda(0).$$

Since the completed cylinder runs to $u = -\infty$, this mode is square integrable exactly when $\lambda < 0$. Thus the boundary values of L^2 solutions on the completed model lie in the negative spectral subspace, while zero modes are not square-integrable on the infinite cylinder and are therefore placed in the forbidden subspace $P_{\geq 0}$. On an oppositely oriented boundary component the tangential operator is $-B_Y$, so the same mode calculation reverses the spectral sign. This elementary model is not the APS Fredholm theorem; it fixes the boundary-orientation convention used in the eta and anomaly formulae below.

Quoted Theorem 153.3 (Atiyah–Patodi–Singer index formula)**.** Source trace. *This is the APS boundary index theorem in the reduced eta convention used in this chapter [57, 58, 59]. For the product-collar data above, the chiral Dirac operator with APS boundary condition is Fredholm and*

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(E)\big]_{2n+2} - \xi(B_Y). \tag{153.5}$$

For non-product data one first deforms to product form near the boundary or adds the corresponding local transgression term. The sum of bulk density, local boundary transgression, and eta term is the invariant integer.

Analytic mechanism behind the boundary term. The theorem is used below through three precise pieces of analytic structure. First, product form near the boundary identifies the normal part of the Dirac operator with the first-order operator (153.3). The spectral projection $P_{\geq 0}$ then makes the boundary problem elliptic in the pseudodifferential sense: boundary values in the forbidden spectral subspace are removed, while the remaining components give a Fredholm operator. Second, the small-time heat-kernel expansion of the APS problem has the same interior coefficient $[\widehat{A}(TX)\,\mathrm{ch}(E)]_{2n+2}$ as the closed index theorem. This is the local part of the formula and is the source of the usual anomaly polynomial. Third, the APS boundary condition is nonlocal along Y, and its nonlocal contribution is exactly the reduced spectral asymmetry $\xi(B_Y)$. The integer on the left side of (153.5) is the compatibility condition tying these local and nonlocal terms together.

In this chapter the APS theorem functions as the global-analysis bridge between two objects already defined above: the local index density on X and the spectral invariant of the boundary Dirac operator B_Y. The QFT statement extracted from it is the following: local anomaly density determines the infinitesimal variation of the fermion phase, while eta invariants retain the integral spectral-flow data that can survive after the local curvature has vanished.

Cylinder variation of the reduced eta invariant. Let B_t, $0 \leq t \leq 1$, be a smooth path of odd-dimensional Dirac operators obtained from a smooth path of metrics and unitary connections on a fixed closed odd-dimensional spin manifold Y. Let

$$X = [0,1] \times Y$$

carry the interpolating product-near-boundary data. Then

$$\xi(B_1) - \xi(B_0) \equiv \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(E)\big]_{2n+2} \pmod{\mathbb{Z}}. \tag{153.6}$$

If the path has no zero crossings and the endpoint kernels have constant dimension, differentiating this formula gives the usual local descent variation of ξ. This is the cylinder specialization of APS. The boundary of $X = [0,1] \times Y$ is

$$\partial X = Y_1 \sqcup (-Y_0).$$

The tangential operator on Y_1 is B_1, while the tangential operator on the oppositely oriented component $-Y_0$ is $-B_0$. Applying (153.5) to X gives

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(E)\big]_{2n+2} - \xi(B_1) - \xi(-B_0).$$

Since $\eta_{-B_0}(0) = -\eta_{B_0}(0)$ and $h(-B_0) = h(B_0)$, one has

$$\xi(-B_0) = -\xi(B_0) + h(B_0).$$

The Fredholm index and $h(B_0)$ are integers. Moving them to the other side gives (153.6) modulo $\mathbb{Z}$.

Exact cylinder bookkeeping. The preceding congruence is often the only part of the APS cylinder formula that survives in anomaly phases, but the exact integer identity is what fixes the sign conventions. With

$$I_X(E) = \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(E)\big]_{2n+2},$$

the APS formula on $\partial X = Y_1 \sqcup (-Y_0)$ gives

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = I_X(E) - \xi(B_1) + \xi(B_0) - h(B_0). \tag{153.7}$$

Equivalently,

$$\xi(B_1) - \xi(B_0) = I_X(E) - h(B_0) - \mathrm{Ind}(D_X^{+,\mathrm{APS}}). \tag{153.8}$$

Thus the endpoint-kernel convention is not an afterthought: including the zero eigenspace in $P_{\geq 0}$ at the incoming boundary contributes the integer $h(B_0)$ in the exact formula and then disappears only after passing to $\mathbb{R}/\mathbb{Z}$. When B_0 and B_1 are invertible, (153.7) becomes

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = I_X(E) - \big(\xi(B_1) - \xi(B_0)\big).$$

If the path has only transverse simple crossings, the integer jump part of $\xi(B_1) - \xi(B_0)$ is exactly the spectral flow $\mathrm{sf}(B_t)$, by Remark 153.1. The remaining smooth variation is represented by the local transgression term whose cylinder integral is $I_X(E)$; the APS index supplies the integer needed to make the exact equality hold. Consequently, in the orientation and APS boundary convention of (153.3)–(153.4), the pure crossing contribution satisfies

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}})_{\mathrm{cross}} = -\,\mathrm{sf}(B_t).$$

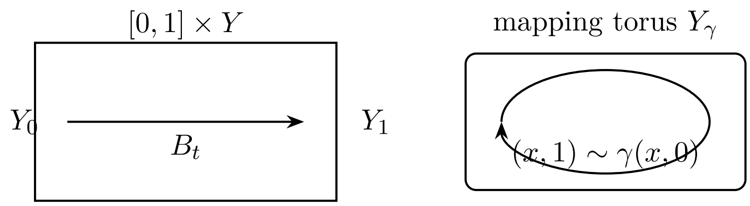

Figure 153.1: The APS cylinder computes the local change of ξ modulo integers. Identifying the two ends by a closed loop of backgrounds gives the mapping torus whose eta invariant computes determinant-line holonomy.

This minus sign is a boundary-orientation convention, not a physical phase: the exponentiated eta phase only remembers the congruence (153.6), while the exact identity above records the Fredholm representative used to compute it.

Figure 153.1 records the cylinder/mapping-torus geometry used in the eta-variation formula: interpolating between boundary operators converts eta change into an APS index modulo integers.

153.3 Determinant-Line Holonomy

Let M be a closed even-dimensional spin manifold, and let $\mathcal{B}$ be a smooth parameter space of background metrics and connections, before quotienting by large gauge transformations. A family of chiral Dirac operators

$$D_b^+ : \Gamma(M, S^+ \otimes E_b) \longrightarrow \Gamma(M, S^- \otimes E_b), \qquad b \in \mathcal{B},$$

defines the determinant line

$$\operatorname{Det} D_b = \bigwedge^{\text{top}} \ker D_b^+ \otimes \Big(\bigwedge^{\text{top}} \ker D_b^-\Big)^* . \tag{153.9}$$

Where kernels jump this formula is not a literal vector bundle chart, but the Quillen determinant construction glues these local descriptions to a smooth complex line bundle over $\mathcal{B}$. The regulated chiral fermion functional integral is a section of this line, not a function, until a trivialization is chosen.

Let $\gamma : S^1 \to \mathcal{B}$ be a loop of backgrounds. The mapping torus

$$Y_\gamma = ([0,1]\times M)/\big((1,x)\sim(0,x) \text{ using } \gamma\big) \tag{153.10}$$

is a closed odd-dimensional spin manifold with the induced bundle and connection. The Dirac operator on Y_γ will be denoted B_{Y_γ}.

Quoted Theorem 153.4 (Bismut–Freed holonomy formula)**.** Source trace. *The determinant-line connection and eta-holonomy formula are the Bismut–Freed holonomy theorem in the Dirac-family case [60]. With the determinant-line and chirality conventions of* (153.9)*, the natural Bismut–Freed connection on* $\operatorname{Det} D$ *has holonomy*

$$\operatorname{Hol}_\gamma(\operatorname{Det} D) = \exp\!\big(-2\pi \mathrm{i}\, \xi(B_{Y_\gamma})\big) . \tag{153.11}$$

Its curvature is the fiber integral over M *of the degree* $(\dim M + 2)$ *component of* $\widehat{A}(TM)\operatorname{ch}(E)$*.*

Local connection forms and holonomy coordinates. The theorem supplies the analytic determinant-line connection. Before using its particular curvature, we record the elementary line-bundle bookkeeping that turns such a connection into a global-anomaly phase. Let $\{U_i\}$ be a cover of a patch of $\mathcal{B}$, and choose nonzero local frames e_i of the determinant line. Write the normalized connection one-form in the convention

$$\nabla e_i = -2\pi \mathrm{i}\, a_i \otimes e_i, \qquad a_i \in \Omega^1(U_i;\mathbb{R}).$$

On an overlap $U_i \cap U_j$, write

$$e_j = \exp(2\pi \mathrm{i} f_{ij})\, e_i, \qquad f_{ij} : U_i \cap U_j \longrightarrow \mathbb{R}/\mathbb{Z}.$$

After choosing a real lift of f_{ij} on a contractible part of the overlap, substituting this transition rule into the connection gives

$$a_j = a_i - df_{ij}. \tag{153.12}$$

Therefore $da_i = da_j$ on overlaps, and the curvature is represented by a single global closed two-form. In the Bismut–Freed determinant line this global two-form is the family-index form stated in Theorem 153.4.

Now let a loop γ be subdivided into arcs $\gamma_r : [t_r, t_{r+1}] \to U_{i_r}$, with $\gamma(t_N) = \gamma(t_0)$, and let $\gamma(t_{r+1}) \in U_{i_r} \cap U_{i_{r+1}}$. Parallel transport along the arc written in the i_r-frame contributes $\exp(2\pi \mathrm{i} \int_{\gamma_r} a_{i_r})$. At the next vertex, the change of frame from e_{i_r} to $e_{i_{r+1}}$ contributes $\exp(-2\pi \mathrm{i} f_{i_r i_{r+1}}(\gamma(t_{r+1})))$. Hence the holonomy is

$$\mathrm{Hol}_\gamma(\nabla) = \exp\left[2\pi \mathrm{i}\left(\sum_r \int_{\gamma_r} a_{i_r} - \sum_r f_{i_r i_{r+1}}(\gamma(t_{r+1}))\right)\right]. \tag{153.13}$$

Changing frames by $e_i \mapsto \exp(2\pi \mathrm{i} h_i) e_i$ sends

$$a_i \mapsto a_i - dh_i, \qquad f_{ij} \mapsto f_{ij} + h_j - h_i.$$

The changes in the arc integrals and the vertex transition terms telescope in (153.13). Thus the closed-loop holonomy is independent of the local frame. On a contractible loop contained in a single patch, (153.13) reduces by Stokes to the exponential of the curvature integral over a spanning disk. On a noncontractible loop the curvature may vanish while (153.13) remains nontrivial; this is exactly the flat global-anomaly possibility later detected by based-loop holonomy in the quotient background groupoid.

Mechanism of determinant-line transport. The determinant line over $\mathcal{B}$ has local trivializations obtained by choosing a spectral cut for $D_b^- D_b^+$ and zeta-regularizing the nonzero eigenvalue product. Changing the cut changes the trivialization by the finite determinant of the eigenmodes crossing the cut, so these local charts glue to the Quillen determinant line. The Bismut–Freed connection is the connection whose local connection form is the finite part of the variation of this regularized determinant, corrected by the heat-kernel counterterm that makes the answer independent of the spectral cut. Its curvature is therefore local: it is the degree-two form on $\mathcal{B}$ obtained by integrating $[\widehat{A}(TM)\,\mathrm{ch}(E)]_{\dim M+2}$ over the physical manifold M.

The spectral-cut chart can be described without suppressing the finite transition map. Fix a positive number a which is not in the spectrum of $K_b^+ = D_b^- D_b^+$. Let

$$E^+_{<a}(b) = \bigoplus_{\lambda<a} \ker(K_b^+ - \lambda), \qquad E^-_{<a}(b) = D_b^+ E^+_{(0,a)}(b) \oplus \ker D_b^-.$$

Here $E^+_{(0,a)}$ excludes the zero modes. The Fredholm determinant line is represented in this chart by

$$L_a(b) = \det(E^+_{<a}(b)) \otimes \det(E^-_{<a}(b))^*.$$

If $a < c$ are two cuts avoiding the spectrum, write

$$E^\pm_{[a,c)}(b) = E^\pm_{<c}(b) \ominus E^\pm_{<a}(b).$$

On this finite-dimensional window, D^+_b is an isomorphism

$$D^+_{[a,c)}(b) : E^+_{[a,c)}(b) \longrightarrow E^-_{[a,c)}(b),$$

and the transition from the a-chart to the c-chart is multiplication by the determinant line element of this isomorphism:

$$\det D^+_{[a,c)}(b) \in \det E^-_{[a,c)}(b) \otimes \det E^+_{[a,c)}(b)^*.$$

For three cuts $a < c < d$, the window splits as

$$E^\pm_{[a,d)} = E^\pm_{[a,c)} \oplus E^\pm_{[c,d)},$$

and determinant multiplicativity gives

$$\det D^+_{[a,d)} = \det D^+_{[c,d)} \, \det D^+_{[a,c)}.$$

This cocycle identity is the finite-dimensional algebra behind the gluing of the local determinant-line charts. The zeta-regularized high-mode determinant and the heat-kernel counterterm supply the infinite-dimensional continuation of the same transition rule.

Compatibility with eta jumps. The determinant-line chart transition and the reduced eta invariant describe the same zero-mode bookkeeping from two different sides. Consider first one real eigenvalue $\lambda(t)$ of a self-adjoint tangential operator B_t crossing through zero from negative to positive, with all other eigenvalues kept fixed away from zero. Its contribution to the reduced eta invariant is

$$\xi_\lambda(t) = \begin{cases} -\frac{1}{2}, & \lambda(t) < 0, \\ \frac{1}{2}, & \lambda(t) = 0, \\ \frac{1}{2}, & \lambda(t) > 0, \end{cases}$$

where the middle value comes from the kernel term $h(B_t)$. The one-sided change of ξ is therefore $+1$, and a downward crossing gives -1. Thus the exponentiated phase $\exp(-2\pi \mathrm{i}\, \xi)$ is continuous across such an integer jump.

In the determinant-line construction the same event appears as a change of low-mode chart. Near a kernel jump, the zeta determinant of the complement and the zero-mode factor carried by the finite-dimensional determinant line $L_a(b)$ together form the fermion determinant vector. When the cut is moved across a small eigenvalue window, the local scalar determinant changes by the finite determinant $\det D^+_{[a,c)}$, while the basis of the determinant-line chart changes by the inverse transition element. Their product is a vector in the Quillen line and is independent of the auxiliary spectral cut. The integer spectral-flow term in the eta description is precisely the phase shadow of this finite chart transition. Consequently the smooth local curvature, the finite spectral-flow jumps, and the mapping-torus eta phase are the curvature, transition, and holonomy data of the same determinant line.

For a loop γ, the holonomy problem is converted into an index problem on the odd-dimensional mapping torus Y_γ. One stretches the circle direction adiabatically. The local curvature contribution becomes the transgression of the family index density, while the finite part left by the adiabatic limit is the reduced eta invariant of the Dirac operator on Y_γ. This is the content of (153.11). Thus the local anomaly polynomial is the curvature of the anomaly line, and a global anomaly is the holonomy of the same line around a closed path in the background groupoid. Cancellation of the local anomaly means that the total anomaly line is flat; cancellation of the global anomaly requires the holonomy of that flat line to be 1 on every closed loop.

Finite gauge transformation as determinant-line transport. Let g be a gauge transformation of a background bundle on M, and let A_t, $0 \le t \le 1$, be a path from A to A^g. The ratio between the transported determinant at A^g and the determinant at A is computed by (153.11) on the mapping torus

$$Y_g = ([0,1] \times M)/\big((1,x) \sim (0,gx)\big). \tag{153.14}$$

If this phase is not 1, the chiral fermion measure does not descend to a function on the quotient by that gauge transformation. Parallel transport along A_t identifies $\operatorname{Det} D_A$ with $\operatorname{Det} D_{A^g}$ by the Bismut–Freed connection on the determinant line bundle over background fields. The gauge transformation g gives a canonical pullback identification of D_{A^g} with D_A, hence of their determinant lines. Composing the parallel transport with this gauge identification gives an automorphism of the one-dimensional line $\operatorname{Det} D_A$, so it is multiplication by a phase. The corresponding closed path in the quotient background groupoid is represented geometrically by gluing the two ends of $[0,1] \times M$ with g, namely by the mapping torus Y_g. The Bismut–Freed holonomy formula applied to this closed family gives (153.11). A phase different from 1 means that the determinant vector changes when the same quotient background is described by the two representatives A and A^g; hence the chiral fermion measure does not descend to a function on the quotient.

Descent to the quotient background groupoid. This last statement is the precise descent criterion for a global gauge anomaly. Let $\mathcal{B}$ be the space of smooth background fields before quotienting, and let $\mathcal{G}$ be the group of gauge transformations acting on it. The quotient is the action groupoid

$$\mathcal{B}//\mathcal{G},$$

whose objects are $A \in \mathcal{B}$ and whose morphisms

$$A \longrightarrow A^g$$

are labelled by $g \in \mathcal{G}$. A fermion determinant line over this groupoid consists of a line L_A over every object together with isomorphisms

$$\Phi_g(A) : L_A \longrightarrow L_{A^g}$$

compatible with composition. In the free chiral-fermion case, $\Phi_g(A)$ is obtained by composing Bismut–Freed parallel transport along a path from A to A^g with the tautological pullback identification by g. Changing the path changes the result by the holonomy of a closed loop, hence by an eta phase of the corresponding mapping torus.

A partition function is a function on the quotient only after choosing nonzero vectors $s_A \in L_A$ satisfying

$$\Phi_g(A)s_A = s_{A^g} \qquad \text{for every } (A,g). \tag{153.15}$$

If one fixes a local trivialization of L, the same condition is expressed by a $U(1)$-valued groupoid 1-cocycle

$$\alpha(A,g) \in U(1), \qquad \Phi_g(A)e_A = \alpha(A,g)e_{A^g},$$

obeying

$$\alpha(A,gh) = \alpha(A,g)\,\alpha(A^g,h). \tag{153.16}$$

A change of local trivialization $e_A \mapsto \beta(A)e_A$ changes α by the coboundary

$$\alpha(A,g) \longmapsto \frac{\beta(A)}{\beta(A^g)}\,\alpha(A,g). \tag{153.17}$$

Thus the obstruction is the cohomology class of this groupoid cocycle. On a based loop (A,g) with $A^g = A$, the value $\alpha(A,g)$ is invariant under (153.17); it is exactly the holonomy computed by (153.11) or by the mod-two Pfaffian formula below. Tensoring independent fermion systems tensors their anomaly lines, so the cocycles multiply and the logarithmic anomaly exponents add.

This based-loop statement has a useful fixed-background form. Let

$$\mathcal{G}_A = \{g \in \mathcal{G} : A^g = A\}$$

be the stabilizer of a background. Restricting (153.16) to $g,h \in \mathcal{G}_A$ gives a character

$$\chi_A(g) = \alpha(A,g), \qquad \chi_A(gh) = \chi_A(g)\chi_A(h).$$

The coboundary factor in (153.17) is trivial on the stabilizer, because $A^g = A$, so χ_A is not changed by a local choice of frame. If an equivariant nonzero section s_A satisfying (153.15) exists, then $\chi_A(g) = 1$ for every stabilizer element. The converse is a concrete descent theorem in the finite action-groupoid model.

Proposition 153.5 (Finite action-groupoid descent criterion)**.** *Let a finite group G act on a finite set $\mathcal{B}_0$ of background representatives on the right, and write the action groupoid as $\mathcal{B}_0//G$. Let*

$$a(A,g) \in \mathbb{R}/\mathbb{Z}$$

be an additive representative of a line cocycle,

$$a(A,gh) = a(A,g) + a(A^g,h). \tag{153.18}$$

Then a is a coboundary,

$$a(A,g) = b(A^g) - b(A) \tag{153.19}$$

for some 0-cochain $b : \mathcal{B}_0 \to \mathbb{R}/\mathbb{Z}$, if and only if its stabilizer character vanishes on every orbit,

$$a(A,h) = 0 \qquad \text{for all } h \in G_A. \tag{153.20}$$

Equivalently, the multiplicative line cocycle $\alpha(A,g) = \exp(2\pi \mathrm{i} a(A,g))$ is trivializable by a choice of local frames exactly when all based-loop holonomies are 1.

Proof. If $a(A,g) = b(A^g) - b(A)$, then for a stabilizer element $h \in G_A$ one has $A^h = A$, so $a(A,h) = b(A) - b(A) = 0$. Conversely, choose one representative A_o in each orbit and set $b(A_o) = 0$. If $A = A_o^g$, define

$$b(A) = a(A_o, g).$$

This is independent of the chosen g. Indeed, if $A_o^g = A_o^{g'}$, then $g' = hg$ for some $h \in G_{A_o}$, and the cocycle identity gives

$$a(A_o, g') = a(A_o, hg) = a(A_o, h) + a(A_o^h, g) = a(A_o, g),$$

because $A_o^h = A_o$ and the stabilizer character vanishes. For an arbitrary arrow $A = A_o^g \to A^k = A_o^{gk}$, the same cocycle identity gives

$$b(A^k) - b(A) = a(A_o, gk) - a(A_o, g) = a(A_o^g, k) = a(A, k).$$

Thus the required b exists. Exponentiating a and b gives the multiplicative statement and matches the frame-change law (153.17). □

This finite theorem is the algebraic core used by the smooth anomaly line. For connected transformations the Bismut–Freed curvature and the local descent calculation determine the infinitesimal part of a. After that curvature has been cancelled, the remaining flat line is detected on stabilizers and other closed loops by the eta or mod-two mapping-torus holonomy. Thus a global anomaly may be found before considering arbitrary families: a nontrivial automorphism character of the anomaly line over one background already prevents the determinant or Pfaffian vector from being a function on the quotient stack of backgrounds.

Dual anomaly lines and the cancellation criterion. Let L be an anomaly line over $\mathcal{B}//\mathcal{G}$. Its dual line $L^\vee$ has fibers

$$L_A^\vee = \mathrm{Hom}(L_A, \mathbb{C}).$$

If $\Phi_g(A) : L_A \to L_{A^g}$ is the transport of L, then the transport of $L^\vee$ is the inverse dual map

$$\Phi_g^\vee(A) = \left(\Phi_g(A)^{-1}\right)^* : L_A^\vee \longrightarrow L_{A^g}^\vee.$$

In a local trivialization, if L is represented by the cocycle $\alpha(A,g)$, then $L^\vee$ is represented by $\alpha(A,g)^{-1}$. Hence

$$\alpha_{L\otimes L^\vee}(A,g) = \alpha(A,g)\alpha(A,g)^{-1} = 1. \tag{153.21}$$

The tensor product $L \otimes L^\vee$ is therefore canonically trivialized by the evaluation pairing. More generally, anomaly cancellation for a collection of fermion systems is the existence of a groupoid-equivariant trivialization of the tensor product of their determinant or Pfaffian lines. Vanishing of the local curvature only says that this tensor product is flat. It still must have trivial based-loop holonomy, because a nontrivial flat line gives a well-defined local anomaly density equal to zero while failing (153.15) on a noncontractible loop of backgrounds. For real Pfaffian lines the inverse line is again a real line; the statement becomes multiplication of signs. Thus two identical four-dimensional $SU(2)$ Weyl doublets cancel the Witten sign because $(-1)^2 = 1$, whereas one doublet gives a nontrivial flat Pfaffian line over the large-gauge loop.

For an infinitesimal gauge transformation connected to the identity, the linearization of α is the consistent local anomaly derived in Chapter 51. For a large gauge transformation such as the generator of $\pi_4(SU(2))$, the local curvature may vanish while the based loop value of α is nontrivial. This is the logical distinction between local anomaly cancellation and global anomaly cancellation.

153.4 Pfaffian Lines and Mod-Two Indices

Some fermion systems have a real or pseudoreal structure that replaces the complex determinant line by a Pfaffian line. The four-dimensional $SU(2)$ fundamental Weyl fermion is the basic example. The fundamental representation is pseudoreal, and the spin representation supplies an anti-linear symmetry that makes the Euclidean quadratic form skew on a real vector space. The path integral is then a Pfaffian. Its possible global anomaly is a sign.

Definition 153.6 (Mod-two index)**.** Let Y be a closed spin manifold of dimension $8k+5$, and let E be a pseudoreal bundle for which the coupled Dirac operator has the corresponding real skew structure. The mod-two index is

$$\mathrm{Ind}_2(B_Y) = \dim\ker B_Y \pmod 2. \tag{153.22}$$

The parity is stable under continuous deformations preserving the real structure. The reason is that eigenvalues away from zero occur in pairs $\lambda, -\lambda$ for the real skew structure relevant to the Pfaffian. Under a deformation, nonzero eigenvalues can enter or leave the kernel only through such paired crossings. Thus the dimension of the kernel can change only by an even integer, and $\dim\ker B_Y$ modulo 2 is invariant.

For such a Pfaffian line the Dai–Freed holonomy specializes to

$$\mathrm{Hol}_\gamma(\mathrm{Pf}\, D) = (-1)^{\mathrm{Ind}_2(B_{Y_\gamma})}. \tag{153.23}$$

This formula is the sign analogue of (153.11).

From determinant phases to Pfaffian signs. The Pfaffian line is a real line, and its holonomy has values in $\{\pm 1\}$. In a real skew Fredholm family, the nonzero spectrum of the self-adjoint representative obtained by multiplying the skew operator by i is symmetric about zero. Along a closed path, the orientation of the Pfaffian line changes precisely when an odd number of eigenvalue pairs passes through zero. The parity of this crossing number is the mod-two index of the Dirac operator on the mapping torus. Formula (153.23) is therefore the real-line analogue of the Bismut–Freed eta phase: the exponent is no longer a reduced eta invariant modulo integers, but a $\mathbb{Z}_2$-valued index.

Finite skew model for the Pfaffian line. The sign mechanism can be seen without functional analysis in a finite oriented real vector space. Let $V = \mathbb{R}^2$ with oriented basis (e_1, e_2), and let

$$q_a = a\, e^1 \wedge e^2$$

be a skew bilinear form. Its Pfaffian in this oriented basis is

$$\mathrm{pf}(q_a) = a, \qquad \det(q_a) = a^2. \tag{153.24}$$

Thus the determinant sees only $|a|$, while the Pfaffian remembers the orientation of the real line generated by q_a. If $a(t)$ crosses through zero once, the real Pfaffian coordinate changes sign. At the crossing the skew form has a two-dimensional kernel; away from the crossing the associated self-adjoint block has a paired nonzero spectrum. This is the finite-dimensional version of the statement that a real skew Fredholm family changes Pfaffian orientation only through paired zero-mode crossings.

For a direct sum of such blocks,

$$(V, q) = \bigoplus_{r=1}^{N} (\mathbb{R}^2, q_{a_r}),$$

with the product orientation, the Pfaffian is multiplicative:

$$\mathrm{pf}(q) = \prod_{r=1}^{N} a_r. \tag{153.25}$$

Consequently the holonomy of the real Pfaffian line around a closed family is the parity of the number of block signs that change:

$$\mathrm{Hol}(\mathrm{Pf}) = (-1)^{N_{\mathrm{cross}} \bmod 2}. \tag{153.26}$$

The mod-two index in (153.23) is the infinite-dimensional, elliptic version of this finite orientation parity. The mapping-torus Dirac operator supplies a canonical way to count the parity of the zero-mode crossings without choosing coordinates along the loop of backgrounds.

153.5 The Witten $SU(2)$ Global Anomaly

Let $M = S^4$, and let $g : S^4 \to SU(2)$ represent the nontrivial element of

$$\pi_4(SU(2)) \simeq \mathbb{Z}_2.$$

Form the mapping torus Y_g as in (153.14). A single left-handed Weyl fermion in the fundamental representation of $SU(2)$ has Pfaffian holonomy

$$\mathrm{Hol}_g(\mathrm{Pf}\, D) = -1. \tag{153.27}$$

Equivalently,

$$\mathrm{Ind}_2(B_{Y_g,\square}) = 1. \tag{153.28}$$

Quoted Theorem 153.7 (Mod-two index theorem for the Witten mapping torus)**.** Source trace. *The global $SU(2)$ anomaly and its mod-two mapping-torus index formulation trace to Witten's anomaly computation, with the determinant/Pfaffian-line language aligned with the Dai–Freed framework [62, 61]. Let R_j be the irreducible $SU(2)$ representation of isospin $j \in \frac{1}{2}\mathbb{Z}_{\geq 0}$, and set $n = 2j$. With the trace-delta normalization of Chapter 152,*

$$\mathrm{tr}_{R_j}(t^a t^b) = T_\Delta(R_j)\delta^{ab}, \qquad T_\Delta(R_j) = \frac{n(n+1)(n+2)}{6}. \tag{153.29}$$

For the mapping torus of the generator of $\pi_4(SU(2))$,

$$\mathrm{Ind}_2(B_{Y_g,R_j}) \equiv T_\Delta(R_j) \pmod 2. \tag{153.30}$$

Clutching datum behind the mapping torus. The QFT object to which Theorem 153.7 is applied is the coupled Dirac operator on the associated bundle over the mapping torus determined by $g : S^4 \to SU(2)$. Start with the trivial principal $SU(2)$-bundle over S^4. In a trivialization write a point as (x, u), $x \in S^4$, $u \in SU(2)$. The clutching bundle over $Y_g = S^1 \times_g S^4$ is

$$P_g = ([0,1] \times S^4 \times SU(2))/\big((1, x, u) \sim (0, x, g(x)u)\big). \tag{153.31}$$

For a representation R, the bundle entering the Dirac operator is

$$E_{g,R} = P_g \times_{SU(2)} R.$$

Choose a smooth path of connections A_t from a connection A to its gauge transform A^g, product near $t = 0, 1$. The connection A_t on the cylinder descends through the clutching relation to a connection on P_g. Changing the interpolation A_t changes the mapping-torus connection through a homotopy of connections and hence does not change the mod-two index.

Two pieces of the setup precede the global mod-two index formula. First, if g_s, $0 \le s \le 1$, is a homotopy of gauge transformations, the same clutching construction over $[0,1]_s \times [0,1]_t \times S^4$, with the t-ends identified by g_s, gives a six-dimensional bordism between (Y_{g_0}, P_{g_0}) and (Y_{g_1}, P_{g_1}). The mod-two index is a bordism invariant, so the sign depends only on the homotopy class $[g] \in \pi_4(SU(2))$. Second, concatenating two gauge transformations amounts to gluing the corresponding mapping cylinders along an intermediate copy of S^4; additivity of the real mod-two index under gluing gives

$$\mathrm{Ind}_2(B_{Y_{g_0 g_1},R}) = \mathrm{Ind}_2(B_{Y_{g_0},R}) + \mathrm{Ind}_2(B_{Y_{g_1},R}) \pmod 2. \tag{153.32}$$

Thus the Pfaffian sign is a character of the component group of the gauge group. For $SU(2)$ on S^4, this component group is $\pi_4(SU(2)) \simeq \mathbb{Z}_2$. The nontrivial content of Theorem 153.7 is the value of this character on the generator, and its representation dependence. The clutching construction above is the part of the global-anomaly argument that belongs directly to the QFT background-field setup.

Trace-delta normalization in the $SU(2)$ representation ring. The arithmetic in Theorem 153.7 uses the same trace convention as the instanton index formula (152.16). Let J_a be the usual Hermitian spin-j generators with $[J_a, J_b] = \mathrm{i}\epsilon^c{}_{ab} J_c$ and J_3-weights

$$m = -j, -j+1, \ldots, j.$$

Rotational invariance of the irreducible representation gives

$$\mathrm{tr}_{R_j}(J_a J_b) = C_j \delta_{ab}.$$

Taking $a = b = 3$ fixes

$$C_j = \sum_{m=-j}^{j} m^2 = \frac{1}{3} j(j+1)(2j+1). \tag{153.33}$$

The monograph's trace-delta basis is $t_a = \sqrt{2}\, J_a$, since the fundamental spin-$\frac{1}{2}$ representation then has $\mathrm{tr}_{\square}(t_a t_b) = \delta_{ab}$. Therefore

$$T_\Delta(R_j) = 2C_j = \frac{2}{3} j(j+1)(2j+1) = \frac{n(n+1)(n+2)}{6}, \qquad n = 2j. \tag{153.34}$$

This derivation fixes the normalization of the integer that appears in the mod-two index theorem; it is not an independent anomaly calculation.

The parity of (153.34) is equally explicit:

$$T_\Delta(R_j) = \binom{n+2}{3}.$$

Lucas' binary criterion for binomial coefficients modulo 2 says that $\binom{N}{3}$ is odd exactly when the two lowest binary digits of N are both 1. With $N = n+2$, this is

$$n+2 \equiv 3 \pmod 4, \qquad \text{equivalently} \qquad n = 2j \equiv 1 \pmod 4. \tag{153.35}$$

Thus the quoted global-analysis input is the mod-two-index equality (153.30); the representation normalization and the $2j \equiv 1 \pmod 4$ criterion are ordinary finite-dimensional $SU(2)$ arithmetic in the chapter's trace convention.

Topological content of the mapping-torus index. The theorem is the point where topology enters the four-dimensional anomaly. The gauge transformation g representing the nontrivial element of $\pi_4(SU(2))$ produces a spin five-manifold Y_g equipped with an $SU(2)$ bundle, and the pair (Y_g, E_{R_j}) defines an element tested by the mod-two Dirac index. For the fundamental representation this element has odd mod-two index; this is the genuinely global datum invisible to the local four-dimensional cubic anomaly polynomial. The theorem further identifies the parity for a general irreducible representation with the trace-delta Dynkin index modulo 2, giving (153.30). Its proof uses the naturality of the coupled Dirac operator under representation operations together with a five-dimensional real-index computation for the generator of the $\pi_4(SU(2))$ mapping torus. The QFT analysis below uses the result only through the explicit parity formula displayed in the theorem.

Once (153.30) is fixed, the remaining anomaly criterion is ordinary arithmetic in the same trace convention used for the local anomaly polynomial.

The isospin-j Weyl fermion has the original spin $SU(2)$ global anomaly precisely when $2j \equiv 1 \pmod 4$. A collection of Weyl fermions in representations R_{j_α} is free of this anomaly precisely when

$$\sum_\alpha T_\Delta(R_{j_\alpha}) \equiv 0 \pmod 2. \tag{153.36}$$

Write $n = 2j$. The integer

$$T_\Delta(R_j) = \frac{n(n+1)(n+2)}{6}$$

is the binomial coefficient $\binom{n+2}{3}$. Its parity is given by Lucas' theorem: $\binom{N}{3}$ is odd exactly when the binary digits of 3 are contained in those of N. Since 3 has binary expansion $\cdots 0011$, this means $N = n+2 \equiv 3 \pmod 4$, or

$$n \equiv 1 \pmod 4.$$

Equation (153.30) then gives the Pfaffian sign. For several Weyl fermions the Pfaffian line is the tensor product of the individual Pfaffian lines, so the signs multiply and the exponents add modulo 2.

Example 153.8 (First few $SU(2)$ representations)**.** The sequence of trace-delta indices is

j	$\frac{1}{2}$	1	$\frac{3}{2}$	2	$\frac{5}{2}$
$T_\Delta(R_j)$	1	4	10	20	35.

Thus a single doublet has the anomaly, a single triplet does not, a single four-dimensional representation does not, and a single six-dimensional representation has the anomaly. The vanishing of the ordinary four-dimensional cubic $SU(2)$ anomaly does not decide this question because $SU(2)$ has no independent symmetric cubic invariant.

153.6 Dai–Freed Inflow

The determinant or Pfaffian of a d-dimensional fermion is a vector in an anomaly line over the background groupoid. A $(d+1)$-dimensional invertible field theory trivializes this line when its boundary variation is the inverse of the fermion-line variation. In the free-fermion model the closed $(d+1)$-manifold partition function is the eta phase [61]:

$$Z_{\mathrm{DF}}(Y) = \exp(2\pi \mathrm{i}\, \xi(B_Y)) \tag{153.37}$$

for a complex chiral determinant, with the corresponding mod-two sign in the real Pfaffian case.

If Y has boundary M, the APS construction assigns not a number but a vector in the inverse determinant line over the boundary background on M. Pairing this vector with the boundary fermion determinant gives a number. Changing the filling changes the trivialization by the closed-manifold phase obtained by gluing the two fillings. This is the precise geometric meaning of anomaly inflow in the eta-invariant model.

Closed phases from bounding manifolds. The closed phase (153.37) is constrained by the APS formula whenever the odd-dimensional pair (Y, E) bounds an even-dimensional pair $(X, \widetilde{E})$ with product structure near $Y = \partial X$. In the convention of (153.5),

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(\widetilde{E})\big]_{\dim X} - \xi(B_Y).$$

The index is an integer, hence

$$\exp(2\pi \mathrm{i}\, \xi(B_Y)) = \exp\left(2\pi \mathrm{i} \int_X \big[\widehat{A}(TX)\,\mathrm{ch}(\widetilde{E})\big]_{\dim X}\right) \tag{153.38}$$

for bounding data. If X and X' are two such fillings, gluing X to $-X'$ gives a closed even-dimensional spin manifold. The closed Atiyah–Singer theorem says that the difference of the two integrals in (153.38) is an integer. Thus the phase is independent of the chosen filling, even though neither integral is itself a canonical real number modulo ordinary equality. This is the point at which the bulk local index density and the boundary eta invariant are tied to the same $U(1)$-valued object.

Boundary vector and gluing law. Let Y now be an odd-dimensional spin manifold with boundary M, and let all geometric data be product type near M. The Dai–Freed construction assigns a vector

$$Z_{\mathrm{DF}}(Y) \in L_M^{-1},$$

where L_M is the determinant or Pfaffian anomaly line of the boundary fermion system. This vector is a trivialization of the boundary anomaly line, not a numerical partition function. The numerical partition function appears only after pairing it with the boundary fermion determinant vector in L_M.

If Y_0 and Y_1 have the same boundary M, with the same boundary background, the ratio between the two boundary trivializations is the closed phase of the glued odd manifold

$$\overline{Y} = Y_0 \cup_M (-Y_1).$$

In the determinant-line pairing this is the gluing identity

$$\big\langle Z_{\mathrm{DF}}(Y_0), Z_{\mathrm{DF}}(-Y_1)\big\rangle = Z_{\mathrm{DF}}\big(Y_0 \cup_M (-Y_1)\big), \tag{153.39}$$

with the evident real-line version in the Pfaffian case. The left side pairs the vector in L_M^{-1} supplied by Y_0 with the dual vector supplied by the orientation reversal of Y_1. The right side is a number because the boundary anomaly lines cancel under gluing. Associativity of gluing is therefore not an extra physical postulate: it is the statement that tensoring one-dimensional determinant lines and composing their canonical pairings give the same number as gluing all odd-dimensional pieces first. This is the finite-line algebra that the eta invariant realizes analytically.

Proposition 153.9 (Dai–Freed boundary pairing cancels the anomaly cocycle)**.** *Let A be a structured background on M, let g be a gauge or background automorphism, and let $\alpha(A,g) : L_A \to L_{A^g}$ denote the determinant- or Pfaffian-line transport. Suppose the boundary fermion functional is a line-valued vector $\Psi(A) \in L_A$ with covariance*

$$\Psi(A^g) = \alpha(A,g)\Psi(A), \tag{153.40}$$

and a Dai–Freed filling Y supplies a vector $Z_{\mathrm{DF}}(Y;A) \in L_A^{-1}$ with inverse covariance

$$Z_{\mathrm{DF}}(Y;A^g) = \alpha(A,g)^{-1} Z_{\mathrm{DF}}(Y;A). \tag{153.41}$$

Then the paired amplitude

$$\mathcal{A}_Y(A) = \big\langle Z_{\mathrm{DF}}(Y;A), \Psi(A)\big\rangle \tag{153.42}$$

is invariant under g. If Y_0 and Y_1 are two fillings with the same boundary background, then

$$\frac{\mathcal{A}_{Y_0}(A)}{\mathcal{A}_{Y_1}(A)} = Z_{\mathrm{DF}}\big(Y_0 \cup_M (-Y_1)\big), \tag{153.43}$$

whenever the denominator is nonzero. Thus inflow does not make the anomalous boundary determinant into a scalar by itself; it supplies the inverse line vector needed to form a scalar, and changing the inverse-line trivialization is measured by a closed invertible-theory phase.

Proof. Work in a local frame e_A of L_A. Write $\Psi(A) = \psi_A e_A$, $Z_{\mathrm{DF}}(Y;A) = z_A e_A^{-1}$, and let the line transport multiply the frame coordinate by a phase $\alpha(A,g)$. The covariance equations give $\psi_{A^g} = \alpha(A,g)\psi_A$ and $z_{A^g} = \alpha(A,g)^{-1} z_A$. Hence

$$\mathcal{A}_Y(A^g) = z_{A^g}\psi_{A^g} = z_A\psi_A = \mathcal{A}_Y(A).$$

For two fillings, the ratio $z_{0,A}/z_{1,A}$ is a scalar because both vectors live in the same inverse line. The gluing law (153.39) identifies this scalar with the closed Dai–Freed phase of $Y_0 \cup_M (-Y_1)$. Pairing both numerator and denominator with the same boundary vector $\Psi(A)$ gives (153.43). □

Composition through an intermediate boundary. The same line-valued mechanism controls the anomaly factor when a physical spacetime is cut into successive pieces. We use the ordinary bordism orientation convention of Chapter 103: a bordism $Y_{01} : M_0 \to M_1$ has

$$\partial Y_{01} = (-M_0) \sqcup M_1.$$

Orientation reversal dualizes the anomaly line, $L_{-M} \simeq L_M^{-1}$. Since the Dai–Freed object for a manifold with boundary is a vector in the inverse line over the full boundary, this gives

$$Z_{\mathrm{DF}}(Y_{01}) \in L_{\partial Y_{01}}^{-1} \simeq (L_{-M_0} \otimes L_{M_1})^{-1} \simeq L_{M_0} \otimes L_{M_1}^{-1}.$$

Thus the Dai–Freed bulk has the dual variance to a relative boundary-QFT transition amplitude from M_0 to M_1, which would live in $L_{M_0}^{-1} \otimes L_{M_1}$. The former is the inverse anomaly factor that cancels the latter; it is not itself the physical transition kernel.

For successive invertible bulk bordisms $Y_{01} : M_0 \to M_1$ and $Y_{12} : M_1 \to M_2$, the resulting Dai–Freed vectors have the form

$$Z_{\mathrm{DF}}(Y_{01}) \in L_{M_0} \otimes L_{M_1}^{-1}, \qquad Z_{\mathrm{DF}}(Y_{12}) \in L_{M_1} \otimes L_{M_2}^{-1}.$$

Their composition is obtained by evaluating the two M_1-factors:

$$Z_{\mathrm{DF}}(Y_{12} \circ Y_{01}) = \big(\mathrm{id}_{L_{M_0}} \otimes \mathrm{ev}_{L_{M_1}} \otimes \mathrm{id}_{L_{M_2}^{-1}}\big)\big(Z_{\mathrm{DF}}(Y_{01}) \otimes Z_{\mathrm{DF}}(Y_{12})\big). \tag{153.44}$$

Here $\mathrm{ev}_{L_{M_1}} : L_{M_1}^{-1} \otimes L_{M_1} \to \mathbb{C}$ is the evaluation pairing, with the displayed tensor order understood. In the real Pfaffian case L_M is a $\mathbb{Z}_2$-graded real superline; the formulas above are written in the order in which the intermediate factors are evaluated, and any reordering of odd Pfaffian factors uses the Koszul sign rule.

This is only the anomaly-line component of locality. A boundary Hilbert-space matrix element, or a Euclidean transition amplitude, also requires an actual state space, pairing or integration measure, gauge treatment, and topology/convergence statement. Once that physical gluing operation has been separately constructed, the anomaly factors on the common cut are paired away by (153.44); the line identity alone does not construct the sum or integral over physical degrees of freedom.

Proposition 153.10 (Intermediate-cut frame cancellation)**.** *Choose local frames e_i of the anomaly lines L_{M_i}. Write*

$$Z_{\mathrm{DF}}(Y_{01}) = z_{01}\, e_0 \otimes e_1^{-1}, \qquad Z_{\mathrm{DF}}(Y_{12}) = z_{12}\, e_1 \otimes e_2^{-1}.$$

Then the composed coefficient in $L_{M_0} \otimes L_{M_2}^{-1}$ is $z_{01}z_{12}$, and it is independent of the choice of frame e_1 on the glued boundary. If the frame on M_1 is changed by $e_1 \mapsto qe_1$, $q \in U(1)$, the two coefficients transform as $z_{01} \mapsto qz_{01}$ and $z_{12} \mapsto q^{-1}z_{12}$; their product is unchanged. The same statement holds for real Pfaffian lines with $q = \pm 1$.

Proof. The evaluation pairing satisfies $\mathrm{ev}_{L_{M_1}}(e_1^{-1} \otimes e_1) = 1$. Substituting the two displayed expressions into (153.44) gives

$$Z_{\mathrm{DF}}(Y_{12} \circ Y_{01}) = z_{01}z_{12}\, e_0 \otimes e_2^{-1}.$$

After the frame change $e_1' = qe_1$, the same vectors are written as

$$Z_{\mathrm{DF}}(Y_{01}) = (qz_{01})\, e_0 \otimes (e_1')^{-1}, \qquad Z_{\mathrm{DF}}(Y_{12}) = (q^{-1}z_{12})\, e_1' \otimes e_2^{-1}.$$

The product of the two coefficients is still $z_{01}z_{12}$, which is the coefficient of the glued bordism in the remaining endpoint lines. $\square$

When a relative boundary-theory amplitude $\mathcal{U}_{02} \in L_{M_0}^{-1} \otimes L_{M_2}$ is paired with the composed bulk vector, all exposed anomaly lines are evaluated and the result is an ordinary number. If the physical theory supplies a valid cut formula for $\mathcal{U}_{02}$ through M_1, then (153.44) says that the anomaly-line part of that cut formula is independent of the artificial frame on M_1. All phase data are carried by the exposed endpoint lines and by the closed-manifold eta phase that compares two different global anomaly-line trivializations, as in (153.43).

Local descent as the infinitesimal limit of inflow. For a contractible loop of background fields, the Dai–Freed holonomy reduces to the exponential of the descent integral determined by the local anomaly polynomial. This statement is not an additional index theorem. Once the Bismut–Freed curvature formula and the APS holonomy formula have been fixed with the conventions above, the remaining passage from global inflow to the local consistent anomaly is ordinary Stokes transgression in background-field space.

Let $\mathcal{B}$ be a coordinate patch in the space of structured backgrounds and let $\gamma = \partial\Sigma$ be an oriented contractible loop bounding a smooth two-chain $\Sigma \subset \mathcal{B}$. Write Ω_{BF} for the normalized curvature two-form of the Bismut–Freed connection, with the sign convention fixed by (153.11): for a disk contained in this patch,

$$\mathrm{Hol}_\gamma(\mathrm{Det}\, D) = \exp\left(2\pi\mathrm{i} \int_\Sigma \Omega_{\mathrm{BF}}\right). \tag{153.45}$$

The curvature theorem identifies Ω_{BF} with the fiber integral over M of the degree-$(d+2)$ component of $\widehat{A}(TM)\,\mathrm{ch}(E)$, again in the same sign convention. Equivalently, if I_{d+2} denotes the normalized anomaly polynomial on the universal family over $\mathcal{B} \times M$, then

$$\int_\Sigma \Omega_{\mathrm{BF}} = \int_{\Sigma\times M} I_{d+2}. \tag{153.46}$$

Now specialize one tangent direction of Σ to a gauge-orbit direction generated by a Lie-algebra-valued parameter λ. Choose a Chern–Simons representative $I_{d+1}^{(0)}$ on physical spacetime and its descent form $I_d^{(1)}(\lambda, A)$, so that

$$I_{d+2} = dI_{d+1}^{(0)}, \qquad \delta_\lambda I_{d+1}^{(0)} = dI_d^{(1)}(\lambda, A). \tag{153.47}$$

Stokes on the two-parameter cylinder in background space turns $\int_{\Sigma\times M} I_{d+2}$ into the integral of $I_d^{(1)}$ over the physical boundary slice. Thus the infinitesimal gauge variation of a local trivialization of the fermion determinant line is

$$\delta_\lambda \log Z_{\mathrm{fermion}}(A) = 2\pi\mathrm{i} \int_M I_d^{(1)}(\lambda, A), \tag{153.48}$$

up to the sign choice already fixed by the determinant-line convention in (153.11). This is the same local descent class used in the perturbative chiral-anomaly calculation and in the anomaly-inflow construction developed earlier in the monograph. Local counterterms change $I_d^{(1)}$ by a relative coboundary; they change the local connection form on the determinant line but not its curvature or its contractible-loop holonomy.

The qualification "contractible" is essential. If the loop is not filled by a disk in the background groupoid, equations (153.45)–(153.48) do not determine the holonomy. The reduced eta invariant may then contain a flat anomaly-line contribution invisible to the local polynomial. The Witten $SU(2)$ anomaly above is exactly of this type: the local cubic descent vanishes, while a nontrivial mapping-torus mod-two index detects the large-gauge holonomy.

Theorem boundary for the global-anomaly construction. The anomaly statements in this chapter use four external global-analysis inputs, and the QFT conclusions are the consequences derived from them in the fixed conventions above. The APS theorem supplies the Fredholm boundary problem and the identity

$$\mathrm{Ind}(D_X^{+,\mathrm{APS}}) = \int_X [\widehat{A}(TX)\,\mathrm{ch}(E)] - \xi(B_{\partial X})$$

with the product-collar and reduced-eta conventions fixed in (153.3)–(153.5). From this input the text derives the cylinder congruence, the endpoint-kernel term, the orientation sign in the spectral-flow bookkeeping, and the local descent variation of the eta phase. The Bismut–Freed theorem supplies the Quillen determinant line, its connection, its local curvature, and the mapping-torus holonomy formula. From these data the text derives the quotient-groupoid cocycle criterion: a chiral determinant descends to the quotient by gauge transformations if and only if the anomaly line admits an equivariant trivialization; local counterterms alter the cocycle by a coboundary; based loop holonomies are invariant. The Dai–Freed construction supplies the boundary vector in the inverse anomaly line, its orientation-dual composition law, and the cancellation of anomaly factors on artificial cuts. From those line-valued statements the text derives the inflow cancellation criterion and the contractible-loop reduction to the same descent representative used in the perturbative anomaly chapter. They do not by themselves construct the physical Hilbert-space pairing, path-integral measure, gauge fixing, or convergence needed for a full QFT gluing theorem. Finally, the real mod-two index theorem supplies the value of the Pfaffian holonomy for the Witten $SU(2)$ mapping torus. The trace-delta normalization, the $2j \equiv 1 \pmod 4$ parity criterion, the tensor-product cancellation condition, and the separation between local cubic anomaly and global sign anomaly are then finite representation-theoretic and anomaly-line consequences in the monograph's conventions.

Thus the remaining quoted material is pure global-analysis infrastructure: Fredholmness and heat-kernel local index theory with APS boundary conditions, construction and holonomy of the determinant/Pfaffian line, and the real KO-theoretic mod-two index calculation on the Witten mapping torus. The QFT-facing anomaly claims are the groupoid descent, local descent, inflow, and cancellation statements derived from those inputs in the preceding paragraphs.

153.7 Interacting Theories and Anomaly Lines

For free fermions, the anomaly line is constructed from a family of Dirac operators. For an interacting QFT, the same structure should be formulated without choosing quadratic fields. The background groupoid has objects given by structured background fields and morphisms given by gauge transformations, diffeomorphisms, and identifications of background data. An anomaly line is a functor from this groupoid to the groupoid of complex lines, equipped with compatible gluing data. The partition function of the anomalous theory is a section of this functorial line.

Local counterterms change the trivialization of the line. They shift the connection one-form and the cocycle representative, but they do not change the curvature class or the holonomy class. Thus a genuine global anomaly is not removed by changing local coordinates on the space of actions.

Open Problem 153.11 (Global anomaly line for interacting QFT). Construct the anomaly line of an interacting QFT over the space of background fields, prove its local curvature and global holonomy formulae, and identify the conditions under which it is represented by an invertible bulk field theory. The free-fermion determinant and Pfaffian lines developed above are models for this structure, not a general construction of it.

Chapter 154

Cosmological Spacetimes and Particle Creation

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter studies free scalar QFT on time-dependent globally hyperbolic backgrounds. The central point is not that "particles are ambiguous" as a slogan, but the precise mathematical statement: a particle interpretation is a choice of positive-frequency subspace, equivalently a compatible complex structure on the real symplectic space of solutions. When the geometry has static asymptotic regions, the in and out complex structures are selected by the asymptotic time translations and their mismatch is measured by Bogoliubov coefficients. When no such asymptotic regions exist, one uses state properties such as the Hadamard condition, adiabatic ultraviolet behavior, and detector response.

154.1 Spatially Flat Robertson–Walker Metrics

Let $M = I \times \mathbb{R}^{d-1}$, with $d \geq 2$, and let

$$g = -dt^2 + a(t)^2 d\mathbf{x}^2 = a(\eta)^2(-d\eta^2 + d\mathbf{x}^2), \qquad d\eta = \frac{dt}{a(t)}. \tag{154.1}$$

Assume $a(\eta) > 0$ is smooth on the conformal-time interval under consideration. We write

$$\mathcal{H}(\eta) = \frac{a'(\eta)}{a(\eta)} \tag{154.2}$$

for the conformal Hubble function. The scalar curvature of (154.1) is

$$R = (d-1)a^{-2}\big(2\mathcal{H}' + (d-2)\mathcal{H}^2\big). \tag{154.3}$$

Consider a real scalar field satisfying

$$(\Box_g - m^2 - \xi R)\phi = 0. \tag{154.4}$$

The Fourier convention is

$$\phi(\eta, \mathbf{x}) = \int \frac{d^{d-1}\mathbf{k}}{(2\pi)^{d-1}}\, \phi_{\mathbf{k}}(\eta) e^{\mathrm{i}\mathbf{k}\cdot\mathbf{x}}, \qquad k = |\mathbf{k}|. \tag{154.5}$$

Remark 154.1 (Robertson–Walker mode equation)*.* Let

$$p = \frac{d-2}{2}, \qquad \chi_{\mathbf{k}}(\eta) = a(\eta)^p \phi_{\mathbf{k}}(\eta). \tag{154.6}$$

Then $\chi_{\mathbf{k}}$ obeys

$$\chi_{\mathbf{k}}'' + \Omega_k(\eta)^2 \chi_{\mathbf{k}} = 0, \tag{154.7}$$

where

$$\Omega_k^2 = k^2 + a^2(m^2 + \xi R) - p\mathcal{H}' - p^2\mathcal{H}^2. \tag{154.8}$$

For a massless conformally coupled scalar, with

$$m = 0, \qquad \xi = \xi_c = \frac{d-2}{4(d-1)}, \tag{154.9}$$

one has $\Omega_k^2 = k^2$.

For the metric (154.1),

$$\Box_g \phi = a^{-2}\left[-\partial_\eta^2 \phi - (d-2)\mathcal{H}\,\partial_\eta \phi + \Delta_{\mathbf{x}}\phi\right].$$

Substituting (154.5) into (154.4) gives

$$\phi_{\mathbf{k}}'' + (d-2)\mathcal{H}\phi_{\mathbf{k}}' + \big(k^2 + a^2(m^2 + \xi R)\big)\phi_{\mathbf{k}} = 0. \tag{154.10}$$

Writing $\phi_{\mathbf{k}} = a^{-p}\chi_{\mathbf{k}}$, with $2p = d-2$, gives

$$\phi_{\mathbf{k}}' = a^{-p}(\chi_{\mathbf{k}}' - p\mathcal{H}\chi_{\mathbf{k}}),$$

and

$$\phi_{\mathbf{k}}'' = a^{-p}\left[\chi_{\mathbf{k}}'' - 2p\mathcal{H}\chi_{\mathbf{k}}' + (p^2\mathcal{H}^2 - p\mathcal{H}')\chi_{\mathbf{k}}\right].$$

The first-derivative terms cancel in (154.10), leaving (154.7) and (154.8). Finally,

$$a^2\xi_c R = \frac{d-2}{4}\big(2\mathcal{H}' + (d-2)\mathcal{H}^2\big) = p\mathcal{H}' + p^2\mathcal{H}^2,$$

so the curvature and rescaling terms cancel when $m = 0$ and $\xi = \xi_c$.

The cancellation in the conformally coupled massless case is an exact calculation, not an adiabatic statement. It is the local manifestation of conformal covariance of the classical wave equation.

154.2 Symplectic Space and Complex Structures

Let $\mathcal{S}$ be the real vector space of smooth solutions of (154.4) with compact Cauchy data. On any Cauchy surface Σ, define

$$\sigma(\phi_1, \phi_2) = \int_\Sigma d\Sigma^\mu \left(\phi_1 \nabla_\mu \phi_2 - \phi_2 \nabla_\mu \phi_1\right). \tag{154.11}$$

The current inside the integral is conserved whenever both fields satisfy the equation of motion, so σ is independent of Σ.

Definition 154.2 (Compatible complex structure)**.** A compatible complex structure on $(\mathcal{S}, \sigma)$ is a real linear map $J : \mathcal{S} \to \mathcal{S}$ such that

$$J^2 = -1, \qquad \sigma(Ju, Jv) = \sigma(u, v), \qquad \sigma(u, Ju) > 0 \quad (u \neq 0). \tag{154.12}$$

It defines a one-particle inner product

$$\langle u, v\rangle_J = \sigma(u, Jv) + \mathrm{i}\sigma(u, v). \tag{154.13}$$

Completing $(\mathcal{S}, \langle\cdot,\cdot\rangle_J)$ gives the one-particle Hilbert space $\mathcal{H}_J$, and the symmetric Fock space $\mathcal{F}_J = \mathrm{Sym}\,\mathcal{H}_J$ gives the associated quasifree representation.

Equivalently, after complexification, J selects the $+\mathrm{i}$-eigenspace as the positive-frequency subspace. This is the precise datum behind a particle interpretation. Different choices of J can be unitarily inequivalent in infinite volume.

Theorem 154.3 (Shale–Stinespring criterion, diagonal discrete form)**.** *Let the one-particle space be a separable bosonic Hilbert space with orthonormal mode basis indexed by a countable set I, paired by an involution $n \mapsto \bar{n}$. Suppose two quasifree complex structures are related mode-by-mode by Bogoliubov coefficients*

$$u_n^{(1)} = \alpha_n u_n^{(2)} + \beta_n \overline{u_{\bar{n}}^{(2)}}, \tag{154.14}$$

with

$$|\alpha_n|^2 - |\beta_n|^2 = 1.$$

Then the two Fock representations are unitarily equivalent precisely when

$$\sum_{n \in I_+} |\beta_n|^2 < \infty, \tag{154.15}$$

where I_+ contains one representative from each non-fixed pair $\{n, \bar{n}\}$, with the evident one-oscillator modification for fixed points. In that case the Bogoliubov transformation is implemented by a unitary operator on Fock space.

Proof. For a finite set of modes the statement is the standard squeeze construction. On one two-mode block write

$$b_n = \alpha_n a_n + \beta_n a_{\bar{n}}^\dagger, \qquad b_{\bar{n}} = \alpha_n a_{\bar{n}} + \beta_n a_n^\dagger,$$

after absorbing harmless phases into the mode vectors. The relation $|\alpha_n|^2 - |\beta_n|^2 = 1$ is exactly the condition that $[b_n, b_n^\dagger] = [b_{\bar{n}}, b_{\bar{n}}^\dagger] = 1$. Put

$$\gamma_n = -\frac{\beta_n}{\alpha_n}.$$

The vector in the old Fock space annihilated by b_n and $b_{\bar{n}}$ is

$$\Omega_{\gamma_n} = (1 - |\gamma_n|^2)^{1/2} \sum_{m=0}^{\infty} \gamma_n^m |m\rangle_n \otimes |m\rangle_{\bar{n}}, \tag{154.16}$$

because applying a_n to the m-th term and applying $\gamma_n a_{\bar{n}}^\dagger$ to the $(m-1)$-st term cancel. The normalization follows from the geometric series and the identity

$$1 - |\gamma_n|^2 = \frac{|\alpha_n|^2 - |\beta_n|^2}{|\alpha_n|^2} = |\alpha_n|^{-2}.$$

The fixed-point one-oscillator block is the usual one-mode squeezed vector and gives the same square-summability condition, with a different harmless normalization convention.

For an infinite countable set, the transformed vacuum is the infinite tensor product of the block vacua Ω_{γ_n}. Von Neumann's criterion for incomplete infinite tensor products says that this tensor product defines a nonzero vector in the reference Fock space exactly when

$$\sum_{n \in I_+} \big(1 - |\langle 0_n 0_{\bar{n}}, \Omega_{\gamma_n}\rangle|\big) < \infty.$$

Here

$$|\langle 0_n 0_{\bar{n}}, \Omega_{\gamma_n}\rangle| = (1 - |\gamma_n|^2)^{1/2}.$$

Since $1 - \sqrt{1-x}$ is comparable to x for $0 \le x \le 1$, the criterion is

$$\sum_{n \in I_+} |\gamma_n|^2 < \infty.$$

Because $|\gamma_n|^2 = |\beta_n|^2/(1+|\beta_n|^2)$, this is equivalent to $\sum_{n\in I_+} |\beta_n|^2 < \infty$: if the γ_n-sum converges, only finitely many $|\beta_n|$ can exceed 1, and on the remaining tail the two sequences are comparable.

When the sum is finite, the finite-mode squeeze implementers converge strongly on the finite-particle domain to an isometry whose range contains the finite-particle domain of the transformed representation; its extension is the implementing unitary. When the sum diverges, the candidate transformed vacuum has zero norm in the reference incomplete tensor product, so no unitary can implement the transformation: a unitary implementer would have to send the transformed vacuum to a nonzero vector annihilated by all b_n, and the block equations above determine that vector uniquely up to phase. □

For a field on a finite spatial box, (154.15) is the literal finite-volume Shale–Stinespring condition. On a noncompact homogeneous spatial slice the momentum label is continuous, and the diagonal map

$$(\beta \bar{f})(\mathbf{k}) = \beta_{\mathbf{k}}\, \overline{f(-\mathbf{k})}$$

is a multiplication operator, composed with parity and conjugation, on $L^2(d^{d-1}\mathbf{k})$. As an operator on a non-atomic L^2-space, such a diagonal multiplication operator is Hilbert–Schmidt only when it vanishes almost everywhere. Thus

$$\int d^{d-1}\mathbf{k}\, |\beta_{\mathbf{k}}|^2 < \infty$$

is a finite particle-density or local/box-normalized diagnostic; it is not, by itself, a statement of global unitary equivalence of the two infinite-volume Fock representations. This distinction is one of the main reasons the complex-structure formulation is cleaner than informal particle language.

154.3 In and Out Modes

Assume now that the scale factor and curvature approach static limits as $\eta \to \pm\infty$, so that

$$\Omega_k(\eta) \longrightarrow \omega_k^{\mathrm{in/out}} > 0 \qquad (\eta \to \mp\infty). \tag{154.17}$$

The in and out positive-frequency modes are normalized by the Wronskian condition

$$\chi_k \overline{\chi_k'} - \chi_k' \overline{\chi_k} = \mathrm{i} \tag{154.18}$$

and by

$$\chi_k^{\mathrm{in/out}}(\eta) \sim \frac{e^{-\mathrm{i}\omega_k^{\mathrm{in/out}}\eta}}{\sqrt{2\omega_k^{\mathrm{in/out}}}} \qquad \text{in the corresponding asymptotic region.} \tag{154.19}$$

Bogoliubov normalization and particle number. Let

$$\chi_k^{\mathrm{in}} = \alpha_k \chi_k^{\mathrm{out}} + \beta_k \overline{\chi_k^{\mathrm{out}}}. \tag{154.20}$$

Then

$$|\alpha_k|^2 - |\beta_k|^2 = 1. \tag{154.21}$$

If $|0, \mathrm{in}\rangle$ is the in-vacuum, the expected out-particle number in the $\mathbf{k}$-mode is

$$\langle 0, \mathrm{in}| a_{\mathbf{k}}^{\mathrm{out}\,*} a_{\mathbf{k}}^{\mathrm{out}} |0, \mathrm{in}\rangle = |\beta_k|^2 \tag{154.22}$$

in finite volume, with the usual delta-function density normalization in infinite volume. The Wronskian

$$W(f, g) = f g' - f' g$$

is conserved for any two solutions of $\chi'' + \Omega_k^2 \chi = 0$. The normalization (154.18) gives

$$W(\chi_k^{\mathrm{out}}, \overline{\chi_k^{\mathrm{out}}}) = \mathrm{i}, \qquad W(\overline{\chi_k^{\mathrm{out}}}, \chi_k^{\mathrm{out}}) = -\mathrm{i}.$$

Substitution of (154.20) therefore gives

$$\mathrm{i} = W(\chi_k^{\mathrm{in}}, \overline{\chi_k^{\mathrm{in}}}) = \mathrm{i}(|\alpha_k|^2 - |\beta_k|^2),$$

which proves (154.21).

The field mode admits both decompositions

$$\widehat{\chi}_{\mathbf{k}} = a_{\mathbf{k}}^{\mathrm{out}} \chi_k^{\mathrm{out}} + a_{-\mathbf{k}}^{\mathrm{out}\,*} \overline{\chi_k^{\mathrm{out}}} = a_{\mathbf{k}}^{\mathrm{in}} \chi_k^{\mathrm{in}} + a_{-\mathbf{k}}^{\mathrm{in}\,*} \overline{\chi_k^{\mathrm{in}}}.$$

Comparing coefficients gives

$$a_{\mathbf{k}}^{\mathrm{out}} = \overline{\alpha_k}\, a_{\mathbf{k}}^{\mathrm{in}} + \overline{\beta_k}\, a_{-\mathbf{k}}^{\mathrm{in}\,*}, \tag{154.23}$$

with the phase convention induced by (154.20). Since $a_{\mathbf{k}}^{\mathrm{in}}|0, \mathrm{in}\rangle = 0$ and $[a_{-\mathbf{k}}^{\mathrm{in}}, a_{-\mathbf{k}}^{\mathrm{in}\,*}] = 1$ in finite volume, (154.22) follows.

Example 154.4 (Instantaneous frequency jump)**.** For a single oscillator mode whose frequency changes suddenly from ω_i to ω_f, continuity of χ and χ' at the jump gives

$$\alpha = \frac{1}{2}\left(\sqrt{\frac{\omega_f}{\omega_i}} + \sqrt{\frac{\omega_i}{\omega_f}}\right), \qquad \beta = \frac{1}{2}\left(\sqrt{\frac{\omega_f}{\omega_i}} - \sqrt{\frac{\omega_i}{\omega_f}}\right), \tag{154.24}$$

and therefore

$$|\beta|^2 = \frac{(\omega_f - \omega_i)^2}{4\omega_i\omega_f}. \tag{154.25}$$

The example is not a smooth cosmological spacetime; it is a normalization check and a limiting model for a transition fast compared with the mode period.

154.4 Adiabatic States and Ultraviolet Control

When no static asymptotic regions exist, one can still impose a high-momentum condition on the positive-frequency modes. The adiabatic ansatz is

$$\chi_k(\eta) = \frac{1}{\sqrt{2W_k(\eta)}} \exp\left(-\mathrm{i}\int^{\eta} W_k(\eta')\, d\eta'\right), \qquad W_k(\eta) > 0. \tag{154.26}$$

Remark 154.5 (Riccati equation for the adiabatic frequency). The ansatz (154.26) solves (154.7) exactly if and only if

$$W_k^2 = \Omega_k^2 - \frac{1}{2}\frac{W_k''}{W_k} + \frac{3}{4}\left(\frac{W_k'}{W_k}\right)^2. \tag{154.27}$$

Write

$$\chi = (2W)^{-1/2} e^{-\mathrm{i}\Theta}, \qquad \Theta' = W.$$

Then

$$\frac{\chi'}{\chi} = -\frac{1}{2}\frac{W'}{W} - \mathrm{i}W$$

and

$$\frac{\chi''}{\chi} = -\mathrm{i}W' - \frac{1}{2}\left(\frac{W'}{W}\right)' + \left(-\frac{1}{2}\frac{W'}{W} - \mathrm{i}W\right)^2.$$

The imaginary terms cancel, leaving

$$\frac{\chi''}{\chi} = -W^2 - \frac{1}{2}\frac{W''}{W} + \frac{3}{4}\left(\frac{W'}{W}\right)^2.$$

Thus $\chi'' + \Omega_k^2\chi = 0$ is equivalent to (154.27).

The adiabatic expansion is obtained by assigning one derivative of $a(\eta)$ one adiabatic order and solving (154.27) recursively. To second adiabatic order, if $\omega_k = \Omega_k$ denotes the zeroth-order positive frequency,

$$W_k = \omega_k - \frac{\omega_k''}{4\omega_k^2} + \frac{3(\omega_k')^2}{8\omega_k^3} + O(\partial_\eta^4). \tag{154.28}$$

An adiabatic state of sufficiently high order is Hadamard for the scalar field on Robertson–Walker spacetime. Conversely, the point-splitting subtraction for $\langle T_{\mu\nu}\rangle$ has the same ultraviolet content as the fourth adiabatic order subtraction in four spacetime dimensions. Equality here means equality of the local large-k singular terms; finite local curvature counterterms remain the renormalization freedom described in Chapter 148.

154.5 Detector Response

Let $x(\tau)$ be a timelike worldline parametrized by proper time, and let $\lambda\chi(\tau)\mu(\tau)\widehat{\phi}(x(\tau))$ be an Unruh–DeWitt coupling with compactly supported switching function χ. For a detector energy gap E, first-order perturbation theory gives

$$P(E) = \lambda^2 \int d\tau\, d\tau'\, e^{-\mathrm{i}E(\tau-\tau')}\chi(\tau)\chi(\tau')W(x(\tau), x(\tau')), \tag{154.29}$$

where W is the Wightman two-point function of the state.

Positivity of the switched detector response. If W is a positive-type two-point function, then

$$P(E) \geq 0$$

for every real E and every smooth compactly supported switching function χ. The content is the positive-type property of the state applied to the detector smearing. Define the test function on spacetime

$$f_E(x) = \int d\tau\, e^{-\mathrm{i}E\tau}\chi(\tau)\delta(x, x(\tau))$$

in the distributional sense. Smearing the two-point function gives

$$P(E)/\lambda^2 = W(\overline{f_E}, f_E).$$

Positive type of the quasifree state is precisely the condition $W(\overline{f}, f) \geq 0$ for every test function f. The worldline smearing can be obtained as the limit of ordinary compactly supported spacetime test functions in a tubular neighborhood of the curve, so the same positivity applies. The approximation by ordinary test functions is part of the mathematical meaning of the idealized pointlike detector; a finite-size detector replaces the delta distribution by a smooth spatial profile and satisfies positivity directly.

Detector response is therefore a local operational probe of a chosen state. Its definition uses the state two-point distribution, the detector trajectory, and the switching/profile data.

154.6 The Bunch–Davies State in de Sitter Space

In the spatially flat patch of d-dimensional de Sitter space,

$$a(\eta) = \frac{-1}{H\eta}, \qquad \eta < 0, \qquad H > 0, \tag{154.30}$$

and $R = d(d-1)H^2$. Equation (154.8) becomes

$$\Omega_k^2 = k^2 - \frac{\nu^2 - \frac{1}{4}}{\eta^2}, \qquad \nu^2 = \frac{(d-1)^2}{4} - \frac{m^2}{H^2} - \xi d(d-1). \tag{154.31}$$

Remark 154.6 (Bunch–Davies mode functions). The mode

$$\chi_k^{\mathrm{BD}}(\eta) = \sqrt{\frac{-\pi\eta}{4}}\, \exp\left[\mathrm{i}\pi\left(\frac{\nu}{2} + \frac{1}{4}\right)\right] H_\nu^{(1)}(-k\eta) \tag{154.32}$$

solves the de Sitter mode equation and obeys

$$\chi_k^{\mathrm{BD}}(\eta) \sim \frac{e^{-\mathrm{i}k\eta}}{\sqrt{2k}} \qquad \eta \to -\infty. \tag{154.33}$$

It is normalized by

$$\chi_k^{\mathrm{BD}}\overline{(\chi_k^{\mathrm{BD}})'} - (\chi_k^{\mathrm{BD}})'\overline{\chi_k^{\mathrm{BD}}} = \mathrm{i}. \tag{154.34}$$

With $z = -k\eta > 0$, equation

$$\chi_k'' + \left(k^2 - \frac{\nu^2 - \frac{1}{4}}{\eta^2}\right)\chi_k = 0$$

is transformed by $\chi_k(\eta) = (-\eta)^{1/2} f(z)$ into Bessel's equation for f of order ν. Thus $H_\nu^{(1)}(z)$ gives a solution. The large-z asymptotic formula

$$H_\nu^{(1)}(z) \sim \sqrt{\frac{2}{\pi z}}\, \exp\left[\mathrm{i}\left(z - \frac{\pi\nu}{2} - \frac{\pi}{4}\right)\right]$$

turns (154.32) into (154.33). The Wronskian identity

$$H_\nu^{(1)}(z)\partial_z H_\nu^{(2)}(z) - \partial_z H_\nu^{(1)}(z) H_\nu^{(2)}(z) = -\frac{4\mathrm{i}}{\pi z}$$

then gives (154.34), with the additional minus sign from $z = -k\eta$.

For $m = 0$ and $\xi = \xi_c$, $\nu = 1/2$ and the Bunch–Davies mode reduces to the conformal Minkowski mode. For a massless minimally coupled scalar in $d = 4$, $\nu = 3/2$; the zero-mode and infrared behavior require separate care and cannot be suppressed by the local high-frequency definition alone.

The Bunch–Davies quasifree state is Hadamard and invariant under the connected de Sitter group for the standard massive range. Other de Sitter-invariant two-point functions must be tested against the Hadamard short-distance condition; de Sitter invariance alone is not a state-selection principle.

154.7 Backreaction Boundary

The expectation value $\langle T_{\mu\nu}\rangle$ in a time-dependent state is defined by the renormalized stress-tensor prescription of Chapter 148. The semiclassical Einstein equation

$$G_{\mu\nu} + \Lambda g_{\mu\nu} = 8\pi G \,\langle T_{\mu\nu}\rangle_{\mathrm{ren}} \tag{154.35}$$

is an equation for a classical metric and a quantum state. The right-hand side depends on the state, on the finite curvature counterterms, and on the renormalization convention for the cosmological constant and Newton constant. Particle production by itself is not a closed backreaction equation; it is one diagnostic extracted from the state when a particle decomposition has been selected.

Open Problem 154.7 (Interacting cosmological QFT). Construct interacting QFT on cosmological spacetimes with Hadamard states, renormalized stress tensor, detector response, particle-production diagnostics where asymptotic regions exist, and controlled semiclassical backreaction. The construction should distinguish the local definition of fields and states from the additional asymptotic structure needed to define particles.

Chapter 155

Microlocal Spectrum Condition And Hadamard Geometry

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops the microlocal form of the positive-frequency condition on curved spacetimes. The replacement for translation-invariant spectral support is a wavefront-set condition on distributions, and the local geometric form of the two-point function is the Hadamard parametrix.

155.1 Wavefront Set

Let $u \in \mathcal{D}'(X)$ be a distribution on a smooth manifold X. A point $(x, k) \in T^*X\backslash\{0\}$ is absent from the wavefront set $\mathrm{WF}(u)$ if there is a cutoff $\chi \in C_c^\infty(X)$ with $\chi(x) \neq 0$ and a conic neighborhood Γ of k such that the Fourier transform of χu decays faster than every power in Γ. The wavefront set records both the singular support and the covector directions of oscillation.

Definition 155.1 (Wavefront set in a chart)**.** Let $u \in \mathcal{D}'(X)$. In a coordinate chart $U \subset X$, write $\widehat{\chi u}(\xi)$ for the Fourier transform of the compactly supported distribution χu, $\chi \in C_c^\infty(U)$, in the chosen coordinates. A nonzero covector $k \in T_x^*X$ is a regular direction for u if there exist $\chi \in C_c^\infty(U)$, $\chi(x) \neq 0$, and an open conic neighborhood $\Gamma \subset \mathbb{R}^D \setminus \{0\}$ of the coordinate representative of k such that, for every N,

$$|\widehat{\chi u}(\xi)| \leq C_N(1 + |\xi|)^{-N}, \qquad \xi \in \Gamma. \tag{155.1}$$

The wavefront set $\mathrm{WF}(u)$ is the complement, in $T^*X \setminus 0$, of the regular directions.

The definition is independent of the chart. Under a change of coordinates, the localized Fourier transform is an oscillatory integral whose phase has non-degenerate mixed Hessian at the point under consideration; integration by parts in directions where the transformed covector is separated from the old singular cone preserves rapid decay. Thus $\mathrm{WF}(u)$ is a closed conic subset of $T^*X \setminus 0$.

Theorem 155.2 (Product criterion for distributions)**.** *Let $u, v \in \mathcal{D}'(X)$. Suppose that there is no*

$$(x,k) \in \mathrm{WF}(u) \quad \textit{and} \quad (x,-k) \in \mathrm{WF}(v). \tag{155.2}$$

Then the pointwise product uv has a unique distributional extension which agrees with the ordinary product when one factor is smooth. Moreover

$$\begin{aligned} \mathrm{WF}(uv) \subset\ & \mathrm{WF}(u) \cup \mathrm{WF}(v) \\ & \cup \{(x, k+\ell) : (x,k) \in \mathrm{WF}(u),\ (x,\ell) \in \mathrm{WF}(v),\ k+\ell \neq 0\}. \end{aligned} \tag{155.3}$$

Proof. The statement is local, so work in one coordinate chart and multiply by a cutoff equal to 1 near the point. If u and v are compactly supported distributions, the formal Fourier transform of the product is the convolution

$$\widehat{uv}(\xi) = (2\pi)^{-D} \int \widehat{u}(\eta)\widehat{v}(\xi-\eta)\,\mathrm{d}\eta. \tag{155.4}$$

The obstruction to defining this integral distributionally at large $|\eta|$ is simultaneous non-decay of $\widehat{u}(\eta)$ and $\widehat{v}(\xi-\eta)$. As $|\eta| \to \infty$, the second direction is asymptotic to $-\eta$. Thus a large-frequency obstruction can occur only from an opposite pair of singular covectors $(k,-k)$, which is excluded by (155.2).

Choose a conic partition of unity in the η-variable. On pieces where η avoids $\mathrm{WF}(u)$, the factor $\widehat{u}(\eta)$ is rapidly decreasing after localization. On pieces where $\xi - \eta$ avoids $\mathrm{WF}(v)$, the factor $\widehat{v}(\xi-\eta)$ is rapidly decreasing. The exclusion of opposite cones gives such a finite conic cover of the large-η region. The bounded-η region is harmless because Fourier transforms of compactly supported distributions have at most polynomial growth. This defines (155.4), and the same conic decomposition proves rapid decay of $\widehat{uv}$ away from the three sets displayed in (155.3).

Uniqueness follows by regularizing u and v with a smoothing approximate identity. The estimates above show convergence in every allowed conic region and independence of the regularization. If one factor is smooth, the construction reduces to ordinary multiplication because the smooth factor has rapidly decreasing localized Fourier transform. □

This criterion is the local analytic reason that Wick products and time-ordered products require subtraction before coincident points are taken.

155.2 Hadamard Two-Point Condition

Let M be a globally hyperbolic Lorentzian spacetime and let ϕ be a real scalar field satisfying

$$P_M\phi = 0, \qquad P_M = -\nabla^\mu\nabla_\mu + m^2 + \xi R[g]. \tag{155.5}$$

A quasifree state is determined by its two-point function

$$\omega_2(x,y) = \omega(\phi(x)\phi(y)).$$

The time orientation on tangent vectors induces a convention on covectors: a nonzero causal covector $k \in T_x^*M$ is future directed when its metric dual

$$k^\sharp = g^{\mu\nu} k_\nu \partial_\mu$$

is a future-directed causal vector. In mostly-plus Minkowski coordinates, this means that a future null covector has $k_0 < 0$. This convention makes the positive-frequency plane wave $e^{-\mathrm{i}Et+\mathrm{i}\mathbf{p}\cdot\mathbf{x}}$ carry future null covector $(-E, \mathbf{p})$.

The microlocal Hadamard condition is

$$\mathrm{WF}(\omega_2) = \{(x, k_x; y, -k_y) : (x, k_x) \sim (y, k_y),\ k_x \in \overline{V}_+^*\}.$$

Here $(x, k_x) \sim (y, k_y)$ means that x and y are joined by a null geodesic and that k_y is the parallel transport of k_x along that geodesic. The cone $\overline{V}_+^*$ is the closed future causal cone in the cotangent space.

The minus sign on the second covector is not a convention that can be dropped. It records that a two-point distribution is a distribution on $M \times M$. If the same future covector is transported from x to y, the corresponding singular phase is locally of the form

$$\exp\bigl(\mathrm{i}\lambda(\Phi(x) - \Phi(y))\bigr), \qquad \lambda \to +\infty,$$

so the covector on the second copy of M is the negative of the transported covector.

155.3 Higher Microlocal Spectrum Condition

For non-Gaussian states, the two-point condition is not enough. The curved-spacetime replacement of the Wightman spectral condition is a family of cone constraints on all n-point distributions.

Definition 155.3 (Microlocal spectrum cone)**.** Let $x_1, \ldots, x_n \in M$. A covector tuple

$$(x_1, k_1; \ldots; x_n, k_n) \in T^*M^n \setminus 0$$

belongs to $\Gamma_n(M)$ if there is a finite directed graph with vertex set $\{1, \ldots, n\}$ such that each edge $e : i \to j$ is assigned a future-directed causal covector field p_e parallel transported along a future-directed causal curve from x_i to x_j, and

$$k_i = \sum_{e:i\to j} p_e(x_i) - \sum_{e:j\to i} p_e(x_i) \qquad (i = 1, \ldots, n). \tag{155.6}$$

The empty graph gives the zero tuple, which is omitted from $T^*M^n \setminus 0$.

Definition 155.4 (Microlocal spectrum condition for a state)**.** A state ω on a scalar field algebra satisfies the microlocal spectrum condition when all n-point distributions

$$\omega_n(f_1, \ldots, f_n) = \omega(\phi(f_1) \cdots \phi(f_n))$$

obey

$$\mathrm{WF}(\omega_n) \subset \Gamma_n(M). \tag{155.7}$$

For $n = 2$, a graph with one edge $1 \to 2$ gives

$$(k_1, k_2) = (p, -p),$$

which is the sign pattern in the Hadamard two-point condition. For quasifree Hadamard states, Wick's theorem reduces every n-point distribution to a finite sum of products of two-point functions. Applying Theorem 155.2 and the graph description above shows that the microlocal spectrum condition for all n follows from the two-point Hadamard condition.

155.4 Hadamard Parametrix

The microlocal condition specifies the singular covector directions. The Hadamard parametrix specifies the local distribution with those singularities. This section constructs its coefficients from the operator (155.5). The construction is local in a normal convex neighborhood $\mathcal{U}$, so every pair $x, y \in \mathcal{U}$ is joined by a unique geodesic lying in $\mathcal{U}$.

Definition 155.5 (Synge function and boundary value)**.** Let $\sigma(x, y)$ be Synge's world function, one half of the signed squared geodesic distance from y to x. Choose a smooth time function T on $\mathcal{U}$ and set

$$\sigma_\epsilon(x, y) = \sigma(x, y) + \mathrm{i}\epsilon(T(x) - T(y)) + \epsilon^2, \qquad \epsilon > 0. \tag{155.8}$$

All formulas involving negative powers or logarithms of σ_ϵ are understood as distributional boundary values as $\epsilon \downarrow 0$.

The basic coincidence identities are

$$\sigma^{;\mu}\sigma_{;\mu} = 2\sigma, \qquad [\sigma] = 0, \qquad [\sigma_{;\mu}] = 0, \qquad [\sigma_{;\mu\nu}] = g_{\mu\nu}, \qquad [\Box_g \sigma] = 4, \tag{155.9}$$

where brackets denote the coincidence limit $y \to x$. The dimension four enters only through the last identity.

Definition 155.6 (Van Vleck determinant)**.** The van Vleck determinant is the biscalar density ratio

$$\Delta(x, y) = \frac{\det\bigl(-\nabla^x_\mu \nabla^y_\nu \sigma(x, y)\bigr)}{|g(x)|^{1/2}|g(y)|^{1/2}}, \tag{155.10}$$

written in any pair of local coordinates and interpreted invariantly by the density factors. It satisfies $\Delta(x, x) = 1$.

Lemma 155.7 (Hadamard coefficient U)**.** *In four spacetime dimensions, the coefficient of σ_ϵ^{-1} in the Hadamard parametrix is*

$$U(x, y) = \Delta(x, y)^{1/2}. \tag{155.11}$$

Equivalently, U is the unique smooth biscalar along each geodesic from y to x satisfying

$$2\sigma^{;\mu}\nabla_\mu U + (\Box_g \sigma - 4)U = 0, \qquad U(x, x) = 1. \tag{155.12}$$

Proof. For a smooth biscalar U, use $\sigma^{;\mu}\sigma_{;\mu} = 2\sigma$ to compute

$$\Box_g(\sigma^{-1}) = (4 - \Box_g \sigma)\sigma^{-2}. \tag{155.13}$$

Since $P_M = -\Box_g + m^2 + \xi R[g]$, the σ^{-2} term in $P_{M,x}(U/\sigma)$ is

$$\frac{2\sigma^{;\mu}\nabla_\mu U + (\Box_g\sigma - 4)U}{\sigma^2}. \tag{155.14}$$

The zeroth-order term $m^2 + \xi R[g]$ contributes only order σ^{-1}. Therefore the most singular coefficient vanishes exactly when (155.12) holds.

It remains to identify the solution. Along the geodesic parameterized by s, the operator $\sigma^{;\mu}\nabla_\mu$ is the radial derivative weighted by squared geodesic distance. The Jacobi-field equation for the geodesic exponential map gives

$$\sigma^{;\mu}\nabla_\mu \log\Delta = 4 - \Box_g\sigma. \tag{155.15}$$

Taking one half of this equation gives (155.12) for $U = \Delta^{1/2}$, and the coincidence normalization follows from the normal-coordinate expansion of the exponential map. Uniqueness follows from the first-order ordinary differential equation along the geodesic. $\Box$

Definition 155.8 (Hadamard parametrix in four dimensions)**.** Let

$$V(x,y) \sim \sum_{j\geq 0} v_j(x,y)\sigma(x,y)^j \tag{155.16}$$

be a formal expansion by smooth biscalars. The local Hadamard parametrix is

$$H_{\epsilon,\ell}(x,y) = \frac{1}{8\pi^2}\left[\frac{U(x,y)}{\sigma_\epsilon(x,y)} + V(x,y)\log\left(\frac{\sigma_\epsilon(x,y)}{\ell^2}\right)\right], \qquad \ell > 0, \tag{155.17}$$

where U is fixed by Lemma 155.7 and the jet of V at the diagonal is fixed by the recursion below.

Theorem 155.9 (Hadamard coefficient recursion)**.** *With P_M as in (155.5), the logarithmic coefficient is determined recursively by*

$$\big(2\sigma^{;\mu}\nabla_\mu + \Box_g\sigma - 2\big)v_0 = P_{M,x}U, \tag{155.18}$$

and, for $j \geq 0$,

$$\big(2\sigma^{;\mu}\nabla_\mu + \Box_g\sigma + 2j\big)v_{j+1} = \frac{1}{j+1}P_{M,x}v_j. \tag{155.19}$$

At coincidence,

$$v_0(x,x) = \frac{1}{2}\left(m^2 + \left(\xi - \frac{1}{6}\right)R[g](x)\right), \tag{155.20}$$

and

$$v_{j+1}(x,x) = \frac{1}{2(j+1)(j+2)}\, P_{M,x}v_j(x,y)\big|_{y=x}. \tag{155.21}$$

For every finite N, the partial parametrix built from $\sum_{j=0}^N v_j\sigma^j$ satisfies $P_{M,x}H_{\epsilon,\ell}^{[N]}$ smooth up to the order fixed by the omitted coefficient; a smooth V with the prescribed diagonal jet exists by Borel's lemma, and changing that smooth representative changes $H_{\epsilon,\ell}$ only by a smooth biscalar.

Proof. The calculation is performed for $x \neq y$ before the boundary value is taken. Put $s = \sigma(x,y)$. For a smooth biscalar v,

$$P_{M,x}(v\log s) = (P_{M,x}v)\log s - \frac{2\sigma^{;\mu}\nabla_\mu v + (\Box_g\sigma - 2)v}{s}. \tag{155.22}$$

Together with Lemma 155.7, the remaining s^{-1} term in $P_{M,x}(U/s + v_0 \log s)$ is canceled precisely by (155.18).

For $j \geq 0$, the coefficient of $s^j \log s$ in

$$P_{M,x}\left(\sum_{\ell \geq 0} v_\ell s^\ell \log s\right)$$

has two contributions. The term $v_j s^j$ contributes

$$s^j P_{M,x} v_j.$$

The lower-derivative part of $P_{M,x}(v_{j+1}s^{j+1})$ contributes

$$-(j+1)s^j \left(2\sigma^{;\mu}\nabla_\mu v_{j+1} + (\Box_g \sigma + 2j)v_{j+1}\right). \tag{155.23}$$

Vanishing of this coefficient gives (155.19). Taking $y \to x$ in (155.18) and using $\sigma^{;\mu} = 0$, $\Box_g \sigma = 4$, $U(x,x) = 1$, and

$$\Box_{g,x} U(x,y)\big|_{y=x} = \frac{1}{6} R[g](x) \tag{155.24}$$

gives (155.20). Taking the coincidence limit of (155.19) gives (155.21).

At each step the transport operator has nonzero diagonal coefficient, so the diagonal value and then all derivatives transverse to the diagonal are fixed by differentiating the transport equation. Borel's lemma produces a smooth biscalar with the prescribed infinite jet. Two such choices differ by a smooth biscalar flat at the diagonal, hence by a smooth contribution to (155.17). □

Remark 155.10 (Hadamard form of a quasifree two-point function)*.* A quasifree two-point function ω_2 is locally Hadamard in $\mathcal{U}$ precisely when

$$\omega_2(x,y) - H_{\epsilon,\ell}(x,y) \tag{155.25}$$

extends to a smooth biscalar on $\mathcal{U} \times \mathcal{U}$, after taking the distributional boundary value. Changing ℓ changes the subtraction by the smooth local term

$$-\frac{1}{4\pi^2} V(x,y) \log(\ell'/\ell). \tag{155.26}$$

The singular terms in (155.17) are fixed by the local equation $P_M \omega_2 = 0$ modulo smooth terms and by the positive-frequency boundary value in (155.8). Theorem 155.9 constructs the unique diagonal jet needed to remove the singular part generated by applying P_M in either variable. Therefore any two local parametrices with the same ℓ differ smoothly. A state is in the Hadamard class exactly when its two-point function has this universal singular part and no further singular remainder, which is (155.25). The scale formula follows by subtracting the two logarithms in (155.17).

155.5 Propagation Of Singularities

For a real principal type operator P, singularities of solutions to $Pu = 0$ propagate along the Hamiltonian flow of the principal symbol. For the Klein–Gordon operator (155.5), the principal symbol is $-g^{\mu\nu}k_\mu k_\nu$. The characteristic set is unchanged if one uses the metric Hamiltonian

$$p(x,k) = g^{\mu\nu}(x) k_\mu k_\nu.$$

The two Hamiltonian vector fields differ by an overall sign, hence by a reversal of the bicharacteristic parameter, not by a different null geodesic. The Hamiltonian vector field on T^*M is

$$H_p = \frac{\partial p}{\partial k_\mu}\frac{\partial}{\partial x^\mu} - \frac{\partial p}{\partial x^\mu}\frac{\partial}{\partial k_\mu}.$$

Thus its integral curves satisfy

$$\dot{x}^\mu = 2g^{\mu\nu}(x)k_\nu, \qquad \dot{k}_\mu = -(\partial_\mu g^{\alpha\beta})(x)k_\alpha k_\beta. \tag{155.27}$$

Let $v^\mu = \dot{x}^\mu$. Then

$$v^\mu = 2k^{\sharp\mu}, \qquad g_{\mu\nu}v^\mu v^\nu = 4p(x,k).$$

On $p = 0$, the projected curve $x(s)$ is therefore null. Lowering the index in the first Hamilton equation gives $k_\mu = \frac{1}{2}g_{\mu\nu}v^\nu$. Differentiate this identity and use the second Hamilton equation together with

$$\partial_\mu g^{\alpha\beta} = -g^{\alpha\rho}g^{\beta\sigma}\partial_\mu g_{\rho\sigma}.$$

One obtains

$$g_{\mu\nu}\left(\ddot{x}^\nu + \Gamma^\nu_{\rho\sigma}\dot{x}^\rho\dot{x}^\sigma\right) = 0.$$

Since g is non-degenerate, $x(s)$ is an affinely parametrized null geodesic, and k is parallel transported along it up to the fixed factor $1/2$.

Hence once the two-point function has positive-frequency wavefront directions on one Cauchy surface, the equation of motion propagates those directions along null geodesics. This is the geometric content of the microlocal spectrum condition.

155.6 Wick Products

For a Hadamard state, define the Wick square by point splitting:

$$:\phi^2:_H(f) = \int_M f(x)\lim_{y\to x}\big(\phi(x)\phi(y) - H(x,y)\mathbf{1}\big)\,\mathrm{d}\,\mathrm{vol}_g(x).$$

Changing the parametrix scale or adding a smooth local bisolution changes the Wick square by a local curvature polynomial:

$$:\phi^2:'_H = :\phi^2:_H + c_1 R + c_2 m^2.$$

Thus the local covariant field is defined only after the finite local renormalization coordinates are specified.

155.7 Time-Ordered Products

The time-ordered two-point distribution has a wavefront set with both future and past directions arranged according to time ordering. Products of time-ordered distributions at coincident points violate the wavefront-set product criterion. Perturbative algebraic renormalization extends these distributions from configuration space with diagonals removed to the full configuration space. The extension freedom is local and covariant, with degree bounded by scaling. Contact terms in curved spacetime are precisely the local distributions supported on these diagonals, with covariance and Ward identities imposed as constraints.

Open Problem 155.11 (Interacting microlocal spectrum condition)*.* Construct interacting locally covariant QFTs on curved backgrounds with Hadamard states, local Wick and time-ordered products, stress tensor, background gauge fields, and anomaly lines, and prove the microlocal spectrum condition for the resulting nonperturbative Wightman-type distributions.

Chapter 156

Perturbative Algebraic QFT On Curved Backgrounds

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops perturbative algebraic QFT on curved backgrounds as a local construction of interacting fields from Hadamard two-point functions, microcausal functionals, time-ordered products, and causal factorization. The framework is perturbative, but its locality and covariance conditions are nonperturbative constraints on the allowed coefficients.

156.1 Functional Spaces And Supports

Let M be an oriented time-oriented globally hyperbolic Lorentzian manifold and let

$$\mathcal{E}(M) = C^\infty(M, \mathbb{R})$$

be the classical configuration space of a real scalar field. It is a Frechet space with the usual seminorms obtained by taking suprema of derivatives on compact subsets in coordinate charts. A functional in this chapter is a smooth map $F : \mathcal{E}(M) \to \mathbb{C}$ in the Bastiani sense: all iterated directional derivatives

$$F^{(n)}(\phi)(h_1, \ldots, h_n) = \frac{\partial^n}{\partial t_1 \cdots \partial t_n} F\left(\phi + \sum_{i=1}^n t_i h_i\right)\Bigg|_{t_1=\cdots=t_n=0}$$

exist and depend jointly continuously on $(\phi, h_1, \dots, h_n)$. When $F^{(n)}(\phi)$ is distributional, the displayed multilinear form is identified with a distributional density on M^n by

$$F^{(n)}(\phi)(h_1, \dots, h_n) = \int_{M^n} F^{(n)}(\phi)(x_1, \dots, x_n) h_1(x_1) \cdots h_n(x_n).$$

This convention suppresses the volume density in the kernel notation.

The support of F is the closed set of points $x \in M$ such that, for every neighborhood $U \ni x$, there are fields ϕ and perturbations $h \in C_c^\infty(U)$ with

$$F(\phi + h) \neq F(\phi).$$

Thus support is defined by actual sensitivity of the functional, not by a chosen formula for it.

Definition 156.1 (Local functional)**.** A compactly supported smooth functional F is local if there are an integer r and a compactly supported smooth density-valued function L on the finite jet bundle $J^r M$, polynomial in the highest derivatives in the usual local-coordinate presentation, such that

$$F(\phi) = \int_M L\big(x, j_x^r \phi\big), \tag{156.1}$$

and such that $F^{(n)}(\phi)$ is supported on the thin diagonal

$$\Delta_n = \{(x, \dots, x) : x \in M\}$$

for every $n \geq 2$. Equivalently, after integrations by parts,

$$F^{(n)}(\phi)(x_1, \dots, x_n) = \sum_{|\alpha_2| + \cdots + |\alpha_n| \leq N} a_{\alpha_2 \cdots \alpha_n}(x_1; \phi) \partial^{\alpha_2} \delta(x_1, x_2) \cdots \partial^{\alpha_n} \delta(x_1, x_n) \tag{156.2}$$

in each coordinate chart, with coefficients depending locally and smoothly on a finite jet of ϕ.

The two descriptions in Definition 156.1 are both needed. The jet formula is the geometric expression of locality; the diagonal-support formula is the microlocal expression used in renormalization.

156.2 Microcausal Functionals

Definition 156.2 (Microcausal functional)**.** Let $F : \mathcal{E}(M) \to \mathbb{C}$ be a compactly supported smooth functional whose functional derivatives are compactly supported distributions,

$$F^{(n)}(\phi) \in \mathcal{E}'(M^n)$$

for all n. The functional is microcausal if

$$\mathrm{WF}(F^{(n)}(\phi)) \cap \Big((\overline{V}_+^*)^n \cup (\overline{V}_-^*)^n \Big) = \varnothing. \tag{156.3}$$

Here $\overline{V}_\pm^* \subset T^*M \setminus 0$ are the closed future and past causal covector cones, using the convention of Chapter 155. The vector space of microcausal functionals is denoted $\mathcal{F}_{\mu c}(M)$, and the subspace of local functionals is denoted $\mathcal{F}_{\mathrm{loc}}(M)$.

The exclusion in (156.3) is exactly the condition needed to contract with Hadamard two-point functions. A Hadamard bidistribution has future covectors in one variable and past covectors in the other. If all covectors in $F^{(n)}$ could point to the same closed time cone, the product criterion of Theorem 155.2 would fail when one contracts the variables against the Hadamard kernel.

156.3 Star Product

Choose a Hadamard two-point function H whose antisymmetric part is

$$H(x,y) - H(y,x) = \mathrm{i}\Delta(x,y),$$

where $\Delta = \Delta_{\mathrm{ret}} - \Delta_{\mathrm{adv}}$ is the causal propagator of the Klein–Gordon operator. For $F, G \in \mathcal{F}_{\mu c}(M)$, define

$$F \star_H G = \sum_{n=0}^{\infty} \frac{\hbar^n}{n!} \left\langle F^{(n)}(\phi), H^{\otimes n} G^{(n)}(\phi) \right\rangle . \tag{156.4}$$

The n-th summand means

$$\int_{M^{2n}} F^{(n)}(\phi)(x_1, \dots, x_n) \prod_{j=1}^{n} H(x_j, y_j) G^{(n)}(\phi)(y_1, \dots, y_n), \tag{156.5}$$

with the integral interpreted as the pairing of distributions. The microcausal cone condition and the Hadamard wavefront set make this pairing well-defined. For polynomial functionals the sum is finite; in general the product is understood in the completed formal space $\mathcal{F}_{\mu c}(M)[[\hbar]]$ when the formal series is meaningful.

Associativity and commutator. The product $\star_H$ is associative on polynomial microcausal functionals. Its first-order commutator is

$$[F, G]_{\star_H} = \mathrm{i}\hbar \{F, G\}_{\mathrm{P}} + O(\hbar^2), \qquad \{F, G\}_{\mathrm{P}} = \left\langle F^{(1)}, \Delta G^{(1)} \right\rangle , \tag{156.6}$$

where $\{\,\cdot\,,\,\cdot\,\}_{\mathrm{P}}$ is the Peierls bracket of the free field. Let m denote pointwise multiplication and set

$$\Gamma_H = \left\langle H, \frac{\delta}{\delta\phi} \otimes \frac{\delta}{\delta\phi} \right\rangle \qquad \text{on} \qquad \mathcal{F} \otimes \mathcal{F}.$$

Then

$$F \star_H G = m \circ e^{\hbar \Gamma_H} (F \otimes G).$$

For three factors let Γ_{ij} contract the i-th and j-th tensor factors. Functional derivatives with respect to different tensor factors commute, so

$$[\Gamma_{12}, \Gamma_{13}] = [\Gamma_{12}, \Gamma_{23}] = [\Gamma_{13}, \Gamma_{23}] = 0.$$

Both $(F \star_H G) \star_H K$ and $F \star_H (G \star_H K)$ are therefore equal to

$$m_3 \circ \exp\big(\hbar(\Gamma_{12} + \Gamma_{13} + \Gamma_{23})\big)(F \otimes G \otimes K),$$

where $m_3(F \otimes G \otimes K) = FGK$. This proves associativity.

The order-$\hbar$ part of the commutator is

$$\hbar \left\langle F^{(1)}, (H - H^{\mathrm{op}}) G^{(1)} \right\rangle = \mathrm{i}\hbar \left\langle F^{(1)}, \Delta G^{(1)} \right\rangle ,$$

which is the free Peierls bracket.

156.4 Change Of Hadamard Function

Proposition 156.3 (Change of Hadamard function)**.** *If H' is another Hadamard two-point function, then*

$$w = H' - H$$

is smooth. Define

$$\alpha_w = \exp\left(\frac{\hbar}{2}\left\langle w, \frac{\delta^2}{\delta\phi^2}\right\rangle\right).$$

Then

$$\alpha_w(F \star_H G) = \alpha_w(F) \star_{H'} \alpha_w(G). \tag{156.7}$$

Thus the abstract algebra is independent of the particular Hadamard parametrix up to a canonical isomorphism determined by the smooth difference.

Proof. Let

$$\Delta_w = \left\langle w, \frac{\delta^2}{\delta\phi^2}\right\rangle.$$

Because w is smooth, Δ_w maps microcausal polynomial functionals to microcausal polynomial functionals. The second-order operator Δ_w satisfies

$$\Delta_w(FG) = (\Delta_w F)G + F(\Delta_w G) + 2\left\langle F^{(1)}, wG^{(1)}\right\rangle. \tag{156.8}$$

Equivalently,

$$e^{\frac{\hbar}{2}\Delta_w} \circ m = m \circ e^{\hbar\Gamma_w}\left(e^{\frac{\hbar}{2}\Delta_w} \otimes e^{\frac{\hbar}{2}\Delta_w}\right), \tag{156.9}$$

where Γ_w is the cross-contraction with kernel w. Therefore

$$\begin{aligned}
\alpha_w(F \star_H G) &= e^{\frac{\hbar}{2}\Delta_w} m e^{\hbar\Gamma_H}(F \otimes G) \\
&= m e^{\hbar\Gamma_w}\left(e^{\frac{\hbar}{2}\Delta_w} \otimes e^{\frac{\hbar}{2}\Delta_w}\right) e^{\hbar\Gamma_H}(F \otimes G) \\
&= m e^{\hbar\Gamma_{H+w}}(\alpha_w F \otimes \alpha_w G) = \alpha_w(F) \star_{H'} \alpha_w(G).
\end{aligned}$$

□

156.5 Time-Ordered Products

Let $H_F = H + \mathrm{i}\Delta_{\mathrm{adv}}$ denote the Feynman bidistribution associated with H. Away from coincident points, the naive time-ordered product is obtained by replacing H in the contraction exponential by H_F. The problem is that H_F has a wavefront set whose products are not defined on diagonals. Thus time ordering is not a pointwise operation on local fields; it is an extension problem for distributions.

A system of time-ordered products is a family of maps

$$T_n : \mathcal{F}_{\mathrm{loc}}(M)^{\otimes n} \longrightarrow \mathcal{F}_{\mu\mathrm{c}}(M)[[\hbar]], \qquad n \geq 1, \tag{156.10}$$

with $T_1 = \mathrm{id}$, symmetric in the n entries, equal to the Feynman contraction formula away from partial diagonals, and satisfying:

$$\text{local covariance}, \qquad \text{causal factorization},$$
$$\text{field independence},$$
$$\text{scaling degree bounds}, \qquad \text{unitarity and Ward identities}.$$

These words are constraints, not decoration. Local covariance means natural dependence on the background metric and couplings. Field independence means that differentiating T_n with respect to the background field inserts the time-ordered derivative of the input local functionals. Scaling degree bounds control the ultraviolet order of singularities. Ward identities are the equations imposed by symmetries; for gauge theories they are properly encoded by the BV quantum master equation.

Theorem 156.4 (Extension with fixed scaling degree)**.** *Let $t^0 \in \mathcal{D}'(\mathbb{R}^N \setminus \{0\})$ have finite scaling degree*

$$\mathrm{sd}(t^0) = \inf\left\{\delta : \lambda^\delta t^0(\lambda x) \to 0 \ \textit{in}\ \mathcal{D}'(\mathbb{R}^N \setminus \{0\}) \ \textit{as}\ \lambda \to 0^+\right\}.$$

Then t^0 has an extension $t \in \mathcal{D}'(\mathbb{R}^N)$ with $\mathrm{sd}(t) = \mathrm{sd}(t^0)$. If $\mathrm{sd}(t^0) < N$, this extension is unique. If $\mathrm{sd}(t^0) \geq N$, two such extensions differ by

$$\sum_{|\alpha| \leq \mathrm{sd}(t^0) - N} c_\alpha \, \partial^\alpha \delta_0, \tag{156.11}$$

with the upper bound understood as its integer part.

Proof. Choose a test function $\rho \in C_c^\infty(\mathbb{R}^N)$ equal to 1 near the origin. For a test function f, subtract its Taylor polynomial at the origin through degree

$$r = \lfloor \mathrm{sd}(t^0) \rfloor - N$$

when $r \geq 0$:

$$f_R(x) = f(x) - \rho(x) \sum_{|\alpha| \leq r} \frac{x^\alpha}{\alpha!} (\partial^\alpha f)(0). \tag{156.12}$$

The subtracted test function vanishes to order $r+1$ at the origin. The definition of scaling degree then implies that $t^0(f_R)$ is finite and independent of how f_R is represented away from the origin. Set

$$t(f) = t^0(f_R) + \sum_{|\alpha| \leq r} c_\alpha (\partial^\alpha f)(0). \tag{156.13}$$

The constants c_α are arbitrary finite renormalization constants. The subtraction raises the vanishing order of the test function precisely enough to preserve the original scaling degree, and the additional $\partial^\alpha \delta_0$ terms have scaling degree $N + |\alpha| \leq \mathrm{sd}(t^0)$.

If $r < 0$, no Taylor coefficient may be added without increasing the scaling degree. An extension is then forced by continuity from $\mathbb{R}^N \setminus \{0\}$, hence unique. In the case $r \geq 0$, any two extensions agree away from the origin, so their difference is a distribution supported at 0. Every distribution supported at one point is a finite linear combination of derivatives of the delta distribution, and the scaling degree bound permits exactly the derivatives in (156.11). □

In pAQFT the role of the origin in Theorem 156.4 is played by a partial diagonal in M^n. The finite ambiguity is therefore a finite sum of local curvature, mass, coupling, and field polynomials multiplying derivatives of delta distributions supported on that diagonal. These are contact terms created by the definition of time-ordered products, not a separate physical process.

156.6 Causal Factorization

If the supports of $F_1, \dots, F_k$ lie nowhere in the past of the supports of $F_{k+1}, \dots, F_n$, causal factorization states

$$T_n(F_1, \dots, F_n) = T_k(F_1, \dots, F_k) \star T_{n-k}(F_{k+1}, \dots, F_n).$$

This identity determines T_n outside the total diagonal from lower orders. Renormalization is precisely the choice of extension to the total and partial diagonals compatible with the listed constraints.

The induction is local in configuration space. On a configuration $(x_1, \dots, x_n)$ not lying on the total diagonal, global hyperbolicity provides a Cauchy time function and one may separate the points into a later cluster and an earlier cluster. Causal factorization expresses T_n there as a $\star_H$-product of already constructed lower-order time-ordered products. On overlaps of such cluster decompositions the lower-order factorization identities and associativity of $\star_H$ give the same distribution. Hence the only new datum at order n is the extension across the total diagonal, subject to covariance, scaling degree, unitarity, and any Ward identities.

156.7 Interacting Fields

Let V be an interaction functional with compact time support. The relative S-matrix is

$$S_V(F) = S(V)^{-1} \star S(V + F),$$

where

$$S(F) = T \exp\left(\frac{\mathrm{i}}{\hbar} F\right).$$

The interacting field associated to a local functional F is the Bogoliubov derivative

$$R_V(F) = \frac{\hbar}{\mathrm{i}} \frac{d}{d\lambda} S_V(\lambda F) \bigg|_{\lambda=0}.$$

Changing the time cutoff of V outside the causal domain of F gives isomorphic interacting algebras by causal factorization.

Proposition 156.5 (Causal support of the Bogoliubov field). *If two interaction functionals V and V' agree on a neighborhood of the causal hull $J(\operatorname{supp} F)$, then the corresponding Bogoliubov fields $R_V(F)$ and $R_{V'}(F)$ are identified by the canonical relative S-matrix isomorphism of the two cutoff theories.*

Proof. Let $C = V' - V$. By hypothesis C vanishes on a neighborhood of $J(\operatorname{supp} F)$. Choose two Cauchy surfaces, one to the past of $\operatorname{supp} F$ and one to its future, both lying inside the region on which $V = V'$ near the causal hull. A smooth partition of unity in the corresponding time slabs decomposes

$$C = A + B,$$

where $\operatorname{supp} A$ is later than $\operatorname{supp} F$ and $\operatorname{supp} B$ is earlier than $\operatorname{supp} F$. The separation is meant in the causal sense used by the time-ordered products: every point of $\operatorname{supp} A$ lies outside the causal past of $\operatorname{supp} F$, and every point of $\operatorname{supp} B$ lies outside its causal future, after the supports have been slightly enlarged to open neighborhoods. Causal factorization gives

$$S(V + A + B + \lambda F) = S(A) \star S(V + \lambda F) \star S(B)$$

in the corresponding ordered region, and similarly with $\lambda = 0$. Thus

$$S(V') = S(A) \star S(V) \star S(B)$$

and, using the inverse in the formal $\star$-algebra,

$$S(V')^{-1} = S(B)^{-1} \star S(V)^{-1} \star S(A)^{-1}.$$

Substitution in

$$S_{V'}(\lambda F) = S(V')^{-1} \star S(V' + \lambda F)$$

therefore gives

$$S_{V'}(\lambda F) = S(B)^{-1} \star S_V(\lambda F) \star S(B).$$

The conjugation

$$\alpha_B(X) = S(B)^{-1} \star X \star S(B)$$

is precisely the relative S-matrix isomorphism between the two time-cutoff choices in the causal domain of F. Differentiating the displayed identity at $\lambda = 0$ gives

$$R_{V'}(F) = \alpha_B(R_V(F)),$$

which is the claimed canonical identification. The construction is independent of the auxiliary partition because two choices differ by factors supported entirely in the past or future of $\operatorname{supp} F$, and the same causal-factorization computation gives the corresponding inner identification. □

156.8 Renormalization Group

Two choices of time-ordered products T and $\widetilde{T}$ are related by maps Z on local functionals:

$$\widetilde{S}(F) = S(Z(F)).$$

The map Z is local, begins with $Z(F) = F + O(F^2)$, preserves the constant term, and has coefficients supported on coincident points. In curved backgrounds these coefficients include curvature terms. This is the perturbative algebraic form of local counterterm freedom.

More explicitly, Z is a formal diffeomorphism of the space of local functionals:

$$Z(F) = F + \sum_{n \geq 2} \frac{1}{n!} Z_n(F^{\otimes n}), \tag{156.14}$$

where each Z_n is symmetric, local, and supported on the thin diagonal in the n-fold product. The defining identity $\widetilde{S}(F) = S(Z(F))$ implies that changing the extension of time-ordered products is equivalent to changing the local interaction functional by finite local terms. In a curved background those terms are not limited to flat-space monomials: covariance permits terms built from the metric, curvature, masses, background couplings, and their covariant derivatives, constrained by dimension, symmetries, and field independence.

156.9 Worked Interacting Scalar Coordinate

The previous sections describe the abstract perturbative construction. A curved-background interacting example must also say which local coordinates are being held fixed and what observable changes when those coordinates are changed. Consider a real scalar with compact spacetime cutoff g, and write the quartic interaction in a Hadamard Wick coordinate H as

$$V_{\lambda,H}(g) = \int_M \mathrm{d}\,\mathrm{vol}_g\; g(x)\,\frac{\lambda}{4!}\Phi_H^4(x). \tag{156.15}$$

Let $H' = H + w$, with w smooth, and write

$$w_\Delta(x) = w(x,x).$$

The smooth-change isomorphism Proposition 156.3 gives the local diagonal identities

$$\begin{aligned}\alpha_w\big(\Phi_H^2(x)\big) &= \Phi_{H'}^2(x) + \hbar w_\Delta(x),\\ \alpha_w\big(\Phi_H^4(x)\big) &= \Phi_{H'}^4(x) + 6\hbar w_\Delta(x)\Phi_{H'}^2(x) + 3\hbar^2 w_\Delta(x)^2.\end{aligned} \tag{156.16}$$

Thus the same abstract quartic interaction, transported to the H' coordinate, is

$$\alpha_w V_{\lambda,H}(g) = \int_M \mathrm{d}\,\mathrm{vol}_g\; g(x)\left[\frac{\lambda}{4!}\Phi_{H'}^4 + \frac{\hbar\lambda}{4}w_\Delta\Phi_{H'}^2 + \frac{\hbar^2\lambda}{8}w_\Delta^2\right](x). \tag{156.17}$$

Equations (156.16) and (156.17) are algebra-coordinate statements. They do not by themselves produce a physical expectation-value shift. If ω_H is a state on the H-presentation and $\omega_{H'}$ is the transported state on the H'-presentation, defined by

$$\omega_{H'}(\alpha_w A) = \omega_H(A),$$

then

$$\omega_{H'}(\alpha_w V_{\lambda,H}(g)) = \omega_H(V_{\lambda,H}(g))\,.$$

This is the same abstract observable in two Hadamard coordinates.

A finite local Wick-renormalization change is a different comparison. It is not an arbitrary smooth difference of two Hadamard two-point functions; local covariance restricts the diagonal scalar inserted into Wick powers. In four dimensions, for the dimension-two part, write

$$c(x) = a_m m^2 + a_R R(x). \tag{156.18}$$

Changing the Wick prescription by this local scalar uses the same polynomial combinatorics as (156.16), with w_Δ replaced by c, but it compares two local covariant composite-field prescriptions in a fixed physical state. The quartic interaction then acquires the finite local terms

$$\int_M \mathrm{d}\,\mathrm{vol}_g\; g(x)\left[\frac{\hbar\lambda}{4}c\Phi_H^2 + \frac{\hbar^2\lambda}{8}c^2\right](x).$$

The quadratic term is the finite coordinate shift

$$\delta m^2 = \frac{\hbar\lambda}{2} a_m m^2, \qquad \delta\xi = \frac{\hbar\lambda}{2} a_R \tag{156.19}$$

in the local scalar operator $\frac{1}{2}(m^2 + \xi R)\Phi^2$. The last term in (156.17) is a finite shift of the purely geometric source functional, producing m^4, $m^2 R$, and R^2 coordinates when (156.18) is used. Those coordinates are precisely the ones that reappear in the stress-tensor and gravitational EFT bookkeeping of Chapters 148 and 157.

This paragraph records only the Wick-coordinate subfamily of the finite renormalization freedom. A complete interacting stress-tensor construction also fixes the time-ordered products used in the Bogoliubov map, the interaction-dependent composite-field counterterms in Φ^4, and the independent conserved local tensors allowed in Proposition 148.9. The Hollands–Wald conservation theorem is a condition on that complete construction: the chosen time-ordered products and contact terms must make the interacting stress tensor conserved, rather than relying on the potential insertion or the Wick-square shift by themselves [10, 11, 12].

The local Wick-square comparison has a visible c-number output only in this fixed-state, changed-prescription sense. If

$$F_f = \int_M \mathrm{d}\,\mathrm{vol}_g\ f(x)\Phi_H^2(x), \qquad f \in C_c^\infty(M),$$

and the second Wick-square prescription is

$$F_f^{(c)} = F_f + \hbar \int_M \mathrm{d}\,\mathrm{vol}_g\ f(x)c(x),$$

then

$$\omega_H\left(F_f^{(c)}\right) - \omega_H(F_f) = \hbar \int_M \mathrm{d}\,\mathrm{vol}_g\ f(x)c(x). \tag{156.20}$$

The right side is state independent because it is a local renormalization coordinate, not particle production and not the transport of a state between two algebra presentations. A physical renormalization condition fixes a_m, a_R or fixes the value of (156.20) on selected backgrounds and states. Without that condition, the number is a coordinate of the composite operator, not an invariant prediction.

Derivation. For a local polynomial at one point, the smooth-change isomorphism acts by

$$\alpha_w = \exp\left(\frac{\hbar}{2} w_\Delta \frac{\partial^2}{\partial\phi^2}\right).$$

Applying this operator to ϕ^2 and ϕ^4 gives (156.16). Multiplication by $\lambda/4!$ gives the coordinate-transport identity (156.17). The local Wick-renormalization comparison uses the same finite polynomial identity with the locally covariant scalar c in place of the generic smooth diagonal w_Δ; the identities (156.19) follow by comparing the coefficient of $\frac{1}{2}(m^2 + \xi R)\Phi^2$. Finally, applying the first line of (156.16) with w_Δ replaced by c inside F_f gives (156.20).

156.10 Gauge Theories And The BV Condition

The preceding scalar construction is not a foundation for gauge theory by itself. A gauge-fixed perturbative algebra contains unphysical fields, ghosts, antifields, and a differential. Consistency is the statement that the interacting quantum BV differential squares to zero, or equivalently that the renormalized time-ordered products can be chosen so that the quantum master equation holds:

$$\frac{1}{2}(S_{\mathrm{BV}}, S_{\mathrm{BV}}) - \mathrm{i}\hbar\, \Delta_{\mathrm{BV}} S_{\mathrm{BV}} = 0 \tag{156.21}$$

in the renormalized algebra. Here $(\,\cdot\,,\,\cdot\,)$ is the BV antibracket and Δ_{BV} denotes the renormalized second-order operator measuring the short-distance contraction of fields with antifields. The equation is not a slogan for gauge invariance. It is the algebraic condition that the interacting BRST operator is a differential and that the physical algebra is its cohomology. If the obstruction to solving (156.21) is a nontrivial local cohomology class, the theory has an anomaly in the chosen background and field content.

Open Problem 156.6 (Nonperturbative curved-background comparison)*.* Relate perturbative algebraic QFT on curved backgrounds to nonperturbative constructions by comparing local algebras, Hadamard states, stress tensors, renormalized composite fields, anomaly terms, and scaling limits in examples where both sides are available.

Chapter 157

Semiclassical Backreaction And Stress-Tensor Fluctuations

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

QFT on a fixed curved background supplies local observables, states, and a renormalized stress tensor. Once the stress tensor is used as a source for geometry, the metric is no longer a passive parameter. A semiclassical problem must therefore specify both a locally covariant quantum field theory on each admissible metric and a gravitational effective action whose metric variation is equated to the stress-tensor expectation value. This chapter develops that statement, the associated linear response theory, and the stress-tensor fluctuation data needed for stochastic backreaction.

157.1 Metric Variation And Curvature Convention

The curvature convention in this chapter is

$$[\nabla_\mu, \nabla_\nu] X^\rho = R^\rho{}_{\sigma\mu\nu} X^\sigma, \qquad R_{\mu\nu} = R^\rho{}_{\mu\rho\nu}, \qquad G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu}. \tag{157.1}$$

Metric variations are taken with respect to $g^{\mu\nu}$. For a renormalized source functional $W[g]$, define the stress tensor by

$$\delta W[g] = -\frac{1}{2} \int_M \mathrm{d}\,\mathrm{vol}_g \, \langle T^{\mathrm{ren}}_{\mu\nu} \rangle_g \, \delta g^{\mu\nu}. \tag{157.2}$$

The minus sign is the same sign that gives $\delta S_{\text{matter}} = -(1/2)\int T_{\mu\nu}\delta g^{\mu\nu}$ in the classical limit with mostly-plus metric.

Ward identity from diffeomorphism covariance. Suppose $W[g]$ is invariant under compactly supported diffeomorphisms and has metric variation of the form (157.2). Then

$$\nabla^\mu \langle T^{\text{ren}}_{\mu\nu}\rangle_g = 0 \tag{157.3}$$

as a distribution.

Let X^μ be a compactly supported vector field and let ψ_s be its flow. Diffeomorphism invariance gives

$$0 = \frac{\mathrm{d}}{\mathrm{d}s} W[\psi_s^* g]\bigg|_{s=0}.$$

Since

$$\delta_X g_{\mu\nu} = \nabla_\mu X_\nu + \nabla_\nu X_\mu, \qquad \delta_X g^{\mu\nu} = -(\nabla^\mu X^\nu + \nabla^\nu X^\mu),$$

equation (157.2) gives

$$0 = \int_M \mathrm{d}\,\mathrm{vol}_g\, \langle T^{\text{ren}}_{\mu\nu}\rangle_g \nabla^\mu X^\nu.$$

Integrating by parts and using compact support of X gives

$$0 = -\int_M \mathrm{d}\,\mathrm{vol}_g\; X^\nu \nabla^\mu \langle T^{\text{ren}}_{\mu\nu}\rangle_g.$$

Since X is arbitrary, the distribution in (157.3) vanishes.

If the theory has a diffeomorphism anomaly, the right side of (157.3) is the local anomaly. In the ordinary scalar, spinor, and vector examples considered in the fixed background chapters, diffeomorphism covariance is imposed on the renormalized stress tensor; trace anomalies are compatible with (157.3).

157.2 Renormalized Stress Tensor

Let (M, g) be globally hyperbolic and let ω be a Hadamard state of a locally covariant QFT. The renormalized stress tensor is an operator-valued distribution

$$T^{\text{ren}}_{\mu\nu}(f^{\mu\nu}), \qquad f^{\mu\nu} \in C_c^\infty(M, S^2TM),$$

or, in perturbative algebraic language, a local covariant Wick polynomial valued in the algebra constructed from the Hadamard parametrix. Its expectation value is

$$\langle T^{\text{ren}}_{\mu\nu}(x)\rangle_{\omega,g}.$$

For Hadamard states this is a smooth tensor field after point splitting and after the finite local curvature terms have been fixed. For a scalar field, the subtraction is the one described in Chapter 148; for an interacting pAQFT model it is the local Wick-polynomial and time-ordered-product renormalization of Chapter 156.

The finite ambiguity in four spacetime dimensions has the form

$$\langle T^{\mathrm{ren}}_{\mu\nu}\rangle \longmapsto \langle T^{\mathrm{ren}}_{\mu\nu}\rangle + c_0 m^4 g_{\mu\nu} + c_1 m^2 G_{\mu\nu} + c_2 H^{(1)}_{\mu\nu} + c_3 H^{(2)}_{\mu\nu}, \tag{157.4}$$

for a massive scalar model, with the evident modifications when additional background couplings are present. The tensors $H^{(i)}_{\mu\nu}$ are local conserved curvature tensors defined in the next section. Thus renormalizing the stress tensor and choosing gravitational EFT coordinates are not independent operations.

157.3 Gravitational Effective Action

In four dimensions, take the local gravitational part of the renormalized effective action to be

$$\Gamma_{\mathrm{grav}}[g] = \int_M \mathrm{d}\,\mathrm{vol}_g \left[\frac{1}{16\pi G_N}(R-2\Lambda) + \frac{\alpha}{2}R^2 + \frac{\beta}{2}R_{\rho\sigma}R^{\rho\sigma}\right], \tag{157.5}$$

up to boundary terms and topological combinations. The factor 1/2 in the curvature-squared terms fixes the normalization

$$E^{\mathrm{grav}}_{\mu\nu} := \frac{2}{\sqrt{|g|}}\frac{\delta\Gamma_{\mathrm{grav}}}{\delta g^{\mu\nu}} = \frac{1}{8\pi G_N}(G_{\mu\nu} + \Lambda g_{\mu\nu}) + \alpha H^{(1)}_{\mu\nu} + \beta H^{(2)}_{\mu\nu}. \tag{157.6}$$

Curvature-squared variational formulas. With the curvature convention (157.1), and with the same metric-variation normalization used in Chapter 148, the curvature-squared Euler tensors in (157.6) are

$$\begin{aligned} H^{(1)}_{\mu\nu} &= 2RR_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R^2 + 2g_{\mu\nu}\Box R - 2\nabla_\mu\nabla_\nu R, \\ H^{(2)}_{\mu\nu} &= 2R_{\mu\rho\nu\sigma}R^{\rho\sigma} - \frac{1}{2}g_{\mu\nu}R_{\rho\sigma}R^{\rho\sigma} + \nabla_\mu\nabla_\nu R - \Box R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}\Box R. \end{aligned} \tag{157.7}$$

Here $\Box = g^{\rho\sigma}\nabla_\rho\nabla_\sigma$.

These formulae are variational identities fixing the local gravitational-coordinate normalization, not an additional structural theorem. The basic first variations are

$$\delta\sqrt{|g|} = -\frac{1}{2}\sqrt{|g|}\,g_{\mu\nu}\delta g^{\mu\nu}, \qquad \delta R = R_{\mu\nu}\delta g^{\mu\nu} + g_{\mu\nu}\Box\delta g^{\mu\nu} - \nabla_\mu\nabla_\nu\delta g^{\mu\nu}, \tag{157.8}$$

after discarding boundary terms. Applying these identities to $\frac{1}{2}\int\sqrt{|g|}R^2$ gives the first line of (157.7).

For $\frac{1}{2}\int\sqrt{|g|}R_{\rho\sigma}R^{\rho\sigma}$, use

$$\delta R_{\mu\nu} = \frac{1}{2}\left(-\Box\delta g_{\mu\nu} - \nabla_\mu\nabla_\nu(g^{\rho\sigma}\delta g_{\rho\sigma}) + \nabla^\rho\nabla_\mu\delta g_{\rho\nu} + \nabla^\rho\nabla_\nu\delta g_{\rho\mu}\right), \tag{157.9}$$

convert $\delta g_{\mu\nu}$ to $-g_{\mu\rho}g_{\nu\sigma}\delta g^{\rho\sigma}$, integrate derivatives off $\delta g^{\mu\nu}$, and commute derivatives on $R_{\mu\nu}$. The commutator terms combine into $2R_{\mu\rho\nu\sigma}R^{\rho\sigma}$, while the derivative terms combine as displayed in the second line of (157.7).

The tensors $H^{(1)}$ and $H^{(2)}$ are conserved. This follows without component calculation: each is the Euler tensor of a diffeomorphism-invariant local functional, so the Ward-identity calculation above applies with the functional replacing W. Their traces in $D = 4$ are

$$g^{\mu\nu} H^{(1)}_{\mu\nu} = 6\Box R, \qquad g^{\mu\nu} H^{(2)}_{\mu\nu} = -2\Box R, \tag{157.10}$$

using the convention in (157.7). These traces are total derivatives, as required by the constant-Weyl-scale invariance of the curvature-squared actions in four dimensions.

157.4 Semiclassical Einstein Equation

A semiclassical solution is not only a metric. It is a pair (g, ω) such that ω is an admissible Hadamard state of the QFT constructed on (M, g) and

$$E^{\mathrm{grav}}_{\mu\nu}[g] = \langle T^{\mathrm{ren}}_{\mu\nu} \rangle_{\omega,g}. \tag{157.11}$$

Written out,

$$\frac{1}{8\pi G_N}(G_{\mu\nu} + \Lambda g_{\mu\nu}) + \alpha H^{(1)}_{\mu\nu} + \beta H^{(2)}_{\mu\nu} = \langle T^{\mathrm{ren}}_{\mu\nu} \rangle_{\omega,g}. \tag{157.12}$$

The left side is conserved by diffeomorphism invariance. Therefore the right side must be the conserved stress tensor of the same renormalization scheme. A change of stress-tensor scheme of the form (157.4) is equivalently a finite change of $G_N, \Lambda, \alpha, \beta$. It is not a physical change until a renormalization condition has fixed these coordinates.

Definition 157.1 (Backreaction datum)**.** A fixed-order semiclassical backreaction datum consists of

$$\mathfrak{B} = (M, \mathcal{C}, \mathcal{A}_g, \mathcal{S}_g, T^{\mathrm{ren}}_{\mu\nu}, G_N, \Lambda, \alpha, \beta, \mathcal{I}).$$

Here $\mathcal{C}$ is the class of metrics considered, $\mathcal{A}_g$ is the locally covariant QFT algebra assigned to g, $\mathcal{S}_g$ is the admissible state space, T^{ren} is the renormalized stress tensor in a fixed scheme, and $\mathcal{I}$ is the initial or boundary data for the metric and state.

The datum matters because the equation is state dependent. For example, the same metric may solve (157.12) for one state and fail for another. Conversely, changing the metric changes the algebra and the Hadamard condition, so the state must be transported or reconstructed as part of the problem.

157.5 Linear Response

Proposition 157.2 (Retarded stress-tensor response at separated points)**.** *Let the locally covariant theory be fixed on a globally hyperbolic background (M, g), let ω be an admissible Hadamard state, and let the renormalized stress tensor and its time-ordered square be chosen in one renormalization scheme. Vary the inverse metric by a compactly supported smooth tensor $h^{\mu\nu} = \delta g^{\mu\nu}$. The metric perturbation couples to the stress tensor through*

$$\delta S_{\mathrm{source}} = -\frac{1}{2} \int_M \mathrm{d}\,\mathrm{vol}_g \; h^{\rho\sigma} T^{\mathrm{ren}}_{\rho\sigma}. \tag{157.13}$$

The first variation of the stress-tensor expectation has the form

$$\delta\langle T_{\mu\nu}(x)\rangle = \frac{1}{2}\int_M \mathrm{d}\,\mathrm{vol}_g(y)\, G^{\mathrm{ret}}_{\mu\nu,\rho\sigma}(x,y)h^{\rho\sigma}(y) + \delta T^{\mathrm{loc}}_{\mu\nu}(x). \tag{157.14}$$

The separated-point retarded kernel is

$$G^{\mathrm{ret}}_{\mu\nu,\rho\sigma}(x,y) = \mathrm{i}\,\Theta(x \succ y)\,\omega\big([T^{\mathrm{ren}}_{\mu\nu}(x), T^{\mathrm{ren}}_{\rho\sigma}(y)]\big)\,, \tag{157.15}$$

where $x \succ y$ means $x \in J^+(y)$. The local term $\delta T^{\mathrm{loc}}_{\mu\nu}$ contains variations of the point-splitting subtraction, curvature counterterms, and contact terms in the definition of the time-ordered stress-tensor product.

Derivation of the retarded commutator. The clean statement is first made for a smeared observable $A(f) = \int A(x)f(x)$ whose support is disjoint from the support of the local counterterm extension of the stress-tensor product. In the interaction-picture or pAQFT notation, the relative S-matrix for the source $V = \delta S_{\mathrm{source}}$ gives, to first order,

$$\delta\omega(A(f)) = \mathrm{i}\,\omega\big([V_{J^-(\mathrm{supp}\,f)}, A(f)]\big) + \delta_{\mathrm{loc}}\omega(A(f)).$$

Only the part of V in the causal past of $\mathrm{supp}\,f$ appears; this is the retarded prescription. The local term δ_{loc} records two effects that cannot be read from separated points: the explicit variation of the composite field A with the metric and the chosen extension of time-ordered products to the diagonal.

Set $A = T^{\mathrm{ren}}_{\mu\nu}$ and insert (157.13). For $y \in J^-(x)$,

$$\mathrm{i}\left[-\frac{1}{2}h^{\rho\sigma}(y)T^{\mathrm{ren}}_{\rho\sigma}(y), T^{\mathrm{ren}}_{\mu\nu}(x)\right] = \frac{1}{2}h^{\rho\sigma}(y)\,\mathrm{i}\,[T^{\mathrm{ren}}_{\mu\nu}(x), T^{\mathrm{ren}}_{\rho\sigma}(y)].$$

After unsmearing away from the diagonal, this gives (157.14) with the kernel (157.15). Microcausality makes the commutator vanish for spacelike separated x, y; the restriction $\Theta(x \succ y)$ removes the advanced part and is therefore the unique causal linear response compatible with the sign convention $\delta W = -(1/2)\int T_{\rho\sigma}\delta g^{\rho\sigma}$. The remaining diagonal ambiguity is exactly the local term $\delta T^{\mathrm{loc}}_{\mu\nu}$. □

The linearized semiclassical equation is therefore

$$\delta E^{\mathrm{grav}}_{\mu\nu}[h] - \frac{1}{2}\int_M \mathrm{d}\,\mathrm{vol}_g(y)\, G^{\mathrm{ret}}_{\mu\nu,\rho\sigma}(x,y)h^{\rho\sigma}(y) = \delta\langle T_{\mu\nu}\rangle_{\mathrm{state}} + \delta T^{\mathrm{loc}}_{\mu\nu}. \tag{157.16}$$

The term $\delta\langle T\rangle_{\mathrm{state}}$ denotes an independent change of state at fixed metric; it is absent if the state is transported by the chosen metric perturbation prescription.

157.6 Noise Kernel

Stress-tensor fluctuations are encoded by the symmetrized connected two-point distribution

$$N_{\mu\nu,\rho\sigma}(x,y) = \frac{1}{2}\,\omega\big(\{T^{\mathrm{ren}}_{\mu\nu}(x), T^{\mathrm{ren}}_{\rho\sigma}(y)\}\big)_{\mathrm{conn}}\,. \tag{157.17}$$

Equivalently, for a real compactly supported test tensor $f^{\mu\nu}$, set

$$T(f) = \int_M \mathrm{d}\,\mathrm{vol}_g \; f^{\mu\nu} T^{\mathrm{ren}}_{\mu\nu}.$$

Then

$$N(f,f) = \frac{1}{2}\omega(\{T(f) - \omega(T(f)), T(f) - \omega(T(f))\}) = \omega\big((T(f) - \omega(T(f)))^2\big) \geq 0. \tag{157.18}$$

Thus N is a positive semidefinite distributional covariance kernel on the real test-tensor space where the renormalized product is defined.

Conservation is the distributional Ward identity

$$\nabla^\mu_x N_{\mu\nu,\rho\sigma}(x,y) = 0, \qquad \nabla^\rho_y N_{\mu\nu,\rho\sigma}(x,y) = 0, \tag{157.19}$$

including diagonal contact terms fixed by the same local covariance conditions that define the stress-tensor product. Away from the diagonal it follows immediately from $\nabla^\mu T^{\mathrm{ren}}_{\mu\nu} = 0$. On the diagonal it is a condition on the renormalized composite product; it is imposed at the level of the local extension across coincident points.

157.7 Stationary States And Fluctuation–Dissipation

If g has a complete timelike Killing field K and ω is a KMS state at inverse temperature β for the associated time evolution, the retarded kernel and the noise kernel are related. For two smeared stress-tensor observables A and B, define

$$C_{AB}(t) = \omega(A(t)B), \qquad \rho_{AB}(t) = \omega([A(t), B]).$$

Let tildes denote Fourier transforms in t. The KMS condition gives

$$\widetilde{C}_{BA}(-\omega) = e^{-\beta\omega}\widetilde{C}_{AB}(\omega). \tag{157.20}$$

Therefore the symmetrized spectrum and the commutator spectrum obey

$$\widetilde{N}_{AB}(\omega) = \frac{1}{2}\coth\left(\frac{\beta\omega}{2}\right)\widetilde{\rho}_{AB}(\omega), \tag{157.21}$$

where

$$\widetilde{N}_{AB}(\omega) = \frac{1}{2}\left(\widetilde{C}_{AB}(\omega) + \widetilde{C}_{BA}(-\omega)\right), \qquad \widetilde{\rho}_{AB}(\omega) = \widetilde{C}_{AB}(\omega) - \widetilde{C}_{BA}(-\omega).$$

This follows directly from KMS analyticity and the definitions of the retarded and symmetrized kernels.

157.8 Einstein–Langevin Equation

A stochastic semiclassical approximation introduces a real Gaussian generalized random tensor $\xi_{\mu\nu}$ with

$$\mathbb{E}[\xi_{\mu\nu}(f^{\mu\nu})] = 0, \qquad \mathbb{E}[\xi(f)\xi(k)] = N(f,k). \tag{157.22}$$

The existence of this Gaussian generalized random field follows from the positivity (157.18): N is a covariance form on a nuclear test-function space, so the Bochner–Minlos theorem constructs the corresponding Gaussian measure on distributions.

After gauge fixing the linearized gravitational operator, the Einstein–Langevin equation is

$$\mathcal{L}_{\mu\nu}{}^{\rho\sigma} h_{\rho\sigma} - \frac{1}{2}\int_M \mathrm{d}\,\mathrm{vol}_g(y)\, G^{\mathrm{ret}}_{\mu\nu,\rho\sigma}(x,y) h^{\rho\sigma}(y) = \xi_{\mu\nu}(x), \tag{157.23}$$

where $\mathcal{L}$ is the gauge-fixed variation of $E^{\mathrm{grav}}_{\mu\nu}$ plus the local stress-tensor response. If $\mathcal{G}_{\mathrm{ret}}$ is a retarded inverse for the full linear operator, then the induced metric covariance is

$$\mathbb{E}[h_{\mu\nu}(x)h_{\rho\sigma}(y)] = \int \mathcal{G}_{\mathrm{ret}\,\mu\nu}{}^{\alpha\beta}(x,u) N_{\alpha\beta,\gamma\delta}(u,v) \mathcal{G}_{\mathrm{ret}\,\rho\sigma}{}^{\gamma\delta}(y,v). \tag{157.24}$$

This equation is meaningful only after the state, stress-tensor renormalization, contact terms, gauge condition, and stochastic test space have all been specified.

Pushforward covariance of the Einstein–Langevin source. Let $\mathcal{E}$ be the real nuclear test-tensor space on which the noise covariance N is defined, and let $\mathcal{E}'$ be its distributional dual. Suppose the gauge-fixed linear operator in (157.23) has a continuous retarded solution map

$$\mathcal{G}_{\mathrm{ret}} : \mathcal{E}' \longrightarrow \mathcal{H}, \tag{157.25}$$

where $\mathcal{H}$ is the chosen linear metric-perturbation distribution space. If ξ is the centered Gaussian generalized random tensor with covariance N, then $h = \mathcal{G}_{\mathrm{ret}}\xi$ is a centered Gaussian random metric perturbation. For any real linear observables $\ell_1, \ell_2 \in \mathcal{H}^*$,

$$\mathbb{E}[\ell_1(h)\ell_2(h)] = N(\mathcal{G}^*_{\mathrm{ret}}\ell_1, \mathcal{G}^*_{\mathrm{ret}}\ell_2), \tag{157.26}$$

where $\mathcal{G}^*_{\mathrm{ret}} : \mathcal{H}^* \to \mathcal{E}$ is the transpose. In kernel notation this is exactly (157.24). The resulting covariance is positive semidefinite on metric observables:

$$\mathbb{E}[\ell(h)^2] \geq 0. \tag{157.27}$$

For a centered Gaussian generalized random tensor, the characteristic functional on $\mathcal{E}$ is

$$\mathbb{E}[e^{\mathrm{i}\xi(f)}] = \exp\left[-\frac{1}{2}N(f,f)\right]. \tag{157.28}$$

For $\ell \in \mathcal{H}^*$,

$$\ell(h) = \ell(\mathcal{G}_{\mathrm{ret}}\xi) = \xi(\mathcal{G}^*_{\mathrm{ret}}\ell). \tag{157.29}$$

Thus the finite collection $(\ell_1(h), \ldots, \ell_n(h))$ has characteristic function

$$\exp\left[-\frac{1}{2}\sum_{a,b} t_a t_b\, N(\mathcal{G}^*_{\mathrm{ret}}\ell_a, \mathcal{G}^*_{\mathrm{ret}}\ell_b)\right], \tag{157.30}$$

which is Gaussian with covariance (157.26). Positivity follows by setting $\ell_1 = \ell_2 = \ell$ and using positivity of N. When ℓ is evaluation against a compactly supported test tensor on the metric side, $\mathcal{G}_{\mathrm{ret}}^{*}\ell$ is represented by the retarded Green kernel in (157.24), producing the displayed kernel formula.

Only gauge-invariant or gauge-fixed metric observables should be inserted in the pushforward covariance formula above. If ℓ is pure gauge and the retarded inverse has been constructed after gauge fixing, $\ell(h)$ is a coordinate artifact, not a physical metric fluctuation. The formula is therefore a covariance statement for the declared linearized problem, not a replacement for the gravitational constraint analysis.

157.9 Finite Response Window And Stability Diagnostics

The preceding formulae become physically useful only after one asks whether the retarded inverse is bounded in the sector being tested. In a stationary background, after gauge fixing and after solving or projecting out the linearized constraints, let e_a, $a = 1, \dots, n$, be a finite set of real metric perturbation modes or gauge-invariant metric observables. Let f_a, $a = 1, \dots, n$, be the corresponding finite set of real smeared stress-tensor sources. The retained linearized equation in frequency space has the form

$$\mathsf{D}_{ab}(\omega)h_b(\omega) = j_a(\omega), \qquad \mathsf{D}(\omega) = \mathsf{K}(\omega) - \frac{1}{2}\Pi^{\mathrm{ret}}(\omega), \tag{157.31}$$

where K is the gravitational and local-contact part of the linearized operator and Π^{ret} is the projected retarded stress-tensor commutator. The source j may include a state perturbation, an external classical stress perturbation, or the stochastic source in the Einstein–Langevin approximation. All factors of G_N, α, β are included in K; equivalently one may multiply the whole equation by $8\pi G_N$, in which case the same test is applied to the rescaled matrix.

Controlled Approximation 157.3 (Finite semiclassical response window)**.** Fix a frequency interval I, a retained metric-source sector as above, and a reduced low-energy gravitational operator in which the cutoff-scale higher-derivative roots have been removed by the EFT prescription. Suppose that the projected retarded response has no pole in the upper half of the complex frequency plane in the strip obtained by continuing I, and that

$$M_I := \sup_{\omega \in I} \left\| \mathsf{D}(\omega + \mathrm{i}0)^{-1} \right\|_2 < \infty. \tag{157.32}$$

Then, for every retained source vector $j(\omega)$,

$$\|h(\omega)\|_2 \le M_I \, \|j(\omega)\|_2, \qquad \omega \in I. \tag{157.33}$$

If the retained stress-tensor noise matrix

$$\mathsf{N}_{ab}(\omega) = N(f_a(\omega), f_b(\omega))$$

is positive semidefinite, then the induced retained metric covariance is

$$\mathsf{C}_h(\omega) = \mathsf{D}(\omega + \mathrm{i}0)^{-1}\mathsf{N}(\omega)\mathsf{D}(\omega + \mathrm{i}0)^{-*}, \tag{157.34}$$

and it obeys

$$v^{*}\mathsf{C}_h(\omega)v \ge 0, \qquad \operatorname{tr} \mathsf{C}_h(\omega) \le M_I^2 \, \operatorname{tr} \mathsf{N}(\omega). \tag{157.35}$$

The retained semiclassical approximation is small in this window only if the dimensionless quantities

$$\varepsilon_{\mathrm{mean}} = \sup_{\omega \in I} \frac{\|h_{\mathrm{mean}}(\omega)\|_2}{h_{\mathrm{ref}}}, \qquad \varepsilon_{\mathrm{fluc}}^2 = \sup_{\omega \in I} \frac{\operatorname{tr} \mathsf{C}_h(\omega)}{h_{\mathrm{ref}}^2} \tag{157.36}$$

are both much smaller than one, and if omitted modes and state changes remain smaller than the same reference scale h_{ref}. Here h_{ref} is fixed by the curvature radius or by the amplitude at which the chosen linearized metric chart ceases to be valid.

The proof is finite-dimensional linear algebra, but the diagnostic is not a mere matrix exercise. Upper-half-plane poles of D^{-1} are linear instabilities or runaway roots of the retained semiclassical problem; large M_I means that a small stress-tensor perturbation is amplified into a large metric response. A positive noise kernel then gives a positive metric covariance by pushforward, and

$$\operatorname{tr}(\mathsf{D}^{-1}\mathsf{N}\mathsf{D}^{-*}) = \operatorname{tr}(\mathsf{D}^{-*}\mathsf{D}^{-1}\mathsf{N}) \leq \|\mathsf{D}^{-1}\|_2^2 \operatorname{tr} \mathsf{N},$$

because $0 \leq \mathsf{D}^{-*}\mathsf{D}^{-1} \leq \|\mathsf{D}^{-1}\|_2^2 \mathbf{1}$ on the retained sector. This is the bridge from the formal semiclassical equation to a physical backreaction statement: the mean response, the fluctuation response, and the absence of unstable response poles must be checked together.

157.10 Worked Retained Potential-Source Coordinate

The response-window criterion is empty unless the source vector is supplied by a declared stress-tensor construction. The following calculation is deliberately narrower than a full interacting stress tensor. It isolates the explicit potential insertion from the scalar interaction of Chapter 156, evaluates that insertion in the reference free quasifree state, and then records how this retained source coordinate would enter the finite response matrix. Work to first order in λ, fix a Hadamard Wick coordinate H, and assume a centered quasifree Hadamard state ω on a stationary region U where the smooth Wick variance

$$\Sigma_{\omega,H}(x) := \omega\big(\Phi_H^2(x)\big) \tag{157.37}$$

is constant. The interaction cutoff is taken to be 1 on U; edges of the cutoff are outside the observables considered here. The potential insertion in the first-order variation of the interaction action gives

$$\delta_\lambda T_{\mu\nu}^{\mathrm{pot}}(x) = -g_{\mu\nu}(x) \frac{\lambda}{4!} \Phi_H^4(x). \tag{157.38}$$

For a centered quasifree state,

$$\omega\big(\Phi_H^4(x)\big) = 3\Sigma_{\omega,H}(x)^2,$$

so the observable output for any test tensor $f^{\mu\nu}$ supported in U is

$$\delta_\lambda \omega\big(T^{\mathrm{pot}}(f)\big) = -\frac{\lambda}{8} \int_U \mathrm{d}\,\mathrm{vol}_g \; f^{\mu\nu}(x) g_{\mu\nu}(x) \Sigma_{\omega,H}^2. \tag{157.39}$$

Equivalently, the local retained potential source coordinate is

$$\delta_\lambda \langle T_{\mu\nu} \rangle_{\omega,H}^{\mathrm{pot}} = -\rho_\lambda g_{\mu\nu}, \qquad \rho_\lambda = \frac{\lambda}{8} \Sigma_{\omega,H}^2. \tag{157.40}$$

Equation (157.40) is not, by itself, the full order-λ expectation value of the renormalized interacting stress tensor. A full first-order source has the bookkeeping ledger

$$\begin{aligned}\delta_\lambda \langle T^{\mathrm{ren}}_{\mu\nu}\rangle^{\mathrm{full}}_{\omega,H} = \delta_\lambda \langle T_{\mu\nu}\rangle^{\mathrm{pot}}_{\omega,H} + \delta_\lambda \left\langle R_V(T^{\mathrm{free}}_{\mu\nu})\right\rangle^{(1)}_{\omega,H} \\ + C^{\mathrm{int}}_{\mu\nu}[g; m, \xi, \lambda, H].\end{aligned} \tag{157.41}$$

The second term is the Bogoliubov/interacting-field correction to the free stress tensor, and $C^{\mathrm{int}}_{\mu\nu}$ collects the chosen time-ordered-product contact terms, interaction-dependent composite-field counterterms, and local stress-tensor curvature terms. The conservation condition

$$\nabla^\mu \delta_\lambda \langle T^{\mathrm{ren}}_{\mu\nu}\rangle^{\mathrm{full}}_{\omega,H} = 0$$

is a Ward condition on this whole sum, not on the potential insertion alone. This is the curved-spacetime pAQFT renormalization problem isolated by Hollands–Wald local Wick products, time-ordered products, and interacting stress-tensor conservation [10, 11, 12].

The displayed ρ_λ is therefore a renormalized composite-field coordinate inside a restricted sector. Under a pure Hadamard coordinate transport $H \to H' = H + w$, the observable and state must be transported together and the expectation value is unchanged. A c-number change of the displayed density instead compares two local covariant Wick prescriptions in the same physical state. If that finite Wick-square renormalization adds the local scalar c, then $\Sigma_{\omega,H}$ is replaced in this comparison by $\Sigma_{\omega,H} + \hbar c$, and

$$\rho^{(c)}_\lambda = \frac{\lambda}{8}\left(\Sigma_{\omega,H} + \hbar c\right)^2. \tag{157.42}$$

This Wick-square-generated shift is only one finite-renormalization subfamily. A general locally covariant Φ^4 prescription also permits independent local lower-field and geometric terms of the form

$$\Phi^4_H \mapsto \Phi^4_H + A_1 m^2 \Phi^2_H + A_2 R \Phi^2_H + A_3 m^4 + A_4 m^2 R + A_5 R^2 + A_6 R_{\alpha\beta} R^{\alpha\beta} + A_7 \Box R,$$

subject to the chosen local covariance, scaling, and action-Ward conditions. The stress tensor has its own independent conserved local curvature tensors, as in Proposition 148.9, plus the interaction-dependent contact terms in (157.41). Fixing the Wick-square prescription by itself therefore does not make the number ρ_λ a physical interacting energy-density prediction.

In the homogeneous retained-coordinate calculation, (157.40) is conserved and may be absorbed into a potential-sector gravitational coordinate

$$\Lambda^{\mathrm{pot}}_{\mathrm{eff}} = \Lambda + 8\pi G_N \rho_\lambda = \Lambda + \pi G_N \lambda \Sigma^2_{\omega,H}. \tag{157.43}$$

The sign follows from the convention $E^{\mathrm{grav}}_{\mu\nu} = \langle T_{\mu\nu}\rangle$: a positive potential energy gives $T_{\mu\nu} = -\rho_\lambda g_{\mu\nu}$ and therefore moves the source to the left side as $+\rho_\lambda g_{\mu\nu}$. For a physical semiclassical equation this scalar coordinate must be replaced by the corresponding scalar component of the conserved, scheme-fixed full source in (157.41).

The same retained potential coordinate can be fed into the response diagnostic as a toy source-coordinate check. With the finite source basis f_a of (157.31), define

$$q_a = \int_U \mathrm{d}\,\mathrm{vol}_g\ f_a^{\mu\nu} g_{\mu\nu}, \qquad j_a^{(\lambda,\mathrm{pot})} = -\rho_\lambda q_a. \tag{157.44}$$

If the response-window hypotheses hold, then

$$\|h_\lambda^{\rm pot}(\omega)\|_2 \le M_I|\rho_\lambda|\|q\|_2, \qquad \omega\in I. \tag{157.45}$$

This is the retained-sector bookkeeping test: an interaction, a state assumption, a renormalization coordinate, an observable potential-insertion output, and a metric-response bound. It becomes a physical backreaction datum only after $\delta_\lambda\langle T_{\mu\nu}\rangle^{\rm pot}$ is replaced by the conserved full source $\delta_\lambda\langle T^{\rm ren}_{\mu\nu}\rangle^{\rm full}_{\omega,H}$. If $\Sigma_{\omega,H}$ varies across the region, the potential term alone has $\nabla^\mu(-\rho_\lambda g_{\mu\nu}) = -\partial_\nu\rho_\lambda$. The full interacting stress tensor must then include the derivative and local counterterm pieces fixed by the same pAQFT renormalization prescription; the potential-only display is no longer a conserved standalone source.

Controlled Approximation 157.4 (Retained interacting potential noise)**.** Keep the same Hadamard Wick coordinate, quasifree state, and potential insertion as in Section 157.10, but now ask for the stress-tensor fluctuation sourced by the interaction. Let

$$C_{\omega,H}(x,y) = \mathrm{Re}(\omega_2(x,y) - H_+(x,y))$$

denote the smooth real Wick covariance retained in the test region; H_+ is the two-point Hadamard parametrix used in this Wick chart, and $C_{\omega,H}(x,x) = \Sigma_{\omega,H}(x)$. The Gaussian generating function for H-Wick powers gives, away from the diagonal and before the contact extension of the stress-tensor square,

$$\begin{aligned}\omega\big(\Phi_H^4(x)\Phi_H^4(y)\big)_{\rm conn}\\ = 72\,\Sigma_{\omega,H}(x)\Sigma_{\omega,H}(y)C_{\omega,H}(x,y)^2 + 24\,C_{\omega,H}(x,y)^4.\end{aligned} \tag{157.46}$$

The disconnected term $9\Sigma_{\omega,H}(x)^2\Sigma_{\omega,H}(y)^2$ has been subtracted. The first term in (157.46) is present whenever the state covariance differs from the Wick coordinate; the shortcut $24C_{\omega,H}(x,y)^4$ is valid only in the special normal-ordering coordinate with vanishing one-point Wick square.

Thus the retained potential contribution to the stress-noise kernel is

$$N^{(\lambda,\rm pot)}_{\mu\nu,\rho\sigma}(x,y) = \lambda^2 g_{\mu\nu}(x)g_{\rho\sigma}(y)\left[\frac18\Sigma_{\omega,H}(x)\Sigma_{\omega,H}(y)C_{\omega,H}(x,y)^2 + \frac{1}{24}C_{\omega,H}(x,y)^4\right], \tag{157.47}$$

in the retained potential sector. For the finite source basis (157.31), set

$$\mathsf{N}^{(\lambda,\rm pot)}_{ab} = \int_{U\times U} q_a(x)\left[\frac18\Sigma_{\omega,H}(x)\Sigma_{\omega,H}(y)C_{\omega,H}(x,y)^2 + \frac{1}{24}C_{\omega,H}(x,y)^4\right] q_b(y)\,\lambda^2\,\mathrm{d\,vol}_g(x)\mathrm{d\,vol}_g(y),$$

where $q_a(x) = f_a^{\mu\nu}(x)g_{\mu\nu}(x)$. This matrix is positive semidefinite because it is the covariance of the retained random variables $-(\lambda/4!)\int q_a\Phi_H^4$. The potential-noise contribution to the retained metric covariance is therefore

$$\mathsf{C}_h^{(\lambda,\rm pot)} = \mathsf{D}^{-1}\mathsf{N}^{(\lambda,\rm pot)}\mathsf{D}^{-*}, \qquad \mathrm{tr}\,\mathsf{C}_h^{(\lambda,\rm pot)} \le M_I^2\,\mathrm{tr}\,\mathsf{N}^{(\lambda,\rm pot)}. \tag{157.48}$$

The full interacting noise kernel also contains cross terms with the Bogoliubov correction to the free stress tensor, local contact extensions of stress-tensor products, derivative terms, and finite composite-operator counterterms. Equation (157.47) is therefore the fluctuation analogue of (157.40): it is a retained potential-sector coordinate. It becomes a physical Einstein–Langevin input only after the conserved full stress tensor and its renormalized square have been fixed in the same locally covariant scheme.

157.11 Validity Conditions And Reduction Of Order

The semiclassical approximation requires more than small curvature. A controlled statement includes

$$\begin{gathered}\ell_{\text{curv}} \gg \ell_{\text{UV}},\\ |\langle T^{\text{ren}}_{\mu\nu}\rangle| \text{ small compared with the gravitational EFT cutoff scales,}\\ N(f,f)^{1/2} \text{ small for the smeared observables used to test the metric,}\\ \text{state stability under the metric perturbations considered,}\\ \text{hyperbolic well-posedness after higher-curvature terms are treated.}\end{gathered} \tag{157.49}$$

Curvature-squared terms contain four derivatives of the metric. Treated as exact equations, they introduce additional modes at the cutoff scale. In a low-energy gravitational EFT these modes are not new physical initial data. They are removed by reduction of order: solve the leading second-order equation, use it to replace higher derivatives in the curvature-squared terms, and keep only the terms through the fixed EFT order. Equivalently, work perturbatively in α and β and discard solutions that are singular as $\alpha, \beta \to 0$.

157.12 Backreaction Specification

A backreaction problem is specified by

$$(M, g, \omega, T^{\text{ren}}_{\mu\nu}, G_N, \Lambda, \alpha, \beta, \mathcal{B}),$$

where $\mathcal{B}$ denotes boundary or initial data, gauge conditions, and state-transport prescriptions. The output is a solution space with stability, state-dependence, and renormalization-coordinate dependence. Black-hole evaporation, cosmological particle creation, and Casimir backreaction are applications of this datum.

Open Problem 157.5 (Backreaction theorem). Formulate and prove a semiclassical backreaction theorem for an interacting Hadamard QFT with renormalized stress tensor, controlled stress-tensor fluctuations, local covariance, and a hyperbolic gravitational EFT evolution. The theorem should specify the topology on metric perturbations and states, the allowed renormalization coordinates, the treatment of higher-derivative terms, and the sense in which the stochastic approximation captures the leading connected stress-tensor fluctuations.

Notation and Convention Guide

This guide records global notation conventions used repeatedly across the monograph. It is a navigation aid, not a replacement for local definitions: when a chapter first uses a load-bearing symbol it must still declare the object, its ambient space or category, and its status. If a symbol has different meanings in different frameworks, the chapter must state the local meaning before use. The entries below therefore function as a consistency check for recurrent notation and as a quick map for readers moving between volumes.

Global Conventions

Symbol or convention	**Meaning and scope**
$\mathbb{M}^D$	D-dimensional Minkowski spacetime with metric $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$, unless a chapter states otherwise. The monograph does not use mostly-minus conventions.
$\mathbb{R}^D$	Euclidean D-space with positive metric $\delta_{\mu\nu}$. Euclidean correlation functions are not automatically probability moments; their status is the one declared in the local reconstruction or regulator datum.
$\mathrm{d}x$, $\mathrm{d}^D x$	Lebesgue measure in the displayed coordinate chart. On manifolds the measure is written with the appropriate density, volume form, or regulator datum.
i, e, id	The imaginary unit, exponential, and identity map or identity operator. Identity operators on a named space may also be written **1**.
$\hbar$	Set to 1 unless explicitly displayed. Semiclassical discussions restore $\hbar$ locally and state the scaling regime.
$U(a) = \exp(\mathrm{i}a^\mu P_\mu)$	Translation convention. A covariant field satisfies $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ on the common invariant domain when point-field notation denotes a smeared operator-valued distribution.
$[A, B]_\pm$	Graded commutator when a parity has been declared; ordinary commutator when all operators are even. Fermionic operator anticommutation is a statement about Hilbert-space operators, distinct from Grassmann path-integral variables.

Hilbert-Space and Operator-Algebra Symbols

Symbol	Meaning and scope
$\mathcal{H}$	Hilbert space of a reconstructed or assumed quantum theory. Domains of unbounded operators are part of the data whenever they enter a proof.
Ω or Ω	Vacuum vector when the Hilbert-space representation has been constructed. Before reconstruction, brackets denote the stated Euclidean, algebraic, or regulated functional expectation.
$\mathcal{A}$, $\mathcal{A}$	Observable algebra. In Wightman chapters this may denote the algebra generated by smeared fields on a common domain; in AQFT chapters $\mathcal{A}(\mathcal{O})$ denotes the local algebra assigned to a spacetime region $\mathcal{O}$.
$\mathcal{R}(\mathcal{O})$	Von Neumann local algebra in a Hilbert-space representation, usually the weak closure of $\mathcal{A}(\mathcal{O})$.
$\mathcal{A}_{\mathrm{qloc}}$	Quasilocal algebra obtained as the inductive C^*-completion of local observable algebras when such a completion is part of the stated AQFT datum.
$\widehat{\Phi}(f)$	Smeared field operator. The test function f, target representation, and common invariant domain must be specified locally. Point notation $\widehat{\Phi}(x)$ is kernel notation subordinate to smearing.
$E(\Delta)$	Spectral projection of a self-adjoint operator or commuting family for the Borel set Δ. For energy-momentum spectra the relevant joint spectral measure is declared in the chapter.
$\mathcal{H}_1$	One-particle subspace associated with an isolated mass shell or other declared spectral component. It is not defined by a perturbative pole alone.
$\mathcal{S}$, $\mathcal{S}'$	Schwartz test functions and tempered distributions. Distributional equalities mean equality after pairing with test functions.
$\mathcal{D}$, $\mathcal{D}'$	Compactly supported smooth test functions and distributions when local support, wavefront set, or microlocal arguments require compact support.

Correlation, Scattering, and Spectral Symbols

Symbol	Meaning and scope
W_n	Lorentzian Wightman distribution. Its arguments are ordered, and its analytic continuation properties are distributional boundary-value statements, not pointwise functions unless the chapter proves a stronger regularity statement.
S_n	Euclidean Schwinger distribution or regulated Euclidean correlator, depending on the declared datum. The symbol is not a literal moment of a Borel measure unless such a measure has been constructed.
G_n, G_n^{conn}	Time-ordered Green function and its connected part, with Lorentzian or Euclidean status stated locally.
$\rho(\mu^2)$, $\mathrm{d}\rho(\mu^2)$	Källén–Lehmann spectral density or positive spectral measure for a gauge-invariant Hilbert-space two-point function. Gauge-variant fields do not inherit this positivity statement.

Symbol	Meaning and scope
Z_ϕ^{pole}	Residue of an isolated one-particle pole in the Källén–Lehmann sense. It is kept distinct from a generating functional $Z[J]$.
$\mathcal{S}$, $S_{\beta\alpha}$	Scattering operator or its matrix elements after Haag–Ruelle wave operators and LSZ hypotheses have been stated. Perturbative diagrammatics for S-matrix elements are downstream of this nonperturbative construction.
$\mathcal{M}(s,t)$	Invariant amplitude in a declared normalization and sheet. A chapter must state whether the object is connected, amputated, physical-sheet, second-sheet, partial-wave, or analytically continued.
s,t,u	Mandelstam invariants, with metric convention fixed by the local chapter. Analytic continuation in these variables is always tied to a sheet convention.

Path-Integral, Effective-Action, and RG Symbols

Symbol	Meaning and scope
$[Dq]$, $[D\phi]$, $D_\Lambda\phi$	Continuum path-integral notation is shorthand for the specified finite-dimensional time slicing, finite-mode regulator, lattice regulator, Gaussian reference measure, perturbative formal expansion, BV pushforward, or constructive measure. The local chapter must state which one is meant.
$Z[J]$	Generating functional for the declared regulator or formal perturbative scheme. $W[J] = \log Z[J]$ denotes the connected functional where this logarithm is defined or formally expanded.
$\Gamma[\phi]$	1PI effective action, defined by a Legendre transform under the local convexity/formal-inversion assumptions. In gauge theory, Γ must be understood in the stated gauge-fixed BV or lattice framework.
S_Λ, I_Λ	Wilsonian action or interaction at scale Λ. The exact meaning depends on the regulator and field coordinates; counterterms are part of the Lagrangian or action specified by that regulator.
μ	Renormalization scale, not a Wilsonian cutoff unless a chapter explicitly constructs a cutoff family with that parameter.
Λ	Cutoff, Wilsonian scale, or lattice ultraviolet scale when supplied as part of a regulator datum. It is not interchangeable with μ.
$\beta^i(g)$	Beta function in the declared coordinate chart on couplings. Scheme changes are coordinate changes; universal claims require the chapter to state the invariant content.
$\mathcal{O}_A$, $[\mathcal{O}_A]_\mu$	Local operator and renormalized local operator at scale μ. The operator regularization scheme and the path-integral regulator are separate data unless the chapter identifies them.

Gauge-Theory and BV Symbols

Symbol	Meaning and scope
G, $\mathfrak{g}$	Gauge group and Lie algebra. Global form and bundle topology are part of the data when line operators, instantons, anomalies, or theta angles are discussed.
A, F_A	Connection and curvature. Locally $F_A = \mathrm{d}A + A \wedge A$ in anti-Hermitian geometric conventions; component conventions are restated in the gauge-theory chapters.
tr	Trace in the declared representation and normalization. Yang–Mills chapters use action normalization compatible with $(4g^2)^{-1}\,\mathrm{tr}\,F_{\mu\nu}F^{\mu\nu}$ after the local Hermitian/anti-Hermitian conversion has been stated.
$c, \bar{c}, B$	Ghost, antighost, and auxiliary field in the stated gauge-fixing convention.
s	BRST or BV differential. Nilpotence may hold off shell, on shell, or after the quantum master equation depending on the construction declared locally.
Φ^A, Φ^*_A	BV fields and antifields. The odd symplectic form, antibracket $(\,\cdot\,,\,\cdot\,)$, and BV Laplacian Δ require a chosen finite-dimensional or regularized measure/Berezinian datum.
$\mathcal{W}_\gamma$	Wilson line or Wilson loop along γ, with representation, orientation, and renormalization prescription stated locally.
T_γ	't Hooft line or magnetic line datum. Its definition requires a prescribed singular bundle/connection behavior around γ, not merely an operator label.

CFT, Integrability, and Thermal Symbols

Symbol	Meaning and scope
Δ, ℓ	Scaling dimension and spin of a local operator or representation. The letter Δ is also used for modular operators and Laplacians in other chapters; the local chapter disambiguates.
$\mathcal{O}_i$	Local operator in a CFT or general QFT. In CFT radial quantization, local operators of definite scaling dimension correspond to energy eigenstates; the linear span of local-operator states is dense in the Hilbert space under the stated positivity/sewing hypotheses, not equal to it as a completed space.
${C_{ij}}^k$	OPE coefficient in a declared normalization of two-point functions and operator basis.
$\mathcal{F}$, $\mathcal{G}$	Conformal block, chiral block, or form factor depending on the chapter. The ambient representation-theoretic decomposition is stated locally.
$S_{ab}(\theta)$	Two-dimensional factorized scattering matrix for rapidity difference θ, after species space, analyticity strip, unitarity, crossing, and CDD ambiguity have been declared.
$Y_a(\theta)$	TBA Y-function for the declared particle or string node. Mirror-channel and physical-channel meanings are not interchangeable.

Symbol	Meaning and scope
β_{th}	Inverse temperature, often written separately from RG beta functions $\beta^i(g)$.
ρ_β, ω_β	Thermal density matrix or KMS state. A density matrix exists only in finite volume or type-I settings; in AQFT the KMS state is a positive normalized functional satisfying the KMS boundary condition.
G^R, ρ_{AB}	Retarded correlator and spectral function in real-time finite-temperature chapters, with contact terms and transport limits stated locally.

Constructive, Lattice, and Stochastic Symbols

Symbol	Meaning and scope
Λ_{lat}, a	Finite lattice and lattice spacing. Do not confuse a lattice region Λ_{lat} with a continuum cutoff scale Λ.
U_ℓ	Compact lattice gauge link variable on an oriented edge ℓ. Haar measure and boundary conditions are part of the finite lattice datum.
D_{W}, D_{ov}	Wilson and overlap lattice Dirac operators when the chapter has fixed gauge background, lattice spacing, mass parameter, and boundary conditions.
Ξ, X	Noise and stochastic convolution in stochastic-quantization chapters. These are distribution-valued random objects after a regulator/renormalization limit has been constructed; finite smooth approximants carry regulator subscripts.
$\mathcal{T}$, Π, Γ	Regularity-structure model space, model realization, and reexpansion maps when the corresponding chapter has defined them.
$\mathcal{K}$, P_t	Kernel or heat semigroup. The chapter states whether it is continuum, lattice, massive, massless, spatial, spacetime, or parabolic.
H_N, P_N	Finite truncation Hamiltonian and projector in Hamiltonian-truncation or DLCQ chapters. Continuum conclusions require an explicit extrapolation or bound beyond finite-matrix diagonalization.
χ^2, Σ	Correlated fit statistic and covariance matrix in numerical-evidence chapters. These are finite data-analysis objects; they are not continuum proof objects unless accompanied by the stated regulator estimates and an explicit theorem that those estimates imply.

Overload Warnings

Several symbols are deliberately reused in different mathematical contexts because the local conventions are standard. The following overloaded symbols require particular attention:

$$\Delta,\quad S,\quad Z,\quad \Gamma,\quad \rho,\quad \beta,\quad \Lambda,\quad \mathcal{F},\quad G,\quad K.$$

Their meanings are never inferred from typography alone. A chapter must declare whether, for example, Δ is a modular operator, Laplacian, scaling dimension, discriminant, or finite difference;

whether S is an action, S-matrix, entropy, or modular S-matrix; and whether Z is a partition function, generating functional, wave-function residue, or central element. This guide records the common uses, but local declarations control the mathematics.

Bibliographic Guide

How this bibliography is used. The references below are source traces for theorem-boundary statements, historical origin of constructions, and convention checks. A citation is not a proof in this monograph. Every result used in the logical development must still be derived in the local text, stated with its hypotheses as a quoted theorem, or marked as a hypothesis, controlled approximation, conjecture, or open problem.

This first seed covers the most frequently quoted foundational lineages: Wightman and OS reconstruction [1, 2, 3, 7, 8, 9, 13], scattering theory [4, 5, 6], perturbative and Wilsonian renormalization [14, 15, 16, 17], AQFT superselection and modular theory [18, 19, 22, 23, 24, 25, 20, 21, 26, 27, 28, 30], constructive and stochastic routes [33, 34], curved-spacetime local covariance and pAQFT [10, 11, 12], CFT and VOA structure [35, 36, 37, 38, 49, 50], anomalies and index theory [54, 55, 56, 57, 58, 59, 60, 61, 62], instantons [63], supersymmetric dynamics [67, 68, 69], and locality laboratories [76]. Later passes should attach additional citations at the precise theorem-boundary sites and expand this guide.
