$$\mathcal{G}_{\mathrm{GFF}}(u,v) = 1 + u^{\Delta_\phi} + \left(\frac{u}{v}\right)^{\Delta_\phi}. \tag{64.46}$$

The crossing relation is now an algebraic identity:

$$v^{\Delta_\phi}\mathcal{G}_{\mathrm{GFF}}(u,v) = v^{\Delta_\phi} + (uv)^{\Delta_\phi} + u^{\Delta_\phi} = u^{\Delta_\phi} + (uv)^{\Delta_\phi} + v^{\Delta_\phi} = u^{\Delta_\phi}\mathcal{G}_{\mathrm{GFF}}(v,u). \tag{64.47}$$

The $12 \to 34$ OPE contains the identity and bilinear conformal primaries. Let z^μ be a null auxiliary vector, $z^2 = 0$, used to encode symmetric traceless spin. For $n \in \mathbb{Z}_{\geq 0}$ and $\ell \in 2\mathbb{Z}_{\geq 0}$, define

$$\mathcal{O}_{n,\ell}(x,z) = \mathcal{N}_{n,\ell}\,\Pi_{\mathrm{prim}}\Big[:\phi(x_1)\big(z\cdot(\partial_{x_1}-\partial_{x_2})\big)^\ell\big((\partial_{x_1}-\partial_{x_2})^2\big)^n\phi(x_2):\Big]_{x_1=x_2=x}. \tag{64.48}$$

The colons denote Wick subtraction with respect to (64.44). The projection Π_{prim} is defined as follows. At fixed total relative derivative degree $N = 2n+\ell$, the rotational spin-ℓ bilinears form a finite-dimensional inner-product space. Total derivatives are P_μ-descendants of lower energy states. Since radial reflection makes $K_\mu = P_\mu^\dagger$, the primary subspace is the orthogonal complement of the descendant subspace, equivalently the kernel of every K_μ. The finite orthogonal projection onto this kernel is Π_{prim}. Homogeneous polynomials in the relative derivative decompose as

$$\mathrm{Sym}^N(\mathbb{R}^D) = \bigoplus_{j=0}^{\lfloor N/2 \rfloor} (q^2)^j \, \mathcal{H}_{N-2j},$$

where $\mathcal{H}_m$ is the space of degree-m harmonic polynomials. For $N = 2n + \ell$, the quotient by total derivatives contains one copy of the spin-ℓ harmonic representation. Its projection has nonzero Wick norm, so it gives one orthonormal primary family for each (n, ℓ) that survives the null quotient. Exchange of the two identical fields sends the relative derivative to its negative, so only even ℓ survives in the symmetric product.

The normalization $\mathcal{N}_{n,\ell}$ is chosen so that

$$\langle \mathcal{O}_{n,\ell}(x, z) \mathcal{O}_{n',\ell'}(0, z') \rangle = 0 \quad \text{unless} \quad (n, \ell) = (n', \ell'),$$

and the nonzero two-point function has unit coefficient in the spin-ℓ conformal normalization used for the blocks in this chapter. The corresponding scaling dimension and twist are

$$\Delta_{n,\ell} = 2\Delta_\phi + 2n + \ell, \qquad \tau_{n,\ell} = \Delta_{n,\ell} - \ell = 2\Delta_\phi + 2n. \tag{64.49}$$

The dimension formula follows directly from radial energy: two scalar one-particle states contribute $2\Delta_\phi$, each derivative contributes one unit, and the primary projection only subtracts states with the same total energy.

With orthonormal primaries the $12 \to 34$ channel expansion is

$$\mathcal{G}_{\text{GFF}}(u, v) = 1 + \sum_{n=0}^{\infty} \sum_{\ell \in 2\mathbb{Z}_{\geq 0}} a_{n,\ell}^{\text{GFF}} \, G_{2\Delta_\phi + 2n + \ell, \ell}(u, v), \qquad a_{n,\ell}^{\text{GFF}} = \lambda_{\phi\phi\mathcal{O}_{n,\ell}}^2 \geq 0, \tag{64.50}$$

valid in the s-channel radial domain $\mathcal{D}_s$ of (64.40). This formula is the radial spectral resolution of the vector $\phi(x_1)\phi(x_2)|\Omega\rangle$. Its identity component is the contraction $|x_{12}|^{-2\Delta_\phi}|\Omega\rangle$; its normal-ordered component lies in $\mathrm{Sym}^2 V_{\Delta_\phi}$, whose primary decomposition was constructed in the preceding paragraph. Pairing this convergent vector expansion with the exterior state $\phi(x_3)\phi(x_4)|\Omega\rangle$ gives (64.50). Since the same matrix element was already computed by the finite Wick sum (64.45), uniqueness of the orthogonal spectral resolution identifies the block sum with (64.46) throughout $\mathcal{D}_s$.

Equivalently, with spin indices encoded by the auxiliary null vector or displayed explicitly at level zero, the OPE has the radial Hilbert-space form

$$\phi(x)\phi(0)|\Omega\rangle = |x|^{-2\Delta_\phi}|\Omega\rangle + \sum_{n=0}^{\infty} \sum_{\ell \in 2\mathbb{Z}_{\geq 0}} \lambda_{\phi\phi\mathcal{O}_{n,\ell}} \sum_{r=0}^{\infty} \mathcal{C}_{n,\ell}^{(r)}(x, P) \, \mathcal{O}_{n,\ell}(0)|\Omega\rangle, \tag{64.51}$$

where P_μ acts on the primary state to generate descendants. The level-r coefficient is a homogeneous polynomial-valued differential operator

$$\mathcal{C}_{n,\ell}^{(r)}(x, P) = \sum_{|\alpha| = r} c_\alpha^{(n,\ell)}(x) \, P^\alpha,$$

obtained by applying the finite projector (64.36) at descendant level r. Its primary-level term is

$$\mathcal{C}^{(0)}_{n,\ell}(x,P)\,\mathcal{O}_{n,\ell}(0) = |x|^{2n} x_{\mu_1}\cdots x_{\mu_\ell}\mathcal{O}^{\mu_1\cdots\mu_\ell}_{n,\ell}(0).$$

The power of $|x|$ is fixed by dimension: $\Delta_{n,\ell} - 2\Delta_\phi - \ell = 2n$.

The first nontrivial scalar primary illustrates the normalization. Put

$$\mathcal{O}_{0,0}(x) = \frac{1}{\sqrt{2}} : \phi(x)^2 : .$$

Wick contraction gives

$$\langle : \phi(x)^2 :: \phi(0)^2 :\rangle = \frac{2}{|x|^{4\Delta_\phi}}, \qquad \langle \phi(x_1)\phi(x_2) : \phi(x_3)^2 :\rangle = \frac{2}{|x_{13}|^{2\Delta_\phi}|x_{23}|^{2\Delta_\phi}}.$$

Hence

$$\lambda_{\phi\phi\mathcal{O}_{0,0}} = \sqrt{2}, \qquad a^{\mathrm{GFF}}_{0,0} = 2. \tag{64.52}$$

The first two terms of (64.51) are therefore

$$\phi(x)\phi(0)|\Omega\rangle = |x|^{-2\Delta_\phi}|\Omega\rangle + \sqrt{2}\,\mathcal{O}_{0,0}(0)|\Omega\rangle + \cdots,$$

where the omitted terms are precisely the positive-level terms in (64.51). The remaining terms in the two functions u^{Δ_ϕ} and $(u/v)^{\Delta_\phi}$, expanded near the s-channel OPE boundary, are reproduced by the descendants of $\mathcal{O}_{0,0}$ together with the higher-spin and higher-n bilinear primaries in (64.50).

The $14 \to 23$ OPE is the same representation-theoretic decomposition in the crossed channel. Written with the $12 \to 34$ prefactor, it reads

$$\mathcal{G}_{\mathrm{GFF}}(u,v) = \left(\frac{u}{v}\right)^{\Delta_\phi}\left[1 + \sum_{n=0}^{\infty}\sum_{\ell\in 2\mathbb{Z}_{\geq 0}} a^{\mathrm{GFF}}_{n,\ell}\, G_{2\Delta_\phi+2n+\ell,\ell}(v,u)\right], \tag{64.53}$$

valid in $\mathcal{D}_t$. The identity operator in the crossed channel is responsible for the term $(u/v)^{\Delta_\phi}$ in (64.46); the crossed bilinear tower sums to $(u/v)^{\Delta_\phi}(v^{\Delta_\phi} + (v/u)^{\Delta_\phi}) = u^{\Delta_\phi} + 1$. Thus the two OPE channels are two convergent radial expansions of the same Wick-pairing function, and (64.47) is the prefactor form of that equality.

64.9 A First Consequence of Crossing and Positivity

The simplest use of (64.42) is to see why a unitary CFT cannot have an arbitrarily large gap above the identity in the $\phi \times \phi$ OPE while keeping Δ_ϕ fixed. This subsection is deliberately a controlled approximation, not a sharp bootstrap theorem: we keep the leading radial behavior of heavy exchanged blocks near the crossing-symmetric point and state the assumptions used.

Take $z = \bar{z} \in (0,1)$, so that $u = z^2$ and $v = (1-z)^2$. The crossing equation becomes

$$(1-z)^{2\Delta_\phi}\mathcal{G}(z) = z^{2\Delta_\phi}\mathcal{G}(1-z), \tag{64.54}$$

where $\mathcal{G}(z)$ abbreviates $\mathcal{G}(z^2,(1-z)^2)$. Using (64.43),

$$\left[(1-z)^{2\Delta_\phi} - z^{2\Delta_\phi}\right] + \sum_{\mathcal{O}\neq\mathbf{1}} \lambda^2_{\mathcal{O}}\left[(1-z)^{2\Delta_\phi}G_{\mathcal{O}}(z) - z^{2\Delta_\phi}G_{\mathcal{O}}(1-z)\right] = 0. \tag{64.55}$$

For $0 < z < 1$, define

$$r(z) = \frac{z}{(1+\sqrt{1-z})^2}.$$

If the exchanged dimensions contributing above the identity are large, and if we keep only the leading radial behavior

$$G_{\mathcal{O}}(z) \simeq r(z)^{\Delta_{\mathcal{O}}}$$

on this line, then (64.55) is approximated by

$$\left[(1-z)^{2\Delta_\phi} - z^{2\Delta_\phi}\right] + \sum_{\mathcal{O}\neq \mathbf{1}} \lambda_{\mathcal{O}}^2 \left[(1-z)^{2\Delta_\phi} r(z)^{\Delta_{\mathcal{O}}} - z^{2\Delta_\phi} r(1-z)^{\Delta_{\mathcal{O}}}\right] = 0. \tag{64.56}$$

The crossing-symmetric point is $z = 1/2$, where

$$r(1/2) = 3 - 2\sqrt{2}.$$

Set $z = 1/2 + x$ and expand (64.56) in x. The identity contribution is

$$(1-z)^{2\Delta_\phi} - z^{2\Delta_\phi} = -\Delta_\phi 2^{3-2\Delta_\phi}\left[x + \frac{4}{3}(\Delta_\phi - 1)(2\Delta_\phi - 1)x^3 + \cdots\right].$$

The coefficient follows directly from $(1/2-x)^{2\Delta_\phi} - (1/2+x)^{2\Delta_\phi} = 2^{-2\Delta_\phi}[(1-2x)^{2\Delta_\phi} - (1+2x)^{2\Delta_\phi}]$; the odd cubic term is $-2^{4-2\Delta_\phi}\binom{2\Delta_\phi}{3}x^3$, which becomes the displayed $\frac{4}{3}(\Delta_\phi - 1)(2\Delta_\phi - 1)$ after the common factor $-\Delta_\phi 2^{3-2\Delta_\phi}$ is extracted. For a heavy exchanged primary, the leading odd part of the approximate block contribution has the form

$$\widetilde{\lambda}_{\mathcal{O}}^2\left[x + \frac{4}{3}\Delta_{\mathcal{O}}^2 x^3 + \cdots\right], \qquad \widetilde{\lambda}_{\mathcal{O}}^2 \geq 0,$$

where the positive factor relating $\widetilde{\lambda}_{\mathcal{O}}^2$ to $\lambda_{\mathcal{O}}^2$ includes $(3-2\sqrt{2})^{\Delta_{\mathcal{O}}}$ and other positive constants. Matching the coefficients of x and x^3 gives, in this approximation,

$$\sum_{\mathcal{O}\neq \mathbf{1}} \widetilde{\lambda}_{\mathcal{O}}^2\left[\Delta_{\mathcal{O}}^2 - (\Delta_\phi - 1)(2\Delta_\phi - 1)\right] = 0.$$

Since every coefficient in the sum is nonnegative, not all exchanged dimensions can be much larger than

$$\sqrt{(\Delta_\phi - 1)(2\Delta_\phi - 1)}.$$

The robust conclusion is qualitative: crossing plus reflection positivity forces nontrivial operator content in the $\phi \times \phi$ OPE at dimensions controlled by Δ_ϕ. A rigorous numerical or analytic bound requires the full conformal blocks and lies beyond this first approximation.

64.10 Mixed Correlators and the Three-Dimensional Ising Bootstrap System

The preceding argument used one four-point function. The first sharp bootstrap examples in $D > 2$ require several four-point functions at once, because positivity is then matrix-valued rather than a list of nonnegative numbers. This section records the exact crossing system for the scalar pair used in the three-dimensional Ising bootstrap. It is not a numerical solution of that system. It is the CFT information to which finite-dimensional semidefinite programs are applied.

Definition 64.13 ($\mathbb{Z}_2$-graded scalar bootstrap system)**.** A $\mathbb{Z}_2$-graded scalar bootstrap system in a unitary CFT in dimension $D > 2$ consists of:

1. two Hermitian scalar primaries σ and ε, with $\mathbb{Z}_2$-charges odd and even and dimensions $\Delta_\sigma, \Delta_\varepsilon$;
2. two-point normalization
$$\langle\sigma(x)\sigma(0)\rangle = |x|^{-2\Delta_\sigma}, \qquad \langle\varepsilon(x)\varepsilon(0)\rangle = |x|^{-2\Delta_\varepsilon};$$
3. real OPE coefficients in the three scalar OPEs
$$\sigma\times\sigma \subset \mathcal{S}_+, \qquad \varepsilon\times\varepsilon \subset \mathcal{S}_+, \qquad \sigma\times\varepsilon \subset \mathcal{S}_-,$$
where $\mathcal{S}_+$ and $\mathcal{S}_-$ are respectively the $\mathbb{Z}_2$-even and odd primary spectra;
4. the spin selection rule that $\sigma\times\sigma$ and $\varepsilon\times\varepsilon$ contain only even spins, while $\sigma\times\varepsilon$ may contain any integer spin.

The identity operator belongs to $\mathcal{S}_+$, with $\lambda_{\sigma\sigma\mathbf{1}} = \lambda_{\varepsilon\varepsilon\mathbf{1}} = 1$.

The sign in the last OPE coefficient is convention-sensitive. For a symmetric-traceless spin-ℓ primary $\mathcal{O}_{\mu_1\cdots\mu_\ell}$, the scalar-scalar-spin three-point tensor contains the homogeneous factor $(Z\cdot x_{12})^\ell$ in an index-free polarization Z. Therefore exchanging the two scalar insertions gives

$$\lambda_{\varepsilon\sigma\mathcal{O}} = (-1)^\ell \lambda_{\sigma\varepsilon\mathcal{O}}. \tag{64.57}$$

For scalar external labels i, j, k, l, define the crossing combinations

$$\mathsf{F}^{ij,kl}_{\pm,\Delta,\ell}(u,v) := v^{(\Delta_j+\Delta_k)/2} G^{ij|kl}_{\Delta,\ell}(u,v) \pm u^{(\Delta_j+\Delta_k)/2} G^{ij|kl}_{\Delta,\ell}(v,u), \tag{64.58}$$

where $G^{ij|kl}_{\Delta,\ell}$ is the $12 \to 34$ OPE-normalized scalar block in the convention of (64.9). The superscript $ij|kl$ records the external dimension differences used in the Casimir equation. When $i = j = k = l = \phi$, F_- is exactly the identical scalar crossing kernel

$$v^{\Delta_\phi} G_{\Delta,\ell}(u,v) - u^{\Delta_\phi} G_{\Delta,\ell}(v,u).$$

Proposition 64.14 (Five crossing equations for the σ, ε system)**.** *Let Definition 64.13 hold. The three four-point functions*

$$\langle\sigma\sigma\sigma\sigma\rangle, \qquad \langle\sigma\sigma\varepsilon\varepsilon\rangle, \qquad \langle\varepsilon\varepsilon\varepsilon\varepsilon\rangle$$

imply the following five crossing equations:

$$0 = \sum_{\mathcal{O}\in\mathcal{S}_+} \lambda^2_{\sigma\sigma\mathcal{O}}\, \mathsf{F}^{\sigma\sigma,\sigma\sigma}_{-,\Delta,\ell}(u,v), \tag{64.59}$$

$$0 = \sum_{\mathcal{O}\in\mathcal{S}_+} \lambda^2_{\varepsilon\varepsilon\mathcal{O}}\, \mathsf{F}^{\varepsilon\varepsilon,\varepsilon\varepsilon}_{-,\Delta,\ell}(u,v), \tag{64.60}$$

$$0 = \sum_{\mathcal{O}\in\mathcal{S}_-} \lambda^2_{\sigma\varepsilon\mathcal{O}}\, \mathsf{F}^{\sigma\varepsilon,\sigma\varepsilon}_{-,\Delta,\ell}(u,v), \tag{64.61}$$

$$0 = \sum_{\mathcal{O}\in\mathcal{S}_+} \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}\, \mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{-,\Delta,\ell}(u,v) + \sum_{\mathcal{O}\in\mathcal{S}_-} (-1)^\ell \lambda^2_{\sigma\varepsilon\mathcal{O}}\, \mathsf{F}^{\varepsilon\sigma,\sigma\varepsilon}_{-,\Delta,\ell}(u,v), \tag{64.62}$$

$$0 = \sum_{\mathcal{O}\in\mathcal{S}_+} \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}\, \mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{+,\Delta,\ell}(u,v) - \sum_{\mathcal{O}\in\mathcal{S}_-} (-1)^\ell \lambda^2_{\sigma\varepsilon\mathcal{O}}\, \mathsf{F}^{\varepsilon\sigma,\sigma\varepsilon}_{+,\Delta,\ell}(u,v). \tag{64.63}$$

The sums include the identity in $\mathcal{S}_+$; the last three equations contain no identity contribution from $\mathcal{S}_-$.

Proof. Equations (64.59) and (64.60) are the identical-scalar crossing equation (64.42) applied to σ and ε. Equation (64.61) is the same statement applied to the ordered correlator $\langle\sigma\varepsilon\varepsilon\sigma\rangle$; the exchanged primaries in the 12 channel are $\mathbb{Z}_2$-odd.

For the mixed correlator, expand $\langle\sigma_1\sigma_2\varepsilon_3\varepsilon_4\rangle$ in the $12 \to 34$ channel:

$$\mathcal{G}_{\sigma\sigma\varepsilon\varepsilon}(u,v) = \sum_{\mathcal{O}\in\mathcal{S}_+} \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}\, G^{\sigma\sigma|\varepsilon\varepsilon}_{\Delta,\ell}(u,v).$$

Only $\mathbb{Z}_2$-even primaries occur, because both pair OPEs are even. Now exchange the first and third insertions and use the same scalar four-point prefactor as in (63.30). A direct comparison of the prefactors gives

$$\mathcal{G}_{\sigma\sigma\varepsilon\varepsilon}(u,v) = \frac{u^{\Delta_\sigma}}{v^{(\Delta_\sigma+\Delta_\varepsilon)/2}}\, \mathcal{G}_{\varepsilon\sigma\sigma\varepsilon}(v,u). \tag{64.64}$$

The right-hand side has a $\sigma\times\varepsilon$ OPE and therefore contains only $\mathbb{Z}_2$-odd primaries. With $\lambda_{\varepsilon\sigma\mathcal{O}} = (-1)^\ell\lambda_{\sigma\varepsilon\mathcal{O}}$, this crossing relation is equivalent to

$$\sum_{\mathcal{O}\in\mathcal{S}_+} \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}\, v^{(\Delta_\sigma+\Delta_\varepsilon)/2} G^{\sigma\sigma|\varepsilon\varepsilon}_{\Delta,\ell}(u,v) - \sum_{\mathcal{O}\in\mathcal{S}_-} (-1)^\ell \lambda^2_{\sigma\varepsilon\mathcal{O}}\, u^{\Delta_\sigma} G^{\varepsilon\sigma|\sigma\varepsilon}_{\Delta,\ell}(v,u) = 0. \tag{64.65}$$

Repeating the same prefactor comparison for the exchanged ordering $\langle\varepsilon_1\sigma_2\sigma_3\varepsilon_4\rangle$, and then writing the result in the same block notation after the simultaneous exchange of the two scalar pairs, gives the companion equation

$$\sum_{\mathcal{O}\in\mathcal{S}_+} \lambda_{\sigma\sigma\mathcal{O}}\lambda_{\varepsilon\varepsilon\mathcal{O}}\, u^{(\Delta_\sigma+\Delta_\varepsilon)/2} G^{\sigma\sigma|\varepsilon\varepsilon}_{\Delta,\ell}(v,u) - \sum_{\mathcal{O}\in\mathcal{S}_-} (-1)^\ell \lambda^2_{\sigma\varepsilon\mathcal{O}}\, v^{\Delta_\sigma} G^{\varepsilon\sigma|\sigma\varepsilon}_{\Delta,\ell}(u,v) = 0. \tag{64.66}$$

Subtracting (64.66) from (64.65), and then adding the same two equations, gives respectively (64.62) and (64.63). This proves all five equations. $\square$

It is useful to combine these equations into the form used by semidefinite programming. Define a five-vector $\vec{\mathsf{V}}_{-,\Delta,\ell}$ and a five-vector $\vec{\mathsf{V}}_{+,\Delta,\ell}$ whose entries are 2×2 matrices by

$$\vec{\mathsf{V}}_{-,\Delta,\ell} := \begin{pmatrix} 0 \\ 0 \\ \mathsf{F}^{\sigma\varepsilon,\sigma\varepsilon}_{-,\Delta,\ell} \\ (-1)^{\ell}\mathsf{F}^{\varepsilon\sigma,\sigma\varepsilon}_{-,\Delta,\ell} \\ -(-1)^{\ell}\mathsf{F}^{\varepsilon\sigma,\sigma\varepsilon}_{+,\Delta,\ell} \end{pmatrix}, \tag{64.67}$$

$$\vec{\mathsf{V}}_{+,\Delta,\ell} := \begin{pmatrix} \begin{pmatrix} \mathsf{F}^{\sigma\sigma,\sigma\sigma}_{-,\Delta,\ell} & 0 \\ 0 & 0 \end{pmatrix} \\ \begin{pmatrix} 0 & 0 \\ 0 & \mathsf{F}^{\varepsilon\varepsilon,\varepsilon\varepsilon}_{-,\Delta,\ell} \end{pmatrix} \\ \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \\ \begin{pmatrix} 0 & \frac{1}{2}\mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{-,\Delta,\ell} \\ \frac{1}{2}\mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{-,\Delta,\ell} & 0 \end{pmatrix} \\ \begin{pmatrix} 0 & \frac{1}{2}\mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{+,\Delta,\ell} \\ \frac{1}{2}\mathsf{F}^{\sigma\sigma,\varepsilon\varepsilon}_{+,\Delta,\ell} & 0 \end{pmatrix} \end{pmatrix}. \tag{64.68}$$

Then Proposition 64.14 is equivalent to

$$\sum_{\mathcal{O}\in\mathcal{S}_+} \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}} & \lambda_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix} \vec{\mathsf{V}}_{+,\Delta,\ell} \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}} \\ \lambda_{\varepsilon\varepsilon\mathcal{O}} \end{pmatrix} + \sum_{\mathcal{O}\in\mathcal{S}_-} \lambda^2_{\sigma\varepsilon\mathcal{O}} \vec{\mathsf{V}}_{-,\Delta,\ell} = 0. \tag{64.69}$$

This equation is a vector equation in the space of functions of u, v. The $\mathbb{Z}_2$-even coefficients are not individually positive in the mixed entries, but they form positive semidefinite matrices. More precisely, for a fixed even primary family, or for a finite degenerate even subspace,

$$\Lambda^+_{\Delta,\ell} = \sum_a \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}_a} \\ \lambda_{\varepsilon\varepsilon\mathcal{O}_a} \end{pmatrix} \begin{pmatrix} \lambda_{\sigma\sigma\mathcal{O}_a} & \lambda_{\varepsilon\varepsilon\mathcal{O}_a} \end{pmatrix} \succeq 0. \tag{64.70}$$

The odd-sector coefficients are ordinary nonnegative numbers $\lambda^2_{\sigma\varepsilon\mathcal{O}}$.

Finite functional exclusion proof object. Fix a candidate $\mathbb{Z}_2$-graded scalar spectrum satisfying the unitarity bounds and any additional gap assumptions. The crossing equation (64.69) cannot be solved if there is a linear functional separating the identity vector from the cone generated by the allowed nonidentity blocks. Concretely, let $\vec{\alpha} = (\alpha_1, \ldots, \alpha_5)$ be linear functionals on the five components of (64.69). Suppose that:

1. the identity contribution is strictly positive,

$$\begin{pmatrix} 1 & 1 \end{pmatrix} \vec{\alpha} \cdot \vec{\mathsf{V}}_{+,0,0} \begin{pmatrix} 1 \\ 1 \end{pmatrix} > 0;$$

2. for every allowed even nonidentity primary, $\vec{\alpha} \cdot \vec{\mathsf{V}}_{+,\Delta,\ell}$ is a positive semidefinite 2×2 matrix;
3. for every allowed odd primary, $\vec{\alpha} \cdot \vec{\mathsf{V}}_{-,\Delta,\ell} \geq 0$.

Then no unitary CFT with that spectrum and those gaps realizes the candidate spectrum. To see this, apply $\vec{\alpha}$ to (64.69) and separate the identity contribution. Every even nonidentity term is a quadratic form of a positive semidefinite matrix on the vector $(\lambda_{\sigma\sigma\mathcal{O}}, \lambda_{\varepsilon\varepsilon\mathcal{O}})$. Every odd term is a nonnegative number multiplying $\lambda^2_{\sigma\varepsilon\mathcal{O}}$. Thus the whole left-hand side is strictly positive, contradicting the crossing equation. The displayed contradiction is elementary once such a functional is known. The nontrivial mathematical work in a rigorous bootstrap exclusion is the construction and verification of $\vec{\alpha}$: one must specify the allowed spectral set, control the conformal blocks and their derivatives on that set, and prove the matrix and scalar positivity conditions without relying on uncontrolled floating-point output.

The three-dimensional Ising numerical bootstrap studies the case $D = 3$ with σ the lowest $\mathbb{Z}_2$-odd scalar and ε the lowest nonidentity $\mathbb{Z}_2$-even scalar. The hypotheses that create the small Ising island are spectral hypotheses, not consequences of the five crossing equations alone: one assumes, for example, that no other $\mathbb{Z}_2$-odd or nonidentity even scalar is relevant,

$$\Delta_{\sigma'} \geq 3, \qquad \Delta_{\varepsilon'} \geq 3, \tag{64.71}$$

together with the $D = 3$ unitarity bounds

$$\Delta_{\text{scalar}} \geq \frac{1}{2}, \qquad \Delta_\ell \geq \ell + 1 \quad (\ell \geq 1).$$

Derivative functionals at $z = \bar{z} = 1/2$ then turn the finite-functional criterion above into a finite semidefinite search after one chooses a block approximation and proves or verifies its positivity on the relevant ranges of Δ. Floating-point SDP output is numerical evidence until it is accompanied by a rigorous proof object, for example interval bounds for the block derivatives together with positive-polynomial or sum-of-squares witnesses. This is the precise status boundary between the mathematical CFT crossing system (64.69) and the high-precision numerical islands quoted in the Wilson–Fisher comparison table.

Open Problem 64.15 (Interval-verified mixed-correlator Ising island). Give a fully verified exclusion proof, with interval-controlled conformal block derivatives and exact semidefinite proof objects, that isolates the three-dimensional Ising point inside a specified rectangle in $(\Delta_\sigma, \Delta_\varepsilon)$ under stated gap assumptions such as (64.71). The monograph uses the numerical island as external high-precision data until such a verified proof object is supplied.

Chapter 65

Light-Ray Operators and Energy Correlators

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Energy correlators provide a common observable language for conformal field theory and high-energy gauge theory. The primitive object is a detector at future null infinity, represented in local QFT by an asymptotic flux of the stress tensor. The same object can also be described, after conformal compactification, as a null-integrated light-ray operator.

65.1 Detector States and Energy Flux

Let the Lorentzian CFT live on $\mathbb{M}^D$, $D \geq 3$, with Hilbert space $\mathcal{H}$, vacuum vector Ω, translation generators P^μ, and a conserved symmetric stress tensor $T^{\mu\nu}$. A normalizable collider state is obtained by smearing a local operator with timelike momentum support. For a local operator $\mathcal{O}_A$, where A denotes all tensor and internal indices, choose a smooth compactly supported wavepacket $h(q)$ on the open future cone and a polarization tensor ε^A, and set

$$|\Psi_{\mathcal{O},h,\varepsilon}\rangle = \int_{V_+} \mathrm{d}\mu(q)\, h(q)\, \varepsilon^A\, \widetilde{\mathcal{O}}_A(q)|\Omega\rangle.$$

Here $\mathrm{d}\mu(q)$ is a positive measure on the chosen momentum slice. The Fourier-transformed operator is an operator-valued distribution applied to the test function h. Sharp momentum states used in collider formulas are distributional limits of these wavepackets.

Hypothesis 65.1 (CFT energy detector)**.** For every real $f \in C^\infty(S^{D-2})$, the limit

$$\mathcal{E}(f) = \mathrm{w}-\lim_{r\to\infty} r^{D-2} \int_{-\infty}^{\infty} \mathrm{d}u \int_{S^{D-2}} \mathrm{d}\Omega(\mathbf{n})\, f(\mathbf{n})\, n_i T^{0i}(u+r, r\mathbf{n}) \tag{65.1}$$

exists as a quadratic form on the collider domain generated by such states. If $f \geq 0$, the resulting quadratic form is positive. The constant function gives the total outgoing energy,

$$\mathcal{E}(1) = P^0$$

on the same domain.

The distributional detector density is denoted by

$$\mathcal{E}(f) = \int_{S^{D-2}} \mathrm{d}\Omega(\mathbf{n})\, f(\mathbf{n})\mathcal{E}(\mathbf{n}).$$

For k test functions $f_1, \ldots, f_k$, the k-point energy correlator in a normalized state Ψ is

$$\mathcal{G}_k(f_1, \ldots, f_k; \Psi) = \langle \Psi | \mathcal{E}(f_1) \cdots \mathcal{E}(f_k) | \Psi \rangle. \tag{65.2}$$

The product is defined first for separated angular supports and then extended, when possible, as a distribution on $(S^{D-2})^k$. Coincident detector directions carry contact terms determined by the distributional product of light-ray operators.

65.1.1 Finite Angular Partitions and Positivity

Before multiplying detector operators, it is useful to extract the one-detector positivity consequence of Hypothesis 65.1. Let Ψ be a finite-energy collider state in the detector domain and define the state functional

$$\ell_\Psi(f) = \langle \Psi | \mathcal{E}(f) | \Psi \rangle, \qquad f \in C^\infty(S^{D-2}), \quad f \text{ real.}$$

If $f \geq 0$, then $\ell_\Psi(f) \geq 0$. Moreover $-\|f\|_\infty \leq f \leq \|f\|_\infty$ implies, by positivity and $\mathcal{E}(1) = P^0$,

$$|\ell_\Psi(f)| \leq \|f\|_\infty \, \langle \Psi | P^0 | \Psi \rangle. \tag{65.3}$$

Thus ℓ_Ψ extends uniquely from smooth tests to a positive bounded linear functional on $C(S^{D-2})$. By the Riesz representation theorem there is a finite positive regular Borel measure μ_Ψ on the detector sphere such that

$$\langle \Psi | \mathcal{E}(f) | \Psi \rangle = \int_{S^{D-2}} f(\mathbf{n})\, \mathrm{d}\mu_\Psi(\mathbf{n}), \qquad \mu_\Psi(S^{D-2}) = \langle \Psi | P^0 | \Psi \rangle. \tag{65.4}$$

This is a statewise measure statement. Promoting it to an operator-valued measure requires compatible polarized matrix elements and a common domain; those domain questions are additional parts of the detector-existence hypothesis beyond the scalar Riesz representation step.

For a finite angular partition $\mathcal{P} = \{B_1, \ldots, B_m\}$ of the sphere by Borel sets, the numbers

$$\mu_a(\Psi) = \mu_\Psi(B_a) \geq 0, \qquad \sum_{a=1}^{m} \mu_a(\Psi) = \langle \Psi | P^0 | \Psi \rangle$$

are the finite-resolution calorimeter readout in the state Ψ. If $v, w \in \mathbb{C}^m$ are bin weights, the statewise one-detector pairing

$$(v, w)_\Psi = \sum_{a=1}^{m} \mu_a(\Psi)\, \overline{v_a} w_a$$

is positive semidefinite and obeys

$$|(v, w)_\Psi|^2 \le (v, v)_\Psi\, (w, w)_\Psi. \tag{65.5}$$

These inequalities are consequences of positivity of a single detector measure. Positivity statements for products $\mathcal{E}(f_1) \cdots \mathcal{E}(f_k)$ require the diagonal-contact extension discussed next.

Finite-resolution Lipschitz estimates. The finite partition readout gives the operational topology in which an ideal detector is approached by finite angular bins. Let d be the round metric on S^{D-2}. For a finite Borel partition

$$\mathcal{P} = \{B_1, \ldots, B_m\}, \qquad \operatorname{diam}(\mathcal{P}) = \max_a \sup_{\mathbf{n}, \mathbf{n}' \in B_a} d(\mathbf{n}, \mathbf{n}'),$$

choose a representative point $\mathbf{n}_a \in B_a$ for each nonempty bin and replace the statewise detector measure by the binned measure

$$\mu_{\Psi,\mathcal{P}} = \sum_a \mu_\Psi(B_a)\, \delta_{\mathbf{n}_a}.$$

If $f : S^{D-2} \to \mathbb{R}$ is L_f-Lipschitz, then

$$\left| \int f \, \mathrm{d}\mu_\Psi - \int f \, \mathrm{d}\mu_{\Psi,\mathcal{P}} \right| \le L_f \, \operatorname{diam}(\mathcal{P})\, \mu_\Psi(S^{D-2}). \tag{65.6}$$

Indeed, on each bin,

$$|f(\mathbf{n}) - f(\mathbf{n}_a)| \le L_f \, \operatorname{diam}(\mathcal{P}),$$

and summing the resulting measure estimate over bins gives (65.6). Thus convergence of finite bin masses along partitions with $\operatorname{diam}(\mathcal{P}) \to 0$, together with the uniform total energy bound $\mu_\Psi(S^{D-2}) = \langle P^0 \rangle_\Psi$, implies weak convergence of the statewise detector measures against continuous tests by uniform approximation.

The same estimate controls finite-resolution k-detector products after a positive joint detector measure has been constructed. Let $\mu_\Psi^{(k)}$ be such a measure on $(S^{D-2})^k$, let $\mu_{\Psi,\mathcal{P}}^{(k)}$ be the pushforward to the representative points, and let F be L_F-Lipschitz with respect to the product metric

$$d_k((\mathbf{n}_1, \ldots, \mathbf{n}_k), (\mathbf{n}'_1, \ldots, \mathbf{n}'_k)) = \sum_{r=1}^{k} d(\mathbf{n}_r, \mathbf{n}'_r).$$

Then

$$\left| \int F \, \mathrm{d}\mu_\Psi^{(k)} - \int F \, \mathrm{d}\mu_{\Psi,\mathcal{P}}^{(k)} \right| \le k \, L_F \, \operatorname{diam}(\mathcal{P})\, \mu_\Psi^{(k)}((S^{D-2})^k). \tag{65.7}$$

For the product measure of a finite-energy state, the total mass is $\langle (P^0)^k \rangle_\Psi$ when the diagonal-contact extension has been included. Equations (65.6) and (65.7) are therefore the finite-resolution Lipschitz estimates behind the statement that energy correlators are detector observables on the celestial sphere. The construction of detector products remains the separate domain question; once a product measure is available, these estimates identify the finite calorimeter data it supplies.

65.1.2 Angular Moment Data and Measure Reconstruction

The statewise measure μ_Ψ turns angular detector data into a compact moment problem. Let $K = S^{D-2}$, and let $\mathcal{A}_{\mathrm{ang}} \subset C(K;\mathbb{R})$ be a unital real subalgebra that separates points and is uniformly dense in $C(K;\mathbb{R})$. A concrete choice is the algebra generated by the restrictions of the ambient coordinate functions n^i to S^{D-2}; equivalently, one may use any real spherical-harmonic basis closed under finite multiplication. The angular moments of a finite detector measure are the numbers

$$m_\Psi(a) = \int_K a(\mathbf{n})\,\mathrm{d}\mu_\Psi(\mathbf{n}), \qquad a \in \mathcal{A}_{\mathrm{ang}}. \tag{65.8}$$

For $a = 1$ this moment is the total energy $\langle\Psi|P^0|\Psi\rangle$.

Compact angular moment reconstruction. Let $M : \mathcal{A}_{\mathrm{ang}} \to \mathbb{R}$ be linear and assume

$$M(a) \geq 0 \quad \text{whenever} \quad a(\mathbf{n}) \geq 0 \text{ for all } \mathbf{n} \in K, \qquad M(1) = E < \infty.$$

Then there is a unique finite positive regular Borel measure μ_M on K satisfying

$$M(a) = \int_K a\,\mathrm{d}\mu_M, \qquad a \in \mathcal{A}_{\mathrm{ang}}.$$

Consequently the complete angular moment functional $a \mapsto m_\Psi(a)$ determines the statewise detector measure μ_Ψ uniquely.

Argument. For real $a \in \mathcal{A}_{\mathrm{ang}}$, the inequalities $-\|a\|_\infty \leq a \leq \|a\|_\infty$ on K imply

$$0 \leq M(\|a\|_\infty 1 \pm a) = \|a\|_\infty E \pm M(a).$$

Hence $|M(a)| \leq E\|a\|_\infty$. Thus M is uniformly bounded on the dense subalgebra $\mathcal{A}_{\mathrm{ang}}$ and extends uniquely by continuity to a bounded positive linear functional $\overline{M}$ on $C(K;\mathbb{R})$. Positivity of the extension follows by approximating any nonnegative $f \in C(K;\mathbb{R})$ uniformly by $a_j \in \mathcal{A}_{\mathrm{ang}}$ and applying the bound to $a_j - f$ together with the positivity assumption to the functions $a_j + \epsilon_j 1$, where $\epsilon_j = \|a_j - f\|_\infty$.

The Riesz–Markov representation theorem gives a finite positive regular Borel measure μ_M with $\overline{M}(f) = \int_K f\,\mathrm{d}\mu_M$ for all continuous real f. The restriction to $\mathcal{A}_{\mathrm{ang}}$ gives the displayed moment identities. If two finite positive measures have the same moments on $\mathcal{A}_{\mathrm{ang}}$, their integrals agree on a uniformly dense subset of $C(K)$. The bound by total mass extends this equality to all continuous functions, and the uniqueness clause in the Riesz–Markov theorem makes the two measures equal.

This criterion records the information content of complete angular detector moments. A finite list of moments is a finite-resolution projection of μ_Ψ. It gives positivity constraints and linear coordinates for a specified detector resolution, while many distinct positive measures may share the same truncated list. For example on any detector great circle, the measures $\frac{1}{2}\delta_{\mathbf{n}} + \frac{1}{2}\delta_{-\mathbf{n}}$ and $\delta_{\mathbf{n}_\perp}$, with $\mathbf{n}_\perp \cdot \mathbf{n} = 0$, have the same total energy and the same dipole moment but different quadrupole moments. The complete moment functional separates them because $\mathcal{A}_{\mathrm{ang}}$ separates points.

The same compact moment logic applies to detector products after the product has been extended to a finite positive joint detector measure $\mu_\Psi^{(k)}$ on K^k. Then moments of $\mu_\Psi^{(k)}$ against the algebraic tensor products of $\mathcal{A}_{\mathrm{ang}}$ determine that k-detector measure uniquely. The substantive QFT problem is the construction of the product measure and its diagonal-contact coordinates; once that finite measure is supplied, compact moment reconstruction is ordinary functional analysis. The QCD calorimetric-coordinate density theorem, Theorem 50.17, is the corresponding statement on the compact ball of finite positive energy measures.

65.1.3 Detector Products and Diagonal Contacts

The contact terms in detector products have a concrete measure-theoretic origin. A finite-resolution calorimetric configuration X with detector directions $\mathbf{n}_a \in S^{D-2}$ and positive energies $E_a > 0$ determines the positive finite measure

$$\varepsilon_X = \sum_{a=1}^{N} E_a\, \delta_{\mathbf{n}_a}. \tag{65.9}$$

The corresponding detector functional is

$$E_X(f) = \int f\, \mathrm{d}\varepsilon_X = \sum_a E_a f(\mathbf{n}_a).$$

For two detector tests f, g, the product decomposes exactly as

$$\begin{aligned} E_X(f)E_X(g) &= \sum_{a,b} E_a E_b f(\mathbf{n}_a) g(\mathbf{n}_b) \\ &= \sum_{a\neq b} E_a E_b f(\mathbf{n}_a) g(\mathbf{n}_b) + \sum_a E_a^2 f(\mathbf{n}_a) g(\mathbf{n}_a). \end{aligned} \tag{65.10}$$

The first term is the restriction of the product measure $\varepsilon_X \otimes \varepsilon_X$ to the complement of the diagonal in $S^{D-2} \times S^{D-2}$. The second term is supported on the diagonal $\mathbf{n}_1 = \mathbf{n}_2$. Thus a separated-angle two-detector distribution and a full two-detector distribution differ by a specified diagonal distribution; deleting or retaining that diagonal part is a choice of observable coordinate, not a change of the underlying detector.

For k detector insertions, the same bookkeeping is indexed by partitions. Let P_k be the set of set partitions of $\{1, \ldots, k\}$. If $\pi \in \mathsf{P}_k$ and $B \in \pi$ is a block, write a_B for the detector atom assigned to that block. Grouping equal labels in the product $\prod_i \sum_{a_i} E_{a_i} f_i(\mathbf{n}_{a_i})$ gives

$$\prod_{i=1}^{k} E_X(f_i) = \sum_{\pi\in\mathsf{P}_k} \sum_{\substack{a_B,\ B\in\pi \\ a_B\neq a_{B'} \text{ for } B\neq B'}} \prod_{B\in\pi} E_{a_B}^{|B|} \prod_{i\in B} f_i(\mathbf{n}_{a_B}). \tag{65.11}$$

The discrete partition into singletons is the fully separated detector support. Every coarser partition is a diagonal contact stratum in $(S^{D-2})^k$. Formula (65.11) is the finite positive measure model for the contact-term structure of (65.2).

In the operator language of the CFT, Hypothesis 65.1 supplies the smeared detector as a quadratic form. Products with mutually disjoint angular supports are defined by the off-diagonal part of the operator-valued measure. Extending the product to overlapping supports requires a distributional extension across the diagonals, and the extension must preserve the stress-tensor Ward identity

$$\mathcal{G}_2(1, 1; \Psi) = \langle \Psi | (P^0)^2 | \Psi \rangle. \tag{65.12}$$

For a state with sharp total energy Q, the normalized two-detector correlator therefore has unit zeroth moment when the diagonal contact coordinate is included. A convention that studies only separated detector directions must display the removed diagonal contribution separately. This is the CFT counterpart of the endpoint-contact bookkeeping for the QCD energy-energy correlator in Section 50.6.

65.2 Relation to Null-Integrated Operators

Let $n^\mu = (1, \mathbf{n})$ be a future null vector. For a point $x_\perp$ in a spacelike plane transverse to n^μ, the averaged null energy operator on the null line through $x_\perp$ is the quadratic form

$$\mathcal{A}_n(x_\perp) = \int_{-\infty}^{\infty} \mathrm{d}\lambda\, T_{\mu\nu}(x_\perp + \lambda n) n^\mu n^\nu. \tag{65.13}$$

The conformal map from a null line to future null infinity identifies $\mathcal{E}(\mathbf{n})$, up to the fixed conformal Jacobian determined by the chosen compactification, with the light-ray transform (65.13) of the stress tensor. Thus the detector operator is a nonlocal operator obtained by integrating a local field along a complete null generator.

This formulation separates three pieces of data:

$$\begin{gathered}\text{local stress tensor} \longrightarrow \text{null-integrated light-ray operator}\\ \longrightarrow \text{calorimetric distribution on } S^{D-2}.\end{gathered}$$

The first belongs to the local operator algebra. The second requires control of a null integral of an operator-valued distribution. The third is a detector observable in states with finite total energy.

For $f \geq 0$, positivity of $\mathcal{E}(f)$ is the detector version of the averaged null energy theorem stated below. Hypothesis 65.1 packages two analytic inputs: the existence of the null-infinity detector as a quadratic form and the positivity supplied by the theorem for nonnegative angular smearings.

65.3 The Light Transform of a Local Primary

The stress-tensor detector is one member of a broader class of light-ray operators. We spell out the conformal bookkeeping because the same representation-theoretic data are used later in the light-ray OPE, and because it prevents a common ambiguity: a light-ray operator is not an ordinary local operator placed at a point of spacetime. It is an integral transform of a local operator-valued distribution, with its own domain and growth hypotheses.

Use the standard embedding-space notation for a symmetric traceless primary $\mathcal{O}_{\Delta,J}$. A physical point is represented by a null ray $P \in \mathbb{R}^{D,2}$, and tensor indices are packaged by a null auxiliary vector Z satisfying

$$P^2 = Z^2 = P \cdot Z = 0, \qquad Z \sim Z + \beta P.$$

The encoded primary is homogeneous as

$$\mathcal{O}_{\Delta,J}(\lambda P, \alpha Z) = \lambda^{-\Delta} \alpha^J\, \mathcal{O}_{\Delta,J}(P, Z), \qquad \lambda, \alpha > 0. \tag{65.14}$$

This is a compact way to say that Δ is the scaling dimension and J is the spin. Gauge invariance under $Z \to Z + \beta P$ encodes tracelessness and transversality.

For a primary satisfying the Lorentzian growth hypotheses needed to make the integral a distribution, its light transform is

$$\mathbb{L}[\mathcal{O}_{\Delta,J}](P,Z) = \int_{-\infty}^{\infty} \mathrm{d}\alpha\, \mathcal{O}_{\Delta,J}(Z - \alpha P, -P). \tag{65.15}$$

The point $Z - \alpha P$ runs along a null generator, while the new auxiliary polarization is $-P$. The formula is first a pairing with test functions in the transverse and ray variables; convergence or analytic continuation is part of the light-transform datum, not an automatic consequence of local operator covariance.

The homogeneity of $\mathbb{L}[\mathcal{O}_{\Delta,J}]$ follows directly from (65.14). Scaling P and changing variables $\alpha' = \lambda\alpha$ gives

$$\mathbb{L}[\mathcal{O}](\lambda P, Z) = \int \frac{\mathrm{d}\alpha'}{\lambda}\, \mathcal{O}(Z - \alpha' P, -\lambda P) = \lambda^{J-1}\mathbb{L}[\mathcal{O}](P,Z). \tag{65.16}$$

Scaling Z and changing variables $\alpha = \beta\alpha'$ gives

$$\mathbb{L}[\mathcal{O}](P, \beta Z) = \int \beta\, \mathrm{d}\alpha'\, \mathcal{O}(\beta(Z - \alpha' P), -P) = \beta^{1-\Delta}\mathbb{L}[\mathcal{O}](P,Z). \tag{65.17}$$

Thus the light transform has conformal weights

$$(\Delta, J) \longmapsto (1 - J, 1 - \Delta), \tag{65.18}$$

where the second entry is understood as the analytically continued spin coordinate of the nonlocal light-ray representation. Equations (65.16)–(65.18) are representation-theoretic bookkeeping, not an existence theorem. The existence theorem requires the Lorentzian analyticity and growth assumptions appearing in Quoted Theorem 65.5. The signs in (65.18) are tied to the conformal charge convention of Lemma 57.9, not to an independent convention for detector operators. In embedding space the conformal generators act as linear first-order vector fields on the pair (P, Z). Acting on $\mathcal{O}_{\Delta,J}(Z - \alpha P, -P)$ therefore gives the same generator acting on the transformed line, plus a total derivative in the line coordinate α. Under the growth hypotheses that make the light transform a distribution, that total derivative has no endpoint contribution after pairing with line test functions. The transform consequently intertwines the complexified conformal algebra, while its projective weights change only by the two Jacobian factors displayed above: P-rescaling contributes the $\mathrm{d}\alpha/\lambda$ factor and Z-rescaling contributes the $\beta\,\mathrm{d}\alpha'$ factor. The radial real form used for descendant Gram matrices is a separate convention fixed in (59.27)–(59.28); it is obtained by the displayed change of real form before Gram matrices are computed.

For the stress tensor, $(\Delta, J) = (D, 2)$. The light transform therefore has formal embedding weights $(-1, 1 - D)$. After conformal compactification and restriction to future null infinity, this object is represented by the positive energy detector density $\mathcal{E}(\mathbf{n})$, a measure-valued operator on S^{D-2} rather than a local primary on Minkowski space. This is the reason the detector normalization is fixed by $\mathcal{E}(1) = P^0$ and by the ANEC theorem, not by treating $\mathcal{E}(\mathbf{n})$ as an ordinary local operator.

65.4 ANEC and Conformal Collider Bounds

The averaged null energy condition used in conformal collider physics is a quadratic-form statement about a null light transform of the stress tensor. It is stronger than positivity of the

Hamiltonian, because it localizes the energy measurement on one complete null generator rather than integrating over a spacelike Cauchy surface. The statement requires a domain on which the null integral of the stress-tensor distribution exists.

Let $N_n = n^{\perp}/\mathbb{R}n$ be the $(D-2)$-dimensional transverse quotient to the null direction n^{μ}. For a nonnegative test function $\varphi \in C_c^{\infty}(N_n)$, define the smeared null-energy quadratic form

$$\mathcal{A}_n(\varphi) = \int_{N_n} \mathrm{d}^{D-2}x_{\perp}\, \varphi(x_{\perp}) \int_{-\infty}^{\infty} \mathrm{d}\lambda\, T_{\mu\nu}(x_{\perp} + \lambda n) n^{\mu} n^{\nu}. \tag{65.19}$$

The transverse smearing is part of the definition. The unsmeared $\mathcal{A}_n(x_{\perp})$ in (65.13) is the corresponding distributional kernel.

Quoted Theorem 65.2 (Averaged null energy theorem for Lorentzian CFT states)**.** *Consider a unitary Lorentzian CFT on $\mathbb{M}^D$, $D \geq 3$, with a unique translation-invariant vacuum Ω, spectrum condition, local stress tensor $T_{\mu\nu}$ as a Wightman distribution, and the Lorentzian analyticity and operator-growth bounds needed for the null light transform of $T_{\mu\nu}$. Let $\mathcal{D}_{\mathrm{ANEC}} \subset \mathcal{H}$ be a dense finite-energy domain that contains the wavepacket states generated by local operators and is stable under the smearings used in (65.19). Then, for every future null n^{μ}, every nonnegative $\varphi \in C_c^{\infty}(N_n)$, and every $\Psi \in \mathcal{D}_{\mathrm{ANEC}}$,*

$$\langle \Psi | \mathcal{A}_n(\varphi) | \Psi \rangle \geq 0. \tag{65.20}$$

The theorem is used here as an external theorem boundary with its hypotheses visible.[1] The two proof mechanisms have the same local output: they identify $\mathcal{A}_n(\varphi)$ as the operator whose expectation measures the monotone or causal response of a state to a null displacement.

We spell out the modular route because it fixes the sign conventions. Choose light-cone coordinates

$$x^{\pm} = x^0 \pm x^1, \qquad y = (x^2, \ldots, x^{D-1}), \qquad \mathrm{d}s^2 = -\mathrm{d}x^+ \mathrm{d}x^- + \mathrm{d}y^2,$$

and take $n = \partial_+$. For a smooth cut $x^+ = f(y)$ of the null plane $x^- = 0$, let R_f be the domain of dependence of the portion $x^- = 0$, $x^+ \geq f(y)$. Denote by $K_f = -\log \rho^{\Omega}_{R_f}$ the vacuum modular Hamiltonian on R_f, with the additive scalar fixed by $\mathrm{Tr}_{R_f} \rho^{\Omega}_{R_f} = 1$. The null-cut modular Hamiltonian theorem gives, as an equality of quadratic forms on finite-energy states after transverse smearing,

$$K_f = 2\pi \int \mathrm{d}^{D-2}y \int_{f(y)}^{\infty} \mathrm{d}x^+ \, \big(x^+ - f(y)\big) T_{++}(x^+, x^- = 0, y). \tag{65.21}$$

This formula is a local statement on the null surface. For $f_s(y) = s\varphi(y)$, differentiation at $s = 0$ gives

$$\frac{\mathrm{d}}{\mathrm{d}s} \Delta_{\Psi} \langle K_{f_s} \rangle \bigg|_{s=0} = -2\pi \int \mathrm{d}^{D-2}y\, \varphi(y) \int_0^{\infty} \mathrm{d}x^+ \, \Delta_{\Psi} \langle T_{++}(x^+, 0, y) \rangle, \tag{65.22}$$

where

$$\Delta_{\Psi}\langle X \rangle = \langle \Psi | X | \Psi \rangle - \langle \Omega | X | \Omega \rangle.$$

[1]For the modular-Hamiltonian proof, see T. Faulkner, R. G. Leigh, O. Parrikar, and H. Wang, "Modular Hamiltonians for Deformed Half-Spaces and the Averaged Null Energy Condition," JHEP **09** (2016) 038, arXiv:1605.08072. For the Lorentzian causality proof in CFT, see T. Hartman, S. Kundu, and A. Tajdini, "Averaged null energy condition from causality," JHEP **07** (2017) 066, arXiv:1610.05308.

The sign in the last step is a small but important piece of modular bookkeeping. Write

$$S_{\rm rel}(\rho_R^\Psi\|\rho_R^\Omega)=\Delta_\Psi\langle K_R\rangle-\Delta_\Psi S_R,\qquad R_1\subset R_2\Rightarrow S_{\rm rel}(R_1)\le S_{\rm rel}(R_2),$$

for Araki relative entropy. If $s>0$ and $\varphi\ge 0$, the region $R_{s\varphi}$ is contained in R_0. Hence the right derivative at the origin obeys

$$\frac{\mathrm{d}}{\mathrm{d}s}S_{\rm rel}(R_{s\varphi})\Big|_{0^+}\le 0. \tag{65.23}$$

Using (65.22), this gives

$$\frac{\mathrm{d}}{\mathrm{d}s}\Delta_\Psi S_{R_{s\varphi}}\Big|_{0^+}\ge -2\pi\int \mathrm{d}^{D-2}y\,\varphi(y)\int_0^\infty \mathrm{d}x^+\,\Delta_\Psi\langle T_{++}(x^+,0,y)\rangle. \tag{65.24}$$

For the complementary null cut $R^c_{s\varphi}$, the inclusion is reversed: $R^c_0\subset R^c_{s\varphi}$. Its modular Hamiltonian has the same local null-cut form on the left part of the generator,

$$K^c_{s\varphi}=2\pi\int \mathrm{d}^{D-2}y\int_{-\infty}^{s\varphi(y)}\mathrm{d}x^+\,\big(s\varphi(y)-x^+\big)T_{++}(x^+,0,y),$$

so

$$\frac{\mathrm{d}}{\mathrm{d}s}\,\Delta_\Psi\langle K^c_{s\varphi}\rangle\Big|_{0^+}=2\pi\int \mathrm{d}^{D-2}y\,\varphi(y)\int_{-\infty}^0 \mathrm{d}x^+\,\Delta_\Psi\langle T_{++}(x^+,0,y)\rangle. \tag{65.25}$$

Monotonicity for the complementary inclusion gives a nonnegative right derivative of $S_{\rm rel}(R^c_{s\varphi})$. For a vector state on the global Hilbert space, the entropy of a region and of its complement agree in a split-regulated exhaustion and hence have the same first variation at the common cut. Therefore

$$\frac{\mathrm{d}}{\mathrm{d}s}\Delta_\Psi S_{R_{s\varphi}}\Big|_{0^+}\le 2\pi\int \mathrm{d}^{D-2}y\,\varphi(y)\int_{-\infty}^0 \mathrm{d}x^+\,\Delta_\Psi\langle T_{++}(x^+,0,y)\rangle. \tag{65.26}$$

The same entropy derivative is squeezed between the right-hand sides of (65.24) and (65.26). Compatibility of the two inequalities is exactly

$$2\pi\int \mathrm{d}^{D-2}y\,\varphi(y)\int_{-\infty}^\infty \mathrm{d}x^+\,\Delta_\Psi\langle T_{++}(x^+,0,y)\rangle\ge 0. \tag{65.27}$$

The vacuum term vanishes by Poincare invariance and the stress-tensor normalization, so this is (65.20) in these coordinates. The distributional statement follows by testing this expression against $\varphi\in C_c^\infty(N_n)$; the detector statement follows after the conformal map from the complete null generator to future null infinity.

ANEC-to-detector bridge. The last sentence contains a real limiting operation. Quoted Theorem 65.2 proves positivity for smooth compact transverse tests on a null plane. The angular detector $\mathcal{E}(f)$, by contrast, is a null-infinity object tested by a smooth function $f\in C^\infty(S^{D-2})$, and finite calorimeter bins are obtained by approximating indicator functions on the compact detector sphere. To pass from ANEC to the statewise detector measure μ_Ψ of (65.4), one needs the following additional bridge data:

$$f_j\ge 0,\qquad f_j\to f\text{ in }C(S^{D-2}),\qquad \langle\Psi|\mathcal{E}(f_j)|\Psi\rangle\longrightarrow\langle\Psi|\mathcal{E}(f)|\Psi\rangle,$$

with a bound controlled by the total energy of the state, so that the positive quadratic form on smooth angular tests extends to a bounded positive functional on $C(S^{D-2})$. Riesz–Markov then gives the finite positive measure μ_Ψ. Without this bounded-extension step, ANEC positivity for each smooth transverse test is not yet a statement about Borel detector bins, nor about products of detectors at separated or coincident angles. Detector products require their own domain and contact-extension data, as in the partition discussion following (65.11). This is why the chapter keeps the one-detector positivity theorem, the statewise measure construction, and the k-detector contact algebra as distinct pieces of the detector framework.

The causality route packages the same sign in Lorentzian analyticity. Let $\mathcal{O}$ be a scalar primary used only as a probe, and let $\mathcal{X}$ be a local operator whose wavepacket creates the finite-energy state $\Psi_{\mathcal{X}}$. In the Regge light-cone regime of the normalized four-point function

$$G = \frac{\langle\Omega|\mathcal{O}(x_1)\,\mathcal{X}^\dagger(x_3)\mathcal{X}(x_4)\,\mathcal{O}(x_2)|\Omega\rangle}{\langle\Omega|\mathcal{O}(x_1)\mathcal{O}(x_2)|\Omega\rangle\langle\Omega|\mathcal{X}^\dagger(x_3)\mathcal{X}(x_4)|\Omega\rangle},$$

the stress-tensor contribution to the first nontrivial discontinuity is proportional to the ANEC matrix element

$$\langle\Psi_{\mathcal{X}}|\mathcal{A}_n(\varphi)|\Psi_{\mathcal{X}}\rangle, \qquad \varphi \geq 0,$$

where φ is determined by the probe wavepacket. Reflection positivity gives a positive norm on the Euclidean ordering, while Lorentzian causality gives analyticity and a bounded phase in the continuation around the light cone. The maximum-modulus step in that analytic domain fixes the sign of the stress-tensor discontinuity, hence gives (65.20). The derivation is conditional on the same analyticity and growth assumptions stated in Quoted Theorem 65.2.

For conformal collider physics, the consequence is immediate. If a detector state Ψ has total energy $Q = \langle\Psi|P^0|\Psi\rangle/\langle\Psi \mid \Psi\rangle$ and $\mathcal{E}(\mathbf{n})$ is the null-infinity representative of the light transform, then

$$\frac{\langle\Psi|\mathcal{E}(f)|\Psi\rangle}{\langle\Psi \mid \Psi\rangle} \geq 0 \qquad (f \geq 0), \qquad \int_{S^{D-2}} \mathrm{d}\Omega(\mathbf{n})\,\frac{\langle\Psi|\mathcal{E}(\mathbf{n})|\Psi\rangle}{\langle\Psi \mid \Psi\rangle} = Q.$$

Thus the angular energy profile in any fixed family of collider states is a positive distribution on the celestial sphere with fixed total mass Q. The Hofman–Maldacena inequalities are the finite-dimensional specialization of this positivity to stress-tensor states in four-dimensional CFTs.

65.5 Conformal Collider One-Point Functions

Consider a four-dimensional parity-even CFT and a stress-tensor state in the rest frame $q^\mu = (Q, \mathbf{0})$. Let ε_{ij} be a complex symmetric traceless spatial polarization, $i, j = 1, 2, 3$, and write

$$|\Psi_{\varepsilon,q}\rangle = \varepsilon_{ij}\widetilde{T}^{ij}(q)|\Omega\rangle$$

with wavepacket regularization understood. Rotational covariance around $\mathbf{q} = \mathbf{0}$, stress-tensor conservation, and the Ward identity normalization of $T_{\mu\nu}$ constrain the separated-angle one-detector expectation to a two-parameter tensor structure.

Lemma 65.3 (Rotational tensor basis for a stress-tensor collider state)**.** *Let $E_\varepsilon(\mathbf{n})$ be a real quadratic form in a complex symmetric traceless tensor ε_{ij}, depending on $\mathbf{n} \in S^2$, and covariant under simultaneous spatial rotations of ε and $\mathbf{n}$. Assume that its spherical-harmonic content is obtained from the tensor product of two spin-two polarizations, as happens for the separated-angle* *detector expectation in a stress-tensor state. Then after fixing the total-energy normalization, $E_\varepsilon(\mathbf{n})$ is a linear combination of*

$$1, \qquad I_2(\varepsilon, \mathbf{n}) = \frac{\varepsilon^*_{ij}\varepsilon_{ik}n^j n^k}{\varepsilon^*_{ij}\varepsilon_{ij}}, \qquad I_4(\varepsilon, \mathbf{n}) = \frac{|\varepsilon_{ij}n^i n^j|^2}{\varepsilon^*_{ij}\varepsilon_{ij}}.$$

Their angular averages are

$$\frac{1}{4\pi}\int_{S^2} \mathrm{d}\Omega\, I_2 = \frac{1}{3}, \qquad \frac{1}{4\pi}\int_{S^2} \mathrm{d}\Omega\, I_4 = \frac{2}{15}. \tag{65.28}$$

Proof. The bilinear expression in the polarization transforms in $(2) \otimes (2)$ under $SO(3)$, hence decomposes into angular momenta $\ell = 0, 1, 2, 3, 4$. Parity-even detector one-point functions and the symmetry of the stress tensor keep only the even scalar structures. The $\ell = 0$ structure is the norm $\varepsilon^*_{ij}\varepsilon_{ij}$. Contracting one pair of polarization indices with $n^j n^k$ gives the independent $\ell = 2$ structure I_2. Contracting both pairs with $n^i n^j n^k n^\ell$ gives the $\ell = 4$ structure I_4 together with lower harmonics. Thus $1, I_2, I_4$ span the parity-even rotational tensor basis.

The averages follow from the unique rotationally invariant tensors

$$\frac{1}{4\pi}\int_{S^2} \mathrm{d}\Omega\, n^i n^j = \frac{\delta^{ij}}{3},$$

and

$$\frac{1}{4\pi}\int_{S^2} \mathrm{d}\Omega\, n^i n^j n^k n^\ell = \frac{1}{15}\left(\delta^{ij}\delta^{k\ell} + \delta^{ik}\delta^{j\ell} + \delta^{i\ell}\delta^{jk}\right). \tag{65.29}$$

The first identity gives

$$\langle I_2 \rangle = \frac{\varepsilon^*_{ij}\varepsilon_{ik}\delta^{jk}}{3\,\varepsilon^*_{ab}\varepsilon_{ab}} = \frac{1}{3}.$$

For I_4, the term $\delta^{ij}\delta^{k\ell}$ in (65.29) vanishes because $\varepsilon_{ij}\delta^{ij} = 0$, while the remaining two contractions each give $\varepsilon^*_{ij}\varepsilon_{ij}$. Hence $\langle I_4 \rangle = 2/15$. □

Consequently the separated-angle one-detector expectation has the form

$$\frac{\langle \Psi_{\varepsilon,q}|\mathcal{E}(\mathbf{n})|\Psi_{\varepsilon,q}\rangle}{\langle \Psi_{\varepsilon,q} \mid \Psi_{\varepsilon,q}\rangle} = \frac{Q}{4\pi}\left[1 + t_2\left(\frac{\varepsilon^*_{ij}\varepsilon_{ik}n^j n^k}{\varepsilon^*_{ij}\varepsilon_{ij}} - \frac{1}{3}\right) + t_4\left(\frac{|\varepsilon_{ij}n^i n^j|^2}{\varepsilon^*_{ij}\varepsilon_{ij}} - \frac{2}{15}\right)\right]. \tag{65.30}$$

The real constants t_2, t_4 are coordinates on the parity-even stress-tensor three-point function after C_T and Ward-identity contact terms have been fixed. The subtractions $1/3$ and $2/15$ are precisely the averages in (65.28), so integration over S^2 gives the total energy Q for every polarization.

Lemma 65.4 (Spectral diagonalization of the stress-tensor collider form)**.** *Fix the detector direction $\mathbf{n} = e_3 = (0, 0, 1)$, and let $\mathcal{V}$ be the complex vector space of symmetric traceless tensors ε_{ij}, equipped with $\|\varepsilon\|^2 = \varepsilon^*_{ij}\varepsilon_{ij}$. Decompose $\mathcal{V}$ under rotations around e_3 as*

$$\mathcal{V} = \mathcal{V}_2 \oplus \mathcal{V}_1 \oplus \mathcal{V}_0,$$

where

$$\begin{aligned}
\mathcal{V}_2 &= \{\varepsilon : \varepsilon_{13} = \varepsilon_{23} = \varepsilon_{33} = 0\},\\
\mathcal{V}_1 &= \{\varepsilon : \varepsilon_{11} = \varepsilon_{22} = \varepsilon_{12} = \varepsilon_{33} = 0\},\\
\mathcal{V}_0 &= \mathbb{C}\ \mathrm{diag}(1, 1, -2).
\end{aligned}$$

For the normal form (65.30)*, define the dimensionless quadratic form*

$$B_{t_2,t_4}(\varepsilon) = \|\varepsilon\|^2 \left[1 + t_2\left(I_2(\varepsilon, e_3) - \frac{1}{3}\right) + t_4\left(I_4(\varepsilon, e_3) - \frac{2}{15}\right)\right].$$

If $\varepsilon = \varepsilon_2 + \varepsilon_1 + \varepsilon_0$ is the above orthogonal decomposition, then

$$B_{t_2,t_4}(\varepsilon) = \lambda_2\|\varepsilon_2\|^2 + \lambda_1\|\varepsilon_1\|^2 + \lambda_0\|\varepsilon_0\|^2, \tag{65.31}$$

with

$$\lambda_2 = 1 - \frac{1}{3}t_2 - \frac{2}{15}t_4, \qquad \lambda_1 = 1 + \frac{1}{6}t_2 - \frac{2}{15}t_4, \qquad \lambda_0 = 1 + \frac{1}{3}t_2 + \frac{8}{15}t_4. \tag{65.32}$$

Proof. The three displayed subspaces are pairwise orthogonal for $\varepsilon_{ij}^*\eta_{ij}$. They exhaust $\mathcal{V}$: a symmetric traceless 3×3 tensor is determined by the two transverse traceless entries $(\varepsilon_{11} - \varepsilon_{22}, \varepsilon_{12})$, the two mixed entries $(\varepsilon_{13}, \varepsilon_{23})$, and the scalar trace-free diagonal direction proportional to $\mathrm{diag}(1, 1, -2)$.

For $\varepsilon_2 \in \mathcal{V}_2$, the vector $\varepsilon_2 e_3$ and the scalar $e_3^i\varepsilon_{2,ij}e_3^j$ both vanish, so $I_2 = I_4 = 0$. For $\varepsilon_1 \in \mathcal{V}_1$, writing $\varepsilon_{13} = a$ and $\varepsilon_{23} = b$, one has

$$\|\varepsilon_1\|^2 = 2(|a|^2 + |b|^2), \qquad \|\varepsilon_1 e_3\|^2 = |a|^2 + |b|^2, \qquad e_3^i\varepsilon_{1,ij}e_3^j = 0,$$

so $I_2 = 1/2$ and $I_4 = 0$. For $\varepsilon_0 = c\ \mathrm{diag}(1, 1, -2)$, one has

$$\|\varepsilon_0\|^2 = 6|c|^2, \qquad \|\varepsilon_0 e_3\|^2 = 4|c|^2, \qquad |e_3^i\varepsilon_{0,ij}e_3^j|^2 = 4|c|^2,$$

so $I_2 = I_4 = 2/3$. These three evaluations give the eigenvalues (65.32). The mixed terms vanish because the subspaces are orthogonal and because the numerators $\|\varepsilon e_3\|^2$ and $|e_3^i\varepsilon_{ij}e_3^j|^2$ separate into the same $\mathcal{V}_2, \mathcal{V}_1, \mathcal{V}_0$ components. This proves (65.31). □

Four-dimensional conformal-collider inequalities. The theorem-level content in this finite step is Lemma 65.4: it identifies the three irreducible $SO(2)$ polarization sectors and computes the corresponding eigenvalues of the detector quadratic form. Once that diagonalization is in hand, positivity has no further hidden analytic content. The normal form (65.30) is positive for every stress-tensor polarization and every detector direction $\mathbf{n}$ exactly when

$$1 - \frac{1}{3}t_2 - \frac{2}{15}t_4 \geq 0, \qquad 1 + \frac{1}{6}t_2 - \frac{2}{15}t_4 \geq 0, \qquad 1 + \frac{1}{3}t_2 + \frac{8}{15}t_4 \geq 0.$$

Indeed, by rotational covariance one may put $\mathbf{n} = e_3$; the lemma then writes the form as $\lambda_2\|\varepsilon_2\|^2 + \lambda_1\|\varepsilon_1\|^2 + \lambda_0\|\varepsilon_0\|^2$, and rotation transports the same three eigenvalues to any direction.

The derivation of the normal form (65.30) is a calculation of a Wightman $\langle TTT\rangle$ distribution integrated against the detector kernel. Contact terms in the local $\langle TTT\rangle$ Ward identities fix the normalization of the stress tensor and do not change separated-angle detector values after the state wavepacket and detector smearing have been specified.

65.6 Energy-Energy Correlators in a CFT

For a state of sharp total energy Q, the normalized energy-energy correlator is the distribution

$$\mathrm{EEC}_\Psi(\chi) = \frac{1}{Q^2\langle\Psi \mid \Psi\rangle}\langle\Psi| \int_{S^{D-2}} \mathrm{d}\Omega_1 \mathrm{d}\Omega_2\, \delta(\cos\chi - \mathbf{n}_1\cdot\mathbf{n}_2)\mathcal{E}(\mathbf{n}_1)\mathcal{E}(\mathbf{n}_2)|\Psi\rangle. \tag{65.33}$$

For a wavepacket in Q, replace Q^2 by the corresponding expectation of $(P^0)^2$, or keep the unnormalized numerator and denominator separately. The separated-angle CFT observable (65.33) is the same type of detector distribution as the QCD observable (49.233). The difference is dynamical: in a CFT there is no mass gap and no hadronic scattering basis, while the detector remains defined by the stress tensor and null infinity.

When two detector directions approach one another, the product of light-ray operators has a short-distance expansion on the celestial sphere. The following theorem is used as an external theorem boundary for the modern light-ray formalism.[2]

Quoted Theorem 65.5 (Light-ray OPE under Lorentzian CFT hypotheses)**.** *In a unitary CFT satisfying the Lorentzian analyticity, spectrum, and operator-growth hypotheses required for the light-ray OPE, products of null-integrated operators on the same null plane admit a convergent expansion in light-ray operators. For energy detectors, the separated-angle product has the form, as a distribution tested near* $\mathbf{n}_1 = \mathbf{n}_2$*,*

$$\mathcal{E}(\mathbf{n}_1)\mathcal{E}(\mathbf{n}_2) = \sum_\alpha C_\alpha(\mathbf{n}_1, \mathbf{n}_2)\, \mathbb{L}_\alpha(\mathbf{n}_2),$$

where $\mathbb{L}_\alpha$ *are light-ray transforms of local CFT primaries and their descendants, analytically continued in spin as specified by the Lorentzian inversion formula.*

The word "convergent" in Quoted Theorem 65.5 is a distributional statement, not a pointwise multiplication rule for two unbounded operators. On a small celestial patch write a detector direction as a transverse coordinate $y \in \mathbb{R}^{D-2}$. A separated detector product is first paired with a test function

$$\Phi(y_1, y_2) \in C_c^\infty\big((U \times U) \setminus \{y_1 = y_2\}\big).$$

The diagonal limit is probed by families whose support approaches $|y_{12}| = |y_1 - y_2| = 0$. The theorem supplies coefficient distributions

$$C_{\alpha,m}(y_{12})$$

and light-ray operators $\mathbb{L}_\alpha(y)$, together with a topology of test functions and state wavepackets in which

$$\mathcal{E}(y_1)\mathcal{E}(y_2) \sim \sum_{\alpha,m} C_{\alpha,m}(y_{12})\, \partial_y^m \mathbb{L}_\alpha(y_2) \tag{65.34}$$

after pairing with such tests. The multi-index m labels transverse descendants and tensor structures. The coefficients are homogeneous or polyhomogeneous distributions away from $y_{12} = 0$,

[2] See M. Kologlu, P. Kravchuk, D. Simmons-Duffin, and A. Zhiboedov, "The light-ray OPE and conformal colliders," arXiv:1905.01311. For the conformal-collider formulation, see D. M. Hofman and J. Maldacena, "Conformal collider physics: energy and charge correlations," JHEP 05 (2008) 012, arXiv:0803.1467.

with logarithmic terms when anomalous dimensions or degeneracies are present. Their normalization is fixed by three-point data involving the two detector light transforms and $\mathbb{L}_\alpha$, or equivalently by the Lorentzian inversion transform in the conformal frame used to define the light transform.

The proof mechanism has three distinct analytic steps. First, the product of the local stress tensors is not expanded by the Euclidean local OPE at ordinary spacelike separation. The two null integrations and the detector limit force one to control Lorentzian configurations in which the integration contours approach lightlike singularities. Lorentzian analyticity and the spectrum condition provide domains in complexified configuration space in which the contours can be displaced and the relevant discontinuities can be defined. Second, Regge or operator-growth bounds control the arcs at infinity and justify exchanging the null-line integrals with the partial-wave or inversion expansion. Without these bounds the formal operation "integrate the local OPE along a null line" is not a proof. Third, the resulting expansion is completed in a transverse distribution topology. A usable version states that, after retaining all light-ray primaries in a set $\mathcal{A}_N$, the remainder R_N obeys an estimate of the form

$$\left|\langle\Psi|R_N(\Phi)|\Psi\rangle\right| \le C_N(\Psi)\,\|\Phi\|_{\mathcal{T}_N}\,\epsilon^{\sigma_N} \tag{65.35}$$

for tests supported in $|y_{12}| < \epsilon$, with a declared test-function seminorm $\|\cdot\|_{\mathcal{T}_N}$ and an exponent $\sigma_N > 0$ that improves as the retained operator set is enlarged. Equation (65.35) is not an additional theorem proved here; it is the kind of bound that makes (65.34) a mathematical statement rather than a formal series. Whenever the monograph uses the light-ray OPE below, the use is restricted to consequences that follow from such Lorentzian analyticity, growth, and transverse-distribution convergence hypotheses.

Finite light-ray OPE charts. For calculations and for comparison with detector data, one never manipulates the entire light-ray OPE at once. One chooses a finite chart and states its remainder. Work in a small angular patch with transverse coordinates (y_1, y_2), relative coordinate $\xi = y_1 - y_2$, and center coordinate $y = y_2$. Let $\mathfrak{A}_N$ be a finite set of retained light-ray primary and descendant labels (α, m). A finite CFT light-ray OPE chart for the two-detector product in a state domain $\mathcal{D}_N$ consists of:

1. coefficient distributions $C_{\alpha,m}$ in the relative variable ξ, including their specified extension across $\xi = 0$ whenever contact terms are retained;
2. light-ray quadratic forms $\mathbb{L}_\alpha(\psi)$ on $\mathcal{D}_N$, where ψ is a smooth compactly supported center-coordinate test;
3. for each test $\Phi \in C_c^\infty(U \times U)$, the induced center tests
$$\psi_{\alpha,m,\Phi}(y) = \left\langle C_{\alpha,m}(\xi), \partial_y^m \Phi(y+\xi, y)\right\rangle_\xi; \tag{65.36}$$
4. a seminorm $\|\cdot\|_{\mathcal{T}_N}$, a neighborhood condition on the support of Φ, and a remainder functional $R_N(\Phi;\Psi)$ such that
$$|R_N(\Phi;\Psi)| \le C_N(\Psi)\,\|\Phi\|_{\mathcal{T}_N}\,\epsilon^{\sigma_N}, \qquad \sigma_N > 0, \tag{65.37}$$
for tests supported in $|\xi| < \epsilon$.

The finite chart represents the detector product by

$$\langle\Psi|\mathcal{E}\mathcal{E}(\Phi)|\Psi\rangle = \sum_{(\alpha,m)\in\mathfrak{A}_N} \langle\Psi|\mathbb{L}_\alpha(\psi_{\alpha,m,\Phi})|\Psi\rangle + R_N(\Phi;\Psi). \tag{65.38}$$

Here $\mathcal{E}\mathcal{E}(\Phi)$ denotes the distributional pairing of the two-detector product with Φ, including the declared contact convention.

This finite chart is the CFT analogue of the QCD finite renormalized light-ray mixing chart in Chapter 49, but the coordinates are fixed-point conformal data rather than scale-dependent renormalized QCD operators. The coefficient extension across $\xi = 0$ is part of the chart. A separated-angle chart that only tests Φ supported away from the diagonal does not determine the coincident detector contact coordinate, hence does not determine the full moment $\mathcal{G}_2(1,1;\Psi) = \langle\Psi|(P^0)^2|\Psi\rangle$.

For a fixed state Ψ, suppose the retained light-ray forms and coefficient maps obey

$$|\langle\Psi|\mathbb{L}_\alpha(\psi)|\Psi\rangle| \le L_\alpha(\Psi)\, p_\alpha(\psi), \qquad p_\alpha(\psi_{\alpha,m,\Phi}) \le K_{\alpha,m}\, \|\Phi\|_{\mathcal{T}_N}. \tag{65.39}$$

Then (65.38) gives the finite detector-functional bound

$$|\langle\Psi|\mathcal{E}\mathcal{E}(\Phi)|\Psi\rangle| \le \left(\sum_{(\alpha,m)\in\mathfrak{A}_N} L_\alpha(\Psi)K_{\alpha,m} + C_N(\Psi)\epsilon^{\sigma_N} \right) \|\Phi\|_{\mathcal{T}_N}. \tag{65.40}$$

Thus the finite light-ray chart consists of coefficient distributions, their diagonal extensions, continuity estimates for the light-ray forms, and a remainder bound in the detector-test topology. These data are what turn a truncated representation-theoretic expansion into a controlled approximation to the energy correlator.

Finite chart changes and contact coordinates. The retained light-ray basis and the diagonal extension convention are part of the finite chart. Write the retained contribution to (65.38) in finite-dimensional notation as

$$V_\Psi(\Phi) = c_\Phi\, \ell_\Psi + k_\Phi + R_N(\Phi;\Psi).$$

Here $\ell_\Psi \in \mathbb{C}^r$ is the column vector of retained light-ray matrix elements, $c_\Phi \in (\mathbb{C}^r)^*$ is the row vector obtained by pairing the coefficient distributions with Φ, and k_Φ denotes the explicit diagonal-contact coordinate in the chosen extension. If $B \in GL(r,\mathbb{C})$ changes the retained light-ray basis, the same detector functional is represented by

$$\ell'_\Psi = B^{-1}\ell_\Psi, \qquad c'_\Phi = c_\Phi B, \qquad c'_\Phi\ell'_\Psi = c_\Phi\ell_\Psi. \tag{65.41}$$

This is ordinary coordinate covariance of the retained finite vector space; it is not a dynamical statement about the exact OPE.

Changing the extension of the relative-coordinate coefficient distributions across the diagonal is different. Let $d_\Phi \in (\mathbb{C}^r)^*$ be the row vector produced by adding diagonal distributions to the retained coefficient maps. The full detector distribution is unchanged only if the explicit contact coordinate is shifted simultaneously:

$$c_\Phi^{\mathrm{new}} = c_\Phi + d_\Phi, \qquad k_\Phi^{\mathrm{new}} = k_\Phi - d_\Phi\ell_\Psi. \tag{65.42}$$

Thus a separated-angle calculation, for which $d_\Phi = 0$ on all tests used, does not determine k_Φ. The Ward identity $\mathcal{G}_2(1,1;\Psi) = \langle\Psi|(P^0)^2|\Psi\rangle$ fixes a condition on the sum $c_\Phi\ell_\Psi + k_\Phi$ for the constant detector test; it does not fix a separated-angle coefficient convention by itself. A finite light-ray OPE chart used for a full energy correlator must therefore state both its retained-basis convention and its diagonal-contact convention.

One-parameter finite chart transport. The same bookkeeping can be differentiated. This is useful because it separates a harmless change of finite coordinates from a genuine change of the detector distribution. Let s parametrize a family of retained-basis changes $B_s \in GL(r,\mathbb{C})$ and diagonal-extension shifts $d_{s,\Phi} \in (\mathbb{C}^r)^*$, both stated in the original retained coordinates. For

$$V_\Psi(\Phi) = c_\Phi\ell_\Psi + k_\Phi + R_N(\Phi;\Psi)$$

define

$$\ell_{s,\Psi} = B_s^{-1}\ell_\Psi, \qquad c_{s,\Phi} = (c_\Phi + d_{s,\Phi})B_s, \qquad k_{s,\Phi} = k_\Phi - d_{s,\Phi}\ell_\Psi. \tag{65.43}$$

Then

$$c_{s,\Phi}\ell_{s,\Psi} + k_{s,\Phi} = c_\Phi\ell_\Psi + k_\Phi.$$

Put $A_s = B_s^{-1}\partial_s B_s$. Differentiating (65.43) gives

$$\partial_s\ell_{s,\Psi} = -A_s\ell_{s,\Psi}, \qquad \partial_s c_{s,\Phi} = c_{s,\Phi}A_s + (\partial_s d_{s,\Phi})B_s, \tag{65.44}$$

$$\partial_s k_{s,\Phi} = -(\partial_s d_{s,\Phi})B_s\ell_{s,\Psi}. \tag{65.45}$$

The $c_{s,\Phi}A_s$ and $-A_s\ell_{s,\Psi}$ terms cancel in $\partial_s(c_s\ell_s + k_s)$; the remaining $(\partial_s d_s)B_s\ell_s$ term cancels only against the contact derivative (65.45). With the opposite contact sign the constant detector test would change by twice this endpoint contribution. Equations (65.44)–(65.45) are finite-chart identities at a conformal fixed point, not anomalous dimensions. Their QCD analogue is the renormalized light-ray mixing chart of Chapter 49, where s is replaced by physical renormalization or rapidity scales after the regulator, subtraction scheme, and endpoint contact convention have been fixed.

Small-angle pushforward to the EEC variable. The finite light-ray chart lives first as a distribution in the two detector directions. The one-variable EEC is obtained by pushing that distribution forward by the opening angle. This geometric step contributes a Jacobian that must be included together with the light-ray OPE coefficient. Put

$$d_\perp = D - 2$$

for the dimension of the detector sphere, fix the second detector direction, and write θ for the geodesic distance of the first detector from it. In geodesic polar coordinates on $S^{d_\perp}$,

$$\mathrm{d}\Omega_1 = (\sin\theta)^{d_\perp - 1}\mathrm{d}\theta\,\mathrm{d}\omega, \qquad \omega \in S^{d_\perp - 1}.$$

The EEC kernel in (65.33) is $\delta(\cos\chi - \cos\theta)$, hence for $0 < \chi < \pi$

$$\int_{S^{d_\perp}} \mathrm{d}\Omega_1\,\delta(\cos\chi - \mathbf{n}_1\cdot\mathbf{n}_2)\,F(\theta,\omega) = (\sin\chi)^{d_\perp - 2}\int_{S^{d_\perp - 1}} \mathrm{d}\omega\,F(\chi,\omega). \tag{65.46}$$

Thus a retained coefficient whose relative-coordinate leading term is homogeneous of degree $-\lambda$,

$$C(\xi) = |\xi|^{-\lambda} C_0(\widehat{\xi}) + \text{higher radial orders}, \qquad \xi = \theta\,\omega,$$

contributes to the small-angle EEC density with leading power

$$\mathrm{EEC}_C(\chi) \sim \chi^{d_\perp - 2 - \lambda} \int_{S^{d_\perp - 1}} \mathrm{d}\omega\, C_0(\omega)\, \langle \Psi | \mathbb{L}(\psi_\omega) | \Psi \rangle, \qquad \chi \downarrow 0, \tag{65.47}$$

up to the center-coordinate smearing and the declared finite-chart remainder. Polyhomogeneous terms $|\xi|^{-\lambda_a} (\log|\xi|)^s C_{a,s}(\widehat{\xi})$ produce the corresponding powers $\chi^{d_\perp - 2 - \lambda_a} (\log \chi)^s$, with curvature corrections from $\sin\chi/\chi$ entering at even higher powers. If one changes from χ to $z = (1 - \cos\chi)/2$, the leading power is divided by two because $z = \chi^2/4 + O(\chi^4)$. Therefore the exponent quoted for a small-angle EEC singularity is a statement about the light-ray coefficient homogeneity, the detector-sphere dimension, and the chosen one-variable kernel.

This formulation also explains the relation with the QCD small-angle EEC. In a CFT the expansion coefficients are fixed-point data of light-ray representations. In asymptotically free QCD, the corresponding small-angle statement is a renormalized collinear light-ray expansion with a scale μ, an anomalous-dimension matrix, endpoint contact coordinates, and a mass-gap-sensitive long-distance remainder. The QCD object is therefore not obtained by simply copying the CFT theorem; it is a separate factorization datum whose detector side is the same stress-tensor observable.

Endpoint distribution charts in the EEC variable. The pushforward to one angular variable is still not the final endpoint distribution. A small-angle light-ray coefficient gives a density on $z > 0$, where

$$z = \frac{1 - \cos\chi}{2}, \qquad z = 0$$

is the coincident-detector endpoint. To compare with the full detector distribution, the density must be extended across $z = 0$ together with an explicit contact coordinate. This is the same logical distinction as in the two-detector chart above: separated-angle data determine a distribution on $(0, z_0)$, while the full detector product also contains diagonal contact strata.

Fix an endpoint interval $0 < z < z_0$. Let $f(z)$ be one singular density appearing in a finite light-ray chart, and suppose that subtracting the Taylor jet of order J of the test function makes the integral finite. The subtracted endpoint extension is the distribution

$$\langle [f]_{J,z_0,+}, \varphi \rangle := \int_0^{z_0} f(z) \left(\varphi(z) - \sum_{j=0}^{J} \frac{z^j}{j!} \varphi^{(j)}(0) \right) \mathrm{d}z. \tag{65.48}$$

For the logarithmic $1/z$ endpoint singularity this reduces to the familiar plus prescription

$$\left\langle \left[\frac{\Theta(z_0 - z)}{z} \right]_+, \varphi \right\rangle = \int_0^{z_0} \frac{\varphi(z) - \varphi(0)}{z}\, \mathrm{d}z.$$

Terms more singular than this are not hidden in the word “plus”: they require the corresponding higher Taylor subtraction and explicit $\delta^{(j)}(z)$ contact coordinates, with $\langle \delta^{(j)}, \varphi \rangle = (-1)^j \varphi^{(j)}(0)$.

A finite endpoint chart for the CFT EEC therefore has the form

$$\mathrm{EEC}_{\Psi}^{(N)} = \mathcal{R}_{z_0,\Psi}^{(N)} + \sum_{a\in A_N} c_a(\Psi)\,[f_a]_{J_a,z_0,+} + \sum_{j=0}^{J_N} K_j^{(N)}(\Psi)\,\delta^{(j)}(z) + R_{z_0,\Psi}^{(N)}. \tag{65.49}$$

Here $\mathcal{R}_{z_0,\Psi}^{(N)}$ is the ordinary distributional bulk representative away from $z=0$, the $c_a(\Psi)$ are the retained light-ray matrix elements and coefficient normalizations after the angular pushforward, and $R_{z_0,\Psi}^{(N)}$ is the declared finite-chart remainder. The coefficients $K_j^{(N)}$ are not determined by knowing the separated-angle asymptotic densities f_a alone. They are fixed only after the diagonal detector extension, Ward identities, and endpoint matching convention have all been specified. In particular, the constant-detector moment fixes a linear combination of the separated-angle integral and the contact coordinates; it does not by itself choose the representative in (65.49).

The dependence on z_0 is a useful sign check. For the basic plus distribution

$$D_{z_*} := \left[\frac{\Theta(z_*-z)}{z}\right]_+$$

one has, as distributions on $[0, z_b]$,

$$D_{z_b} = D_{z_a} + \frac{\mathbf{1}_{z_a<z<z_b}}{z} - \log\frac{z_b}{z_a}\,\delta(z), \qquad 0<z_a<z_b. \tag{65.50}$$

Testing (65.50) against φ gives exactly

$$\int_0^{z_a} \frac{\varphi-\varphi(0)}{z}\mathrm{d}z + \int_{z_a}^{z_b} \frac{\varphi(z)}{z}\mathrm{d}z - \log\frac{z_b}{z_a}\varphi(0) = \int_0^{z_b} \frac{\varphi-\varphi(0)}{z}\mathrm{d}z.$$

Equivalently, if the ordinary annulus $z_a<z<z_b$ is moved from the bulk representative into the endpoint plus-chart, the explicit $\delta(z)$ coordinate must shift by the annulus constant $\log(z_b/z_a)$ times the coefficient of $1/z$. With the opposite sign, the constant test changes, so the total-energy Ward identity would fail. The QCD endpoint formula (49.254) is the running-coupling, scheme-dependent analogue of this fixed-point distributional identity.

This endpoint chart gives a nonperturbative meaning to the collinear expansion of energy correlators in a CFT. It is the conformal counterpart of the QCD statement that small-angle energy correlators are governed by collinear operator data and anomalous dimensions. In QCD the running coupling and the mass gap alter the long-distance behavior; in a CFT the light-ray OPE is an operator expansion intrinsic to the fixed point, supplemented by the distributional contact data needed to recover the full detector product.

65.7 Comparison with QCD Detector Observables

The QCD and CFT constructions share the same operator-theoretic skeleton:

$$T^{\mu\nu} \quad\rightsquigarrow\quad \mathcal{E}(\mathbf{n}) \quad\rightsquigarrow\quad \mathcal{G}_k(\mathbf{n}_1,\dots,\mathbf{n}_k).$$

In QCD, the physical final-state resolution is a hadronic spectral sum and perturbation theory enters through asymptotically free short-distance coefficient functions. In a CFT, the state can be created directly by local operators and the angular dependence is constrained by conformal representation theory. The common lesson is mathematical rather than phenomenological: a detector observable is defined by the stress tensor in the physical Hilbert space, and partonic or conformal expansions are calculational representations of that observable under stated hypotheses.

Two-Dimensional Sigma Models, Orbifolds, and Twist Fields

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The two-dimensional construction block beginning here uses several coordinates on CFT data, and they have different proof burdens. This chapter starts with regulated sigma-model couplings, exact toroidal and WZW/coset laboratories, finite orbifolds, and twist-field deformations. Chapter 67 then treats chiral algebra, modular data, and fixed-channel sewing estimates. Chapter 68 uses Liouville theory as the nonrational test case where probabilistic construction, bootstrap coordinates, and direct integrals must be compared. Chapter 69 adds boundary conditions and bordered-surface sewing. Finally Chapter 70 records the spin and superconformal chiral-algebra constraints that any full spin CFT or supersymmetric RG construction must satisfy.

The status convention is the same throughout this block. A local calculation such as a one-loop beta tensor, KZ flatness identity, finite orbifold sector count, Cardy matrix entry, or spectral-flow coefficient proves only the local algebra it displays. A fixed-channel analytic statement additionally needs convergence, topological vector spaces, positive pairings, or common operator domains. A full CFT construction requires Hilbert spaces or state spaces, local fields as distributions, reflection positivity when appropriate, modular covariance, anomaly-line bookkeeping, and sewing maps compatible across decompositions. Comparisons such as sigma-model exactness, Liouville probabilistic/bootstrap equivalence, rational versus nonrational sewing, and GLSM mirror-flow identifications remain theorem targets unless those data have been supplied in one common normalization.

66.1 Sigma-Model Data as Two-Dimensional QFT Data

Let Σ be an oriented Euclidean surface with metric γ, and let M be a smooth target manifold. A bosonic nonlinear sigma-model regularized datum consists of:

$$X : \Sigma \longrightarrow M, \qquad G \in \Gamma(S^2T^*M), \qquad \mathcal{B}, \qquad \Phi \in C^\infty(M),$$

where G is a Riemannian metric, $\mathcal{B}$ is a $U(1)$-gerbe connection with curvature $H \in \Omega^3_{\mathrm{cl}}(M)$, and Φ is the dilaton coupling to the scalar curvature of Σ. In a local trivialization of the gerbe, with two-form potential B, the Euclidean action representative is

$$\begin{aligned} S[X;\gamma] = \frac{1}{4\pi\alpha'} \int_\Sigma \mathrm{d}^2\sigma \sqrt{\gamma}\, \gamma^{ab} G_{ij}(X) \partial_a X^i \partial_b X^j \\ + \frac{\mathrm{i}}{4\pi\alpha'} \int_\Sigma \mathrm{d}^2\sigma\, \epsilon^{ab} B_{ij}(X) \partial_a X^i \partial_b X^j + \frac{1}{4\pi} \int_\Sigma \mathrm{d}^2\sigma \sqrt{\gamma}\, R_\gamma \Phi(X). \end{aligned} \tag{66.1}$$

The invariant meaning of the B-term is the gerbe holonomy of $X^*\mathcal{B}$. When the gerbe is trivial this holonomy is represented by the integral of a globally defined two-form B. The consistency condition is that $[H/(2\pi\alpha')]$ has integral periods in the normalization of (66.1). On a surface with boundary one must also specify brane data that trivialize the pulled-back gerbe on the boundary; this chapter restricts to closed Σ.

Definition 66.1 (Conformal sigma-model point)**.** A conformal sigma-model point is a continuum two-dimensional QFT obtained from a specified sigma-model regulator and coupling coordinates for which the renormalized stress tensor has vanishing trace on flat separated-point correlators and has only the stated Weyl-anomaly contact terms on curved source surfaces. Equivalently, in a coordinate chart on the space of sigma-model couplings, the local Weyl-anomaly coefficients

$$\widehat{\beta}^G_{ij}, \qquad \widehat{\beta}^B_{ij}, \qquad \widehat{\beta}^\Phi$$

vanish up to target-space diffeomorphisms and B-field gauge transformations, with $\widehat{\beta}^\Phi$ allowing a constant term that records the central charge. The exact QFT datum is the continuum hierarchy of local correlators and defect correlators. A finite-order loop approximation to the tensors above is a controlled large-radius criterion inside a specified asymptotic expansion.

The diffeomorphism ambiguity in Definition 66.1 is physical: if $\xi \in \Gamma(TM)$, the field redefinition $X^i \mapsto X^i + \xi^i(X)$ changes the metric and two-form couplings by

$$\delta_\xi G_{ij} = (\mathcal{L}_\xi G)_{ij}, \qquad \delta_\xi B_{ij} = (\mathcal{L}_\xi B)_{ij},$$

and therefore changes beta functions by a vector field on coupling space. Similarly $B \mapsto B + \mathrm{d}\Lambda$ leaves the closed-surface path integral unchanged except for the corresponding gerbe-gauge convention. The scheme-independent trace identity is consequently formulated modulo these redundant coordinate directions.

66.2 The One-Loop Metric Beta Tensor

The first local test of conformality is the one-loop Weyl-anomaly coefficient. We record the derivation with its regulator and expansion hypotheses because the Ricci tensor is a statement about the local logarithmic divergence of the two-dimensional QFT.

66.2.1 Covariant Background Fields and the Mean-Zero Split

The symbol $X = x + \xi$ is not meaningful on a curved target. The background field method used here is instead the following local construction. Fix a background map $x : \Sigma \to M$. A fluctuation is a section $\xi \in \Gamma(x^*TM)$, and the full map is

$$X(\sigma) = \exp_{x(\sigma)} \xi(\sigma).$$

This is defined whenever $\xi(\sigma)$ lies in a normal neighborhood of $x(\sigma)$. Equivalently, $X(\sigma) = \lambda_\sigma(1)$, where $\lambda_\sigma(t)$ is the target geodesic satisfying

$$\lambda_\sigma(0) = x(\sigma), \qquad \dot{\lambda}_\sigma(0) = \xi(\sigma).$$

In local coordinates this begins as

$$X^i = x^i + \xi^i - \frac{1}{2}\Gamma^i{}_{jk}(x)\xi^j\xi^k + O(\xi^3). \tag{66.2}$$

The fluctuation field ξ is therefore a target vector at the background point, not a coordinate difference between two points of M.

The effective action is also defined with a mean-field convention. Introduce an auxiliary covector source $J_i(\sigma)$ along x, and define the source-dependent local functional integral by

$$\exp(-\Gamma[x]) = \int [D\xi] \, \exp\left(-S[\exp_x \xi] + \int_\Sigma \mathrm{d}^d\sigma\sqrt{\gamma}\, J_i\xi^i\right)\Bigg|_{\langle\xi^i(\sigma)\rangle_J=0}. \tag{66.3}$$

The source J is not an additional sigma-model coupling. It is the Legendre-transform device that enforces that the chosen background map x, rather than $x + \langle\xi\rangle$, is the mean field.

Mean-zero source at one loop. Assume that, in a chosen coordinate patch on field space, the action expanded around x has the form

$$S[\exp_x \xi] = S[x] + \int \sqrt{\gamma}\, L_i\xi^i + \frac{1}{2}\int \sqrt{\gamma}\, \xi^i\mathcal{A}_{ij}\xi^j + O(\xi^3), \tag{66.4}$$

where $\mathcal{A}$ is the quadratic fluctuation operator and L_i is the first variation density. Ignoring zero modes and using a regulator for the determinant, the Gaussian part of (66.3) has

$$\langle\xi\rangle_J = \mathcal{A}^{-1}(J - L). \tag{66.5}$$

Thus the condition $\langle\xi\rangle_J = 0$ fixes $J = L$, and the one-loop effective action is

$$\Gamma[x] = S[x] + \frac{1}{2}\log\det{}'\mathcal{A} + \text{local measure terms} + \text{higher-loop terms}. \tag{66.6}$$

At Gaussian order the exponent in (66.3) is

$$-S[x] - \frac{1}{2}\langle\xi, \mathcal{A}\xi\rangle + \langle J - L, \xi\rangle,$$

where the brackets include the $\sqrt{\gamma}$ density and target indices. Completing the square gives

$$-S[x] - \frac{1}{2}\langle\xi - \mathcal{A}^{-1}(J-L), \mathcal{A}(\xi - \mathcal{A}^{-1}(J-L))\rangle + \frac{1}{2}\langle J - L, \mathcal{A}^{-1}(J-L)\rangle.$$

The Gaussian mean is therefore $\mathcal{A}^{-1}(J-L)$, which proves (66.5). Setting $J=L$ removes the linear term and leaves the regulated determinant of $\mathcal{A}$, giving (66.6). If $\mathcal{A}$ has zero modes, they are separated as collective coordinates or fixed by an additional gauge slice; this affects the global measure but not the local ultraviolet pole that determines the beta tensor.

For the pure metric action, the first variation density is

$$L_i = -\frac{1}{2\pi\alpha'} G_{ij}(x)\nabla^a \partial_a x^j, \tag{66.7}$$

on a closed source surface. Hence $J=0$ is allowed only when the background map is a classical harmonic map. The effective-action definition above permits one to compute the local counterterms for an arbitrary slowly varying background x; this is why the beta tensor is an off-shell local tensor on coupling space, rather than only an equation evaluated on classical solutions.

Proposition 66.2 (Second variation and the curvature vertex)**.** *Let $B=\Phi=0$, assume Σ is closed, and set*

$$S_G[X] = \frac{1}{4\pi\alpha'}\int_\Sigma \mathrm{d}^d\sigma\sqrt{\gamma}\,\gamma^{ab}G_{ij}(X)\partial_a X^i\partial_b X^j.$$

For the geodesic variation $X_s=\exp_x(s\xi)$, the expansion through second order is

$$\begin{aligned} S_G[X_s] = S_G[x] &- \frac{s}{2\pi\alpha'}\int_\Sigma \sqrt{\gamma}\,G_{ij}(x)\xi^i\nabla^a\partial_a x^j \\ &+ \frac{s^2}{4\pi\alpha'}\int_\Sigma \sqrt{\gamma}\,\gamma^{ab}\left[G_{ij}(x)D_a\xi^i D_b\xi^j - R_{ikj\ell}(x)\partial_a x^i\partial_b x^j\xi^k\xi^\ell\right] + O(s^3). \end{aligned} \tag{66.8}$$

Here

$$D_a\xi^i = \partial_a\xi^i + \Gamma^i{}_{jk}(x)\partial_a x^j\xi^k$$

and the curvature convention is

$$R(U,V)W = \nabla_U\nabla_V W - \nabla_V\nabla_U W - \nabla_{[U,V]}W. \tag{66.9}$$

The displayed component ordering is defined by

$$R_{ikj\ell}\partial_a x^i\partial_b x^j\xi^k\xi^\ell = \langle R(\xi,\partial_a x)\partial_b x,\xi\rangle.$$

Consequently the quadratic fluctuation action used below is precisely the s^2-coefficient in (66.8) at $s=1$.

Proof. Let $V=\partial_s X_s$ and $W_a=\partial_a X_s$. Since the target connection is torsion free,

$$\nabla_s W_a = \nabla_a V,$$

and since $s\mapsto X_s(\sigma)$ is a geodesic for every σ,

$$\nabla_s V = 0.$$

Differentiate the Lagrangian density $\gamma^{ab}\langle W_a,W_b\rangle$. At $s=0$,

$$\frac{\mathrm{d}}{\mathrm{d}s}\gamma^{ab}\langle W_a,W_b\rangle = 2\gamma^{ab}\langle D_a\xi,\partial_b x\rangle.$$

Integrating by parts on the closed source surface gives the first-order term in (66.8). For the second derivative,

$$\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}s^2}\gamma^{ab}\langle W_a, W_b\rangle = \gamma^{ab}\left[\langle \nabla_s\nabla_a V, W_b\rangle + \langle \nabla_a V, \nabla_s W_b\rangle\right].$$

The commutator identity and $\nabla_s V = 0$ give

$$\nabla_s\nabla_a V = R(V, W_a)V.$$

Metric compatibility and the skew-adjointness of $R(V, W_a)$ in its last two entries imply

$$\langle R(V, W_a)V, W_b\rangle = -\langle R(V, W_a)W_b, V\rangle.$$

Evaluating at $s = 0$, where $V = \xi$ and $W_a = \partial_a x$, therefore gives

$$\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}s^2}\gamma^{ab}\langle W_a, W_b\rangle\Big|_{s=0} = \gamma^{ab}\left[\langle D_a\xi, D_b\xi\rangle - \langle R(\xi, \partial_a x)\partial_b x, \xi\rangle\right],$$

which is (66.8) in components. □

Lemma 66.3 (One-loop metric divergence)**.** *Let M be Riemannian, assume Σ is closed, and set $B = \Phi = 0$. Use dimensional regularization around $d = 2 - \epsilon$ two source dimensions and the covariant background-field expansion*

$$X(\sigma) = \exp_{x(\sigma)}\xi(\sigma),$$

where $\xi(\sigma) \in T_{x(\sigma)}M$. With the action normalization (66.1), the logarithmic one-loop divergence in the background effective action is

$$\Gamma^{(1)}_{\mathrm{div}}[x] = -\frac{1}{4\pi\epsilon}\int_\Sigma \mathrm{d}^2\sigma\sqrt{\gamma}\,\gamma^{ab}R_{ij}(x)\partial_a x^i\partial_b x^j. \tag{66.10}$$

Consequently the metric beta tensor begins as

$$\mu\frac{\mathrm{d}G_{ij}}{\mathrm{d}\mu} = \alpha' R_{ij} + O(\alpha'^2) \tag{66.11}$$

in this coupling coordinate.

Proof. By Proposition 66.2, the quadratic action for ξ is

$$S_2 = \frac{1}{4\pi\alpha'}\int_\Sigma \mathrm{d}^d\sigma\sqrt{\gamma}\left[\gamma^{ab}G_{ij}(x)D_a\xi^i D_b\xi^j - \gamma^{ab}R_{ikjl}(x)\partial_a x^i\partial_b x^j\xi^k\xi^\ell\right], \qquad d = 2 - \epsilon.$$

The covariant derivative $D_a\xi^i = \partial_a\xi^i + \Gamma^i{}_{jk}(x)\partial_a x^j\xi^k$ makes target diffeomorphism covariance manifest. To extract a local pole, freeze the background at a point σ_0, choose geodesic normal coordinates on Σ at σ_0 and an orthonormal frame of x^*TM parallel at σ_0, and keep only terms with two derivatives of the slowly varying background map x. Derivatives of the connection and intrinsic curvature of Σ either contribute higher-derivative terms or the universal two-dimensional metric anomaly, not the metric counterterm being computed here.

The free kinetic action in this frame is

$$S_{\text{kin}} = \frac{1}{4\pi\alpha'} \int \mathrm{d}^d\sigma\, \delta_{ij}\partial_a\xi^i\partial^a\xi^j = \frac{1}{2}\int \mathrm{d}^d\sigma\, \xi^i \left(\frac{-\partial^2}{2\pi\alpha'}\right)\xi^i.$$

Thus the free covariance is $2\pi\alpha'(-\partial^2)^{-1}$. Introduce an auxiliary mass m only to separate the ultraviolet pole from the infrared zero mode. The coincident scalar Green kernel has the local heat-kernel representation

$$\begin{aligned}(-\partial^2 + m^2)^{-1}(\sigma_0, \sigma_0) &= \int_0^\infty \mathrm{d}s\,(4\pi s)^{-d/2}\mathrm{e}^{-m^2 s} \\ &= (4\pi)^{-d/2}\Gamma(1-d/2)(m^2)^{d/2-1} = \frac{1}{2\pi\epsilon} + O(\epsilon^0).\end{aligned} \tag{66.12}$$

Restoring covariance gives the singular part

$$\langle\xi^k(\sigma)\xi^\ell(\sigma)\rangle_{\text{div}} = 2\pi\alpha'\,\frac{1}{2\pi\epsilon}\,G^{k\ell}(x(\sigma)) = \frac{\alpha'}{\epsilon}G^{k\ell}(x(\sigma)). \tag{66.13}$$

The curvature interaction in S_2 is

$$S_{\text{curv}} = -\frac{1}{4\pi\alpha'}\int \sqrt{\gamma}\,\gamma^{ab}R_{ikj\ell}(x)\partial_a x^i\partial_b x^j\xi^k\xi^\ell.$$

Since

$$\Gamma[x] = S[x] - \log\langle \mathrm{e}^{-S_{\text{curv}}}\rangle_{\text{kin}} = S[x] + \langle S_{\text{curv}}\rangle_{\text{kin}} + O((\partial x)^4),$$

the logarithmic pole is

$$\begin{aligned}\Gamma^{(1)}_{\text{div}}[x] &= -\frac{1}{4\pi\alpha'}\int\sqrt{\gamma}\,\gamma^{ab}R_{ikj\ell}\partial_a x^i\partial_b x^j\langle\xi^k\xi^\ell\rangle_{\text{div}} \\ &= -\frac{1}{4\pi\epsilon}\int\sqrt{\gamma}\,\gamma^{ab}R_{ij}\partial_a x^i\partial_b x^j,\end{aligned}$$

where $R_{ikj\ell}G^{k\ell} = R_{ij}$ in the component ordering fixed in Proposition 66.2. Since a local metric term in the action is multiplied by $1/(4\pi\alpha')$, cancelling (66.10) requires $\delta G_{ij} = (\alpha'/\epsilon)R_{ij}$ in minimal subtraction. Requiring the bare coupling representative to be independent of μ then gives (66.11). □

With $H = \mathrm{d}B$ and dilaton included, the one-loop Weyl-anomaly coefficients in the same normalization have the form

$$\widehat{\beta}^G_{ij} = \alpha'\left(R_{ij} - \frac{1}{4}H_i{}^{k\ell}H_{jk\ell} + 2\nabla_i\nabla_j\Phi\right) + O(\alpha'^2), \tag{66.14}$$

$$\widehat{\beta}^B_{ij} = \alpha'\left(-\frac{1}{2}\nabla^k H_{kij} + \nabla^k\Phi\, H_{kij}\right) + O(\alpha'^2). \tag{66.15}$$

The tensor $\widehat{\beta}^\Phi$ fixes the scalar Weyl anomaly and the central charge. Its nonconstant part is scheme dependent under dilaton and metric redefinitions, while its constant part is the physical c-number in the two-dimensional stress-tensor anomaly.

66.3 One-Loop Weyl Anomaly and the Target-Space Variational Package

The formulas above are often quoted as target-space equations of motion. The precise statement is more structured. After a regulator and a local renormalization scheme have been chosen, ordinary coordinate beta functions are not themselves the local Weyl-anomaly coefficients. The local Weyl coefficients differ from them by redundant directions: target diffeomorphisms, B-field gauge transformations, and the dilaton-gradient terms displayed below. The hypotheses in this section are therefore: Σ is closed, the target fields are smooth on the coordinate patch under consideration, dimensional regularization is used near two source dimensions, and all formulas are first-order statements in the large-radius α'-expansion.

Lemma 66.4 (One-loop string-frame functional)**.** *Let $H = \mathrm{d}B$. Up to the constant central-charge term in $\widehat{\beta}^{\Phi}$, the one-loop Weyl-anomaly equations for (G, B, Φ) are generated by the local target-space functional*

$$\mathcal{I}_0[G, B, \Phi] = \int_M \mathrm{d}^D x \sqrt{G}\, \mathrm{e}^{-2\Phi} \left(R(G) + 4|\nabla\Phi|^2 - \frac{1}{12} H_{ijk} H^{ijk} \right). \tag{66.16}$$

Assume either that M is compact or that all variations have compact support, so that target-space boundary terms can be discarded. Define

$$E_{ij} = R_{ij} + 2\nabla_i \nabla_j \Phi - \frac{1}{4} H_i{}^{k\ell} H_{jk\ell}, \tag{66.17}$$

$$S_\Phi = R + 4\nabla^2\Phi - 4|\nabla\Phi|^2 - \frac{1}{12} H^2. \tag{66.18}$$

Then the fixed-Φ metric variation is

$$\delta_G \mathcal{I}_0 = \int_M \mathrm{d}^D x \sqrt{G}\, \mathrm{e}^{-2\Phi} \left(E_{ij} - \frac{1}{2} G_{ij} S_\Phi \right) \delta G^{ij}, \tag{66.19}$$

and the dilaton variation is

$$\delta_\Phi \mathcal{I}_0 = -2 \int_M \mathrm{d}^D x \sqrt{G}\, \mathrm{e}^{-2\Phi} S_\Phi \, \delta\Phi. \tag{66.20}$$

Variation with respect to B gives

$$\nabla^k H_{kij} - 2\nabla^k \Phi \, H_{kij} = 0, \tag{66.21}$$

and variation with respect to G, after the scalar equation is used to choose the trace representative, gives

$$R_{ij} - \frac{1}{4} H_i{}^{k\ell} H_{jk\ell} + 2\nabla_i \nabla_j \Phi = 0. \tag{66.22}$$

The scalar Weyl-anomaly coefficient may be represented as

$$\widehat{\beta}^{\Phi} = \frac{D - 26}{6} + \alpha' \left(|\nabla\Phi|^2 - \frac{1}{2}\nabla^2\Phi - \frac{1}{24} H_{ijk} H^{ijk} \right) + O(\alpha'^2). \tag{66.23}$$

With the reparametrization ghosts included, the conformality condition is the vanishing of the matter-plus-ghost scalar anomaly.

Proof. For the B-variation, use

$$\delta H_{ijk} = \nabla_i \delta B_{jk} + \nabla_j \delta B_{ki} + \nabla_k \delta B_{ij}. \tag{66.24}$$

Because H is antisymmetric,

$$\delta(H_{ijk}H^{ijk}) = 2H^{ijk}\delta H_{ijk} = 6H^{ijk}\nabla_i \delta B_{jk}. \tag{66.25}$$

Thus

$$\delta_B \mathcal{I}_0 = -\frac{1}{2}\int \sqrt{G}\,\mathrm{e}^{-2\Phi} H^{ijk}\nabla_i \delta B_{jk}.$$

Integrating by parts gives

$$\delta_B \mathcal{I}_0 = \frac{1}{2}\int \sqrt{G}\,\nabla_i(\mathrm{e}^{-2\Phi} H^{ijk})\delta B_{jk},$$

which is equivalent to (66.21). Multiplying the left side of (66.21) by $-\alpha'/2$ gives exactly (66.15).

For the metric variation, the Palatini identity gives

$$\begin{aligned}\delta(\sqrt{G}\,\mathrm{e}^{-2\Phi}R) = \sqrt{G}\,\mathrm{e}^{-2\Phi}\Big[R_{ij} - \frac{1}{2}G_{ij}R + 2\nabla_i\nabla_j\Phi \\ - 4\nabla_i\Phi\nabla_j\Phi + G_{ij}(4|\nabla\Phi|^2 - 2\nabla^2\Phi)\Big]\delta G^{ij} + \text{boundary terms.}\end{aligned}$$

The variation of $4|\nabla\Phi|^2 = 4G^{ij}\partial_i\Phi\partial_j\Phi$, including the variation of $\sqrt{G}$, is

$$\sqrt{G}\,\mathrm{e}^{-2\Phi}\left(4\nabla_i\Phi\nabla_j\Phi - 2G_{ij}|\nabla\Phi|^2\right)\delta G^{ij}.$$

The nontrace $\nabla_i\Phi\nabla_j\Phi$ terms therefore cancel. The coefficient of the H-term is fixed directly: $H_{abc}H^{abc}$ contains three inverse metrics, while the variation of $\sqrt{G}$ contributes the trace term. Thus

$$\delta_G\left(-\frac{1}{12}\sqrt{G}\,\mathrm{e}^{-2\Phi}H^2\right) = \sqrt{G}\,\mathrm{e}^{-2\Phi}\left(-\frac{1}{4}H_i{}^{k\ell}H_{jk\ell} + \frac{1}{24}G_{ij}H^2\right)\delta G^{ij}.$$

Combining the three fixed-Φ variations gives (66.19), because the trace coefficient is

$$-\frac{1}{2}R + 2|\nabla\Phi|^2 - 2\nabla^2\Phi + \frac{1}{24}H^2 = -\frac{1}{2}S_\Phi.$$

The scalar equation $S_\Phi = 0$ therefore removes exactly the trace part of the metric variation and leaves the chosen representative (66.22), which is the vanishing of (66.14).

Finally, varying Φ gives

$$-2\left(R + 4|\nabla\Phi|^2 - \frac{1}{12}H^2\right)\delta\Phi + 8\nabla^i\Phi\,\nabla_i\delta\Phi.$$

After integration by parts with the $\mathrm{e}^{-2\Phi}$ density, this becomes (66.20); equivalently the scalar combination is

$$R - \frac{1}{12}H^2 + 4\nabla^2\Phi - 4|\nabla\Phi|^2$$

before the universal free-field determinant is added. That determinant supplies the constant $(D-26)/6$ after the bosonic ghosts are included. In the flat linear-dilaton test $G_{ij} = \delta_{ij}$, $H = 0$, and $\Phi = V_iX^i + \Phi_0$, equation (66.23) becomes

$$\frac{D-26}{6} + \alpha' V^2 = 0,$$

equivalently $D + 6\alpha' V^2 = 26$, matching the central-charge convention used below in Remark 66.9. □

Lemma 66.5 (Local one-loop origin of the H-coefficients)**.** *Work in the same dimensional-regularization and minimal-subtraction scheme as Lemma 66.3. Freeze the background map at a point, choose a local orthonormal target frame parallel at that point, and keep only logarithmic poles with two derivatives of the slowly varying background $x : \Sigma \to M$. The B-field interaction has the local covariant expansion*

$$
\begin{aligned}
S_B[x,\xi] &= \frac{\mathrm{i}}{4\pi\alpha'}\int \epsilon^{ab}B_{ij}(x)\partial_a x^i\partial_b x^j \\
&\quad + \frac{\mathrm{i}}{4\pi\alpha'}\int \epsilon^{ab}H_{k\ell i}(x)\xi^k D_a\xi^\ell\partial_b x^i \\
&\quad + \frac{\mathrm{i}}{8\pi\alpha'}\int \epsilon^{ab}\nabla_\ell H_{kij}(x)\xi^\ell\xi^k\partial_a x^i\partial_b x^j + O(\xi^3,\partial^3 x).
\end{aligned}
\tag{66.26}
$$

With the dimensional-continuation convention

$$
\epsilon^{ab}\epsilon^{cd}\gamma_{ac} = \gamma^{bd} + O(\epsilon) \quad \textit{inside logarithmic poles,} \tag{66.27}
$$

the one-loop pole from the last line of (66.26) is

$$
\Gamma^{(1)}_{B,\mathrm{tad,div}} = \frac{\mathrm{i}}{8\pi\epsilon}\int \epsilon^{ab}\nabla^k H_{kij}(x)\partial_a x^i\partial_b x^j, \tag{66.28}
$$

and the connected bubble from the middle line is

$$
\Gamma^{(1)}_{B,\mathrm{bub,div}} = \frac{1}{16\pi\epsilon}\int \sqrt{\gamma}\,\gamma^{ab}H_i{}^{k\ell}H_{jk\ell}(x)\partial_a x^i\partial_b x^j. \tag{66.29}
$$

Consequently the minimal-subtraction counterterms contain

$$
\delta B_{ij} = -\frac{\alpha'}{2\epsilon}\nabla^k H_{kij}, \qquad \delta G_{ij} = -\frac{\alpha'}{4\epsilon}H_i{}^{k\ell}H_{jk\ell}, \tag{66.30}
$$

which are precisely the H-dependent non-dilaton coefficients in (66.14) and (66.15).

Proof. The expansion (66.26) is most cleanly obtained by differentiating the pulled-back gerbe representative along the geodesic family $X_s = \exp_x(s\xi)$. The linear term in s is $\iota_\xi H$ up to an exact two-form on Σ, which is a B-field gauge variation on closed Σ. Covariantizing the Σ-derivative of ξ gives the middle vertex. Differentiating once more gives the ∇H vertex, and the Taylor factor $1/2$ gives the coefficient in the third line.

The tadpole uses only the coincident pole (66.13):

$$
\left\langle \xi^\ell(\sigma)\xi^k(\sigma)\right\rangle_{\mathrm{div}} = \frac{\alpha'}{\epsilon}G^{\ell k}.
$$

Substituting this in the third line of (66.26) gives (66.28). Since the local B-coupling in the action has prefactor $\mathrm{i}/(4\pi\alpha')$, cancellation of this pole requires the first counterterm in (66.30).

For the bubble, let $\Delta = (-\partial^2 + m^2)^{-1}$ be the scalar local Green kernel used in (66.12). The only local logarithmic contraction needed, after freezing x, is

$$
\int \mathrm{d}^d\sigma'\,\partial_a\Delta(\sigma-\sigma')\,\partial_c\Delta(\sigma-\sigma') = \frac{\gamma_{ac}}{4\pi\epsilon} + O(\epsilon^0). \tag{66.31}
$$

In momentum space this is the rotational identity

$$\int \frac{\mathrm{d}^d p}{(2\pi)^d} \frac{p_a p_c}{(p^2+m^2)^2} = \frac{\gamma_{ac}}{d} \int \frac{\mathrm{d}^d p}{(2\pi)^d} \frac{p^2}{(p^2+m^2)^2} = \frac{\gamma_{ac}}{4\pi\epsilon} + O(\epsilon^0),$$

using $d = 2 - \epsilon$; terms proportional to $m^2/(p^2+m^2)^2$ are finite in the logarithmic pole part. The free covariance contributes $(2\pi\alpha')^2$, the two Wick pairings give the same tensor after using antisymmetry of $H_{k\ell i}$, and the connected effective action contains

$$-\frac{1}{2}\left(\frac{\mathrm{i}}{4\pi\alpha'}\right)^2 \left\langle \left(\int \epsilon^{ab} H_{k\ell i} \xi^k D_a \xi^\ell \partial_b x^i \right)^2 \right\rangle_c .$$

Combining the factors gives

$$-\frac{1}{2}\left(\frac{\mathrm{i}}{4\pi\alpha'}\right)^2 \cdot 2 \cdot \frac{\pi(\alpha')^2}{\epsilon} = \frac{1}{16\pi\epsilon}.$$

The target-index contractions give $H_{k\ell i} H_{mnj} G^{km} G^{\ell n} = H_i{}^{k\ell} H_{jk\ell}$, and (66.27) converts the two antisymmetric two-dimensional tensors into γ^{bd}. This proves (66.29). Comparing with the metric action prefactor $1/(4\pi\alpha')$ gives the second counterterm in (66.30).

The two counterterms are local and gauge invariant after being expressed in terms of H. Adding the dilaton-gradient redundant direction below converts these coordinate beta representatives into the hatted Weyl-anomaly coefficients. □

66.4 Minimal Subtraction as Geometry on Coupling Space

The sigma-model coupling is not a finite list of numbers. It is the point (G, B, Φ) in an infinite-dimensional space of target-space fields, quotiented by target diffeomorphisms and gerbe gauge transformations. A minimal-subtraction counterterm is therefore a local tensorial functional of (G, H, Φ), and a change of renormalization scheme is a local change of coordinates on this space.

Definition 66.6 (Local sigma-model scheme)**.** A local perturbative sigma-model renormalization scheme assigns bare fields (G^0, B^0, Φ^0) to renormalized fields (G, B, Φ) by expansions

$$G^0_{ij} = \mu^{-\epsilon} \left[G_{ij} + \sum_{\ell \geq 1} \sum_{r=1}^{\ell} \frac{(\alpha')^\ell}{\epsilon^r} C^{(\ell,r)}_{ij}(G, H, \Phi) \right], \tag{66.32}$$

$$B^0_{ij} = \mu^{-\epsilon} \left[B_{ij} + \sum_{\ell \geq 1} \sum_{r=1}^{\ell} \frac{(\alpha')^\ell}{\epsilon^r} D^{(\ell,r)}_{ij}(G, H, \Phi) \right], \tag{66.33}$$

where the coefficients are local covariant expressions built from finitely many target derivatives. Minimal subtraction keeps only pole terms in ϵ. Two such schemes are equivalent if their renormalized fields are related by local target diffeomorphisms, B-field gauge transformations, and finite local tensor redefinitions.

Finite redefinitions and beta-vector fields. Use condensed notation g^A for the collection of local couplings (G_{ij}, B_{ij}, Φ), including the target point and tensor indices in the label A. Let a finite local scheme change be

$$g'^A = g^A + F^A(g), \qquad F^A = O((\alpha')^r), \tag{66.34}$$

where F is a covariant local tensor functional modulo the redundant diffeomorphism and B-gauge directions. If $\beta = \beta^A(g)\partial_A$ is the beta-vector field in the original coordinates, then, to first order in F,

$$\beta'^A(g') = \beta^A(g') + [\beta, F]^A(g') + O(F^2), \qquad [\beta, F]^A = \beta^B \partial_B F^A - F^B \partial_B \beta^A. \tag{66.35}$$

Since the leading sigma-model beta field starts at order α', a finite counterterm of order $(\alpha')^r$ first affects the displayed representative one order later, at order $(\alpha')^{r+1}$.

Differentiate (66.34) with respect to $\log \mu$ at fixed bare fields:

$$\beta'^A(g') = \frac{\mathrm{d}g'^A}{\mathrm{d}\log\mu} = \beta^A(g) + \partial_B F^A(g)\, \beta^B(g) + O(F^2).$$

To express the result in the new coordinate g', invert (66.34) to first order,

$$g^A = g'^A - F^A(g') + O(F^2),$$

and expand

$$\beta^A(g) = \beta^A(g') - F^B(g')\partial_B \beta^A(g') + O(F^2).$$

Combining the two displayed equations gives (66.35). The same computation is valid for local tensor fields once the index A is interpreted as a DeWitt index and ∂_A as the corresponding functional derivative.

Hatted beta functions and redundant directions. Let β^G, β^B be coordinate beta functions in a chosen local scheme. A target vector field W and one-form Λ change the representatives by

$$\widehat{\beta}^G_{ij} = \beta^G_{ij} + (\mathcal{L}_W G)_{ij}, \tag{66.36}$$

$$\widehat{\beta}^B_{ij} = \beta^B_{ij} + (\mathcal{L}_W B)_{ij} + (\mathrm{d}\Lambda)_{ij}. \tag{66.37}$$

In particular, the dilaton-gradient terms in (66.14)–(66.15) are the one-loop representative obtained from

$$W^i = \alpha' \nabla^i \Phi + O(\alpha'^2), \qquad \Lambda_i = O(\alpha'^2). \tag{66.38}$$

A target diffeomorphism generated by W changes the local action by replacing G and B with their Lie derivatives. Since the trace of the stress tensor measures the response of the renormalized action to a Weyl change at fixed bare fields, adding a redundant flow direction changes the coordinate beta functions by the same Lie derivatives. A gerbe gauge change adds $\mathrm{d}\Lambda$ to the two-form representative and leaves $H = \mathrm{d}B$ fixed on closed source surfaces. Finally, $(\mathcal{L}_{\nabla\Phi} G)_{ij} = 2\nabla_i \nabla_j \Phi$, and

$$(\mathcal{L}_{\nabla\Phi} B)_{ij} = \nabla^k \Phi\, H_{kij} + \nabla_i(\nabla^k \Phi B_{kj}) - \nabla_j(\nabla^k \Phi B_{ki}),$$

so the non-gauge part is the $\nabla\Phi \cdot H$ term in (66.15).

Lemma 66.7 (Torsionful one-loop package)**.** *Let $H = \mathrm{d}B$, and define the metric connections*

$$\nabla_i^{\pm} v^k = \nabla_i v^k \pm \frac{1}{2} H^k{}_{i\ell} v^\ell.$$

Write R^-_{ij} for the Ricci tensor of ∇^-. Through one loop, and in the same local scheme as (66.14)–(66.15), the symmetric and antisymmetric Weyl-anomaly coefficients are the two parts of the nonsymmetric tensor

$$\alpha'^{-1}\left(\widehat{\beta}^G_{ij} + \widehat{\beta}^B_{ij}\right) = R^-_{ij} + 2\nabla^-_i \nabla_j \Phi. \tag{66.39}$$

Equivalently,

$$(R^-_{ij})_{(ij)} = R_{ij} - \frac{1}{4} H_i{}^{k\ell} H_{jk\ell}, \tag{66.40}$$

$$(R^-_{ij})_{[ij]} = -\frac{1}{2} \nabla^k H_{kij}. \tag{66.41}$$

The exterior derivative of the antisymmetric beta representative is a three-form beta tensor for H, and it automatically obeys $\mathrm{d}\beta^H = 0$. This is the one-loop seed of the Curci–Paffuti consistency condition: higher-loop representatives must be chosen so that target diffeomorphism invariance, B-field gauge invariance, and the Bianchi identity $\mathrm{d}H = 0$ are preserved simultaneously.

Proof. Let $K^k{}_{ij} = -H^k{}_{ij}/2$, so that $\Gamma^{-\,k}_{ij} = \Gamma^k_{ij} + K^k{}_{ij}$. Since $H^k{}_{ik} = 0$, the Ricci tensor of ∇^- is

$$R^-_{ij} = R_{ij} + \nabla_k K^k{}_{ij} + K^k{}_{k\ell} K^\ell{}_{ij} - K^k{}_{j\ell} K^\ell{}_{ik}. \tag{66.42}$$

The trace term vanishes and the derivative term is $-\frac{1}{2}\nabla^k H_{kij}$. The quadratic term is

$$-K^k{}_{j\ell} K^\ell{}_{ik} = -\frac{1}{4} H^k{}_{j\ell} H^\ell{}_{ik} = -\frac{1}{4} H_i{}^{k\ell} H_{jk\ell},$$

after lowering indices and using total antisymmetry of H. This proves (66.40) and (66.41).

For the dilaton term, $\nabla^-_i \nabla_j \Phi$ means applying ∇^- to the covector $\nabla_j \Phi$:

$$\nabla^-_i \nabla_j \Phi = \nabla_i \nabla_j \Phi + \frac{1}{2} H^k{}_{ij} \nabla_k \Phi.$$

Therefore $2\nabla^-_i \nabla_j \Phi$ contributes $2\nabla_i \nabla_j \Phi$ to the symmetric part and $\nabla^k \Phi\, H_{kij}$ to the antisymmetric part. Combining these terms with the displayed Ricci tensor gives exactly (66.14) and (66.15). Finally $\beta^H = \mathrm{d}\widehat{\beta}^B$ is exact as a three-form representative, so $\mathrm{d}\beta^H = \mathrm{d}^2 \widehat{\beta}^B = 0$; possible global gerbe data affect large gauge sectors, not this local identity. □

Controlled Approximation 66.8 (Two-loop metric beta tensor)**.** For $B = \Phi = 0$, dimensional regularization and minimal subtraction give, in the standard Riemann-normal-coordinate scheme,

$$\mu \frac{\mathrm{d}G_{ij}}{\mathrm{d}\mu} = \alpha' R_{ij} + \frac{(\alpha')^2}{2} R_{ik\ell m} R_j{}^{k\ell m} + O((\alpha')^3). \tag{66.43}$$

The displayed coefficient is a controlled perturbative statement in the large-radius expansion. Starting at two loops, finite local redefinitions of G change the displayed tensor by Lie derivatives and by terms proportional to lower-order equations of motion. Thus the tensor (66.43) is a scheme representative, while vanishing of the Weyl anomaly modulo redundant directions is the invariant statement.

RG time versus Hamilton Ricci flow. Let $B = \Phi = 0$, and restrict to the one-loop metric flow

$$\frac{\partial G_{ij}}{\partial \tau} = \alpha' R_{ij}(G), \qquad \tau = \log \mu. \tag{66.44}$$

If

$$t = -\frac{\alpha'}{2}\tau, \tag{66.45}$$

then $G(t)$ satisfies Hamilton's Ricci-flow equation

$$\frac{\partial G_{ij}}{\partial t} = -2R_{ij}(G). \tag{66.46}$$

Thus the ultraviolet sigma-model flow, in the convention $\tau = \log \mu$, is backward relative to the usual increasing Ricci-flow time t. This is a statement about the one-loop local beta-vector field on the space of target metrics. It does not assert that the nonlinear sigma model has been constructed nonperturbatively at every point of the flow, nor that a finite-time singularity of Ricci flow is by itself a theorem about the continuum QFT.

By the chain rule,

$$\frac{\partial G_{ij}}{\partial t} = \frac{\partial \tau}{\partial t}\frac{\partial G_{ij}}{\partial \tau} = \left(-\frac{2}{\alpha'}\right)\alpha' R_{ij} = -2R_{ij}.$$

The remaining assertions are hypotheses bookkeeping. Equation (66.44) is a perturbative beta-function equation in a specified coupling coordinate and regulator scheme, while Ricci flow is a geometric partial differential equation for smooth metrics. The two equations agree at the displayed order after the time reparametrization (66.45); this agreement does not supply the operator algebra, Hilbert space, stress tensor, or sewing data of a continuum CFT.

Constant-curvature radius flow. Let M have dimension $n \geq 2$, and let γ be a metric of constant sectional curvature σ, where $\sigma = +1$ for the unit sphere and $\sigma = -1$ for the unit hyperbolic metric. Put

$$G_{ij} = r^2\gamma_{ij}, \qquad \lambda = \frac{\alpha'}{r^2}, \qquad B = \Phi = 0. \tag{66.47}$$

In the pure-metric minimal-subtraction representative (66.43), the radius parameter obeys

$$\frac{\mathrm{d}r^2}{\mathrm{d}\log \mu} = (n-1)\alpha'\left(\sigma + \frac{\alpha'}{r^2}\right) + O\!\left(\frac{(\alpha')^3}{r^4}\right), \tag{66.48}$$

and the dimensionless large-radius coupling obeys

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log \mu} = -(n-1)\lambda^2(\sigma + \lambda) + O(\lambda^4). \tag{66.49}$$

In particular, for the sphere,

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log \mu} = -(n-1)\lambda^2 - (n-1)\lambda^3 + O(\lambda^4), \tag{66.50}$$

which is the asymptotic-freedom sign in the convention $\lambda = \alpha'/r^2$. For the hyperbolic sign,

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log \mu} = (n-1)\lambda^2 - (n-1)\lambda^3 + O(\lambda^4). \tag{66.51}$$

The hyperbolic formula is a local curvature check of signs and scaling; it is not a claim that an arbitrary noncompact hyperbolic target, without additional infrared and spectral data, defines a full CFT.

For the scaled constant-curvature metric $G = r^2\gamma$, the sectional curvature is $K = \sigma/r^2$. Hence

$$R_{ij} = (n-1)K\, G_{ij} = (n-1)\sigma\, \gamma_{ij}, \tag{66.52}$$

and the standard constant-curvature contraction gives

$$R_{ik\ell m}R_j{}^{k\ell m} = 2(n-1)K^2 G_{ij} = \frac{2(n-1)}{r^2}\gamma_{ij}. \tag{66.53}$$

Substituting these identities into (66.43) gives

$$\frac{\partial G_{ij}}{\partial \log \mu} = \left[(n-1)\sigma\alpha' + (n-1)\frac{(\alpha')^2}{r^2}\right]\gamma_{ij} + O\!\left(\frac{(\alpha')^3}{r^4}\right)\gamma_{ij}.$$

Because $G_{ij} = r^2\gamma_{ij}$, this is exactly (66.48). Finally, $\lambda = \alpha'/r^2$ and α' is held fixed, so

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = -\frac{\alpha'}{r^4}\frac{\mathrm{d}r^2}{\mathrm{d}\log\mu} = -(n-1)\lambda^2(\sigma+\lambda) + O(\lambda^4),$$

which proves (66.49).

Remark 66.9 (Flat target, linear dilaton, and the critical constant). For flat D-dimensional target and linear dilaton $\Phi(X) = V_i X^i + \Phi_0$, the nonconstant tensor beta functions vanish, and the scalar Weyl anomaly is the central-charge condition

$$c_{\text{matter}} = D + 6\alpha' V^2.$$

Coupling to the bosonic reparametrization ghosts imposes $c_{\text{matter}} = 26$. This is a convention-sensitive statement about the constant part of $\widehat{\beta}^{\Phi}$; it is not the same as the vanishing of the nonconstant metric and B-field tensors.

66.5 Supersymmetric Sigma-Model CFTs

The supersymmetric cases are not separate from CFT; they are additional structure on the same two-dimensional local QFT. A $\mathcal{N} = (1,1)$ sigma model is obtained by replacing X by a map of the source supermanifold into M. Its component fields include X^i and two-dimensional Majorana fermions valued in X^*TM. The target metric connection is replaced by the torsionful connections

$$\nabla^{(\pm)} = \nabla^G \pm \frac{1}{2}G^{-1}H$$

in the left- and right-moving fermion covariant derivatives.

The heterotic $\mathcal{N} = (0,1)$ sigma model adds two-dimensional fermions valued in a vector bundle $E \to M$ with connection A. Its assumptions are stronger than those of the bosonic model: E must carry a compatible fiber metric, the spin structure on Σ must be specified, and gauge and gravitational anomalies must be cancelled by the B-field transformation law. In a convention where Tr denotes the gauge trace and tr the Lorentz trace, the Green–Schwarz-improved three-form is

$$H = \mathrm{d}B + \frac{\alpha'}{4}\big(\omega_3(\nabla^+) - \omega_3(A)\big), \qquad \mathrm{d}H = \frac{\alpha'}{4}\big(\mathrm{tr}\, R(\nabla^+)\wedge R(\nabla^+) - \mathrm{Tr}\, F\wedge F\big). \tag{66.54}$$

Here ∇^+ is the torsionful target connection chosen in this representative. Replacing ∇^+ by another connection changes (66.54) by a local counterterm and hence by a scheme change, provided the Chern–Simons convention is changed consistently.

Controlled Approximation 66.10 (Heterotic one-loop representative)**.** In the large-radius and weak-bundle-curvature expansion, the heterotic one-loop Weyl-anomaly representative contains the gauge equation

$$\widehat{\beta}^A_i = -\frac{\alpha'}{2}\left(D^j F_{ji} + \frac{1}{2}H_i{}^{jk}F_{jk} - 2\nabla^j\Phi\, F_{ji}\right) + O(\alpha'^2), \tag{66.55}$$

where D is induced by A and by the Levi-Civita connection on target indices. The metric and B-field equations are modified at the same order by gauge-curvature terms and by the Bianchi identity (66.54). The invariant statement is not the vanishing of the displayed coordinate tensor alone, but the vanishing of the local Weyl anomaly modulo target diffeomorphisms, bundle gauge transformations, and B-field gauge transformations.

Derivation of the displayed gauge equation. The pullback connection couples the bundle fermions through $A_i(X)\partial X^i$. In a covariant background-field expansion, the linear fluctuation of this coupling is $F_{ij}\xi^i\partial X^j$, and the quadratic fluctuation contains $D_iF_{jk}\xi^i\xi^j\partial X^k$. The one-loop tadpole therefore gives a pole proportional to D^jF_{ji}. The mixed contraction with the torsion vertex in the B-coupling contributes $\frac{1}{2}H_i{}^{jk}F_{jk}$. These two terms are the ordinary coordinate beta function for A in this scheme.

The dilaton-gradient term is a redundant direction. The vector field $W^i = \alpha'\nabla^i\Phi$ acts on the pulled-back connection by

$$(\mathcal{L}_W A)_i = W^j F_{ji} + D_i(W^j A_j).$$

The second term is a bundle gauge transformation, so the gauge-invariant part of the Weyl-anomaly representative receives only W^jF_{ji}. This is the $-2\nabla^j\Phi\, F_{ji}$ term inside the parentheses in (66.55).

For $\mathcal{N} = (2,2)$, the target must carry compatible complex structures. In the basic Kähler case, M is a complex manifold with Kähler metric

$$G_{I\bar{J}} = \partial_I\partial_{\bar{J}}K$$

in local coordinates. The classical $U(1)_V \times U(1)_A$ currents are the candidates for the R-symmetry currents of the infrared superconformal algebra. Their anomaly is controlled by $c_1(TM)$ in the large-radius presentation. Thus $c_1(TM) = 0$ is the first topological condition for an unbroken axial R-symmetry, and Ricci-flatness of a Kähler metric is the one-loop version of (66.11). In a compact Kähler class with $c_1(TM) = 0$, Yau's theorem supplies a Ricci-flat representative; the QFT statement that the corresponding sigma model is a conformal field theory is the existence of the continuum SCFT obtained after all higher-order local terms and nonperturbative sectors of maps $\Sigma \to M$ are included.

$\mathcal{N} = (2,2)$ **one-loop Kähler beta tensor.** Assume the regulator preserves $\mathcal{N} = (2,2)$ supersymmetry and that the target is Kähler in the coordinate patch under consideration. In a local superspace scheme whose counterterms are Kähler-potential counterterms, the one-loop metric beta tensor is

$$\beta_{I\bar{J}} = \alpha' R_{I\bar{J}} = -\alpha' \partial_I \partial_{\bar{J}} \log\det(G_{K\bar{L}}), \tag{66.56}$$

and the II and $\bar{I}\bar{J}$ components vanish in holomorphic coordinates. A one-loop conformal representative therefore requires the Ricci form

$$\rho = -\mathrm{i}\partial\bar{\partial} \log\det(G_{K\bar{L}})$$

to vanish in its Kähler class, modulo Kähler-potential redefinitions and target diffeomorphisms.

For a Kähler metric, the only nonzero Christoffel symbols are $\Gamma^I{}_{JK} = G^{I\bar{L}}\partial_J G_{K\bar{L}}$ and their complex conjugates. Hence

$$R_{I\bar{J}} = -\partial_{\bar{J}}\Gamma^K{}_{IK} = -\partial_I\partial_{\bar{J}} \log\det(G_{K\bar{L}}),$$

where the last equality is the matrix identity $\partial_I \log\det G = \mathrm{tr}(G^{-1}\partial_I G)$. The background-field one-loop divergence is the restriction of Lemma 66.3 to complex coordinates. Supersymmetry rules out a local metric counterterm that is not of type $(1,1)$ and, in the stated superspace scheme, writes the counterterm as a local correction to K. This gives (66.56).

Remark 66.11 (Higher-loop supersymmetric sigma-model status). For two-dimensional supersymmetric nonlinear sigma models, higher-loop beta functions can be computed in superspace schemes that preserve the manifest two-dimensional supersymmetry. In $\mathcal{N} = (2,2)$ Kähler models, the classic four-loop calculations exhibit the first scheme-invariant higher-curvature obstruction in the corresponding supersymmetric scheme, while many lower-loop terms can be moved by local Kähler-potential and target-coordinate redefinitions. This statement is used here only as a perturbative large-radius status boundary: it records what the local superspace calculation controls, but it does not by itself prove nonperturbative existence of a compact Calabi–Yau sigma-model SCFT, nor does it specify the global CFT Hilbert space.

The local operators corresponding to Kähler and complex-structure deformations are represented at large radius by

$$\delta G_{I\bar{J}}(X)\psi^I\bar{\psi}^{\bar{J}}, \qquad \delta J_{\bar{I}}{}^J(X)G_{J\bar{K}}\psi^{\bar{I}}\bar{\psi}^{\bar{K}},$$

with the precise operator representatives depending on the regularization and on the choice of local coordinates on the conformal manifold. The cohomological labels $H^{1,1}(M)$ and $H^{d-1,1}(M)$ are the large-radius tangent-space labels; the corresponding QFT objects are the renormalized local operators together with their contact-term convention.

66.6 Toroidal Sigma Models and Narain Lattice CFTs

Flat torus sigma models are the first place where the target-space description and the exact operator description can both be written without an asymptotic expansion. The exact description is a lattice CFT. We record it before discussing orbifolds because most elementary orbifolds act on a specified lattice theory, and because locality, spin, and modular covariance are already visible in the parent theory.

Let
$$\mathbb{R}^{n_L,n_R} = \mathbb{R}^{n_L} \oplus \mathbb{R}^{n_R}$$
with bilinear form
$$k \circ \ell = k_L \cdot \ell_L - k_R \cdot \ell_R.$$
For a lattice $\Gamma \subset \mathbb{R}^{n_L,n_R}$, define the dual lattice
$$\Gamma^\vee = \{x \in \Gamma \otimes_{\mathbb{Z}} \mathbb{R} \mid x \circ y \in \mathbb{Z} \text{ for all } y \in \Gamma\}.$$
The lattice is integral if $\Gamma \subset \Gamma^\vee$, even if $k \circ k \in 2\mathbb{Z}$ for every $k \in \Gamma$, and unimodular if $\Gamma = \Gamma^\vee$.

The chiral bosons are normalized by
$$X_L^i(z)X_L^j(0) \sim -\delta^{ij}\log z, \qquad X_R^{i'}(\bar z)X_R^{j'}(0) \sim -\delta^{i'j'}\log \bar z.$$
For $k = (k_L, k_R) \in \Gamma$, the exponential field is
$$V_k(z,\bar z) = \varepsilon_k : \exp(\mathrm{i}k_L \cdot X_L(z) + \mathrm{i}k_R \cdot X_R(\bar z)) :, \tag{66.57}$$
where the symbols ε_k are cocycle operators. They multiply by
$$\varepsilon_k\varepsilon_\ell = \epsilon(k,\ell)\varepsilon_{k+\ell}, \qquad \epsilon(k,\ell) \in \{\pm 1\}, \tag{66.58}$$
after a choice of basis and cocycle representative. Oscillator descendants are obtained by applying $\partial^r X_L^i$ and $\bar\partial^s X_R^{i'}$. The conformal weights of a descendant at oscillator levels $N, \bar N \in \mathbb{Z}_{\geq 0}$ are
$$h = \frac{1}{2}k_L^2 + N, \qquad \bar h = \frac{1}{2}k_R^2 + \bar N. \tag{66.59}$$

Proposition 66.12 (Locality, spin, and cocycles)**.** *The exponential fields (66.57) are mutually local bosonic fields only if Γ is integral and even. Given an even integral lattice, the cocycle can be chosen so that*
$$\epsilon(k,\ell+m)\epsilon(\ell,m) = \epsilon(k,\ell)\epsilon(k+\ell,m), \tag{66.60}$$
$$\epsilon(\ell,k) = (-1)^{k\circ\ell}\epsilon(k,\ell). \tag{66.61}$$
With such a choice the OPE algebra of the exponential fields is associative and has the required exchange law.

Proof. The free-field contraction gives
$$V_k(z,\bar z)V_\ell(0) \sim \epsilon(k,\ell)\, z^{k_L\cdot\ell_L}\,\bar z^{k_R\cdot\ell_R}V_{k+\ell}(0) + \cdots . \tag{66.62}$$
Taking z once counterclockwise around the origin sends $\bar z$ once clockwise around the origin and therefore multiplies the leading term by
$$\exp(2\pi\mathrm{i}(k_L \cdot \ell_L - k_R \cdot \ell_R)) = \exp(2\pi\mathrm{i}k \circ \ell).$$
Single-valued separated-point correlators of the exponential fields require $k \circ \ell \in \mathbb{Z}$ for all $k, \ell \in \Gamma$, which is integrality. The spin of V_k is
$$h - \bar h = \frac{1}{2}(k_L^2 - k_R^2) = \frac{1}{2}k \circ k,$$

modulo integers from oscillators, so integer spin requires evenness.

Associativity of the product of three cocycle operators is exactly (66.60). The exchange of two radially ordered exponentials changes $z-\zeta$ to $\zeta - z$ and $\bar z - \bar\zeta$ to $\bar\zeta - \bar z$, producing the phase $(-1)^{k\circ\ell}$. Hence the cocycle must obey (66.61). To see existence concretely, choose an integral basis e_i of Γ, write $k=\sum_i m^i e_i$, $\ell = \sum_i n^i e_i$, and put

$$A_{ij} = e_i \circ e_j, \qquad \epsilon(k,\ell) = (-1)^{\sum_{i>j} A_{ij} m^i n^j}. \tag{66.63}$$

The exponent is bilinear, so (66.60) follows by expanding both sides. Since A_{ii} is even and $A_{ij} = A_{ji}$,

$$\sum_{i>j} A_{ij} n^i m^j - \sum_{i>j} A_{ij} m^i n^j \equiv \sum_{i,j} A_{ij} m^i n^j = k\circ\ell \pmod 2,$$

which gives (66.61). □

The torus amplitude of the oscillator Fock spaces and lattice zero modes is

$$Z_\Gamma(\tau,\bar\tau) = \frac{1}{\eta(\tau)^{n_L}\overline{\eta(\tau)}^{n_R}} \sum_{k\in\Gamma} q^{k_L^2/2} \bar q^{k_R^2/2}, \qquad q = \mathrm{e}^{2\pi\mathrm{i}\tau}. \tag{66.64}$$

This formula is a trace over the Hilbert space on the circle. If $n_L \neq n_R$, the theory has chiral gravitational anomaly $c_L - c_R = n_L - n_R$; then the torus amplitude is naturally a section of the corresponding determinant line rather than an invariant scalar function.

Lemma 66.13 (Modular behavior of the lattice trace)**.** *For an even integral Γ, the lattice sum in (66.64) has trivial $T:\tau\mapsto\tau+1$ phase before the oscillator determinant is included. The full trace obeys*

$$Z_\Gamma(\tau+1,\bar\tau+1) = \exp\left(-\frac{2\pi\mathrm{i}}{24}(n_L - n_R)\right) Z_\Gamma(\tau,\bar\tau). \tag{66.65}$$

Under $S:\tau\mapsto -1/\tau$, Poisson summation sends the lattice Γ to $\Gamma^\vee$. Therefore an ordinary scalar modular invariant lattice partition function requires unimodularity together with the cancellation of the gravitational-anomaly phase. In particular, an even unimodular lattice of signature (n_L,n_R) can exist only when $n_L - n_R \equiv 0 \pmod 8$, whereas a standalone scalar torus partition function further requires $n_L - n_R \equiv 0 \pmod{24}$. For an ordinary toroidal sigma model $n_L = n_R$, the anomaly condition is automatic.

Proof. For the T-transformation, each lattice term is multiplied by

$$\exp\bigl(\pi\mathrm{i}(k_L^2 - k_R^2)\bigr) = \exp(\pi\mathrm{i}k\circ k),$$

which is 1 precisely for an even lattice. The Dedekind eta function obeys $\eta(\tau+1) = \mathrm{e}^{2\pi\mathrm{i}/24}\eta(\tau)$, and its antiholomorphic factor carries the conjugate phase. This gives (66.65).

For S, write the theta sum as a Gaussian sum over Γ with positive real part controlled by $\operatorname{Im}\tau > 0$. Poisson summation replaces the sum over Γ by a sum over $\Gamma^\vee$ and produces the Gaussian determinant factors $(-\mathrm{i}\tau)^{n_L/2}(\mathrm{i}\bar\tau)^{n_R/2}$. These are exactly the factors by which $\eta(\tau)^{n_L}\overline{\eta(\tau)}^{n_R}$ transforms, after the same branch convention is used for the determinant line. Thus S closes on a single lattice trace only when $\Gamma = \Gamma^\vee$; otherwise it mixes the trace with the discriminant-group components. The classification theorem for even unimodular lattices gives the congruence $n_L - n_R \equiv 0 \pmod 8$. The remaining scalar-invariance condition is the absence, or cancellation by another sector, of the chiral gravitational anomaly, which is the T-phase in (66.65). □

We now relate this exact operator construction to the Lagrangian torus sigma model. Let the target be

$$T^d = \mathbb{R}^d/2\pi\mathbb{Z}^d$$

with constant metric G and constant antisymmetric B-field. Choose a vielbein E with $G = E^T E$. A circle state is labeled by momentum $m \in (\mathbb{Z}^d)^\vee$ and winding $w \in \mathbb{Z}^d$. With the action normalization (66.1), the left and right momenta are

$$k_L(m,w) = \frac{1}{\sqrt{2\alpha'}}\left(E^{-T}(\alpha' m - Bw) + Ew\right), \tag{66.66}$$

$$k_R(m,w) = \frac{1}{\sqrt{2\alpha'}}\left(E^{-T}(\alpha' m - Bw) - Ew\right). \tag{66.67}$$

The set of all $(k_L(m,w), k_R(m,w))$ is a lattice $\Gamma(G,B) \subset \mathbb{R}^{d,d}$, and

$$k(m,w) \circ k(m',w') = m(w') + m'(w). \tag{66.68}$$

Thus $k(m,w) \circ k(m,w) = 2m(w)$. The B-dependence cancels from the integral pairing; it changes the embedding of the fixed abstract lattice $(\mathbb{Z}^d)^\vee \oplus \mathbb{Z}^d$ into $\mathbb{R}^{d,d}$, not its bilinear form.

The moduli of such toroidal CFTs are consequently better described as positive d-planes in $\mathbb{R}^{d,d}$ modulo automorphisms of the integral lattice:

$$\mathcal{M}_{\text{torus},d} = O(d,d;\mathbb{Z})\backslash O(d,d;\mathbb{R})/(O(d)\times O(d)), \tag{66.69}$$

up to the separate constant-dilaton coupling to the Euler characteristic and the usual fixed-point qualifications of an orbifold quotient. A T-duality is an isomorphism of the exact CFT data: it is an automorphism of the even unimodular lattice together with the induced map of cocycles, vertex operators, stress tensors, and correlation functions. A Buscher path-integral derivation is a derivation of this equality in a Lagrangian coordinate patch; the exact statement is the lattice-theoretic isomorphism of the local QFT.

66.7 Buscher Duality from a Gauged Isometry

We now record the local path-integral derivation of the Buscher rules. The derivation is formal unless a regulator preserving the gauge symmetry and the measure transformation is supplied, but it is the correct perturbative calculation behind the toroidal lattice isomorphism above.

Let X^0 be a coordinate along a circle isometry, and assume

$$\partial_0 G_{\mu\nu} = \partial_0 B_{\mu\nu} = \partial_0 \Phi = 0.$$

Write i,j for the remaining target coordinates and

$$E_{\mu\nu} = G_{\mu\nu} + B_{\mu\nu}.$$

In local light-cone coordinates $\sigma^\pm$ on Σ, the isometry is gauged by replacing $\partial_\pm X^0$ with gauge fields $A_\pm$ and adding a Lagrange multiplier $\widetilde{X}^0$ for flatness:

$$\begin{aligned} S_{\text{gauged}} = \frac{1}{4\pi\alpha'}\int &\Big[E_{00}A_+A_- + E_{0i}A_+\partial_- X^i + E_{i0}\partial_+X^i A_- + E_{ij}\partial_+X^i\partial_-X^j\Big] \\ &+ \frac{1}{4\pi\alpha'}\int \widetilde{X}^0(\partial_+A_- - \partial_-A_+). \end{aligned} \tag{66.70}$$

Integrating out $\widetilde{X}^0$ forces $A_\pm = \partial_\pm X^0$ locally and recovers the original model, modulo the usual global sum over circle bundles. Integrating out $A_\pm$ instead gives the dual model.

Proposition 66.14 (Buscher rules)**.** *The Gaussian integration over $A_\pm$ in (66.70) gives the dual background*

$$E'_{00} = \frac{1}{E_{00}}, \qquad E'_{0i} = \frac{E_{0i}}{E_{00}}, \qquad E'_{i0} = -\frac{E_{i0}}{E_{00}}, \tag{66.71}$$

$$E'_{ij} = E_{ij} - \frac{E_{i0}E_{0j}}{E_{00}}. \tag{66.72}$$

Equivalently,

$$G'_{00} = \frac{1}{G_{00}}, \qquad G'_{0i} = \frac{B_{0i}}{G_{00}}, \qquad B'_{0i} = \frac{G_{0i}}{G_{00}}, \tag{66.73}$$

$$G'_{ij} = G_{ij} - \frac{G_{0i}G_{0j} - B_{0i}B_{0j}}{G_{00}}, \tag{66.74}$$

$$B'_{ij} = B_{ij} - \frac{G_{0i}B_{0j} - B_{0i}G_{0j}}{G_{00}}. \tag{66.75}$$

The one-loop determinant of the $A_\pm$ Gaussian changes the dilaton by

$$\Phi' = \Phi - \frac{1}{2}\log G_{00}. \tag{66.76}$$

Proof. Integrate the Lagrange-multiplier term by parts and collect the terms linear in $A_\pm$:

$$S_{\text{gauged}} = \frac{1}{4\pi\alpha'}\int \left[E_{00}A_+A_- + A_+J_- + J_+A_- + E_{ij}\partial_+X^i\partial_-X^j\right],$$

where

$$J_- = E_{0i}\partial_-X^i + \partial_-\widetilde{X}^0, \qquad J_+ = E_{i0}\partial_+X^i - \partial_+\widetilde{X}^0.$$

The equations of motion for $A_\pm$ are

$$E_{00}A_- + J_- = 0, \qquad E_{00}A_+ + J_+ = 0.$$

Substituting the solution back completes the square and gives the effective term

$$-\frac{1}{E_{00}}J_+J_-.$$

Reading off the coefficients of $\partial_+\widetilde{X}^0\partial_-\widetilde{X}^0$, $\partial_+\widetilde{X}^0\partial_-X^i$, $\partial_+X^i\partial_-\widetilde{X}^0$, and $\partial_+X^i\partial_-X^j$ gives (66.71)–(66.72). Splitting $E' = G' + B'$ into symmetric and antisymmetric parts gives (66.73)–(66.75).

The functional determinant from the Gaussian integral over $A_\pm$ is the only remaining convention-sensitive point. A gauge-invariant cell regularization makes its coefficient transparent. First take G_{00} to be constant and choose a finite cell decomposition of the closed source surface with N_0 vertices, N_1 edges, and N_2 faces. Put the gauged field A on edges, the gauge parameter on vertices, and the dual scalar $\widetilde{X}^0$ on faces. Normalize the scalar and gauge-parameter measures by the L^2 norm induced by G_{00}, and normalize the dual scalar measure by the dual metric $G'_{00} = G_{00}^{-1}$.

Ignoring only zero modes and holonomy sums, which do not change the local coefficient of $\log G_{00}$, the G_{00}-dependent factors in the finite-dimensional Gaussian are:

$$\underbrace{(G_{00})^{-N_1/2}}_{A\text{-edge Gaussian}} \quad \underbrace{(G_{00})^{N_0/2}}_{\text{gauge normalization}} \quad \underbrace{(G_{00})^{N_2/2}}_{\text{dual scalar measure}} .$$

The product is

$$(G_{00})^{(N_0-N_1+N_2)/2} = (G_{00})^{\chi(\Sigma)/2}. \tag{66.77}$$

This is the finite-dimensional origin of the half coefficient; it is not a choice that can be read from the classical saddle alone.

For slowly varying $G_{00}(X^i)$, locality of the ultraviolet regulator promotes the constant factor (66.77) to the local curvature counterterm

$$\exp\left[\frac{1}{8\pi}\int_\Sigma \sqrt{\gamma}\, R_\gamma \, \log G_{00}(X)\right],$$

up to terms with derivatives of G_{00} that belong to the same higher-derivative α'-scheme choice as the other Buscher covariance corrections. Since the dilaton coupling in (66.1) contributes $\exp[-(4\pi)^{-1}\int \sqrt{\gamma}\, R_\gamma \Phi]$ to the path integral, this local determinant factor is exactly equivalent to (66.76). This last step is where the path-integral measure, rather than only the classical action, enters the Buscher rules. □

Remark 66.15 (Involutivity). Applying the transformation (66.73)–(66.75) twice returns (G, B). The dilaton also returns to its original value after the second shift. In E-variables the rules are

$$E'_{00} = E_{00}^{-1}, \qquad E'_{0i} = E_{0i}E_{00}^{-1}, \qquad E'_{i0} = -E_{i0}E_{00}^{-1}, \qquad E'_{ij} = E_{ij} - E_{i0}E_{0j}E_{00}^{-1}.$$

A direct substitution gives $E''_{00} = E_{00}$, $E''_{0i} = E_{0i}$, $E''_{i0} = E_{i0}$, and $E''_{ij} = E_{ij}$. For the dilaton,

$$\Phi'' = \Phi - \frac{1}{2}\log G_{00} - \frac{1}{2}\log G'_{00} = \Phi - \frac{1}{2}\log G_{00} + \frac{1}{2}\log G_{00} = \Phi.$$

Controlled Approximation 66.16 (Beta functions and Buscher covariance)**.** Order by order in α', Buscher duality maps Weyl-anomaly coefficients of the original background to those of the dual background after the corresponding local field redefinitions have been chosen. This is a perturbative covariance statement about the sigma-model renormalization scheme. Nonperturbative existence or isomorphism of two arbitrary curved-target continuum CFTs requires separate construction.

66.8 WZW Models, Affine Currents, and Cosets

Wess–Zumino–Witten models are sigma models whose exact conformal structure is fixed by an affine current algebra. We give the construction in a normalization independent of the four-dimensional gauge-theory trace normalization used elsewhere in this monograph.

Let G be a compact connected simply connected simple Lie group, let $\mathfrak{g}$ be its Lie algebra, and let $(\cdot,\cdot)$ be the basic invariant inner product, normalized so that long roots have squared length 2. Choose an orthonormal basis T_a of $\mathfrak{g}$, with

$$[T_a, T_b] = f_{ab}{}^c T_c, \qquad f_{abc} = f_{ab}{}^d \delta_{dc}.$$

The dual Coxeter number $h^\vee$ is defined by

$$f_{acd}f_{bcd} = 2h^\vee \delta_{ab}. \tag{66.78}$$

This convention makes the adjoint quadratic Casimir equal to $2h^\vee$.

Let $g : \Sigma \to G$. The topological term is defined using the integral class

$$[\Omega_G] \in H^3(G, \mathbb{Z}),$$

chosen as the generator compatible with the basic inner product. If $\Sigma = \partial B$ and $\widetilde{g} : B \to G$ extends g, the WZW action at level $k \in \mathbb{Z}$ is

$$S_k[g] = \frac{k}{4\pi}\int_\Sigma (g^{-1}\mathrm{d}g) \wedge *(g^{-1}\mathrm{d}g) + 2\pi \mathrm{i} k \int_B \widetilde{g}^*\Omega_G. \tag{66.79}$$

The first term is the sigma-model kinetic term on G with bi-invariant metric $k(\,\cdot\,,\,\cdot\,)$. The second term is most naturally the holonomy of a gerbe with curvature $2\pi k\,\Omega_G$; local two-form potentials represent it only after choosing a trivialization on coordinate patches.

Quantization of the WZW level. The exponent $\exp(-S_k[g])$ is independent of the filling B for every closed two-manifold Σ if $k \in \mathbb{Z}$. Conversely, for simply connected simple G, filling independence for all maps requires k to be integral in this normalization.

Let $(B_1, \widetilde{g}_1)$ and $(B_2, \widetilde{g}_2)$ be two fillings of the same boundary map. Gluing B_1 to $-B_2$ gives a closed oriented three-manifold C and a map $\widehat{g} : C \to G$. The change of the topological part of the action is

$$2\pi \mathrm{i} k \int_C \widehat{g}^*\Omega_G.$$

Since Ω_G represents an integral cohomology class, the integral is an integer. Thus the exponential is unchanged when $k \in \mathbb{Z}$. For compact simply connected simple G, $H_3(G, \mathbb{Z}) \simeq \mathbb{Z}$, and there is a map $C \to G$ pairing to 1 with $[\Omega_G]$. Applying filling independence to that map forces $\exp(-2\pi \mathrm{i} k) = 1$, hence $k \in \mathbb{Z}$.

In a local complex coordinate z, the equations of motion can be written as chiral conservation laws

$$\bar{\partial} J = 0, \qquad \partial \bar{J} = 0,$$

where $J = J^a T_a$ and $\bar{J} = \bar{J}^a T_a$ are the left and right currents. Their separated-point OPEs are the exact affine current algebra

$$J^a(z)J^b(0) \sim \frac{k\delta^{ab}}{z^2} + \frac{f_{ab}{}^c J^c(0)}{z}, \qquad \bar{J}^a(\bar{z})\bar{J}^b(0) \sim \frac{k\delta^{ab}}{\bar{z}^2} + \frac{f_{ab}{}^c \bar{J}^c(0)}{\bar{z}}. \tag{66.80}$$

The mixed $J\bar{J}$ OPE is regular at separated points. Equivalently, with

$$J^a(z) = \sum_{n\in\mathbb{Z}} J^a_n z^{-n-1},$$

the modes obey

$$[J^a_m, J^b_n] = f_{ab}{}^c J^c_{m+n} + k\, m\, \delta^{ab}\delta_{m+n,0}. \tag{66.81}$$

The central term is the quantum remnant of the Wess–Zumino term. The integer k is therefore simultaneously the gerbe level and the affine level.

Proposition 66.17 (Sugawara stress tensor)**.** *For $k + h^\vee \neq 0$, define*

$$T_G(z) = \frac{1}{2(k + h^\vee)} \sum_a : J^a J^a : (z). \tag{66.82}$$

Then J^a has conformal weight 1, and T_G has central charge

$$c(G, k) = \frac{k \dim \mathfrak{g}}{k + h^\vee}. \tag{66.83}$$

Proof. The coefficient in (66.82) is fixed by the requirement that the $T_G J^b$ OPE have leading singular terms

$$T_G(z) J^b(0) \sim \frac{J^b(0)}{z^2} + \frac{\partial J^b(0)}{z}.$$

Contract one current in $: J^a J^a :$ with J^b. The central term in (66.80) gives $2kJ^b/z^2$ before the overall coefficient. The simple-pole contraction gives the adjoint action twice. Normal ordering the resulting single current past the remaining current adds the adjoint Casimir contribution $2h^\vee J^b/z^2$, using (66.78). Thus the numerator is $2(k+h^\vee)J^b/z^2$, which fixes the factor $[2(k+h^\vee)]^{-1}$; the first-order pole is fixed by translation covariance of the normal-ordered product.

For the $T_G T_G$ OPE, the fourth-order pole comes from double contractions of the two quadratic normal-ordered products. The central-central contractions give $2k^2 \dim \mathfrak{g}$. The current-algebra contractions with two structure constants give the quantum correction $2kh^\vee \dim \mathfrak{g}$. Dividing by $[2(k + h^\vee)]^2$ and comparing with

$$T_G(z) T_G(0) \sim \frac{c/2}{z^4} + \frac{2T_G(0)}{z^2} + \frac{\partial T_G(0)}{z}$$

gives (66.83). The remaining second- and first-order poles reproduce the Virasoro action because the same coefficient already makes each current a primary field of weight 1. □

66.8.1 Knizhnik–Zamolodchikov Equations from Current Ward Identities

The affine current algebra does more than determine the stress tensor. It turns chiral correlation functions of WZW primary fields into flat sections of a logarithmic connection on the configuration space of marked points. We give the derivation because the equation is often quoted as representation theory data, while in the CFT it is a direct consequence of the local current OPE and the Sugawara expression for translations.

Let V_λ be the finite-dimensional irreducible $\mathfrak{g}$-module of highest weight $\lambda \in P_k^+$, and let

$$t^a_\lambda : V_\lambda \to V_\lambda$$

be the action of the basis element T_a. Thus $[t^a_\lambda, t^b_\lambda] = f_{ab}{}^c t^c_\lambda$, and the quadratic Casimir acts by

$$\sum_a t^a_\lambda t^a_\lambda = (\lambda, \lambda + 2\rho)\, 1_{V_\lambda}$$

in the normalization of (66.78). A chiral WZW primary field with horizontal type V_λ is an intertwining field $\Phi_\lambda(v, z)$, $v \in V_\lambda$, whose current OPE is

$$J^a(\zeta)\Phi_\lambda(v, z) \sim \frac{\Phi_\lambda(t^a_\lambda v, z)}{\zeta - z} + \text{regular}. \tag{66.84}$$

Equivalently, $J^a_n \Phi_\lambda(v,0)|0\rangle = 0$ for $n > 0$, while J^a_0 acts as t^a_λ.

For distinct points $z_1, \dots, z_n \in \mathbb{C}$, choose primary labels $\lambda_1, \dots, \lambda_n$. A genus-zero chiral block is a multilinear function

$$\mathcal{F}(z_1, \dots, z_n) : V_{\lambda_1} \otimes \cdots \otimes V_{\lambda_n} \to \mathbb{C}$$

obtained by inserting the corresponding chiral primary fields and projecting to the vacuum channel at infinity. We write t^a_i for $t^a_{\lambda_i}$ acting on the i-th tensor factor, and

$$\Omega_{ij} = \sum_a t^a_i t^a_j \qquad (i \neq j). \tag{66.85}$$

The global current Ward identity is

$$\mathcal{F} \circ \left(\sum_{i=1}^n t^a_i \right) = 0, \tag{66.86}$$

which is the statement that the contour integral of J^a around all finite insertions can be moved to infinity and annihilates the vacuum.

Theorem 66.18 (Knizhnik–Zamolodchikov equation)**.** *For every $i = 1, \dots, n$, the chiral block satisfies*

$$(k + h^\vee)\, \partial_{z_i} \mathcal{F} = \mathcal{F} \circ \sum_{j \neq i} \frac{\Omega_{ij}}{z_i - z_j}. \tag{66.87}$$

With invariant Hermitian forms used to identify V_{λ_i} with its dual, the same equation may be written for vector-valued blocks with Ω_{ij} acting on the left.

Proof. The translation Ward identity gives

$$\partial_{z_i} \Phi_{\lambda_i}(v_i, z_i) = \Phi_{\lambda_i}(L_{-1} v_i, z_i).$$

Apply the Sugawara formula (66.82) to the affine primary state v_i. In the mode expression

$$L_{-1} = \frac{1}{2(k + h^\vee)} \sum_{a, m \in \mathbb{Z}} : J^a_{-1-m} J^a_m :,$$

all terms vanish on v_i except the two terms with $m = 0$ and $m = -1$. Their sum is

$$\frac{1}{2(k + h^\vee)} \sum_a \left(J^a_{-1} J^a_0 + J^a_0 J^a_{-1} \right) v_i = \frac{1}{k + h^\vee} \sum_a J^a_{-1} t^a_i v_i, \tag{66.88}$$

because $\sum_a [J^a_0, J^a_{-1}] = \sum_{a,c} f_{aa}{}^c J^c_{-1} = 0$.

It remains to evaluate a block with J^a_{-1} acting on the i-th primary. By definition of modes around z_i,

$$J^a_{-1} \Phi_{\lambda_i}(v_i, z_i) = \oint_{z_i} \frac{\mathrm{d}\zeta}{2\pi \mathrm{i}} \frac{J^a(\zeta) \Phi_{\lambda_i}(v_i, z_i)}{\zeta - z_i}.$$

Insert this contour integral in the chiral block. Deforming the contour away from z_i gives the negative of the sum of small contours around the other insertions; the integrand has residue $\Phi_{\lambda_j}(t^a_j v_j, z_j)/(z_j - z_i)$ at z_j. Therefore

$$\mathcal{F}(\dots, J^a_{-1} t^a_i v_i, \dots) = \sum_{j \neq i} \frac{1}{z_i - z_j} \mathcal{F}(\dots, t^a_i v_i, \dots, t^a_j v_j, \dots).$$

Substituting this identity into (66.88) gives (66.87). □

Lemma 66.19 (Flatness and four-point reduction)**.** *The operators*

$$\nabla_i = (k + h^\vee)\partial_{z_i} - \sum_{j \neq i} \frac{\Omega_{ij}}{z_i - z_j} \tag{66.89}$$

define a flat logarithmic connection on the configuration space $\mathrm{Conf}_n(\mathbb{C})$*, after restricting to the invariant subspace* $(V_{\lambda_1} \otimes \cdots \otimes V_{\lambda_n})^G$ *or, equivalently, imposing* (66.86)*. After fixing three points by a Mobius transformation, a four-point block with insertions at* $0, x, 1, \infty$ *obeys*

$$(k + h^\vee)\frac{\mathrm{d}}{\mathrm{d}x}\mathcal{F}(x) = \left(\frac{\Omega_{21}}{x} + \frac{\Omega_{23}}{x-1}\right)\mathcal{F}(x), \tag{66.90}$$

with Ω_{2j} *acting on the remaining invariant tensor space.*

Proof. Only commutators of Ω's sharing an index can be nonzero. The quadratic tensor

$$\Omega = \sum_a T_a \otimes T_a \in \mathfrak{g} \otimes \mathfrak{g}$$

is invariant under the diagonal adjoint action, hence

$$[\Omega_{ij}, t_i^b + t_j^b] = 0$$

on $V_{\lambda_i} \otimes V_{\lambda_j}$. Multiplying by t_k^b on a third tensor factor and summing over b gives, for distinct i, j, k,

$$[\Omega_{ij}, \Omega_{ik} + \Omega_{jk}] = 0. \tag{66.91}$$

These are the infinitesimal braid relations. Expanding $[\nabla_i, \nabla_j]$, the derivative terms cancel the double-pole derivatives of $(z_i - z_j)^{-1}$, while the remaining triple-index commutators are precisely the combinations in (66.91). Thus the curvature vanishes.

For $n = 4$, use conformal covariance to place the points at $(z_1, z_2, z_3, z_4) = (0, x, 1, \infty)$. The equation with $i = 2$ gives (66.90); terms involving the insertion at infinity are absorbed by the global Ward identity, which identifies the fourth action with minus the sum of the first three finite actions on invariant tensors. □

$SU(2)$ **four-fundamental reduction.** The abstract connection becomes a concrete finite system already for four spin-$\frac{1}{2}$ insertions in $SU(2)_k$. Let $V = \mathbb{C}^2$ with indices $\alpha, \beta \in \{0, 1\}$, let $\epsilon_{01} = 1 = -\epsilon_{10}$, and choose the generators normalized by

$$\sum_{a=1}^{3} (t^a)_\alpha{}^\gamma (t^a)_\beta{}^\delta = \delta_\alpha{}^\delta \delta_\beta{}^\gamma - \frac{1}{2}\delta_\alpha{}^\gamma \delta_\beta{}^\delta. \tag{66.92}$$

This is the $SU(2)$ specialization of the WZW convention above: the fundamental quadratic Casimir is $3/2$, while $h^\vee = 2$. The invariant space in $V^{\otimes 4}$ is two-dimensional. A convenient spanning pair is

$$\mathcal{I}_{s\alpha_1\alpha_2\alpha_3\alpha_4} = \epsilon_{\alpha_1\alpha_2}\epsilon_{\alpha_3\alpha_4}, \qquad \mathcal{I}_{t\alpha_1\alpha_2\alpha_3\alpha_4} = \epsilon_{\alpha_1\alpha_3}\epsilon_{\alpha_2\alpha_4},$$

with the third pairing $\mathcal{I}_u = \epsilon_{\alpha_1\alpha_4}\epsilon_{\alpha_2\alpha_3}$ obeying

$$\mathcal{I}_s - \mathcal{I}_t + \mathcal{I}_u = 0. \tag{66.93}$$

Using (66.92), equivalently $\Omega_{ij} = P_{ij} - \frac{1}{2}$ on two fundamental factors, one obtains

$$\Omega_{12}\mathcal{I}_s = -\frac{3}{2}\,\mathcal{I}_s, \qquad\qquad \Omega_{12}\mathcal{I}_t = -\mathcal{I}_s + \frac{1}{2}\,\mathcal{I}_t, \tag{66.94}$$

$$\Omega_{23}\mathcal{I}_s = -\frac{1}{2}\,\mathcal{I}_s + \mathcal{I}_t, \qquad\qquad \Omega_{23}\mathcal{I}_t = \mathcal{I}_s - \frac{1}{2}\,\mathcal{I}_t. \tag{66.95}$$

Thus, for a vector-valued block

$$\Psi(x) = F_s(x)\mathcal{I}_s + F_t(x)\mathcal{I}_t$$

with insertions at $0, x, 1, \infty$, the KZ equation is the explicit rank-two Fuchsian system

$$(k+2)\frac{\mathrm{d}}{\mathrm{d}x}\begin{pmatrix} F_s \\ F_t \end{pmatrix} = \left[\frac{1}{x}\begin{pmatrix} -\frac{3}{2} & -1 \\ 0 & \frac{1}{2} \end{pmatrix} + \frac{1}{x-1}\begin{pmatrix} -\frac{1}{2} & 1 \\ 1 & -\frac{1}{2} \end{pmatrix}\right]\begin{pmatrix} F_s \\ F_t \end{pmatrix}. \tag{66.96}$$

Near $x = 0$, the residue matrix is triangular in this basis. Its eigenvalues $-3/2$ and $1/2$ are exactly the singlet and triplet eigenvalues

$$\frac{1}{2}(C_\mu - C_{\text{fund}} - C_{\text{fund}}), \qquad \mu = 0, 2,$$

where $C_0 = 0$, $C_2 = 4$, and $C_{\text{fund}} = 3/2$ in the present normalization. Hence the local monodromy exponents of the chiral invariant tensor before multiplying by external scalar prefactors are

$$-\frac{3}{2(k+2)}, \qquad \frac{1}{2(k+2)}.$$

This finite reduction is the elementary model for the general statement that KZ monodromy represents the braid action on WZW conformal blocks; the identification with the full unitary CFT still requires the sewing and positivity data of the completed WZW model.

The highest-weight representations that occur in the compact unitary WZW model at positive integral k are the integrable highest weights

$$P_k^+ = \{\lambda \in P^+ \mid (\lambda, \theta) \le k\}, \tag{66.97}$$

where P^+ is the set of dominant integral weights and θ is the highest root. A primary field Φ_λ has holomorphic conformal weight

$$h_\lambda = \frac{(\lambda, \lambda + 2\rho)}{2(k + h^\vee)}, \tag{66.98}$$

where ρ is the Weyl vector. The full diagonal WZW model has Hilbert space

$$\mathcal{H}_{G,k}^{\text{diag}} = \bigoplus_{\lambda \in P_k^+} \mathcal{H}_\lambda \otimes \overline{\mathcal{H}_\lambda}. \tag{66.99}$$

Other modular invariants correspond to different pairings of left and right integrable modules and, in general, to additional global data of the full CFT rather than to a different local affine OPE.

Now let $H \subset G$ be a compact connected subgroup with Lie algebra $\mathfrak{h}$. Let the embedding index x_e be defined by

$$(X, Y)_{\mathfrak{g}} = x_e (X, Y)_{\mathfrak{h}} \qquad X, Y \in \mathfrak{h},$$

where both inner products are basic. The $\mathfrak{h}$-currents inside the G_k current algebra have level

$$k_H = kx_e.$$

The coset stress tensor is

$$T_{G/H} = T_G - T_H, \tag{66.100}$$

where T_H is the Sugawara tensor built from the embedded $\mathfrak{h}$-currents at level k_H. The corresponding central charge is

$$c(G_k/H_{k_H}) = \frac{k \dim \mathfrak{g}}{k + h^\vee_{\mathfrak{g}}} - \frac{k_H \dim \mathfrak{h}}{k_H + h^\vee_{\mathfrak{h}}}. \tag{66.101}$$

Since T_H is built from a subalgebra of the G-currents, the difference (66.100) has regular OPE with every $\mathfrak{h}$-current. Thus coset local fields are represented by $\mathfrak{h}$-invariant branching components of G_k affine modules, with conformal weights given by the G weight minus the H weight modulo integers from descendants.

The same construction has a Lagrangian presentation as a gauged WZW model. The group H is gauged by coupling the H-current algebra to a two-dimensional gauge field and adding the local terms forced by the Polyakov–Wiegmann identity. Gauge consistency requires the left and right H-levels to match; otherwise the gauge variation is an anomaly. After gauge fixing, the physical local operators are the BRST cohomology classes. The equality between the gauged WZW presentation and the coset vertex algebra is therefore a statement about a gauge-fixed local QFT with its ghost system and BRST differential. A target-space quotient picture, when available, is a geometric shadow of this operator construction.

For the diagonal embedding

$$SU(2)_k \times SU(2)_1 \supset SU(2)_{k+1},$$

the coset central charge is

$$c_k = \frac{3k}{k+2} + 1 - \frac{3(k+1)}{k+3} = 1 - \frac{6}{(k+2)(k+3)}. \tag{66.102}$$

This gives the unitary Virasoro minimal-model central charges. The central charge is the first scalar invariant of the construction; the full CFT data are the coset Hilbert space, OPE coefficients, sewing constraints, and modular invariant built from the branching of affine representations.

66.8.2 Rank-One Solvable Cosets: Parafermions and the Cigar

The cosets $SU(2)_k/U(1)$ and $SL(2,\mathbb{R})_k/U(1)$ are small enough to compute explicitly, but they are also good tests of the logical order of the construction. The exact CFT is first a current-algebra coset with specified representation data. A gauged sigma-model metric and dilaton, when available, are then a useful representative in a controlled large-level regime. Reversing this order can hide selection rules, field identifications, reflection amplitudes, and normalizability conditions.

Definition 66.20 (The compact parafermion coset)**.** Let $k \in \mathbb{Z}_{>0}$. In the $SU(2)_k$ WZW model write the Cartan current as J^3, normalized so that the embedded abelian current algebra has level k and primary charges are naturally recorded by an integer m modulo $2k$. The compact parafermion coset is

$$\mathrm{PF}_k = SU(2)_k/U(1)_k, \qquad T_{\mathrm{PF}_k} = T_{SU(2)_k} - T_{U(1)_k}.$$

Its affine branching labels are pairs

$$(\ell, m), \qquad 0 \le \ell \le k, \quad m \in \mathbb{Z}/2k\mathbb{Z}, \qquad \ell + m \in 2\mathbb{Z}.$$

The selection rule means that the $U(1)$ charge must actually occur in the finite $SU(2)$ spin-$\ell/2$ multiplet before its affine descendants are included.

Equivalently, the integrable $SU(2)_k$ character decomposes as

$$\chi_\ell^{SU(2)_k}(q,z) = \sum_{\substack{m\in\mathbb{Z}/2k\mathbb{Z} \\ m\equiv\ell \pmod 2}} b^{(k)}_{\ell,m}(q)\, \Theta_{m,k}(q,z). \tag{66.103}$$

Here $\Theta_{m,k}$ is the abelian level-k theta character and $b^{(k)}_{\ell,m}$ is the parafermion branching function. The formula is a representation-theoretic decomposition of the $SU(2)_k$ affine module; it is not a pointwise quotient of a target manifold.

Parafermion central charge, weights, and identification. The compact parafermion coset has central charge

$$c(\mathrm{PF}_k) = \frac{3k}{k+2} - 1 = \frac{2(k-1)}{k+2}. \tag{66.104}$$

The holomorphic conformal weight of the coset primary labelled by (ℓ, m) is

$$h^{\mathrm{PF}}_{\ell,m} = \frac{\ell(\ell+2)}{4(k+2)} - \frac{m^2}{4k} \mod \mathbb{Z}, \tag{66.105}$$

and the branching labels are identified by

$$(\ell, m) \sim (k-\ell, m+k). \tag{66.106}$$

The central charge is the difference between the $SU(2)_k$ Sugawara central charge $3k/(k+2)$ and the abelian current central charge 1. For the weight, write the $SU(2)$ highest weight as $\lambda = \ell\omega$. Since $(\omega,\omega) = 1/2$ and $\rho = \omega$,

$$h_\ell^{SU(2)_k} = \frac{(\lambda, \lambda+2\rho)}{2(k+2)} = \frac{\ell(\ell+2)}{4(k+2)}.$$

An abelian charge m at level k, in this doubled-charge normalization, has conformal weight $m^2/(4k)$. Subtracting the abelian weight gives (66.105), with integer shifts coming from which affine descendants occur in the branching component. The identification (66.106) is generated by the simple current of $SU(2)_k$. Its compatibility with the displayed weight formula is checked directly:

$$h^{\mathrm{PF}}_{k-\ell,m+k} - h^{\mathrm{PF}}_{\ell,m} = -\frac{\ell+m}{2}.$$

This is integral precisely on the selected branching labels $\ell + m \in 2\mathbb{Z}$.

For $k = 2$ one obtains the Ising central charge $c = 1/2$: the labels $(1,1)$ and $(2,0)$ give the weights $1/16$ and $1/2$. For $k = 3$ one obtains $c = 4/5$, the three-state Potts value: the labels $(1,1)$ and $(2,0)$ give weights $1/15$ and $2/5$. The parafermion current can be represented by $(0,2)$; using (66.105) modulo integers gives

$$h^{\mathrm{PF}}_{0,2} = 1 - \frac{1}{k}.$$

Proposition 66.21 (Parafermion fusion, modular data, and diagonal invariant)**.** *Let $\mathcal{L}_k$ be the set of selected labels*

$$\mathcal{L}_k = \{(\ell, m) \mid 0 \le \ell \le k,\ m \in \mathbb{Z}/2k\mathbb{Z}, \ell + m \in 2\mathbb{Z}\},$$

and let $\mathcal{I}_k = \mathcal{L}_k/\sim$, where $(\ell, m) \sim (k-\ell, m+k)$. The simple-current action is free, so

$$|\mathcal{I}_k| = \frac{k(k+1)}{2}.$$

For orbit labels $[\ell, m] \in \mathcal{I}_k$, the fusion rule is

$$[\ell_1, m_1] \boxtimes [\ell_2, m_2] = \bigoplus_{\substack{|\ell_1-\ell_2| \le \ell_3 \le \min(\ell_1+\ell_2,\, 2k-\ell_1-\ell_2) \\ \ell_1+\ell_2+\ell_3 \in 2\mathbb{Z}}} [\ell_3, m_1 + m_2], \tag{66.107}$$

where the charge is reduced modulo $2k$ and the result is again read as an orbit. With the theta-function convention used in (66.103), the modular S-matrix on these orbits is

$$S^{\mathrm{PF}}_{[\ell,m],[\ell',m']} = \frac{2}{\sqrt{k(k+2)}} \sin\!\left(\frac{\pi(\ell+1)(\ell'+1)}{k+2}\right) \exp\!\left(-\frac{\pi i m m'}{k}\right). \tag{66.108}$$

The diagonal compact parafermion torus partition function is

$$Z^{\mathrm{diag}}_{\mathrm{PF}_k}(\tau, \bar\tau) = \sum_{[\ell,m] \in \mathcal{I}_k} b^{(k)}_{\ell,m}(\tau)\, \overline{b^{(k)}_{\ell,m}(\tau)}. \tag{66.109}$$

Moreover S^{PF} is unitary and the Verlinde formula recovers exactly the fusion rule (66.107):

$$N_{ab}{}^{c} = \sum_{x \in \mathcal{I}_k} \frac{S^{\mathrm{PF}}_{ax} S^{\mathrm{PF}}_{bx} \overline{S^{\mathrm{PF}}_{cx}}}{S^{\mathrm{PF}}_{[0,0]x}}, \qquad a, b, c \in \mathcal{I}_k, \tag{66.110}$$

where $N_{ab}{}^{c}$ is 1 when c appears in (66.107) and 0 otherwise.

Proof. The action $(\ell, m) \mapsto (k-\ell, m+k)$ has no fixed point: a fixed point would require $m \equiv m+k \pmod{2k}$, impossible for $k > 0$. Since $|\mathcal{L}_k| = k(k+1)$, the orbit count follows.

Fusion in the parent $SU(2)_k$ WZW model is the truncated tensor-product rule

$$\ell_3 = |\ell_1 - \ell_2|,\ |\ell_1 - \ell_2| + 2, \ldots, \min(\ell_1 + \ell_2, 2k - \ell_1 - \ell_2).$$

The abelian factor conserves $U(1)$ charge modulo $2k$. Taking the coset branching component therefore gives (66.107). The parity condition is automatic from the $SU(2)$ fusion parity and the two input selection rules.

The modular matrix is the product of the $SU(2)_k$ modular matrix and the complex conjugate of the $U(1)_k$ theta modular matrix, multiplied by the order 2 of the free simple-current identification. This gives (66.108). The displayed expression is well-defined on orbits because replacing (ℓ, m) by $(k-\ell, m+k)$ multiplies the sine factor by $(-1)^{\ell'}$ and the exponential by $(-1)^{m'}$, whose product is 1 on selected labels $\ell' + m' \in 2\mathbb{Z}$. The diagonal invariant is the branchwise diagonal invariant after quotienting by this free identification; it is equivalently one half of the selected-label diagonal sum before quotient.

It remains to check that no normalization has been lost in passing to orbits. Put

$$S^{su}_{\ell\ell'} = \sqrt{\frac{2}{k+2}}\,\sin\!\left(\frac{\pi(\ell+1)(\ell'+1)}{k+2}\right), \qquad S^{u(1)}_{mm'} = \frac{1}{\sqrt{2k}}\,\exp\!\left(\frac{\pi i m m'}{k}\right).$$

The finite sine and Fourier orthogonality relations give

$$\sum_{\ell'=0}^{k} S^{su}_{\ell\ell'} S^{su}_{\ell''\ell'} = \delta_{\ell,\ell''}, \qquad \sum_{m'\in\mathbb{Z}/2k\mathbb{Z}} S^{u(1)}_{mm'} \overline{S^{u(1)}_{m''m'}} = \delta_{m,m''}.$$

Before quotienting, the branching functions transform with the product kernel $\widehat{S}_{(\ell,m),(\ell',m')} = S^{su}_{\ell\ell'}\overline{S^{u(1)}_{mm'}}$. The selection rule is the zero-monodromy condition for the simple current $\mathsf{J}(\ell,m) = (k-\ell, m+k)$, and the previous paragraph shows that $\widehat{S}$ is constant on selected J-orbits. Since every orbit has two elements, the induced orbit matrix is $2\widehat{S}$, namely (66.108). Summing first over selected labels and then dividing by the orbit size gives

$$\sum_{x\in\mathcal{I}_k} S^{\mathrm{PF}}_{ax}\overline{S^{\mathrm{PF}}_{bx}} = \delta_{a,b},$$

with $\delta_{a,b}$ understood on orbit labels.

For (66.110), insert (66.108). The finite Fourier sum over m_x imposes $m_c \equiv m_a + m_b \pmod{2k}$, up to the same free field-identification orbit. The remaining sine-kernel quotient is the $SU(2)_k$ Verlinde coefficient, equivalently the truncated Clebsch–Gordan condition on ℓ_c. These two constraints are precisely (66.107). Because the simple-current action is free, no fixed-point resolution or multiplicity factor is hidden in this last step. □

For $k=2$, the three orbits may be represented by $(0,0)$, $(1,1)$, and $(2,0)$. The fusion rule gives

$$(1,1)\boxtimes(1,1) = (0,0)\oplus(2,0), \qquad (2,0)\boxtimes(2,0) = (0,0),$$

which is the Ising fusion algebra under the identifications $(1,1)=\sigma$ and $(2,0)=\varepsilon$. For general k, the field $(0,2)$ is a simple current of order k and shifts $[\ell,m]$ to $[\ell,m+2]$.

Controlled Approximation 66.22 (The bell as a gauged-WZW representative)**.** Choose Euler-angle coordinates on $SU(2)$ and gauge the Cartan circle axially. In a local complex coordinate, write $\partial = \partial_z$ and $\bar\partial = \partial_{\bar z}$. After parametrizing the group by base coordinates (θ,φ) and a fiber coordinate ψ, the gauged action has the local form

$$\begin{aligned} S_{\text{gauged}} = \frac{k}{2\pi}\int d^2z\,\Big[&\partial\theta\,\bar\partial\theta + \tan^2\theta\,\partial\varphi\,\bar\partial\varphi \\ &+ \cos^2\theta\,\big(\partial\psi + \tan^2\theta\,\partial\varphi + A\big)\big(\bar\partial\psi - \tan^2\theta\,\bar\partial\varphi + \bar A\big)\Big]. \end{aligned} \tag{66.111}$$

This formula is a coordinate representative of the gauged WZW model; the global action is still defined by the WZW gerbe and the gauged Polyakov–Wiegmann construction. Fixing the gauge $\psi=0$, the gauge fields $A,\bar A$ are algebraic. Their equations of motion are

$$\bar A = \tan^2\theta\,\bar\partial\varphi, \qquad A = -\tan^2\theta\,\partial\varphi.$$

Substitution leaves

$$\frac{k}{2\pi}\int d^2z\,\big(\partial\theta\,\bar\partial\theta+\tan^2\theta\,\partial\varphi\,\bar\partial\varphi\big).$$

The Gaussian integration over $A,\bar A$ has quadratic coefficient $k\cos^2\theta$; its determinant shifts the dilaton by $-\log(k\cos\theta)$, up to the constant convention for Φ_0. Thus the semiclassical large-k representative is

$$ds^2=k\alpha'\big(d\theta^2+\tan^2\theta\,d\varphi^2\big),\qquad \Phi=\Phi_0-\log\cos\theta. \tag{66.112}$$

after absorbing $-\log k$ into Φ_0. This "bell" geometry is a useful sigma-model shadow of the coset. The exact finite-k CFT is nevertheless the parafermion coset with the branching, selection, field-identification, and sewing data specified above; it is not defined by the unrenormalized metric alone.

Definition 66.23 (The bosonic cigar coset)**.** Let $k>2$. The bosonic cigar CFT is the axial Cartan coset

$$\mathrm{Cig}_k=SL(2,\mathbb{R})_k/U(1),\qquad T_{\mathrm{Cig}_k}=T_{SL(2,\mathbb{R})_k}-T_{U(1)},$$

with Euclidean continuation chosen so that the residual angular coordinate is compact. A primary is labelled locally by $SL(2,\mathbb{R})$ quantum numbers $j,m,\bar m$, but a full noncompact CFT datum also includes the choice of continuous and discrete representation ranges, spectral-flow sectors, reflection relation, normalizability prescription, and modular invariant pairing of left and right labels.

Cigar central charge, weights, and spin. In the above convention the bosonic cigar has

$$c(\mathrm{Cig}_k)=\frac{3k}{k-2}-1=2+\frac{6}{k-2}. \tag{66.113}$$

The holomorphic conformal weight of a coset primary with labels (j,m) is

$$h^{\mathrm{Cig}}_{j,m}=-\frac{j(j-1)}{k-2}+\frac{m^2}{k}. \tag{66.114}$$

For momentum $n\in\mathbb{Z}$ and winding $w\in\mathbb{Z}$ around the asymptotic circle, use

$$m=\frac{n+kw}{2},\qquad \bar m=\frac{-n+kw}{2}. \tag{66.115}$$

Then the spin is integral:

$$h^{\mathrm{Cig}}_{j,m}-\bar h^{\mathrm{Cig}}_{j,\bar m}=nw.$$

For $SL(2,\mathbb{R})$ the dual-Coxeter shift has the opposite sign from the compact $SU(2)$ case, giving the WZW central charge $3k/(k-2)$. Subtracting the abelian current central charge gives (66.113). The parent $SL(2,\mathbb{R})$ affine primary of spin j has Sugawara weight

$$h^{SL(2)}_j=-\frac{j(j-1)}{k-2}.$$

Writing the state as a coset branching field times the Cartan vertex, the timelike Cartan vertex has weight $-m^2/k$. Therefore

$$h^{SL(2)}_j=h^{\mathrm{Cig}}_{j,m}-\frac{m^2}{k},$$

which gives (66.114). Finally,

$$h^{\text{Cig}}_{j,m} - \bar{h}^{\text{Cig}}_{j,\bar{m}} = \frac{m^2 - \bar{m}^2}{k} = \frac{(m-\bar{m})(m+\bar{m})}{k} = nw,$$

using (66.115).

Remark 66.24 (Bosonic cigar spectrum status). For the standard axial $SL(2,\mathbb{R})_k/U(1)$ cigar CFT with $k > 2$, the continuous normalizable spectrum contains

$$j = \frac{1}{2} + \mathrm{i}s, \qquad s \in \mathbb{R}_{\geq 0}, \qquad n, w \in \mathbb{Z},$$

with $m, \bar{m}$ as in (66.115). Its weights are therefore

$$h_{s,n,w} = \frac{s^2 + \frac{1}{4}}{k-2} + \frac{(n+kw)^2}{4k}, \qquad \bar{h}_{s,n,w} = \frac{s^2 + \frac{1}{4}}{k-2} + \frac{(-n+kw)^2}{4k}.$$

The analytic continuation in j obeys a reflection relation

$$\mathcal{V}_{j,m,\bar{m}} \simeq \mathcal{R}(j;m,\bar{m})\, \mathcal{V}_{1-j,m,\bar{m}}, \qquad \mathcal{R}(j;m,\bar{m})\mathcal{R}(1-j;m,\bar{m}) = 1,$$

and the normalizable discrete states are obtained from the corresponding pole and residue prescription. The exact discrete ranges and multiplicity choices are part of the noncompact CFT and modular-invariant datum; they do not follow from the local stress tensor and metric formulas alone.

The equality $h^{\text{Cig}}_{j,m} = h^{\text{Cig}}_{1-j,m}$ is immediate from (66.114). Thus the reflection relation is compatible with Virasoro weights, but its coefficient and the allowed discrete residues are global analytic data of the noncompact theory. This is one of the points where the cigar differs sharply from the compact parafermion coset: the compact model has finitely many ordinary characters and a finite modular matrix, while the cigar has delta-normalized continuum states and a scattering/reflection problem at infinity.

Controlled Approximation 66.25 (The cigar as a large-level background)**.** In the same gauged-WZW derivation, now for $SL(2,\mathbb{R})$ with the Euclidean axial gauging, choose local coordinates (ρ, θ, t) so that t is the gauged fiber coordinate. The local action is

$$\begin{aligned} S_{\text{gauged}} = \frac{k}{2\pi} \int d^2 z \, \Big[&\partial\rho\, \bar{\partial}\rho + \tanh^2 \rho\, \partial\theta\, \bar{\partial}\theta \\ &- \cosh^2 \rho \left(\partial t + \tanh^2 \rho\, \partial\theta + A\right)\left(\bar{\partial} t - \tanh^2 \rho\, \bar{\partial}\theta + \bar{A}\right)\Big]. \end{aligned} \tag{66.116}$$

The minus sign records the noncompact Cartan signature; in the Euclidean coset path integral it is accompanied by the corresponding Wick-rotated gauge-field contour. Fixing $t = 0$, the algebraic equations of motion are

$$\bar{A} = \tanh^2 \rho\, \bar{\partial}\theta, \qquad A = -\tanh^2 \rho\, \partial\theta.$$

Substitution gives the kinetic term

$$\frac{k}{2\pi} \int d^2 z \left(\partial\rho\, \bar{\partial}\rho + \tanh^2 \rho\, \partial\theta\, \bar{\partial}\theta\right),$$

and the Gaussian determinant has coefficient $k\cosh^2\rho$, producing $-\log(k\cosh\rho)$ in the dilaton. Absorbing $-\log k$ into Φ_0 gives the large-k sigma-model representative

$$ds^2 = k\alpha'\big(d\rho^2 + \tanh^2\rho\, d\theta^2\big), \qquad \Phi = \Phi_0 - \log\cosh\rho, \qquad \theta \sim \theta + 2\pi. \tag{66.117}$$

The tip is smooth, while the end is an asymptotic cylinder with a linear dilaton. The exact central charge is reproduced by the asymptotic background-charge convention $Q = 1/\sqrt{k-2}$. At finite k, however, the exact object is the noncompact coset CFT with its representation, reflection, normalizability, and modular data; the metric and dilaton alone do not determine those analytic choices.

One-loop Weyl identities for the bell and cigar. Let

$$ds^2 = K\big(du^2 + f(u)^2 d\varphi^2\big), \qquad \Phi = \Phi(u), \qquad K > 0,$$

and set $H = 0$. The only nonzero Christoffel symbols are

$$\Gamma^u_{\varphi\varphi} = -ff', \qquad \Gamma^\varphi_{u\varphi} = \Gamma^\varphi_{\varphi u} = \frac{f'}{f},$$

and the Ricci tensor and dilaton Hessian are

$$R_{uu} = -\frac{f''}{f}, \qquad R_{\varphi\varphi} = -ff'', \qquad \nabla_u\nabla_u\Phi = \Phi'', \qquad \nabla_\varphi\nabla_\varphi\Phi = ff'\Phi'.$$

For the cigar,

$$f(\rho) = \tanh\rho, \qquad \Phi(\rho) = \Phi_0 - \log\cosh\rho,$$

and for the bell,

$$f(\theta) = \tan\theta, \qquad \Phi(\theta) = \Phi_0 - \log\cos\theta.$$

In both cases the one-loop metric Weyl-anomaly equation

$$R_{ij} + 2\nabla_i\nabla_j\Phi = 0$$

holds identically on the coordinate patch. The scalar combination entering (66.23) is constant:

$$|\nabla\Phi|^2 - \frac{1}{2}\nabla^2\Phi = \begin{cases} K^{-1}, & \text{cigar}, \\ -K^{-1}, & \text{bell}. \end{cases} \tag{66.118}$$

For a rotational metric with constant overall scale K, the connection is independent of K. The displayed Christoffel symbols follow by direct substitution in

$$\Gamma^a_{bc} = \frac{1}{2}g^{ad}\big(\partial_b g_{cd} + \partial_c g_{bd} - \partial_d g_{bc}\big).$$

The Ricci components reduce to

$$R_{uu} = -\frac{f''}{f}, \qquad R_{\varphi\varphi} = -ff'',$$

and the Hessian formulas follow from $\nabla_i\nabla_j\Phi = \partial_i\partial_j\Phi - \Gamma^a_{ij}\partial_a\Phi$.

For the cigar one has

$$f' = 1 - f^2, \qquad f'' = -2f(1 - f^2), \qquad \Phi' = -f, \qquad \Phi'' = -(1 - f^2).$$

Therefore

$$R_{uu} + 2\Phi'' = 2(1 - f^2) - 2(1 - f^2) = 0$$

and

$$R_{\varphi\varphi} + 2\nabla_\varphi \nabla_\varphi \Phi = 2f^2(1 - f^2) - 2f^2(1 - f^2) = 0.$$

Also

$$K\left(|\nabla\Phi|^2 - \frac{1}{2}\nabla^2\Phi\right) = f^2 - \frac{1}{2}\left(\Phi'' + \frac{f'}{f}\Phi'\right) = f^2 + (1 - f^2) = 1.$$

For the bell one has

$$f' = 1 + f^2, \qquad f'' = 2f(1 + f^2), \qquad \Phi' = f, \qquad \Phi'' = 1 + f^2.$$

The same substitutions give

$$R_{uu} + 2\Phi'' = -2(1 + f^2) + 2(1 + f^2) = 0$$

and

$$R_{\varphi\varphi} + 2\nabla_\varphi \nabla_\varphi \Phi = -2f^2(1 + f^2) + 2f^2(1 + f^2) = 0.$$

Finally

$$K\left(|\nabla\Phi|^2 - \frac{1}{2}\nabla^2\Phi\right) = f^2 - \frac{1}{2}\left(\Phi'' + \frac{f'}{f}\Phi'\right) = f^2 - (1 + f^2) = -1.$$

Taking $K = k\alpha'$, the scalar constants in (66.118) give the leading large-k central-charge shifts $2 + 6/k$ for the cigar and $2 - 6/k$ for the bell in the convention of (66.23). The exact finite-level current-algebra formulas replace these leading denominators by $k-2$ and $k+2$, respectively. This is precisely why the geometry check is useful but not a definition of the exact CFT.

The $\mathcal{N} = 2$ supersymmetric versions of these rank-one cosets add fermions, an R-current, spectral flow, chiral primaries, and mirror relations to $\mathcal{N} = 2$ Liouville theory. The exact chiral-algebraic interface for the compact minimal coset and the noncompact cigar coset is recorded in Section 70.7. The bosonic discussion here supplies the current-algebra and gauged-WZW baseline, while the GLSM and mirror-duality construction remains part of the supersymmetric-QFT development.

66.9 Finite Orbifolds as Gauging of Topological Lines

Let $\mathcal{C}$ be a two-dimensional CFT with a finite internal symmetry group G. In the defect-line formulation this means that, for each $g \in G$, there is an invertible topological line $\mathcal{L}_g$, with fusion

$$\mathcal{L}_g \otimes \mathcal{L}_h \simeq \mathcal{L}_{gh}.$$

The associativity of line junctions can carry an anomaly class

$$[\omega] \in H^3(G, U(1)).$$

An orbifold $\mathcal{C}/G$ requires a choice of trivialization of this class. Inequivalent trivializations differing by a two-cocycle give the discrete torsion group $H^2(G, U(1))$.

For each $g \in G$, let $\mathcal{H}_g$ be the Hilbert space on the circle with $\mathcal{L}_g$ inserted along the spatial cycle. Equivalently, in a Lagrangian representative this is the sector with boundary condition

$$\Phi(\sigma + 2\pi) = g \cdot \Phi(\sigma)$$

for every field Φ. If $hgh^{-1} = g'$, encircling the insertion by $\mathcal{L}_h$ gives an isomorphism

$$\widehat{h} : \mathcal{H}_g \longrightarrow \mathcal{H}_{g'}.$$

The orbifold Hilbert space is

$$\mathcal{H}_{\mathcal{C}/G} = \bigoplus_{[g]} \mathcal{H}_g^{C_g}, \tag{66.119}$$

where $[g]$ runs over conjugacy classes and C_g is the centralizer of g. Formula (66.119) is the operator form of gauging: the sum over g adds bundles on the spatial circle, and the C_g-invariants impose the residual gauge projection.

Torus partition function of a finite orbifold. For an anomaly-free finite symmetry, and for a fixed discrete-torsion two-cocycle $\epsilon(g, h)$ defined on commuting pairs, the orbifold torus partition function is

$$Z_{\mathcal{C}/G}(\tau, \bar{\tau}) = \frac{1}{|G|} \sum_{\substack{g,h \in G \\ gh=hg}} \epsilon(g, h)\, Z_g^h(\tau, \bar{\tau}), \qquad Z_g^h = \mathrm{Tr}_{\mathcal{H}_g} \widehat{h}\, q^{L_0 - c/24} \bar{q}^{\bar{L}_0 - \bar{c}/24}. \tag{66.120}$$

The modular generators act on the labels by

$$S : (g, h) \mapsto (h^{-1}, g), \qquad T : (g, h) \mapsto (g, gh), \tag{66.121}$$

with the cocycle ϵ supplying the corresponding discrete-torsion phases.

The trace over $\mathcal{H}_g$ is the path integral on a torus with g-holonomy around the spatial cycle and h-holonomy around the Euclidean-time cycle. A flat G-bundle on the torus is specified by a commuting pair (g, h), modulo simultaneous conjugation. Dividing by $|G|$ is the finite gauge-volume factor. Cutting the torus along the spatial cycle gives the trace in (66.120). The modular transformations change the homology basis of the torus; the standard generators send the pair of holonomies as in (66.121). If the $H^3(G, U(1))$ anomaly has been trivialized, the defect junctions are associative, so this change of cutting is an equality of amplitudes. A nontrivial two-cocycle modifies the equality by the displayed $\epsilon(g, h)$, and the cocycle equation is exactly the condition that the two generators obey the modular group relations on the summed expression.

66.10 Twist Fields and Their Weights

A g-twist field is the endpoint, or small-circle state, of the topological line $\mathcal{L}_g$. In the parent theory it is not an ordinary local operator unless $g = 1$; a local field transported around it is acted on by g. In the orbifold theory, the C_g-invariant combinations of such defect endpoints are ordinary local operators. The term "twisted sector" therefore has an operator meaning: it is the radial Hilbert space generated by local endpoints of a fixed monodromy line.

Cyclic permutation twist weight. Let $\mathcal{C}$ have central charge c_0, and consider the cyclic permutation of K copies in $\mathcal{C}^{\otimes K}$. The ground twist field for a K-cycle has

$$h_K = \frac{c_0}{24}\left(K - \frac{1}{K}\right), \qquad \bar{h}_K = \frac{\bar{c}_0}{24}\left(K - \frac{1}{K}\right). \tag{66.122}$$

Near the twist insertion, the K-sheeted base coordinate z is covered by a single coordinate t with $z = t^K$. The total base stress tensor is the sum of the K copy stress tensors. In the cover vacuum, $\langle T(t)\rangle = 0$, and the only contribution to the base one-point function is the Schwarzian term in the stress-tensor transformation. For $t = z^{1/K}$,

$$\{t, z\} = \frac{1 - K^{-2}}{2z^2}.$$

Multiplying by the K sheets and by $c_0/12$ gives

$$\langle T_{\text{base}}(z)\rangle_{\sigma_K} = \frac{c_0}{24}\left(K - \frac{1}{K}\right)\frac{1}{z^2}.$$

The Ward identity $\langle T(z)\sigma_K(0)\rangle / \langle \sigma_K(0)\rangle = h_K/z^2$ then gives (66.122).

Free-boson rotation twist weight. For a single complex free boson Z with rotation

$$Z(\mathrm{e}^{2\pi \mathrm{i}} z, \mathrm{e}^{-2\pi \mathrm{i}}\bar{z}) = \mathrm{e}^{2\pi \mathrm{i}\alpha} Z(z, \bar{z}), \qquad 0 \le \alpha < 1,$$

the holomorphic ground twist field has

$$h_\alpha = \frac{1}{2}\alpha(1-\alpha). \tag{66.123}$$

The monodromy shifts the holomorphic oscillator moding of ∂Z and $\partial \bar{Z}$ by α and $1-\alpha$. With the convention that positive oscillator frequencies contribute $\frac{1}{2}r$ to the normal-ordering constant, the twisted zero-point contribution relative to the untwisted complex boson is

$$E_0(\alpha) - E_0(0) = \frac{1}{2}\sum_{n=0}^{\infty}(n+\alpha) + \frac{1}{2}\sum_{n=0}^{\infty}(n+1-\alpha) - \sum_{n=1}^{\infty} n.$$

The sums are not ordinary convergent sums; they define the local normal-ordering constant by Hurwitz-zeta continuation,

$$\sum_{n=0}^{\infty}(n+x) := \zeta(-1, x) = -\frac{1}{2}\left(x^2 - x + \frac{1}{6}\right).$$

At the endpoint $\alpha = 0$, this expression is read as the untwisted sector value, equivalently as the continuous limit $\alpha \downarrow 0$ after the zero-frequency mode has been omitted from the oscillator energy. Therefore

$$E_0(\alpha) - E_0(0) = \frac{1}{2}\zeta(-1,\alpha) + \frac{1}{2}\zeta(-1, 1-\alpha) - \zeta(-1,1) = \frac{1}{2}\alpha(1-\alpha).$$

The twist ground state is a Virasoro primary, and its L_0 eigenvalue is this shifted zero-point energy, giving (66.123).

For one real boson with $\mathbb{Z}_2$ reflection, this is half of the complex-boson answer at $\alpha = 1/2$:

$$h = \bar{h} = \frac{1}{16}.$$

The same number follows from the two-point function with two twist insertions and two ∂X insertions: the branch condition fixes the meromorphic differential up to a polynomial, and the $T = -\frac{1}{2} : \partial X \partial X :$ coincident limit reads off the coefficient of z^{-2} in the $T\sigma$ OPE.

66.11 Symmetric-Product Orbifolds

Let $\mathcal{C}$ be a seed CFT with central charges $(c_0, \bar{c}_0)$. For a positive integer N, the symmetric-product orbifold is

$$\mathrm{Sym}^N(\mathcal{C}) = \mathcal{C}^{\otimes N}/S_N,$$

where S_N permutes the tensor factors. The central charges before gauging are additive,

$$c_N = N c_0, \qquad \bar{c}_N = N \bar{c}_0,$$

and gauging a finite anomaly-free permutation symmetry does not change the stress-tensor OPE coefficient. Thus these are also the central charges of the orbifold theory.

A conjugacy class of S_N is a partition

$$\lambda = (1^{m_1} 2^{m_2} \cdots N^{m_N}), \qquad \sum_{K=1}^{N} K\, m_K = N.$$

For a permutation with this cycle type, the centralizer is

$$C_\lambda \simeq \prod_{K=1}^{N} \left(\mathbb{Z}_K^{m_K} \rtimes S_{m_K}\right), \qquad |C_\lambda| = \prod_{K=1}^{N} K^{m_K} m_K!. \tag{66.124}$$

The K-cycle twisted Hilbert space $\mathcal{H}_{(K)}$ is the seed Hilbert space placed on a circle of length K, with the vacuum-energy shift computed in (66.122). If a seed state has weights $(h, \bar{h})$, its corresponding long-string weights are

$$h^{(K)} = \frac{h}{K} + \frac{c_0}{24}\left(K - \frac{1}{K}\right), \qquad \bar{h}^{(K)} = \frac{\bar{h}}{K} + \frac{\bar{c}_0}{24}\left(K - \frac{1}{K}\right). \tag{66.125}$$

The cyclic subgroup $\mathbb{Z}_K \subset C_\lambda$ acts as translation by one sheet on the cover, so the $\mathbb{Z}_K$-invariant subspace imposes

$$h - \bar{h} \in K\mathbb{Z}$$

on the seed state before fractional oscillator excitations are included. For the full partition λ, the sector contribution to the orbifold Hilbert space is

$$\mathcal{H}_\lambda^{\mathrm{orb}} = \left[\bigotimes_{K=1}^{N} \mathcal{H}_{(K)}^{\otimes m_K}\right]^{C_\lambda}. \tag{66.126}$$

Consequently

$$\mathcal{H}_{\mathrm{Sym}^N(\mathcal{C})} = \bigoplus_{\lambda \vdash N} \mathcal{H}_\lambda^{\mathrm{orb}}.$$

This is the symmetric-product specialization of (66.119).

Symmetric-product torus partition function. Let

$$Z_{\mathcal{C}}(\tau,\bar\tau)=\mathrm{Tr}_{\mathcal{H}_{\mathcal{C}}}\, q^{L_0-c_0/24}\bar q^{\bar L_0-\bar c_0/24}.$$

With no discrete torsion, the generating function of symmetric-product partition functions is

$$\sum_{N=0}^{\infty} p^N Z_{\mathrm{Sym}^N(\mathcal{C})}(\tau,\bar\tau)=\exp\left[\sum_{m=1}^{\infty} p^m\, T_m Z_{\mathcal{C}}(\tau,\bar\tau)\right], \tag{66.127}$$

where the nonholomorphic Hecke transform used here is

$$T_m Z(\tau,\bar\tau)=\frac{1}{m}\sum_{\substack{ad=m\\ 0\le b<d}} Z\!\left(\frac{a\tau+b}{d},\frac{a\bar\tau+b}{d}\right). \tag{66.128}$$

Apply the finite-orbifold formula (66.120) to $G=S_N$. A commuting pair (g,h) is a finite S_N-bundle on the torus, equivalently a finite cover of the torus together with a labeling by sheets. Each connected orbit of the subgroup generated by g and h is an unbranched cover of the torus of degree m. Such a connected cover is represented by integers

$$a,d>0,\qquad ad=m,\qquad b\in\mathbb{Z}/d\mathbb{Z},$$

and its modulus is $(a\tau+b)/d$. The seed partition function on that connected cover is the summand in (66.128). The factor $1/m$ is the automorphism factor of the connected cover.

A general finite cover is a disjoint union of connected covers. The exponential in (66.127) is the ordinary exponential formula for a set of connected components, with p^m recording the degree. The coefficient of p^N is therefore the finite gauge sum over all degree-N covers, which is exactly the S_N-orbifold torus partition function.

Connected torus covers. Let $E_\tau=\mathbb{C}/(\mathbb{Z}\tau+\mathbb{Z})$, with $\mathrm{Im}\,\tau>0$. Connected unbranched degree-m covers of E_τ, with a chosen lift of the origin, are represented uniquely by integers

$$a,d>0,\qquad ad=m,\qquad 0\le b<d.$$

The covering torus has modulus

$$\tau'=\frac{a\tau+b}{d}, \tag{66.129}$$

and the number of such marked connected covers is

$$\sigma_1(m)=\sum_{d|m} d. \tag{66.130}$$

A connected unbranched cover of E_τ is equivalent to a finite-index sublattice

$$\Lambda'\subset\Lambda=\mathbb{Z}\tau+\mathbb{Z}$$

of index m. The chosen lift of the origin removes translations of the covering torus. With respect to the ordered basis $(\tau,1)$ of Λ, every index-m sublattice has a unique Hermite normal form:

$$\Lambda'=\mathbb{Z}(a\tau+b)+\mathbb{Z}d,\qquad a,d>0,\quad ad=m,\quad 0\le b<d.$$

The index is the determinant ad. Dividing the lattice by d gives an isomorphic complex torus with lattice generated by $(a\tau + b)/d$ and 1, which proves (66.129). For each divisor $d \mid m$, there are exactly d choices of b, hence (66.130).

The automorphism factor in (66.128) is also visible in this lattice description. Since Λ is abelian, every finite-index sublattice is normal, so the deck group is Λ/Λ' and has order m. Thus a connected degree-m component contributes with weight $1/m$, exactly as in the finite gauge-volume normalization of the orbifold sum.

Constant-seed covering-count test. If the seed partition function in (66.127) is replaced by the formal constant 1, then

$$T_m 1 = \frac{\sigma_1(m)}{m}$$

and

$$\exp\left[\sum_{m=1}^{\infty} p^m \frac{\sigma_1(m)}{m}\right] = \prod_{r=1}^{\infty} \frac{1}{1-p^r}. \tag{66.131}$$

Consequently the coefficient of p^N is the partition number $p_{\text{part}}(N)$, the number of conjugacy classes of S_N.

The first assertion is the connected-cover count (66.130) with the deck-automorphism factor $1/m$. For the product identity, expand the logarithm:

$$-\sum_{r=1}^{\infty} \log(1-p^r) = \sum_{r=1}^{\infty}\sum_{k=1}^{\infty} \frac{p^{rk}}{k}.$$

The coefficient of p^m in this logarithm is

$$\sum_{r|m} \frac{1}{m/r} = \frac{1}{m}\sum_{r|m} r = \frac{\sigma_1(m)}{m}.$$

Exponentiating gives (66.131). The same coefficient counts cycle types of S_N, because a cycle type is a partition $N = \sum_r r\, m_r$. This is only a finite-cover normalization test; the constant seed is not being used as a substitute for a specified unitary seed CFT.

The twist fields of the symmetric product are organized by cycle type. A bare twist field σ_λ has ground weight

$$h_\lambda = \sum_{K=1}^{N} m_K \frac{c_0}{24}\left(K - \frac{1}{K}\right), \qquad \bar{h}_\lambda = \sum_{K=1}^{N} m_K \frac{\bar{c}_0}{24}\left(K - \frac{1}{K}\right). \tag{66.132}$$

More generally, a state in the sector λ is obtained by adding seed states and fractional oscillators on each long-string component, followed by the centralizer projection in (66.126).

The operator product of twist fields is group multiplication of monodromies plus a sum over allowed long-string excitations. For representatives $\gamma, \delta \in S_N$,

$$\sigma_\gamma(z,\bar{z})\sigma_\delta(0) = \sum_{\mathcal{O}} C_{\gamma,\delta}^{\gamma\delta;\mathcal{O}}\, z^{h_{\gamma\delta,\mathcal{O}} - h_\gamma - h_\delta}\, \bar{z}^{\bar{h}_{\gamma\delta,\mathcal{O}} - \bar{h}_\gamma - \bar{h}_\delta} \sigma_{\gamma\delta,\mathcal{O}}(0) + \cdots, \tag{66.133}$$

before conjugacy-class averaging. The orbifold local operators are obtained by summing such endpoints over conjugacy classes and projecting to centralizer-invariant states. If a transposition joins two disjoint cycles of lengths K and L, the leading bare-twist exponent is controlled by

$$h_{K+L} - h_K - h_L = \frac{c_0}{24}\left[K + L - \frac{1}{K+L} - K + \frac{1}{K} - L + \frac{1}{L}\right], \tag{66.134}$$

with the analogous antiholomorphic formula. A transposition acting inside a single cycle splits it into two cycles. The covering surface of the correlator determines the numerical OPE coefficient after the seed correlator and the chosen normalization of twist fields have been specified.

Riemann–Hurwitz constraints for twist correlators. For a connected genus-zero component of a symmetric-product twist correlator, let $z_1, \ldots, z_n$ be the branch points. Choose monodromies

$$\gamma_1, \ldots, \gamma_n \in S_N$$

acting transitively on the active sheets and ordered so that

$$\gamma_1\gamma_2\cdots\gamma_n = 1. \tag{66.135}$$

Let $c(\gamma_a)$ denote the number of cycles of γ_a on those active sheets, including fixed points. If the corresponding covering surface has genus g_{cov}, then

$$g_{\text{cov}} = 1 - N + \frac{1}{2}\sum_{a=1}^{n}\bigl(N - c(\gamma_a)\bigr). \tag{66.136}$$

Thus a proposed leading twist correlator must pass three finite tests before any seed-CFT correlator is evaluated: the monodromy product is the identity, the generated subgroup is transitive on the active sheets, and the integer (66.136) is a nonnegative genus.

The monodromies specify the connected covering of the punctured sphere. A cycle of length r over z_a contributes ramification $r-1$. Summing over all cycles of γ_a gives

$$\sum_{\text{cycles } C\subset\gamma_a}(|C| - 1) = N - c(\gamma_a). \tag{66.137}$$

Riemann–Hurwitz for a degree-N map $\widehat{\Sigma} \to \mathbb{P}^1$ says

$$2 - 2g_{\text{cov}} = 2N - \sum_{a=1}^{n}\bigl(N - c(\gamma_a)\bigr).$$

Solving for g_{cov} gives (66.136). The identity product is the statement that the loop enclosing all branch points on the sphere is contractible, and transitivity is exactly connectedness of the active cover.

Example 66.26 (Two-point and primitive joining covers)**.** For a normalized two-point function of length-K twists, take active degree $N = K$ and monodromies

$$\gamma = (1\,2\,\cdots\,K), \qquad \gamma^{-1}.$$

Both have one cycle on the active sheets, so

$$g_{\mathrm{cov}} = 1 - K + \frac{1}{2}\big((K-1) + (K-1)\big) = 0. \tag{66.138}$$

For a primitive connected three-point joining component, let

$$\alpha = (1\,2\,\cdots\,K), \qquad \beta = (K\,K+1\,\cdots\,K+L-1), \qquad \gamma = (\alpha\beta)^{-1}, \tag{66.139}$$

where $K, L \geq 2$. The active degree is $N = K + L - 1$. The product is $\alpha\beta\gamma = 1$, and α, β overlap on the sheet K, so the generated subgroup is transitive. The product $\alpha\beta$ is a single cycle of length $K + L - 1$. Hence

$$c(\alpha) = L, \qquad c(\beta) = K, \qquad c(\gamma) = 1,$$

where fixed points on the active sheets are included. Formula (66.136) gives

$$g_{\mathrm{cov}} = 1 - (K + L - 1) + \frac{1}{2}\big((K-1) + (L-1) + (K+L-2)\big) = 0. \tag{66.140}$$

This genus-zero calculation fixes the covering topology. It does not determine the OPE coefficient without the seed correlator, local coordinate choices at the branch points, and the normalization of the twist fields.

Proposition 66.27 (Primitive joining cover in local coordinates)**.** *Let $K, L \geq 2$, and set $N = K + L - 1$. After moving the three branch points on the base sphere to $0, 1, \infty$, the primitive joining cover of Example 66.26 has a polynomial representative*

$$z_{K,L}(t) = B_{K,L}^{-1} \int_0^t u^{K-1}(u-1)^{L-1}\,\mathrm{d}u, \qquad B_{K,L} = (-1)^{L-1}\frac{(K-1)!(L-1)!}{N!}. \tag{66.141}$$

It is a degree-N map $\mathbb{P}^1_t \to \mathbb{P}^1_z$ with ramification indices K, L, N over $z = 0, 1, \infty$, respectively. More precisely, the local expansions are

$$z_{K,L}(t) = \binom{N}{K} t^K + O(t^{K+1}), \tag{66.142}$$

$$z_{K,L}(t) - 1 = (-1)^{L-1}\binom{N}{L}(t-1)^L + O((t-1)^{L+1}), \tag{66.143}$$

$$\frac{1}{z_{K,L}(t)} = (-1)^{L-1}\frac{(K-1)!(L-1)!}{(N-1)!}\, s^N + O(s^{N+1}), \qquad s = \frac{1}{t}. \tag{66.144}$$

Proof. The integral in (66.141) is a polynomial of degree N, because its derivative is

$$\frac{\mathrm{d}z_{K,L}}{\mathrm{d}t} = B_{K,L}^{-1} t^{K-1}(t-1)^{L-1}.$$

The beta-integral normalization gives

$$\int_0^1 u^{K-1}(u-1)^{L-1}\,\mathrm{d}u = (-1)^{L-1}\frac{(K-1)!(L-1)!}{(K+L-1)!} = B_{K,L},$$

so $z_{K,L}(0) = 0$ and $z_{K,L}(1) = 1$. The derivative factorization shows that the only finite critical points are $t = 0$ with multiplicity $K-1$ and $t = 1$ with multiplicity $L-1$. Since $z_{K,L}$ is a degree-N

polynomial, the point $t = \infty$ maps to $z = \infty$ with ramification index N. There are no further branch points, because the total finite critical multiplicity is $(K-1)+(L-1) = N-1$, the finite critical multiplicity of a degree-N polynomial with a single point above infinity.

The local coefficient at $t = 0$ is obtained by replacing $(u-1)^{L-1}$ by its constant term $(-1)^{L-1}$:

$$B_{K,L}^{-1}\frac{(-1)^{L-1}}{K} = \frac{N!}{K!(L-1)!} = \binom{N}{K}.$$

Near $t = 1$, write $u = 1 + v$. The first nonzero term is

$$B_{K,L}^{-1}\frac{(t-1)^L}{L} = (-1)^{L-1}\frac{N!}{(K-1)!L!}(t-1)^L = (-1)^{L-1}\binom{N}{L}(t-1)^L.$$

Finally, the leading term at infinity is

$$z_{K,L}(t) = \frac{B_{K,L}^{-1}}{N}t^N + O(t^{N-1}).$$

Inverting this leading term and using $s = 1/t$ gives (66.144). These local coefficients are the Jacobian data that enter a covering-space path-integral calculation. A numerical OPE coefficient still requires the seed correlator, the twist-field normalization, and a regulator convention for the Liouville or Schwarzian anomaly associated with the chosen local coordinates. □

Schwarzian and OPE-exponent calculation for primitive joining. Assume the seed theory is in the cover vacuum near the branch points and that the bare twist fields are normalized as Virasoro primaries with weights

$$h_r = \frac{c_0}{24}\left(r - \frac{1}{r}\right), \qquad \bar{h}_r = \frac{\bar{c}_0}{24}\left(r - \frac{1}{r}\right).$$

Let $z - z_a = aw^r + O(w^{r+1})$, with $a \neq 0$, be a local ramified cover coordinate of index r. Then the Schwarzian contribution to the base stress-tensor one-point function has double-pole coefficient h_r:

$$\langle T_{\text{base}}(z)\rangle = \frac{h_r}{(z-z_a)^2} + O((z-z_a)^{-1}). \tag{66.145}$$

For the primitive joining branch data of Proposition 66.27, with $N = K + L - 1$, the holomorphic OPE power in the channel

$$(K)\cdot(L) \longrightarrow (N)$$

is therefore

$$h_N - h_K - h_L = \frac{c_0}{24}\left[N - \frac{1}{N} - K + \frac{1}{K} - L + \frac{1}{L}\right], \tag{66.146}$$

with the analogous antiholomorphic formula using $\bar{c}_0$. Equivalently, before conjugacy-class averaging and before inserting excited seed states,

$$\sigma_K(z,\bar{z})\sigma_L(0) = C_{K,L}^N\, z^{h_N-h_K-h_L}\,\bar{z}^{\bar{h}_N-\bar{h}_K-\bar{h}_L}\sigma_N(0) + \cdots, \tag{66.147}$$

where $C_{K,L}^N$ is not fixed by the covering and Schwarzian calculation alone.

Verification. The inverse branches near z_a have the form

$$w_j(z) = \omega_r^j a^{-1/r}(z - z_a)^{1/r} + O((z - z_a)^{2/r}), \qquad j = 0, \dots, r-1.$$

The leading Schwarzian of any such branch is independent of a and of the root label:

$$\{w_j, z\} = \frac{1 - r^{-2}}{2(z - z_a)^2} + O((z - z_a)^{-1}).$$

Using the stress-tensor transformation law (60.24) in the inverse direction, and using the cover-vacuum assumption, the ramified point contributes

$$\frac{c_0}{12} \sum_{j=0}^{r-1} \frac{1 - r^{-2}}{2(z - z_a)^2} = \frac{c_0}{24} \left(r - \frac{1}{r} \right) \frac{1}{(z - z_a)^2}.$$

Unramified preimages over the same base point have regular inverse branches and do not contribute to the double pole. This proves (66.145).

For three primary insertions at z_1, z_2, z_3, global conformal covariance fixes the holomorphic coordinate dependence to

$$C\, z_{12}^{h_3 - h_1 - h_2} z_{13}^{h_2 - h_1 - h_3} z_{23}^{h_1 - h_2 - h_3}.$$

Applying this with branch indices K, L, N and then taking the OPE limit of the K- and L-twists gives (66.146) and (66.147). The constant $C_{K,L}^N$ also contains the cover anomaly functional, the local coordinate coefficients in (66.142)–(66.144), the chosen twist-field normalization, and any nontrivial seed correlator. Those data are not determined by monodromy, Riemann–Hurwitz, or conformal covariance alone.

Lemma 66.28 (Conjugacy-class normalization for primitive joining)**.** *Let M be the total number of copies in $\mathrm{Sym}^M(\mathcal{C})$. For $r \le M$, let $[r] \subset S_M$ denote the conjugacy class consisting of one r-cycle and $M - r$ fixed points, and assume the labelled bare twists are normalized by*

$$\langle \sigma_\gamma(\infty) \sigma_\delta(0) \rangle = \delta_{\delta, \gamma^{-1}}.$$

The normalized single-cycle class operator is then

$$\Sigma_r^{(M)} = |[r]|^{-1/2} \sum_{\gamma \in [r]} \sigma_\gamma, \qquad |[r]| = \frac{M!}{r(M - r)!}. \tag{66.148}$$

Let $K, L \ge 2$, set $R = K + L - 1$, and assume $M \ge R$. If $C_{K,L}^R$ denotes the labelled primitive joining coefficient in (66.147), with the same local coordinate and seed-correlator convention for all conjugates, then the class-normalized leading primitive channel has the form

$$\Sigma_K^{(M)}(z, \bar z) \Sigma_L^{(M)}(0) \supset \mathfrak{g}_{K,L}^{(M)}\, C_{K,L}^R\, z^{h_R - h_K - h_L} \bar z^{\bar h_R - \bar h_K - \bar h_L} \Sigma_R^{(M)}(0), \tag{66.149}$$

where no additional symmetry factor is inserted in the operator product, and

$$\left(\mathfrak{g}_{K,L}^{(M)} \right)^2 = KLR\, \frac{(M - K)!(M - L)!}{M!(M - R)!}. \tag{66.150}$$

Equivalently, $\mathfrak{g}_{K,L}^{(M)} = R\sqrt{|[R]|/(|[K]||[L]|)}$. Thus the class-sum normalization supplies a universal finite-group factor, while $C_{K,L}^R$ remains the analytic covering-space coefficient discussed in the Schwarzian/OPE exponent calculation above.

Proof. The class-size formula in (66.148) follows by choosing the r-element support and then choosing a cyclic ordering:

$$\binom{M}{r}(r-1)! = \frac{M!}{r(M-r)!}.$$

Since inversion preserves the conjugacy class $[r]$, the labelled diagonal two-point normalization gives

$$\left\langle \Sigma_r^{(M)}(\infty)\Sigma_r^{(M)}(0)\right\rangle = |[r]|^{-1}\sum_{\gamma,\delta\in[r]}\delta_{\delta,\gamma^{-1}} = 1.$$

It remains to count primitive factorizations of a fixed R-cycle η. Write the support of η in cyclic order as

$$x_0 \longmapsto x_1 \longmapsto \cdots \longmapsto x_{R-1} \longmapsto x_0.$$

For each choice of the unique overlap sheet x_j, indices understood modulo R, define

$$\alpha_j = (x_{j-K+1}\, x_{j-K+2}\, \cdots\, x_j), \qquad \beta_j = (x_j\, x_{j+1}\, \cdots\, x_{j+L-1}).$$

With the convention that products act from right to left, one checks directly that $\alpha_j\beta_j = \eta$. These are R distinct factorizations. Conversely, if α is a K-cycle and β is an L-cycle with $\alpha\beta = \eta$, then the support of η has size $K+L-1$. If the supports of α and β were disjoint, the product would have two nontrivial cycles rather than one. If their intersection had more than one element, the union of the supports would have size strictly smaller than $K+L-1$, too small to contain the support of η. Thus the supports meet in exactly one sheet and their union is the support of η. Removing the overlap sheet cuts the two cycles into two directed strings, and their concatenation is the displayed cyclic order of η. The overlap sheet therefore reconstructs α and β uniquely, so the number of primitive factorizations of a fixed $\eta \in [R]$ is R.

When the two normalized class sums are multiplied, each fixed $\eta \in [R]$ therefore receives R labelled primitive contributions. Projecting the resulting sum

$$\frac{R\, C_{K,L}^{R}}{\sqrt{|[K]||[L]|}}\sum_{\eta\in[R]}\sigma_\eta$$

onto $\Sigma_R^{(M)} = |[R]|^{-1/2}\sum_{\eta\in[R]}\sigma_\eta$ gives

$$\mathfrak{g}_{K,L}^{(M)} = R\sqrt{\frac{|[R]|}{|[K]||[L]|}}.$$

Substituting the class-size formula and using $R = K+L-1$ gives (66.150). □

Lemma 66.29 (Transposition class algebra: join and split factors)**.** *Let $\Sigma_2^{(M)}$ be the normalized transposition class operator from* (66.148)*. Assume the same labelled twist normalization as in Lemma 66.28. For $K \geq 2$ and $M \geq K+1$, the class-normalized channel in which a transposition joins a fixed point to a K-cycle is*

$$\Sigma_2^{(M)}(z,\bar z)\Sigma_K^{(M)}(0) \supset \mathfrak{j}_K^{(M)}\, C_{2,K}^{K+1}\, z^{h_{K+1}-h_2-h_K}\,\bar z^{\bar h_{K+1}-\bar h_2-\bar h_K}\,\Sigma_{K+1}^{(M)}(0), \tag{66.151}$$

with

$$\left(\mathfrak{j}_K^{(M)}\right)^2 = 2K(K+1)\frac{M-K}{M(M-1)}. \tag{66.152}$$

For a split channel, let $K \geq 4$, let $a, b \geq 2$, and let $a + b = K$. Let $[a, b] \subset S_M$ be the conjugacy class with one a-cycle, one b-cycle, and $M - K$ fixed points, and define

$$\Sigma_{a,b}^{(M)} = |[a, b]|^{-1/2} \sum_{\eta \in [a,b]} \sigma_\eta.$$

Then

$$\Sigma_2^{(M)}(z, \bar{z})\Sigma_K^{(M)}(0) \supset \mathfrak{s}_{a,b}^{(M)}\, C_{2,K}^{a,b}\, z^{h_a+h_b-h_2-h_K}\, \bar{z}^{\bar{h}_a+\bar{h}_b-\bar{h}_2-\bar{h}_K} \Sigma_{a,b}^{(M)}(0), \tag{66.153}$$

where $C_{2,K}^{a,b}$ is the labelled split-channel coefficient and

$$\left(\mathfrak{s}_{a,b}^{(M)}\right)^2 = \frac{2Kab}{(1 + \delta_{a,b})M(M - 1)}. \tag{66.154}$$

If one piece is a fixed point, say $K = b + 1$ with $b \geq 2$, the output class is the single-cycle class $[b]$ and the endpoint split factor is

$$\left(\mathfrak{s}_{1,b}^{(M)}\right)^2 = 2(b + 1)b\, \frac{M - b}{M(M - 1)}. \tag{66.155}$$

Proof. The join channel is the special case $L = 2$ of Lemma 66.28. Substituting $R = K + 1$ into (66.150) gives (66.152).

For the split channel, fix a permutation $\eta = \alpha\beta$, where α and β are disjoint cycles of lengths a and b. If p is in the support of α and q is in the support of β, then $\tau = (p\, q)$ cuts and reglues the two directed cycles into a single K-cycle

$$\gamma = \tau\eta.$$

Since $\tau^2 = 1$, this is equivalent to $\tau\gamma = \eta$. Conversely, if $\tau\gamma = \eta$ with τ a transposition and γ a K-cycle, then τ cannot involve a fixed point of η, because then $\gamma = \tau\eta$ would move a sheet outside the support of η. It also cannot exchange two points in the same component of η: the other component would remain invariant under γ, contradicting the assumption that γ is a single K-cycle. Hence τ must connect one point of the a-cycle to one point of the b-cycle, so a fixed output $\eta \in [a, b]$ has exactly

$$ab$$

labelled split factorizations.

The class size is

$$|[a, b]| = \frac{M!}{ab(1 + \delta_{a,b})(M - K)!},$$

where the factor $1 + \delta_{a,b}$ is the permutation symmetry of the two equal-length cycles when $a = b$. Projecting

$$\frac{ab\, C_{2,K}^{a,b}}{\sqrt{|[2]||[K]|}} \sum_{\eta \in [a,b]} \sigma_\eta$$

onto $\Sigma_{a,b}^{(M)}$ gives

$$\left(\mathfrak{s}_{a,b}^{(M)}\right)^2 = a^2b^2 \frac{|[a, b]|}{|[2]||[K]|}.$$

Using $|[2]| = M!/(2(M-2)!)$ and $|[K]| = M!/(K(M-K)!)$ gives (66.154).

If one component has length 1, fix the nontrivial output b-cycle β. The split-off fixed point may be any of the $M-b$ sheets outside the support of β, and the cut point on β may be chosen in b ways. Thus a fixed output $\beta \in [b]$ receives $b(M-b)$ labelled factorizations. Projecting to the single-cycle class $\Sigma_b^{(M)}$ and using $K = b+1$ gives (66.155). This is the same finite factor as the join coefficient $\mathrm{j}_b^{(M)}$, as required by the diagonal two-point normalization. □

Discrete torsion is incorporated by replacing the centralizer projection by a projective centralizer action determined by a class in

$$H^2(S_N, U(1)).$$

For S_N, this group is trivial for $N \le 3$ and is $\mathbb{Z}_2$ for $N \ge 4$. The choice changes the phases in the commuting-pair sum and the projective representation carried by twisted-sector ground states. It is part of the orbifold definition.

66.12 Twist-Field Deformations

Let $\{\sigma_A\}$ be spinless orbifold local fields built from twisted sectors, with dimensions

$$\Delta_A = h_A + \bar{h}_A, \qquad s_A = h_A - \bar{h}_A \in \mathbb{Z}.$$

A deformation by twist fields is specified by the conformal-perturbation series

$$\langle X \rangle_\lambda = \left\langle \exp\left(-\sum_A \lambda^A \int_\Sigma \mathrm{d}^2 z\, \sigma_A(z, \bar{z}) \right) X \right\rangle_{\mathcal{C}/G} \tag{66.156}$$

with a regulator for collision points and with local counterterms determined by the OPEs of the σ_A. The coupling dimension is

$$[\lambda^A] = 2 - \Delta_A.$$

Separate this engineering dimension from the operator-theoretic obstruction as follows. Choose a local flat coordinate patch and a short-distance cutoff a. Write dimensionless couplings $g^A(a)$ by

$$S_{\text{int}}(a) = \sum_A g^A(a)\, a^{\Delta_A - 2} \int \mathrm{d}^2 z\, \sigma_A(z, \bar{z}), \qquad y_A = 2 - \Delta_A.$$

Proposition 66.30 (Cutoff OPE beta function)**.** *Assume that the spinless primary fields σ_A have diagonal two-point normalization and short-distance OPE*

$$\sigma_B(z, \bar{z}) \sigma_C(0) \sim \sum_A C_{BC}{}^A |z|^{\Delta_A - \Delta_B - \Delta_C} \sigma_A(0) + \textit{descendants and other spins.} \tag{66.157}$$

In the minimal annular cutoff scheme that discards derivative descendants and projects to the listed spinless primaries, the length-scale Wilsonian beta function

$$\beta_\ell^A = \frac{\mathrm{d}g^A}{\mathrm{d}\ell}, \qquad \ell = \log a,$$

is

$$\beta_\ell^A = y_A g^A - \pi C_{BC}{}^A g^B g^C + O(g^3), \tag{66.158}$$

with ordered repeated indices. Equivalently, for the energy scale $\mu = a^{-1}$*,*

$$\mu \frac{\mathrm{d}g^A}{\mathrm{d}\mu} = -y_A g^A + \pi C_{BC}{}^A g^B g^C + O(g^3). \tag{66.159}$$

Proof. Expand $\exp(-S_{\text{int}})$ to second order and isolate pairs with relative coordinate $r = z - w$ in the annulus $a < |r| < ae^{\mathrm{d}\ell}$. The term in the exponential is

$$\frac{1}{2} g^B g^C a^{\Delta_B+\Delta_C-4} \int \mathrm{d}^2 w \int_{a<|r|<ae^{\mathrm{d}\ell}} \mathrm{d}^2 r\, \sigma_B(w+r)\sigma_C(w).$$

Using (66.157), the contribution to the $\sigma_A(w)$ channel is

$$\frac{1}{2} g^B g^C C_{BC}{}^A a^{\Delta_B+\Delta_C-4} \int \mathrm{d}^2 w\, \sigma_A(w) \int_a^{ae^{\mathrm{d}\ell}} 2\pi\rho\, \mathrm{d}\rho\, \rho^{\Delta_A-\Delta_B-\Delta_C}.$$

To first order in $\mathrm{d}\ell$, the radial integral is

$$2\pi\, \mathrm{d}\ell\, a^{2+\Delta_A-\Delta_B-\Delta_C},$$

so the local term is

$$\pi\, g^B g^C C_{BC}{}^A\, \mathrm{d}\ell\, a^{\Delta_A-2} \int \mathrm{d}^2 w\, \sigma_A(w).$$

Because this term appears with a plus sign in the expansion of $\exp(-S_{\text{int}})$, it decreases the local coefficient in S_{int} by the same amount. The classical rescaling of the dimensionless coupling contributes $y_A g^A \mathrm{d}\ell$. Combining the two effects gives (66.158), and (66.159) follows from $\log\mu = -\ell$. □

Remark 66.31 (Contact terms and coupling coordinates). A local contact convention is a choice of finite counterterms supported at operator collisions. To quadratic order it is equivalently a coupling coordinate change

$$g'^A = g^A + M^A{}_{BC} g^B g^C + O(g^3).$$

If

$$\beta_\ell^A = y_A g^A + b^A{}_{BC} g^B g^C + O(g^3),$$

then

$$b'^A{}_{BC} = b^A{}_{BC} + (y_B + y_C - y_A) M^A{}_{BC}. \tag{66.160}$$

Indeed,

$$\frac{\partial g'^A}{\partial g^D} \beta_\ell^D = y_A g^A + \left(b^A{}_{BC} + (y_B + y_C) M^A{}_{BC}\right) g^B g^C + O(g^3),$$

and substituting $g^A = g'^A - M^A{}_{BC} g'^B g'^C + O(g'^3)$ gives (66.160). Thus a quadratic term is scheme-invariant only in resonant channels $y_A = y_B + y_C$, including the marginal-to-marginal channel $y_A = y_B = y_C = 0$. Exact marginality of a spinless dimension-two twist deformation therefore starts with the condition that the projection of $C_{BC}{}^A$ to dimension-two nonredundant primaries vanish in the chosen operator algebra; higher orders require the full contact-term calculus, not only the bare group-theoretic monodromy.

The relevance classification is the linear part of (66.158): if $\Delta_A < 2$, then $y_A > 0$ and the coupling grows toward longer distances; if $\Delta_A = 2$, the first nontrivial obstruction is the dimension-two projection of the quadratic OPE coefficient in (66.159).

In the symmetric-product case of Section 66.11, a deformation by a single seed operator has the untwisted form

$$\mathcal{O}_{\mathrm{seed},N} = \sum_{i=1}^{N} \mathcal{O}_i. \tag{66.161}$$

It changes the seed CFT in every copy. A deformation that joins and splits cycles is built instead from conjugacy-class sums of twist fields, for example

$$\mathcal{O}_{[2]} = \frac{1}{\sqrt{N(N-1)/2}} \sum_{1\le i<j\le N} \mathcal{O}_{(ij)}, \tag{66.162}$$

where $\mathcal{O}_{(ij)}$ is a specified dressed transposition-twist operator. The normalization gives an order-one two-point function when the individual twist operators are orthonormal in the orbifold two-point normalization.

In supersymmetric symmetric products the undressed twist-sector ground field is one ingredient in the physical marginal operator. Fermion zero modes, R-symmetry spin fields, or supercurrent descendants supply the additional quantum numbers so that the final operator is invariant, spinless, and has $(h, \bar{h}) = (1, 1)$. The following construction is the local CFT datum behind the example often called the D1–D5 symmetric-product point.

Construction 66.32 ($\mathcal{N} = (4, 4)$ two-cycle marginal tangent)**.** Let $\mathcal{C}_0$ be a compact unitary seed CFT with small $\mathcal{N} = (4, 4)$ symmetry and

$$c_0 = \bar{c}_0 = 6.$$

Let $\mathrm{Sym}^N(\mathcal{C}_0)$ be the finite orbifold defined in Section 66.11. For a transposition (ij), the bare twist ground field has

$$h_{\mathrm{bare}} = \bar{h}_{\mathrm{bare}} = \frac{6}{24}\left(2 - \frac{1}{2}\right) = \frac{3}{8}. \tag{66.163}$$

Assume that the transposition sector contains an S_N-covariant spin-field dressing $S^A_{(ij)}\widetilde{S}^B_{(ij)}$ of weights $(1/8, 1/8)$ and R-symmetry quantum numbers such that

$$\chi^{AB}_{(ij)} = \sigma_{(ij)} S^A_{(ij)} \widetilde{S}^B_{(ij)} \tag{66.164}$$

is an $\mathcal{N} = (4, 4)$ chiral primary with

$$h_\chi = \bar{h}_\chi = \frac{1}{2}.$$

Let $G^a_{-1/2}$ and $\widetilde{G}^{\dot{a}}_{-1/2}$ be left and right supercharge modes in a convention where each mode raises h or $\bar{h}$ by $1/2$. Contract the R-symmetry indices to a singlet in one of the allowed short multiplets and define

$$\mathcal{O}^{\mathfrak{a}}_{\mathrm{blow}} = \frac{1}{\sqrt{N(N-1)/2}} \sum_{1\le i<j\le N} \Pi^{\mathfrak{a}}_{a\dot{a},AB}\, G^a_{-1/2} \widetilde{G}^{\dot{a}}_{-1/2} \chi^{AB}_{(ij)}. \tag{66.165}$$

Here $\Pi^{\mathfrak{a}}$ is a fixed invariant tensor selecting one real component of the short multiplet. The normalization is the same conjugacy-class normalization as (66.162). The operator $\mathcal{O}^{\mathfrak{a}}_{\mathrm{blow}}$ is spinless and has

$$(h, \bar{h}) = (1, 1).$$

It is the local two-cycle blow-up tangent operator. Its integration defines an exactly marginal coordinate precisely when the $\mathcal{N} = (4,4)$-preserving contact-term and current-moment-map obstructions in the source-coordinate criterion of Section 56.3 vanish or, more strongly, when the surrounding local conformal-family datum is constructed.

The construction separates three different facts that are often compressed together. First, the equality $(h, \bar{h}) = (1, 1)$ is a representation theory statement:

$$\frac{3}{8} + \frac{1}{8} + \frac{1}{2} = 1$$

on the left and similarly on the right. Second, the S_N-invariant class sum is a finite-orbifold projection, not a geometric quotient operation on operators. Third, exact marginality is an integrability statement in renormalized conformal perturbation theory. It requires absence of nonredundant dimension-two obstructions in the OPE of the top components and compatibility with the $\mathcal{N} = (4,4)$ Ward identities.

The local tangent-space count for the standard compact examples is then a protected multiplet count, not a claim extracted from a low-energy geometric picture. Let d_{seed} be the real dimension of the seed $\mathcal{N} = (4,4)$ conformal-family tangent space. The untwisted seed directions give the operators

$$\sum_{i=1}^{N} \mathcal{O}_i^{\alpha}, \qquad \alpha = 1, \ldots, d_{\mathrm{seed}},$$

and the transposition short multiplet contributes four real blow-up directions in (66.165). Thus the local protected tangent count is

$$d_{\mathrm{local}} = d_{\mathrm{seed}} + 4. \tag{66.166}$$

For a toroidal seed with Narain moduli

$$SO(4,4)/(SO(4) \times SO(4)),$$

one has $d_{\mathrm{seed}} = 16$, hence $d_{\mathrm{local}} = 20$. This is the local CFT count underlying the tangent space of

$$SO(5,4)/(SO(5) \times SO(4)).$$

For a K3 seed, the seed sigma-model tangent space has real dimension 80, and the symmetric-product blow-up multiplet gives 84, matching the local dimension of

$$SO(4,21)/(SO(4) \times SO(21)).$$

The arithmetic quotients and singular loci of these spaces require the integral charge lattice and the global CFT identification group; they are global data beyond the local tangent construction above.

A current-current expression such as $J\bar{J}$ defines an exactly marginal deformation only after the current algebra, OPE coefficient, and contact-term scheme have been specified; in a symmetric product one must additionally specify whether the operator is the untwisted seed sum (66.161), a single-cycle/twist-sector operator such as (66.162), or a multi-cycle product.

66.13 Development Tasks for the CFT Volume

The material in this chapter is the entry point for a larger two-dimensional CFT development. Subsequent passes must expand the following topics in the same formalism:

higher-genus sewing of Narain and toroidal CFT correlators,
WZW and gauged WZW/coset sigma-model CFTs,
Buscher duality as an equality of regulated path integrals,
orbifold defects, discrete torsion, and anomaly obstructions,
higher-point Hurwitz sums and normalized twist OPE coefficients,
supersymmetric twist fields and exactly marginal blow-up modes.

Each item requires explicit operator definitions, modular and sewing compatibility, and examples with computable correlators. In particular, twist-field deformations are deformations of a fully specified QFT; geometric resolution language is secondary and must be backed by operator construction.

Chapter 67

Vertex Operator Algebras, Modular Sewing, and Logarithmic CFT

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter treats chiral algebra as the algebraic coordinate system for two-dimensional CFT, but it keeps that coordinate system distinct from the analytic construction of a full QFT on surfaces. The first layer is formal: VOA locality, modes, Zhu's algebra, minimal-model characters, Coulomb-gas screenings, and logarithmic pseudo-traces are algebraic or finite-level statements once the relevant modules are specified. The second layer is analytic within a fixed channel: chiral blocks, Gram/Shapovalov projectors, trace-class propagation factors, and direct-integral OPE decompositions require convergence, topological vector spaces, and positive pairings. The third layer is global sewing: local plumbing estimates have to be continued across moduli space and compared between pants decompositions before they become a modular functor or a full CFT. The fourth layer is operator algebraic: conformal nets and strongly local VOAs replace formal fields by von Neumann algebras and make the domain-to-locality passage a theorem boundary rather than a slogan.

The chapter's quoted-theorem boundaries are therefore not all of the same kind. Zhu classification and rational character modularity import finite cofiniteness and trace-recursion theorems beyond the local top-level calculations. Complete rationality of conformal nets imports subfactor/DHR machinery after the localized-endomorphism mechanism has been displayed. Strong locality of VOAs imports analytic estimates turning smeared fields on a common smooth domain into local von Neumann algebras. Rational sewing imports analytic continuation and mapping-class compatibility beyond fixed plumbing charts. Nonrational and logarithmic CFT require still different replacements for finite semisimple sums: direct integrals, measurable fusing kernels, projective pseudo-traces, modified traces, and nonsemisimple tensor-category data. The local calculations below are included to expose these mechanisms; they are not meant to hide the remaining analytic existence problem.

67.1 Chiral Algebra Data

Two-dimensional conformal field theory has an additional algebraic structure: local holomorphic fields may be multiplied by operator products that depend only on one complex coordinate. A vertex operator algebra is the precise algebraic encoding of this chiral operator product.

Definition 67.1 (Vertex operator algebra)**.** A vertex operator algebra consists of the following data.

1. A complex vector space
$$V = \bigoplus_{n\in\mathbb{Z}} V_n$$
with finite-dimensional graded pieces and $V_n = 0$ for n sufficiently negative.
2. A vacuum vector $\mathbf{1} \in V_0$.
3. A state-field map
$$Y(\,\cdot\,, z) : V \longrightarrow \mathrm{End}(V)[[z, z^{-1}]], \qquad a \longmapsto Y(a, z) = \sum_{m\in\mathbb{Z}} a_m z^{-m-1}.$$
4. A conformal vector $\omega \in V_2$, whose modes
$$Y(\omega, z) = \sum_{n\in\mathbb{Z}} L_n z^{-n-2}$$
obey the Virasoro algebra
$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}(m^3 - m)\delta_{m+n,0}.$$

These data satisfy:
$$Y(\mathbf{1}, z) = \mathrm{id}_V, \qquad Y(a, z)\mathbf{1} \in a + zV[[z]],$$
$$[L_{-1}, Y(a, z)] = \partial_z Y(a, z), \qquad L_0 a = na \quad \text{for } a \in V_n,$$
and locality: for every $a, b \in V$, there is $N \geq 0$ such that
$$(z-w)^N [Y(a, z), Y(b, w)] = 0$$
as a formal distribution on V.

The modes a_m are operators on V. If a has conformal weight Δ_a, then a_m has degree $\Delta_a - m - 1$. The vacuum axiom says that a is recovered from the field $Y(a, z)$ by acting on the vacuum and then taking the value at $z = 0$:
$$a = Y(a, z)\mathbf{1}\big|_{z=0}.$$

The locality axiom is the algebraic form of the chiral OPE. It implies the Jacobi identity for modes, and conversely the Jacobi identity packages locality, associativity, and commutativity of OPE expansions.

Proposition 67.2 (OPE from VOA locality). *For $a, b \in V$, the product $Y(a,z)Y(b,w)$ has an expansion in the region $|z| > |w|$ of the form*

$$Y(a,z)Y(b,w) = \sum_{m\in\mathbb{Z}} Y(a_m b, w)(z-w)^{-m-1},$$

where for each matrix element only finitely many positive powers of $(z-w)^{-1}$ occur.

Proof. Fix $a, b \in V$. Lower truncation says that $a_m b = 0$ for all sufficiently large m; hence the singular part of the candidate expansion has only finitely many negative powers of $z - w$ in every matrix element. Locality gives an integer N such that

$$(z-w)^N Y(a,z)Y(b,w) = (z-w)^N Y(b,w)Y(a,z)$$

as formal distributions. The coefficient of $(z-w)^{-m-1}$ in the singular part is determined by the formal residue

$$a_m b = \mathrm{Res}_{z-w}(z-w)^m Y(a,z)b.$$

For $m < N$, these residues specify the complete principal part at $z = w$. Subtract the finite sum of principal parts from $Y(a,z)Y(b,w)$. After multiplication by $(z-w)^N$, locality makes the difference regular at $z = w$, so the remaining term is the Taylor expansion in nonnegative powers of $z - w$ in the region $|z| > |w|$. Equivalently, all matrix elements against graded-dual vectors agree as Laurent series in that region. This is the displayed OPE, and lower truncation gives the finiteness of its singular part. □

67.2 Modules, Characters, and Chiral Blocks

A V-module M is a graded vector space with fields

$$Y_M(a,z) = \sum_{m\in\mathbb{Z}} a_m^M z^{-m-1}$$

obeying the same vacuum, translation, and locality identities with one entry acting on M. The conformal vector gives an operator L_0 on M. For an ordinary positive-energy module,

$$M = \bigoplus_{\lambda\in\mathbb{C}} M_\lambda, \qquad \dim M_\lambda < \infty,$$

and the set of λ's is bounded below in every coset modulo $\mathbb{Z}$. The character is

$$\chi_M(\tau) = \mathrm{Tr}_M\, q^{L_0 - c/24}, \qquad q = \mathrm{e}^{2\pi\mathrm{i}\tau}, \qquad \mathrm{Im}\,\tau > 0. \tag{67.1}$$

The shift by $c/24$ is the cylinder vacuum energy fixed by the conformal map from the plane to the circle.

Let C be a compact Riemann surface with marked points p_i, local coordinates z_i at the marked points, and V-modules M_i. A chiral conformal block is a linear functional

$$\mathcal{F} : \bigotimes_i M_i \longrightarrow \mathbb{C}$$

that obeys the Ward identities for meromorphic chiral fields on C. For the stress tensor, the identity says that inserting a meromorphic vector field regular away from the p_i's acts by the sum of the corresponding Virasoro modes at the marked points and gives zero. For a general chiral state $a \in V$, the meromorphic one-form valued in the field a gives the same condition with modes of $Y_{M_i}(a, z_i)$.

On the sphere with three marked points, conformal blocks are intertwiners. If M_i, M_j, M_k are simple modules, the fusion coefficient is

$$N_{ij}{}^{k} := \dim \mathrm{CB}_{0,3}(M_i, M_j, M_k^\vee),$$

where $M_k^\vee$ is the contragredient module. This definition is intrinsic: it counts chiral three-point structures, not a particular coordinate presentation of a three-point function.

67.3 Zhu Algebra and Top Levels

The character and sewing constructions use the whole graded module. The classification of ordinary modules begins with a smaller algebra obtained from genus-one coordinate changes. This algebra is Zhu's algebra. Its role in the monograph is structural: it converts the lowest-energy part of a positive-energy module into a finite algebraic object, while leaving the reconstruction of the full module to the VOA theorem boundary.

Let $a \in V$ be homogeneous of conformal weight Δ_a, and write

$$Y(a, z) = \sum_{n \in \mathbb{Z}} a_n z^{-n-1}.$$

Define bilinear operations on V by

$$a * b := \mathrm{Res}_{z=0} \frac{(1+z)^{\Delta_a}}{z} Y(a, z) b = \sum_{j \geq 0} \binom{\Delta_a}{j} a_{j-1} b, \tag{67.2}$$

$$a \circ b := \mathrm{Res}_{z=0} \frac{(1+z)^{\Delta_a}}{z^2} Y(a, z) b = \sum_{j \geq 0} \binom{\Delta_a}{j} a_{j-2} b. \tag{67.3}$$

The sums are finite on each pair a, b by lower truncation. Let

$$O(V) = \mathrm{span}_{\mathbb{C}}\{a \circ b \mid a, b \in V \text{ homogeneous}\}.$$

Definition 67.3 (Zhu algebra)**.** The Zhu algebra of a VOA V is the quotient vector space

$$A(V) = V/O(V) \tag{67.4}$$

with product

$$[a]\,[b] := [a * b]. \tag{67.5}$$

The formal identities below imply that this product is independent of the chosen representatives and is associative; they are the same component-Jacobi residue identities used in Proposition 67.4. We denote the class of $a \in V$ by $[a] \in A(V)$.

The exponent $(1+z)^{\Delta_a}$ is not decorative. It is the coordinate factor relating the punctured plane coordinate to the genus-one coordinate used in torus one-point functions. The quotient by $O(V)$ removes the descendant terms that vanish on lowest-energy states.

Proposition 67.4 (Top-level action)**.** *Let M be an ordinary positive-energy V-module with lowest conformal weight h_M, so that*

$$M = \bigoplus_{n\geq 0} M_{h_M+n}.$$

For a homogeneous $a \in V$, set

$$o_M(a) := a_{\Delta_a-1}\big|_{M_{h_M}}. \tag{67.6}$$

Then $o_M(a \circ b) = 0$ on M_{h_M}, and

$$o_M(a * b) = o_M(a)o_M(b). \tag{67.7}$$

Thus M_{h_M} is an $A(V)$-module.

Proof. The mode a_n sends an L_0-eigenvector of weight λ to weight

$$\lambda + \Delta_a - n - 1. \tag{67.8}$$

Thus every lowest-weight vector $v \in M_{h_M}$ is killed by u_n whenever u is homogeneous and $n > \Delta_u - 1$. Equivalently,

$$M_{h_M} \subset \Omega(M) := \{v \in M \mid u_n v = 0 \text{ for all homogeneous } u \in V,\ n > \Delta_u - 1\}. \tag{67.9}$$

The remaining step is a finite component calculation from the module Jacobi identity. In mode form, that identity says

$$\sum_{i\geq 0} \binom{m}{i} (a_{n+i}b)_{m+k-i} = \sum_{i\geq 0} (-1)^i \binom{n}{i} \big(a_{m+n-i}b_{k+i} - (-1)^n b_{n+k-i}a_{m+i}\big). \tag{67.10}$$

All sums are finite on a fixed vector by lower truncation. Substitute $n = j-2$ and sum with the coefficients $\binom{\Delta_a}{j}$ from (67.3). The resulting finite sum is reorganized by the binomial identity $(1+z)^{\Delta_a} = (1+z)(1+z)^{\Delta_a-1}$; every summand in $o_M(a\circ b)v$ contains a factor $u_r v$ with $r > \Delta_u - 1$, hence vanishes for $v \in M_{h_M}$. Substituting $n = j-1$ and summing with the coefficients in (67.2) leaves exactly the term $a_{\Delta_a-1}b_{\Delta_b-1}v$; the remaining terms again contain a mode killing $\Omega(M)$. Therefore

$$o_M(a \circ b)v = 0, \qquad o_M(a * b)v = o_M(a)o_M(b)v \tag{67.11}$$

for every $v \in M_{h_M}$. This proves that $O(V)$ is in the kernel of the top-level action and that the induced action is multiplicative. □

Quoted Theorem 67.5 (Zhu classification theorem)**.** *Let V be a grading-restricted VOA of CFT type:*

$$V_n = 0 \quad (n < 0), \qquad V_0 = \mathbb{C}\mathbf{1}, \qquad \dim V_n < \infty.$$

For every simple ordinary positive-energy V-module M, the lowest space M_{h_M} is a simple $A(V)$-module. Conversely, every simple $A(V)$-module U has a universal $\mathbb{N}$-gradable weak V-module generated from U as its top level; when the irreducible quotient is ordinary, this construction is *inverse to $M \mapsto M_{h_M}$. In particular, if every simple $A(V)$-module induces an ordinary simple module, then simple ordinary positive-energy V-modules are classified by simple $A(V)$-modules.*

If V is rational in the sense that the ordinary module category is semisimple with finitely many simple objects and finite-dimensional graded pieces, then $A(V)$ is finite-dimensional and semisimple. If, in addition,

$$C_2(V) := \mathrm{span}_{\mathbb{C}}\{a_{-2}b \mid a, b \in V\} \quad \textit{has finite codimension in } V,$$

then the same finite label set appears in the vector of characters $(\chi_i(\tau))_{i\in I}$ entering the modular-invariance theorem. This is the Zhu module-classification and character-finiteness theorem in the form used here [37].

Induction mechanism behind Zhu's theorem. The quoted theorem hides a concrete algebraic construction, so we record the mechanism used later when examples are checked. Let $\mathfrak{g}(V)$ be the Lie algebra generated by symbols $a[m]$, for homogeneous $a \in V$ and $m \in \mathbb{Z}$, modulo the translation relation

$$(L_{-1}a)[m] = -m\, a[m-1],$$

with bracket

$$[a[m], b[n]] = \sum_{j\geq 0} \binom{m}{j} (a_j b)[m+n-j]. \tag{67.12}$$

The degree of $a[m]$ is $\Delta_a - m - 1$. Thus $\mathfrak{g}(V)$ has a triangular decomposition into positive, zero, and negative degree modes. On the top level of an ordinary module, positive degree modes vanish and zero degree modes act by $o(a) = a_{\Delta_a - 1}$. Proposition 67.4 identifies this zero-degree action with the Zhu algebra action.

Conversely, let U be a simple $A(V)$-module. Give U an action of the nonnegative part of $\mathfrak{g}(V)$ by letting positive degree modes act by zero and letting degree-zero modes act through $A(V)$. The induced graded vector space

$$\mathcal{M}_{\mathrm{ind}}(U) = U(\mathfrak{g}(V)) \otimes_{U(\mathfrak{g}(V)_{\geq 0})} U \tag{67.13}$$

is generated by U under negative degree modes. The VOA Jacobi identity imposes additional relations beyond the Lie brackets (67.12); quotienting by those relations gives the universal N-gradable weak module generated from U. Its maximal proper graded submodule with zero intersection with U, when it exists, gives the irreducible quotient. Every simple ordinary module is generated from its top level by the negative modes, so it is obtained from this construction. The analytic and finiteness content of Quoted Theorem 67.5 is exactly the assertion that, under the stated hypotheses, the quotient produced in this way is ordinary and that the process exhausts the ordinary simple modules.

Example 67.6 (Ising Zhu algebra as a top-weight test)**.** For the Ising VOA $L(1/2, 0)$, the Zhu algebra is generated by the class $[\omega]$ of the conformal vector. The three simple modules have top weights

$$0, \qquad \frac{1}{16}, \qquad \frac{1}{2}.$$

Equivalently, the semisimple Zhu algebra is the quotient

$$A(L(1/2,0)) \cong \mathbb{C}[x] \Big/ \left(x \left(x - \frac{1}{16} \right) \left(x - \frac{1}{2} \right) \right), \tag{67.14}$$

where x acts as L_0 on the top level. The idempotents of this three-dimensional algebra are the Lagrange polynomials

$$e_0 = 32\left(x - \frac{1}{16}\right)\left(x - \frac{1}{2}\right), \tag{67.15}$$

$$e_{1/16} = -\frac{256}{7}x\left(x - \frac{1}{2}\right), \tag{67.16}$$

$$e_{1/2} = \frac{32}{7}x\left(x - \frac{1}{16}\right). \tag{67.17}$$

They obey $e_h(h') = \delta_{h,h'}$, $e_h^2 = e_h$ in the quotient (67.14), and $e_0 + e_{1/16} + e_{1/2} = 1$. Thus they project to the vacuum, spin, and energy top levels, respectively.

67.4 Unitary Virasoro Minimal Models

The preceding VOA definitions are deliberately general. The smallest nontrivial unitary chiral CFTs arise when the chiral algebra is just the Virasoro algebra and the representation category is finite. This finiteness is not automatic: it is a consequence of null vectors in highest-weight Virasoro modules together with positivity.

Let $M(c, h)$ be the Verma module generated by a highest-weight vector $|h\rangle$ satisfying

$$L_0|h\rangle = h|h\rangle, \qquad L_n|h\rangle = 0 \quad (n > 0),$$

for the Virasoro algebra of central charge c. In radial quantization of a unitary chiral theory,

$$L_n^\dagger = L_{-n}.$$

Thus each finite descendant level carries a Hermitian Gram form. The first two levels already show the mechanism. At level one,

$$\|L_{-1}|h\rangle\|^2 = \langle h|L_1L_{-1}|h\rangle = 2h,$$

so a unitary module has $h \geq 0$, and $h = 0$ makes $L_{-1}|0\rangle$ a null translation descendant of the vacuum. At level two, in the ordered basis $(L_{-2}|h\rangle, L_{-1}^2|h\rangle)$, the Gram matrix is

$$M^{(2)}(c, h) = \begin{pmatrix} 4h + \frac{c}{2} & 6h \\ 6h & 4h(2h+1) \end{pmatrix}. \tag{67.18}$$

Indeed,

$$\langle h|L_2L_{-2}|h\rangle = \langle h|(4L_0 + c/2)|h\rangle,$$
$$\langle h|L_2L_{-1}^2|h\rangle = 6h,$$

and

$$\langle h|L_1^2L_{-1}^2|h\rangle = 4h(2h+1),$$

obtained by commuting positive modes to the right until they annihilate $|h\rangle$. If $\det M^{(2)}(c, h) = 0$ and $h \neq 0, -1/2$, the null vector is

$$\left(L_{-2} - \frac{3}{2(2h+1)}L_{-1}^2\right)|h\rangle. \tag{67.19}$$

Null descendants are not optional in a unitary CFT: they have zero inner product with every state and must be quotiented to obtain the physical irreducible module.

Quoted Theorem 67.7 (Unitary Virasoro highest-weight classification)**.** *Let $L(c,h)$ be an irreducible positive-energy highest-weight module for the Virasoro algebra with positive-definite Hermitian form and $L_n^\dagger = L_{-n}$. Then either*

$$c \geq 1, \qquad h \geq 0,$$

or there is an integer $m \geq 3$ such that

$$c = c_m := 1 - \frac{6}{m(m+1)} \tag{67.20}$$

and

$$h = h_{r,s}^{(m)} := \frac{\big((m+1)r - ms\big)^2 - 1}{4m(m+1)} \tag{67.21}$$

for integers

$$1 \leq r \leq m-1, \qquad 1 \leq s \leq m.$$

The identification

$$h_{r,s}^{(m)} = h_{m-r,m+1-s}^{(m)} \tag{67.22}$$

leaves $m(m-1)/2$ distinct irreducible modules. The rational unitary Virasoro minimal model $\mathcal{M}(m, m+1)$ has precisely these simple chiral modules. This is the Friedan–Qiu–Shenker necessity theorem together with the Goddard–Kent–Olive coset sufficiency theorem, stated here only at the representation-classification boundary [39, 40].

The theorem is the deep unitarity input. The monograph uses it as a classification boundary, not as a substitute for the local representation calculations above. The mechanism begins with the Kac determinant. Introduce a real parameter $b > 0$ by

$$c = 1 - 6(b^{-1} - b)^2, \qquad h_{r,s}(b) = \frac{(rb^{-1} - sb)^2 - (b^{-1} - b)^2}{4}.$$

At descendant level N, the determinant of the Virasoro Verma Gram form is, up to a positive normalization depending on the chosen ordered monomial basis,

$$\det M^{(N)}(c,h) = C_N \prod_{\substack{r,s \geq 1 \\ rs \leq N}} \big(h - h_{r,s}(b)\big)^{p(N-rs)}, \qquad C_N > 0, \tag{67.23}$$

where $p(k)$ is the number of integer partitions of k. Formula (67.23) is algebraic: it records exactly where a singular vector can occur in a Verma module. Unitarity then imposes an inequality on every principal minor of every level Gram matrix. For $c < 1$, these inequalities are so restrictive that the zero hyperplanes $h = h_{r,s}(b)$ must occur in an interlacing pattern compatible with quotienting null submodules. The full Friedan–Qiu–Shenker/Goddard–Kent–Olive argument proves that this happens precisely when

$$b^2 = \frac{m}{m+1}, \qquad m = 3, 4, \ldots,$$

and the surviving irreducible highest weights are the Kac-table weights in (67.21). Thus the quoted theorem supplies the all-level part of the classification: positivity of the null quotients at every descendant level and exhaustion of the $0 < c < 1$ positive-energy highest-weight modules.

A convenient nonredundant list of representatives is the triangular set

$$1 \leq s \leq r \leq m-1.$$

Rocha–Caridi characters. The next step uses one further representation-theoretic input: the Rocha–Caridi alternating character formula for the irreducible quotients in the unitary Kac table. Its content is the Euler-character statement of the singular-vector resolution of the irreducible Virasoro module. Once this character formula is accepted, the modular S-matrix below is a finite theta-function calculation.

Put $K = m(m+1)$, $q = e^{2\pi i\tau}$, and

$$\Theta_{\lambda,K}(\tau) = \sum_{n\in\mathbb{Z}} q^{(2Kn+\lambda)^2/(4K)}, \qquad \lambda \in \mathbb{Z}/2K\mathbb{Z}.$$

For $1 \le r \le m-1$, $1 \le s \le m$, define

$$\lambda^-_{r,s} = (m+1)r - ms, \qquad \lambda^+_{r,s} = (m+1)r + ms.$$

The irreducible minimal-model character is

$$\chi^{(m)}_{r,s}(\tau) = \frac{\Theta_{\lambda^-_{r,s},K}(\tau) - \Theta_{\lambda^+_{r,s},K}(\tau)}{\eta(\tau)}. \tag{67.24}$$

Proposition 67.8 (Unitary minimal-model modular data from characters)**.** *Let $\mathcal{M}(m, m+1)$ be the diagonal unitary Virasoro minimal model with $m \ge 3$, and assume that its irreducible chiral characters are the Rocha–Caridi characters (67.24). Its chiral character vector is indexed by Kac-table orbits*

$$[r, s] = [m-r, m+1-s], \qquad 1 \le r \le m-1, \quad 1 \le s \le m,$$

or equivalently by the triangular representatives $1 \le s \le r \le m-1$. The modular transformation $\tau \mapsto -1/\tau$ is represented by

$$S_{(r,s),(r',s')} = 2\sqrt{\frac{2}{m(m+1)}}\,(-1)^{1+sr'+rs'} \sin\left(\frac{\pi(m+1)rr'}{m}\right) \sin\left(\frac{\pi m s s'}{m+1}\right), \tag{67.25}$$

and $\tau \mapsto \tau+1$ is represented by the diagonal matrix

$$T_{(r,s),(r,s)} = \exp\left(2\pi i \left(h^{(m)}_{r,s} - \frac{c_m}{24}\right)\right). \tag{67.26}$$

The formula for S is well-defined on Kac-table orbits, is unitary on the orbit basis, and together with T gives the genus-one modular representation on characters.

Proof. The representation-theoretic content imported into the proposition is exactly the character formula (67.24), whose source is the Virasoro minimal-model character theory following the Friedan–Qiu–Shenker and Goddard–Kent–Olive classification [39, 40]. The modular matrix itself is then computed as follows. Poisson summation gives

$$\Theta_{\lambda,K}(-1/\tau) = \sqrt{\frac{-i\tau}{2K}} \sum_{\mu\in\mathbb{Z}/2K\mathbb{Z}} e^{-\pi i\lambda\mu/K}\Theta_{\mu,K}(\tau), \qquad \eta(-1/\tau) = \sqrt{-i\tau}\,\eta(\tau). \tag{67.27}$$

Therefore

$$\chi^{(m)}_{r,s}(-1/\tau) = \frac{1}{\sqrt{2K}} \sum_{\mu\in\mathbb{Z}/2K\mathbb{Z}} \left(e^{-\pi i\lambda^-_{r,s}\mu/K} - e^{-\pi i\lambda^+_{r,s}\mu/K}\right) \frac{\Theta_{\mu,K}(\tau)}{\eta(\tau)}.$$

Because $\Theta_{\mu,K} = \Theta_{-\mu,K}$, the coefficient of $\Theta_{\lambda^-_{r',s'},K}/\eta$ after grouping the pair $\pm\lambda^-_{r',s'}$ is

$$\begin{aligned}\frac{2}{\sqrt{2K}}&\left[\cos\left(\frac{\pi\lambda^-_{r,s}\lambda^-_{r',s'}}{K}\right)-\cos\left(\frac{\pi\lambda^+_{r,s}\lambda^-_{r',s'}}{K}\right)\right]\\&=2\sqrt{\frac{2}{m(m+1)}}\,(-1)^{1+sr'+rs'}\sin\left(\frac{\pi(m+1)rr'}{m}\right)\sin\left(\frac{\pi mss'}{m+1}\right).\end{aligned}\tag{67.28}$$

The same calculation gives the negative of (67.28) for $\Theta_{\lambda^+_{r',s'},K}/\eta$, so the coefficient of the character $\chi^{(m)}_{r',s'}$ is exactly (67.25). The T-matrix follows from $\Theta_{\lambda,K}(\tau+1) = e^{\pi\mathrm{i}\lambda^2/(2K)}\Theta_{\lambda,K}(\tau)$, $\eta(\tau+1) = e^{\pi\mathrm{i}/12}\eta(\tau)$, and $(\lambda^+_{r,s})^2 - (\lambda^-_{r,s})^2 = 4Krs$, which makes the two theta terms in (67.24) acquire the same phase $e^{2\pi\mathrm{i}(h^{(m)}_{r,s}-c_m/24)}$.

The label identification is a quotient, not a mnemonic. The involution

$$J(r,s) = (m-r, m+1-s)$$

has no fixed points: a fixed point would require $2r = m$ and $2s = m+1$, which cannot hold simultaneously in integers. Thus every orbit has two members, and the factor $2\sqrt{2/(m(m+1))}$ in (67.25) is the quotient normalization. If one starts from the product of the two sine matrices for $SU(2)_{m-2}$ and $SU(2)_{m-1}$, restriction to the J-orbits multiplies the parent normalization by $\sqrt{2}$. This is the finite normalization step that is often hidden in physics derivations. □

It is useful to state the resulting fusion rule without appealing to any picture of fields. Let $n^{(k)c}_{ab}$ be the $SU(2)_k$ fusion coefficient for $0 \le a, b, c \le k$:

$$n^{(k)c}_{ab} = \begin{cases}1, & |a-b| \le c \le \min(a+b, 2k-a-b) \text{ and } a+b+c \in 2\mathbb{Z},\\ 0, & \text{otherwise.}\end{cases}$$

For triangular representatives $a = (r,s)$, $b = (r',s')$, and $c = (r'',s'')$, the unitary minimal-model Verlinde coefficient is

$$\begin{aligned}N_{ab}{}^{c} &= n^{(m-2)\quad r''-1}_{r-1,r'-1}\, n^{(m-1)\quad s''-1}_{s-1,s'-1}\\&\quad + n^{(m-2)\quad m-r''-1}_{r-1,r'-1}\, n^{(m-1)\quad m-s''}_{s-1,s'-1}.\end{aligned}\tag{67.29}$$

The first term fuses to the displayed representative of the target orbit; the second fuses to its J-image.

Proposition 67.9 (Minimal-model fusion from the finite quotient)**.** *Assume the modular data of Proposition 67.8. The Verlinde formula, derived later in this chapter from modular diagonalization and displayed in* (67.77)*, gives exactly* (67.29)*. In particular the coefficients are nonnegative integers.*

Proof. Let

$$S^{(k)}_{ab} = \sqrt{\frac{2}{k+2}}\sin\left(\frac{\pi(a+1)(b+1)}{k+2}\right)$$

be the $SU(2)_k$ sine matrix. The finite sine orthogonality relation

$$\sum_{x=0}^{k} S^{(k)}_{ax} S^{(k)}_{bx} = \delta_{ab}$$

is the ordinary orthogonality of sine functions on the finite interval. Put

$$\theta_x = \frac{\pi(x+1)}{k+2}, \qquad \chi_a(\theta) = \frac{\sin((a+1)\theta)}{\sin\theta}.$$

Then $S^{(k)}_{ax} = S^{(k)}_{0x}\chi_a(\theta_x)$, and the Verlinde coefficient is the finite inner product

$$n^{(k)c}_{ab} = \sum_{x=0}^{k} \big(S^{(k)}_{0x}\big)^2 \chi_a(\theta_x)\chi_b(\theta_x)\chi_c(\theta_x). \tag{67.30}$$

The ordinary $SU(2)$ character identity gives

$$\chi_a\chi_b = \sum_{\substack{|a-b|\le d\le a+b \\ a+b+d \text{ even}}} \chi_d. \tag{67.31}$$

On the finite grid θ_x there are the affine-wall relations

$$\chi_{k+1}(\theta_x) = 0, \qquad \chi_{k+1+r}(\theta_x) = -\chi_{k+1-r}(\theta_x) \quad (r \ge 1), \tag{67.32}$$

which follow from $(k+2)\theta_x = \pi(x+1)$. Substituting (67.31) in (67.30), reducing all terms by (67.32), and using finite orthogonality gives

$$n^{(k)c}_{ab} = \begin{cases} 1, & |a-b| \le c \le \min(a+b, 2k-a-b), \quad a+b+c \in 2\mathbb{Z}, \\ 0, & \text{otherwise.} \end{cases} \tag{67.33}$$

Indeed, if $a+b \le k$ no wall term occurs and this is the ordinary $SU(2)$ tensor-product interval. If $a+b > k$, the reflected terms across the wall $k+1$ cancel exactly the labels $c > 2k-a-b$, leaving the truncated alcove interval displayed above.

For the minimal model, the matrix (67.25) is the signed product of the $SU(2)_{m-2}$ and $SU(2)_{m-1}$ sine matrices, followed by the fixed-point-free quotient by J. The sign is the simple-current selection rule in the Verlinde sum. Therefore the quotient coefficient is obtained from the parent product by summing over the two representatives c and Jc of the target orbit. Written in triangular labels, this gives exactly (67.29). Each summand is a product of 0-1 $SU(2)_k$ fusion coefficients, so the result is a nonnegative integer. □

67.4.1 Coulomb-Gas Blocks and Screening Charges

There is a second, complementary description of Virasoro minimal-model chiral blocks: a free chiral scalar with background charge, together with contour integrals of screening fields. This construction is useful only after its domain of validity is stated carefully. It constructs chiral blocks and intertwining maps in a free-field resolution of Virasoro modules; it is not by itself a definition of the full nonchiral CFT, nor does it replace the Hilbert space positivity and sewing data discussed above.

Let $\varphi(z)$ be a chiral scalar normalized by

$$\varphi(z)\varphi(w) \sim -\log(z-w), \qquad \partial\varphi(z)\partial\varphi(w) \sim -\frac{1}{(z-w)^2}. \tag{67.34}$$

For a complex background-charge parameter α_0, define

$$T_{\alpha_0}(z) = -\frac{1}{2} :\partial\varphi\,\partial\varphi:(z) + \mathrm{i}\alpha_0\partial^2\varphi(z). \tag{67.35}$$

For $V_\alpha(z) =: e^{\mathrm{i}\alpha\varphi(z)}:$, Wick contraction gives

$$T_{\alpha_0}(z)V_\alpha(w) \sim \frac{h(\alpha)V_\alpha(w)}{(z-w)^2} + \frac{\partial V_\alpha(w)}{z-w}, \qquad h(\alpha) = \frac{1}{2}\alpha(\alpha - 2\alpha_0), \tag{67.36}$$

and

$$c = 1 - 12\alpha_0^2. \tag{67.37}$$

The sign of the improvement term in (67.35) is fixed by the convention (67.34); changing the sign of φ changes α and α_0 together and leaves (67.36) invariant.

For the unitary model $\mathcal{M}(m, m+1)$, set

$$\alpha_+^2 = \frac{2(m+1)}{m}, \qquad \alpha_-^2 = \frac{2m}{m+1}, \qquad \alpha_+\alpha_- = -2, \qquad \alpha_0 = \frac{\alpha_+ + \alpha_-}{2}. \tag{67.38}$$

Thus $m\alpha_+ + (m+1)\alpha_- = 0$. The charge associated with the Kac label (r,s) is

$$\alpha_{r,s} = \frac{1-r}{2}\alpha_+ + \frac{1-s}{2}\alpha_-. \tag{67.39}$$

Substitution into (67.37) and (67.36) gives

$$c = 1 - \frac{6}{m(m+1)} = c_m, \qquad h(\alpha_{r,s}) = \frac{\big((m+1)r - ms\big)^2 - 1}{4m(m+1)} = h_{r,s}^{(m)}. \tag{67.40}$$

The Kac reflection is charge conjugation in the background-charge scalar:

$$\alpha_{m-r,m+1-s} = 2\alpha_0 - \alpha_{r,s}, \qquad h(2\alpha_0 - \alpha) = h(\alpha).$$

Definition 67.10 (Screening currents and Coulomb-gas block datum)**.** The screening currents are

$$S_\pm(u) = V_{\alpha_\pm}(u). \tag{67.41}$$

Because $\alpha_+\alpha_- = -2$, (67.36) gives $h(\alpha_+) = h(\alpha_-) = 1$. Given external charges β_i, insertion points z_i, and nonnegative integers $N_\pm$, remove from $\mathbb{C}^{N_+ + N_-}$ all diagonals $u_a = u_{a'}$, $v_b = v_{b'}$, $u_a = v_b$, and all collision hyperplanes with the external points z_i. The multivalued factor in (67.43) determines a rank-one local system $\mathcal{L}$ on this complement; a twisted cycle Γ means a singular chain with coefficients in $\mathcal{L}^\vee$ whose twisted boundary vanishes. Endpoint prescriptions in a compactification, when used, are part of the choice of this relative twisted homology class. A genus-zero Coulomb-gas block datum consists of such a twisted cycle Γ and the neutrality condition

$$\sum_i \beta_i + N_+\alpha_+ + N_-\alpha_- = 2\alpha_0. \tag{67.42}$$

The corresponding chiral integral is

$$\mathcal{F}_\Gamma(z_i) = \int_\Gamma \prod_{a=1}^{N_+} \mathrm{d}u_a \prod_{b=1}^{N_-} \mathrm{d}v_b \prod_{i<j} (z_i - z_j)^{\beta_i\beta_j} \\ \times \prod_{a,i} (u_a - z_i)^{\alpha_+\beta_i} \prod_{b,i} (v_b - z_i)^{\alpha_-\beta_i} \prod_{a<a'} (u_a - u_{a'})^{\alpha_+^2} \prod_{b<b'} (v_b - v_{b'})^{\alpha_-^2} \prod_{a,b} (u_a - v_b)^{-2}. \tag{67.43}$$

Lemma 67.11 (Screenings produce Virasoro intertwiners)**.** *For any closed contour or twisted cycle Γ on which boundary terms vanish, insertion of the screening charges*

$$Q_\pm(\Gamma) = \int_\Gamma S_\pm(u)\,\mathrm{d}u$$

commutes with the Virasoro action generated by T_{α_0}. Consequently (67.43), when convergent or defined by analytic continuation from a convergent chamber, satisfies the Virasoro Ward identities for a chiral block with external weights $h(\beta_i)$.

Proof. First suppose that Γ is represented by a compact twisted chain in a convergence chamber, so that all contour deformations and integrations by parts below are ordinary absolutely convergent operations after choosing local branches. Since $S_\pm$ have weight 1,

$$T(z)S_\pm(u) \sim \frac{S_\pm(u)}{(z-u)^2} + \frac{\partial_u S_\pm(u)}{z-u}.$$

The commutator of $L_n = \oint z^{n+1} T(z)\mathrm{d}z/(2\pi\mathrm{i})$ with the local field $S_\pm(u)$ is therefore

$$[L_n, S_\pm(u)] = \partial_u\big(u^{n+1} S_\pm(u)\big)\,.$$

Thus

$$[L_n, Q_\pm(\Gamma)] = \int_\Gamma d_u\big(u^{n+1} S_\pm(u)\big)\,,$$

where the differential is read as the flat covariant derivative on the rank-one local system carried by the multivalued integrand. Twisted Stokes gives

$$\int_\Gamma \nabla_{\mathcal{L}}\eta = \int_{\partial_{\mathcal{L}}\Gamma} \eta.$$

The right hand side vanishes because $\partial_{\mathcal{L}}\Gamma = 0$. In the single-valued special case this is the usual statement that the integral of a total derivative around a closed contour is zero; in the multivalued case the coefficients of the twisted chain are exactly what cancels the monodromy terms on adjacent boundary faces. For several screenings the same argument is applied to each screening coordinate, and the commutator with the product of screening integrations is the sum of these twisted exact terms. Hence the integrated screening charges commute with all Virasoro modes in the sense of chiral blocks.

It remains to identify the Ward identity obeyed by the unintegrated free field correlator. Wick contraction with (67.35) gives the primary terms (67.36) at each finite exponential insertion. The contour of $\partial\varphi$ around all finite exponential insertions measures the total finite charge $\sum_i \beta_i + N_+\alpha_+ + N_-\alpha_-$. The improvement term in T_{α_0} is equivalently a background charge $2\alpha_0$ at infinity on the sphere. Therefore the stress-tensor contour at infinity has the vacuum behavior needed for the genus-zero Virasoro Ward identity exactly when (67.42) holds. The screening integrations preserve that identity because their Virasoro commutators are the twisted exact terms just shown to integrate to zero.

When the displayed integral is defined by meromorphic continuation, the Ward identity is first proved in a nonempty convergence chamber with the same twisted homology class. Both sides are meromorphic functions of the charges and insertion positions away from collision and resonance divisors, so the identity extends to the continued block on the common domain of definition. □

One-screening Dotsenko–Fateev beta integral. Let $A, B \in \mathbb{C}$ with initially $\operatorname{Re} A > -1$, $\operatorname{Re} B > -1$, and choose the principal branch on $(0,1)$. Then the one-screening integral

$$I(A,B) = \int_0^1 u^A (1-u)^B \, \mathrm{d}u \tag{67.44}$$

is

$$I(A,B) = \frac{\Gamma(A+1)\Gamma(B+1)}{\Gamma(A+B+2)}. \tag{67.45}$$

Both sides define the meromorphic continuation of the same chiral block coordinate in A, B, with poles exactly where endpoint subtractions or resonant descendants have to be specified.

In the convergence chamber this is Euler's beta integral: write

$$\Gamma(A+1)\Gamma(B+1) = \int_0^\infty \int_0^\infty e^{-x-y} x^A y^B \, \mathrm{d}x \, \mathrm{d}y.$$

Use the change of variables $t = x+y$, $u = x/(x+y)$. The Jacobian is t, so the double integral factors as

$$\left(\int_0^\infty e^{-t} t^{A+B+1} \mathrm{d}t \right) \left(\int_0^1 u^A (1-u)^B \mathrm{d}u \right) = \Gamma(A+B+2) I(A,B).$$

Division by $\Gamma(A+B+2)$ gives (67.45). Meromorphic continuation follows because the gamma-function expression is meromorphic and agrees with the integral on a connected open convergence chamber.

Two-screening Selberg chamber. The first place where the Dotsenko–Fateev integrals are not just repeated Euler beta integrals is the two-screening factor. In a real convergence chamber, suppressing the common external-position prefactors, put

$$I_2(A,B,C) = \int_0^1 \int_0^1 u^A (1-u)^B v^A (1-v)^B |u-v|^{2C} \, \mathrm{d}u \, \mathrm{d}v. \tag{67.46}$$

For $\operatorname{Re} A, \operatorname{Re} B > -1$ and

$$\operatorname{Re} C > -\min\{1/2, \operatorname{Re}(A+1), \operatorname{Re}(B+1)\},$$

Selberg's $n = 2$ formula gives

$$I_2(A,B,C) = \frac{\Gamma(A+1)\Gamma(B+1)\Gamma(A+C+1)\Gamma(B+C+1)\Gamma(2C+1)}{\Gamma(A+B+C+2)\Gamma(A+B+2C+2)\Gamma(C+1)}. \tag{67.47}$$

For nonnegative integer A, B, C the same identity is already visible by elementary finite algebra. By symmetry,

$$I_2(A,B,C) = 2\int_{0<v<u<1} u^A(1-u)^B v^A(1-v)^B(u-v)^{2C}\,\mathrm{d}v\,\mathrm{d}u.$$

Expand the three polynomials

$$(1-u)^B, \qquad (1-v)^B, \qquad (u-v)^{2C}.$$

The term with powers i, j, k contributes

$$2(-1)^{i+j+k}\binom{B}{i}\binom{B}{j}\binom{2C}{k}\frac{1}{A+j+k+1}\,\frac{1}{2A+i+j+2C+2}. \tag{67.48}$$

Summing (67.48) over $0 \le i, j \le B$ and $0 \le k \le 2C$ gives exactly (67.47) with gamma functions replaced by factorials. Thus the new datum in the two-screening block is not an additional copy of the one-screening endpoint powers; it is the screening–screening exponent $2C$, which is $\alpha_\pm^2$ in the Coulomb-gas block and is the source of the Selberg/Vandermonde factors in multi-screening Dotsenko–Fateev formulas.

Screening-to-BPZ construction budget. The preceding formulas are coordinates on a block space; they are not yet a proof that a chosen contour family is the correct minimal-model correlator. On a finite jet test space in the cross-ratio, one should separate the following finite vectors:

$$\mathcal{C}_{\mathrm{DF}}, \quad \mathcal{C}_{\mathrm{Ward}}, \quad \mathcal{C}_{\mathrm{tw}}, \quad \mathcal{C}_{\mathrm{BPZ}}, \quad \mathcal{C}_{\mathrm{cont}}, \quad \mathcal{C}_{\mathrm{full}}.$$

They denote, respectively, the raw Dotsenko–Fateev screening integrals, the same coordinates after the Virasoro Ward/intertwiner check, the projection to closed twisted cycles, the comparison with a BPZ solution basis, the analytically continued block coordinates in a second channel, and the nonchiral sewing pairing. If $\mathsf{M}_{\mathrm{cont}}$ is the finite connection matrix between the chosen BPZ bases, define

$$E_{\mathrm{scr}} = \mathcal{C}_{\mathrm{Ward}} - \mathcal{C}_{\mathrm{DF}}, \qquad E_{\mathrm{tw}} = \mathcal{C}_{\mathrm{tw}} - \mathcal{C}_{\mathrm{Ward}}, \tag{67.49}$$

$$E_{\mathrm{BPZ}} = \mathcal{C}_{\mathrm{BPZ}} - \mathcal{C}_{\mathrm{tw}}, \qquad E_{\mathrm{cont}} = \mathcal{C}_{\mathrm{cont}} - \mathsf{M}_{\mathrm{cont}}\mathcal{C}_{\mathrm{BPZ}}, \tag{67.50}$$

$$E_{\mathrm{pair}} = \mathcal{C}_{\mathrm{full}} - \mathcal{C}_{\mathrm{cont}}. \tag{67.51}$$

Then the finite comparison identity is

$$\mathcal{C}_{\mathrm{full}} - \mathsf{M}_{\mathrm{cont}}\mathcal{C}_{\mathrm{DF}} = \mathsf{M}_{\mathrm{cont}}(E_{\mathrm{scr}} + E_{\mathrm{tw}} + E_{\mathrm{BPZ}}) + E_{\mathrm{cont}} + E_{\mathrm{pair}}. \tag{67.52}$$

Indeed, add and subtract the intermediate coordinates before applying the connection matrix. If the norm of $\mathsf{M}_{\mathrm{cont}}$ on this finite test space is at most κ, and if the five residuals are bounded by $\varepsilon_{\mathrm{scr}}, \varepsilon_{\mathrm{tw}}, \varepsilon_{\mathrm{BPZ}}, \varepsilon_{\mathrm{cont}}, \varepsilon_{\mathrm{pair}}$, then

$$\|\mathcal{C}_{\mathrm{full}} - \mathsf{M}_{\mathrm{cont}}\mathcal{C}_{\mathrm{DF}}\| \le \kappa(\varepsilon_{\mathrm{scr}} + \varepsilon_{\mathrm{tw}} + \varepsilon_{\mathrm{BPZ}}) + \varepsilon_{\mathrm{cont}} + \varepsilon_{\mathrm{pair}}. \tag{67.53}$$

The residuals have distinct meanings:

- E_{scr} measures failure of the screening insertion to satisfy the Ward/intertwiner relation in the declared regularization.

- E_{tw} measures failure of the contour to be a closed twisted cycle, including endpoint and relative-boundary prescriptions.
- E_{BPZ} measures the finite BPZ differential-equation residual after quotienting by null vectors.
- E_{cont} measures analytic continuation and connection-matrix error between the two chosen channel bases.
- E_{pair} measures the nonchiral reflection-positive pairing and sewing residual.

Thus a Dotsenko–Fateev formula becomes a theorem-level minimal-model block construction only when these five residuals vanish compatibly as the finite jet space is enlarged.

Remark 67.12 (What the Dotsenko–Fateev formulas do and do not prove). Multiple screening integrals are Selberg-type generalizations of (67.44). Their contour choices span spaces of solutions to the BPZ differential equations and are a powerful way to compute chiral-block connection matrices and selected structure constants. The load-bearing data are the charges, the neutrality equation, the twisted cycle, and the analytic continuation prescription. A single displayed integral, without those data and without the nonchiral sewing pairing, is not a construction of the full minimal model. Conversely, once the Hilbert space, null quotient, modular data, and sewing constraints have been fixed, the Coulomb-gas integrals give concrete coordinates on the same chiral block spaces and make many BPZ solutions explicitly computable.

Consequently the diagonal A-series full CFT has genus-one partition function

$$Z_m(\tau, \bar{\tau}) = \sum_{1 \le s \le r \le m-1} \left|\chi_{r,s}(\tau)\right|^2,$$

which is modular invariant because the same unitary S and diagonal T act on the holomorphic and antiholomorphic character vectors.

For $m = 3$, one obtains

$$c_3 = \frac{1}{2}, \qquad h_{1,1} = 0, \qquad h_{2,1} = \frac{1}{2}, \qquad h_{2,2} = \frac{1}{16}.$$

The same spin field may also be represented as $h_{1,2} = 1/16$, which is the label making its level-two null vector manifest. For $c = 1/2$ and $h = 1/16$, the matrix (67.18) has determinant zero and (67.19) becomes

$$\left(L_{-2} - \frac{4}{3}L_{-1}^2\right)|\sigma\rangle = 0. \tag{67.54}$$

Proposition 67.13 (Ising spin four-point function from the BPZ equation)**.** *Normalize the Ising spin field by $\langle\sigma(z, \bar{z})\sigma(0)\rangle = |z|^{-1/4}$. Let*

$$\langle\sigma(z_1, \bar{z}_1)\cdots\sigma(z_4, \bar{z}_4)\rangle = |z_{12}|^{-1/4}|z_{34}|^{-1/4} f(z, \bar{z})$$

in the usual four-point cross-ratio frame. The null vector (67.54) implies the holomorphic BPZ equation

$$\left[\partial_z^2 + \frac{2-5z}{4z(1-z)}\partial_z - \frac{3}{64(1-z)^2}\right] f(z, \bar{z}) = 0, \tag{67.55}$$

and the analogous antiholomorphic equation. A basis of local holomorphic solutions is

$$f_\pm(z) = (1-z)^{-1/8}\sqrt{1 \pm \sqrt{z}}.$$

If

$$\mathcal{F}_0(z) = \frac{f_+(z) + f_-(z)}{2}, \qquad \mathcal{F}_\varepsilon(z) = f_+(z) - f_-(z),$$

then single-valuedness, normalization, and crossing fix

$$f(z, \bar{z}) = |\mathcal{F}_0(z)|^2 + \frac{1}{4}|\mathcal{F}_\varepsilon(z)|^2, \qquad C_{\sigma\sigma\varepsilon} = \frac{1}{2} \tag{67.56}$$

up to the sign convention for ε.

Proof. The BPZ equation follows from the null vector as follows. Insert (67.54) at one point in the four-point function. The L_{-1}^2 term is the second derivative with respect to that point. The L_{-2} term is computed by writing L_{-2} as a small contour integral of $T(\zeta)$, expanding the contour to surround the other three insertions, and using the primary Ward identity

$$T(\zeta)\sigma(z_i) \sim \frac{(1/16)\sigma(z_i)}{(\zeta - z_i)^2} + \frac{\partial_{z_i}\sigma(z_i)}{\zeta - z_i}.$$

Fixing three points by $PSL_2(\mathbb{C})$ covariance reduces the resulting Ward identity to (67.55). Direct substitution checks that f_+ and f_- solve the second-order equation.

The two solutions are multivalued, but the full correlator must be single-valued. Around $z = 0$, the combinations $\mathcal{F}_0$ and $\mathcal{F}_\varepsilon$ have the OPE behavior of the identity and energy channels in $\sigma \times \sigma = \mathbf{1} \oplus \varepsilon$. Therefore the most general diagonal single-valued expression in this basis is

$$f(z, \bar{z}) = |\mathcal{F}_0(z)|^2 + C^2|\mathcal{F}_\varepsilon(z)|^2$$

with $C^2 \geq 0$ by reflection positivity. The holomorphic solutions obey the reduced crossing transformation

$$f_+(1-z) = \left(\frac{1-z}{z}\right)^{1/8} \frac{f_+(z) + f_-(z)}{\sqrt{2}}, \qquad f_-(1-z) = \left(\frac{1-z}{z}\right)^{1/8} \frac{f_+(z) - f_-(z)}{\sqrt{2}}.$$

The scalar prefactor is not part of the fusion matrix: it is the conformal weight factor coming from the external spin fields. In the cross-ratio frame $G(z, \bar{z}) = |z|^{-1/4} f(z, \bar{z})$, crossing says $|1 - z|^{-1/4} f(1-z, 1-\bar{z}) = |z|^{-1/4} f(z, \bar{z})$, and this exactly cancels the modulus square of $((1-z)/z)^{1/8}$. Thus the matrix part is the invariant datum. Equivalently,

$$\mathcal{F}_0(1-z) = \left(\frac{1-z}{z}\right)^{1/8} \left(\frac{1}{\sqrt{2}}\mathcal{F}_0(z) + \frac{1}{2\sqrt{2}}\mathcal{F}_\varepsilon(z)\right),$$

$$\mathcal{F}_\varepsilon(1-z) = \left(\frac{1-z}{z}\right)^{1/8} \left(\sqrt{2}\,\mathcal{F}_0(z) - \frac{1}{\sqrt{2}}\mathcal{F}_\varepsilon(z)\right).$$

The remaining crossing condition for the matrix part then forces the coefficient of the mixed term $\mathcal{F}_0\overline{\mathcal{F}_\varepsilon} + \text{c.c.}$ to vanish:

$$\frac{1}{2} - 2C^2 = 0.$$

Thus $C^2 = 1/4$. The coefficients of $|\mathcal{F}_0|^2$ and $|\mathcal{F}_\varepsilon|^2$ then also match, giving (67.56). $\square$

67.5 Sewing and Higher-Genus Blocks

Sewing is the operation that constructs higher-genus surfaces and higher-point blocks from lower-genus pieces. Let C_1 and C_2 have marked points with coordinates z and w. Removing disks and imposing

$$zw = q, \qquad |q| < 1,$$

glues the two punctures into an annulus. If the two glued punctures carry a module M_a and its dual $M_a^\vee$, a sewn chiral block has the form

$$\mathcal{F}_{\mathrm{sewn}}(q) = \sum_\alpha q^{h_a+n_\alpha-c/24}\mathcal{F}_1(\cdots, e_\alpha)\mathcal{F}_2(e^\alpha, \cdots). \tag{67.57}$$

Here $\{e_\alpha\}$ is a homogeneous basis of M_a, e^α is the dual basis with respect to the invariant pairing, and $L_0 e_\alpha = (h_a + n_\alpha)e_\alpha$. The exponent records propagation along the sewn annulus.

The formula is meaningful only after specifying a topology on the module and a convergence domain for the sum. For a unitary positive-energy chiral module M_a write

$$M_a = \widehat{\bigoplus_{n\geq 0}} M_{a,h_a+n}, \qquad d_a(n) = \dim M_{a,h_a+n},$$

where L_0 has eigenvalue $h_a + n$ on M_{a,h_a+n}. For $0 < |q| < 1$ define the annular propagation operator

$$P_a(q) = q^{L_0-c/24}, \qquad P_a(q)e = q^{h_a+n-c/24}e \quad (e \in M_{a,h_a+n}), \tag{67.58}$$

with a fixed branch of $\log q$ on the sewing coordinate chart. Its trace norm is

$$\|P_a(q)\|_1 = |q|^{h_a-c/24}\sum_{n\geq 0} d_a(n)|q|^n = |\chi_a(q)|, \tag{67.59}$$

up to the phase carried by $q^{L_0-c/24}$. Thus the first analytic condition behind sewing is ordinary character convergence at the modulus $|q|$.

Definition 67.14 (Hilbert sewing datum)**.** Let M_a be a unitary chiral module with nondegenerate invariant Hermitian pairing. A one-channel Hilbert sewing datum consists of:

1. two continuous linear functionals ℓ_1, ℓ_2 on the Hilbert completion of M_a, representing the two lower-genus chiral blocks with one M_a-leg and one $M_a^\vee$-leg;
2. a sewing parameter q for which the propagator $P_a(q)$ is trace class;
3. a choice of dual homogeneous bases $\{e_\alpha\}$, $\{e^\alpha\}$ satisfying $\langle e^\alpha, e_\beta\rangle = \delta^\alpha{}_\beta$.

The sewn block is the scalar

$$\mathrm{Sew}_{a,q}(\ell_1, \ell_2) = \sum_\alpha \ell_1(e_\alpha)\, q^{L_0(e_\alpha)-c/24}\, \ell_2(e^\alpha), \tag{67.60}$$

provided the series is absolutely convergent.

Lemma 67.15 (Trace-class estimate for one-channel sewing)**.** *Assume $P_a(q)$ is trace class and that $\ell_i(v) = \langle u_i, v\rangle$ for vectors u_i in the Hilbert completion of M_a. Then the series (67.60) is absolutely convergent and satisfies*

$$|\mathrm{Sew}_{a,q}(\ell_1, \ell_2)| \leq \|u_1\|\, \|u_2\|\, \|P_a(q)\|_1. \tag{67.61}$$

In particular the sewn block is independent of the chosen orthonormal homogeneous basis.

Proof. Choose the homogeneous basis orthonormal. With $\lambda_\alpha = q^{L_0(e_\alpha)-c/24}$,

$$\mathrm{Sew}_{a,q}(\ell_1,\ell_2) = \sum_\alpha \langle u_1, e_\alpha\rangle \lambda_\alpha \langle e_\alpha, u_2\rangle = \langle u_1, P_a(q)u_2\rangle$$

when the finite-level partial sums are taken first. Trace class implies compactness and boundedness, with $\|P_a(q)\| \le \|P_a(q)\|_1$. Hence

$$|\langle u_1, P_a(q)u_2\rangle| \le \|u_1\|\,\|P_a(q)\|_1\,\|u_2\|.$$

Absolute convergence of the displayed basis expansion follows directly from

$$\sum_\alpha |\langle u_1, e_\alpha\rangle|\,|\lambda_\alpha|\,|\langle e_\alpha, u_2\rangle| \le \|u_1\|\,\|u_2\| \sup_{\|v\|=\|w\|=1} \sum_\alpha |\lambda_\alpha||\langle v, e_\alpha\rangle|\,|\langle e_\alpha, w\rangle| \le \|u_1\|\,\|u_2\| \sum_\alpha |\lambda_\alpha|.$$

The last sum is the trace norm in this diagonal homogeneous basis. If $P_a(q)$ is not diagonal in the chosen orthonormal basis, apply the same argument to its singular-value decomposition

$$P_a(q) = \sum_r s_r\,|v_r\rangle\langle w_r|, \qquad s_r \ge 0, \qquad \sum_r s_r = \|P_a(q)\|_1,$$

which gives the same estimate by Cauchy–Schwarz in the r-sum. The finite-level partial sums converge in trace norm to $P_a(q)$, so their matrix elements converge to $\langle u_1, P_a(q)u_2\rangle$. Since this inner product is an operator-theoretic scalar, not a coordinate expression, changing the orthonormal homogeneous basis does not change the sewn block. □

Remark 67.16 (Torus trace from self-sewing). Let M_a be a unitary positive-energy module and let v be a chiral state whose vertex operator $Y(v,1)$ preserves the common domain of $P_a(q)$. Sewing the two punctures of the sphere two-point block $\langle e^\alpha, Y(v,1)e_\alpha\rangle$ gives

$$Z_a(v;q) = \mathrm{Tr}_{M_a}\left(Y(v,1)q^{L_0-c/24}\right). \tag{67.62}$$

For $v = \mathbf{1}$, this is the character

$$Z_a(\mathbf{1};q) = \chi_a(q) = \mathrm{Tr}_{M_a}\, q^{L_0-c/24}. \tag{67.63}$$

Indeed, if $\{e_\alpha\}$ is a homogeneous orthonormal basis, the self-sewn block is

$$\sum_\alpha q^{L_0(e_\alpha)-c/24}\langle e_\alpha, Y(v,1)e_\alpha\rangle,$$

which is exactly the trace of $Y(v,1)q^{L_0-c/24}$ on finite-level truncations and hence, whenever the trace is convergent, the operator trace. Setting $v = \mathbf{1}$ gives $Y(\mathbf{1},1) = \mathrm{id}_{M_a}$.

Definition 67.17 (Sewing graph for a chiral block)**.** A chiral sewing graph Γ consists of:

1. vertices v, each labelled by a genus g_v, external insertion labels, and a finite-dimensional chiral block functional $\mathcal{F}_v$;
2. internal edges e, each joining two marked local coordinates or two marked coordinates on the same vertex surface;
3. for every internal edge e, a channel label a_e, a pair of dual chiral modules M_{a_e}, $M_{a_e}^\vee$, and a sewing parameter q_e with $|q_e| < 1$;

4. an orientation convention specifying which end of each edge carries M_{a_e} and which carries $M_{a_e}^{\vee}$.

Its geometric genus is

$$g(\Gamma) = \sum_v g_v + b_1(\Gamma), \tag{67.64}$$

where $b_1(\Gamma)$ is the first Betti number of the graph.

Given Γ, the formal sewn block is obtained by inserting a dual basis on every internal edge and multiplying the propagator factors:

$$\mathcal{F}_\Gamma(\{q_e\}) = \sum_{\{\alpha_e\}} \left(\prod_e q_e^{L_0(e_{\alpha_e}) - c/24} \right) \prod_v \mathcal{F}_v(\ldots, e_{\alpha_e}, e^{\alpha_e}, \ldots). \tag{67.65}$$

The genus formula (67.64) follows because sewing two connected components adds genera, while sewing two punctures on the same connected component adds one independent cycle.

Finite-channel sewing estimate. Assume a rational unitary chiral theory with finitely many channel labels, and fix a sewing graph Γ. Suppose that for each edge e, $P_{a_e}(q_e)$ is trace class, and that every vertex block functional $\mathcal{F}_v$ extends continuously to the Hilbert tensor product of its incident channel modules. Then the edge-basis sum (67.65) converges absolutely for the chosen $\{q_e\}$. Its value is independent of the orthonormal homogeneous bases used on internal edges.

Insert finite-level projectors $E_{a_e,\le N}$ on every internal edge. For fixed cutoffs the sum is finite. Choose orthonormal homogeneous bases on the cutoff subspaces and write

$$\lambda_{e,\alpha} = q_e^{L_0(e_\alpha) - c/24}$$

for the diagonal matrix coefficient of the annular propagator on edge e. If $\mathbf{e}_v(\boldsymbol{\alpha})$ denotes the tensor product of the unit basis vectors incident on v, then continuity of the vertex block functional gives the pointwise bound

$$|\mathcal{F}_v(\mathbf{e}_v(\boldsymbol{\alpha}))| \le \|\mathcal{F}_v\|.$$

Therefore the absolute value of the finite cutoff contraction is bounded by

$$\begin{aligned} \sum_{\{\alpha_e\}} \left(\prod_e |\lambda_{e,\alpha_e}| \right) \left(\prod_v |\mathcal{F}_v(\mathbf{e}_v(\boldsymbol{\alpha}))| \right) &\le \left(\prod_v \|\mathcal{F}_v\| \right) \prod_e \left(\sum_{\alpha_e} |\lambda_{e,\alpha_e}| \right) \\ &\le \left(\prod_v \|\mathcal{F}_v\| \right) \left(\prod_e \|P_{a_e}(q_e)\|_1 \right). \end{aligned} \tag{67.66}$$

The first inequality uses only that the same edge index is seen by the two incident vertices; after taking absolute values the indices separate into a product of one-edge sums. The second inequality is equality in a homogeneous diagonal basis and is bounded by the trace norm in any orthonormal basis. Since the right hand side of (67.66) is finite and independent of the cutoffs, the finite absolute sums are dominated by the full product of the edge ℓ^1 sums. Enlarging the cutoff on one or more edges adds a tail whose absolute value is bounded by the same product with at least one edge sum replaced by its trace-norm tail; these tails tend to zero. Hence the cutoff net is absolutely Cauchy. Equivalently, if one replaces $P_{a_e}(q_e)$ by its singular-value truncations, the tensor product of the edge operators converges in trace norm because

$$\left\| \bigotimes_e P_{a_e}(q_e) \right\|_1 = \prod_e \|P_{a_e}(q_e)\|_1$$

for finite tensor products of trace-class operators, and the vertex functionals are bounded on the Hilbert tensor products. This operator description also proves basis independence: two homogeneous orthonormal bases give the same trace-class tensor contraction after the cutoff limit.

The estimate is intentionally local. It controls a plumbing chart with fixed channel labels and $|q_e| < 1$. It does not prove that the resulting functions analytically continue between different pants decompositions, nor that two such continuations agree on the overlap of coordinate charts. Those are the analytic sewing and Moore–Seiberg compatibility statements isolated next.

Hypothesis 67.18 (Analytic sewing theorem for rational chiral data)**.** For the rational chiral theories treated as fully constructed in this chapter, the absolutely convergent local sewing series (67.65) analytically continue over the appropriate cover of the moduli space of pointed curves, assemble into finite-rank vector bundles of chiral blocks, and are compatible with changes of pants decomposition by the fusing, braiding, and modular moves. The compatibility maps obey the pentagon, hexagon, and genus-one modular identities.

This hypothesis is not a cosmetic assumption. The trace-class estimates above control a local plumbing coordinate chart near $q_e = 0$. They do not by themselves prove global analytic continuation, mapping-class-group covariance, or equality of two different decompositions of the same Riemann surface. Those assertions are precisely the higher-genus sewing theorem.

Definition 67.19 (Sewing-compatible rational chiral theory)**.** For this chapter, a rational chiral theory is a VOA V with finitely many simple ordinary modules $\{M_i\}_{i \in I}$, semisimple module category, finite-dimensional conformal-block spaces, nondegenerate two-point pairings, and convergent sewing expansions (67.57) in a neighborhood of $q = 0$, satisfying Hypothesis 67.18. The analytic continuations of these blocks along the moduli space of pointed curves give a projectively flat vector bundle of conformal blocks.

The mapping class group acts on this bundle. In genus zero the elementary moves are associativity and braiding of OPE channels. In genus one the generators are

$$S : \tau \mapsto -1/\tau, \qquad T : \tau \mapsto \tau + 1.$$

The compatibility of sewing with these moves is the Moore–Seiberg system: pentagon, hexagon, and modular identities for associativity, braiding, and twist data. The modern algebraic home of this system is a modular tensor category when the module category is semisimple.

67.5.1 Moore–Seiberg Data as Defect-Junction Consistency

The Moore–Seiberg equations should be read as equalities of conformal-block transport maps, or equivalently as equalities of topological-line junction networks after the physical null quotient of Definition 121.3. This is the same physical-defect category used in Chapter 121; here its objects are the topological lines labelled by chiral sectors.

Let $\mathcal{C}$ be a semisimple chiral sector category with simple objects $\{M_i\}_{i\in I}$. For simple labels define the fusion spaces

$$V_{ij}^k := \mathrm{Hom}_{\mathcal{C}}(M_i \boxtimes M_j, M_k), \qquad N_{ij}{}^k = \dim V_{ij}^k. \tag{67.67}$$

A vector in V_{ij}^k is a trivalent junction at which the two lines i, j fuse to the line k. For four external labels i, j, k, ℓ, the two standard pants decompositions have block spaces

$$\bigoplus_m V_{ij}^m \otimes V_{mk}^\ell, \qquad \bigoplus_n V_{jk}^n \otimes V_{in}^\ell. \tag{67.68}$$

The fusing matrix is the change of basis

$$F_{ijk}^\ell : \bigoplus_m V_{ij}^m \otimes V_{mk}^\ell \longrightarrow \bigoplus_n V_{jk}^n \otimes V_{in}^\ell. \tag{67.69}$$

The braiding maps are linear isomorphisms

$$R_{ij}^k : V_{ij}^k \longrightarrow V_{ji}^k, \tag{67.70}$$

and the twist is a scalar θ_i on each simple line in the semisimple case. They are the local coordinates of a topological defect category: F changes the parenthesization of three fusions, R exchanges two adjacent lines, and θ records a full rotation of one line.

The pentagon is the assertion that the two composites from $(((a \boxtimes b) \boxtimes c) \boxtimes d)$ to $a \boxtimes (b \boxtimes (c \boxtimes d))$ agree:

$$\alpha_{a,b,c\boxtimes d} \circ \alpha_{a\boxtimes b,c,d} = (\mathbf{1}_a \boxtimes \alpha_{b,c,d}) \circ \alpha_{a,b\boxtimes c,d} \circ (\alpha_{a,b,c} \boxtimes \mathbf{1}_d). \tag{67.71}$$

Here $\alpha_{a,b,c} : (a \boxtimes b) \boxtimes c \to a \boxtimes (b \boxtimes c)$ is represented, in the bases (67.68), by the corresponding F-matrix. In multiplicity sectors the pentagon is an equality of linear maps between direct sums of junction spaces. Physically it says that the correlator obtained by fusing four nearby topological lines is independent of the order in which the intermediate collars are shrunk.

The two hexagons say that moving one line past a fused pair is the same as moving it past the two constituents one at a time, with the associators included. With braiding $c_{a,b} : a \boxtimes b \to b \boxtimes a$, one of the two hexagons is

$$c_{a,b\boxtimes c} = \alpha_{b,c,a}^{-1} \circ (\mathbf{1}_b \boxtimes c_{a,c}) \circ \alpha_{b,a,c} \circ (c_{a,b} \boxtimes \mathbf{1}_c) \circ \alpha_{a,b,c}^{-1}, \tag{67.72}$$

as a map $a \boxtimes (b \boxtimes c) \to (b \boxtimes c) \boxtimes a$. The other hexagon is the parallel identity for $c_{a\boxtimes b,c}$. The balancing identity

$$\theta_{a\boxtimes b} = c_{b,a} \circ c_{a,b} \circ (\theta_a \boxtimes \theta_b)$$

then fixes how a Dehn twist acts on a fused pair. In a rational unitary CFT, these equalities are the local algebraic part of sewing: they identify different cuts of the same punctured surface after analytic continuation around the moduli space.

This formulation also fixes the status of the algebraic classification problem. A solution of the pentagon, hexagon, and modular equations is a candidate topological-line and conformal-block datum. To obtain a QFT one must still construct the Hilbert space of states, local fields or local algebras, positive pairings, convergent correlation functions, and sewing maps whose analytic continuations realize the displayed F, R, and θ. Conversely, once those analytic and positivity structures are constructed, the Moore–Seiberg equations follow from equality of two correlation-function limits in the defect category. The monograph therefore uses the equations as structural constraints and as coordinates on known classes of rational CFT data; the definition of the CFT itself includes the analytic and Hilbert-space structures just listed.

67.6 Modular Tensor Category and Verlinde Formula

Let $\mathcal{C}$ be the semisimple ribbon category of modules of a rational chiral theory. Its simple objects are M_i, with tensor product

$$M_i \boxtimes M_j \cong \bigoplus_k N_{ij}{}^k M_k.$$

The matrices $(N_i)_j{}^k = N_{ij}{}^k$ are the fusion matrices. The category has a braiding, duals, and twists $\theta_i = \mathrm{e}^{2\pi \mathrm{i} h_i}$. Its modular S-matrix is the Hopf-link pairing normalized so that the vacuum label 0 corresponds to V. In a unitary theory S is unitary and

$$d_i := \frac{S_{i0}}{S_{00}}$$

is the quantum dimension of M_i.

Quoted Theorem 67.20 (Modularity of rational chiral characters)**.** *For a rational, C_2-cofinite, positive-energy VOA satisfying the analytic finiteness hypotheses needed for sewing, the characters $\chi_i(\tau)$ of simple modules span a finite-dimensional representation of $SL(2,\mathbb{Z})$:*

$$\chi_i(-1/\tau) = \sum_j S_{ij}\chi_j(\tau), \qquad \chi_i(\tau+1) = \sum_j T_{ij}\chi_j(\tau).$$

The representation agrees with the modular data of the semisimple module category. This is Zhu's modular-invariance theorem, with the tensor-category identification supplied by the Huang–Lepowsky theory in the rational setting [37, 38].

Finite trace-recursion mechanism. The proof boundary in Quoted Theorem 67.20 is analytic, but the algebraic source of finite modular closure is explicit. Use Zhu's square-bracket coordinate

$$Y[a,z] := Y(\mathrm{e}^{zL_0}a, \mathrm{e}^z - 1) = \sum_{n\in\mathbb{Z}} a[n]z^{-n-1}, \tag{67.73}$$

and write

$$Z_i(v,\tau) = \mathrm{Tr}_{M_i}\, o(v)\, q^{L_0 - c/24}.$$

Let

$$\wp(z,\tau) = z^{-2} + \sum_{\ell\geq 1}(2\ell+1)G_{2\ell+2}(\tau)z^{2\ell}, \qquad G_{2k}(\tau) = \sum_{(m,n)\in\mathbb{Z}^2\setminus\{0\}} (m\tau+n)^{-2k}. \tag{67.74}$$

The genus-one Ward identity obtained by moving an a-contour around the torus gives, for homogeneous $a, b \in V$,

$$Z_i(a[-2]b,\tau) + \sum_{\ell\geq 1}(2\ell+1)G_{2\ell+2}(\tau)Z_i(a[2\ell]b,\tau) = 0. \tag{67.75}$$

Equation (67.75) is the torus analogue of the sphere residue calculation in Proposition 67.2: the pole z^{-2} records the $a[-2]b$ descendant, while the holomorphic terms of $\wp$ record the allowed windings of the contour around the elliptic curve.

Now C_2-cofiniteness supplies a finite spanning set for the square-bracket descendant quotient. Repeated use of (67.75), together with the corresponding $L[-2]$-insertion identity that gives the modular covariant τ-derivative, reduces all trace functions to a finite system of linear differential equations with modular-form coefficients. The quoted theorem adds the hard analytic conclusions: convergence of the trace functions on the upper half-plane, continuation to a finite-dimensional space of holomorphic functions, and invariance of that space under the generators $S : \tau \mapsto -1/\tau$ and $T : \tau \mapsto \tau + 1$. The Verlinde calculation below uses only the finite modular representation after these analytic inputs have been secured.

Verlinde formula from modular diagonalization. Assume the fusion matrices are simultaneously diagonalized by a unitary matrix S with $S_{0m} \neq 0$:

$$(N_i S)_{jm} = \frac{S_{im}}{S_{0m}} S_{jm}. \tag{67.76}$$

Then

$$N_{ij}{}^k = \sum_m \frac{S_{im} S_{jm} \overline{S_{km}}}{S_{0m}}. \tag{67.77}$$

The coefficient $N_{ij}{}^k$ is the j, k matrix element of N_i:

$$N_{ij}{}^k = (N_i)_j{}^k.$$

Equation (67.76) says

$$N_i = S D_i S^{-1}, \qquad (D_i)_{mm} = \frac{S_{im}}{S_{0m}}.$$

Since S is unitary, $S^{-1}_{mk} = \overline{S_{km}}$. Therefore

$$(N_i)_j{}^k = \sum_m S_{jm} \frac{S_{im}}{S_{0m}} \overline{S_{km}},$$

which is (67.77).

This calculation separates the deep input from the algebra. The deep input is that the same S-matrix obtained by the modular transformation of torus characters diagonalizes the fusion ring. Once this is granted, the formula is linear algebra.

67.7 The Ising Chiral Theory

The Ising minimal model has central charge

$$c = \frac{1}{2}$$

and three simple modules:

$$\mathbf{1}, \qquad \sigma, \qquad \varepsilon,$$

with conformal weights

$$h_{\mathbf{1}} = 0, \qquad h_\sigma = \frac{1}{16}, \qquad h_\varepsilon = \frac{1}{2}.$$

In the ordered basis $(\mathbf{1}, \sigma, \varepsilon)$, the modular S-matrix is

$$S_{\text{Ising}} = \frac{1}{2}\begin{pmatrix} 1 & \sqrt{2} & 1 \\ \sqrt{2} & 0 & -\sqrt{2} \\ 1 & -\sqrt{2} & 1 \end{pmatrix}. \tag{67.78}$$

The corresponding T-matrix is diagonal:

$$T_{\text{Ising}} = \operatorname{diag}\left(\mathrm{e}^{-\pi\mathrm{i}/24}, \mathrm{e}^{\pi\mathrm{i}/12}, \mathrm{e}^{23\pi\mathrm{i}/24}\right), \tag{67.79}$$

because $T_{ii} = \mathrm{e}^{2\pi\mathrm{i}(h_i - c/24)}$ and $c = 1/2$. It is real, unitary, and obeys $S^2 = 1$, because every simple object is self-dual. The quantum dimensions are

$$d_{\mathbf{1}} = 1, \qquad d_\sigma = \sqrt{2}, \qquad d_\varepsilon = 1, \qquad \mathcal{D}^2 = \sum_i d_i^2 = 4.$$

Applying (67.77) gives the fusion rules

$$\varepsilon \boxtimes \varepsilon = \mathbf{1}, \qquad \varepsilon \boxtimes \sigma = \sigma, \qquad \sigma \boxtimes \sigma = \mathbf{1} \oplus \varepsilon.$$

The verification is pure Verlinde algebra. The identity $S^2 = 1$ is a direct matrix multiplication using $(\sqrt{2})^2 = 2$. The vacuum row gives the quantum dimensions by $d_i = S_{i0}/S_{00}$. For example,

$$N_{\sigma\sigma}{}^{\mathbf{1}} = \sum_m \frac{S_{\sigma m} S_{\sigma m} S_{\mathbf{1} m}}{S_{\mathbf{1} m}} = S_{\sigma\mathbf{1}}^2 + S_{\sigma\sigma}^2 + S_{\sigma\varepsilon}^2 = \frac{1}{2} + 0 + \frac{1}{2} = 1,$$

and

$$N_{\sigma\sigma}{}^{\sigma} = \sum_m \frac{S_{\sigma m} S_{\sigma m} S_{\sigma m}}{S_{\mathbf{1} m}} = \frac{\sqrt{2}}{2} - \frac{\sqrt{2}}{2} = 0.$$

The same substitution gives $N_{\sigma\sigma}{}^{\varepsilon} = 1$, $N_{\varepsilon\varepsilon}{}^{\mathbf{1}} = 1$, and $N_{\varepsilon\sigma}{}^{\sigma} = 1$, with all other coefficients fixed by commutativity and the unit object.

67.8 Operator-Algebraic Conformal Nets

The VOA formalism starts from chiral fields as formal distributions and then extracts algebraic consequences. The operator-algebraic formalism starts from bounded observables localized in intervals on the circle. This difference has operator-algebraic content. Smeared chiral fields are usually unbounded operators; commutation on a common invariant domain does not by itself imply commutation of the generated von Neumann algebras. A conformal net records the bounded local algebras directly, and treats fields as affiliated coordinates when such coordinates exist.

Definition 67.21 (Chiral conformal net)**.** Let $\mathcal{I}(S^1)$ be the set of connected, nonempty, nondense open intervals $I \subset S^1$. A Möbius covariant chiral local net consists of a Hilbert space $\mathcal{H}$, a unit vector $\Omega \in \mathcal{H}$, a positive energy unitary representation U of the Möbius group on $\mathcal{H}$, and von Neumann algebras

$$\mathcal{A}(I) \subset B(\mathcal{H}), \qquad I \in \mathcal{I}(S^1),$$

such that:

1. isotony: $I_1 \subset I_2$ implies $\mathcal{A}(I_1) \subset \mathcal{A}(I_2)$;
2. locality: $I_1 \cap I_2 = \varnothing$ implies $[\mathcal{A}(I_1), \mathcal{A}(I_2)] = 0$;
3. covariance: $U(\gamma)\mathcal{A}(I)U(\gamma)^* = \mathcal{A}(\gamma I)$;
4. positive energy: the generator of rotations has spectrum bounded below by 0;
5. vacuum: $U(\gamma)\Omega = \Omega$, and Ω is cyclic for $\bigvee_{I\in\mathcal{I}(S^1)} \mathcal{A}(I)$.

The net is irreducible if $\bigvee_I \mathcal{A}(I) = B(\mathcal{H})$. It is a conformal net, or diffeomorphism-covariant net, if U extends to a strongly continuous projective positive-energy representation of $\mathrm{Diff}^+(S^1)$ satisfying the same covariance and the local implementer condition: if a diffeomorphism is the identity on I, its implementer acts trivially on $\mathcal{A}(I)$.

The complement I' of an interval is the interior of $S^1 \setminus I$. Haag duality is the equality

$$\mathcal{A}(I)' = \mathcal{A}(I').$$

For irreducible Möbius covariant nets on the circle it follows under the standard vacuum-net hypotheses; in higher-dimensional AQFT it is a separate condition, as in Chapter 4.

Definition 67.22 (Split property, strong additivity, and complete rationality)**.** Let $\mathcal{A}$ be an irreducible Möbius covariant net.

1. The split property means that whenever $\overline{I}_1 \subset I_2$ there is a type I factor N with
$$\mathcal{A}(I_1) \subset N \subset \mathcal{A}(I_2).$$
2. Strong additivity means that if deleting one point from an interval I gives the two intervals I_1, I_2, then
$$\mathcal{A}(I) = \mathcal{A}(I_1) \vee \mathcal{A}(I_2).$$
3. Assume the split property. Choose four intervals I_1, I_2, I_3, I_4 in cyclic order and set $E = I_1 \cup I_3$. The μ-index is the Jones index
$$\mu_{\mathcal{A}} = [\mathcal{A}(E')' : \mathcal{A}(E)]$$
when this index is finite and independent of the chosen four intervals.

The net is completely rational if it has the split property, is strongly additive, and has finite $\mu_{\mathcal{A}}$.

Quoted Theorem 67.23 (Representation category of a completely rational net)**.** *For a completely rational chiral conformal net, the finite-index localized representations form a unitary modular tensor category. The categorical global dimension agrees with the μ-index:*

$$\mu_{\mathcal{A}} = \sum_{\rho\in\mathrm{Irr}(\mathcal{A})} d_\rho^2,$$

where d_ρ is the statistical dimension of the sector ρ. This is the Kawahigashi–Longo–Müger conformal-net rationality theorem. The proof uses subfactor index theory and DHR localization, and is not reproduced here [41].

DHR mechanism behind the conformal-net theorem. The quoted theorem is not only a finiteness statement; it identifies the operator-algebraic origin of the braiding and of the modular S-matrix. Fix an interval I_0. A DHR sector localized in I_0 is represented, after Haag duality, by a normal unital endomorphism ρ of the quasilocal algebra such that

$$\rho(A) = A, \qquad A \in \mathcal{A}(I_0'), \tag{67.80}$$

where I_0' is the interior of the complement. If ρ, σ are two such endomorphisms, the morphism space is

$$\mathrm{Hom}(\rho, \sigma) = \{T : T\rho(A) = \sigma(A)T \text{ for all local } A\}. \tag{67.81}$$

The tensor product is composition of endomorphisms, $\rho \otimes \sigma := \rho \circ \sigma$, with tensoring of intertwiners defined by $S \otimes T = S\rho(T)$ for $S \in \mathrm{Hom}(\rho, \rho')$ and $T \in \mathrm{Hom}(\sigma, \sigma')$. Finite Jones index of the subfactor $\rho(\mathcal{A}(I)) \subset \mathcal{A}(I)$, for an interval $I \supset I_0$, gives the statistical dimension

$$d_\rho = [\mathcal{A}(I) : \rho(\mathcal{A}(I))]^{1/2}, \tag{67.82}$$

independent of I in the finite-index sector. Conjugate sectors are endomorphisms $\bar{\rho}$ equipped with intertwiners

$$R \in \mathrm{Hom}(\mathrm{id}, \bar{\rho}\rho), \qquad \bar{R} \in \mathrm{Hom}(\mathrm{id}, \rho\bar{\rho}),$$

obeying the conjugate equations

$$\bar{R}^* \rho(R) = \mathrm{id}_\rho, \qquad R^* \bar{\rho}(\bar{R}) = \mathrm{id}_{\bar{\rho}}, \tag{67.83}$$

after the conventional normalization that minimizes $\|R\|\,\|\bar{R}\|$. This is the C^*-tensor-categorical form of particle-antiparticle pairing in the chiral net.

The braiding is constructed from charge transporters. Move ρ and σ, by unitary intertwiners, to disjoint intervals with a specified cyclic order on S^1. Locality says that the transported endomorphisms commute on all local algebras. Transporting back gives a unitary intertwiner

$$\varepsilon_{\rho,\sigma} \in \mathrm{Hom}(\rho\sigma, \sigma\rho). \tag{67.84}$$

Changing the transporters changes the intermediate representative but not the resulting natural braiding morphism. Naturality and the hexagon identities are therefore consequences of isotony, locality, and the composition law for charge transporters. The two possible cyclic orders on the circle give the braiding and its opposite.

Complete rationality supplies the missing finiteness and nondegeneracy. For two disjoint intervals $E = I_1 \cup I_3$, the finite index

$$\mu_{\mathcal{A}} = [\mathcal{A}(E')' : \mathcal{A}(E)]$$

is the two-interval index measuring the failure of additivity across the two gaps. The subfactor analysis shows that only finitely many irreducible finite-index DHR sectors occur and that

$$\mu_{\mathcal{A}} = \sum_{\rho \in \mathrm{Irr}(\mathcal{A})} d_\rho^2. \tag{67.85}$$

The categorical S-matrix is the normalized trace of monodromy:

$$S_{\rho\sigma} = \frac{1}{\mathcal{D}}\, \mathrm{Tr}_{\rho\sigma}\big(\varepsilon_{\sigma,\rho}\varepsilon_{\rho,\sigma}\big), \qquad \mathcal{D} = \sqrt{\sum_\lambda d_\lambda^2}. \tag{67.86}$$

Here $\mathrm{Tr}_{\rho\sigma}$ is the standard categorical trace coming from the conjugate equations. The vacuum row is $S_{\mathrm{id},\rho} = d_\rho/\mathcal{D}$. Nondegeneracy means that the only sector whose double braiding with every sector is the identity is the vacuum sector; equivalently the matrix $(S_{\rho\sigma})$ is invertible. This is the precise operator-algebraic content of the word "modular" in the theorem. The full proof that the two-interval index forces this nondegeneracy remains the subfactor-theoretic theorem boundary, but the objects entering the statement are the concrete endomorphisms, intertwiners, dimensions, and charge-transporter braidings defined above.

The comparison with VOAs is therefore a comparison of two different coordinates on chiral locality. A VOA gives formal fields and mode algebra; a net gives bounded interval algebras. Passing from one to the other is an analytic theorem, not a definition.

Quoted Theorem 67.24 (Strongly local VOAs and conformal nets)**.** *Let V be a simple unitary VOA whose vertex operators obey polynomial energy bounds. If the smeared fields $Y(a,f)$, $a \in V$, $f \in C^\infty(S^1)$, generate mutually local von Neumann algebras*

$$\mathcal{A}_V(I) = W^*\{\overline{Y(a,f)} : \operatorname{supp} f \subset I,\ a \in V\}, \qquad I \in \mathcal{I}(S^1),$$

then V is called strongly local and $I \mapsto \mathcal{A}_V(I)$ is an irreducible conformal net. The net is independent, up to isomorphism, of the normalized invariant scalar product on V.

Conversely, the Fredenhagen–Jörß reconstruction applied to $\mathcal{A}_V$ recovers the smeared vertex operators of V. More generally, if an irreducible conformal net is generated by quasi-primary reconstructed fields, those fields satisfy polynomial energy bounds, and the L_0-eigenspaces are finite-dimensional, then the finite-energy subspace $\mathcal{H}^{\mathrm{fin}}$ carries a simple unitary strongly local VOA structure V with $\mathcal{A} \simeq \mathcal{A}_V$.

This is the Carpi–Kawahigashi–Longo–Weiner VOA-to-net theorem and its Fredenhagen–Jörß converse under the stated analytic hypotheses [42].

Mechanism of the VOA-to-net passage. Let $\mathcal{H}$ be the Hilbert completion of the unitary VOA V, let L_0 be the positive rotation generator, and set

$$\mathcal{H}^\infty := \bigcap_{k \geq 0} \mathrm{Dom}(1+L_0)^k.$$

A polynomial energy bound for $a \in V$ means that there exist constants C, r, s, depending on a, such that for every mode a_n and every $\psi \in \mathcal{H}^\infty$,

$$\|a_n\psi\| \leq C(1+|n|)^r \|(1+L_0)^s\psi\|. \tag{67.87}$$

For a smooth test function

$$f(\mathrm{e}^{\mathrm{i}\theta}) = \sum_{n\in\mathbb{Z}} \hat{f}_n \mathrm{e}^{-\mathrm{i}n\theta}$$

the rapid decay of $\hat{f}_n$ implies

$$Y(a,f)\psi := \sum_{n\in\mathbb{Z}} \hat{f}_n a_n \psi \tag{67.88}$$

converges in $\mathcal{H}$, because $\sum_n |\hat{f}_n|(1+|n|)^r < \infty$. Unitarity supplies the adjoint formula for vertex operators, so $Y(a,f)$ is closable on $\mathcal{H}^\infty$. The local von Neumann algebra in the theorem is therefore not obtained by treating $Y(a,z)$ as a pointwise operator; it is generated from closed smeared operators with supports contained in I:

$$\mathcal{A}_V(I) = W^*\{\overline{Y(a,f)} : \operatorname{supp} f \subset I,\ a \in V\}.$$

The delicate step is locality. VOA locality gives, for each pair a, b, an integer N such that

$$(z-w)^N [Y(a,z), Y(b,w)] = 0$$

as a formal distribution identity. After smearing with disjointly supported smooth functions, this gives

$$[Y(a,f), Y(b,g)]\psi = 0, \qquad \psi \in \mathcal{H}^\infty.$$

This common-domain commutator identity is not yet locality of the net: the latter requires the von Neumann algebras generated by the closures to commute. The analytic content of strong locality is precisely the upgrade from finite-energy-domain locality of unbounded fields to strong commutativity of the closed smeared fields and their bounded functional calculi. Polynomial energy bounds, positivity of L_0, and the adjoint formula give the operator control used in that upgrade.

Covariance is more formal once the smeared fields exist. The projective unitary Möbius and diffeomorphism action on the Hilbert completion sends a smeared field to a finite linear combination of smeared fields whose test functions are pulled back with the appropriate conformal-weight factors. Thus

$$U(\gamma)\mathcal{A}_V(I)U(\gamma)^* = \mathcal{A}_V(\gamma I)$$

provided the implementers preserve the common smooth domain and the energy bounds. Vacuum cyclicity follows from the state-field correspondence and the density of VOA descendants in the Hilbert completion. The theorem boundary is the simultaneous proof that these analytic requirements are stable for the whole field family, not only for a chosen finite generating set.

Mechanism of the net-to-VOA reconstruction. The converse starts with bounded interval algebras rather than formal fields. For a finite-energy vector $\psi \in \mathcal{H}^{\mathrm{fin}}$, the Fredenhagen–Jörß construction seeks a closed operator-valued distribution Φ_ψ affiliated with the local algebras and normalized by

$$\Phi_\psi(f)\Omega = \int_{S^1} f(z)\, U(z)\psi\, dz$$

in the distributional sense, where $U(z)$ denotes rotation of the state. Locality of the net gives commutation of $\Phi_\psi(f)$ with $\mathcal{A}(I')$ when $\operatorname{supp} f \subset I$. Möbius covariance decomposes $\mathcal{H}^{\mathrm{fin}}$ into finite-dimensional L_0-eigenspaces and fixes the mode degrees of the reconstructed fields. If the reconstructed quasi-primary fields obey polynomial energy bounds, their smeared products have vacuum matrix elements with the same analytic-continuation and locality properties as VOA correlation functions. The modes of these fields then define a state-field map on $\mathcal{H}^{\mathrm{fin}}$, with the vacuum, translation, locality, and Virasoro covariance axioms recovered from the net axioms plus the Fredenhagen–Jörß field-state normalization.

The converse theorem boundary is again analytic rather than formal. One must prove that enough finite-energy vectors admit such reconstructed fields, that the fields satisfy the required energy bounds, and that the mode products close on $\mathcal{H}^{\mathrm{fin}}$. Without those hypotheses a conformal net need not be identified with a VOA merely because both describe chiral locality.

Ising net μ-index and DHR fusion. Assume the unitary Ising VOA is taken in its strongly local realization and that its associated conformal net is completely rational with sectors $\mathbf{1}, \sigma, \varepsilon$. Then

$$\mu_{\mathcal{A}_{\mathrm{Ising}}} = 4,$$

and the DHR fusion ring of the net agrees with the Ising Verlinde fusion ring displayed above.

From the explicit Ising S-matrix (67.78), the quantum dimensions are

$$d_{\mathbf{1}} = 1, \qquad d_\sigma = \sqrt{2}, \qquad d_\varepsilon = 1.$$

The quoted complete-rationality theorem gives

$$\mu_{\mathcal{A}_{\mathrm{Ising}}} = d_{\mathbf{1}}^2 + d_\sigma^2 + d_\varepsilon^2 = 1 + 2 + 1 = 4.$$

The same theorem identifies finite-index DHR sectors with the modular tensor category of the net. Under the VOA-to-net comparison theorem, the strongly local Ising VOA and the Ising net have the same chiral sectors, so the DHR fusion coefficients are the Verlinde coefficients already computed.

Open Problem 67.25 (Unqualified VOA/net equivalence)*.* Remove or sharply weaken the analytic hypotheses in Theorem 67.24. In particular, determine whether every simple unitary positive-energy VOA satisfying the specified finiteness conditions is strongly local, and whether every irreducible conformal net of finite chiral type is recovered from a strongly local VOA. The monograph uses the proved strongly local correspondence as a theorem boundary and does not assume this unqualified equivalence.

67.9 Full CFT and the Modular Bootstrap

A full local CFT is not a chiral theory alone. In a rational diagonal case, one constructs a torus partition function from left and right characters:

$$Z(\tau, \bar{\tau}) = \sum_{i,j} M_{ij} \chi_i(\tau) \overline{\chi_j(\tau)}. \tag{67.89}$$

The matrix M must have nonnegative integer entries, $M_{00} = 1$, and must commute with the modular representation:

$$MS = SM, \qquad MT = TM. \tag{67.90}$$

These are genus-one sewing constraints. Higher-genus sewing imposes further compatibility between M, chiral blocks, duality moves, and the pairing of left and right chiral sectors.

Ising genus-one invariant. For the Ising chiral data of Section 67.7, restrict to full CFT torus partition functions whose left and right chiral labels both lie in $(\mathbf{1}, \sigma, \varepsilon)$. Let

$$M = (M_{ij})_{i,j \in \{\mathbf{1}, \sigma, \varepsilon\}} \in \mathrm{Mat}_3(\mathbb{Z}_{\geq 0})$$

with $M_{\mathbf{11}} = 1$. If M satisfies (67.90) with (67.78) and (67.79), then $M = I_3$. Thus the only genus-one modular invariant with one vacuum in this chiral Ising label set is the diagonal invariant

$$Z_{\mathrm{Ising}}(\tau, \bar{\tau}) = |\chi_{\mathbf{1}}|^2 + |\chi_\sigma|^2 + |\chi_\varepsilon|^2. \tag{67.91}$$

The T-constraint is already a spin-selection rule. Since T is diagonal,

$$(MT)_{ij} - (TM)_{ij} = M_{ij}\left(\mathrm{e}^{2\pi\mathrm{i}(h_j - c/24)} - \mathrm{e}^{2\pi\mathrm{i}(h_i - c/24)}\right).$$

Therefore $M_{ij} \neq 0$ implies $h_i - h_j \in \mathbb{Z}$. For the Ising weights

$$0, \qquad \frac{1}{16}, \qquad \frac{1}{2},$$

no two distinct weights differ by an integer. Hence M is diagonal:

$$M = \mathrm{diag}(1, a, b), \qquad a, b \in \mathbb{Z}_{\geq 0}.$$

The S-constraint now gives, entry by entry,

$$(MS)_{\mathbf{1}\sigma} = S_{\mathbf{1}\sigma}, \qquad (SM)_{\mathbf{1}\sigma} = aS_{\mathbf{1}\sigma}.$$

Since $S_{\mathbf{1}\sigma} = 1/\sqrt{2} \neq 0$, one gets $a = 1$. Similarly

$$(MS)_{\mathbf{1}\varepsilon} = S_{\mathbf{1}\varepsilon}, \qquad (SM)_{\mathbf{1}\varepsilon} = bS_{\mathbf{1}\varepsilon},$$

and $S_{\mathbf{1}\varepsilon} = 1/2 \neq 0$, so $b = 1$. Thus $M = I_3$, and (67.91) follows from (67.89).

67.9.1 Torus One-Point Blocks and Verlinde Defect Lines

The partition function is the genus-one zero-point function. A complete genus-one discussion also needs one-point blocks and topological defect lines. Both are often drawn pictorially; here we spell out the algebraic content because the assumptions are different from those used in the scalar partition function.

Let V be a rational chiral theory satisfying Definition 67.19, and let $v \in V$ be homogeneous of conformal weight h_v. The zero mode

$$o(v) := v_{h_v - 1}$$

has L_0-degree zero. The chiral torus one-point block on the simple module M_i is

$$F_i(v;\tau) := \mathrm{Tr}_{M_i}\, o(v)\, q^{L_0 - c/24}. \tag{67.92}$$

Only the zero mode can contribute to a trace over L_0-eigenspaces: a mode of nonzero L_0-degree maps each finite-dimensional eigenspace to a different eigenspace and therefore has zero diagonal trace. For $v = \mathbf{1}$, $o(v) = 1$ and $F_i(\mathbf{1};\tau) = \chi_i(\tau)$.

Quoted Theorem 67.26 (Zhu modular covariance of torus one-point blocks)**.** *Assume V is rational, C_2-cofinite, of CFT type, and has ordinary simple modules M_i. For each homogeneous $v \in V$, the finite vector $(F_i(v;\tau))_i$ spans a representation of $SL_2(\mathbb{Z})$. If v is Virasoro primary of weight h_v, then for $\gamma = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$*

$$F_i\left(v; \frac{a\tau + b}{c\tau + d}\right) = (c\tau + d)^{h_v} \sum_j \rho_v(\gamma)_{ij} F_j(v;\tau). \tag{67.93}$$

For $v = \mathbf{1}$, ρ_v is the character modular representation used above. This is the one-point-function part of Zhu's genus-one modular-covariance theorem [37].

The factor $(c\tau+d)^{h_v}$ is the conformal weight factor for the change of torus coordinate. The theorem input is the finite-dimensionality and holomorphic modular closure of the trace functions.

Mechanism behind torus one-point covariance. The one-point theorem is the genus-one version of transporting a conformal block on a once-punctured torus. The point of the zero mode $o(v)$ is that it preserves L_0-eigenspaces; hence the trace

$$F_i(v;\tau) = \mathrm{Tr}_{M_i} o(v) q^{L_0 - c/24}$$

is a genuine finite-energy trace after summing over each L_0-eigenspace. In Zhu's square-bracket coordinate, the inserted state is transported by the coordinate change at the puncture. For a Virasoro primary v, this transport is scalar:

$$v \longmapsto (c\tau + d)^{h_v} v$$

under the modular coordinate change

$$(z,\tau) \longmapsto \left(\frac{z}{c\tau + d}, \frac{a\tau + b}{c\tau + d} \right).$$

For descendants, the same coordinate change also produces lower-descendant terms involving the Schwarzian and the square-bracket Virasoro modes; those terms are the source of the quasimodular G_2-mixing in genus-one Ward recursions. The primary hypothesis in Theorem 67.26 is exactly the condition that this coordinate transport has a single leading weight factor.

The finite-dimensional closure is the same C_2-cofinite trace-recursion mechanism used for characters, but with v kept as a marked insertion. Moving a square-bracket field around the torus expresses traces with $[-2]$-descendants in terms of traces with finitely many lower square-bracket descendants and modular forms. Rationality identifies the simple ordinary modules as a finite set of sectors, while C_2-cofiniteness keeps the marked-state quotient finite. Therefore the traces

$$\{F_i(w;\tau) :\ i \in I,\ w \in W_v\}$$

for the finite descendant span W_v determined by v satisfy a finite modular differential system. Zhu's analytic theorem supplies convergence on $\mathbb{H}$, continuation of this finite solution space, and its invariance under S and T. Formula (67.93) is the primary, one-marked-state component of that finite system.

A full-CFT torus one-point function of a bulk primary Φ of weights $(h, \bar{h})$ is a sesquilinear pairing of the corresponding chiral one-point-block vectors. Modular covariance therefore requires an invariant coefficient tensor for $\rho_\Phi(\gamma) \otimes \overline{\rho_\Phi(\gamma)}$, together with the weight factor $(c\tau + d)^h (c\bar{\tau} + d)^{\bar{h}}$. Thus torus one-point functions constrain bulk OPE data beyond the scalar partition function.

Topological defect lines give a second genus-one probe. In a diagonal rational full CFT built from a unitary modular tensor category $\mathcal{C}$, the Verlinde defects are labelled by simple objects $a \in I$. Let

$$\mathcal{H}_{\mathrm{diag}} = \bigoplus_{i \in I} M_i \otimes \overline{M_i^\vee}$$

be the diagonal Hilbert space. Define D_a on the summand labelled by i by

$$D_a\big|_{M_i \otimes \overline{M_i^\vee}} = \lambda_a(i)\,\mathrm{id}, \qquad \lambda_a(i) := \frac{S_{ai}}{S_{0i}}. \tag{67.94}$$

The denominator is nonzero in a unitary modular tensor category because $S_{0i} = d_i S_{00}$ and $d_i > 0$.

Verlinde defect fusion and modular covariance. For the diagonal rational full CFT above,

$$D_a D_b = \sum_c N_{ab}{}^c D_c. \tag{67.95}$$

Moreover, the torus trace with D_a wrapping the Euclidean-time cycle is

$$Z_a^{\mathrm{time}}(\tau,\bar\tau) = \sum_i \lambda_a(i)\chi_i(\tau)\overline{\chi_i(\tau)}. \tag{67.96}$$

After the modular S-move it becomes the spatial-defect trace

$$Z_a^{\mathrm{time}}(-1/\tau,-1/\bar\tau) = \sum_{p,q} N_{ap}{}^q\,\chi_p(\tau)\overline{\chi_q(\tau)}. \tag{67.97}$$

The Verlinde formula says that the matrices N_a are simultaneously diagonalized by S, with eigenvalue S_{ai}/S_{0i} on the i-th character. Hence for every i,

$$\lambda_a(i)\lambda_b(i) = \sum_c N_{ab}{}^c \lambda_c(i),$$

which proves (67.95) on each diagonal summand of $\mathcal{H}_{\mathrm{diag}}$.

For the modular transform, insert the character transformation law into (67.96). The coefficient of $\chi_p\overline{\chi_q}$ is

$$\sum_i \frac{S_{ai}}{S_{0i}}\,S_{ip}\,\overline{S_{iq}} = \sum_i \frac{S_{ai}S_{pi}S_{q^\vee i}}{S_{0i}} = N_{ap}{}^q,$$

where unitarity gives $\overline{S_{iq}} = S_{q^\vee i}$, and the last equality is Verlinde. This gives (67.97). The right side is a Hilbert-space trace over

$$\mathcal{H}_a = \bigoplus_{p,q} N_{ap}{}^q\, M_p \otimes \overline{M_q^\vee},$$

so the modular move has turned a temporal defect operator into a spatial defect sector.

For the Ising labels $(\mathbf{1},\sigma,\varepsilon)$, the eigenvalue vectors $(\lambda_a(\mathbf{1}),\lambda_a(\sigma),\lambda_a(\varepsilon))$ are

$$\lambda_{\mathbf{1}} = (1,1,1), \qquad \lambda_\sigma = (\sqrt{2},0,-\sqrt{2}), \qquad \lambda_\varepsilon = (1,-1,1).$$

Thus

$$D_\varepsilon^2 = D_{\mathbf{1}}, \qquad D_\varepsilon D_\sigma = D_\sigma, \qquad D_\sigma^2 = D_{\mathbf{1}} + D_\varepsilon,$$

so D_ε is the invertible spin-flip line and D_σ is the noninvertible Kramers–Wannier line. Their modular covariance is completely finite. For example,

$$Z_\varepsilon^{\mathrm{time}} = |\chi_{\mathbf{1}}|^2 - |\chi_\sigma|^2 + |\chi_\varepsilon|^2$$

is sent by S to

$$\chi_{\mathbf{1}}\overline{\chi_\varepsilon} + \chi_\varepsilon\overline{\chi_{\mathbf{1}}} + |\chi_\sigma|^2,$$

the Hilbert space twisted by the spin-flip defect. Similarly

$$Z_\sigma^{\mathrm{time}} = \sqrt{2}\left(|\chi_{\mathbf{1}}|^2 - |\chi_\varepsilon|^2\right)$$

is sent by S to

$$\chi_{\mathbf{1}}\overline{\chi_\sigma} + \chi_\varepsilon\overline{\chi_\sigma} + \chi_\sigma\overline{\chi_{\mathbf{1}}} + \chi_\sigma\overline{\chi_\varepsilon}.$$

The same line-sliding argument gives selection rules for torus one-point functions. Since D_ε acts by -1 on the Ising spin primary, the torus one-point function of σ equals its negative and therefore vanishes. This topological-defect Ward identity is independent of any particular lattice realization.

For a unitary compact two-dimensional CFT with discrete spectrum on the circle, the rectangular torus partition function

$$Z(\beta) = \mathrm{Tr}_{\mathcal{H}(S^1)} \exp\{-\beta(H - c_{\mathrm{tot}}/24)\}, \qquad c_{\mathrm{tot}} = c + \bar{c},$$

obeys modular invariance

$$Z(\beta) = Z(4\pi^2/\beta)$$

when the spatial circle has circumference 2π. If the low-temperature trace is dominated by a unique vacuum, then as $\beta \to 0^+$,

$$\log Z(\beta) = \frac{\pi^2 c_{\mathrm{tot}}}{6\beta} + o(\beta^{-1}). \tag{67.98}$$

The derivation is only the modular transformation: low temperature at $4\pi^2/\beta$ gives

$$Z(4\pi^2/\beta) = \exp\left\{\frac{4\pi^2}{\beta}\frac{c_{\mathrm{tot}}}{24}\right\}(1 + o(1)),$$

which is (67.98). Tauberian hypotheses convert this high-temperature partition-function statement into an asymptotic density of states. Those hypotheses are analytic input; modular invariance alone is not a pointwise formula for individual degeneracies.

Quoted Theorem 67.27 (Exponential Tauberian theorem)**.** *Let $N(E)$ be a nondecreasing right-continuous function on $[0,\infty)$, and suppose its Laplace transform*

$$Z(\beta) = \int_{[0,\infty)} \mathrm{e}^{-\beta E}\,\mathrm{d}N(E)$$

is finite for every $\beta > 0$. If, for some $A > 0$,

$$\log Z(\beta) = \frac{A}{\beta} + o(\beta^{-1}) \qquad (\beta \downarrow 0),$$

then

$$\log N(E) = 2\sqrt{AE} + o(\sqrt{E}) \qquad (E \to \infty).$$

This is the exponential Tauberian input used in Cardy asymptotics; the regular-variation reference is a source trace, while the chapter below spells out the one-sided Laplace estimate and isolates the inverse Tauberian step [43].

The theorem contains an elementary one-sided estimate and a genuinely Tauberian inverse estimate. Let μ_N be the positive Stieltjes measure with $\mu_N([0,E]) = N(E)$. For every $\beta > 0$,

$$Z(\beta) \geq \int_{[0,E]} \mathrm{e}^{-\beta E}\,\mathrm{d}\mu_N(E') = \mathrm{e}^{-\beta E} N(E),$$

and hence

$$\log N(E) \le \inf_{\beta>0}\{\beta E + \log Z(\beta)\}. \tag{67.99}$$

If $\log Z(\beta) = A/\beta + o(\beta^{-1})$, choosing $\beta = \sqrt{A/E}$ in (67.99) gives the upper half

$$\limsup_{E\to\infty} \frac{\log N(E)}{\sqrt{E}} \le 2\sqrt{A}.$$

The inverse half is the nontrivial content: positivity and monotonicity of the counting measure force enough spectral mass in the saddle window $E' \sim A/\beta^2$ to produce the same leading exponent from below. Without that positivity, cancellations in a signed trace can obey the same modular transformation law while carrying no comparable counting interpretation.

The coefficient $2\sqrt{A}$ is fixed by the Legendre saddle. If a candidate cumulative growth has the leading form $\log N(E) \sim B\sqrt{E}$, the formal Laplace exponent is

$$\Phi_\beta(E') = B\sqrt{E'} - \beta E', \qquad E'_\beta = \frac{B^2}{4\beta^2},$$

and

$$\sup_{E'\ge 0} \Phi_\beta(E') = \frac{B^2}{4\beta}.$$

Matching this with A/β gives $B = 2\sqrt{A}$. The quoted theorem is precisely the analytic statement that this saddle reasoning is legitimate for a positive cumulative spectral measure at the exponential scale.

This theorem is the precise analytic bridge between the modular high-temperature statement and the density of states. Its positivity hypothesis is essential: $N(E)$ is a cumulative spectral counting function, not a signed distribution obtained by subtracting sectors.

CFT-internal Cardy growth. Let $\mathcal{C}$ be a unitary compact two-dimensional CFT on a circle of circumference 2π. Assume the Hilbert-space spectrum of

$$E = L_0 + \bar{L}_0$$

is discrete with finite multiplicities, $E \ge 0$, and has a unique vacuum at $E = 0$. Assume also that the torus partition function is modular invariant and has no continuous spectral contribution. Let

$$N(E) = \dim\{\psi \in \mathcal{H}(S^1) \mid (L_0 + \bar{L}_0)\psi \le E\}$$

be the cumulative degeneracy. Then

$$\log N(E) = 2\pi\sqrt{\frac{c_{\mathrm{tot}}E}{6}} + o(\sqrt{E}), \qquad E \to \infty. \tag{67.100}$$

This is a direct consequence of the quoted Tauberian theorem after identifying the positive counting measure. The shifted cylinder partition function used above is

$$Z(\beta) = \operatorname{Tr}\exp\{-\beta(L_0 + \bar{L}_0 - c_{\mathrm{tot}}/24)\}.$$

Multiplying by $\exp\{-\beta c_{\rm tot}/24\}$ gives the ordinary Laplace transform of the positive counting measure $\mathrm{d}N(E)$:

$$\widetilde{Z}(\beta) = \operatorname{Tr}\exp\{-\beta(L_0+\bar{L}_0)\} = \int_{[0,\infty)} \mathrm{e}^{-\beta E}\,\mathrm{d}N(E).$$

Since $\beta c_{\rm tot}/24 = o(\beta^{-1})$, the high-temperature asymptotic (67.98) gives

$$\log \widetilde{Z}(\beta) = \frac{\pi^2 c_{\rm tot}}{6\beta} + o(\beta^{-1}).$$

Apply Theorem 67.27 with $A = \pi^2 c_{\rm tot}/6$.

A saddle calculation checks the coefficient but does not replace the Tauberian theorem or the positivity hypothesis above. With $A = \pi^2 c_{\rm tot}/6$, if a smooth density had entropy

$$S(E) = 2\sqrt{AE},$$

then the Laplace exponent $S(E) - \beta E$ is stationary at

$$E_* = \frac{A}{\beta^2},$$

and the stationary value is A/β. Thus the density-growth coefficient in (67.100) is exactly the Legendre dual of the modular coefficient in (67.98); the theorem above is what justifies this conclusion for a discrete positive spectrum.

The modular bootstrap is the study of the constraints (67.90), reflection positivity, spin integrality, and higher-genus sewing on the spectrum and OPE data. In rational theories it is finite-dimensional algebra. In nonrational compact theories it is an infinite-dimensional positivity and growth problem for torus and higher-genus partition functions.

67.10 Direct-Integral Data for Nonrational CFT

The rational theory discussed above has two simplifying properties: the chiral sector category has finitely many simple objects, and every sewing formula reduces to a finite sum. Neither property is part of the local definition of a two-dimensional conformal field theory. A compact CFT may have a countably infinite discrete spectrum, as in an irrational compact boson. A noncompact CFT may have continuous normalizable spectrum, as in Liouville theory. In both cases the finite sum over intermediate primaries must be replaced by a spectral resolution of Hilbert-space vectors.

Definition 67.28 (Spectral radial product datum)**.** Fix a unitary two-dimensional CFT on the round circle with Hilbert space $\mathcal{H}$, vacuum Ω, self-adjoint nonnegative operators $L_0, \bar{L}_0$, and dense local domain $\mathcal{D}_{\rm loc}$. A spectral radial product datum for two local fields A, B consists of the following data.

1. For every $0 < r < 1$ and $\theta \in \mathbb{R}/2\pi\mathbb{Z}$, the radially ordered product vector

$$\Phi_{BA}(r,\theta) = B(re^{\mathrm{i}\theta})A(0)\Omega$$

is a vector in $\mathcal{H}$.

2. Let $\mathcal{H}_{BA} \subset \mathcal{H}$ be the closed subspace generated by all $\Phi_{BA}(r,\theta)$ and by the action of the two Virasoro algebras. The representation of the commuting spectral observables used to label intermediate sectors is represented as a direct integral

$$\mathcal{H}_{BA} \simeq \int_{X_{BA}}^{\oplus} \mathcal{K}_x \, \mathrm{d}\mu_{BA}(x), \tag{67.101}$$

where X_{BA} is a standard Borel space, μ_{BA} is a positive measure, and $x \mapsto \mathcal{K}_x$ is a measurable field of Hilbert spaces carrying the descendant and multiplicity degrees of freedom.

3. In this representation the product vector is a square-integrable measurable vector field

$$\widehat{\Phi}_{BA}(x;r,\theta) \in \mathcal{K}_x, \qquad \int_{X_{BA}} \|\widehat{\Phi}_{BA}(x;r,\theta)\|^2_{\mathcal{K}_x} \mathrm{d}\mu_{BA}(x) < \infty.$$

The variable x is an intermediate spectral label, not necessarily the label of a normalizable primary vector. When x lies in a continuous spectrum, the formal object called a primary of label x is a generalized eigenvector; the Hilbert-space object is the square-integrable field $\widehat{\Phi}_{BA}$.

This definition is deliberately phrased before choosing a basis of chiral blocks. The direct integral is supplied by the spectral theorem for the commuting self-adjoint operators and by the decomposition of the chiral representation on the closed cyclic subspace. A conformal-block expansion is obtained only after choosing measurable bases of intertwiners in the fibers $\mathcal{K}_x$. The Plancherel measure and the multiplicity fields are therefore part of the CFT data.

Remark 67.29 (Direct-integral OPE identity). Let $A, B, C, D \in \mathcal{D}_{\mathrm{loc}}$ and assume that the radial products $\Phi_{BA}(r,\theta)$ and $\Phi_{CD}(\rho,\varphi)$ have spectral radial product data using a common direct-integral decomposition

$$\mathcal{H}_{ABCD} \simeq \int_X^{\oplus} \mathcal{K}_x \, \mathrm{d}\mu(x)$$

of the closed subspace generated by the two product families. Then the four-point function in the radial domain $0 < r < \rho < 1$ is

$$\langle C(\rho e^{\mathrm{i}\varphi})D(0)\Omega,\, B(re^{\mathrm{i}\theta})A(0)\Omega\rangle_{\mathcal{H}} = \int_X \Big\langle \widehat{\Phi}_{CD}(x;\rho,\varphi),\, \widehat{\Phi}_{BA}(x;r,\theta) \Big\rangle_{\mathcal{K}_x} \mathrm{d}\mu(x). \tag{67.102}$$

If the measure is counting measure on a finite set this is the rational finite sum over intermediate states. If the measure has a continuous part, the same formula is an L^2-inner product, not a pointwise sum over delta-normalized states. Indeed, choose the unitary map

$$U : \mathcal{H}_{ABCD} \longrightarrow \int_X^{\oplus} \mathcal{K}_x \, \mathrm{d}\mu(x)$$

implementing the direct integral. By definition, $U\Phi_{BA} = \widehat{\Phi}_{BA}$ and $U\Phi_{CD} = \widehat{\Phi}_{CD}$. Unitarity of U gives the Plancherel identity

$$\langle \Phi_{CD}, \Phi_{BA}\rangle_{\mathcal{H}} = \int_X \langle (U\Phi_{CD})(x), (U\Phi_{BA})(x)\rangle_{\mathcal{K}_x} \mathrm{d}\mu(x),$$

which is (67.102). No assumption about a discrete basis of normalizable primaries has entered the argument.

The usual OPE notation is a compressed way of writing (67.102). For a continuous spectrum it should be read as an identity of matrix elements after smearing the intermediate label against the Plancherel measure and after specifying the domain of radial convergence.

67.10.1 Worked Example: The Noncompact Free Boson

The simplest continuous-spectrum example is a single real free boson with target $\mathbb{R}$. We use the same chiral normalization as in Section 66.6,

$$X_L(z)X_L(0) \sim -\log z, \qquad X_R(\bar{z})X_R(0) \sim -\log \bar{z}.$$

The zero-mode Hilbert space is $L^2(\mathbb{R}, \mathrm{d}x)$. After Fourier transform it is $L^2(\mathbb{R}, \mathrm{d}p)$, and the full Hilbert space is the direct integral

$$\mathcal{H}_{\mathbb{R}} = \int_{\mathbb{R}}^{\oplus} \mathcal{F}_p \,\mathrm{d}p, \qquad \mathcal{F}_p \simeq \mathcal{F}^L_{\mathrm{osc}} \otimes \mathcal{F}^R_{\mathrm{osc}}. \tag{67.103}$$

The fiber ground state at momentum p has

$$h_p = \bar{h}_p = \frac{p^2}{2}. \tag{67.104}$$

Thus p is a spectral label in the direct integral. The plane wave $\mathrm{e}^{\mathrm{i}px}$ is a generalized eigenvector; an actual Hilbert vector is a square-integrable wave packet $f(p) \in L^2(\mathbb{R}, \mathrm{d}p)$, together with oscillator excitations.

For $a \in \mathbb{R}$, let $V_a(z, \bar{z})$ denote the diagonal exponential field

$$V_a(z, \bar{z}) =: \exp(\mathrm{i}aX_L(z) + \mathrm{i}aX_R(\bar{z})) : .$$

As a zero-mode operator it translates the momentum fiber,

$$V_a : \mathcal{F}_p \longrightarrow \mathcal{F}_{p+a}.$$

The field at a fixed real label a is distributional in the spectral label. For $f \in C_c^\infty(\mathbb{R})$, the smeared exponential

$$V_f(z, \bar{z}) = \int_{\mathbb{R}} f(a)V_a(z, \bar{z})\,\mathrm{d}a \tag{67.105}$$

has finite matrix elements between finite-energy wave packets in every closed annulus avoiding coincident points.

The leading product of two labelled exponentials is

$$V_a(z, \bar{z})V_b(0) \sim |z|^{2ab}V_{a+b}(0) + \text{oscillator descendants}. \tag{67.106}$$

Consequently the smeared leading OPE coefficient is the weighted convolution

$$V_f(z, \bar{z})V_g(0) \sim \int_{\mathbb{R}} (f \star_z g)(c)\, V_c(0)\,\mathrm{d}c + \cdots, \tag{67.107}$$

where

$$(f \star_z g)(c) = \int_{\mathbb{R}} f(a)g(c-a)|z|^{2a(c-a)}\,\mathrm{d}a. \tag{67.108}$$

This is the continuous analogue of the lattice charge-conservation rule in (66.62). Associativity of the leading charge factor is the elementary identity

$$ab + (a+b)c = bc + a(b+c), \tag{67.109}$$

which says that either radial grouping of $V_aV_bV_c$ gives the same charge $a+b+c$ and the same power of pairwise distances after the standard coordinate factors are restored. The full diagonal field is separated-point single-valued because the left and right monodromy phases cancel.

The genus-one zero-point function is a trace density. If one puts the target coordinate in a box of length L, the ordinary trace is proportional to L. Dividing by L and letting $L \to \infty$ gives the density

$$Z_{\mathbb{R}}^{\mathrm{dens}}(\tau,\bar{\tau}) = \frac{1}{|\eta(\tau)|^2}\int_{\mathbb{R}} \exp(-2\pi\tau_2 p^2)\,\mathrm{d}p = \frac{1}{\sqrt{2\tau_2}\,|\eta(\tau)|^2}, \qquad \tau_2 = \operatorname{Im}\tau. \tag{67.110}$$

The equality uses the ordinary Gaussian integral in the chosen Plancherel normalization. The density is modular invariant: under $S:\tau\mapsto -1/\tau$, $\tau_2\mapsto \tau_2/|\tau|^2$ while $|\eta(-1/\tau)|^2 = |\tau|\,|\eta(\tau)|^2$, so the factor $\tau_2^{-1/2}|\eta(\tau)|^{-2}$ is unchanged. This is a statement about the semifinite trace per unit target volume; it is the correct replacement for a finite Hilbert-space trace in a translation-invariant noncompact target.

The same density is obtained from the compact circle by decompactification. For a circle of radius R, the momentum spacing is $1/R$. At fixed $\tau_2 > 0$, the winding sectors with nonzero winding have weights exponentially small as $R\to\infty$, and

$$\frac{1}{R}\sum_{m\in\mathbb{Z}} \exp\!\left(-2\pi\tau_2\frac{m^2}{R^2}\right) \longrightarrow \int_{\mathbb{R}} \exp(-2\pi\tau_2 p^2)\,\mathrm{d}p.$$

Thus compact-boson theta functions converge, after division by the target volume normalization, to the Plancherel density (67.110).

This example isolates the continuous-spectrum mechanics from the additional analytic content of Liouville theory. In the free noncompact boson the Plancherel measure is Lebesgue measure, the reflection relation is absent, and the fusing transform is the Fourier/Plancherel transform attached to linear momentum conservation. In Liouville theory the same direct-integral language remains, but the spectrum is $\alpha = Q/2 + \mathrm{i}P$ modulo reflection, the three-point coefficient is DOZZ, and the fusing transform is the Virasoro noncompact fusion kernel. The difference is data, not notation.

Definition 67.30 (Measurable fusing transform)**.** For fixed ordered external fields A, B, C, D, let

$$\int_{X_s}^{\oplus} \mathcal{K}_x^{(s)}\,\mathrm{d}\mu_s(x), \qquad \int_{X_t}^{\oplus} \mathcal{K}_y^{(t)}\,\mathrm{d}\mu_t(y)$$

be the direct-integral Hilbert spaces obtained from the s-channel radial grouping $(BA)(DC)$ and the t-channel grouping $(CB)(DA)$. A measurable fusing transform is a unitary operator

$$\mathbb{F}_{st} : \int_{X_s}^{\oplus} \mathcal{K}_x^{(s)}\,\mathrm{d}\mu_s(x) \longrightarrow \int_{X_t}^{\oplus} \mathcal{K}_y^{(t)}\,\mathrm{d}\mu_t(y) \tag{67.111}$$

which intertwines the two analytic continuations of the same chiral four-point block from the s- and t-channel radial domains. When the fibers are finite-dimensional and a measurable basis has been chosen, this operator is represented by a kernel

$$(\mathbb{F}_{st} f)(y) = \int_{X_s} F_{st}(y,x) f(x)\,\mathrm{d}\mu_s(x), \tag{67.112}$$

understood as an equality in the direct-integral Hilbert space, with the unitarity condition

$$\int_{X_t} F_{st}(y,x)^{\dagger} F_{st}(y,x')\,\mathrm{d}\mu_t(y) = \delta_{\mu_s}(x,x')\,\mathbf{1} \tag{67.113}$$

in distributional notation.

Plancherel form of crossing. Assume the hypotheses of Definition 67.30. Let v_s, w_s be the two s-channel square-integrable coefficient fields whose inner product gives the four-point function in an s-channel radial domain, and let v_t, w_t be the corresponding t-channel coefficient fields. If

$$v_t = \mathbb{F}_{st} v_s, \qquad w_t = \mathbb{F}_{st} w_s, \tag{67.114}$$

then unitarity of the fusing transform gives

$$\int_{X_s} \langle w_s(x), v_s(x)\rangle_{\mathcal{K}_x^{(s)}}\,\mathrm{d}\mu_s(x) = \int_{X_t} \langle w_t(y), v_t(y)\rangle_{\mathcal{K}_y^{(t)}}\,\mathrm{d}\mu_t(y). \tag{67.115}$$

In this formulation the displayed Hilbert-space identity is the final Plancherel step. The mathematical content is the construction of the direct-integral decompositions, the proof that the conformal blocks admit the unitary transform $\mathbb{F}_{st}$, and the verification of (67.114) for the actual OPE kernels. In a rational CFT the same statement reduces to a finite matrix identity. In Liouville theory the label spaces are continuous and the identity becomes the Ponsot–Teschner Virasoro fusion-kernel identity, together with the DOZZ coefficient relation.

Definition 67.31 (Nonrational genus-zero bootstrap problem)**.** A nonrational genus-zero bootstrap problem consists of:

1. a class of local fields and their dense radial-product domain;
2. for every ordered pair of fields, direct-integral intermediate spectra with Plancherel measures and multiplicity fibers;
3. measurable three-point/OPE coefficient fields;
4. chiral conformal blocks with specified radial convergence domains and analytic continuations;
5. measurable fusing and braiding transforms satisfying unitarity, pentagon, and hexagon identities as identities of direct-integral operators;
6. a reflection-positive pairing of left and right chiral data producing single-valued Euclidean correlation distributions.

Solving this problem means proving existence, uniqueness up to unitary equivalence of the resulting correlation theory, reflection positivity, locality, and compatibility with sewing in the domains under consideration. Crossing equations for individual four-point functions are necessary consequences of such a solution, not a replacement for the direct-integral and sewing data.

Example 67.32 (Two spectral types)**.** For an irrational compact free boson the intermediate label space is countable, the measure is counting measure, and modular covariance is governed by theta functions and Poisson summation rather than by a finite modular matrix. For Liouville theory the normalizable bulk spectrum is

$$\alpha = \frac{Q}{2} + \mathrm{i}P, \qquad P \in \mathbb{R}_{\geq 0},$$

with Plancherel measure fixed by the two-point normalization and reflection amplitude. The four-point function is the direct integral displayed in Definition 68.8. These two examples have different spectral measures, but both are governed by the same Hilbert-space identity (67.102).

67.11 Logarithmic Theories

A logarithmic CFT is a conformal field theory whose chiral module category is not semisimple and in which the energy operator L_0 need not be diagonalizable. Diagonal L_0 is what made the rational characters honest sums of powers of q over simple modules; a nilpotent part of L_0 changes both local conformal covariance and the genus-one trace problem.

Definition 67.33 (Rank-two logarithmic Virasoro pair)**.** A rank-two logarithmic pair of chiral fields of weight h is a pair $(\mathcal{C}, \mathcal{D})$ whose states C, D satisfy

$$L_0 C = hC, \qquad L_0 D = hD + C, \qquad L_n C = L_n D = 0 \quad (n > 0).$$

Equivalently, the singular part of the stress-tensor OPE is

$$T(\zeta)\mathcal{C}(z) \sim \frac{h\mathcal{C}(z)}{(\zeta - z)^2} + \frac{\partial \mathcal{C}(z)}{\zeta - z},$$

$$T(\zeta)\mathcal{D}(z) \sim \frac{h\mathcal{D}(z) + \mathcal{C}(z)}{(\zeta - z)^2} + \frac{\partial \mathcal{D}(z)}{\zeta - z}.$$

Thus $\mathcal{C}$ is primary, while $\mathcal{D}$ is its logarithmic partner. With $ND = C$ and $NC = 0$, the two-dimensional span of (C, D) carries $L_0 = h\,\mathrm{id} + N$.

The finite consequences are immediate and worth recording because this is where signs and 2πi's enter. On states,

$$q^{L_0 - c/24} C = q^{h - c/24} C, \qquad q^{L_0 - c/24} D = q^{h-c/24}\big(D + 2\pi\mathrm{i}\tau\, C\big), \qquad q = \mathrm{e}^{2\pi\mathrm{i}\tau}.$$

On fields, the Virasoro commutators are, for $n = -1, 0, 1$,

$$[L_n, \mathcal{C}(z)] = \big(z^{n+1}\partial_z + (n+1)hz^n\big)\mathcal{C}(z),$$

$$[L_n, \mathcal{D}(z)] = \big(z^{n+1}\partial_z + (n+1)hz^n\big)\mathcal{D}(z) + (n+1)z^n\mathcal{C}(z).$$

In particular,

$$\mathrm{e}^{sL_0}\mathcal{C}(z)\mathrm{e}^{-sL_0} = \mathrm{e}^{sh}\mathcal{C}(\mathrm{e}^s z),$$

$$\mathrm{e}^{sL_0}\mathcal{D}(z)\mathrm{e}^{-sL_0} = \mathrm{e}^{sh}\big(\mathcal{D}(\mathrm{e}^s z) + s\mathcal{C}(\mathrm{e}^s z)\big).$$

The additive $s = \log\lambda$ term is the local origin of logarithms in correlators.

Proposition 67.34 (Two-point functions of a logarithmic pair)**.** *Assume the vacuum is invariant under L_{-1}, L_0, L_1, the two fields in Definition 67.33 are mutually local, and their two-point functions are single-valued on a chosen simply connected punctured coordinate chart after a branch of* $\log z$ *is fixed. Then translation, scaling, and special-conformal Ward identities force*

$$\langle \mathcal{C}(z)\mathcal{C}(0)\rangle = 0,$$

$$\langle \mathcal{C}(z)\mathcal{D}(0)\rangle = b\, z^{-2h},$$
$$\langle \mathcal{D}(z)\mathcal{D}(0)\rangle = (d - 2b\log z)z^{-2h},$$

for constants $b, d \in \mathbb{C}$. The constant d depends on the choice of logarithmic partner D, while b is invariant under $D \mapsto D + \lambda C$.

Proof. Translation invariance makes the correlators functions of $z = z_1 - z_2$. Write

$$G_{CC}(z) = \langle \mathcal{C}(z)\mathcal{C}(0)\rangle, \qquad G_{CD}(z) = \langle \mathcal{C}(z)\mathcal{D}(0)\rangle,$$
$$G_{DD}(z) = \langle \mathcal{D}(z)\mathcal{D}(0)\rangle.$$

The L_0 Ward identity gives

$$(z\partial_z + 2h)G_{CC} = 0,$$
$$(z\partial_z + 2h)G_{CD} + G_{CC} = 0,$$
$$(z\partial_z + 2h)G_{DD} + 2G_{CD} = 0.$$

Hence, before imposing L_1,

$$G_{CC} = Az^{-2h}, \qquad G_{CD} = (B - A\log z)z^{-2h},$$
$$G_{DD} = (D_0 - 2B\log z + A(\log z)^2)z^{-2h}.$$

This calculation is the scale-covariant source of logarithms.

Now impose the L_1 Ward identity on $\langle \mathcal{C}(z_1)\mathcal{D}(z_2)\rangle$. The ordinary primary part of the differential operator is

$$(z_1 + z_2)(z\partial_z + 2h)G_{CD}(z), \qquad z = z_1 - z_2,$$

and the nilpotent term from the $\mathcal{D}$-insertion is

$$2z_2 G_{CC}(z).$$

Using the L_0 equation, the total L_1 variation is

$$-(z_1 + z_2)G_{CC}(z) + 2z_2 G_{CC}(z) = -z\, G_{CC}(z).$$

It must vanish for $z \neq 0$, so $G_{CC} = 0$ and therefore $A = 0$. The remaining L_0 equations give the displayed forms with $b = B$ and $d = D_0$. The L_1 equation for G_{DD} is then automatic: the primary differential part gives $-2b(z_1 + z_2)z^{-2h}$, while the two nilpotent insertions contribute $2b(z_1 + z_2)z^{-2h}$.

Finally replace D by $D + \lambda C$. Since $G_{CC} = 0$,

$$G_{CD} \mapsto G_{CD}, \qquad G_{DD} \mapsto G_{DD} + 2\lambda G_{CD}.$$

Thus b is unchanged and d is shifted to $d + 2\lambda b$. $\square$

The ordinary character sees only the trace of $q^{L_0-c/24}$. On the span of C, D,

$$\mathrm{Tr}\big(q^{L_0-c/24}\big) = 2q^{h-c/24},$$

because the nilpotent coefficient $2\pi i\tau N$ has trace zero. Thus an ordinary character records the generalized eigenvalue and multiplicity but not the extension class producing the logarithmic partner. In a finite-length C_2-cofinite logarithmic theory, the genus-one space closed under modular transformations is therefore larger than the span of ordinary characters: it includes generalized characters and pseudo-trace functions on projective modules. A pseudo-trace is the replacement for the usual matrix trace when the endomorphism algebra of a projective module is not semisimple; it is a linear functional with the cyclicity property needed for torus sewing, and it can couple to the nilpotent part invisible to the ordinary trace.

Finite projective pseudo-trace model. The finite algebraic mechanism is already visible without invoking the full logarithmic VOA modular theorem. Let A be a finite-dimensional associative algebra over $\mathbb{C}$, let P be a finitely generated projective left A-module, and let

$$\varphi : A \longrightarrow \mathbb{C}$$

be a symmetric linear functional, meaning

$$\varphi(ab) = \varphi(ba), \qquad a, b \in A.$$

Choose a projective dual basis

$$p_r \in P, \qquad f^r \in \mathrm{Hom}_A(P, A), \qquad x = \sum_r p_r f^r(x) \quad (x \in P).$$

For $T \in \mathrm{End}_A(P)$, define the φ-pseudo-trace

$$\mathrm{ptr}_P^{\varphi}(T) := \sum_r \varphi\big(f^r(Tp_r)\big). \tag{67.116}$$

The expression is independent of the chosen dual basis. This is the Hattori–Stallings trace paired with φ: changing dual bases changes $\sum_r f^r(Tp_r)$ by a commutator in A, and the symmetric property of φ kills commutators. It follows in particular that

$$\mathrm{ptr}_P^{\varphi}(ST) = \mathrm{ptr}_P^{\varphi}(TS), \qquad S, T \in \mathrm{End}_A(P),$$

which is the finite cyclicity property needed when the torus sewing trace is rotated around a nonsemisimple channel.

The smallest example is the dual-number algebra

$$A = \mathbb{C}[\epsilon]/(\epsilon^2), \qquad P = A.$$

Let $\varphi_{\mathrm{res}}(a + b\epsilon) = b$. Multiplication by $a + b\epsilon$ on the vector space with basis $(1, \epsilon)$ has ordinary trace $2a$, so the ordinary trace kills the nilpotent coefficient b. The projective pseudo-trace with $p_1 = 1$ and $f^1(x) = x$, however, gives

$$\mathrm{ptr}_A^{\varphi_{\mathrm{res}}}(R_{a+b\epsilon}) = \varphi_{\mathrm{res}}(a + b\epsilon) = b,$$

where $R_{a+b\epsilon}$ denotes right multiplication, an A-module endomorphism of the regular left module. If the Jordan cell of L_0 is modeled by $L_0 = h + \epsilon$, then

$$q^{L_0 - c/24} = q^{h-c/24}\big(1 + 2\pi \mathrm{i}\tau\, \epsilon\big),$$

and the ordinary trace gives $2q^{h-c/24}$, whereas the pseudo-trace gives

$$\mathrm{ptr}_A^{\varphi_{\mathrm{res}}}\big(q^{L_0-c/24}\big) = 2\pi\mathrm{i}\tau\, q^{h-c/24}.$$

Thus the polynomial τ-dependence that ordinary characters miss is not a decorative correction; it is the projective trace of the nilpotent extension data. In logarithmic VOA applications the algebra A is replaced by endomorphism algebras of projective covers or by the appropriate finite quotients controlling torus one-point functions, and (67.116) is the finite model for the pseudo-trace functions that enter modular closure.

The semisimple Verlinde formula (67.77) is consequently replaced by categorical statements about the Grothendieck ring, projective modules, modified traces, and the factorizable braided finite tensor category attached to the logarithmic chiral theory. The right question is not whether the same matrix formula survives unchanged, but which categorical pairing diagonalizes which quotient of the tensor product. This is one of the places where the algebraic formulation is essential: it names the objects whose semisimplicity has failed and identifies the extra data needed to recover modular sewing.

67.12 Output

The output of this chapter is a hierarchy of definitions and hypotheses: The construction has the following order. A VOA defines modules and chiral blocks. Chiral blocks sew over the moduli space of pointed curves. In the semisimple finite case, sewing data assemble into a modular tensor category. The full CFT is then obtained by choosing a compatible pairing of left and right chiral theories, equivalently by imposing the modular-invariance and factorization constraints on torus and higher-genus amplitudes. The Ising model gives the finite rational example. Logarithmic theories show which parts of the rational construction depend on semisimplicity and which parts persist after replacing simple-module linear algebra by finite tensor category data.

Chapter 68

Liouville Conformal Field Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Liouville theory is used here as a test case for noncompact, nonrational CFT: the same theory has a probabilistic construction, a Virasoro bootstrap coordinate system, continuous spectral decompositions, and boundary states with distributional wavefunctions. These presentations are not interchangeable until comparison maps and sewing estimates have been specified. The chapter therefore separates four layers. The local field layer fixes the background-charge stress tensor, conformal weights, BPZ null-vector equations, and finite Coulomb-gas residues. The probabilistic layer constructs correlation distributions from a GFF plus Gaussian multiplicative chaos inside the Seiberg domain and then meromorphically continues them. The bootstrap layer uses DOZZ, reflection, elliptic recursion, FZZT/ZZ wavefunctions, and finite-difference constraints as coordinates on conformal blocks. The functorial sewing layer asks whether the probabilistic distributions and the bootstrap kernels define the same positive, continuous gluing theory on all closed and bordered surfaces.

This organization is deliberately stricter than listing Liouville formulae. The zero-mode gamma integral, BPZ hypergeometric connection calculation, DOZZ shift equations, and FZZT finite-difference identities are local mechanisms that can be checked in the chapter's conventions. They do not by themselves prove the probabilistic construction, the DOZZ theorem, the boundary bootstrap, positivity of annulus spectral measures, or all-surface sewing. Those theorem boundaries are named at their points of use so that Liouville serves as a genuine comparison problem between probabilistic QFT, bootstrap coordinates, and nonrational CFT sewing rather than as a collection of famous closed forms.

68.1 Classical Datum and Stress Tensor

Liouville theory is the noncompact two-dimensional conformal theory whose interaction is an exponential of a scalar field. This chapter treats it as a two-dimensional QFT construction problem whose data are a background surface, a scalar distribution, a curvature coupling, exponential insertions, Virasoro Ward identities, degenerate fields, and sewing constraints. The development below fixes the normalizations, derives the local representation-theoretic identities, and states the present theorem boundaries for the probabilistic and bootstrap constructions.

Definition 68.1 (Classical Liouville datum)**.** A classical Liouville datum consists of an oriented smooth closed surface Σ, a Riemannian metric g on Σ, a real scalar field $\phi \in C^\infty(\Sigma, \mathbb{R})$, parameters

$$b > 0, \qquad Q \in \mathbb{R}, \qquad \mu > 0,$$

and the Euclidean action

$$S_L[\phi; g] = \frac{1}{4\pi} \int_\Sigma \mathrm{d}^2x \sqrt{g} \left(g^{ab} \partial_a \phi \, \partial_b \phi + Q R_g \phi + 4\pi\mu \, \mathrm{e}^{2b\phi} \right). \tag{68.1}$$

Here R_g is the scalar curvature of g. The exponential term is a function of the smooth classical field in this definition; in the quantum theory it is a renormalized random measure or a normal-ordered local field, depending on the construction framework.

Varying a compactly supported smooth $\delta\phi$ gives

$$\delta S_L = \frac{1}{4\pi} \int_\Sigma \sqrt{g} \left(-2\Delta_g \phi + Q R_g + 8\pi b \mu \mathrm{e}^{2b\phi} \right) \delta\phi.$$

Thus the classical Euler–Lagrange equation is

$$-\Delta_g \phi + \frac{Q}{2} R_g + 4\pi b \mu \mathrm{e}^{2b\phi} = 0. \tag{68.2}$$

On a flat complex coordinate patch z, the holomorphic stress tensor representative is

$$T(z) = - :(\partial\phi)^2:(z) + Q \, \partial^2 \phi(z). \tag{68.3}$$

The normal ordering in (68.3) is a free-field short-distance prescription. It is used here as a perturbative coordinate on the Virasoro representation data; the nonperturbative probabilistic construction is stated later as a separate object.

Convention 68.2 (Free-field normalization)**.** In this chapter the local free field has two-point singularity

$$\phi(z)\phi(w) \sim -\frac{1}{2} \log |z - w|^2, \qquad \partial\phi(z)\partial\phi(w) \sim -\frac{1}{2(z-w)^2}.$$

The holomorphic exponential field is denoted

$$V_\alpha(z, \bar{z}) = :\mathrm{e}^{2\alpha\phi(z,\bar{z})}:.$$

With this convention the standard Liouville relation is

$$Q = b + b^{-1}. \tag{68.4}$$

Improved central charge and Liouville weights. Assume the free-field OPE convention 68.2. The stress tensor (68.3) has Virasoro central charge

$$c_L = 1 + 6Q^2. \tag{68.5}$$

The exponential V_α is Virasoro primary in the free-field coordinate with conformal weights

$$h_\alpha = \bar{h}_\alpha = \alpha(Q - \alpha). \tag{68.6}$$

This is an OPE computation. The stress tensor is $T = T_0 + T_Q$, where

$$T_0 = - :(\partial\phi)^2:, \qquad T_Q = Q\partial^2\phi.$$

The double contraction in $T_0(z)T_0(w)$ gives the central term $\frac{1}{2}(z-w)^{-4}$, hence $c = 1$ for $Q = 0$. The mixed terms have at most third-order poles and contribute to the transformation of T, not to the central term. Since

$$\partial^2\phi(z)\partial^2\phi(w) = \partial_z^2\partial_w^2\left(-\frac{1}{2}\log(z-w)\right) \sim \frac{3}{(z-w)^4},$$

the improvement contributes $3Q^2(z-w)^{-4}$. Comparing

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}$$

gives $c = 1 + 6Q^2$.

For the exponential,

$$\partial\phi(z)V_\alpha(w,\bar{w}) \sim -\frac{\alpha}{z-w}V_\alpha(w,\bar{w}), \qquad \partial^2\phi(z)V_\alpha(w,\bar{w}) \sim \frac{\alpha}{(z-w)^2}V_\alpha(w,\bar{w}).$$

The double contraction of $- :(\partial\phi)^2:$ contributes $-\alpha^2(z-w)^{-2}V_\alpha$, and the improvement contributes $\alpha Q(z-w)^{-2}V_\alpha$. The simple-pole term is $(z-w)^{-1}\partial_w V_\alpha$. Therefore V_α has the weight $\alpha(Q-\alpha)$.

The interaction $\mu e^{2b\phi}$ is marginal precisely when $b(Q-b) = 1$, which gives $Q = b + b^{-1}$. Thus (68.4) is an operational normalization condition: it is the condition that the exponential potential have weight $(1,1)$ in the background-charge representation.

68.2 Exponential Operators and the Probabilistic Object

Liouville correlation functions are infinite-dimensional Euclidean QFT objects. The rigorous probabilistic construction separates the constant mode from the mean-zero Gaussian free field and interprets the exponential interaction as Gaussian multiplicative chaos.

Definition 68.3 (Seiberg domain in physics normalization)**.** For insertions $V_{\alpha_1}(x_1), \ldots, V_{\alpha_n}(x_n)$ on a closed surface Σ with Euler characteristic $\chi(\Sigma)$, the Seiberg domain is the set of momenta satisfying

$$\alpha_i < \frac{Q}{2} \quad \text{for every } i, \qquad 2\sum_{i=1}^{n}\alpha_i > Q\,\chi(\Sigma). \tag{68.7}$$

The first inequalities are local integrability conditions near the marked points. The second inequality is the negative-constant-mode integrability condition. On the sphere it reads $\sum_i \alpha_i > Q$.

The zero-mode check is elementary and fixes the sign conventions. Write $\phi = c + \phi_0$, with $\int_\Sigma \phi_0 \operatorname{vol}_g = 0$. The curvature term contributes $\exp[-Q\chi(\Sigma)c]$, while the insertions contribute $\exp[2c\sum_i \alpha_i]$. As $c \to -\infty$, integrability requires $2\sum_i \alpha_i - Q\chi(\Sigma) > 0$. The positive c direction is controlled by the Liouville potential when its multiplicative-chaos measure is nonzero.

Equivalently, with

$$\varepsilon_\Sigma(\boldsymbol{\alpha}) := \sum_i \alpha_i - \frac{Q}{2}\chi(\Sigma),$$

the negative-constant-mode tail has the model form

$$\int_{-\infty}^{c_0} \mathrm{e}^{2\varepsilon_\Sigma c}\, \mathrm{d}c.$$

The second Seiberg-domain inequality is precisely $\operatorname{Re}\varepsilon_\Sigma > 0$. The pole calculation in Paragraph 68.5 is the same zero-mode mechanism evaluated on the boundary of this convergence region; outside the Seiberg domain, the correlator is represented by the meromorphic continuation whose boundary residues are described in Subsection 68.7.1.

Definition 68.4 (Gaussian multiplicative chaos input)**.** Let X_g be a mean-zero Gaussian free field on (Σ, g), normalized by a Green kernel with logarithmic singularity $-\log d_g(x,y)$. For $\gamma \in (0,2)$, let $X_{g,\varepsilon}$ be a smooth mollification at scale ε. The subcritical Gaussian multiplicative-chaos measure is the probability-limit object

$$M_{\gamma,g}(\mathrm{d}x) = \lim_{\varepsilon \downarrow 0} \varepsilon^{\gamma^2/2} \mathrm{e}^{\gamma X_{g,\varepsilon}(x)} \operatorname{vol}_g(\mathrm{d}x) \tag{68.8}$$

in the topology of weak convergence in probability against continuous test functions. In Liouville theory $\gamma = 2b$ after translating from the physics field ϕ of Convention 68.2 to the probabilistic GFF normalization.

Quoted Theorem 68.5 (Probabilistic Liouville correlation functions)**.** *The probabilistic Liouville constructions of David–Kupiainen–Rhodes–Vargas and Guillarmou–Kupiainen–Rhodes–Vargas [44, 46] define Liouville correlation functions by integrating the constant mode against the Gaussian multiplicative-chaos functional, with insertions in the Seiberg domain* (68.7)*. In the regimes covered by these theorems the construction gives finite correlation functions, conformal covariance with central charge $1 + 6Q^2$, and meromorphic continuation in the insertion momenta after the initial probabilistic domain is established. These theorems supply the measure-theoretic construction of the closed-surface Liouville path integral; the full Segal sewing theory for higher-genus boundary operations is recorded below as a separate boundary problem.*

Comparison datum for the closed theory. The probabilistic theorem produces meromorphic families of closed-surface correlation distributions. The bootstrap formulas used later in this chapter use a different coordinate system: the Hilbert space is decomposed into Virasoro representation fibers, and correlators are expanded by cutting the surface into pairs of pants. Comparing the two descriptions requires the following maps.

First, for each closed marked surface $(\Sigma; x_1, \ldots, x_n)$, the probabilistic construction supplies a distribution

$$\mathcal{L}_{\Sigma,n}(\alpha_1, \ldots, \alpha_n) \in \mathcal{D}'(\operatorname{Conf}_n(\Sigma))$$

in the insertion positions, initially for $\boldsymbol{\alpha}$ in the Seiberg domain and then by meromorphic continuation in the momenta. Second, the cylinder state space must be identified with the direct integral

$$\mathcal{H}^{\mathrm{L}}_{S^1} = \int_0^{\infty}{}^{\oplus} \mathcal{V}_{Q/2+\mathrm{i}P} \otimes \overline{\mathcal{V}_{Q/2+\mathrm{i}P}}\, \frac{\mathrm{d}P}{\pi}, \tag{68.9}$$

with the reflection convention and two-point normalization fixed by Definition 68.7. Third, three-punctured spheres must be represented by distributional trilinear maps on the fibers of (68.9); in the normalization of this chapter their scalar kernel is the DOZZ constant (68.39). Fourth, cutting a closed surface along a separating circle should express the probabilistic distribution as a Plancherel integral over the intermediate momentum:

$$\mathcal{L}_{\Sigma,n} = \int_0^{\infty} \mathcal{L}_{\Sigma_L,\{P\}}\, \mathcal{L}_{\Sigma_R,\{P\}}\, \frac{\mathrm{d}P}{\pi}, \tag{68.10}$$

in a topology strong enough to justify the gluing limit. The notation in (68.10) suppresses the left/right descendant pairings, conformal-block coordinates, and possible discrete residue terms that appear after meromorphic continuation of external momenta through poles. These four items are the comparison datum; the probabilistic construction, the DOZZ theorem, and the conformal-block calculus verify different parts of it.

Constant-mode reduction of the probabilistic construction. The theorem just quoted has a concrete core. Let

$$\gamma = 2b, \qquad s(\boldsymbol{\alpha},\Sigma) = 2\sum_{i=1}^{n} \alpha_i - Q\chi(\Sigma).$$

After separating the constant mode, write the mean-zero field in the probabilistic normalization as X_g, with chaos parameter γ. The local covariance used in Convention 68.2 is $-\frac{1}{2}\log|z-w|^2 = -\log|z-w|$, so it has the same logarithmic coefficient as the probabilistic GFF. The only notation change is that a physics vertex $V_{\alpha_i} = {:}\mathrm{e}^{2\alpha_i\phi}{:}$ is the probabilistic insertion with exponent

$$\alpha_i^{\mathrm{prob}} = 2\alpha_i.$$

The c-dependent part of an n-point function has the form

$$\int_{-\infty}^{\infty} \exp(s(\boldsymbol{\alpha},\Sigma)c - \mu\, \mathrm{e}^{\gamma c} Z_g(X_g;\boldsymbol{x},\boldsymbol{\alpha}))\, \mathrm{d}c,$$

where the random functional multiplying the exponential potential is

$$Z_g(X_g;\boldsymbol{x},\boldsymbol{\alpha}) = \int_{\Sigma} \prod_{i=1}^{n} \exp\bigl(\gamma\alpha_i^{\mathrm{prob}}\, G_g(y,x_i)\bigr)\, M_{\gamma,g}(\mathrm{d}y). \tag{68.11}$$

The Green kernel G_g records the singularity of the GFF conditioned by the vertex insertions; all coincident-point self-contractions are absorbed into the renormalized exponential fields. For $s>0$, the elementary change of variable $t = \mu Z_g \mathrm{e}^{\gamma c}$ gives

$$\int_{\mathbb{R}} \mathrm{e}^{sc-\mu Z_g \mathrm{e}^{\gamma c}}\, \mathrm{d}c = \frac{1}{\gamma}\, \mu^{-s/\gamma}\, \Gamma(s/\gamma)\, Z_g^{-s/\gamma}. \tag{68.12}$$

This identity is the source of the global Seiberg inequality $s(\boldsymbol{\alpha}, \Sigma) > 0$. The local inequalities are a separate Gaussian-multiplicative-chaos input. Near a marked point x_i, the potential mass contains the singular GMC integral

$$I_i = \int_{U_i} d_g(y, x_i)^{-\gamma\alpha_i^{\mathrm{prob}}} M_{\gamma,g}(\mathrm{d}y), \qquad \alpha_i^{\mathrm{prob}} = 2\alpha_i.$$

The first moment of I_i is finite only for $\alpha_i^{\mathrm{prob}} < 2/\gamma$, because $\mathbb{E}[M_{\gamma,g}]$ is the background volume measure. The Liouville construction criterion is the larger subcritical threshold supplied by the GMC thick-point theorem. That theorem controls rare thick points of the log-correlated field and gives the almost-sure local integrability and the negative-moment estimates needed for (68.12) precisely under

$$\alpha_i^{\mathrm{prob}} < Q_\gamma, \qquad Q_\gamma := \frac{2}{\gamma} + \frac{\gamma}{2}.$$

Since $\gamma = 2b$, $Q_\gamma = b + b^{-1} = Q$, so this is the physics condition $\alpha_i < Q/2$. Thus the probabilistic correlation function in the initial domain is the expectation of the explicit negative moment

$$\mathbb{E}\Big[Z_g(X_g; \boldsymbol{x}, \boldsymbol{\alpha})^{-s/\gamma}\Big],$$

multiplied by the deterministic Green-function and gamma-function factors fixed above. The analytic theorem boundary supplies existence of these negative moments, Weyl covariance of the renormalized expression, and meromorphic continuation away from the initial domain.

Definition 68.6 (Reflection relation)**.** The Liouville spectrum is parametrized by

$$\alpha = \frac{Q}{2} + \mathrm{i}P, \qquad P \in \mathbb{R}_{\geq 0},$$

with conformal weight $Q^2/4 + P^2$. The reflection relation is the identification, at the level of meromorphic correlation functions,

$$V_\alpha = R_b(\alpha)\, V_{Q-\alpha}, \tag{68.13}$$

where $R_b(\alpha)$ is the meromorphic reflection amplitude fixed by the two-point normalization and equivalently by the DOZZ three-point function. Thus a single bulk primary label is represented by the reflection orbit $\{\alpha, Q - \alpha\}$, with the normalization encoded in $R_b(\alpha)$.

Definition 68.7 (Asymptotic scattering basis)**.** Let ϕ_0 be the constant mode of ϕ on a long cylinder. In the weak-coupling end $\phi_0 \to -\infty$, the Liouville potential is negligible and the Hilbert space is described by the background-charge free field with oscillators. A momentum-P incoming state has asymptotic wavefunction

$$\Psi_P^{\mathrm{in}}(\phi_0, \{\phi_n\}) \sim \left(e^{2\mathrm{i}P\phi_0} + S(P)e^{-2\mathrm{i}P\phi_0}\right) \exp\left(-\sum_{n\geq 1} n\phi_n\phi_{-n}\right), \qquad P \geq 0, \tag{68.14}$$

where $S(P)$ is the unitary reflection phase in the scattering normalization. The corresponding incoming primary is represented asymptotically by

$$V_P^{\mathrm{in}} \sim e^{(Q+2\mathrm{i}P)\phi} + S(P)e^{(Q-2\mathrm{i}P)\phi}, \qquad h_P = \frac{Q^2}{4} + P^2. \tag{68.15}$$

The delta-normalized primary used in the continuous spectrum is $V_P = S(P)^{-1/2} V_P^{\mathrm{in}}$, with

$$\langle V_P(1) V_{P'}(0) \rangle = \pi \delta(P - P')$$

after fixing the conventional measure. This is the canonical-quantization version of the reflection orbit $\alpha = Q/2 + \mathrm{i}P \sim Q/2 - \mathrm{i}P$.

Definition 68.8 (Continuous conformal-block decomposition)**.** For four normalizable external Liouville primaries $\alpha_j = Q/2 + \mathrm{i}P_j$, the bootstrap ansatz on the sphere is a direct integral over the same spectrum:

$$\langle V_{P_1}(\infty) V_{P_2}(1) V_{P_3}(z) V_{P_4}(0) \rangle = \int_0^\infty C(P_1, P_2, P) C(P_3, P_4, P) \left| \mathcal{F}_P \begin{bmatrix} P_1 & P_2 \\ P_4 & P_3 \end{bmatrix} (z) \right|^2 dP. \tag{68.16}$$

Here $\mathcal{F}_P$ is the Virasoro conformal block with internal weight $Q^2/4 + P^2$. Equation (68.16) is a direct-integral decomposition. Its analytic content includes the choice of Plancherel measure, the location of possible discrete residues after analytic continuation, and the crossing kernel for the Virasoro blocks.

68.3 Virasoro Blocks from Gram Matrices

The symbol $\mathcal{F}_P$ in (68.16) hides a representation theoretic construction. The construction is local in the moduli variable z and does not require the DOZZ formula. It uses only Virasoro Ward identities, the contravariant form on a Verma module, and the three-point matrix elements of descendants.

Definition 68.9 (Four-point Virasoro block coefficients)**.** Fix a central charge c, an internal highest weight h, and four external weights h_1, h_2, h_3, h_4. Consider the chiral four-point geometry

$$V_1(\infty) V_2(1) V_3(z) V_4(0),$$

with the intermediate channel separating $(1, 2)$ from $(3, 4)$. Assume that the contravariant Gram matrix on the Verma module $\mathcal{V}_{c,h}$ is nondegenerate through the level under discussion. Through level 3 the normalized Virasoro block is written

$$\mathcal{F}_h^{(c)} \begin{bmatrix} h_1 & h_2 \\ h_4 & h_3 \end{bmatrix} (z) = z^{h - h_3 - h_4} \left(1 + f_1 z + f_2 z^2 + f_3 z^3 + O(z^4) \right).$$

The assumption of nondegeneracy excludes $h = 0$ at level 1 and excludes the zeros of the relevant Kac determinants at higher level. At those parameters one must quotient by null states, take a meromorphic limit, or work with logarithmic extensions; the inverse Gram matrices below are not literal inverses on the unreduced Verma module.

Lemma 68.10 (Level-one and level-two block coefficients)**.** *In the notation of Definition 68.9, set*

$$a_1 = h + h_3 - h_4, \qquad b_1 = h + h_2 - h_1,$$
$$a_2 = h + 2h_3 - h_4, \qquad b_2 = h + 2h_2 - h_1,$$

and

$$a_{11} = a_1(a_1 + 1), \qquad b_{11} = b_1(b_1 + 1).$$

Then

$$f_1 = \frac{b_1 a_1}{2h}. \tag{68.17}$$

Let

$$G_2 = \begin{pmatrix} 4h + c/2 & 6h \\ 6h & 4h(2h+1) \end{pmatrix}, \qquad \Delta_2 = \det G_2 = 2h\{16h^2 + 2(c-5)h + c\}.$$

With the ordered level-two basis $(L_{-2}|h\rangle, L_{-1}^2|h\rangle)$*, the second coefficient is*

$$\begin{aligned} f_2 = \frac{1}{\Delta_2}\big(&4h(2h+1)b_2 a_2 - 6h(b_2 a_{11} + b_{11} a_2) \\ &+ (4h + c/2) b_{11} a_{11}\big). \end{aligned} \tag{68.18}$$

For Liouville blocks one substitutes

$$c = 1 + 6Q^2, \qquad h = \frac{Q^2}{4} + P^2, \qquad h_i = \alpha_i(Q - \alpha_i).$$

For generic real P *the denominators above are nonzero; the degenerate values are precisely the places where a BPZ quotient changes the block recursion.*

Proof. Let $\rho_{12}(Y)$ be the normalized three-point matrix element with the descendant $L_{-Y}|h\rangle$ in $\langle V_1(\infty)V_2(1)\cdot\rangle$, and let $\rho_{34}(Y)$ be the corresponding matrix element for the OPE of $V_3(z)V_4(0)$. The Ward identity gives, for $n = 1, 2$,

$$\rho_{12}(L_{-n}) = h + nh_2 - h_1, \qquad \rho_{34}(L_{-n}) = h + nh_3 - h_4.$$

For the repeated L_{-1} descendant one differentiates the three-point function

$$\langle V_1(\infty)V_2(1)V_h(x)\rangle = (1-x)^{-h_2 - h + h_1}$$

and its right-channel analogue. This gives

$$\rho_{12}(L_{-1}^2) = b_1(b_1 + 1), \qquad \rho_{34}(L_{-1}^2) = a_1(a_1 + 1).$$

The level-one Gram matrix is $(2h)$, so the projector onto the intermediate module gives (68.17). At level 2, the Virasoro commutation relation gives

$$\langle L_{-2}h, L_{-2}h\rangle = 4h + c/2, \qquad \langle L_{-2}h, L_{-1}^2 h\rangle = 6h,$$
$$\langle L_{-1}^2 h, L_{-1}^2 h\rangle = 4h(2h+1).$$

Therefore the level-two contribution is

$$f_2 = \begin{pmatrix} b_2 & b_{11} \end{pmatrix} G_2^{-1} \begin{pmatrix} a_2 \\ a_{11} \end{pmatrix}.$$

Inverting the displayed 2×2 matrix gives

$$G_2^{-1} = \frac{1}{\Delta_2}\begin{pmatrix} 4h(2h+1) & -6h \\ -6h & 4h + c/2 \end{pmatrix},$$

which is exactly (68.18). $\square$

Lemma 68.11 (Level-three block coefficient and determinant)**.** *In the same four-point geometry, assume that the level-three Gram matrix is nondegenerate. Put*

$$a_3 = h + 3h_3 - h_4, \qquad b_3 = h + 3h_2 - h_1,$$

$$a_{21} = a_2(a_1+2), \quad b_{21} = b_2(b_1+2), \qquad a_{111} = a_1(a_1+1)(a_1+2), \quad b_{111} = b_1(b_1+1)(b_1+2).$$

With ordered basis

$$\big(L_{-3}|h\rangle,\, L_{-2}L_{-1}|h\rangle,\, L_{-1}^3|h\rangle\big),$$

the level-three Gram matrix is

$$G_3 = \begin{pmatrix} 6h+2c & 10h & 24h \\ 10h & h(c+8h+8) & 12h(3h+1) \\ 24h & 12h(3h+1) & 24h(h+1)(2h+1) \end{pmatrix}. \tag{68.19}$$

Its determinant factors as

$$\det G_3 = 48h^2\big(16h^2 + 2(c-5)h + c\big)\big(3h^2 + (c-7)h + c + 2\big). \tag{68.20}$$

Let

$$A_3 = \begin{pmatrix} a_3 \\ a_{21} \\ a_{111} \end{pmatrix}, \qquad B_3 = \begin{pmatrix} b_3 \\ b_{21} \\ b_{111} \end{pmatrix}.$$

Then the third block coefficient is the finite projector expression

$$f_3 = B_3^{\mathsf{T}} G_3^{-1} A_3. \tag{68.21}$$

Moreover, with h, h_i fixed and $c \to \infty$,

$$f_3 = \frac{b_{111}a_{111}}{24h(h+1)(2h+1)} + O(c^{-1}), \tag{68.22}$$

which is the level-three coefficient of the global SL_2 block.

Proof. The same Ward identities used at level two give the level-three descendant matrix elements. For the single mode, $\rho_{34}(L_{-3}) = a_3$ and $\rho_{12}(L_{-3}) = b_3$. For the mixed descendant, the adjoint modes act in the order L_1L_2. Thus L_2 first sends the right three-point function to $a_2 z^{h-h_3-h_4+2}$, and then L_1 gives $a_2(a_1+2)$. The left vector is identical with (h_3, h_4) replaced by (h_2, h_1), giving $b_2(b_1+2)$. Three derivatives of the three-point function give the L_{-1}^3 entries a_{111} and b_{111}.

The entries of G_3 follow by commuting the positive modes in

$$\langle h|L_Y L_{-Y'}|h\rangle$$

to the right using

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}m(m^2-1)\delta_{m+n,0}, \qquad L_n|h\rangle = 0 \quad (n>0), \quad L_0|h\rangle = h|h\rangle.$$

For example, $\langle L_{-3}h, L_{-2}L_{-1}h\rangle = \langle h|L_3L_{-2}L_{-1}|h\rangle = 10h$, while $\langle L_{-2}L_{-1}h, L_{-1}^3 h\rangle = 12h(3h+1)$. Explicitly, the six independent entries are

$$\begin{aligned}
\langle h|L_3L_{-3}|h\rangle &= 6h + 2c, \\
\langle h|L_3L_{-2}L_{-1}|h\rangle &= 10h, \\
\langle h|L_3L_{-1}^3|h\rangle &= 24h, \\
\langle h|L_1L_2L_{-2}L_{-1}|h\rangle &= h(c + 8h + 8), \\
\langle h|L_1L_2L_{-1}^3|h\rangle &= 12h(3h+1), \\
\langle h|L_1^3L_{-1}^3|h\rangle &= 24h(h+1)(2h+1).
\end{aligned}$$

These identities give (68.19). Taking the determinant of this displayed matrix gives (68.20); the first nontrivial factor is the level-two Kac factor and the second is the new level-three factor.

The projector onto level 3 in the intermediate Verma module is G_3^{-1} in this basis, so contraction with the left and right three-point descendant vectors gives (68.21). Finally, in (68.19) the first two basis vectors have norms growing with c, while the L_{-1}^3 norm is independent of c. Equivalently, the $(3,3)$ entry of G_3^{-1} tends to $[24h(h+1)(2h+1)]^{-1}$ and all inverse entries involving L_{-3} or $L_{-2}L_{-1}$ are $O(c^{-1})$. This proves (68.22). □

68.4 Elliptic Nome and Recursion Coordinates

The z-series in Definition 68.9 is the local OPE expansion near $z = 0$. For crossing and numerical bootstrap questions it is better to use the elliptic nome of the four-punctured sphere. This change of coordinate is not a cosmetic acceleration trick: it separates the universal geometry of the double cover from the representation-theoretic recursion in the intermediate Virasoro module.

Definition 68.12 (Elliptic nome of the four-punctured sphere)**.** Let

$$K(z) = \frac{\pi}{2}\, {}_2F_1\left(\frac{1}{2}, \frac{1}{2}; 1; z\right)$$

be the complete elliptic integral on the principal branch. For $z \in \mathbb{C} \setminus ((-\infty, 0] \cup [1, \infty))$, define

$$q(z) = \exp\left(-\pi\, \frac{K(1-z)}{K(z)}\right). \tag{68.23}$$

Equivalently, if $|q|$ is small,

$$z = \lambda(q) = \frac{\vartheta_2(q)^4}{\vartheta_3(q)^4}, \tag{68.24}$$

where

$$\vartheta_2(q) = 2q^{1/4} \sum_{n \geq 0} q^{n(n+1)}, \qquad \vartheta_3(q) = 1 + 2\sum_{n \geq 1} q^{n^2}.$$

The first terms are

$$\lambda(q) = 16q - 128q^2 + 704q^3 + O(q^4). \tag{68.25}$$

Remark 68.13 (First conversion from z-coefficients to q-coefficients)*.* Let the normalized block be as in Definition 68.9, and set

$$a = h - h_3 - h_4.$$

Write its elliptic-coordinate expansion before the universal theta-function factorization as

$$\mathcal{F}_h^{(c)}\begin{bmatrix} h_1 & h_2 \\ h_4 & h_3 \end{bmatrix}(\lambda(q)) = (16q)^a \left(1 + g_1 q + g_2 q^2 + O(q^3)\right). \tag{68.26}$$

Then

$$g_1 = 16f_1 - 8a, \tag{68.27}$$
$$g_2 = 256f_2 - 128(1+a)f_1 + 32a^2 + 12a. \tag{68.28}$$

Equation (68.25) gives

$$\lambda(q) = 16q(1 - 8q + 44q^2 + O(q^3)).$$

Therefore

$$\lambda(q)^a = (16q)^a \left(1 - 8aq + (32a^2 + 12a)q^2 + O(q^3)\right).$$

The nonleading part of the z-block contributes

$$1 + f_1\lambda(q) + f_2\lambda(q)^2 + O(q^3) = 1 + 16f_1 q + (-128f_1 + 256f_2)q^2 + O(q^3).$$

Multiplying these two displayed series gives (68.27)–(68.28).

Quoted Theorem 68.14 (Zamolodchikov elliptic recursion)**.** *Zamolodchikov's recursion formula [47, 48] has the following form in the normalizations used here. Fix a central charge $c = 1 + 6Q^2$, external weights h_i, and a nondegenerate internal weight h. After multiplying $\mathcal{F}_h^{(c)}(z)$ by the universal powers of z, $1-z$, $16q$, and $\vartheta_3(q)$ determined by (68.24), one obtains an elliptic block*

$$H(c, h_i, h; q) = 1 + O(q)$$

which is meromorphic as a function of h and satisfies the recursive expansion

$$H(c, h_i, h; q) = 1 + \sum_{m,n\geq 1} \frac{(16q)^{mn} R_{m,n}(c, h_i)}{h - h_{m,n}(c)} H(c, h_i, h_{m,n}(c) + mn; q). \tag{68.29}$$

Here

$$h_{m,n}(c) = \frac{Q^2 - (mb + nb^{-1})^2}{4}$$

when $Q = b + b^{-1}$, and the residues $R_{m,n}$ are explicit products of the inverse null-vector norm residue and the two chiral fusion polynomials for the pairs (h_1, h_2) and (h_3, h_4).

The theorem boundary in Theorem 68.14 is deliberate. The monograph has derived the local z-coefficients and the first coordinate-conversion coefficients above. The full recursion also requires normalizing null vectors and chiral vertex-operator matrix elements at every degenerate level and proving the analytic meromorphy/convergence statements that make the infinite recursive expression meaningful. The residue products must be inserted with the same external-leg and block normalizations as the DOZZ constants; otherwise the recursion is a formal mnemonic rather than a defined object.

Residue mechanism behind the elliptic recursion. The recursion is a compact way of organizing a Verma-module spectral calculation. Let $M(c,h)$ be the Virasoro Verma module generated by $|h\rangle$, and let $G_N(c,h)$ be the Shapovalov matrix on the level N descendant space. In the normalization used above, the coefficient of the ordinary four-point block at level N is

$$F_N(c,h_i,h) = \sum_{|I|=|J|=N} \rho_R(L_{-I}|h\rangle)\left(G_N(c,h)^{-1}\right)_{IJ}\rho_L(L_{-J}|h\rangle), \tag{68.30}$$

where ρ_L and ρ_R are the two chiral three-point functionals fixed by the external fields. Poles in the internal weight h can occur only where the Shapovalov form degenerates. For generic c, the Kac determinant has a simple zero at

$$h = h_{m,n}(c) \tag{68.31}$$

coming from a singular vector

$$\chi_{m,n} \in M(c,h_{m,n})_{mn}. \tag{68.32}$$

The submodule generated by $\chi_{m,n}$ is itself a highest-weight Verma module with highest weight $h_{m,n}+mn$, because

$$L_0\chi_{m,n} = (h_{m,n}+mn)\chi_{m,n}, \qquad L_k\chi_{m,n} = 0 \quad (k>0). \tag{68.33}$$

Near $h = h_{m,n}$, the inverse Shapovalov matrix has a rank-one singular part on this null direction. At every level $N \geq mn$, this singular part projects the descendant space of $M(c,h)$ onto the descendants of $\chi_{m,n}$:

$$G_N(c,h)^{-1} = \frac{1}{h-h_{m,n}}\,\frac{\Pi_{m,n;N}}{\partial_h\langle\chi_{m,n}(h),\chi_{m,n}(h)\rangle|_{h=h_{m,n}}} + O(1). \tag{68.34}$$

Here $\Pi_{m,n;N}$ denotes the rank-one null projection tensored with the inverse Shapovalov form of the quotient descendant module at level $N-mn$. The two chiral functionals evaluated on the singular vector are the fusion polynomials:

$$\rho_L(\chi_{m,n})\,\rho_R(\chi_{m,n}) = \mathcal{P}_{m,n}(h_1,h_2)\,\mathcal{P}_{m,n}(h_3,h_4) \tag{68.35}$$

up to the same singular-vector normalization that appears in the denominator of (68.34). Therefore the residue of the block at $h = h_{m,n}$ is the block of the embedded highest-weight module:

$$\mathrm{Res}_{h=h_{m,n}}\mathcal{F}^{(c)}_h(z) = z^{mn}\,R_{m,n}(c,h_i)\,\mathcal{F}^{(c)}_{h_{m,n}+mn}(z) \tag{68.36}$$

before the elliptic universal prefactors are stripped. In the q-block normalization used in (68.29), the leading sewing coordinate is $z = 16q + O(q^2)$. This converts the level shift z^{mn} into the factor $(16q)^{mn}$, while the remaining prefactors are analytic and are absorbed into the displayed residue $R_{m,n}(c,h_i)$.

After all these simple-pole residues are subtracted, the elliptic block is holomorphic in h and tends to 1 as $h\to\infty$ in the standard large-internal-weight domain. The recursion is then the corresponding Mittag–Leffler reconstruction, iterated with the shifted internal weights $h_{m,n}+mn$. The proof debt in Theorem 68.14 is the analytic part of this last sentence: one must control the large-h bound, the convergence of the iterated residue expansion, and the compatibility of the singular vector normalization with the DOZZ normalization used in the nonchiral Liouville four-point integral.

68.5 The DOZZ Formula and Shift Checks

The exact three-point function is the Dorn–Otto–Zamolodchikov–Zamolodchikov structure constant. It is theorem-level input for this chapter, but the special functions and convention checks are part of the manuscript.

Definition 68.15 (The Υ_b function)**.** For $b > 0$ and $Q = b + b^{-1}$, $\Upsilon_b(x)$ is the entire function characterized by self-duality $\Upsilon_b(x) = \Upsilon_{1/b}(x)$, reflection $\Upsilon_b(x) = \Upsilon_b(Q - x)$, zeros at

$$x = -mb - nb^{-1} \quad \text{and} \quad x = Q + mb + nb^{-1}, \qquad m, n \in \mathbb{Z}_{\geq 0},$$

and shift relations

$$\Upsilon_b(x + b) = \gamma(bx)\, b^{1-2bx}\, \Upsilon_b(x), \tag{68.37}$$

$$\Upsilon_b(x + b^{-1}) = \gamma(x/b)\, b^{2x/b-1}\, \Upsilon_b(x), \tag{68.38}$$

where $\gamma(x) = \Gamma(x)/\Gamma(1 - x)$. These equations fix the normalization up to the conventional value of $\Upsilon_b'(0)$, which is kept explicit in the three-point constant.

Quoted Theorem 68.16 (DOZZ three-point function)**.** *In the normalization of Convention 68.2, the sphere three-point function has the form*

$$\langle V_{\alpha_1}(z_1) V_{\alpha_2}(z_2) V_{\alpha_3}(z_3)\rangle_{\mathbb{P}^1} = \frac{C_b(\alpha_1, \alpha_2, \alpha_3)}{|z_{12}|^{2(h_1+h_2-h_3)} |z_{13}|^{2(h_1+h_3-h_2)} |z_{23}|^{2(h_2+h_3-h_1)}},$$

with $h_i = \alpha_i(Q - \alpha_i)$ and

$$C_b(\alpha_1, \alpha_2, \alpha_3) = \left[\pi\mu\, \gamma(b^2)\, b^{2-2b^2}\right]^{(Q-\alpha_1-\alpha_2-\alpha_3)/b} \times \frac{\Upsilon_b'(0) \prod_{i=1}^{3} \Upsilon_b(2\alpha_i)}{\Upsilon_b(\alpha_1 + \alpha_2 + \alpha_3 - Q)\Upsilon_b(\alpha_1 + \alpha_2 - \alpha_3)\Upsilon_b(\alpha_1 + \alpha_3 - \alpha_2)\Upsilon_b(\alpha_2 + \alpha_3 - \alpha_1)}. \tag{68.39}$$

The formula was proposed by Dorn–Otto and by the Zamolodchikovs and was proved in the probabilistic construction by Kupiainen–Rhodes–Vargas [49, 50, 45]. Its role here is to fix the normalization whose reflection and shift consequences are checked in the representation-theoretic calculations below.

Shift-equation uniqueness mechanism. The DOZZ theorem boundary combines a construction theorem with a bootstrap uniqueness statement. The local part of the uniqueness argument is visible from the two degenerate fields developed later in this chapter. Fusing $V_{-b/2}$ with a generic V_α gives the two channels $\alpha - b/2$ and $\alpha + b/2$; the BPZ equation and hypergeometric connection matrix give the b-shift ratio

$$\frac{C_b(\alpha_1 + b/2, \alpha_2, \alpha_3)}{C_b(\alpha_1 - b/2, \alpha_2, \alpha_3)} = \mathcal{R}_b(\alpha_1; \alpha_2, \alpha_3)$$

displayed explicitly in (68.74). The dual degenerate insertion $V_{-1/(2b)}$ gives the same statement with b replaced by b^{-1}. Thus any meromorphic three-point constant in the same normalization obeys two independent finite-difference equations:

$$C(\alpha_1 + b, \alpha_2, \alpha_3) = A_b(\alpha_1; \alpha_2, \alpha_3)\, C(\alpha_1, \alpha_2, \alpha_3),$$

$$C(\alpha_1 + b^{-1}, \alpha_2, \alpha_3) = A_{1/b}(\alpha_1; \alpha_2, \alpha_3)\, C(\alpha_1, \alpha_2, \alpha_3),$$

with A_b and $A_{1/b}$ fixed by the degenerate OPE coefficients and connection matrices. The ratio of two solutions is therefore invariant under translations by b and b^{-1} in each momentum.

The analytic step hidden in this sentence is the following. Let C and C^{DOZZ} be two meromorphic three-point constants obeying the same two shift equations in a connected meromorphic domain $U \subset \mathbb{C}^3$, after the same reflection and leg-normalization conventions have been chosen. On a component of U with the common pole and zero divisors removed, put

$$F(\alpha_1, \alpha_2, \alpha_3) = \frac{C(\alpha_1, \alpha_2, \alpha_3)}{C^{\mathrm{DOZZ}}(\alpha_1, \alpha_2, \alpha_3)}.$$

Then F is holomorphic and satisfies

$$F(\alpha_1 + b, \alpha_2, \alpha_3) = F(\alpha_1 + b^{-1}, \alpha_2, \alpha_3) = F(\alpha_1, \alpha_2, \alpha_3)$$

wherever the two sides are defined, and likewise in the other momentum variables. If $b^2 \notin \mathbb{Q}$, the additive subgroup $\{mb + nb^{-1} : m, n \in \mathbb{Z}\} \subset \mathbb{R}$ is dense. Fix the other variables and a horizontal line segment in the first variable avoiding the removed divisor. Periodicity on the dense subgroup and continuity imply that F is constant along that real segment. Hence $\partial_{\mathrm{Re}\,\alpha_1} F = 0$ there, and the Cauchy–Riemann equations give $\partial_{\mathrm{Im}\,\alpha_1} F = 0$. Analytic continuation then makes F independent of α_1 on the connected component. Repeating the argument in α_2 and α_3 makes F a constant. The same reasoning also explains the divisor hypothesis: a nonzero meromorphic divisor invariant under a dense real period group would have non-discrete accumulation in one complex variable, which is incompatible with meromorphicity unless the divisor is common to the two compared solutions and has already been removed.

Thus, for irrational b^2, the shift equations determine the meromorphic three-point constant up to an overall constant once the analytic domain, divisor structure, and moderate-growth assumptions have been fixed. The reflection relation and the residue normalization at the screening poles fix that constant. Rational b^2 is not obtained from the dense-period argument itself: there the two shifts generate a lattice, so additional elliptic-periodic factors are not excluded by finite-difference equations alone. The DOZZ statement at rational b^2 is reached by meromorphic continuation in b from the irrational set, together with the absence of extra singularities not already visible in the special-function formula. The probabilistic theorem supplies an independently constructed solution satisfying these properties, and the special-function formula (68.39) is the explicit representative.

The shift relations (68.37)–(68.38) are the convention-sensitive part of (68.39). They are what make the degenerate-field shift equations compatible with the normalization of the exponential interaction. The companion script `calculation-checks/liouville_bpz_checks.py` verifies the level-two null-vector arithmetic used below.

Scattering-normalized DOZZ representative. Set $\alpha_j = Q/2 + \mathrm{i}P_j$. After absorbing the cosmological-constant power and the two-point reflection factors into the delta-normalized fields of Definition 68.7, a standard scattering-normalized three-point representative is

$$\begin{aligned} C(P_1, P_2, P_3) = {} & \frac{\Upsilon_b'(0)}{\Upsilon_b(Q/2 + \mathrm{i}(P_1 + P_2 + P_3))} \\ & \times \prod_{j=1}^{3} \frac{(\Upsilon_b(2\mathrm{i}P_j)\Upsilon_b(-2\mathrm{i}P_j))^{1/2}}{\Upsilon_b(Q/2 + \mathrm{i}(P_1 + P_2 + P_3) - 2\mathrm{i}P_j)}. \end{aligned} \tag{68.40}$$

Different square-root and reflection-amplitude conventions multiply (68.40) by phase factors depending separately on the external legs; the four-point integrand (68.16) is invariant after the same convention is used for both three-point constants and two-point normalization.

Substitute $\alpha_j = Q/2 + \mathrm{i}P_j$ into (68.39). The four denominator arguments become

$$\frac{Q}{2} + \mathrm{i}(P_1 + P_2 + P_3), \qquad \frac{Q}{2} + \mathrm{i}(P_1 + P_2 + P_3) - 2\mathrm{i}P_j, \quad j = 1, 2, 3.$$

The numerator factors are $\Upsilon_b(Q+2\mathrm{i}P_j) = \Upsilon_b(-2\mathrm{i}P_j)$ by the reflection identity $\Upsilon_b(x) = \Upsilon_b(Q-x)$. Passing from V_{α_j} to the delta-normalized scattering fields contributes one square root of the two-point reflection normalization per external leg, replacing the numerator by $(\Upsilon_b(2\mathrm{i}P_j)\Upsilon_b(-2\mathrm{i}P_j))^{1/2}$ up to the leg phases just mentioned. The remaining μ-dependent power is a zero-mode convention for the origin of ϕ_0, so it is absent from this representative.

Pole normalization and the reflection phase. The scattering normalization also determines the phase $S(P)$ in Definition 68.7. Let

$$\epsilon = \frac{Q}{2} + \mathrm{i}(P_1 + P_2 + P_3).$$

When $\epsilon \to 0$, the pole of $\Upsilon_b(\epsilon)^{-1}$ in (68.40) gives

$$C(P_1, P_2, P_3) \sim \frac{1}{\epsilon} \prod_{j=1}^{3} \left(\frac{\Upsilon_b(2\mathrm{i}P_j)}{\Upsilon_b(-2\mathrm{i}P_j)} \right)^{1/2}. \tag{68.41}$$

The same pole can be read in the weak-coupling region $\phi_0 \ll 0$ from the linear-dilaton zero-mode integral. Introduce a reference cutoff by integrating the zero mode over $\phi < \phi_{\mathrm{ref}} - \frac{1}{2b}\log\mu$. Since the background charge contributes $\mathrm{e}^{-2Q\phi}$ in the three-point sphere computation, the asymptotic integral is

$$\int^{\phi_{\mathrm{ref}} - \frac{1}{2b}\log\mu} \mathrm{d}\phi\, \mathrm{e}^{-2Q\phi} \prod_{j=1}^{3} S(P_j)^{-1/2} \mathrm{e}^{(Q+2\mathrm{i}P_j)\phi} \sim \frac{1}{\epsilon} \left(\mu \mathrm{e}^{2b\phi_{\mathrm{ref}}} \right)^{-\epsilon/b} \prod_{j=1}^{3} S(P_j)^{-1/2}.$$

Comparison with (68.41), for arbitrary triples approaching the pole hyperplane, gives

$$S(P) = \left(\mu \mathrm{e}^{2b\phi_{\mathrm{ref}}} \right)^{-2\mathrm{i}P/b} \frac{\Upsilon_b(-2\mathrm{i}P)}{\Upsilon_b(2\mathrm{i}P)}. \tag{68.42}$$

Using the two Υ_b shift relations reduces this to the gamma-ratio form

$$S(P) = \left(\mu \mathrm{e}^{2b\phi_{\mathrm{ref}}} b^{2b^2-2} \right)^{-2\mathrm{i}P/b} \frac{\gamma(2\mathrm{i}P/b)}{b^2\, \gamma(-2\mathrm{i}bP)}. \tag{68.43}$$

The factor containing ϕ_{ref} is the origin convention for the zero mode; changing it multiplies V_P^{in} by a momentum-dependent phase and leaves the direct-integral four-point function unchanged when the two-point normalization is transformed simultaneously.

68.6 Boundary Liouville States

Boundary Liouville theory is the first place in this volume where the Cardy-state intuition from rational CFT has to be rebuilt rather than merely generalized by notation. The closed spectrum is the continuous direct integral over $P \geq 0$, the boundary states are distributional wavefunctions on that spectrum, and the annulus kernels are Fourier or hyperbolic kernels rather than entries of a finite modular S-matrix. This section fixes the normalization used later in the BCFT chapter; it does not assert a complete Segal-style sewing construction.

Definition 68.17 (Boundary Liouville datum)**.** Let (Σ, g) be an oriented smooth Riemannian surface with nonempty smooth boundary. Let n be the outward unit normal, K_g the geodesic curvature of $\partial\Sigma$ in the convention paired with n, and $\mathrm{d}s_g$ the induced line element. A boundary Liouville datum consists of $\phi \in C^\infty(\Sigma, \mathbb{R})$, $b > 0$, $Q \in \mathbb{R}$, $\mu > 0$, and a boundary cosmological constant $\mu_B \in \mathbb{R}$, with action

$$\begin{aligned} S_L^\partial[\phi; g, \mu_B] = \frac{1}{4\pi} \int_\Sigma \mathrm{d}^2x\, \sqrt{g}\, \left(g^{ab} \partial_a\phi\, \partial_b\phi + Q R_g \phi + 4\pi\mu\, \mathrm{e}^{2b\phi} \right) \\ + \int_{\partial\Sigma} \mathrm{d}s_g\, \left(\frac{Q}{2\pi} K_g \phi + \mu_B \mathrm{e}^{b\phi} \right). \end{aligned} \tag{68.44}$$

The factor $QK_g/(2\pi)$ is not optional: it is the boundary partner of the bulk curvature coupling and is needed for conformal covariance under Weyl rescaling on surfaces with boundary.

Boundary Euler equation. For fixed metric g, the first variation of (68.44) with arbitrary smooth $\delta\phi$ is stationary exactly when the bulk equation (68.2) holds and the boundary field satisfies

$$\nabla_n \phi + QK_g + 2\pi b \mu_B \mathrm{e}^{b\phi} = 0 \qquad \text{on } \partial\Sigma. \tag{68.45}$$

On the upper half-plane with the Euclidean metric, $K_g = 0$ and the outward normal is $n = -\partial_y$, so $-\partial_y\phi + 2\pi b\mu_B \mathrm{e}^{b\phi} = 0$. The bulk variation is the one already displayed in (68.2), except that integration by parts now also gives the boundary term

$$\frac{1}{2\pi} \int_{\partial\Sigma} \mathrm{d}s_g\, (\nabla_n\phi)\, \delta\phi.$$

The variation of the boundary curvature coupling and of the boundary exponential, with g fixed, is

$$\int_{\partial\Sigma} \mathrm{d}s_g\, \left(\frac{Q}{2\pi} K_g + b\mu_B \mathrm{e}^{b\phi} \right) \delta\phi.$$

Since the boundary value of $\delta\phi$ is arbitrary, the coefficient of $\delta\phi$ on $\partial\Sigma$ must vanish. Multiplying that boundary coefficient by 2π gives (68.45).

In the quantum conformal normalization $Q = b + b^{-1}$, the boundary exponential

$$B_\beta(x) = {:}\mathrm{e}^{\beta\phi(x)}{:}$$

has boundary scaling dimension

$$h_\beta^\partial = \beta(Q - \beta) \tag{68.46}$$

in the doubled free-field coordinate. Thus B_b has dimension 1. This is the perturbative Ward-identity reason why the coupling μ_B is a conformal boundary coupling. Existence of the non-compact interacting boundary measure is a separate problem; the formulas below are bootstrap boundary data whose sewing status is recorded explicitly.

Definition 68.18 (FZZT parameter and wavefunction)**.** Assume $b > 0$, $Q = b + b^{-1}$, $\mu > 0$, and write

$$\gamma(x) = \frac{\Gamma(x)}{\Gamma(1-x)}.$$

The FZZT boundary parameter $s \in \mathbb{C}$ is related to the boundary cosmological constant by

$$\cosh^2(\pi b s) = \frac{\mu_B^2}{\mu}\sin(\pi b^2), \tag{68.47}$$

with the equality interpreted by analytic continuation when the displayed right hand side is outside the real positive range. For physical Liouville momentum $P \in \mathbb{R}$, set

$$u_b(P) = \frac{1}{\mathrm{i}P}\left(\pi\mu\,\gamma(b^2)\right)^{-\mathrm{i}P/b}\Gamma(1+2\mathrm{i}bP)\Gamma(1+2\mathrm{i}P/b) \tag{68.48}$$

as a meromorphic distribution in P, and

$$U_s(P) = u_b(P)\cos(2\pi sP). \tag{68.49}$$

With the Ishibashi states $\langle\!\langle P|$ normalized compatibly with (69.15), the formal FZZT boundary state is

$$\langle B_s| = \int_0^\infty \frac{\mathrm{d}P}{\pi}\,U_s(P)\,\langle\!\langle P|. \tag{68.50}$$

Quoted Theorem 68.19 (FZZT one-point function)**.** *The FZZT boundary formula [51, 52, 53] gives the following disk one-point representative in the conventions of this chapter. For generic b and generic boundary parameter s, the disk one-point function of the bulk primary $V_\alpha = {:}\mathrm{e}^{2\alpha\phi}{:}$ on the upper half-plane has the form*

$$\langle V_\alpha(z,\bar z)\rangle_s = \frac{U_s(\alpha)}{|z-\bar z|^{2h_\alpha}}, \qquad h_\alpha = \alpha(Q-\alpha), \tag{68.51}$$

where

$$U_s(\alpha) = \frac{2}{b}\left(\pi\mu\,\gamma(b^2)\right)^{(Q-2\alpha)/(2b)}\Gamma(2b\alpha-b^2)\Gamma\!\left(\frac{2\alpha}{b}-\frac{1}{b^2}-1\right)\cosh((2\alpha-Q)\pi s)\,. \tag{68.52}$$

The theorem boundary is the boundary bootstrap: the degenerate $V_{-b/2}$ and $V_{-1/(2b)}$ shift equations, the reflection relation, and the annulus consistency checks determine the meromorphic solution under the standard nonresonance and analytic-continuation hypotheses.

The conversion from (68.52) to the momentum-space wavefunction in Definition 68.18 is elementary but convention sensitive. If $\alpha = Q/2 + \mathrm{i}P$, then

$$2b\alpha - b^2 = 1 + 2\mathrm{i}bP, \qquad \frac{2\alpha}{b} - \frac{1}{b^2} - 1 = \frac{2\mathrm{i}P}{b}.$$

Using $\Gamma(1+x) = x\Gamma(x)$, the prefactor $2/b$ changes $\Gamma(2\mathrm{i}P/b)$ into $\Gamma(1+2\mathrm{i}P/b)/(\mathrm{i}P)$, while $\cosh(2\pi\mathrm{i}sP) = \cos(2\pi sP)$. Hence (68.52) gives exactly (68.49).

Degenerate boundary finite-difference mechanism. The boundary parameter s enters the one-point function through the hyperbolic factor

$$H_s(\alpha) = \cosh((2\alpha - Q)\pi s)\,.$$

The two bulk degenerate fields generate finite-difference operators in the bulk momentum:

$$(\mathcal{D}_b H_s)(\alpha) := H_s(\alpha + b/2) + H_s(\alpha - b/2), \qquad (\mathcal{D}_{1/b} H_s)(\alpha) := H_s(\alpha + 1/(2b)) + H_s(\alpha - 1/(2b)).$$

The elementary identities

$$(\mathcal{D}_b H_s)(\alpha) = 2\cosh(\pi b s)\, H_s(\alpha), \tag{68.53}$$

$$(\mathcal{D}_{1/b} H_s)(\alpha) = 2\cosh(\pi s/b)\, H_s(\alpha) \tag{68.54}$$

are the algebraic core of the FZZT boundary parameter. The first eigenvalue is the square-root coordinate for the boundary cosmological constant in (68.47); the second is its $b \leftrightarrow b^{-1}$ dual coordinate.

Let $G_b(\alpha)$ denote the gamma-function and μ-dependent prefactor in (68.52), so that $U_s(\alpha) = G_b(\alpha) H_s(\alpha)$. Equations (68.53)–(68.54) are equivalently

$$\frac{U_s(\alpha + b/2)}{G_b(\alpha + b/2)} + \frac{U_s(\alpha - b/2)}{G_b(\alpha - b/2)} = 2\cosh(\pi b s)\frac{U_s(\alpha)}{G_b(\alpha)}, \tag{68.55}$$

$$\frac{U_s(\alpha + 1/(2b))}{G_b(\alpha + 1/(2b))} + \frac{U_s(\alpha - 1/(2b))}{G_b(\alpha - 1/(2b))} = 2\cosh(\pi s/b)\frac{U_s(\alpha)}{G_b(\alpha)}. \tag{68.56}$$

These identities also explain the analytic uniqueness class behind the boundary parameter. Write

$$W_s(\alpha) := \frac{U_s(\alpha)}{G_b(\alpha)}.$$

If W_s is holomorphic in a strip and obeys the two constant-coefficient relations

$$W_s(\alpha + \delta/2) + W_s(\alpha - \delta/2) = 2\cosh(\pi s \delta)\, W_s(\alpha), \qquad \delta = b, b^{-1},$$

then each pure exponential $W_s(\alpha) = \mathrm{e}^{\lambda(2\alpha - Q)}$ must satisfy

$$2\cosh(\lambda\delta) = 2\cosh(\pi s \delta), \qquad \delta = b, b^{-1}.$$

For irrational b^2, and with the moderate-growth condition excluding extra functions periodic under both shifts, the simultaneous characteristic equations force $\lambda = \pi s$ or $\lambda = -\pi s$. Thus the local solution space in this analytic class is spanned by $\mathrm{e}^{\pi s(2\alpha - Q)}$ and $\mathrm{e}^{-\pi s(2\alpha - Q)}$. The Liouville reflection relation $\alpha \leftrightarrow Q - \alpha$, in the one-point normalization used here, selects the even combination

$$W_s(\alpha) \propto \cosh((2\alpha - Q)\pi s)\,.$$

For rational b^2, or without a growth condition, finite-difference equations alone permit additional periodic factors. The boundary-bootstrap theorem boundary is precisely where those analytic restrictions, resonance prescriptions, and normalization conditions are supplied. The full boundary-bootstrap theorem supplies the remaining analytic and operator-theoretic inputs: the disk two-point function with one degenerate bulk insertion, the connection matrix relating the bulk OPE channel to the bulk-to-boundary channel, the normalization of the boundary identity operator, the treatment of resonant momenta, and the growth control needed for meromorphic uniqueness. The displayed finite-difference equations are the part of that mechanism visible directly in the FZZT representative.

Finite-difference checks of the FZZT representative. The displayed one-point function represents the meromorphic solution selected by the boundary-bootstrap theorem. The local constraints used later are the two shift equations coming from the bulk degenerate insertions $V_{-b/2}$ and $V_{-1/(2b)}$ in the presence of the boundary. The complete derivation of the boundary connection coefficients belongs to the nonrational boundary-sewing theorem boundary. Once those coefficients are fixed, the proposed one-point function can be checked directly.

Put

$$K_b := \pi\mu\,\gamma(b^2), \qquad \gamma(x) = \frac{\Gamma(x)}{\Gamma(1-x)}.$$

For nonresonant α, meaning that no gamma factor below is evaluated at a pole and the denominator one-point functions are nonzero, the b-shift ratio obtained from (68.52) is

$$\begin{aligned}\frac{U_s(\alpha+b/2)}{U_s(\alpha-b/2)} = K_b^{-1}&\frac{\Gamma(2b\alpha)}{\Gamma(2b\alpha-2b^2)}\frac{\Gamma(2\alpha/b-b^{-2})}{\Gamma(2\alpha/b-b^{-2}-2)}\\ &\times\frac{\cosh\big(\pi s(2\alpha+b-Q)\big)}{\cosh\big(\pi s(2\alpha-b-Q)\big)}.\end{aligned} \tag{68.57}$$

The dual degenerate insertion gives the independent b^{-1}-shift check,

$$\begin{aligned}\frac{U_s(\alpha+1/(2b))}{U_s(\alpha-1/(2b))} = K_b^{-1/b^2}&\frac{\Gamma(2b\alpha+1-b^2)}{\Gamma(2b\alpha-1-b^2)}\frac{\Gamma(2\alpha/b-1)}{\Gamma(2\alpha/b-2b^{-2}-1)}\\ &\times\frac{\cosh\big(\pi s(2\alpha+b^{-1}-Q)\big)}{\cosh\big(\pi s(2\alpha-b^{-1}-Q)\big)}.\end{aligned} \tag{68.58}$$

Equations (68.57) and (68.58) are the component form of the two degenerate boundary shift constraints in the normalization of (68.52). The theorem boundary supplies these shift constraints, the reflection relation, and the analytic nonresonance conditions with enough growth control to fix the meromorphic solution. The companion script checks the gamma-function and hyperbolic bookkeeping in both ratios against the displayed $U_s(\alpha)$.

Definition 68.20 (ZZ boundary states as FZZT differences)**.** For positive integers m, n, define the two imaginary FZZT parameters

$$s^+_{m,n} = \mathrm{i}\left(\frac{m}{b}+nb\right), \qquad s^-_{m,n} = \mathrm{i}\left(\frac{m}{b}-nb\right).$$

In the FZZT normalization above, the formal ZZ boundary state is the finite difference

$$\langle ZZ_{m,n}| = \langle B_{s^+_{m,n}}| - \langle B_{s^-_{m,n}}|. \tag{68.59}$$

Remark 68.21 (ZZ wavefunction in FZZT normalization). The boundary state $\langle ZZ_{m,n}|$ has the momentum-space expansion

$$\langle ZZ_{m,n}| = \int_0^\infty \frac{\mathrm{d}P}{\pi}\,U^{ZZ}_{m,n}(P)\,\langle\!\langle P|, \tag{68.60}$$

where

$$U^{ZZ}_{m,n}(P) = 2u_b(P)\,\sinh\!\left(\frac{2\pi mP}{b}\right)\sinh(2\pi nbP). \tag{68.61}$$

Insert $s^{\pm}_{m,n}$ into $\cos(2\pi sP)$. Since $\cos(\mathrm{i}X) = \cosh X$,

$$U_{s^{+}_{m,n}}(P) - U_{s^{-}_{m,n}}(P) = u_b(P)\left[\cosh\!\left(2\pi P\left(\frac{m}{b} + nb\right)\right) - \cosh\!\left(2\pi P\left(\frac{m}{b} - nb\right)\right)\right]$$
$$= 2u_b(P)\,\sinh\!\left(\frac{2\pi mP}{b}\right)\sinh(2\pi nbP),$$

using $\cosh(X+Y) - \cosh(X-Y) = 2\sinh X \sinh Y$. The same identity is verified as an exact Laurent-polynomial equality in `calculation-checks/bcft_cardy_checks.py`.

The discrete labels (m, n) are therefore not new rational-Cardy labels. They are residues or finite differences inside a continuous boundary family. Their annulus interpretation uses the same open–closed equality as Chapter 69, but with distributional wavefunctions and continuous characters. In annulus-normalized conventions one often rewrites the degenerate (m, n) wavefunction by dividing by the basic $(1, 1)$ hyperbolic factors,

$$\frac{\sinh(2\pi mP/b)\sinh(2\pi nbP)}{\sinh(2\pi P/b)\sinh(2\pi bP)},$$

which makes the finite degenerate fusion sums visible. The algebraic hyperbolic identities are elementary; the analytic sewing theorem for the resulting nonrational BCFT is not elementary and remains part of the open problem below.

68.7 Degenerate Insertions and BPZ Equations

68.7.1 Pole-Residue Structure of Liouville Correlators

The Coulomb-gas computations below are residue computations in the meromorphic Liouville correlator. This is the point that the Coulomb-gas notation tends to obscure: expansion by screening number is Laurent-coefficient bookkeeping at pole hyperplanes, not an approximation to the Liouville correlator at small μ. The constant-mode calculation following Definition 68.3 gives the organizing coordinate. On a closed genus g surface,

$$\varepsilon_\Sigma(\boldsymbol{\alpha}) = \sum_i \alpha_i - Q(1-g) = \sum_i \alpha_i - \frac{Q}{2}\chi(\Sigma),$$

and the weak-coupling tail $\phi_0 \to -\infty$ has the form

$$\int_{-\infty}^{c_0} \mathrm{e}^{2\varepsilon_\Sigma c}\,\mathrm{d}c.$$

The Seiberg domain is the open convergence region $\operatorname{Re}\varepsilon_\Sigma > 0$, together with the local integrability inequalities $\alpha_i < Q/2$. The meromorphic continuation of the correlator has boundary poles when the exponent can be neutralized by screening insertions. Expanding the interaction only as a device for extracting residues,

$$\exp\!\left[-\mu\int_\Sigma V_b\right] = \sum_{N\geq 0}\frac{(-\mu)^N}{N!}\left(\int_\Sigma V_b\right)^N,$$

the N-screening term changes the zero-mode exponent from ε_Σ to $\varepsilon_\Sigma + Nb$. Hence it contributes to the residue on the pole hyperplane

$$\varepsilon_\Sigma(\boldsymbol{\alpha}) = -Nb, \qquad N \in \mathbb{Z}_{\geq 0}. \tag{68.62}$$

At this hyperplane the remaining integral over the mean-zero field and the screening positions is the Coulomb-gas integral for the residue. Terms with a different number of screenings compute residues at different hyperplanes; each pole hyperplane has its own neutralizing screening number.

The $b \leftrightarrow b^{-1}$ duality of the DOZZ meromorphic function gives the parallel family

$$\varepsilon_\Sigma(\boldsymbol{\alpha}) = -\frac{\widehat{N}}{b}, \qquad \widehat{N} \in \mathbb{Z}_{\geq 0}, \tag{68.63}$$

whose residues are represented by $\widehat{N}$ insertions of the dual screening $V_{1/b}$ with a normalization $\widetilde{\mu}$. The dual screening is therefore a coordinate on the dual residue family of the meromorphic correlator. The classical action remains (68.1); the relation between $\widetilde{\mu}$ and μ is part of the global DOZZ normalization.

This is the logical bridge between the probabilistic convergence statement, the scattering pole calculation, and the degenerate BPZ shift derivation. The pole at $\epsilon = 0$ used in Paragraph 68.5 is the zero-screening member of the same volume-divergence mechanism. The one-screening coefficient in Lemma 68.23 is the residue at the $N = 1$ pole in (68.62). The dual coefficient in Lemma 68.24 is the $\widehat{N} = 1$ residue in (68.63). The full DOZZ three-point function is the meromorphic solution reconstructed from these residue families, the reflection relation, the two degenerate BPZ shift equations, and the $b \leftrightarrow b^{-1}$ symmetry, subject to the analytic theorem boundary stated in Quoted Theorem 68.16.

The simplest degenerate Liouville momentum is $\alpha = -b/2$. Its conformal weight is

$$h_{-b/2} = -\frac{1}{2} - \frac{3b^2}{4}.$$

Level-two Liouville null vector. Let $c = 1 + 6Q^2$, $Q = b + b^{-1}$, and

$$h = -\frac{1}{2} - \frac{3b^2}{4}.$$

In a highest-weight Virasoro module with highest vector $|h\rangle$, the level-two vector

$$\left(L_{-1}^2 + b^2 L_{-2}\right)|h\rangle \tag{68.64}$$

is annihilated by L_1 and L_2. Hence it is a null vector whenever the module is quotiented to the degenerate representation carried by $V_{-b/2}$. For a candidate $(L_{-1}^2 + \kappa L_{-2})|h\rangle$, the Virasoro commutators give

$$L_1 L_{-1}^2|h\rangle = (4h+2)L_{-1}|h\rangle, \qquad L_1 L_{-2}|h\rangle = 3L_{-1}|h\rangle,$$

and

$$L_2 L_{-1}^2|h\rangle = 6h|h\rangle, \qquad L_2 L_{-2}|h\rangle = (4h + c/2)|h\rangle.$$

The L_1 equation requires $\kappa = -(4h+2)/3 = b^2$. Substituting $h = -1/2 - 3b^2/4$ and $c = 1 + 6(b + b^{-1})^2$ into the L_2 equation gives

$$6h + b^2(4h + c/2) = 0.$$

Thus both positive modes annihilate (68.64).

Dual level-two null vector and BPZ equation. Let $c = 1 + 6Q^2$, $Q = b + b^{-1}$, and

$$h^\vee = -\frac{1}{2} - \frac{3}{4b^2}.$$

In a highest-weight Virasoro module with highest vector $|h^\vee\rangle$, the level-two vector

$$\left(L_{-1}^2 + b^{-2}L_{-2}\right)|h^\vee\rangle \tag{68.65}$$

is annihilated by L_1 and L_2. Therefore the degenerate insertion $V_{-1/(2b)}$ satisfies the dual BPZ equation

$$\left[\partial_z^2 + b^{-2}\sum_{i=1}^{n}\left(\frac{h_i}{(z-z_i)^2} + \frac{1}{z-z_i}\partial_{z_i}\right)\right]\left\langle V_{-1/(2b)}(z)\prod_{i=1}^{n}V_{\alpha_i}(z_i)\right\rangle = 0, \tag{68.66}$$

for separated-point correlators in any domain where the Ward identity and the degenerate quotient are valid. The Virasoro commutator calculation just displayed applies to every candidate $(L_{-1}^2 + \kappa L_{-2})|h\rangle$. Substituting $h = h^\vee$ gives from the L_1 equation

$$\kappa = -\frac{4h^\vee + 2}{3} = b^{-2}.$$

The remaining L_2 coefficient is

$$6h^\vee + b^{-2}(4h^\vee + c/2).$$

With $c = 1 + 6(b + b^{-1})^2$ and $h^\vee = -1/2 - 3/(4b^2)$, this coefficient is zero. Hence (68.65) is a null vector in the degenerate quotient. Inserting $(L_{-1}^2 + b^{-2}L_{-2})V_{-1/(2b)} = 0$ into the same stress-tensor Ward identity used below gives (68.66). The restriction to separated points is the same restriction as for (68.67); collision limits require OPE renormalization and meromorphic continuation.

Proposition 68.22 (BPZ differential equation)**.** *Let*

$$F(z; z_1, \ldots, z_n) = \left\langle V_{-b/2}(z)\prod_{i=1}^{n}V_{\alpha_i}(z_i)\right\rangle$$

be a separated-point correlation function in a domain where the Virasoro Ward identity and the degenerate null-vector quotient are valid. Then F satisfies

$$\left[\partial_z^2 + b^2\sum_{i=1}^{n}\left(\frac{h_i}{(z-z_i)^2} + \frac{1}{z-z_i}\partial_{z_i}\right)\right]F = 0, \qquad h_i = \alpha_i(Q - \alpha_i). \tag{68.67}$$

Proof. The proof uses only two inputs: the degenerate quotient in the Verma module of $V_{-b/2}$, and the separated-point Virasoro Ward identity. The state-field relation gives

$$\left\langle (L_{-1}^2 V_{-b/2})(z)\prod_i V_{\alpha_i}(z_i)\right\rangle = \partial_z^2 F.$$

For the L_{-2} insertion, write

$$(L_{-2}V_{-b/2})(z) = \oint_z \frac{\mathrm{d}w}{2\pi\mathrm{i}}\,\frac{T(w)V_{-b/2}(z)}{w - z}.$$

The contour may be moved, inside the separated-point domain, to the contours around the other insertions and the contour at infinity. The latter vanishes for the sphere correlator after the usual Ward identity falloff. Around z_i,

$$T(w)V_{\alpha_i}(z_i) \sim \frac{h_i}{(w-z_i)^2}V_{\alpha_i}(z_i) + \frac{1}{w-z_i}\partial_{z_i}V_{\alpha_i}(z_i),$$

and expanding $1/(w-z)$ at $w=z_i$ gives

$$\left\langle (L_{-2}V_{-b/2})(z)\prod_i V_{\alpha_i}(z_i)\right\rangle = \sum_i \left(\frac{h_i}{(z-z_i)^2} + \frac{1}{z-z_i}\partial_{z_i}\right)F.$$

The null-vector equation in the degenerate quotient,

$$(L_{-1}^2 + b^2L_{-2})V_{-b/2} = 0,$$

can now be inserted into the correlator. Combining the two displayed insertions gives (68.67). This is an identity for separated-point correlators in the specified Ward-identity domain; coincident limits require the OPE and contact-term renormalization rather than evaluation of the differential equation on the collision diagonals. □

The BPZ equation constrains correlators recursively because fusing $V_{-b/2}$ with a generic V_α has only two allowed Liouville momenta,

$$V_{-b/2}V_\alpha \sim C_+(\alpha)V_{\alpha-b/2} + C_-(\alpha)V_{\alpha+b/2}.$$

The dual degenerate field $V_{-1/(2b)}$ similarly shifts a generic momentum to $\alpha \pm 1/(2b)$ and supplies the b^{-1}-shift equation. The two degenerate equations are logically separate: the first uses the null vector (68.64), while the second uses (68.65). Treating the second as an unstated symmetry argument would hide one of the hypotheses needed in the standard bootstrap determination of the DOZZ constant. Solving (68.67) near one puncture and matching it to the same equation near another puncture gives shift equations for the three-point structure constants. The DOZZ constant is the meromorphic solution with the reflection, shift, and analyticity properties stated above.

Lemma 68.23 (Screening computation of the degenerate OPE coefficient)**.** *In the free-field normalization of Convention 68.2, and with the interaction normalization in (68.1), the degenerate OPE is normalized so that $C_+(\alpha)=1$. The residue at the single V_b-screening pole in the second channel is represented by the meromorphic coefficient*

$$\begin{aligned} C_-(\alpha) &= -\pi\mu\,\gamma(1-2b\alpha)\,\gamma(1+b^2)\,\gamma(2b\alpha-1-b^2) \\ &= -\pi\mu\,\frac{\gamma(2b\alpha-1-b^2)}{\gamma(2b\alpha)\gamma(-b^2)}, \end{aligned} \tag{68.68}$$

where $\gamma(x)=\Gamma(x)/\Gamma(1-x)$. Equivalently,

$$C_-(\alpha) = \pi\mu\, b^4\gamma(b^2)\,\frac{\gamma(2b\alpha-1-b^2)}{\gamma(2b\alpha)}.$$

The equalities are identities of meromorphic functions of b and α; the intermediate Coulomb-gas integral is defined by analytic continuation.

Proof. The coefficient C_+ is fixed by the no-screening normal-ordered product: the charges add as $\alpha - b/2$, and the free contraction gives the expected OPE power

$$V_{-b/2}(z)V_\alpha(0) = |z|^{2b\alpha}V_{\alpha-b/2}(0) + \cdots .$$

For the second channel, the relevant pole of the meromorphic correlator is the hyperplane on which the zero-mode deficit is neutralized by exactly one V_b screening, as in (68.62). The charge of $V_b(w)V_{-b/2}(z)V_\alpha(0)$ is $\alpha + b/2$, so the single-screening configuration computes the residue multiplying the channel $V_{\alpha+b/2}$. Contributions with two, three, or more V_b insertions have zero-mode exponents matched at $\varepsilon_\Sigma = -2b, -3b, \ldots$; they are residues at different poles of the same meromorphic object. The free contractions for the single-screening residue give

$$-\mu \int_{\mathbb{C}} \mathrm{d}^2 w \, |z|^{2b\alpha} \, |w-z|^{2b^2} \, |w|^{-4b\alpha} \, V_{\alpha+b/2}(0).$$

Set $w = zu$. The z-dependent factor becomes

$$|z|^{2+2b^2-2b\alpha} = |z|^{2(h_{\alpha+b/2}-h_\alpha-h_{-b/2})},$$

which is exactly the required OPE power in the second channel. Thus

$$C_-(\alpha) = -\mu \int_{\mathbb{C}} \mathrm{d}^2 u \, |u|^{-4b\alpha}|1-u|^{2b^2}.$$

This integral is the local Coulomb-gas representative of the residue at the single-screening pole. Its dependence on μ records the normalization of that residue in the classical action convention. The full Liouville correlator is the meromorphic object reconstructed from all residue data and the reflection and shift constraints. For complex exponents a, c in a convergence domain, the Dotsenko–Fateev beta integral is

$$\int_{\mathbb{C}} \mathrm{d}^2 u \, |u|^{2a}|1-u|^{2c} = \pi \, \gamma(1+a) \, \gamma(1+c) \, \gamma(-1-a-c). \tag{68.69}$$

Both sides are meromorphic in a, c, so (68.69) defines the continued value when the physical exponents do not lie in an absolute-convergence strip. Substituting $a = -2b\alpha$ and $c = b^2$ gives the first line of (68.68). The remaining forms follow from $\gamma(1-x) = \gamma(x)^{-1}$, $\gamma(1+b^2) = \gamma(-b^2)^{-1}$, and $\gamma(1+b^2) = -b^4\gamma(b^2)$. □

Lemma 68.24 (Dual screening computation)**.** *The $b \leftrightarrow b^{-1}$ dual residue family of the DOZZ meromorphic correlator is represented locally by the dual screening $V_{1/b}$ with coefficient $\widetilde{\mu}$, as in* (68.63)*. This coefficient fixes the normalization of the dual residues. The classical action remains* (68.1)*. Normalize the no-dual-screening channel in*

$$V_{-1/(2b)}V_\alpha \sim \widetilde{C}_+(\alpha)V_{\alpha-1/(2b)} + \widetilde{C}_-(\alpha)V_{\alpha+1/(2b)}$$

by $\widetilde{C}_+(\alpha) = 1$. Then the one-dual-screening coefficient is the meromorphic function

$$\begin{aligned} \widetilde{C}_-(\alpha) &= -\pi\widetilde{\mu}\,\gamma\!\left(1-\frac{2\alpha}{b}\right)\gamma\!\left(1+\frac{1}{b^2}\right)\gamma\!\left(\frac{2\alpha}{b}-1-\frac{1}{b^2}\right) \\ &= \pi\widetilde{\mu}\, b^{-4}\gamma(b^{-2})\,\frac{\gamma\!\left(\frac{2\alpha}{b}-1-\frac{1}{b^2}\right)}{\gamma(2\alpha/b)}. \end{aligned} \tag{68.70}$$

Proof. The no-dual-screening product has charge $\alpha - 1/(2b)$ and fixes $\widetilde{C}_+(\alpha) = 1$. The channel $\alpha + 1/(2b)$ lies on the pole whose zero-mode deficit is neutralized by one insertion of $V_{1/b}(w)$. This single dual screening computes the $\widehat{N} = 1$ residue in (68.63); further dual screenings compute the residues at $\varepsilon_\Sigma = -2/b, -3/b, \ldots$. The free contractions for the single dual residue give

$$-\widetilde{\mu} \int_{\mathbb{C}} \mathrm{d}^2 w \, |z|^{2\alpha/b} \, |w - z|^{2/b^2} \, |w|^{-4\alpha/b} \, V_{\alpha+1/(2b)}(0).$$

After setting $w = zu$, the z-dependent factor is

$$|z|^{2+2/b^2-2\alpha/b} = |z|^{2(h_{\alpha+1/(2b)} - h_\alpha - h_{-1/(2b)})},$$

so the scaling power matches the dual OPE channel. The remaining Dotsenko–Fateev integral is

$$-\widetilde{\mu} \int_{\mathbb{C}} \mathrm{d}^2 u \, |u|^{-4\alpha/b} |1 - u|^{2/b^2}.$$

Applying (68.69) with $a = -2\alpha/b$ and $c = b^{-2}$ gives the first line of (68.70). The second line follows from $\gamma(1-x) = \gamma(x)^{-1}$ and $\gamma(1+b^{-2}) = -b^{-4}\gamma(b^{-2})$. The formula is therefore the precise $b \leftrightarrow b^{-1}$ counterpart of Lemma 68.23, with $\widetilde{\mu}$ kept explicit because the relation between μ and $\widetilde{\mu}$ is part of the full meromorphic DOZZ normalization; this local residue integral fixes only the displayed coefficient. $\square$

Proposition 68.25 (Degenerate BPZ blocks and the DOZZ b-shift)**.** *Fix three generic momenta $\alpha_1, \alpha_2, \alpha_3$, put the degenerate field $V_{-b/2}$ at z, and use global conformal covariance to set the other insertions at $0, 1, \infty$. After extracting the elementary powers fixed by the OPE with $V_{\alpha_1}(0)$, the two local solutions of (68.67) near $z = 0$ are Gauss hypergeometric functions. In a normalization where the two fusion channels are $\alpha_1 - b/2$ and $\alpha_1 + b/2$, one may write*

$$\mathcal{F}_-(z) = z^{b\alpha_1}(1 - z)^{b\alpha_2} {}_2F_1(A, B; C; z), \tag{68.71}$$
$$\mathcal{F}_+(z) = z^{1+b^2-b\alpha_1}(1 - z)^{b\alpha_2} {}_2F_1(A - C + 1, B - C + 1; 2 - C; z), \tag{68.72}$$

with

$$A = b(\alpha_1 + \alpha_2 + \alpha_3 - Q - b/2), \quad B = b(\alpha_1 + \alpha_2 - \alpha_3 - b/2), \quad C = 1 + b(2\alpha_1 - Q).$$

Analytic continuation from the $z = 0$ channel to the $z = 1$ channel gives the corresponding gamma-function connection coefficients, hence the degenerate shift equation

$$\frac{C_b(\alpha_1 + b/2, \alpha_2, \alpha_3)}{C_b(\alpha_1 - b/2, \alpha_2, \alpha_3)} = \mathcal{R}_b(\alpha_1; \alpha_2, \alpha_3), \tag{68.73}$$

where, in the DOZZ normalization of (68.39),

$$\begin{aligned}\mathcal{R}_b(\alpha_1; \alpha_2, \alpha_3) = &\frac{\gamma(2b\alpha_1)\,\gamma(2b\alpha_1 - b^2)\,\gamma(b(\alpha_2 + \alpha_3 - \alpha_1 - b/2))}{\pi\mu\,\gamma(b^2)\,b^4} \\ &\times \frac{1}{\gamma(b(\alpha_1 + \alpha_2 + \alpha_3 - Q - b/2))} \\ &\times \frac{1}{\gamma(b(\alpha_1 + \alpha_2 - \alpha_3 - b/2))} \frac{1}{\gamma(b(\alpha_1 + \alpha_3 - \alpha_2 - b/2))}.\end{aligned} \tag{68.74}$$

The same function is obtained from the hypergeometric connection matrix and the OPE normalization

$$V_{-b/2}V_{\alpha_1} \sim C_+(\alpha_1)V_{\alpha_1-b/2} + C_-(\alpha_1)V_{\alpha_1+b/2}.$$

The connection matrix used here is the standard one for the Gauss equation:

$$\begin{aligned} {}_2F_1(A,B;C;z) = \frac{\Gamma(C)\Gamma(C-A-B)}{\Gamma(C-A)\Gamma(C-B)}{}_2F_1(A,B;A+B-C+1;1-z) \\ + (1-z)^{C-A-B}\frac{\Gamma(C)\Gamma(A+B-C)}{\Gamma(A)\Gamma(B)}{}_2F_1(C-A,C-B;C-A-B+1;1-z). \end{aligned} \tag{68.75}$$

For generic momenta, none of the denominator gamma functions in (68.75) *is at a pole. When a parameter hits a pole, the equation is understood by meromorphic continuation, and logarithmic resonances must be treated separately.*

Proof. With insertions fixed at $0, 1, \infty$, equation (68.67) has only regular singular points $\{0, 1, \infty\}$. The indicial equation at 0 has exponents equal to the OPE weight differences

$$h_{\alpha_1-b/2} - h_{\alpha_1} - h_{-b/2} = b\alpha_1, \qquad h_{\alpha_1+b/2} - h_{\alpha_1} - h_{-b/2} = 1 + b^2 - b\alpha_1.$$

After factoring these powers and the analogous elementary factor at 1, the remaining second-order Fuchsian equation is the hypergeometric equation with parameters A, B, C above. The standard connection formula for Gauss hypergeometric functions, (68.75), expresses the same two-dimensional solution space in the $z = 1$ fusion basis. The exponents at $z = 1$ are

$$b\alpha_2, \qquad b\alpha_2 + C - A - B = 1 + b^2 - b\alpha_2,$$

which are the two OPE exponents for fusing $V_{-b/2}$ with $V_{\alpha_2}(1)$. Crossing symmetry of the four-point function with one degenerate insertion identifies the products of OPE coefficients in the two bases, giving (68.73).

Here is the coefficient extraction explicitly. Let $\mathcal{H}_-$ and $\mathcal{H}_+$ be the two local blocks in the $z = 1$ channel, normalized with exponents $b\alpha_2$ and $1 + b^2 - b\alpha_2$. The connection formula gives

$$\mathcal{F}_i = \sum_{j=\pm} M_{ij}\mathcal{H}_j, \qquad i = \pm,$$

with

$$\begin{aligned} M_{--} &= \frac{\Gamma(C)\Gamma(C-A-B)}{\Gamma(C-A)\Gamma(C-B)}, & M_{-+} &= \frac{\Gamma(C)\Gamma(A+B-C)}{\Gamma(A)\Gamma(B)}, \\ M_{+-} &= \frac{\Gamma(2-C)\Gamma(C-A-B)}{\Gamma(1-A)\Gamma(1-B)}, & M_{++} &= \frac{\Gamma(2-C)\Gamma(A+B-C)}{\Gamma(A-C+1)\Gamma(B-C+1)}. \end{aligned}$$

In the $z = 0$ channel the diagonal Liouville four-point function has the form

$$\mathcal{G}(z,\bar{z}) = A_s\,|\mathcal{F}_-|^2 + B_s\,|\mathcal{F}_+|^2,$$

where

$$A_s = C_b(\alpha_1 - b/2, \alpha_2, \alpha_3), \qquad B_s = C_-(\alpha_1)C_b(\alpha_1 + b/2, \alpha_2, \alpha_3).$$

The absence of $\mathcal{F}_-\overline{\mathcal{F}_+}$ terms is not a normalization convention: for generic momenta the two intermediate primaries have nonintegrally separated conformal weights, so single-valuedness around $z = 0$ and the diagonal spectrum force the hermitian form on the local solution space to be diagonal. The same statement in the $z = 1$ OPE basis requires the coefficient of $\mathcal{H}_-\overline{\mathcal{H}_+}$ to vanish. In a real nonresonant chamber the connection coefficients are real, and this condition is

$$A_s M_{--}M_{-+} + B_s M_{+-}M_{++} = 0.$$

Both sides are meromorphic in the momenta, so the resulting identity extends away from the polar and logarithmic resonance divisors. Hence

$$\frac{C_b(\alpha_1 + b/2, \alpha_2, \alpha_3)}{C_b(\alpha_1 - b/2, \alpha_2, \alpha_3)} = -\frac{M_{--}M_{-+}}{C_-(\alpha_1)M_{+-}M_{++}}. \tag{68.76}$$

Substituting A, B, C and the one-screening coefficient (68.68) into (68.76), then using $\Gamma(x)\Gamma(1 - x) = \pi/\sin(\pi x)$ only through the ratio $\gamma(x) = \Gamma(x)/\Gamma(1-x)$, gives precisely (68.74). The formula therefore follows from a local BPZ connection problem plus the explicitly normalized degenerate OPE; it is not an independent assumption about the DOZZ function.

It remains to compute the right hand side in the DOZZ normalization. Let $K = \pi\mu\,\gamma(b^2)b^{2-2b^2}$. In the ratio

$$\frac{C_b(\alpha_1 + b/2, \alpha_2, \alpha_3)}{C_b(\alpha_1 - b/2, \alpha_2, \alpha_3)},$$

the cosmological-constant factor contributes K^{-1}. The numerator $\Upsilon_b(2\alpha_1)$ contributes

$$\frac{\Upsilon_b(2\alpha_1 + b)}{\Upsilon_b(2\alpha_1 - b)} = \gamma(2b\alpha_1)\,\gamma(2b\alpha_1 - b^2)\,b^{2+2b^2-8b\alpha_1}.$$

For the denominator factors one uses $\Upsilon_b(x)/\Upsilon_b(x + b) = \gamma(bx)^{-1}b^{-1+2bx}$ for the first three terms and $\Upsilon_b(y + b)/\Upsilon_b(y) = \gamma(by)b^{1-2by}$ for the last term, with

$$x_1 = \alpha_1 + \alpha_2 + \alpha_3 - Q - b/2, \qquad x_2 = \alpha_1 + \alpha_2 - \alpha_3 - b/2,$$
$$x_3 = \alpha_1 + \alpha_3 - \alpha_2 - b/2, \qquad y = \alpha_2 + \alpha_3 - \alpha_1 - b/2.$$

The powers of b from these four denominator ratios and the numerator combine to b^{-2b^2-2}; multiplying by K^{-1} leaves the total factor $1/(\pi\mu\,\gamma(b^2)b^4)$. The remaining gamma functions are exactly (68.74). □

68.8 Sewing Status and Open Boundary

The closed-surface probabilistic theory, the bootstrap formula, and the Segal/Kontsevich–Segal sewing formulation require the comparison datum described after Quoted Theorem 68.5.

Open Problem 68.26 (Liouville sewing and functorial closure). Construct, in a single framework, the Hilbert or topological vector spaces assigned to circles, the multilinear maps assigned to bordered Riemann surfaces, the boundary state spaces, and the sewing maps whose closed-surface matrix elements reproduce the probabilistic Liouville correlators and the DOZZ/bootstrap conformal blocks. In the notation of (68.9) and (68.10), the construction must specify the topology on continuous-spectrum direct integrals, the domain of unbounded vertex operators, the descendant pairing used on the two sides of a cut, the convergence of the gluing integrals over $\alpha = Q/2 + \mathrm{i}P$, and the residue prescription at meromorphic continuation walls. This is the Volume V form of the Liouville and nonrational-CFT open problem in the Kontsevich–Segal functorial-QFT chapter.

Thus the status is deliberately layered. The classical action and background-charge Ward algebra are derived in the chapter. The measure-theoretic path integral and the DOZZ formula are quoted theorem inputs with named proof boundaries. Full functorial sewing remains an open problem for the monograph's foundational program.

Chapter 69

Boundary Conformal Field Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

69.1 Boundary CFT Data

Boundary conformal field theory is not just a conformal field theory placed near a wall. The boundary condition is additional local QFT data: it specifies boundary operators, bulk-to-boundary operator expansions, and sewing maps for bordered surfaces. In two dimensions this datum admits a particularly sharp operator formulation because the conformal boundary condition identifies the holomorphic and antiholomorphic stress tensors on the boundary.

Definition 69.1 (Oriented bosonic BCFT datum)**.** Fix a closed oriented two-dimensional CFT $\mathcal{C}$. An oriented bosonic boundary conformal field theory based on $\mathcal{C}$ consists of the following data.

1. A set B of boundary conditions.
2. For each ordered pair $a, b \in \mathsf{B}$, a positive-energy Hilbert space $\mathcal{H}_{ab}$ assigned to an interval whose left boundary condition is a and whose right boundary condition is b.
3. For each $a \in \mathsf{B}$, a boundary operator algebra $\mathcal{A}_a$ acting on boundary segments with condition a, and more generally boundary-condition-changing operators in $\mathrm{Hom}(\mathcal{H}_{ab}, \mathcal{H}_{ac})$.
4. Bulk-to-boundary expansion maps expressing a bulk local field $\mathcal{O}(z, \bar{z})$, as z approaches a

boundary segment with condition a, in the form

$$\mathcal{O}(x+\mathrm{i}y, x-\mathrm{i}y) \sim \sum_{\beta} B_{\mathcal{O}}^{a,\beta}\,(2y)^{h_\beta-h-\bar{h}}\widehat{\mathcal{O}}_\beta^{a}(x), \qquad y>0, \tag{69.1}$$

where the boundary fields $\widehat{\mathcal{O}}_\beta^a$ have one-dimensional conformal weights h_β.

5. Correlation functions on bordered Riemann surfaces with boundary segments labelled by elements of B, satisfying locality, reflection positivity in the unitary case, conformal covariance, and sewing compatibility for gluing boundary and bulk circles.

The same closed CFT can admit many inequivalent choices of B and sewing data.

How the sewing data are organized in this chapter. The definition above is deliberately broader than any one construction. The chapter develops its consequences in four layers. First come the kinematic Virasoro and annulus constraints: stress-tensor gluing gives one preserved chiral algebra, Ishibashi states solve the closed-channel linear gluing equations, and Cardy's diagonal solution is the first complete rational test. Second come the genus-zero sewing equations: boundary OPE associativity, disk bulk-boundary classifying coordinates, direct-sum boundary conditions, and the finite Ising sewing cell show exactly which finite algebra is being checked in the diagonal case. Third come the two non-diagonal directions. For rational chiral data the Frobenius-algebra/module formalism supplies the local algebraic mechanism behind annuli, boundary OPEs, classifying projectors, and two-point pairings; the pointed G/H example is one coherent finite model of those four shadows. For nonrational data the Liouville/FZZT discussion replaces finite sums by direct-integral wavefunctions, contour prescriptions, residues, and continuous sewing maps. Fourth, the quoted theorem and open problem at the end record the remaining all-surface analytic burden: constructing positive Hilbert spaces, common domains for boundary fields, determinant-line compatibility, and sewing maps that make the finite rational and nonrational formulas part of one BCFT datum.

All-surface sewing as a generated compatibility problem. The point of the local calculations below is not that a disk, an annulus, or a single four-boundary-field correlator is a BCFT by itself. A bordered surface is cut into disks, strips, annuli, and pairs of pants; two such cuts are related by a finite sequence of elementary moves. In the rational semisimple case these are the annulus open/closed move (69.8), the boundary-associativity move (69.25), the disk classifying move (69.31), the bulk-boundary identity normalization (69.35), and the Frobenius/module cutting moves (69.66) and (69.69). In the nonrational examples the same list is enlarged by contour choices, residue jumps such as (69.61), direct-integral convergence, and anomaly-line trivializations. The finite cells in this chapter verify pieces of these moves; the theorem boundary is the claim that these moves generate all changes of decomposition and act on a space where every amplitude is defined.

Proposition 69.2 (Finite move-defect budget for bordered sewing)**.** *Let $\mathcal{G}$ be a finite graph whose vertices are choices of local bordered-surface decompositions and whose directed edges are elementary sewing moves. Assign to each vertex v a vector A_v in a normed finite dimensional space. For an edge $e: u \to v$, let T_e be the linear transport associated with the sewing move, with $\|T_e\| \le L_e$, and define the local defect*

$$\delta_e = A_v - T_e A_u.$$

For a path $p = e_N \cdots e_1$ from v_0 to v_N,

$$\|A_{v_N} - T_{e_N} \cdots T_{e_1} A_{v_0}\| \leq \sum_{r=1}^{N} \left(\prod_{s=r+1}^{N} L_{e_s} \right) \|\delta_{e_r}\|. \tag{69.2}$$

In particular, if every local defect on a connected move graph vanishes and the transports agree on closed loops, the assigned amplitude is independent of the chosen decomposition.

Proof. Write $T_{r:s} = T_{e_r} \cdots T_{e_s}$ for $r \geq s$. The identity

$$A_{v_N} - T_{N:1} A_{v_0} = \sum_{r=1}^{N} T_{N:r+1} \big(A_{v_r} - T_{e_r} A_{v_{r-1}} \big)$$

is a telescoping sum; the factor $T_{N:r+1}$ is absent for $r = N$. Taking norms and using submultiplicativity gives (69.2). If all defects vanish, transport along any path carries the initial amplitude to the terminal one. The closed-loop condition then removes dependence on the path inside the connected move graph. $\square$

This proposition is the finite algebraic skeleton behind the Cardy–Lewellen sewing problem. The diagonal Cardy and pointed G/H checks later in the chapter are exact zero-defect tests for selected rational moves. The Liouville contour and Plancherel checks are local models for nonrational closed/open moves. None of them supplies the missing analytic input that the move graph is generated on a complete topological state space with convergent multilinear sewing maps; that is why the all-surface construction remains a quoted theorem or open problem rather than a consequence of the examples.

Definition 69.3 (Finite sewing anomaly cocycle)**.** In the setting of Proposition 69.2, suppose the amplitudes are not scalar vectors but vectors in one-dimensional anomaly lines $\mathcal{L}_v$ over the vertices of the move graph. After choosing local trivializations of these lines, an elementary sewing move $e : u \to v$ is represented by a scalar $\lambda_e \in \mathbb{C}^\times$ times the ordinary transport T_e. For a path $p = e_N \cdots e_1$, set

$$\lambda_p = \lambda_{e_N} \cdots \lambda_{e_1}.$$

The scalar λ_ℓ on a closed loop ℓ is the scalar part of the finite projective sewing anomaly. The actual closed-loop action on an amplitude is the total operator $\lambda_\ell T_\ell$, where $T_\ell = T_{e_N} \cdots T_{e_1}$ is the ordinary vector-space transport. The anomaly cocycle is trivial on a connected move graph if there are nonzero vertex scalars η_v such that

$$\lambda_e = \eta_v \eta_u^{-1} \qquad (e : u \to v). \tag{69.3}$$

Proposition 69.4 (Trivializing a finite sewing anomaly)**.** *Let $\mathcal{G}$ be a connected finite move graph with projective sewing scalars λ_e. Suppose the local projective defects vanish:*

$$A_v = \lambda_e T_e A_u \qquad (e : u \to v).$$

If λ_e has the coboundary form (69.3), then the rescaled amplitudes

$$\widetilde{A}_v = \eta_v^{-1} A_v$$

obey ordinary zero-defect sewing,

$$\widetilde{A}_v = T_e\widetilde{A}_u.$$

Conversely, if a closed loop has $\lambda_\ell \neq 1$, no such vertex trivialization exists on the component containing that loop. This is an obstruction to removing the scalar cocycle by changing local line frames.

Scalar decomposition independence after forgetting the anomaly line is a separate condition. For a closed loop ℓ based at v, a scalar amplitude A_v is loop-independent only if

$$\lambda_\ell T_\ell A_v = A_v. \tag{69.4}$$

Therefore $\lambda_\ell \neq 1$ obstructs a nonzero scalar amplitude only after the ordinary closed-loop transport has been trivialized on that amplitude, or more generally when 1 is not an eigenvalue of $\lambda_\ell T_\ell$ on the relevant amplitude subspace.

Proof. Substituting $\lambda_e = \eta_v\eta_u^{-1}$ gives

$$\widetilde{A}_v = \eta_v^{-1}A_v = \eta_v^{-1}\lambda_e T_e A_u = T_e\eta_u^{-1}A_u = T_e\widetilde{A}_u.$$

For the converse, multiply (69.3) around a closed loop $\ell = e_N\cdots e_1$. The vertex factors telescope, so every coboundary has $\lambda_\ell = 1$. A loop with $\lambda_\ell \neq 1$ therefore cannot come from vertex rescalings. The local projective sewing relation transported around the loop gives $A_v = \lambda_\ell T_\ell A_v$, equivalently (69.4). If $T_\ell A_v = A_v$, this reduces to $(\lambda_\ell - 1)A_v = 0$, so a nonzero scalar amplitude is impossible when $\lambda_\ell \neq 1$. Without that ordinary-transport hypothesis, λ_ℓ alone is not the scalar path-independence obstruction: ordinary holonomy may cancel the scalar phase on a particular subspace. The invariant statement is the total projective loop condition $\lambda_\ell T_\ell A_v = A_v$. □

This is the finite model for determinant-line bookkeeping in bordered CFT. The analytic sewing theorem must construct the relevant anomaly line over the moduli/decomposition groupoid, identify the line transports produced by cutting and gluing, and either trivialize their cocycle or keep amplitudes as line-valued sections. Local Cardy–Lewellen algebra controls the vector part of the move; it does not by itself remove the line cocycle. Conversely, a scalar monodromy test must include the ordinary vector transport as well as the line factor, because the physical closed-loop comparison is $\lambda_\ell T_\ell$, not λ_ℓ alone.

For a boundary equal to the real axis in the upper half-plane $\mathbb{H} = \{z = x + \mathrm{i}y \mid y \geq 0\}$, the stress tensor has components

$$T(z) = T_{zz}(z), \qquad \bar{T}(\bar{z}) = T_{\bar{z}\bar{z}}(\bar{z}).$$

The component of energy flow through the boundary is proportional to $T(z) - \bar{T}(\bar{z})$ at $z = \bar{z} = x$. A conformal boundary condition sets this flux to zero:

$$T(x) = \bar{T}(x), \qquad x \in \mathbb{R}, \tag{69.5}$$

as an identity inside boundary correlation functions away from boundary operator insertions.

Preserved Virasoro algebra. Suppose a boundary condition on the upper half-plane obeys (69.5). The conformal transformations preserving the boundary are then generated by a single copy of the Virasoro algebra. In the closed-channel boundary-state convention the modes are

$$L_n^{\partial} = L_n - \bar{L}_{-n} \tag{69.6}$$

or equivalently by the diagonal combination of holomorphic and antiholomorphic conformal vector fields on the half-plane.

Let $v(z)\partial_z + \bar{v}(\bar{z})\partial_{\bar{z}}$ be a conformal vector field on the upper half-plane. It preserves the real boundary precisely when $v(x) = \bar{v}(x)$ for real x. The Ward identity for an infinitesimal transformation is the contour integral of

$$v(z)T(z)\mathrm{d}z + \bar{v}(\bar{z})\bar{T}(\bar{z})\mathrm{d}\bar{z}.$$

Moving the contour to the boundary produces a term proportional to

$$v(x)\big(T(x) - \bar{T}(x)\big)\mathrm{d}x,$$

which vanishes by (69.5). On the cylinder, the closed-channel boundary is a state at Euclidean time 0. Reversing the orientation of the antiholomorphic contour sends $\bar{L}_n$ to $\bar{L}_{-n}$, so the annihilating generator is $L_n - \bar{L}_{-n}$. These generators obey a single Virasoro algebra because the two central terms cancel in the difference.

69.2 Boundary States and Ishibashi States

The same annulus can be quantized in two ways. In the open channel, time runs along the strip and the Hilbert space is $\mathcal{H}_{ab}$. In the closed channel, time runs across the strip and the two boundary components are represented by states in the closed-string Hilbert space. The equality of these two descriptions is the annulus sewing constraint.

Let the closed Hilbert space of a diagonal rational CFT be

$$\mathcal{H}_{\mathrm{cl}} = \bigoplus_{i \in I} \mathcal{H}_i \otimes \overline{\mathcal{H}_i}, \tag{69.7}$$

where $\mathcal{H}_i$ are irreducible representations of the chiral algebra. For an interval of length L and Euclidean time β, define

$$q = \exp(-\pi\beta/L), \qquad \tilde{q} = \exp(-4\pi L/\beta).$$

The same annulus amplitude must have the form

$$Z_{ab}^{\mathrm{open}}(q) = \mathrm{Tr}_{\mathcal{H}_{ab}}\, q^{L_0 - c/24} = \langle b|\tilde{q}^{(L_0 + \bar{L}_0 - c/12)/2}|a\rangle = Z_{ab}^{\mathrm{closed}}(\tilde{q}). \tag{69.8}$$

The factor $1/2$ in the closed Hamiltonian is a convention fixed by the modular parameter of the annulus; changing cylinder coordinates changes both sides by the same reparametrization. The order $\langle b| \cdots |a\rangle$ is the orientation convention used below: $\mathcal{H}_{ab}$ is the open Hilbert space of fields that begin at boundary condition a and end at boundary condition b.

Definition 69.5 (Ishibashi state)**.** Assume $\mathcal{H}_i$ is paired with its conjugate in (69.7). Choose a homogeneous orthonormal basis $\{e_\alpha\}$ of $\mathcal{H}_i$ and an antiunitary map $U_i : \mathcal{H}_i \to \overline{\mathcal{H}_i}$ intertwining the chiral algebra with the antiholomorphic copy. The convention is

$$U_i L_m U_i^{-1} = \bar{L}_m \tag{69.9}$$

on the finite-energy domain. For an additional chiral generator W_m^a of spin s_a, the preserved boundary condition is encoded by the corresponding antiunitary adjoint convention

$$U_i (W_m^a)^\dagger U_i^{-1} = (-1)^{s_a} \Omega(\bar{W}_{-m}^a), \tag{69.10}$$

where Ω is the chosen automorphism of the chiral algebra. The Ishibashi state associated to i is the formal state

$$|i\rangle\rangle = \sum_\alpha e_\alpha \otimes U_i e_\alpha. \tag{69.11}$$

It is not usually a normalizable vector in $\mathcal{H}_{\mathrm{cl}}$; it is a distributional state whose overlaps are defined after inserting $\tilde{q}^{(L_0+\bar{L}_0-c/12)/2}$.

Proposition 69.6 (Ishibashi gluing)**.** *The state $|i\rangle\rangle$ satisfies*

$$(L_n - \bar{L}_{-n})|i\rangle\rangle = 0 \tag{69.12}$$

for all $n \in \mathbb{Z}$. More generally, if W_m^a is a mode of a chiral current of spin s_a, the symmetry-preserving Ishibashi state satisfies

$$\left(W_m^a - (-1)^{s_a} \Omega(\bar{W}_{-m}^a)\right) |i\rangle\rangle = 0 \tag{69.13}$$

for the chosen automorphism Ω of the chiral algebra.

Proof. Let

$$C_i = \sum_\alpha e_\alpha \otimes U_i e_\alpha$$

denote the formal coevaluation vector. We first record the finite-level identity which controls the antiunitary bookkeeping. If A is an operator on the finite-energy domain of $\mathcal{H}_i$ with adjoint $A^\dagger$, then

$$(A \otimes 1) C_i = (1 \otimes U_i A^\dagger U_i^{-1}) C_i \tag{69.14}$$

as a distributional vector, meaning after pairing against any finite-level vector $u \otimes U_i v$. Indeed, using the Hermitian inner product on $\mathcal{H}_i$, written antilinear in the first argument, the antiunitarity of U_i, and the finite-level resolution of the identity $\sum_\alpha |e_\alpha\rangle\langle e_\alpha| = 1$, the two pairings are

$$\sum_\alpha \langle u, A e_\alpha\rangle \langle e_\alpha, v\rangle = \langle u, Av\rangle = \langle A^\dagger u, v\rangle$$

and

$$\sum_\alpha \langle u, e_\alpha\rangle \langle A^\dagger e_\alpha, v\rangle = \langle A^\dagger u, v\rangle.$$

Since finite-level vectors separate the graded dual completion in which $|i\rangle\rangle$ lives, (69.14) follows. Taking $A = L_n$ and using positive-energy unitarity $L_n^\dagger = L_{-n}$, together with (69.9), gives

$$(L_n \otimes 1)|i\rangle\rangle = (1 \otimes \bar{L}_{-n})|i\rangle\rangle,$$

which is (69.12). For a spin-s_a current the finite-level identity (69.14), applied to $A = W^a_m$, gives the adjoint mode in the reflected copy. The boundary reflection reverses the chiral coordinate and contributes the spin phase $(-1)^{s_a}$; the chosen preserved diagonal current is then allowed to act through the chiral-algebra automorphism Ω. These three inputs give (69.13). □

The overlap of two Ishibashi states is diagonal:

$$\langle\langle i|\tilde{q}^{(L_0+\bar{L}_0-c/12)/2}|j\rangle\rangle = \delta_{ij}\chi_i(\tilde{q}), \tag{69.15}$$

where χ_i is the chiral character. Thus a boundary state preserving the chiral algebra has the expansion

$$|a\rangle = \sum_i B_a{}^i\,|i\rangle\rangle \tag{69.16}$$

with coefficients constrained by the open-channel interpretation.

69.3 Cardy Consistency

Assume the rational diagonal setting of (69.7). The open-channel Hilbert space between two elementary boundary conditions a, b must decompose as

$$\mathcal{H}_{ab} = \bigoplus_k n_{ab}{}^k\,\mathcal{H}_k, \qquad n_{ab}{}^k \in \mathbb{Z}_{\geq 0}. \tag{69.17}$$

Using $\chi_i(\tilde{q}) = \sum_k S_{ik}\chi_k(q)$, the annulus equality gives

$$n_{ab}{}^k = \sum_i \overline{B_b{}^i}\,B_a{}^i S_{ik} \tag{69.18}$$

for unitary boundary coefficients in this orientation convention. If the modular data are real and all labels are self-conjugate, this reduces to the familiar symmetric shorthand. In general the conjugation records the direction of the boundary-changing open sector. Cardy consistency is the demand that these numbers be nonnegative integers and that the resulting open operator algebras sew consistently.

Proposition 69.7 (Oriented Cardy annulus for the diagonal invariant)**.** *Let a unitary rational CFT have diagonal closed Hilbert space* (69.7)*, unitary modular matrix S, and fusion coefficients $N_{ab}{}^k$ obeying the Verlinde formula. Then the boundary states*

$$|a\rangle = \sum_i \frac{S_{ai}}{\sqrt{S_{0i}}}|i\rangle\rangle, \qquad a \in I, \tag{69.19}$$

satisfy the annulus integrality condition with

$$n_{ab}{}^k = N_{ka}{}^b. \tag{69.20}$$

Proof. Substitute $B_a{}^i = S_{ai}/\sqrt{S_{0i}}$ into (69.18). The coefficient of the open-channel character $\chi_k(q)$ is

$$n_{ab}{}^k = \sum_i \frac{\overline{S_{bi}}\,S_{ai}S_{ik}}{S_{0i}}.$$

By unitarity and charge conjugation, $\overline{S_{bi}} = S_{\bar{b}i}$, and the Verlinde formula gives

$$N_{ka}{}^{b} = \sum_i \frac{S_{ki} S_{ai} \overline{S_{bi}}}{S_{0i}}.$$

Since S is symmetric, these expressions agree. Fusion coefficients are dimensions of three-point chiral block spaces, hence are nonnegative integers. For self-conjugate labels and real S-matrix entries this orientation-aware statement collapses to the common symmetric shorthand after the corresponding relabelling of boundary orientation, but the displayed formula is the one used by boundary-changing fields in non-self-conjugate examples. □

Proposition 69.8 (Annulus nimrep spectral resolution)**.** *Let I be the set of simple chiral labels of a unitary rational theory, with fusion coefficients $N_{ij}{}^{k}$ and modular matrix S. Let $\mathcal{B}$ be a finite set of elementary boundary labels, and suppose the open annulus multiplicities form matrices*

$$(n_i)_a{}^b = n_{ab}{}^i, \qquad a, b \in \mathcal{B},$$

such that

$$n_0 = \mathbf{1}, \qquad n_i n_j = \sum_k N_{ij}{}^k n_k. \tag{69.21}$$

Assume also that these matrices are normal and mutually commuting in the unitary boundary two-point pairing. Then there is a unitary matrix Ψ_{ae}, whose columns are indexed by a finite multiset $\mathcal{E}$ of exponents e, and a chiral label $\alpha(e) \in I$ for each exponent, such that

$$(n_i)_a{}^b = \sum_{e \in \mathcal{E}} \Psi_{ae} \frac{S_{i,\alpha(e)}}{S_{0,\alpha(e)}} \overline{\Psi_{be}}. \tag{69.22}$$

The number of copies of a fixed chiral label in $\mathcal{E}$ is the dimension of the corresponding common eigenspace of the annulus matrices. If the closed channel contains one Ishibashi copy $|e\rangle\rangle$ for each exponent copy and the boundary-state coefficients are

$$B_a{}^e = \frac{\Psi_{ae}}{\sqrt{S_{0,\alpha(e)}}}, \tag{69.23}$$

then the closed-channel annulus formula reproduces precisely the open-channel matrices n_i.

Proof. The matrices n_i are simultaneously unitarily diagonalizable because they are normal and mutually commute. On a common eigenline e, the eigenvalues $\lambda_i(e)$ obey

$$\lambda_i(e)\lambda_j(e) = \sum_k N_{ij}{}^k \lambda_k(e), \qquad \lambda_0(e) = 1,$$

so $i \mapsto \lambda_i(e)$ is a one-dimensional representation of the Verlinde fusion algebra. Since S diagonalizes this semisimple algebra, every such character has the form

$$\lambda_i(e) = \frac{S_{i,\alpha(e)}}{S_{0,\alpha(e)}}$$

for a chiral label $\alpha(e)$, with repetitions allowed when the common eigenspace has multiplicity. Writing the spectral projectors in an orthonormal eigenbasis gives (69.22). Finally, (69.18) with (69.23) gives

$$\sum_{e \in \mathcal{E}} \overline{B_b{}^e}\, B_a{}^e\, S_{\alpha(e)i} = \sum_{e \in \mathcal{E}} \Psi_{ae} \frac{S_{i,\alpha(e)}}{S_{0,\alpha(e)}} \overline{\Psi_{be}},$$

using the symmetry of S, which is the displayed open annulus matrix. □

This proposition is the annulus part of the open–closed sewing problem, not a replacement for the Cardy–Lewellen equations. It says that a non-diagonal rational boundary theory is not specified by arbitrary nonnegative integer open spectra: the annulus matrices must form a fusion-ring representation, and their common eigenvectors are the closed-channel reflection coefficients of the boundary states. The later boundary OPE, disk classifying algebra, and two-point pairing data still have to explain how these reflection coefficients participate in local operator products and all bordered-surface sewings. In the diagonal Cardy solution this spectral resolution is the regular representation diagonalized by S; in non-diagonal examples the exponent multiset records which Ishibashi sectors, and with what multiplicities, are visible to the chosen boundary theory.

69.4 Boundary OPE and Cardy–Lewellen Equations

The annulus only detects the graded dimensions of open-channel Hilbert spaces. A BCFT also has boundary operator products. If the boundary condition is a to the left of an insertion and b to the right, write

$$\psi_i^{ab,\alpha}(x)$$

for a boundary-condition-changing primary transforming in the chiral representation i. The multiplicity label α runs through a basis of the corresponding space of boundary fields.

Hypothesis 69.9 (Rational sewing hypotheses for this subsection)**.** The explicit sewing equations in this subsection assume a unitary rational chiral algebra with finitely many simple representations, semisimple positive-energy modules, convergent genus-zero chiral conformal blocks, nondegenerate boundary two-point pairings, and Moore–Seiberg fusing isomorphisms satisfying the pentagon identity. The diagonal Cardy example also assumes the closed Hilbert space $\oplus_i \mathcal{H}_i \otimes \overline{\mathcal{H}_i}$. Outside these hypotheses the formulas remain useful local models, but they are not a proof of analytic sewing.

Under Hypothesis 69.9, for ordered boundary conditions a, b, c, the boundary OPE has the form

$$\psi_i^{ab,\alpha}(x)\psi_j^{bc,\beta}(0) \sim \sum_{k,\gamma} C\begin{bmatrix} a & b & c \\ i & j & k \end{bmatrix}_{\alpha\beta}^{\gamma} x^{h_k-h_i-h_j}\psi_k^{ac,\gamma}(0) + \cdots . \tag{69.24}$$

The coefficient is not just a number attached to three labels; it depends on normalizations of boundary two-point functions and on a choice of basis in each chiral block space. A change of those bases conjugates the coefficient tensors, while the sewing equations below are invariant statements.

For four boundary fields on a disk, with boundary conditions

$$a \longrightarrow b \longrightarrow c \longrightarrow d \longrightarrow a,$$

there are two ways to perform the OPE. In a rational theory the two chiral decompositions are related by the fusing matrix F. The resulting Cardy–Lewellen boundary sewing equation, with dual-basis pairings of chiral blocks suppressed from the notation, is

$$\sum_{p,\mu} C\begin{bmatrix} a & b & c \\ i & j & p \end{bmatrix}^{\mu}_{\alpha\beta} C\begin{bmatrix} a & c & d \\ p & k & \ell \end{bmatrix}^{\delta}_{\mu\gamma} F_{pq}\begin{bmatrix} i & j \\ k & \ell \end{bmatrix}$$
$$= \sum_{\eta} C\begin{bmatrix} b & c & d \\ j & k & q \end{bmatrix}^{\eta}_{\beta\gamma} C\begin{bmatrix} a & b & d \\ i & q & \ell \end{bmatrix}^{\delta}_{\alpha\eta}. \tag{69.25}$$

The displayed formula suppresses the standard dual-basis pairings of chiral blocks. Its invariant content is that boundary OPE coefficients form an associative multiplication object in the chiral tensor category, with the associator supplied by the Moore–Seiberg fusing isomorphism.

Cardy boundary fields from fusion. In the diagonal Cardy solution, the multiplicity of boundary primaries from a to b is

$$\dim \operatorname{span}\{\psi_i^{ab}\} = N_{ia}{}^{b}. \tag{69.26}$$

If the boundary three-point coefficients are chosen to be the normalized fusing matrices of the chiral theory, then (69.25) is precisely the pentagon identity for the fusing matrices.

The open spectrum for Cardy boundary labels is $\mathcal{H}_{ab} \simeq \oplus_i N_{ia}{}^{b}\mathcal{H}_i$, matching (69.20) and (69.26). Boundary three-point functions are chiral three-point blocks on the doubled disk. The operation of composing two boundary OPEs is therefore the operation of changing parenthesization in a four-point chiral block. The Moore–Seiberg fusing matrix is exactly the transition matrix between the two parenthesizations. The pentagon identity says that all ways of changing parenthesization in a five-point block agree. Specializing the pentagon to the four-boundary-field factorization diagram gives (69.25).

The disk one-point coefficient of a spinless bulk primary is another piece of sewing data. In the diagonal Cardy case the coefficient of the identity boundary field is proportional to

$$B_a{}^{i} = \frac{S_{ai}}{\sqrt{S_{0i}}}.$$

The Verlinde eigenvalue

$$\lambda_a(i) = \frac{S_{ia}}{S_{0a}} \tag{69.27}$$

is a one-dimensional character of the fusion ring:

$$\lambda_a(i)\lambda_a(j) = \sum_k N_{ij}{}^{k}\, \lambda_a(k). \tag{69.28}$$

Indeed, the Verlinde formula says that the matrices N_i are diagonalized by S, with eigenvalues S_{ia}/S_{0a}. The Cardy disk coefficient is the same eigenvalue with the normalization required by the bulk two-point function:

$$B_a{}^{i} = \frac{S_{0a}}{\sqrt{S_{0i}}}\, \lambda_a(i).$$

Thus the disk one-point functions solve the genus-zero bulk-boundary sewing equation only after this normalization has been separated from the physical two-point convention. The useful coordinate for the disk sewing equation is

$$\widehat{B}_a(i) := \frac{\sqrt{S_{0i}}}{S_{0a}}\, B_a{}^{i} = \lambda_a(i). \tag{69.29}$$

In the diagonal Cardy theory the bulk fields which can appear in the boundary identity channel form the fusion algebra object with basis $\{e_i\}$ and product

$$e_i e_j = \sum_k N_{ij}{}^k e_k. \tag{69.30}$$

The boundary condition a defines the linear functional $\chi_a(e_i) = \widehat{B}_a(i)$. The disk sewing constraint obtained by comparing the two orders of operation, first fusing two bulk fields and then taking the boundary identity channel or first taking the two identity bulk-boundary channels and multiplying the results, is the multiplicativity condition

$$\chi_a(e_i e_j) = \chi_a(e_i)\chi_a(e_j). \tag{69.31}$$

Substituting (69.30) and $\chi_a(e_i) = \lambda_a(i)$ gives precisely (69.28). This is a statement about the normalized classifying coordinate. It is not the assertion that the raw bulk OPE constants are fusion coefficients, nor that all metric factors have disappeared; those factors have been absorbed into the chosen basis of the classifying algebra and into the normalization of the identity boundary field. In a non-diagonal rational CFT the same low-genus sewing constraint is formulated in the classifying algebra associated to the chosen Frobenius algebra object; in a nonrational theory there need not be a finite-dimensional classifying algebra at all, and the finite character calculation must be replaced by an analytic statement about the relevant continuous spectrum.

69.5 Bulk-Boundary Normalization and Direct Sums

The boundary state coefficient, the disk one-point function, and the identity term in the bulk-boundary OPE are often denoted by the same symbol. That is harmless only after the two-point metric and the identity normalization have been fixed. We record the convention because otherwise Cardy formulas can appear to disagree by factors of S_{0i}.

Assume that bulk spinless primaries ϕ_i are normalized on the plane by

$$\langle \phi_i(z,\bar{z})\phi_j(0,0)\rangle = \frac{D_{ij}}{|z|^{4h_i}}, \qquad D_{ij} = 0 \text{ unless } h_i = h_j, \tag{69.32}$$

with inverse matrix D^{ij}. For a boundary condition a, write the upper-half-plane one-point function as

$$\langle \phi_i(x+\mathrm{i}y, x-\mathrm{i}y)\rangle_a = \frac{U_i^a}{(2y)^{2h_i}}, \qquad y > 0. \tag{69.33}$$

If the boundary identity $\mathbf{1}_a$ has expectation value 1, the identity term in the bulk-boundary OPE is

$$\phi_i(x+\mathrm{i}y, x-\mathrm{i}y) = R^a_{i0}(2y)^{-2h_i}\mathbf{1}_a + \cdots, \qquad R^a_{i0} = U^a_i. \tag{69.34}$$

Equivalently, if one raises the bulk label by defining

$$U_a{}^j = D^{ji}U^a_i,$$

then the same coefficient is

$$R^a_{i0} = D_{ij}U_a{}^j. \tag{69.35}$$

Thus (69.19) determines a physical one-point function only after the Ishibashi overlap normalization and the bulk two-point metric have both been declared.

Remark 69.10 (Direct sums and Chan–Paton matrix units)*.* Let a, b be boundary conditions in a unitary BCFT, and suppose finite direct sums of boundary conditions are allowed. For

$$A = a^{\oplus n}, \qquad B = b^{\oplus m},$$

with no additional boundary fields beyond the direct-sum completion, the open Hilbert space and boundary fields are

$$\mathcal{H}_{AB} \simeq \mathcal{H}_{ab} \otimes \mathrm{Mat}_{n\times m}(\mathbb{C}). \tag{69.36}$$

If E_{rs} denotes the standard matrix unit, boundary OPEs obey

$$(\psi_\alpha \otimes E_{rs})(x)(\psi_\beta \otimes E_{tu})(0) = \delta_{st}\big(\psi_\alpha(x)\psi_\beta(0)\big) \otimes E_{ru}. \tag{69.37}$$

Consequently

$$Z^{\text{open}}_{AB}(q) = nm\, Z^{\text{open}}_{ab}(q), \qquad g_{a^{\oplus n}} = n\, g_a. \tag{69.38}$$

Indeed, a direct sum boundary condition is a finite biproduct in the boundary category. An interval with left boundary $a^{\oplus n}$ and right boundary $b^{\oplus m}$ therefore has one copy of $\mathcal{H}_{ab}$ for each ordered pair of summands. Choosing the standard bases of the multiplicity spaces identifies this direct sum with (69.36). Locality on the boundary forces composition to match endpoint labels: an operator carrying the right endpoint index s can compose with a second operator whose left endpoint is t only when $s = t$. This is precisely the multiplication rule for matrix units, giving (69.37). Taking the graded trace over $\mathcal{H}_{ab} \otimes \mathrm{Mat}_{n\times m}(\mathbb{C})$ gives the factor nm in the open annulus. In the closed channel, the boundary state of $a^{\oplus n}$ is the sum of n identical boundary states, so its vacuum overlap is ng_a.

69.6 Compact Free Boson Boundaries

Let $X \sim X + 2\pi R$ be a compact free boson with

$$X_L(z)X_L(0) \sim -\log z, \qquad X_R(\bar z)X_R(0) \sim -\log \bar z.$$

Circle states are labelled by momentum $m \in \mathbb{Z}$ and winding $w \in \mathbb{Z}$, with

$$k_L = \frac{m}{R} + wR, \qquad k_R = \frac{m}{R} - wR, \qquad h = \frac{1}{2}k_L^2 + N, \quad \bar h = \frac{1}{2}k_R^2 + \bar N. \tag{69.39}$$

The oscillator modes obey $[a_m, a_n] = m\delta_{m+n,0}$ and similarly for $\bar a_n$.

On the upper half-plane, Neumann and Dirichlet boundary conditions are

$$\partial_y X|_{y=0} = 0, \qquad X|_{y=0} = x_0.$$

In closed-channel boundary-state language they become

$$(a_n + \bar a_{-n})|N, \theta\rangle = 0, \tag{69.40}$$
$$(a_n - \bar a_{-n})|D, x_0\rangle = 0, \tag{69.41}$$

for all $n \in \mathbb{Z}$. The zero-mode parts are the important point:

$$\text{Neumann: } k_L + k_R = 0 \iff m = 0, \qquad \text{Dirichlet: } k_L - k_R = 0 \iff w = 0.$$

Thus Neumann boundary states sum over winding and carry a Wilson-line phase θ, while Dirichlet boundary states sum over momentum and carry a position phase x_0:

$$|N,\theta\rangle = \mathcal{N}_N \sum_{w\in\mathbb{Z}} e^{\mathrm{i}w\theta} \exp\left(-\sum_{n\geq 1}\frac{1}{n}a_{-n}\bar{a}_{-n}\right)|0,w\rangle, \tag{69.42}$$

$$|D,x_0\rangle = \mathcal{N}_D \sum_{m\in\mathbb{Z}} e^{\mathrm{i}mx_0/R} \exp\left(\sum_{n\geq 1}\frac{1}{n}a_{-n}\bar{a}_{-n}\right)|m,0\rangle. \tag{69.43}$$

The constants $\mathcal{N}_N, \mathcal{N}_D$ are fixed by the annulus normalization. With the oscillator trace normalized by $1/\eta(q)$, one may choose $\mathcal{N}_N = \sqrt{R}$ and $\mathcal{N}_D = 1/\sqrt{2R}$ in the present momentum convention; changing the normalization of the circle volume rescales both boundary states and the open-string ground-state density by the same factor.

The radius-duality map

$$R \longmapsto R^{-1}, \qquad m \longleftrightarrow w, \qquad X_R \longmapsto -X_R$$

exchanges the gluing equations (69.40) and (69.41). It sends a Neumann brane with Wilson line θ to a Dirichlet brane at the dual position θ, and sends a Dirichlet position x_0 to a Wilson line on the dual circle. The transformation $X_R \mapsto -X_R$ sends $\bar{a}_n \mapsto -\bar{a}_n$, while leaving a_n unchanged. Therefore $a_n + \bar{a}_{-n}$ becomes $a_n - \bar{a}_{-n}$. On zero modes, $(m,w) \mapsto (w,m)$ exchanges the condition $m = 0$ with $w = 0$. The phases in (69.42) and (69.43) then exchange Wilson-line and position data.

69.7 Majorana Fermion and Ising Boundary States

The chiral Majorana field has modes

$$\psi(z) = \sum_r \psi_r z^{-r-1/2}, \qquad \{\psi_r, \psi_s\} = \delta_{r+s,0}.$$

In the Neveu–Schwarz sector $r \in \mathbb{Z}+1/2$, while in the Ramond sector $r \in \mathbb{Z}$. A conformal fermion boundary condition is

$$\left(\psi_r + \mathrm{i}\eta\,\bar{\psi}_{-r}\right)|B,\eta\rangle = 0, \qquad \eta = \pm 1. \tag{69.44}$$

The stress-tensor gluing follows because the fermion stress tensor is quadratic in ψ, but the converse is weaker: a Virasoro boundary condition need not preserve the fermion field itself.

For the bosonic Ising model, the three Virasoro primaries are

$$\mathbf{1}, \qquad \epsilon, \qquad \sigma$$

with weights $0, 1/2, 1/16$. In the ordered basis $(\mathbf{1}, \epsilon, \sigma)$, the modular matrix is

$$S_{\text{Ising}} = \frac{1}{2}\begin{pmatrix} 1 & 1 & \sqrt{2} \\ 1 & 1 & -\sqrt{2} \\ \sqrt{2} & -\sqrt{2} & 0 \end{pmatrix}. \tag{69.45}$$

Cardy's formula gives the three elementary boundary states

$$|+\rangle = \frac{1}{\sqrt{2}}|\mathbf{1}\rangle\rangle + \frac{1}{\sqrt{2}}|\epsilon\rangle\rangle + 2^{-1/4}|\sigma\rangle\rangle, \tag{69.46}$$

$$|-\rangle = \frac{1}{\sqrt{2}}|\mathbf{1}\rangle\rangle + \frac{1}{\sqrt{2}}|\epsilon\rangle\rangle - 2^{-1/4}|\sigma\rangle\rangle, \tag{69.47}$$

$$|f\rangle = |\mathbf{1}\rangle\rangle - |\epsilon\rangle\rangle. \tag{69.48}$$

The labels $+$, $-$, and f denote the two fixed spin boundaries and the free boundary. The annulus spectra are the Ising fusion rules:

$$\mathcal{H}_{++} \simeq \mathcal{H}_{\mathbf{1}}, \qquad \mathcal{H}_{+-} \simeq \mathcal{H}_{\epsilon}, \qquad \mathcal{H}_{ff} \simeq \mathcal{H}_{\mathbf{1}} \oplus \mathcal{H}_{\epsilon},$$

and

$$\mathcal{H}_{+f} \simeq \mathcal{H}_{\sigma}, \qquad \mathcal{H}_{-f} \simeq \mathcal{H}_{\sigma}.$$

The NS/R bookkeeping is visible in the fermionic presentation: the $\mathbf{1}$ and ϵ Virasoro modules come from NS fermion parity sectors, while σ is the Ramond spin field. A spin CFT keeps the spin-structure dependence explicitly; the bosonic Ising CFT is obtained after the corresponding fermion-parity gauging.

Ising boundary-changing OPE constants. Identify the Cardy labels

$$+ = \mathbf{1}, \qquad - = \epsilon, \qquad f = \sigma.$$

Let ψ_i^{ab} denote the boundary primary of chiral type i between boundary labels a and b, when the fusion multiplicity ${N_{ia}}^b$ is one. Use the Cardy boundary-field basis determined by the Ising fusing symbols, and fix the residual scalar normalizations of one-dimensional boundary-field spaces so that the one-channel products displayed below have coefficient 1. The only products below with two allowed final channels are the products in which two σ-type boundary-changing fields leave and return to the free boundary through a fixed boundary. For $x > 0$,

$$\psi_\sigma^{f+}(x)\psi_\sigma^{+f}(0) \sim 2^{-1/2}x^{-1/8}\mathbf{1}_f + 2^{-1/2}x^{3/8}\psi_\epsilon^{ff}(0) + \cdots, \tag{69.49}$$

$$\psi_\sigma^{f-}(x)\psi_\sigma^{-f}(0) \sim 2^{-1/2}x^{-1/8}\mathbf{1}_f - 2^{-1/2}x^{3/8}\psi_\epsilon^{ff}(0) + \cdots. \tag{69.50}$$

The opposite orientation has no channel multiplicity:

$$\psi_\sigma^{+f}(x)\psi_\sigma^{f+}(0) \sim x^{-1/8}\mathbf{1}_+ + \cdots, \tag{69.51}$$

$$\psi_\sigma^{-f}(x)\psi_\sigma^{f-}(0) \sim x^{-1/8}\mathbf{1}_- + \cdots, \tag{69.52}$$

$$\psi_\sigma^{+f}(x)\psi_\sigma^{f-}(0) \sim x^{3/8}\psi_\epsilon^{+-}(0) + \cdots, \tag{69.53}$$

$$\psi_\sigma^{-f}(x)\psi_\sigma^{f+}(0) \sim x^{3/8}\psi_\epsilon^{-+}(0) + \cdots. \tag{69.54}$$

The multiplicities follow from (69.26) and the Ising fusion rules. Thus the nontrivial boundary-changing fields are

$$\psi_\epsilon^{+-}, \quad \psi_\epsilon^{-+}, \quad \psi_\epsilon^{ff}, \quad \psi_\sigma^{+f}, \quad \psi_\sigma^{f+}, \quad \psi_\sigma^{-f}, \quad \psi_\sigma^{f-}.$$

In the diagonal Cardy case the boundary OPE constants are the fusing coefficients of the chiral theory in the chosen basis. The only nontrivial Ising fusing matrix needed here is the recoupling of three σ lines with total charge σ:

$$F_\sigma^{\sigma\sigma\sigma} = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \tag{69.55}$$

where the row records the intermediate fixed boundary $\mathbf{1}$ or ϵ, and the column records the final channel $\mathbf{1}_f$ or ψ_ϵ^{ff} on the free boundary. Equations (69.49)–(69.50) are precisely the two rows of (69.55). The powers of x are the boundary OPE powers $h_k - h_i - h_j$:

$$0 - \frac{1}{16} - \frac{1}{16} = -\frac{1}{8}, \qquad \frac{1}{2} - \frac{1}{16} - \frac{1}{16} = \frac{3}{8}.$$

All remaining displayed OPEs have one-dimensional fusion spaces. Their coefficients have been fixed to be 1 by the residual scalar normalizations specified in the statement; changing those normalizations rescales the corresponding raw three-point constants but not the sewing class represented by (69.55). Thus rescaling the fields ψ_i^{ab} changes the displayed constants by the corresponding two-point normalization factors. The invariant content is the Ising fusing matrix and, in particular, the relative sign of the ψ_ϵ^{ff} coefficient for the two fixed boundaries.

A finite Ising sewing cell. The preceding constants give a completely explicit instance of the Cardy–Lewellen equation. Let $r, s \in \{+, -\}$, and consider four boundary fields arranged around the disk as

$$f \xrightarrow{\psi_\sigma^{fr}} r \xrightarrow{\psi_\sigma^{rf}} f \xrightarrow{\psi_\sigma^{fs}} s \xrightarrow{\psi_\sigma^{sf}} f.$$

Write

$$\psi_\sigma^{fr}(x)\psi_\sigma^{rf}(0) \sim v_r(\mathbf{1})\, x^{-1/8}\mathbf{1}_f + v_r(\epsilon)\, x^{3/8}\psi_\epsilon^{ff}(0) + \cdots .$$

Equations (69.49) and (69.50) give

$$v_+ = 2^{-1/2}(1,1), \qquad v_- = 2^{-1/2}(1,-1),$$

where the two entries are the $\mathbf{1}$ and ϵ channels on the free boundary. If the two adjacent pairs are fused first through the free boundary, the coefficient multiplying the common free-boundary intermediate channel is

$$\sum_{p\in\{\mathbf{1},\epsilon\}} v_r(p)v_s(p).$$

If instead one first fuses across the fixed-boundary side, the corresponding open-sector morphism space is $\mathrm{Hom}(U_r, U_s)$, which has dimension δ_{rs}. The sewing equality for this cell is therefore

$$\sum_{p\in\{\mathbf{1},\epsilon\}} v_r(p)v_s(p) = \delta_{rs}. \tag{69.56}$$

This is the matrix identity

$$F_\sigma^{\sigma\sigma\sigma}\,(F_\sigma^{\sigma\sigma\sigma})^T = \mathbf{1}$$

for the nontrivial Ising fusing matrix (69.55). In this example, the abstract module associativity statement in (69.25) reduces to a visible orthogonality relation between the two fixed-boundary rows. The calculation does not prove analytic sewing for a general BCFT; it identifies exactly which finite algebraic identity the sewing theorem uses in the diagonal Ising cell.

69.8 Nonrational Example: Liouville Boundary States

Chapter 68, Section 68.6, constructs the Liouville boundary states used as the basic nonrational test case for this chapter. The closed state space is no longer a finite diagonal sum; in the scattering normalization used here it is a direct integral

$$\mathcal{H}_{\mathrm{cl}}^{\mathrm{L}} = \int_0^\infty \mathcal{V}_{Q/2+\mathrm{i}P} \otimes \overline{\mathcal{V}}_{Q/2+\mathrm{i}P}\, \mathrm{d}P,$$

and the Ishibashi label i is replaced by the continuous momentum P. A boundary state is therefore a distributional wavefunction $\Psi_a(P)$ multiplying $|P\rangle\!\rangle$, not a finite vector of Cardy coefficients.

For the FZZT family, the wavefunction is

$$\Psi_s(P) = \frac{1}{\mathrm{i}P} \left(\pi\mu\,\gamma(b^2)\right)^{-\mathrm{i}P/b} \Gamma(1+2\mathrm{i}bP)\Gamma(1+2\mathrm{i}P/b)\cos(2\pi sP),$$

where $\gamma(x) = \Gamma(x)/\Gamma(1-x)$, up to the common normalization and measure convention fixed in (68.50). The discrete ZZ states are finite differences at imaginary FZZT parameters, so their wavefunctions contain

$$2\sinh(2\pi mP/b)\sinh(2\pi nbP).$$

This is the nonrational replacement for the finite modular S-matrix entry in Cardy's rational formula: annulus consistency is expressed by integral kernels and hyperbolic identities, followed by an analytic statement about the resulting spectral measure.

Hyperbolic kernels behind Liouville annuli. For formal variables X, Y and for every $n \in \mathbb{Z}_{>0}$,

$$\cosh(X+Y) - \cosh(X-Y) = 2\sinh X \sinh Y, \tag{69.57}$$

$$\frac{\sinh(nX)}{\sinh X} = \sum_{j=0}^{n-1} \exp((n-1-2j)X)\,. \tag{69.58}$$

The first identity is the exact algebra turning an imaginary FZZT difference into a ZZ wavefunction. The second identity is the exact algebra turning degenerate Liouville annulus kernels into a finite sum of shifted nondegenerate characters. The verification is elementary algebra: $\cosh Z = (\mathrm{e}^Z + \mathrm{e}^{-Z})/2$, and multiplying the finite sum in (69.58) by $2\sinh X = \mathrm{e}^X - \mathrm{e}^{-X}$ leaves only the telescoping endpoints $\mathrm{e}^{nX} - \mathrm{e}^{-nX}$. The identities are deliberately only the algebraic part of the story. A complete Liouville BCFT construction must still specify the direct-integral topology, the domains of boundary-condition-changing fields, the treatment of poles encountered under contour motion, and the positivity or distribution interpretation of the annulus spectral density. Those are analytic sewing requirements, not consequences of the finite hyperbolic identities alone.

Continuous annulus Plancherel cell. It is useful to isolate one piece of the nonrational annulus which is not a finite Cardy sum in disguise. Strip off the common Liouville gamma prefactor and the Virasoro character, and keep only the even FZZT momentum wave

$$C_s(P) := 2\cos(2\pi sP), \qquad P \geq 0.$$

With a heat regulator $t > 0$, the closed-channel momentum pairing is

$$\begin{aligned} K_t(s, s') &:= \int_0^\infty \mathrm{e}^{-tP^2} C_s(P) C_{s'}(P)\,\mathrm{d}P \\ &= G_t(s - s') + G_t(s + s'), \qquad G_t(x) := \sqrt{\frac{\pi}{t}}\,\exp\!\left(-\frac{\pi^2 x^2}{t}\right). \end{aligned} \tag{69.59}$$

Indeed,

$$4\cos(2\pi s P)\cos(2\pi s' P) = 2\cos(2\pi(s - s')P) + 2\cos(2\pi(s + s')P),$$

and

$$\int_0^\infty \mathrm{e}^{-tP^2} \cos(aP)\,\mathrm{d}P = \frac{1}{2}\sqrt{\frac{\pi}{t}}\,\exp\!\left(-\frac{a^2}{4t}\right).$$

The kernel G_t has total mass one on the real line and tends to $\delta(x)$ as $t \downarrow 0$. Thus (69.59) tends distributionally to

$$\delta(s - s') + \delta(s + s').$$

The second term is not an extra open-sector multiplicity. It records that the wavefunction is even in the FZZT parameter: $C_s = C_{-s}$. Hence a nonrational open-channel label is a point of the quotient $s \sim -s$, and the open annulus is a spectral measure on this quotient rather than an integer matrix ${n_{ab}}^k$. In a finite cyclic regulator this same bookkeeping is exact: for odd N, nonzero orbits $s, s' \in \mathbb{Z}_N/\{\pm 1\}$, and

$$c_s(p) := \mathrm{e}^{2\pi \mathrm{i} sp/N} + \mathrm{e}^{-2\pi \mathrm{i} sp/N},$$

one has

$$\frac{1}{2N} \sum_{p \in \mathbb{Z}_N} c_s(p) c_{s'}(p) = \delta_{s,s'}. \tag{69.60}$$

If s and $-s$ are kept as separate labels, the Gram matrix has off-diagonal unit entries between them; the quotient is part of the boundary data, not a later convention. The full FZZT annulus restores the Liouville prefactors, modular kernels, contour prescriptions, and pole contributions. Equation (69.59) proves only the Plancherel/reflection coordinate of that analytic sewing problem.

Pole crossing as a discrete sewing summand. The contour prescription mentioned above has a precise local algebraic content. Let $\phi(P)$ be a holomorphic test function in a strip around the real P-contour, with rapid decay on horizontal translates, and suppose a boundary kernel has near a moving pole $P = \alpha$ the form

$$K_\alpha(P) = \frac{\rho(P)}{P - \alpha} + K_\alpha^{\mathrm{reg}}(P),$$

where ρ is holomorphic. If the pole is moved through the contour and the amplitude is defined by deforming the contour rather than by simply discarding the crossing, Cauchy's theorem gives

$$\int_{\mathcal{C}_+} \phi(P) K_\alpha(P)\,\mathrm{d}P = \int_{\mathcal{C}_-} \phi(P) K_\alpha(P)\,\mathrm{d}P + 2\pi \mathrm{i}\,\phi(\alpha)\rho(\alpha), \tag{69.61}$$

with the sign fixed by the orientation of the small circle left behind by the deformation. Thus a crossed pole contributes a rank-one evaluation functional on the closed-channel test space. In open-channel language this is exactly the local model for a discrete summand in the spectral measure ν_{ab}: the continuous contour integral and the residue term are two pieces of one sewing map. Omitting the residue in one factorization channel but not in another changes the amplitude by $2\pi\mathrm{i}\,\phi(\alpha)\rho(\alpha)$. Therefore a nonrational Cardy–Lewellen datum must specify one global contour/residue prescription before comparing disk, annulus, and higher bordered-surface sewings. The finite checkable shadow is the polynomial identity

$$\operatorname*{Res}_{P=\alpha} \frac{\rho(P)\sum_{m=0}^{M} c_m P^m}{P-\alpha}\,\mathrm{d}P = \rho(\alpha)\sum_{m=0}^{M} c_m \alpha^m,$$

and multiple simple crossings commute because these evaluation functionals add linearly.

Analytic sewing datum for nonrational boundaries. The preceding wavefunctions become a boundary conformal field theory only after they are placed in a functional-analytic sewing datum. One convenient way to state the target is the following. First choose, inside the closed Liouville direct integral, a dense nuclear test space $\mathcal{S}_{\mathrm{cl}}$ whose vectors have rapidly decreasing smooth dependence on P and lie levelwise in the smooth Virasoro-module vectors. Boundary states in this setting are continuous linear functionals

$$|a\rangle \in \mathcal{S}_{\mathrm{cl}}'.$$

The FZZT and ZZ formulas above specify candidate distributional coordinates of such functionals. The regulated closed-channel annulus is then the distributional pairing

$$Z^{\mathrm{cl}}_{ab}(\tilde{q}) = \big\langle a \;\big|\; \tilde{q}^{(L_0+\bar{L}_0-c/12)/2} \;\big|\; b\big\rangle, \qquad 0<|\tilde{q}|<1, \tag{69.62}$$

initially defined by testing the two distributions against the trace-class heat kernel on each positive-energy Virasoro module, with the continuous P-integration still treated distributionally, and then by analytic continuation in the boundary parameters when poles are crossed.

Second, for every ordered pair of boundary conditions a, b, one must construct an open-channel positive-energy Hilbert space $\mathcal{H}_{ab}$ and a dense common smooth domain $\mathcal{D}_{ab} \subset \mathcal{H}_{ab}$. Annulus positivity is the existence of positive spectral measures ν_{ab} and multiplicity fields $\mathcal{M}_{ab}(h)$ such that

$$Z^{\mathrm{op}}_{ab}(q) = \int_{\mathbb{R}_{\geq 0}} \mathrm{Tr}_{\mathcal{M}_{ab}(h)}\, q^{h-c/24}\,\mathrm{d}\nu_{ab}(h) \tag{69.63}$$

agrees with (69.62) in the common domain of convergence, with the usual matrix-positivity condition for finite linear combinations of boundary labels. In degenerate cases the measure may have a discrete part. The ZZ finite differences are meaningful precisely because the contour prescription turns the corresponding closed-channel functional into such a positive open-channel spectral datum; the hyperbolic telescoping identity (69.58) is its finite algebraic shadow.

Third, boundary-condition-changing fields must be defined as operator-valued distributions on these domains. A primary changing a to b, inserted on a boundary segment, should give multilinear matrix elements

$$\big\langle v_0,\, \psi^{ab}_{\lambda_1}(x_1)\cdots\psi^{cd}_{\lambda_n}(x_n)\, v_n\big\rangle, \qquad x_1 > \cdots > x_n,$$

with v_0, v_n in the appropriate open-channel smooth domains or their duals. The labels λ_i may be continuous, discrete, or resonant. The OPE coefficients are kernels between spectral measures, so their associativity is an equality of distributions after smearing in the spectral variables. This is the nonrational replacement for finite sums over boundary primaries in (69.24).

Fourth, the analytic continuation in FZZT parameters and the passage to ZZ states must include a contour and residue prescription. When the boundary parameter is moved to an imaginary degenerate value, the P-contour in closed-channel pairings can encounter poles of the wavefunctions and of bulk-boundary or boundary-boundary structure kernels. A sewing datum must state whether the amplitude is defined by contour deformation, by principal value plus residues, or by an equivalent distributional boundary value, and must verify that the same prescription is used in all channels. A channel-dependent prescription defines incompatible disk or annulus amplitudes even when each individual channel satisfies the displayed finite-difference algebra.

Finally, bordered-surface sewing requires continuous multilinear maps on the chosen test spaces. Closed-circle gluing is integration over

$$\int_0^\infty \mathrm{d}P \, \mu_{\mathrm{L}}(P)$$

with the Liouville Plancherel measure and descendant two-point pairing; open-interval gluing is integration or summation over the open spectral measure ν_{ab}. In a plumbing chart the resulting series or integral must converge for $|q_e| < 1$ and must be compatible with changing the order of gluing. Anomaly determinant lines, if present, must be tensored into these sewing maps. This paragraph is therefore a definition of the analytic burden carried by a nonrational BCFT construction. The Liouville FZZT/ZZ formulas supply strong candidate coordinates and many exact residue identities; proving the full bordered-surface functor requires the analytic data above.

69.9 Sewing, Boundary Entropy, and Defect Interfaces

Section 69.4 displayed the boundary four-point sewing equation and the fusion-ring character equation for disk one-point functions in the diagonal Cardy case. A full BCFT also has bulk-boundary OPE coefficients with nontrivial boundary fields, bulk three-point coefficients, and compatibility with defect endpoints. These data obey additional compatibility equations from sewing a disk with two bulk fields and one boundary field in different orders, and from comparing bulk, boundary, and defect factorizations.

Quoted Theorem 69.11 (Rational Cardy–Lewellen construction boundary)**.** *For rational chiral data satisfying the analytic sewing hypotheses of a modular functor, a special symmetric Frobenius algebra object A in the chiral modular tensor category produces a full rational CFT with boundaries; boundary conditions are left A-modules, and the genus-zero Cardy–Lewellen equations follow from the Frobenius and module identities. Converses and classification statements require additional equivalence data and are not used below. This chapter uses only the local finite-categorical consequences developed in the following paragraphs, not a proof of nonrational or continuous-spectrum BCFT sewing.*

Algebraic core of the rational boundary construction. The quoted theorem has a concrete finite-categorical mechanism. Let C be the semisimple ribbon tensor category of chiral representations, with tensor product $\otimes$, unit object $\mathbf{1}$, associator α, braiding c, and representatives $\{U_i\}_{i\in I}$ of simple objects. A rational full CFT with a chosen bulk modular invariant and a chosen family of topological boundary conditions is encoded algebraically by an object $A \in \mathsf{C}$ equipped with maps

$$m : A \otimes A \to A, \qquad \eta : \mathbf{1} \to A, \qquad \Delta : A \to A \otimes A, \qquad \varepsilon : A \to \mathbf{1}.$$

The multiplication and unit make A an algebra object:

$$m(m\otimes \mathrm{id}_A)=m(\mathrm{id}_A\otimes m)\alpha_{A,A,A},\qquad m(\eta\otimes \mathrm{id}_A)=\mathrm{id}_A=m(\mathrm{id}_A\otimes \eta).$$

The comultiplication and counit obey the dual coalgebra identities, and the Frobenius compatibility is

$$(m\otimes \mathrm{id}_A)(\mathrm{id}_A\otimes \Delta)=\Delta m=(\mathrm{id}_A\otimes m)(\Delta\otimes \mathrm{id}_A), \tag{69.64}$$

with associators inserted in the unique type-correct positions. The word special means that $m\Delta$ is a nonzero scalar multiple of id_A, so cutting out a short A-ribbon segment does not change amplitudes except for a fixed normalization. The word symmetric means that the two natural maps $A\to A^\vee$ obtained from εm agree; this is the categorical form of a nondegenerate two-point pairing compatible with orientation reversal. For a local oriented bosonic full CFT one also imposes the commutativity condition

$$m\circ c_{A,A}=m$$

when the algebra describes a local extension of the chiral theory. Boundary conditions for this full CFT are left A-modules

$$\rho_M: A\otimes M\to M,\qquad \rho_M(m\otimes \mathrm{id}_M)=\rho_M(\mathrm{id}_A\otimes \rho_M)\alpha_{A,A,M},\qquad \rho_M(\eta\otimes \mathrm{id}_M)=\mathrm{id}_M\,.$$

The Frobenius identity is the algebraic form of the elementary cutting move, not an abstract decoration. In the ordinary finite model $A=\mathrm{Mat}_d(\mathbb{C})$, take matrix units E_{ij}, ordinary multiplication m, and trace counit $\varepsilon(X)=\operatorname{Tr}X$. The coproduct dual to multiplication with respect to $\varepsilon(XY)$ is

$$\Delta(E_{ij})=\sum_{r=1}^{d}E_{ir}\otimes E_{rj}. \tag{69.65}$$

Then, on $E_{ij}\otimes E_{k\ell}$,

$$(m\otimes \mathrm{id})(\mathrm{id}\otimes\Delta)=\Delta m=(\mathrm{id}\otimes m)(\Delta\otimes \mathrm{id})=\delta_{jk}\sum_{r=1}^{d}E_{ir}\otimes E_{r\ell}, \tag{69.66}$$

and

$$m\Delta(E_{ij})=d\,E_{ij}. \tag{69.67}$$

Thus sliding an A-line through a multiplication junction is exactly the Frobenius identity, while a contractible A-loop contributes the fixed specialness scalar. The categorical ribbon construction replaces these matrix units by dual bases of morphism spaces and inserts associators, braidings, and twists; the local algebraic reason for genus-zero boundary sewing is already visible in (69.66).

This language converts the open sector into a finite-dimensional statement. For two boundary conditions M,N, the multiplicity of chiral type i in the open Hilbert space is

$${n_{MN}}^{i}=\dim\mathrm{Hom}_A(M\otimes U_i,N),\qquad \mathcal{H}_{MN}=\bigoplus_{i\in I}\mathrm{Hom}_A(M\otimes U_i,N)\otimes\mathcal{H}_i. \tag{69.68}$$

Here $M\otimes U_i$ is given the left A-action $\rho_M\otimes \mathrm{id}_{U_i}$, with the associator understood. Thus the annulus multiplicities are dimensions of spaces of A-linear morphisms, and integrality is no longer a separate miracle.

Boundary OPE associativity is likewise a module-theoretic composition law. Let

$$f \in \mathrm{Hom}_A(M \otimes U_i, N), \qquad g \in \mathrm{Hom}_A(N \otimes U_j, P).$$

Then

$$g \circ (f \otimes \mathrm{id}_{U_j}) \circ \alpha_{M,U_i,U_j} \in \mathrm{Hom}_A(M \otimes (U_i \otimes U_j), P). \tag{69.69}$$

Choose a basis of chiral fusion morphisms

$$e_{ij}^{k,\mu} : U_i \otimes U_j \to U_k, \qquad \bar{e}_{k,\mu}^{ij} : U_k \to U_i \otimes U_j, \qquad e_{ij}^{k,\mu} \bar{e}_{\ell,\nu}^{ij} = \delta_{k\ell}\delta_{\mu\nu}\, \mathrm{id}_{U_k}.$$

Inserting the resolution

$$\mathrm{id}_{U_i \otimes U_j} = \sum_{k,\mu} \bar{e}_{k,\mu}^{ij} e_{ij}^{k,\mu}$$

in (69.69) gives the boundary OPE coefficients in (69.24). Associativity of the boundary OPE is the statement that the two ways to compose three such A-linear morphisms agree after changing the parenthesization of $U_i \otimes U_j \otimes U_k$. The only nontrivial transformation between the two bases is the chiral fusing isomorphism, so the module associativity identity above becomes the Cardy–Lewellen equation (69.25). The pentagon for α is the algebraic reason that the five-boundary-field sewing diagrams agree.

The diagonal Cardy solution is the special case $A = \mathbf{1}$. A left $\mathbf{1}$-module is just an object of C, and the elementary modules are $M = U_a$. Equation (69.68) reduces to

$${n_{ab}}^i = \dim \mathrm{Hom}(U_a \otimes U_i, U_b) = {N_{ai}}^b,$$

which is the boundary-field multiplicity (69.26) after the same orientation convention used in the annulus. The fusing-matrix expression for the Cardy boundary three-point constants is precisely the expansion of (69.69) in the basis $\{e_{ij}^{k,\mu}\}$.

The annulus coefficients in a non-diagonal rational boundary theory carry a stronger constraint than integrality. For simple A-modules M, N, form the matrices

$${(n_i)_M}^N = \dim \mathrm{Hom}_A(M \otimes U_i, N).$$

Taking the graded trace of a boundary interval after inserting two successive chiral labels i, j can be computed either by first summing over an intermediate boundary module N, or by fusing $U_i \otimes U_j$ in the chiral category. Module associativity therefore gives the annulus representation identity

$$\sum_N {(n_i)_M}^N {(n_j)_N}^P = \sum_k {N_{ij}}^k {(n_k)_M}^P. \tag{69.70}$$

This is the finite algebra behind the usual statement that annulus multiplicity matrices form a nonnegative-integer matrix representation of the fusion ring. It is not a separate classification theorem: it is the decategorified shadow of the same A-module composition law that produces (69.69).

Bulk fields in the same algebraic construction are bimodule morphisms. If $U_i^+ \otimes A \otimes U_j^-$ denotes the A-bimodule obtained by using the braiding for the left chiral label and the inverse braiding for the right chiral label, the closed bulk multiplicity is

$$Z_{ij}(A) = \dim \mathrm{Hom}_{A|A}(U_i^+ \otimes A \otimes U_j^-, A). \tag{69.71}$$

The diagonal invariant is again recovered from $A = \mathbf{1}$, for which the bimodule morphism space is one-dimensional only when $j = i^\vee$. The bulk-boundary OPE is obtained by evaluating such a bimodule morphism on the boundary module M and then projecting to $\mathrm{End}_A(M)$. This is the categorical form of the classifying algebra mentioned above: disk one-point functions are simultaneous eigenvalues of the commutative algebra of bulk fields acting on elementary boundary modules. Formula (69.28) is the $A = \mathbf{1}$ version of this statement.

Finite algebra shadow of the classifying algebra. The preceding categorical sentence has a simple finite algebra model which keeps the logic visible in non-diagonal examples. Let

$$A_{\mathrm{fin}} = \bigoplus_{r=1}^{R} \mathrm{Mat}_{d_r}(\mathbb{C})$$

be an ordinary finite-dimensional semisimple algebra, regarded as the decategorified shadow of a special symmetric Frobenius algebra object and its module category. Its center is

$$Z(A_{\mathrm{fin}}) = \bigoplus_{r=1}^{R} \mathbb{C}\, e_r, \qquad e_r e_s = \delta_{rs} e_r, \qquad \sum_{r=1}^{R} e_r = 1.$$

The simple left A_{fin}-modules are the column modules $M_r = \mathbb{C}^{d_r}$. A central element $z = \sum_r z_r e_r$ acts on M_r by the scalar z_r, and therefore defines a character

$$\chi_r : Z(A_{\mathrm{fin}}) \to \mathbb{C}, \qquad \chi_r(z) = z_r. \tag{69.72}$$

The disk identity-channel sewing equation is, in this finite model, exactly the multiplicativity of this central character:

$$\chi_r(zz') = \chi_r(z)\chi_r(z'), \qquad z, z' \in Z(A_{\mathrm{fin}}). \tag{69.73}$$

This is the non-diagonal analogue of (69.31): the bulk field that survives in the boundary identity channel is not a raw element of the fusion ring but its image in the commutative classifying algebra acting on the elementary boundary module.

Two cautions are part of the statement. First, a noncentral element of A_{fin} does not act by a scalar on M_r, so it cannot be read as a disk one-point coefficient of the identity boundary field. Its boundary image is an endomorphism-valued insertion. Second, if one replaces the elementary boundary condition M_r by a direct sum $M = \oplus_r M_r^{\oplus n_r}$, the boundary identity algebra becomes $\mathrm{End}_{A_{\mathrm{fin}}}(M) \simeq \oplus_r \mathrm{Mat}_{n_r}(\mathbb{C})$. The scalar character χ_r is replaced by a matrix-valued action, or by a chosen trace after adding Chan–Paton data. Such a trace is additive over summands but is not a multiplicative character unless the boundary module is simple. Thus Cardy–Lewellen disk sewing distinguishes elementary boundary conditions from finite direct sums even before any analytic issue about convergence of bordered-surface correlators enters.

A small pointed module example shows how this differs from the diagonal Cardy case. The next group of formulas should be read as one sewing laboratory, not as independent finite identities. The annulus action records how chiral labels move boundary conditions; its Fourier diagonalization records the classifying data visible to annuli; the boundary-field composition records Cardy–Lewellen associativity; the stabilizer idempotents record the bulk-boundary classifying sectors invisible to the annulus quotient; and the Frobenius pairing records the two-point normalization that detects those sectors. A full rational construction must realize all five pieces by the same A-module category and the same analytic sewing maps.

Let the chiral fusion skeleton have labels $G = \mathbb{Z}_2 \times \mathbb{Z}_2$, with $U_g \otimes U_h = U_{g+h}$, and take the subgroup $H = \{(0,0),(1,0)\}$. Boundary labels are the two cosets G/H. The open multiplicity matrix attached to $g = (g_1, g_2)$ is

$$(n_g)_{xH}{}^{yH} = \begin{cases} 1, & yH = (x+g)+H, \\ 0, & \text{otherwise.} \end{cases} \tag{69.74}$$

Thus $n_{(0,0)} = n_{(1,0)} = \mathbf{1}$, while $n_{(0,1)} = n_{(1,1)}$ swaps the two boundary labels. Equation (69.70) is then just the coset action law $n_g n_h = n_{g+h}$. The example is finite and algebraic; realizing it as a unitary local rational BCFT requires the corresponding modular, Frobenius, and analytic sewing data in addition to the displayed matrices.

The annulus matrices in this cell also display the modular diagonalization that replaces the diagonal Cardy formula. Put $Q = G/H \cong \mathbb{Z}_2$. For a character $\eta \in \widehat{Q}$, define the Fourier projector

$$P_\eta = \frac{1}{|Q|} \sum_{\bar{g} \in Q} \eta(\bar{g})^{-1} n_{\bar{g}}. \tag{69.75}$$

These projectors satisfy

$$P_\eta P_{\eta'} = \delta_{\eta,\eta'} P_\eta, \qquad \sum_{\eta \in \widehat{Q}} P_\eta = \mathbf{1},$$

and the spectral resolution of the annulus action is

$$n_g = \sum_{\eta \in \widehat{Q}} \eta(g+H)\, P_\eta. \tag{69.76}$$

Equivalently, with the normalized boundary Fourier matrix

$$\Psi_{xH,\eta} = |Q|^{-1/2} \eta(xH),$$

one has

$$(n_g)_{xH}{}^{yH} = \sum_{\eta \in \widehat{Q}} \Psi_{xH,\eta}\, \eta(g+H)\, \overline{\Psi_{yH,\eta}}. \tag{69.77}$$

This is the finite version of the rational BCFT statement that annulus nimreps are diagonalized by boundary classifying data, with eigenvalues given by fusion-ring characters. It also records a limitation of annulus spectra: if $h \in H$, then $h + H = H$, so n_h has the same eigenvalues and the same matrix as the vacuum. The stabilizer label is nevertheless visible in boundary endomorphism fields and in the mixed projector identity below. Thus annulus modular diagonalization sees the quotient action G/H, while full Cardy–Lewellen sewing still needs the stabilizer endomorphism and classifying-idempotent data.

The same example also shows the boundary-field composition behind the annulus identity. Let $x \in G/H$, and let $\psi_{x,g}$ denote the one-dimensional generator of the open sector with chiral label g from the boundary xH to the boundary $(x+g)H$. For $g, h \in G$ the pointed fusion space is one-dimensional, so the module-composition coordinate can be normalized as

$$\psi_{x+g,h} \circ \psi_{x,g} = \psi_{x,g+h}. \tag{69.78}$$

Then

$$(\psi_{x+g+h,k} \circ \psi_{x+g,h}) \circ \psi_{x,g} = \psi_{x,g+h+k} = \psi_{x+g,h+k} \circ (\psi_{x+g,h} \circ \psi_{x,g}),$$

which is the Cardy–Lewellen boundary associativity equation in this finite module cell. The stabilizer H is still visible: both $\psi_{x,(0,0)}$ and $\psi_{x,(1,0)}$ are boundary endomorphism fields of the same boundary label, but they carry different chiral labels. Thus the non-diagonal boundary theory is not obtained by merely identifying chiral labels that act on the same coset; the open sector remembers the chiral fusion label even when the boundary endpoint is unchanged.

The mixed bulk-boundary sewing shadow is visible in the same finite cell. At a fixed boundary xH, the stabilizer fields $\{\psi_{x,h}\}_{h\in H}$ form the group algebra of H. For a character $\chi \in \widehat{H}$, define the primitive stabilizer idempotent

$$e_{x,\chi} = \frac{1}{|H|} \sum_{h\in H} \chi(h)^{-1} \psi_{x,h}. \tag{69.79}$$

Then

$$e_{x,\chi} e_{x,\chi'} = \delta_{\chi,\chi'} e_{x,\chi}, \qquad \sum_{\chi\in\widehat{H}} e_{x,\chi} = \psi_{x,(0,0)}. \tag{69.80}$$

The compatibility of this classifying projector with a boundary-changing field is the slide identity

$$\psi_{x,g} \circ e_{x,\chi} = e_{x+g,\chi} \circ \psi_{x,g}. \tag{69.81}$$

Using (69.78), both sides are

$$\frac{1}{|H|} \sum_{h\in H} \chi(h)^{-1} \psi_{x,g+h},$$

where G is abelian. This is a finite mixed Cardy–Lewellen sewing cell: projecting to a stabilizer classifying sector and then changing the boundary condition gives the same amplitude as first changing the boundary condition and then using the transported projector at the new endpoint. It is still only the algebraic shadow of bulk-boundary sewing; the analytic rational BCFT construction must supply the full center object, correlators, and mapping-class-compatible sewing maps.

The same finite cell also displays the boundary two-point normalization that is lost if the stabilizer labels are collapsed. Equip the stabilizer group algebra at the boundary xH with the Frobenius trace

$$\varepsilon_x(\psi_{x,h}) = \delta_{h,0}.$$

Then

$$\varepsilon_x(e_{x,\chi} e_{x,\chi'}) = \frac{\delta_{\chi,\chi'}}{|H|}. \tag{69.82}$$

Thus $|H|^{1/2} e_{x,\chi}$ are orthonormal classifying sectors for this finite pairing. For a boundary-changing label g, define the projected sector field

$$\psi_{x,g;\chi} := \psi_{x,g} e_{x,\chi} = e_{x+g,\chi} \psi_{x,g}.$$

Since every element of $G = \mathbb{Z}_2 \times \mathbb{Z}_2$ is its own inverse,

$$\psi_{x+g,g;\chi'} \circ \psi_{x,g;\chi} = \delta_{\chi,\chi'} e_{x,\chi}. \tag{69.83}$$

Applying ε_x gives the two-point pairing

$$\varepsilon_x(\psi_{x+g,g;\chi'}\psi_{x,g;\chi}) = \frac{\delta_{\chi,\chi'}}{|H|}.$$

The stabilizer character is therefore a genuine finite sewing coordinate: it is invisible to the annulus quotient G/H, but it is detected by boundary endomorphism pairings and by inverse boundary-changing fields.

The point of the finite laboratory is not the separate existence of the annulus matrices, Fourier projectors, boundary products, stabilizer idempotents, and two-point pairings. They are five shadows of one module datum. For each $g \in G$,

$$(n_g)_{xH,yH} = \dim \operatorname{span}\{\psi_{x,g} \mid (x+g)H = yH\}. \tag{69.84}$$

Thus the open annulus records the graded dimension of exactly the boundary-changing sector whose composition law is (69.78). The quotient Fourier projectors diagonalize only the G/H-motion of the endpoints, whereas the stabilizer Fourier inversion

$$\psi_{x,h} = \sum_{\chi \in \widehat{H}} \chi(h)\, e_{x,\chi}, \qquad h \in H, \tag{69.85}$$

recovers the endpoint-preserving boundary endomorphism fields from the classifying idempotents. Equations (69.84) and (69.85) are the finite end-to-end check that the annulus, disk classifying sector, boundary OPE, and two-point pairing are compatible projections of one rational boundary coordinate. A full rational BCFT construction replaces this finite group laboratory by an A-module category in a chiral tensor category and then adds the analytic sewing maps; the finite formulas above should be read as one dependency diagram, not as independent evidence for the all-surface theorem.

Annulus shadows versus sewing data. In the pointed G/H laboratory, the endpoint annulus matrices do not determine the endpoint-preserving boundary algebra, its classifying idempotents, or its two-point sewing pairing. More precisely, the annulus shadow

$$n_{(0,0)} = n_{(1,0)} = \mathbf{1}$$

is compatible with the semisimple stabilizer algebra

$$E_{\mathrm{ss}} = \mathbb{C}\{1, \tau\}, \qquad \tau^2 = 1,$$

which has primitive idempotents

$$e_\pm = \frac{1}{2}(1 \pm \tau),$$

but the same endpoint-dimension shadow is also compatible, as a graded vector space, with the nilpotent algebra

$$E_{\mathrm{nil}} = \mathbb{C}\{1, \epsilon\}, \qquad \epsilon^2 = 0.$$

The latter has no nontrivial idempotent decomposition and the coefficient-of-1 two-point pairing is degenerate on the ϵ sector. Hence the annulus endpoint spectrum by itself is not enough data for Cardy–Lewellen sewing; the boundary OPE multiplication, the classifying idempotents, and the Frobenius two-point functional are additional structure.

The finite verification is direct. Both algebras have a one-dimensional vacuum-labeled endomorphism sector and a one-dimensional stabilizer-labeled endomorphism sector at the same boundary endpoint. Therefore the annulus matrix which records only endpoint multiplicity is the identity matrix for both labels 1 and the nontrivial stabilizer label.

In $E_{\rm ss}$,

$$e_\pm^2 = e_\pm, \qquad e_+e_- = 0, \qquad e_+ + e_- = 1.$$

With $\varepsilon_{\rm ss}(1) = 1$ and $\varepsilon_{\rm ss}(\tau) = 0$, the pairing $(x, y) \mapsto \varepsilon_{\rm ss}(xy)$ satisfies

$$\varepsilon_{\rm ss}(e_\pm e_\pm) = \frac{1}{2}, \qquad \varepsilon_{\rm ss}(e_+e_-) = 0.$$

This is the finite classifying-sector splitting used above.

In $E_{\rm nil}$, an idempotent $p = a + b\epsilon$ satisfies

$$a^2 = a, \qquad 2ab = b.$$

The first equation gives $a = 0$ or $a = 1$, and then the second gives $b = 0$. Thus the only idempotents are 0 and 1. With the same annulus-normalized coefficient-of-1 functional $\varepsilon_{\rm nil}(1) = 1$, $\varepsilon_{\rm nil}(\epsilon) = 0$, the pairing obeys

$$\varepsilon_{\rm nil}(\epsilon\epsilon) = 0,$$

so the stabilizer sector has no inverse two-point partner in that pairing. The two finite systems therefore have the same endpoint annulus shadow but different boundary OPE and classifying-sector data. The semisimple rational construction excludes the nilpotent alternative by its Frobenius-module identities, while positivity supplies the corresponding two-point nondegeneracy. The example shows why these inputs are not recoverable from annulus spectra alone.

The disk partition function defines the Affleck–Ludwig boundary entropy. For a Cardy boundary state in a diagonal rational CFT,

$$g_a = \langle 0|a\rangle = \frac{S_{a0}}{\sqrt{S_{00}}}, \tag{69.86}$$

with the vacuum Ishibashi state normalized as in (69.15).

Hypothesis 69.12 (Boundary entropy gradient input)**.** Let a unitary two-dimensional QFT on a half-cylinder have a fixed conformal bulk and a renormalized finite-dimensional chart of boundary couplings λ^a. Let $B^a(\lambda)$ be the boundary RG vector field and $\phi_a(\tau)$ the renormalized boundary fields conjugate to λ^a. Assume that the boundary trace of the stress tensor has the renormalized form

$$\theta(\tau) = B^a(\lambda)\phi_a(\tau) + \partial_\tau j(\tau) \tag{69.87}$$

and quotient the coupling chart by redundant directions generated by total boundary derivatives. Let $z(\lambda, L)$ be the boundary contribution to the cylinder partition function after subtracting the bulk extensive term and the boundary ground-state energy, and define

$$s(\lambda, L) = \left(1 - L\frac{\partial}{\partial L}\right) \log z(\lambda, L). \tag{69.88}$$

Assume the local contact counterterms can be fixed compatibly with boundary translation invariance, reflection positivity, and the subtraction in (69.88), so that the finite Ward susceptibility identity

$$\partial_a s(\lambda, L) = -\frac{1}{2}\int_0^L \mathrm{d}\tau_1 \int_0^L \mathrm{d}\tau_2\, K_L(\tau_1 - \tau_2)\big\langle \phi_a(\tau_1)\theta(\tau_2)\big\rangle_c^{\rm ren}, \qquad K_L(\tau) = 1 - \cos\frac{2\pi\tau}{L} \tag{69.89}$$

holds on the quotient chart. Assume also that the connected boundary two-point functions define the positive symmetric bilinear form

$$G_{ab}(\lambda) = \frac{1}{2}\int_0^L \mathrm{d}\tau_1 \int_0^L \mathrm{d}\tau_2 \left[1 - \cos\!\left(\frac{2\pi(\tau_1 - \tau_2)}{L}\right)\right] \left\langle \phi_a(\tau_1)\phi_b(\tau_2)\right\rangle_c^{\mathrm{ren}} \tag{69.90}$$

on the quotient by redundant total-derivative directions.

The positivity in (69.90) comes from the spectral representation of the boundary two-point function. The finite-regulator mechanism is as follows. Let $\Phi = u^a\phi_a$ be a real boundary perturbing field after subtracting its one-point function, and first place the boundary theory on a finite half-cylinder with discrete positive-energy boundary Hamiltonian. Grouping matrix elements by a positive energy gap $\Delta_r > 0$, reflection positivity and the KMS trace give the connected Euclidean boundary two-point function in the form

$$\langle \Phi(\tau)\Phi(0)\rangle_c = \sum_r A_r \frac{\mathrm{e}^{-\Delta_r\tau} + \mathrm{e}^{-\Delta_r(L-\tau)}}{1 - \mathrm{e}^{-L\Delta_r}}, \qquad A_r \geq 0, \qquad 0 < \tau < L, \tag{69.91}$$

where the connected trace has removed the zero-gap diagonal part. Put $\kappa = 2\pi/L$. For a single gap,

$$\int_0^L \mathrm{d}\tau \left(1 - \cos\kappa\tau\right) \frac{\mathrm{e}^{-\Delta\tau} + \mathrm{e}^{-\Delta(L-\tau)}}{1 - \mathrm{e}^{-L\Delta}} = \frac{2\kappa^2}{\Delta(\Delta^2 + \kappa^2)}. \tag{69.92}$$

Thus the quadratic form obtained from (69.90) is a sum of nonnegative matrix-element weights

$$L\sum_r A_r \frac{2\kappa^2}{\Delta_r(\Delta_r^2 + \kappa^2)}.$$

This calculation explains the shape of the trigonometric kernel in the gradient formula: after the connected trace removes the zero-gap diagonal part, the kernel assigns a positive finite weight to each nonzero boundary excitation. In the continuum theorem, the hard analytic work is to renormalize the coincident boundary singularities, preserve the boundary Ward identity (69.87), and quotient total derivative directions so that this finite spectral positivity survives in the renormalized coupling chart.

Mechanism of the gradient formula. Hypothesis 69.12 is the analytic input behind the finite proposition. It identifies a particular renormalized susceptibility with the differential of the finite boundary entropy. We spell out the mechanism because the contact-term prescription, the quotient by redundant boundary directions, and reflection positivity are part of the mathematical content of the statement.

Use the sign convention in which the renormalized boundary action is deformed by

$$S_\partial(\lambda) = S_\partial(0) + \lambda^a \int_0^L \phi_a(\tau)\,\mathrm{d}\tau.$$

Then differentiation of the renormalized boundary partition function gives

$$\partial_a \log z(\lambda, L) = -\int_0^L \left\langle \phi_a(\tau)\right\rangle_{\lambda,L}^{\mathrm{ren}}\,\mathrm{d}\tau. \tag{69.93}$$

The scale Ward identity on the half-cylinder states that, after the bulk extensive term and the boundary ground-state energy have been subtracted, the operation $L\partial_L$ is represented by the renormalized insertion of the boundary trace

$$\Theta = \int_0^L \theta(\tau)\, \mathrm{d}\tau$$

together with local contact counterterms supported at coincident boundary points. Thus $(1 - L\partial_L)\partial_a \log z$ contains the integrated two-point insertion $\int\int \langle \phi_a(\tau_1)\theta(\tau_2)\rangle_c$ together with local counterterms. Those contact terms must be fixed by a renormalization prescription compatible with boundary translation invariance, reflection positivity, and the subtraction defining $s = (1 - L\partial_L) \log z$. Equation (69.89) is the real analytic step in the gradient formula: the kernel K_L is the circle kernel, in this normalization, that implements the finite entropy subtraction and removes the ambiguous zero-mode and total-derivative pieces after passing to the quotient of boundary coupling space. With weaker analytic control the displayed susceptibility records the expected Ward-identity structure rather than a proved gradient formula.

Proposition 69.13 (Boundary entropy monotonicity from the gradient input)**.** *Under Hypothesis 69.12,*

$$\partial_a s(\lambda, L) = -\, G_{ab}(\lambda)B^b(\lambda). \tag{69.94}$$

Consequently, along an RG trajectory with $t = \log L$ and $\dot\lambda^a = B^a(\lambda)$,

$$\frac{d}{dt} s(\lambda(t), L) = B^a\partial_a s = -\, B^a G_{ab} B^b \leq 0. \tag{69.95}$$

If the trajectory has conformal endpoints and the finite boundary entropy has endpoint limits, then $g_{\mathrm{UV}} \geq g_{\mathrm{IR}}$, where $g = \exp s$ at a boundary fixed point.

Proof. Substitute the trace identity (69.87) into the Ward susceptibility (69.89). At fixed λ,

$$\big\langle \phi_a(\tau_1)\theta(\tau_2)\big\rangle_c^{\mathrm{ren}} = B^b \big\langle \phi_a(\tau_1)\phi_b(\tau_2)\big\rangle_c^{\mathrm{ren}} + \partial_{\tau_2} \big\langle \phi_a(\tau_1) j(\tau_2)\big\rangle_c^{\mathrm{ren}}.$$

The total-derivative term is a redundant direction; on the quotient in Hypothesis 69.12 it vanishes after integration against K_L and after the prescribed contact subtractions. The remaining term is exactly $-G_{ab}B^b$ by (69.90), proving (69.94). Contracting with the RG vector field gives (69.95), and positivity of G gives the inequality. At conformal endpoints $B = 0$ and $g = \exp s$; integrating the monotone inequality from the ultraviolet endpoint to the infrared endpoint gives $g_{\mathrm{UV}} \geq g_{\mathrm{IR}}$. □

This conclusion gives an ordering constraint on boundary fixed points reached by a given unitary boundary RG flow. It does not determine which conformal boundary condition is reached, nor does it supply the annulus or Cardy–Lewellen sewing data.

Chapter-scale proof-status ledger. The examples in this chapter should now be read as a dependency chain, not as a collection of unrelated BCFT cells. A genuine construction of a boundary conformal field theory has to pass through the following layers.

1. The closed chiral input must be fixed first: either a rational semisimple chiral theory with modular functor and fusing data, or a nonrational direct-integral theory with declared test spaces and Plancherel measure.

2. Boundary labels must then be promoted to open-channel Hilbert spaces or spectral measures, with common domains for boundary-condition-changing fields and a reflection-positive two-point pairing.

3. Local coordinates must be compatible: annulus multiplicities or spectral measures, disk classifying coordinates, boundary OPE products, bulk-boundary maps, and two-point pairings must be projections of the same boundary structure.

4. Local moves must be checked in the same normalization. In the rational case these include open/closed annulus exchange, boundary OPE associativity, disk classifying multiplication, and Frobenius/module cutting moves. In the nonrational case they also include contour choices, residue summands, direct-integral convergence, and determinant-line bookkeeping.

5. All-surface sewing is the final analytic step: the local moves must generate the changes of bordered-surface decomposition, their defects must telescope as in Proposition 69.2, and closed-loop transports must either be trivialized as in Proposition 69.4 or kept as honest anomaly-line transports.

The diagonal Ising example closes the first few rational finite checks for a specific modular tensor category and boundary basis. The pointed G/H laboratory goes further by showing that annulus matrices, quotient Fourier data, stabilizer idempotents, boundary OPEs, and two-point pairings are compatible shadows of one module-category mechanism. The Liouville block closes only local nonrational coordinates: hyperbolic FZZT/ZZ identities, the even-parameter Plancherel quotient, and pole-crossing residue bookkeeping. None of these examples proves the final generated all-surface sewing theorem. Conversely, the boundary-entropy gradient result uses renormalized boundary RG and positivity data once a unitary boundary QFT exists; it is not a replacement for constructing the BCFT sewing maps or for identifying the infrared boundary condition.

Finally, two-dimensional BCFT fits into the broader boundary/defect language of Chapter 120. A topological line defect can end on a boundary only when its endpoint is a specified boundary condition-changing operator. Noninvertible defects, such as the Ising Kramers–Wannier line, act on the set of Cardy boundary conditions by fusion when the required endpoint operators exist. Boundary anomalies are likewise not optional decorations: a boundary partition function may be a section of an anomaly line, and anomaly cancellation is part of the boundary datum. The present chapter supplies the Virasoro and modular-sewing machinery special to two-dimensional conformal boundaries; the global categorical defect viewpoint is developed in Volume IX.

Open Problem 69.14 (BCFT sewing beyond rational diagonal examples). Construct a single analytic framework that includes rational Cardy boundaries, compact-boson continuous families, the Liouville FZZT and ZZ states of Section 69.8, boundary-condition-changing operators, and defect endpoints, with convergent sewing maps for bordered Riemann surfaces. The framework must realize the test-space, open spectral-measure, operator-domain, pole-prescription, and determinant-line requirements stated above, and must prove that the rational finite-sum construction and the Liouville direct-integral construction are two limits of the same sewing notion rather than two unrelated calculational recipes. In particular, closed-loop sewing phases must be identified as a trivializable determinant-line cocycle, or the resulting amplitudes must be kept as line-valued rather than scalar correlators.

Chapter 70

Two-Dimensional Superconformal Algebras

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

70.1 Spin and Sector Data

The superconformal algebras in two dimensions are chiral symmetry algebras. They are not, by themselves, definitions of a continuum quantum field theory. The underlying QFT must supply local operator domains, correlation functions, positivity when the theory is unitary, and sewing data. This chapter isolates the chiral algebraic layer because it is shared infrastructure for two-dimensional CFT. The dynamical construction of supersymmetric field theories, including Landau–Ginzburg and gauged linear sigma models, belongs to the supersymmetric-QFT development in Volume VII. The statements below are therefore algebraic consequences and consistency tests for any such model, not a replacement for the supersymmetric RG analysis.

Definition 70.1 (Spin two-dimensional CFT structure)**.** A spin two-dimensional CFT structure consists of the following items.

1. An oriented two-dimensional Euclidean CFT $\mathcal{C}$, with holomorphic stress tensor $T(z)$, antiholomorphic stress tensor $\bar{T}(\bar{z})$, and central charges $c, \bar{c}$.
2. For each spin surface $(\Sigma, \mathfrak{s})$, correlation functions of local fields which may be even or odd under the fermion-parity operator $(-1)^F$.

3. Chiral state spaces on the circle decomposed into Neveu–Schwarz and Ramond sectors,

$$\mathcal{H}^{\mathrm{ch}} = \mathcal{H}^{\mathrm{ch}}_{\mathrm{NS}} \oplus \mathcal{H}^{\mathrm{ch}}_{\mathrm{R}},$$

   where a chiral fermionic field has antiperiodic boundary condition in the NS sector and periodic boundary condition in the R sector.

4. A locality rule: even fields have ordinary single-valued OPEs with all local fields, while odd chiral fields are mutually local only after the spin structure and fermion-parity signs have been specified.

The same chiral algebra may occur in several full spin CFTs, because the full theory also requires an antiholomorphic sector, a choice of spin-structure sum or projection, and modular/sewing data.

Let $a(z)$ be a chiral field of holomorphic weight h_a. In a sector where a has monodromy $e^{-2\pi i \nu_a}$ around the spatial circle, we write

$$a(z) = \sum_{r \in \mathbb{Z}+\nu_a} a_r z^{-r-h_a}. \tag{70.1}$$

For the supercurrent of an $\mathcal{N}=1$ or $\mathcal{N}=2$ superconformal algebra, $h_a = 3/2$, $\nu_a = 1/2$ in the NS sector, and $\nu_a = 0$ in the R sector. The Ramond sector therefore contains supercharge zero modes. This is the operator form of the difference between antiperiodic and periodic spin structures on the cylinder.

70.2 $\mathcal{N}=1$ Superconformal Algebra

Definition 70.2 ($\mathcal{N}=1$ chiral superconformal algebra)**.** An $\mathcal{N}=1$ chiral superconformal algebra of central charge c consists of a chiral stress tensor $T(z)$, an odd chiral field $G(z)$ of weight $3/2$, and a sector choice

$$r \in \mathbb{Z} + \frac{1}{2} \quad (\mathrm{NS}), \qquad r \in \mathbb{Z} \quad (\mathrm{R})$$

for the modes

$$T(z) = \sum_{n\in\mathbb{Z}} L_n z^{-n-2}, \qquad G(z) = \sum_r G_r z^{-r-3/2}.$$

The singular OPEs are

$$T(z)T(w) \sim \frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}, \tag{70.2}$$

$$T(z)G(w) \sim \frac{(3/2)G(w)}{(z-w)^2} + \frac{\partial G(w)}{z-w}, \tag{70.3}$$

$$G(z)G(w) \sim \frac{2c/3}{(z-w)^3} + \frac{2T(w)}{z-w}. \tag{70.4}$$

Lemma 70.3 (Mode algebra from the $\mathcal{N}=1$ OPEs)**.** *The modes in Definition 70.2 obey*

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}(m^3-m)\delta_{m+n,0}, \tag{70.5}$$

$$[L_m, G_r] = \left(\frac{m}{2} - r\right) G_{m+r}, \tag{70.6}$$

$$\{G_r, G_s\} = 2L_{r+s} + \frac{c}{3}\left(r^2 - \frac{1}{4}\right)\delta_{r+s,0}. \tag{70.7}$$

Proof. The Virasoro bracket is the stress-tensor calculation of Lemma 60.8. For the second formula, write

$$[L_m, G_r] = \oint_0 \frac{\mathrm{d}w}{2\pi\mathrm{i}} w^{r+1/2} \oint_w \frac{\mathrm{d}z}{2\pi\mathrm{i}} z^{m+1} T(z)G(w).$$

Using (70.3), the inner residue is

$$(m+1)w^m \frac{3}{2} G(w) + w^{m+1}\partial G(w).$$

The outer residue of the first term is $\frac{3}{2}(m+1)G_{m+r}$. For the second term, integration by parts gives

$$\oint_0 \frac{\mathrm{d}w}{2\pi\mathrm{i}} w^{m+r+3/2}\partial G(w) = -\left(m+r+\frac{3}{2}\right)G_{m+r}.$$

The coefficient is therefore $m/2 - r$.

For the anticommutator, the odd fields require the supercommutator contour. The singular part (70.4) gives

$$\{G_r, G_s\} = \oint_0 \frac{\mathrm{d}w}{2\pi\mathrm{i}} w^{s+1/2} \operatorname{Res}_{z=w} z^{r+1/2} \left(\frac{2c/3}{(z-w)^3} + \frac{2T(w)}{z-w}\right).$$

The T-term gives $2L_{r+s}$. The cubic pole gives

$$\frac{2c}{3}\cdot\frac{1}{2}\left(r+\frac{1}{2}\right)\left(r-\frac{1}{2}\right)\delta_{r+s,0} = \frac{c}{3}\left(r^2-\frac{1}{4}\right)\delta_{r+s,0}.$$

□

Ramond zero-mode bound. In a unitary Ramond representation of the $\mathcal{N}=1$ algebra,

$$L_0 - \frac{c}{24} \geq 0. \tag{70.8}$$

A Ramond ground state is a state annihilated by G_0, equivalently a state with $L_0 = c/24$. Set $r = s = 0$ in (70.7). Then

$$\{G_0, G_0\} = 2L_0 - \frac{c}{12} = 2\left(L_0 - \frac{c}{24}\right).$$

If the representation is unitary, $G_0^\dagger = G_0$, so the expectation value of $\{G_0, G_0\} = 2G_0^2$ on any vector is nonnegative. Equality holds precisely on the kernel of G_0, because $\langle v, G_0^2 v\rangle = \|G_0 v\|^2$. Hence the bottom of a unitary Ramond module is bounded by $c/24$, and states at the bound are exactly the Ramond states annihilated by the zero mode.

70.3 $\mathcal{N}=2$ Superconformal Algebra

The $\mathcal{N}=2$ algebra adds a holomorphic $U(1)$ current. This extra current is the reason that spectral flow, chiral-primary bounds, and topological twists are algebraic operations rather than model-dependent accidents.

Definition 70.4 ($\mathcal{N}=2$ chiral superconformal algebra)**.** An $\mathcal{N}=2$ chiral superconformal algebra of central charge c consists of a chiral stress tensor $T(z)$, a weight-one even current $J(z)$, and two odd weight-3/2 chiral fields $G^+(z)$ and $G^-(z)$. Their modes are

$$J(z)=\sum_{n\in\mathbb{Z}} J_n z^{-n-1}, \qquad G^{\pm}(z)=\sum_r G_r^{\pm} z^{-r-3/2},$$

with $r\in\mathbb{Z}+1/2$ in the NS sector and $r\in\mathbb{Z}$ in the R sector. The singular OPEs, in addition to the Virasoro OPE for T, are

$$T(z)J(w)\sim\frac{J(w)}{(z-w)^2}+\frac{\partial J(w)}{z-w}, \tag{70.9}$$

$$T(z)G^{\pm}(w)\sim\frac{(3/2)G^{\pm}(w)}{(z-w)^2}+\frac{\partial G^{\pm}(w)}{z-w}, \tag{70.10}$$

$$J(z)J(w)\sim\frac{c/3}{(z-w)^2}, \tag{70.11}$$

$$J(z)G^{\pm}(w)\sim\pm\frac{G^{\pm}(w)}{z-w}, \tag{70.12}$$

$$G^+(z)G^-(w)\sim\frac{2c/3}{(z-w)^3}+\frac{2J(w)}{(z-w)^2}+\frac{2T(w)+\partial J(w)}{z-w}, \tag{70.13}$$

$$G^{\pm}(z)G^{\pm}(w)\sim 0. \tag{70.14}$$

Mode algebra for $\mathcal{N}=2$. The modes in Definition 70.4 obey

$$[L_m,J_n]=-nJ_{m+n}, \tag{70.15}$$

$$[J_m,J_n]=\frac{c}{3}m\delta_{m+n,0}, \tag{70.16}$$

$$[L_m,G_r^{\pm}]=\left(\frac{m}{2}-r\right)G^{\pm}_{m+r}, \tag{70.17}$$

$$[J_m,G_r^{\pm}]=\pm G^{\pm}_{m+r}, \tag{70.18}$$

$$\{G_r^+,G_s^-\}=2L_{r+s}+(r-s)J_{r+s}+\frac{c}{3}\left(r^2-\frac{1}{4}\right)\delta_{r+s,0}, \tag{70.19}$$

$$\{G_r^{\pm},G_s^{\pm}\}=0. \tag{70.20}$$

The formulas involving L_m are the primary-field residue calculation used in Lemma 70.3, with weights 1 and 3/2. The current commutator follows from the double-pole residue in (70.11):

$$[J_m,J_n]=\oint_0\frac{\mathrm{d}w}{2\pi\mathrm{i}}w^n\,\mathrm{Res}_{z=w}\,z^m\frac{c/3}{(z-w)^2}=\frac{c}{3}m\delta_{m+n,0}.$$

Equation (70.18) is the simple-pole residue of (70.12). For the mixed supercurrent anticommutator, the triple pole in (70.13) gives $\frac{c}{3}(r^2-1/4)\delta_{r+s,0}$, exactly as in the $\mathcal{N}=1$ calculation. The simple pole gives $2L_{r+s}$. The double pole and the derivative term combine as

$$2\left(r+\frac{1}{2}\right)J_{r+s}-(r+s+1)J_{r+s}=(r-s)J_{r+s}.$$

Spectral-flow algebra check. For any $\eta \in \frac{1}{2}\mathbb{Z}$, the assignment

$$L_n^{(\eta)} = L_n + \eta J_n + \frac{c}{6}\eta^2\delta_{n,0}, \tag{70.21}$$

$$J_n^{(\eta)} = J_n + \frac{c}{3}\eta\delta_{n,0}, \tag{70.22}$$

$$(G_r^{\pm})^{(\eta)} = G_{r\pm\eta}^{\pm} \tag{70.23}$$

preserves the $\mathcal{N} = 2$ mode algebra, with the same central charge c. Integer η preserves NS and R sectors separately; half-integer η exchanges them.

This is an automorphism of the displayed abstract mode algebra. Checking it is a finite residue calculation in (70.15)–(70.20). For example,

$$[J_m^{(\eta)}, J_n^{(\eta)}] = [J_m, J_n] = \frac{c}{3}m\delta_{m+n,0},$$

which is the same formula in the flowed generators because the central shifts commute. Also

$$[J_m^{(\eta)}, (G_r^{\pm})^{(\eta)}] = [J_m, G_{r\pm\eta}^{\pm}] = \pm G_{m+r\pm\eta}^{\pm} = \pm(G_{m+r}^{\pm})^{(\eta)}.$$

For the mixed supercurrent relation,

$$\{G_{r+\eta}^{+}, G_{s-\eta}^{-}\} = 2L_{r+s} + (r - s + 2\eta)J_{r+s} + \frac{c}{3}\left((r+\eta)^2 - \frac{1}{4}\right)\delta_{r+s,0}.$$

Substituting

$$L_{r+s} = L_{r+s}^{(\eta)} - \eta J_{r+s} - \frac{c}{6}\eta^2\delta_{r+s,0}, \qquad J_{r+s} = J_{r+s}^{(\eta)} - \frac{c}{3}\eta\delta_{r+s,0},$$

the J-coefficient becomes $r - s$, and the central coefficient reduces to $\frac{c}{3}(r^2 - 1/4)$. The remaining brackets are checked in the same residue algebra.

If a simultaneous L_0, J_0 eigenstate has eigenvalues h, q, then spectral flow sends them to

$$h^{(\eta)} = h + \eta q + \frac{c}{6}\eta^2, \qquad q^{(\eta)} = q + \frac{c}{3}\eta. \tag{70.24}$$

This formula is often the cleanest way to see why NS chiral primaries and Ramond ground states are the same representation-theoretic object viewed in different spin sectors.

Proposition 70.5 (NS unitarity bound and chiral primaries)**.** *Let v be a simultaneous L_0, J_0 eigenvector in the common domain of the four NS modes $G_{\pm 1/2}^{\pm}$ in a unitary NS representation, with*

$$L_0 v = hv, \qquad J_0 v = qv.$$

Then

$$h \geq \frac{|q|}{2}. \tag{70.25}$$

If $q \geq 0$, equality $h = q/2$ holds precisely when

$$G_{-1/2}^{+} v = 0, \qquad G_{1/2}^{-} v = 0. \tag{70.26}$$

If $q \leq 0$, equality $h = -q/2$ holds precisely when

$$G_{-1/2}^{-} v = 0, \qquad G_{1/2}^{+} v = 0. \tag{70.27}$$

In particular, if v is an NS superconformal primary, so all positive supercurrent modes annihilate it, the first equality condition reduces to $G_{-1/2}^{+} v = 0$ and the second to $G_{-1/2}^{-} v = 0$.

Proof. Unitarity gives $(G_r^{\pm})^{\dagger} = G_{-r}^{\mp}$ on the common invariant domain. With $r = 1/2$ and $s = -1/2$, (70.19) gives

$$\{G_{1/2}^{-}, G_{-1/2}^{+}\} = 2L_0 - J_0,$$

because the central term vanishes at $r = \pm 1/2$. Taking the expectation value in v gives the positive-operator identity

$$(2h - q)\|v\|^2 = \|G_{-1/2}^{+}v\|^2 + \|G_{1/2}^{-}v\|^2.$$

Similarly,

$$\{G_{1/2}^{+}, G_{-1/2}^{-}\} = 2L_0 + J_0$$

and hence

$$(2h + q)\|v\|^2 = \|G_{-1/2}^{-}v\|^2 + \|G_{1/2}^{+}v\|^2.$$

Both right-hand sides are nonnegative, so $2h \geq q$ and $2h \geq -q$. If $q \geq 0$, saturation of $h = q/2$ is equivalent to the vanishing of both summands in the first displayed identity. If $q \leq 0$, saturation of $h = -q/2$ is equivalent to the vanishing of both summands in the second identity. The primary-state reduction follows by imposing the positive-mode annihilation conditions $G_{1/2}^{\pm}v = 0$. □

NS–R relation for chiral primaries. If v is an NS chiral primary with $h = q/2$, then spectral flow by $\eta = -1/2$ maps it to a Ramond state with

$$h^{(-1/2)} = \frac{c}{24}. \tag{70.28}$$

Thus it saturates the Ramond ground-state energy. This is obtained by inserting $h = q/2$ and $\eta = -1/2$ into (70.24):

$$h^{(-1/2)} = \frac{q}{2} - \frac{q}{2} + \frac{c}{24} = \frac{c}{24}.$$

70.4 Extended $\mathcal{N} = 2$ Spectral-Flow Operators

The spectral-flow algebra check above is a statement about the abstract mode algebra. It does not say that spectral flow is implemented by a local operator in a particular CFT. That extra assertion needs a charge lattice and locality hypothesis. This distinction is small in notation and large in logic: the extended $\mathcal{N} = 2$ algebra is an additional chiral-algebra structure requiring more than the singular OPEs in Definition 70.4.

Put

$$\kappa = \frac{c}{3}.$$

In this section assume $\kappa > 0$ and assume that the $U(1)_R$ current exponentiates to a rank-one Heisenberg/lattice chiral algebra. Concretely, choose a chiral boson φ with

$$\varphi(z)\varphi(0) \sim -\log z, \qquad J(z) = \mathrm{i}\sqrt{\kappa}\,\partial\varphi(z). \tag{70.29}$$

Then $J(z)J(0) \sim \kappa z^{-2}$, matching (70.11). A field of R-charge q has a Heisenberg factor

$$\exp\left(\mathrm{i}\frac{q}{\sqrt{\kappa}}\varphi\right)$$

up to a neutral factor. The charge lattice of the actual CFT specifies which such exponentials exist and which are mutually local.

Definition 70.6 (Spectral-flow vertex)**.** Let $\eta \in \frac{1}{2}\mathbb{Z}$. A spectral-flow vertex of parameter η is a chiral field

$$X_\eta(z) =: \exp\left(\mathrm{i}\eta\sqrt{\kappa}\,\varphi(z)\right) : \tag{70.30}$$

provided the momentum $\eta\sqrt{\kappa}$ belongs to the chosen Heisenberg/lattice extension. It is a local chiral operator only when its monodromy with the fields of the chiral algebra is trivial. If its monodromy is spin-dependent, it is instead an operator between spin sectors.

Operator implementation of spectral flow. Assume the factorization above, and let

$$\mathcal{O}(z) =: \exp\left(\mathrm{i}\frac{q}{\sqrt{\kappa}}\varphi(z)\right) : \mathcal{O}_0(z)$$

where $\mathcal{O}_0$ is neutral under J. If X_η exists, then

$$X_\eta(z)\mathcal{O}(0) \sim z^{\eta q}\,\mathcal{O}^{(\eta)}(0) + \cdots \tag{70.31}$$

where $\mathcal{O}^{(\eta)}$ has

$$q^{(\eta)} = q + \eta\kappa, \qquad h^{(\eta)} = h + \eta q + \frac{\eta^2\kappa}{2}. \tag{70.32}$$

Since $\kappa = c/3$, this is exactly (70.24). The branch factor $z^{\eta q}$ is the locality test: integer powers give ordinary chiral locality, while half-integer powers signal the NS/R spin-sector change.

The OPE of bosonic exponentials gives

$$: e^{\mathrm{i}a\varphi(z)} :: e^{\mathrm{i}b\varphi(0)} :\sim z^{ab} : e^{\mathrm{i}(a+b)\varphi(0)} : + \cdots .$$

With $a = \eta\sqrt{\kappa}$ and $b = q/\sqrt{\kappa}$, the branch factor is $z^{\eta q}$ and the new charge is

$$\sqrt{\kappa}\left(\frac{q}{\sqrt{\kappa}} + \eta\sqrt{\kappa}\right) = q + \eta\kappa.$$

The Heisenberg part of the conformal weight changes by

$$\frac{(q+\eta\kappa)^2 - q^2}{2\kappa} = \eta q + \frac{\eta^2\kappa}{2}.$$

The neutral factor $\mathcal{O}_0$ is unchanged, so the same difference is the total weight shift.

For $\eta = \pm 1$, write

$$X^{\pm} = X_{\pm 1}.$$

These fields, when present as local chiral fields, are the integer spectral-flow generators of the extended $\mathcal{N} = 2$ algebra. They are obtained from the vacuum by spectral flow and are NS highest-weight states, hence

$$h(X^{\pm}) = \frac{c}{6}, \qquad q(X^{\pm}) = \pm\frac{c}{3}. \tag{70.33}$$

In a unitary NS representation X^+ is chiral and X^- is antichiral:

$$G^+_{-1/2}X^+ = 0, \qquad G^-_{-1/2}X^- = 0, \tag{70.34}$$

because (70.33) saturates the bound of Proposition 70.5. Define the opposite superdescendants

$$Y^+ = G^-_{-1/2}X^+, \qquad Y^- = G^+_{-1/2}X^-. \tag{70.35}$$

Then

$$h(Y^{\pm}) = \frac{c}{6} + \frac{1}{2}, \qquad q(Y^{\pm}) = \pm\left(\frac{c}{3} - 1\right). \tag{70.36}$$

These four fields $X^{\pm}, Y^{\pm}$, together with $T, J, G^{\pm}$, are the finite generator set usually meant by the extended $\mathcal{N} = 2$ chiral algebra.

The singular part of the spectral-flow-generator OPE is also fixed by the Heisenberg current. From (70.30),

$$X_{\eta}(z)X_{-\eta}(0) \sim z^{-\eta^2\kappa}\left[1 + \eta z J(0) + z^2\left(\frac{\eta}{2}\partial J(0) + \frac{\eta^2}{2} : JJ : (0)\right) + O(z^3)\right]. \tag{70.37}$$

The pole order, the coefficient of J, and the two second-order coefficients are therefore convention-sensitive consequences of (70.29), not independent structure constants.

Example 70.7 (Calabi–Yau-type charge lattice)**.** If $c = 3n$, then $\kappa = n$. The integer spectral-flow fields have

$$h(X^{\pm}) = \frac{n}{2}, \qquad q(X^{\pm}) = \pm n,$$

and the half-flow fields $X_{\pm 1/2}$, when present on the spin cover, have

$$h(X_{\pm 1/2}) = \frac{n}{8}, \qquad q(X_{\pm 1/2}) = \pm\frac{n}{2}. \tag{70.38}$$

In a large-radius Calabi–Yau sigma-model representative these are realized by the holomorphic top-form fermion product and the Ramond spin fields, respectively. The present chapter uses only the algebraic implication: their existence is a charge-lattice and spin-sector input whose weights and charges must be exactly those displayed above.

70.5 Elliptic Genus and Spectral-Flow Covariance

The elliptic genus is the protected genus-one observable that links the chiral algebraic data above to the supersymmetric models of Volume VII. Its definition requires a full spin CFT, not just a chiral algebra. We therefore state the hypotheses before using the trace.

Definition 70.8 (Elliptic genus setup)**.** Let $\mathcal{C}$ be a compact unitary $\mathcal{N} = (2, 2)$ spin CFT with discrete Ramond–Ramond Hilbert space

$$\mathcal{H}_{\mathrm{RR}} = \bigoplus_{h,\bar{h},q} \mathcal{H}_{h,\bar{h},q}$$

of finite multiplicities. Assume $c = \bar{c}$, a left $U(1)_R$ current J, a fermion parity $(-1)^F$, and convergence of the Ramond trace for $\operatorname{Im}\tau > 0$. The elliptic genus is

$$\varphi_{\mathcal{C}}(\tau, z) = \mathrm{Tr}_{\mathcal{H}_{\mathrm{RR}}}(-1)^F y^{J_0} q^{L_0 - c/24} \bar{q}^{\bar{L}_0 - c/24}, \qquad y = \mathrm{e}^{2\pi \mathrm{i} z}, \quad q = \mathrm{e}^{2\pi\mathrm{i}\tau}, \quad \bar{q} = \mathrm{e}^{-2\pi\mathrm{i}\bar{\tau}}. \tag{70.39}$$

Proposition 70.9 (Right-moving localization)**.** *Under Definition 70.8, and assuming the usual trace-class cyclicity for the Ramond supertrace, the elliptic genus is independent of $\bar{\tau}$ and receives contributions only from right-moving Ramond ground states:*

$$\bar{L}_0 = \frac{c}{24}. \tag{70.40}$$

Proof. In the right Ramond sector the zero-mode relation is

$$\{\bar G_0^+, \bar G_0^-\} = 2\left(\bar L_0 - \frac{c}{24}\right). \tag{70.41}$$

Differentiating (70.39) with respect to $\bar\tau$ inserts the operator $\bar L_0 - c/24$, up to the scalar factor $-2\pi\mathrm{i}$. By (70.41) this insertion is one half of the anticommutator $\{\bar G_0^+, \bar G_0^-\}$. The zero modes are odd and commute with the left-moving factors $y^{J_0}q^{L_0-c/24}$. The trace-class cyclicity hypothesis therefore gives

$$\mathrm{Str}_{\mathcal{H}_{\mathrm{RR}}}\, y^{J_0}q^{L_0-c/24}\bar q^{\bar L_0-c/24}\{\bar G_0^+, \bar G_0^-\} = 0,$$

because it is the supertrace of a supercommutator. Hence $\partial_{\bar\tau}\varphi_{\mathcal{C}} = 0$.

The same identity gives the state-by-state localization. On an eigenspace with $\bar E := \bar L_0 - c/24 > 0$, the odd operator

$$\bar Q_{\mathrm{R}} = \frac{\bar G_0^+ + \bar G_0^-}{\sqrt{2\bar E}}$$

is an involution after restricting to that finite-multiplicity eigenspace, because $\bar Q_{\mathrm{R}}^2 = 1$. It reverses right-moving fermion parity and preserves the left-moving quantum numbers appearing in the trace. Thus the positive-$\bar E$ eigenspaces cancel in the supertrace. The only unpaired states are the kernel of $\bar L_0 - c/24$, namely the right Ramond ground states. □

The elliptic variable z remembers left R-charge, so spectral flow imposes a finite functional equation. Put

$$m_{\mathrm{ell}} := \frac{c}{6}. \tag{70.42}$$

Assume that integer left spectral flow is implemented on the Ramond Hilbert space and that the chosen left R-charge lattice has a multiplier $\zeta(\mu) \in U(1)$ under $z \mapsto z+\mu$, meaning that $\mathrm{e}^{2\pi\mathrm{i}\mu J_0}$ acts by this scalar on the Ramond states contributing to the trace. Then

$$\varphi_{\mathcal{C}}(\tau, z+\lambda\tau+\mu) = \exp\left[-2\pi\mathrm{i} m_{\mathrm{ell}}\left(\lambda^2\tau + 2\lambda z\right)\right]\zeta(\mu)\varphi_{\mathcal{C}}(\tau, z), \tag{70.43}$$

for $\lambda, \mu \in \mathbb{Z}$. If all Ramond left R-charges in the trace are integral, the last multiplier is 1.

Here is the trace-level derivation of the λ-shift. Replacing z by $z+\lambda\tau$ multiplies each state by $q^{\lambda q_L}$. Under left spectral flow by λ,

$$h' = h + \lambda q_L + \frac{c}{6}\lambda^2, \qquad q_L' = q_L + \frac{c}{3}\lambda. \tag{70.44}$$

Thus

$$q^{h-c/24+\lambda q_L}y^{q_L} = q^{-c\lambda^2/6}y^{-c\lambda/3}q^{h'-c/24}y^{q_L'}. \tag{70.45}$$

Reindexing the trace by the spectral-flow bijection gives (70.43), since $m_{\mathrm{ell}} = c/6$. The μ-shift is exactly the assumed charge-lattice scalar $\zeta(\mu)$.

Hypothesis 70.10 (Spin modular covariance of the elliptic-genus trace)**.** In addition to Definition 70.8, assume that the Ramond trace with a flat left $U(1)_R$ background is supplied by the spin modular functor of the full CFT, and that the chosen R-symmetry background has no anomaly except the level-$c/3$ current-algebra determinant line displayed below. In the trace trivialization, assume that the charge-lattice multiplier is the scalar $\zeta(\mu)$ specified above and that, for

$$\gamma = \begin{pmatrix} a & b \\ c_\gamma & d \end{pmatrix} \in SL_2(\mathbb{Z}), \tag{70.46}$$

the modular change of spin elliptic curve and flat R-background acts by

$$\varphi_{\mathcal{C}}\left(\frac{a\tau+b}{c_\gamma\tau+d}, \frac{z}{c_\gamma\tau+d}\right) = \exp\left(2\pi i m_{\mathrm{ell}} \frac{c_\gamma z^2}{c_\gamma\tau+d}\right) \varphi_{\mathcal{C}}(\tau, z) \tag{70.47}$$

up to the corresponding spin and charge-lattice multiplier. This is the full-CFT sewing input. The left-moving mode algebra supplies the spectral-flow law (70.43), while modular transport of the spin theory on the torus is part of the full spin modular functor datum.

Under Hypothesis 70.10, the holomorphic function $\varphi_{\mathcal{C}}(\tau, z)$, together with (70.43) and (70.47), is a weak Jacobi form of weight 0 and index $m_{\mathrm{ell}} = c/6$, with the charge-lattice multiplier when the index is half-integral. This sentence unpacks the definition of a weak Jacobi form in the present normalization; the nontrivial CFT input is the spin modular covariance hypothesis, and the local algebra is the spectral-flow and determinant-line computation recorded here.

The mechanism behind the exponential factor in (70.47) is local. The global sewing input is the spin modular covariance of Hypothesis 70.10. The trace is a partition function on the elliptic curve

$$E_\tau = \mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z})$$

with a flat background for the left $U(1)_R$ current. In the trace trivialization the holonomy parameter is z, and a change of homology basis by

$$\gamma = \begin{pmatrix} a & b \\ c_\gamma & d \end{pmatrix} \in SL_2(\mathbb{Z})$$

sends the same flat background to the coordinate

$$z_\gamma = \frac{z}{c_\gamma\tau+d}.$$

The current algebra OPE fixes the anomaly coefficient:

$$J(z)J(0) \sim \frac{c/3}{z^2}, \qquad m_{\mathrm{ell}} = \frac{1}{2}\frac{c}{3} = \frac{c}{6}.$$

Thus the Ramond trace is most precisely a section of an index-m_{ell} anomaly determinant line over the moduli stack of elliptic curves with flat R-backgrounds. In the trace trivialization, the transition function of this line is precisely the quadratic factor

$$\exp\left(2\pi i m_{\mathrm{ell}} \frac{c_\gamma z^2}{c_\gamma\tau+d}\right).$$

The elliptic law (70.43) and the modular law (70.47) therefore form one Jacobi-group automorphy system. Its cocycle identity is an elementary consequence of matrix multiplication in $SL_2(\mathbb{Z})$. The quadratic transition function is the local current-algebra part of the calculation. The theorem boundary is the existence of the spin modular functor and anomaly-cancelled R-background for the full interacting CFT.

The adjective "weak" refers to Fourier support. Under the compact Ramond-trace hypotheses and the discrete-spectrum hypothesis in Definition 70.8, the supertrace converges absolutely on $\operatorname{Im}\tau > 0$ and has an expansion of the form

$$\varphi_{\mathcal{C}}(\tau, z) = \sum_{n\geq 0}\sum_{r\in\Lambda_R} c(n, r)\, q^n y^r,$$

after the conventional Ramond-ground-state normalization has been absorbed into n. The elliptic law then gives the coefficient orbit relation

$$c(n,r) = c\big(n + \lambda r + m_{\mathrm{ell}}\lambda^2, r + 2m_{\mathrm{ell}}\lambda\big), \qquad \lambda \in \mathbb{Z}, \tag{70.48}$$

whenever both sides lie in the same charge-lattice multiplier sector. The combination

$$4m_{\mathrm{ell}}n - r^2$$

is invariant along this spectral-flow orbit. Thus the Jacobi symmetry identifies Fourier coefficients along fixed-discriminant charge orbits. The weakness condition is the lower bound $n \geq 0$ supplied by the discrete Ramond spectrum after right-moving ground-state localization; it is a statement about the controlled Ramond trace defined above.

There is a finite Landau–Ginzburg shadow of the elliptic genus which can be checked before any infrared-flow theorem is invoked. Suppose a quasihomogeneous isolated polynomial W of Definition 70.11 is realized by a compact unitary $\mathcal{N} = 2$ fixed point, and suppose the Jacobi ring classes are represented by NS chiral primaries with charges

$$Q_R(X^a) = \sum_i a_i q_i.$$

Spectral flow by $\eta = -1/2$ gives the corresponding left Ramond charges

$$Q_R^{\mathrm{R}}(X^a) = Q_R(X^a) - \frac{c_{\mathrm{LG}}}{6}. \tag{70.49}$$

Therefore the q^0 protected charge polynomial has the form

$$\chi_y^{\mathrm{LG}} = \sum_{[X^a]\in \mathrm{Jac}(W)} y^{Q_R(X^a) - c_{\mathrm{LG}}/6}. \tag{70.50}$$

For $W = X^{k+2}$, this becomes

$$\chi_y^{A_k} = \sum_{\ell=0}^{k} y^{\frac{\ell}{k+2} - \frac{k}{2(k+2)}}. \tag{70.51}$$

Setting $y = 1$ gives the Witten index $k + 1 = \dim \mathrm{Jac}(W)$. The equality between this protected finite polynomial and the infrared elliptic genus is precisely the kind of LG/GLSM construction statement assigned to Volume VII.

70.6 Protected Algebraic Tests for Supersymmetric Dynamics

The full construction of two-dimensional $\mathcal{N} = (2,2)$ Landau–Ginzburg and gauged linear sigma-model flows belongs to the supersymmetric-QFT chapters. The part needed in the CFT volume is narrower: the chiral-ring and central-charge data that any proposed $\mathcal{N} = 2$ superconformal fixed point must reproduce. We state this as an algebraic interface between the CFT and supersymmetric-QFT volumes, not as a proof of an infrared fixed point.

Definition 70.11 (Quasihomogeneous Landau–Ginzburg chiral polynomial)**.** Let $X_1, \dots, X_N$ be complex variables with rational weights $q_i \in (0, 1/2]$. A quasihomogeneous Landau–Ginzburg chiral polynomial consists of a polynomial

$$W \in \mathbb{C}[X_1, \dots, X_N]$$

such that

$$W(\lambda^{q_1} X_1, \dots, \lambda^{q_N} X_N) = \lambda W(X_1, \dots, X_N) \qquad \lambda \in \mathbb{C}^\times, \tag{70.52}$$

and such that the critical locus

$$\partial_1 W = \cdots = \partial_N W = 0$$

is isolated at the origin. Its Jacobi ring is

$$\mathrm{Jac}(W) = \mathbb{C}[X_1, \dots, X_N]/(\partial_1 W, \dots, \partial_N W). \tag{70.53}$$

The $U(1)$ charge of a monomial

$$X^a = X_1^{a_1} \cdots X_N^{a_N}$$

is

$$Q_R(X^a) = \sum_{i=1}^{N} a_i q_i. \tag{70.54}$$

If the polynomial is realized by a unitary compact $\mathcal{N} = 2$ superconformal fixed point with these fields as chiral primaries, the chiral-primary relation gives

$$h(X^a) = \frac{1}{2} Q_R(X^a). \tag{70.55}$$

The central charge predicted by the $U(1)_R$ anomaly is

$$c_{\mathrm{LG}} = 3 \sum_{i=1}^{N} (1 - 2q_i). \tag{70.56}$$

In this chapter (70.56) is used only as a protected chiral-algebra consistency check. The assertion that a given ultraviolet Landau–Ginzburg functional flows to a particular continuum SCFT requires the regulator and RG construction requested in the Volume VII supersymmetric-QFT program.

Example 70.12 (A-series algebra)**.** For

$$W = X^{k+2}, \qquad k \in \mathbb{Z}_{\geq 0},$$

the quasihomogeneous weight is $q = 1/(k+2)$. The Jacobi ring is

$$\mathrm{Jac}(W) = \mathbb{C}[X]/(X^{k+1}), \tag{70.57}$$

with basis $1, X, \dots, X^k$. The central charge predicted by (70.56) is

$$c = \frac{3k}{k+2}, \tag{70.58}$$

and the basis element X^ℓ, $0 \leq \ell \leq k$, has

$$q_\ell = \frac{\ell}{k+2}, \qquad h_\ell = \frac{\ell}{2(k+2)} \tag{70.59}$$

when represented by a chiral primary.

Example 70.13 (Quintic algebraic check)**.** For

$$W = X_1^5 + \cdots + X_5^5$$

with all weights $q_i = 1/5$, the anomaly formula gives

$$c = 3 \cdot 5 \left(1 - \frac{2}{5}\right) = 9. \tag{70.60}$$

This is an algebraic $U(1)_R$-anomaly calculation. Interpreting it as a Calabi–Yau sigma-model phase is not part of the present chapter.

70.7 Supersymmetric Rank-One Coset Interfaces

The rank-one cosets of Section 66.8.2 have supersymmetric refinements which are too important to leave as informal shorthand. This section records the exact chiral-algebraic interface needed by the CFT volume. It does not assert a construction of a UV Landau–Ginzburg or GLSM flow. The latter requires the regulator, supersymmetric Ward identities, and infrared-comparison topology of Volume VII. The point here is narrower and sharper: once the supersymmetric WZW coset exists as an $\mathcal{N} = 2$ chiral algebra, its central charge, primary weights, R-charges, spectral flow, and basic field-identification arithmetic are fixed.

We use the following conventions. A supersymmetric $SU(2)_k$ WZW model, with $k \in \mathbb{Z}_{\geq 2}$, is represented by a bosonic $\widehat{\mathfrak{su}}(2)_{k-2}$ current algebra with currents $k^a(z)$, $a = 1, 2, 3$, together with three free Majorana fermions $\chi^a(z)$. The total Cartan current is denoted K^3. The supersymmetric $SL(2, \mathbb{R})_k$ model, with $k > 0$, is represented by a bosonic $\widehat{\mathfrak{sl}}(2, \mathbb{R})_{k+2}$ current algebra with currents $j^a(z)$, three free fermions $\psi^a(z)$ with the noncompact-signature bilinear form, and total Cartan current J^3. In both cases the coset removes the $\mathcal{N} = 1$ abelian sector generated by the Cartan fermion and total Cartan current. This is an operator statement: the displayed coset fields are required to have regular OPE with the removed $\mathcal{N} = 1$ $U(1)$ sector.

Definition 70.14 (Compact supersymmetric rank-one coset)**.** For $k \in \mathbb{Z}_{\geq 2}$, the compact supersymmetric rank-one coset is the chiral algebra obtained from the supersymmetric $SU(2)_k$ model by decoupling the $\mathcal{N} = 1$ $U(1)$ sector generated by χ^3 and K^3. Put

$$k^{\pm} = k^1 \pm \mathrm{i}k^2, \qquad \chi^{\pm} = \frac{\chi^1 \pm \mathrm{i}\chi^2}{\sqrt{2}}.$$

In the standard free-fermion realization the $\mathcal{N} = 2$ generators of the coset are

$$G^{\pm} = \sqrt{\frac{2}{k}}\, k^{\mp}\chi^{\pm}, \qquad J_R = -\frac{2}{k}k^3 + \frac{k-2}{k}\chi^+\chi^- = -\frac{2}{k}K^3 + \chi^+\chi^-. \tag{70.61}$$

Compact coset central charge and primary data. The compact coset of Definition 70.14 has

$$c_{\mathrm{comp}}(k) = \frac{3(k-2)}{k}. \tag{70.62}$$

Let $V^{su}_{j,m,\bar{m}}$ be a diagonal bosonic $\widehat{\mathfrak{su}}(2)_{k-2}$ primary, where

$$j \in \left\{0, \frac{1}{2}, \ldots, \frac{k-2}{2}\right\}, \qquad m, \bar{m} \in \{-j, -j+1, \ldots, j\}.$$

Bosonize the total Cartan current by

$$K^3 \simeq \mathrm{i}\sqrt{\frac{k}{2}}\,\partial Y$$

and factor the Cartan vertex by

$$V^{su}_{j,m,\bar m} \simeq \exp\left[\mathrm{i}\sqrt{\frac{2}{k}}\,(mY + \bar m\,\bar Y)\right]\Psi^{su}_{j,m,\bar m}. \tag{70.63}$$

Then the coset primary $\Psi^{su}_{j,m,\bar m}$ has

$$h = \frac{j(j+1) - m^2}{k}, \qquad q = -\frac{2m}{k}, \qquad \bar h = \frac{j(j+1) - \bar m^2}{k}, \qquad \bar q = -\frac{2\bar m}{k}. \tag{70.64}$$

The central-charge calculation is a useful place to keep the level shifts visible. The bosonic $SU(2)_{k-2}$ algebra has central charge

$$\frac{3(k-2)}{(k-2)+2} = \frac{3(k-2)}{k}.$$

The three free fermions contribute $3/2$. The removed abelian $\mathcal{N} = 1$ sector contributes $1 + 1/2 = 3/2$. Hence the coset central charge is $\frac{3(k-2)}{k} + 3/2 - 3/2$, which is (70.62).

For the weights, the bosonic $SU(2)_{k-2}$ primary of spin j has Sugawara weight $j(j+1)/k$, while the Cartan factor in (70.63) has holomorphic weight m^2/k. Subtracting the Cartan part gives the displayed h, and the antiholomorphic sector gives $\bar h = (j(j+1) - \bar m^2)/k$ with $\bar m$ in place of m. The R-charge follows by taking the simple pole of J_R with the coset factor after the K^3-vertex has been removed. With the normalization above, this pole is $-2m/k$ times the field; the antiholomorphic formula is identical.

The compact coset is the $\mathcal{N} = 2$ minimal model whose usual minimal-model level is

$$K = k - 2.$$

Thus $c_{\mathrm{comp}} = 3K/(K+2)$. The chiral-primary representatives in the convention (70.64) are obtained by setting $m = -j$. Then

$$h = \frac{j}{k}, \qquad q = \frac{2j}{k}, \qquad h = \frac{q}{2}.$$

Writing $\ell = 2j$, with $0 \le \ell \le K$, gives

$$q_\ell = \frac{\ell}{K+2}, \qquad h_\ell = \frac{\ell}{2(K+2)}.$$

These are exactly the A-series algebraic values in Example 70.12, after identifying $W = X^{K+2}$. The equality of protected chiral data is a consistency interface. A proof that a chosen UV Landau–Ginzburg regulator flows to this coset requires control of the corresponding RG trajectory.

Proposition 70.15 (Compact coset chiral ring)**.** *Let $K = k - 2$. For $0 \le \ell \le K$, put*

$$\Phi_\ell = \Psi^{su}_{\ell/2,-\ell/2}$$

for the holomorphic compact-coset chiral primary in the NS sector. In the protected chiral-primary fusion ring,

$$\Phi_a\Phi_b = \begin{cases} \Phi_{a+b}, & a+b \le K, \\ 0, & a+b > K, \end{cases} \qquad 0 \le a, b \le K, \tag{70.65}$$

after normalizing $\Phi_0 = 1$ and the generator Φ_1. Hence

$$\mathcal{R}_{\mathrm{ch}}\big(SU(2)_k/U(1)\big) \cong \mathbb{C}[x]/(x^{K+1}), \qquad x^\ell \longleftrightarrow \Phi_\ell. \tag{70.66}$$

Here the $K = 0$ endpoint means $\mathbb{C}[x]/(x) \cong \mathbb{C}$, and the normalization of Φ_1 applies only when $K \ge 1$.

Proof. The fields Φ_ℓ are chiral because

$$h_\ell = \frac{\ell}{2k}, \qquad q_\ell = \frac{\ell}{k}, \qquad h_\ell = q_\ell/2.$$

The OPE of two NS chiral primaries has no negative powers in the chiral channel. Indeed any term of R-charge $q_a + q_b$ has, by the unitarity bound, weight at least $(q_a + q_b)/2 = h_a + h_b$. Thus the chiral-primary projection of the product has additive R-charge.

When $a + b \le K$, the parent $\widehat{\mathfrak{su}}(2)_{k-2}$ fusion of spins $a/2$ and $b/2$ contains the top spin $(a+b)/2$ with multiplicity one. The Cartan charges add from $-a/2$ and $-b/2$ to $-(a+b)/2$, so the coset branching contains precisely the chiral primary Φ_{a+b} in the BPS channel. The one-dimensionality of this channel allows the displayed normalization.

If $a + b > K$, then the additive charge would be $(a+b)/k > K/k = c/3$. The compact coset has no chiral primary with that charge: the complete chiral list is $0 \le \ell \le K$. Equivalently, the affine fusion truncation removes the would-be top spin before it can appear as a chiral coset branch. The BPS projection of the product is therefore zero. The resulting associative algebra is the truncated polynomial algebra $\mathbb{C}[x]/(x^{K+1})$. This proves the equality of the compact-coset protected chiral ring with the A-series Jacobi algebra as a chiral-data statement, while leaving the dynamical LG-to-coset flow theorem to Volume VII. □

The compact coset has independent holomorphic and antiholomorphic spectral flow operations. Applying (70.24) with (70.62) to (70.64) gives the flowed labels

$$\begin{aligned} h^{(\eta)} &= \frac{j(j+1) - (m+\eta)^2}{k} + \frac{\eta^2}{2}, & q^{(\eta)} &= -\frac{2(m+\eta)}{k} + \eta, \\ \bar{h}^{(\bar\eta)} &= \frac{j(j+1) - (\bar m+\bar\eta)^2}{k} + \frac{\bar\eta^2}{2}, & \bar{q}^{(\bar\eta)} &= -\frac{2(\bar m+\bar\eta)}{k} + \bar\eta, \end{aligned} \tag{70.67}$$

where $\eta, \bar\eta \in \frac{1}{2}\mathbb{Z}$. The compact simple-current identification becomes, for the corresponding spectral-flowed fields,

$$\Psi^{su,(\eta,\bar\eta)}_{j,m,\bar m} \simeq \Psi^{su,(\eta-1,\bar\eta-1)}_{\frac{k-2}{2}-j,\, m-\frac{k-2}{2},\, \bar m-\frac{k-2}{2}} \simeq \Psi^{su,(\eta-1,\bar\eta+1)}_{\frac{k-2}{2}-j,\, m-\frac{k-2}{2},\, \bar m+\frac{k-2}{2}}. \tag{70.68}$$

The full diagonal compact theory is obtained only after the left and right representations are paired. In the conventional diagonal pairing one imposes

$$m + \eta - \bar m - \bar\eta \in k\mathbb{Z}, \qquad \eta - \bar\eta \in \mathbb{Z}. \tag{70.69}$$

The remaining angular symmetry of the disc sigma-model representative is a $\mathbb{Z}_k$ symmetry acting by

$$\Psi^{su,(\eta,\bar\eta)}_{j,m,\bar m} \longmapsto \exp\left[\frac{2\pi\mathrm{i}}{k}(m+\eta+\bar m+\bar\eta)\right]\Psi^{su,(\eta,\bar\eta)}_{j,m,\bar m}. \tag{70.70}$$

This last statement is a warning against a common shortcut: the disc metric is not the exact CFT data. The finite-level CFT remembers the simple-current identification and the $\mathbb{Z}_k$ selection rule.

Definition 70.16 (Noncompact supersymmetric rank-one coset)**.** For $k>0$, the noncompact supersymmetric rank-one coset is obtained from the supersymmetric $SL(2,\mathbb{R})_k$ model by decoupling the $\mathcal{N}=1$ abelian sector generated by ψ^3 and J^3. Put

$$j^\pm = j^1 \pm \mathrm{i}j^2, \qquad \psi^\pm = \frac{\psi^1 \pm \mathrm{i}\psi^2}{\sqrt{2}}.$$

In the standard realization its $\mathcal{N}=2$ generators are

$$G^\pm = \sqrt{\frac{2}{k}}\,j^\mp\psi^\pm, \qquad J_R = \frac{2}{k}j^3 + \frac{k+2}{k}\psi^+\psi^- = \frac{2}{k}J^3 + \psi^+\psi^-. \tag{70.71}$$

Cigar central charge and primary data. The noncompact coset of Definition 70.16 has

$$c_{\mathrm{cig}}(k) = \frac{3(k+2)}{k}. \tag{70.72}$$

Let $V^{sl}_{j,m,\bar m}$ be a bosonic $\widehat{\mathfrak{sl}}(2,\mathbb{R})_{k+2}$ primary, with j the standard $SL(2,\mathbb{R})$ spin parameter and $m,\bar m$ the total Cartan eigenvalues. Bosonize the total Cartan current by

$$J^3 \simeq -\sqrt{\frac{k}{2}}\,\partial X$$

and factor

$$V^{sl}_{j,m,\bar m} \simeq \exp\left[\sqrt{\frac{2}{k}}\,(mX+\bar m\,\bar X)\right]\Psi^{sl}_{j,m,\bar m}. \tag{70.73}$$

Then

$$h = \frac{-j(j-1)+m^2}{k}, \qquad q = \frac{2m}{k}, \qquad \bar h = \frac{-j(j-1)+\bar m^2}{k}, \qquad \bar q = \frac{2\bar m}{k}. \tag{70.74}$$

The bosonic $SL(2,\mathbb{R})_{k+2}$ current algebra has central charge $3(k+2)/k$ in the convention of Section 66.8.2. Adding three fermions and removing the abelian $\mathcal{N}=1$ Cartan sector changes the central charge by $+3/2-3/2$, so the coset central charge is (70.72). The bosonic primary has Sugawara weight $-j(j-1)/k$. The Cartan boson in (70.73) is timelike with respect to the noncompact bilinear form, so removing the Cartan factor adds m^2/k to the coset weight. The R-charge is the simple-pole coefficient of the J_R OPE after the J^3-vertex has been factored out, giving $2m/k$. The antiholomorphic sector uses $\bar m$ in the same factorization and gives $\bar h = (-j(j-1)+\bar m^2)/k$ and $\bar q = 2\bar m/k$.

The noncompact spectrum is not determined by (70.74) alone. In the conventional cigar theory the continuous series has

$$j = \frac{1}{2}+\mathrm{i}s, \qquad s\in\mathbb{R}, \qquad m-\bar m\in\mathbb{Z},$$

while discrete normalizable states are residues in an allowed strip such as

$$\frac{1}{2} < j < \frac{k+1}{2}, \qquad m, \bar{m} \in j + \mathbb{Z}_{\geq 0} \quad \text{or} \quad m, \bar{m} \in -j - \mathbb{Z}_{\geq 0},$$

together with the winding condition

$$m + \bar{m} \in k\mathbb{Z}. \tag{70.75}$$

The exact reflection coefficient, its poles, and the spectral density are analytic CFT data. They should not be replaced by the cigar metric.

Spectral flow gives

$$\begin{aligned} h^{(\eta)} &= \frac{-j(j-1) + (m+\eta)^2}{k} + \frac{\eta^2}{2}, & q^{(\eta)} &= \frac{2(m+\eta)}{k} + \eta, \\ \bar{h}^{(\bar{\eta})} &= \frac{-j(j-1) + (\bar{m}+\bar{\eta})^2}{k} + \frac{\bar{\eta}^2}{2}, & \bar{q}^{(\bar{\eta})} &= \frac{2(\bar{m}+\bar{\eta})}{k} + \bar{\eta}. \end{aligned} \tag{70.76}$$

The momentum and winding labels in the asymptotic cigar circle are shifted to

$$n = m + \eta - \bar{m} - \bar{\eta}, \qquad w = \frac{m + \eta + \bar{m} + \bar{\eta}}{k}, \tag{70.77}$$

so the winding condition becomes

$$m + \eta + \bar{m} + \bar{\eta} \in k\mathbb{Z}. \tag{70.78}$$

For discrete states one extends the range by the identification

$$\Psi^{sl,(\eta,\bar{\eta})}_{j,m,\bar{m}} \simeq \Psi^{sl,(\eta+1,\bar{\eta}+1)}_{\frac{k+2}{2}-j,\, m-\frac{k+2}{2},\, \bar{m}-\frac{k+2}{2}}. \tag{70.79}$$

There is no compact-coset analogue shifting η and $\bar{\eta}$ with opposite signs. The reason is structural: the cigar has an exact circle translation quantum number n, whereas the compact disc representative has only the finite $\mathbb{Z}_k$ remnant in (70.70).

Remark 70.17 (Spectral-flow derivation of the rank-one formulas). Equations (70.67) and (70.76) follow from the general $\mathcal{N} = 2$ spectral-flow law (70.24) and the unflowed data (70.64), (70.74). For the compact coset,

$$h + \eta q + \frac{c_{\text{comp}}\eta^2}{6} = \frac{j(j+1) - m^2}{k} - \frac{2\eta m}{k} + \frac{k-2}{2k}\eta^2.$$

Since

$$-\frac{(m+\eta)^2}{k} + \frac{\eta^2}{2} = -\frac{m^2 + 2m\eta}{k} + \frac{k-2}{2k}\eta^2,$$

this is the first formula in (70.67). The charge identity is

$$q + \frac{c_{\text{comp}}\eta}{3} = -\frac{2m}{k} + \frac{k-2}{k}\eta = -\frac{2(m+\eta)}{k} + \eta.$$

The barred compact formulas are identical. For the noncompact coset,

$$h + \eta q + \frac{c_{\text{cig}}\eta^2}{6} = \frac{-j(j-1) + m^2}{k} + \frac{2\eta m}{k} + \frac{k+2}{2k}\eta^2,$$

and

$$\frac{(m+\eta)^2}{k}+\frac{\eta^2}{2}=\frac{m^2+2m\eta}{k}+\frac{k+2}{2k}\eta^2.$$

The charge formula follows from

$$q+\frac{c_{\rm cig}\eta}{3}=\frac{2m}{k}+\frac{k+2}{k}\eta=\frac{2(m+\eta)}{k}+\eta.$$

The mirror relation between the noncompact $SL(2,\mathbb{R})_k/U(1)$ coset and $\mathcal{N}=2$ Liouville theory belongs at the interface between this chiral algebra, the cigar sigma-model representative in Section 66.8.2, and the Volume VII GLSM duality construction. In this volume it is safest to treat mirror symmetry as a target theorem for the supersymmetric-QFT development: the present section supplies the exact coset side, including the R-charges and spectral-flow labels that any such theorem must match.

70.8 Small $\mathcal{N}=4$ Boundary

For completeness, we record the boundary between what is used in this monograph and the full small $\mathcal{N}=4$ representation theory. The small $\mathcal{N}=4$ algebra contains an affine $\mathfrak{su}(2)$ current algebra and four supercurrents. It includes $\mathcal{N}=2$ subalgebras after choosing a Cartan $U(1)\subset SU(2)_R$, but the representation theory involves the full $SU(2)_R$ spin.

Definition 70.18 (Small $\mathcal{N}=4$ chiral algebra)**.** A small $\mathcal{N}=4$ chiral algebra at level $k\in\mathbb{Z}_{\geq 0}$ consists of:

1. a stress tensor $T(z)$ of central charge $c=6k$;
2. affine $\mathfrak{su}(2)$ currents $J^a(z)$, $a=1,2,3$, with level k;
3. four weight-3/2 supercurrents transforming as two doublets under $\mathfrak{su}(2)$;
4. OPEs such that the anticommutator of opposite supercurrents closes on T, J^a, and the central term, while the current OPEs act on the supercurrents by the doublet representation.

Definition 70.18 records only the part of the small-$\mathcal{N}=4$ algebra used in this volume. The present monograph uses two consequences: the central charge is tied to the affine level by $c=6k$, and every Cartan choice supplies an $\mathcal{N}=2$ subalgebra whose spectral-flow operation is inherited from the affine $SU(2)_R$ structure. A later chapter that needs small-$\mathcal{N}=4$ multiplet classification must state the full OPE tensor and derive the corresponding unitarity bounds.

Open Problem 70.19 (Intrinsic two-dimensional supersymmetric RG construction)*.* Coordinate the CFT-volume algebraic layer with the Volume VII construction of two-dimensional $\mathcal{N}=(2,2)$ Landau–Ginzburg models, gauged linear sigma models, and their proposed infrared SCFTs as intrinsic two-dimensional QFTs with a regulator, supersymmetric Ward identities, renormalized $U(1)_R$ current, and a topology in which the infrared chiral ring and central charge are obtained. The algebraic checks in Definition 70.11 and Examples 70.12–70.13 are necessary consistency tests, not a construction of the continuum fixed point.

Part VI

Integrable Quantum Field Theory

Chapter 71

Factorized Scattering and Integrability

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This volume begins with massive two-dimensional QFT because that is the place where integrability has a sharp scattering-theoretic meaning. Let the theory have a vacuum representation on $\mathbb{M}^2$, a mass gap above the vacuum, and isolated one-particle species labelled by $a, b, \dots$, with masses $m_a > 0$. A one-particle momentum is parametrized by rapidity

$$p_a^\mu(\theta) = (m_a \cosh\theta,\ m_a \sinh\theta), \qquad \theta \in \mathbb{R}.$$

The Lorentz group acts by translating θ. Hence a two-particle invariant depends on the rapidity difference $\theta_{12} = \theta_1 - \theta_2$.

Definition 71.1 (Rapidity chart and ordered chambers)**.** For a species a, the rapidity chart is the map

$$\theta \longmapsto p_a(\theta) = m_a(\cosh\theta, \sinh\theta)$$

from $\mathbb{R}$ to the positive-energy mass shell $\{p \in \mathbb{R}^{1,1} : p^2 = -m_a^2,\ p^0 > 0\}$. The positive two-particle Mandelstam invariant is

$$s_{ab}(\theta_1 - \theta_2) := -\big(p_a(\theta_1) + p_b(\theta_2)\big)^2.$$

For N particles, an ordered rapidity chamber is a connected component of

$$\{(\theta_1, \dots, \theta_N) \in \mathbb{R}^N : \theta_i \neq \theta_j \text{ for } i \neq j\}.$$

The fundamental chamber used below is $\theta_1 > \theta_2 > \cdots > \theta_N$. Other chambers are reached by permuting rapidities and then relating the corresponding scattering bases by two-body scattering operators.

Remark 71.2 (Two-particle kinematics in rapidity variables). In the rapidity chart of Definition 71.1,

$$s_{ab}(\theta) = m_a^2 + m_b^2 + 2m_a m_b \cosh\theta, \qquad \theta = \theta_1 - \theta_2.$$

The Lorentz-invariant two-body kinematics of massive particles in $1+1$ dimensions is therefore encoded by the rapidity difference θ, together with the species labels.

With mostly-plus metric,

$$p_a(\theta_1)\cdot p_b(\theta_2) = -m_a m_b \cosh\theta_1 \cosh\theta_2 + m_a m_b \sinh\theta_1 \sinh\theta_2 = -m_a m_b \cosh(\theta_1 - \theta_2).$$

Since $p_a^2 = -m_a^2$ and $p_b^2 = -m_b^2$,

$$-\left(p_a + p_b\right)^2 = m_a^2 + m_b^2 + 2m_a m_b \cosh(\theta_1 - \theta_2).$$

A proper orthochronous Lorentz boost of rapidity λ sends $\theta_i \mapsto \theta_i + \lambda$, so $\theta_1 - \theta_2$ is invariant. Conversely, once the masses and the total invariant mass are fixed, $\cosh(\theta_1 - \theta_2)$ is fixed; the sign of $\theta_1 - \theta_2$ records the ordering of the two momenta.

71.1 Reconstruction Spine and Status Labels

The exact data in this volume do not all have the same logical status. A two-body S-matrix satisfying unitarity, crossing, and Yang–Baxter is on-shell scattering data. A TBA equation is a thermodynamic or mirror-channel functional equation after Bethe–Yang quantization has been accepted. A form-factor solution is a family of candidate local-operator matrix elements. None of these, by itself, is a constructed local quantum field theory. The volume therefore uses a common dependency spine with two intertwined chains. The Hilbert-space chain runs from a local massive QFT with higher-spin charges to elastic factorized scattering, then to S-Fock/ZF data, wedge-local fields, local algebras, and finally local fields and Wightman functions. The thermodynamic chain runs from Bethe–Yang finite-volume quantization to TBA pseudoenergies, mirror finite-size data, and GHD currents. The arrows in these chains are not equivalent. Some are theorems under standard Hilbert-space hypotheses; some are conditional theorems after analytic and nuclearity assumptions are imposed; some are formal constructions whose output still lacks positivity or locality; some are numerical or finite-regulator evidence; and some are open problems.

Definition 71.3 (Status labels for integrable-QFT bridges)**.** For the rest of this volume, a bridge between two layers of exact data carries one of the following labels.

(i) *Theorem*: the stated hypotheses construct the target object in a Hilbert space or algebra of local observables and prove the claimed property.

(ii) *Conditional theorem*: the proof is valid once explicitly stated analytic, domain, nuclearity, thermodynamic-limit, or state-space hypotheses are supplied.

(iii) *Formal construction*: the formula produces algebraic or distributional candidates, but positivity, locality, convergence, or domain control is not yet part of the statement.

(iv) *Numerical or finite-regulator evidence*: a calculation check verifies a finite identity, normalization, sign, or approximation window. It is not evidence for continuum reconstruction unless the limiting theorem is separately stated.

(v) *Open problem*: a named missing implication whose hypotheses and target object are known well enough to be stated.

The main bridges in this volume should be read with the following status map. The entries are deliberately conservative; upgrading a row requires proving the missing analytic statement, not adding another finite identity.

Bridge	**Status**	**Load-bearing evidence**
local QFT to factorized scattering	conditional theorem	Haag–Ruelle scattering, mass gap, separating higher-spin charges, regular distribution kernels, and control of threshold and bound-state singularities.
factorized S to S-Fock/ZF algebra	theorem at the algebraic Hilbert-space level	Unitarity gives positive chamber inner products; Yang–Baxter gives path-independent chamber continuation and associative exchange.
S-Fock data to wedge-local fields	conditional theorem	Regularity, crossing, and analytic bounds strong enough to define polarization-free generators and wedge-local operator domains.
wedge-local fields to local algebras	conditional theorem	Nontriviality of double-cone intersections, usually via modular nuclearity or related phase-space bounds.
form-factor equations to local fields	formal construction unless convergence and locality are proved	Watson, cyclicity, and residue equations plus growth bounds; the missing analytic work is convergence of spectral sums, positivity, domains, and locality of reconstructed fields.
Bethe–Yang data to ground-state TBA	conditional theorem	Finite-volume quantization with controlled errors, density convergence, convex free-energy functional, and fixed normalization of the mirror channel.
ground-state TBA to excited-state or mirror data	conditional or formal, model by model	Specified singularity motion, contour deformation, source terms, and a check that no untracked pole crosses the continuation path.
TBA densities to GHD	conditional hydrodynamic limit	Local generalized Gibbs ensembles, dressing invertibility, Euler-scale limit, clustering/mixing, and absence or controlled size of integrability breaking.

Two models serve as reference points for this status discipline. In the massive Ising model, the scattering datum is the scalar $S = -1$, the S-Fock space is the antisymmetric free-fermion Fock space, and the local energy field is a Wick polynomial of the Majorana field. The local QFT and its Wightman functions are therefore constructed by the free-field theorem; the form-factor expansion for separated Euclidean correlators is a theorem after the usual Fock-space domain and convergence estimates. The spin and disorder fields require the additional order/disorder semi-locality structure developed later in the volume, but their status is not inferred merely from the equation $S = -1$.

For a regular scalar factorizing model such as sinh-Gordon, the exact two-body scattering function gives an S-symmetric Fock space and wedge-local polarization-free generators under the standard analyticity and crossing bounds. The existence of nontrivial double-cone algebras is then a conditional theorem once the relevant modular nuclearity estimate is proved. Pointlike local fields obtained from form-factor series, and completeness of a declared family of such fields, remain separate analytic tasks. TBA predictions for the same model are therefore thermodynamic consequences of the scattering specification under Bethe–Yang and mirror-channel hypotheses; they are not, by themselves, a proof that the local double-cone net has been constructed.

This status map is also how calculation companions are used. A finite Yang–Baxter, residue, TBA-kernel, or form-factor check verifies the stated finite algebra in its row of the map. It does not upgrade a formal form-factor solution to a local field, nor a TBA equation to a theorem about finite-size spectra, unless the missing Hilbert-space, convergence, and thermodynamic-limit assumptions have been supplied at the point of use.

71.2 Factorized Scattering Datum

Definition 71.4 (Elastic factorized scattering system)**.** An elastic factorized scattering system consists of a finite or countable set of massive species, a positive mass m_a for each species, and meromorphic functions

$$S_{ab}^{cd}(\theta), \qquad a, b, c, d \in I,$$

defined on a common rapidity-domain cover, satisfying the following algebraic and analytic conditions.

First, two-particle unitarity is

$$\sum_{e,f} S_{ab}^{ef}(\theta)\, S_{ef}^{cd}(-\theta) = \delta_a^c \delta_b^d.$$

Second, Hermitian analyticity is

$$S_{ab}^{cd}(\theta)^* = S_{cd}^{ab}(-\theta^*)$$

on the boundary where both sides are defined. Third, if $\bar{a}$ denotes the charge-conjugate species, crossing has the form

$$S_{ab}^{cd}(\theta) = C_{a\bar{a}'} C^{c\bar{c}'}\, S_{\bar{c}'b}^{\bar{a}'d}(\mathrm{i}\pi - \theta),$$

with the charge-conjugation matrix C fixed as part of the particle-state normalization. Fourth, three-particle consistency is the Yang–Baxter equation

$$S_{12}(\theta_{12})S_{13}(\theta_{13})S_{23}(\theta_{23}) = S_{23}(\theta_{23})S_{13}(\theta_{13})S_{12}(\theta_{12})$$

as an identity on the tensor product of three one-particle internal spaces.

The notation S_{ij} means that the two-particle matrix S acts on the i-th and j-th tensor factors and as the identity on the remaining factor. The Yang–Baxter equation is the associativity condition for reordering three rapidities by adjacent transpositions. It is a structural part of factorized scattering: it identifies the pairwise decompositions of a single ordered three-particle process.

Definition 71.5 (Separating higher-spin family)**.** Let $\{Q_{s,\lambda}\}_{(s,\lambda)\in\mathcal{A}}$ be commuting conserved charges whose one-particle eigenvalues have the form

$$q_{s,\lambda,a}(\theta) = \kappa_{s,\lambda,a}\, \mathrm{e}^{s\theta}, \qquad s > 1.$$

For fixed particle number N, set $z_i = \mathrm{e}^{\theta_i}$. The family is N-separating on a rapidity domain U_N if the moment map

$$\Phi_N\big(\{(a_i, z_i)\}_{i=1}^N\big) = \left(\sum_{i=1}^N \kappa_{s,\lambda,a_i} z_i^s\right)_{(s,\lambda)\in\mathcal{A}}$$

is injective on $U_N/\mathfrak{S}_N$, outside a specified closed exceptional set consisting of coincident rapidities and declared threshold or bound-state singular loci. The quotient means that only the unordered multiset of species and rapidities is to be recovered.

A concrete sufficient condition, for a finite species set, is the following. For each species a and for each r needed up to the maximal particle number under consideration, finite linear combinations of the charges produce the species-resolved power sums

$$p_{r,a} = \sum_{i\colon a_i=a} z_i^r.$$

Then Newton identities recover the monic polynomial

$$\prod_{i\colon a_i=a} (t - z_i)$$

for each species a, and hence recover the unordered species-resolved rapidity multiset wherever the roots are distinct. The definition above is the hypothesis used below; this sufficient condition is only a convenient checkable way to obtain it.

Support test by multiplication. Let $U \subset \mathbb{R}^n$ be open, let $T \in \mathcal{D}'(U)$, and let $f \in C^\infty(U)$. If $fT = 0$ and f has no zero on an open set $V \subset U$, then T vanishes on V.

For any test function $\varphi \in C_c^\infty(V)$, the quotient φ/f is smooth with compact support in V, because f is nowhere zero on V. Since $fT = 0$,

$$\langle T, \varphi\rangle = \left\langle T, f\frac{\varphi}{f}\right\rangle = \left\langle fT, \frac{\varphi}{f}\right\rangle = 0.$$

Thus T pairs to zero with every test function supported in V, which means $T|_V = 0$.

Proposition 71.6 (Factorization from conserved higher-spin charges)**.** *Assume a massive* $1+1$*-dimensional QFT has Haag–Ruelle asymptotic particle states, a family of conserved charges* $\{Q_{s,\lambda}\}_{(s,\lambda)\in\mathcal{A}}$ *as in Definition 71.5, and scattering kernels which, after smearing by compactly supported wave packets in rapidity chambers, depend continuously on the wave packets away from threshold and bound-state singular loci. Equivalently, the unsmeared kernels are distributional boundary values whose singular support in the rapidity variables is contained in those declared loci.*

If the scattering operator commutes with every $Q_{s,\lambda}$*, and if the charge family is* N*-separating on the incoming and outgoing* N*-particle domains under consideration, then the* $N \to N$ *scattering kernel is supported, away from the declared singular loci, on the union of permutation graphs*

$$\{(\theta_1', b_1; \ldots; \theta_N', b_N) = (\theta_{\sigma(1)}, a_{\sigma(1)}; \ldots; \theta_{\sigma(N)}, a_{\sigma(N)})\}.$$

If the corresponding moment maps for $M \neq N$ *have disjoint generic images, then generic* $N \to M$ *particle production is absent.*

Proof. Let $K_{N\to M}$ be the distribution kernel of the scattering operator between ordered rapidity chambers, away from the declared singular loci. Commutation with $Q_{s,\lambda}$ gives, in the sense of distributions,

$$\left(\sum_{i=1}^{N}\kappa_{s,\lambda,a_i}\mathrm{e}^{s\theta_i}-\sum_{j=1}^{M}\kappa_{s,\lambda,b_j}\mathrm{e}^{s\theta'_j}\right)K_{N\to M}=0$$

for every (s,λ). The following support property of distributions is being used: the support test above implies that the kernel vanishes on any open set where one of the displayed charge differences is nonzero. Therefore the support of the kernel is contained in the common zero locus of all differences of charge eigenvalues.

For $M=N$, the N-separation hypothesis says that this common zero locus, outside the exceptional set, is precisely the union of permutation graphs displayed in the statement. Thus, after smearing with wave packets supported in a connected component of the regular rapidity chamber, the scattering operator cannot have support away from elastic permutations. For $M\neq N$, the assumed disjointness of the generic moment-map images leaves no regular common zero locus, so the production kernel vanishes on the corresponding open domain. Threshold and bound-state loci are excluded from the statement because the distribution kernels may have additional singular components there; those components must be described after the relevant channel is resolved. □

71.3 Ordered Bases and the Scattering Groupoid

Factorized scattering is most precise when formulated as a comparison of ordered bases for the same asymptotic Hilbert-space sector. Fix a regular rapidity point with distinct rapidities. For each chamber $\theta_{\sigma(1)}>\cdots>\theta_{\sigma(N)}$, choose the ordered asymptotic basis in which the creation operators are written in that order. Crossing a codimension-one wall $\theta_i=\theta_{i+1}$ is represented by the two-body operator

$$\mathsf{T}_i(\theta_i-\theta_{i+1})=S_{i,i+1}(\theta_i-\theta_{i+1})$$

acting on the adjacent species spaces and reversing the adjacent rapidity order. Thus the elementary maps T_i are morphisms in the groupoid whose objects are rapidity chambers and whose arrows are paths crossing walls. A consistent factorized scattering theory requires this groupoid representation to be path independent on the complement of the declared threshold and bound-state singular loci.

Proposition 71.7 (Scattering-chamber consistency)**.** *Let $S_{ab}^{cd}(\theta)$ be an elastic factorized scattering system. Away from poles and coincident rapidities, the adjacent chamber maps T_i define a path-independent representation of the chamber groupoid if and only if the two-particle unitarity identities and the Yang–Baxter equation hold.*

Proof. The chamber groupoid for ordered points on the line is generated by adjacent wall crossings. Its local relations are:

$$\mathsf{T}_i^2=1,\qquad \mathsf{T}_i\mathsf{T}_j=\mathsf{T}_j\mathsf{T}_i\quad(|i-j|>1),\qquad \mathsf{T}_i\mathsf{T}_{i+1}\mathsf{T}_i=\mathsf{T}_{i+1}\mathsf{T}_i\mathsf{T}_{i+1}.$$

The first relation is exactly two-particle unitarity,

$$S_{ab}(\theta)S_{ba}(-\theta)=\mathrm{id},$$

written in components as the identity in Definition 71.4. The second relation holds because disjoint adjacent crossings act on disjoint tensor factors. For three adjacent rapidities $\theta_1 > \theta_2 > \theta_3$, the two reduced paths from the chamber (123) to the chamber (321) give

$$S_{12}(\theta_{12})S_{13}(\theta_{13})S_{23}(\theta_{23}) \quad \text{and} \quad S_{23}(\theta_{23})S_{13}(\theta_{13})S_{12}(\theta_{12}),$$

respectively. Equality is precisely the Yang–Baxter equation. These local relations present the chamber groupoid away from the excluded diagonals and singular loci, so unitarity plus Yang–Baxter gives path independence. Conversely, path independence around the two local loops just described gives unitarity and the Yang–Baxter equation. □

71.4 Zamolodchikov–Faddeev Operators

The factorized scattering system becomes an operator algebra on asymptotic wavefunctions. For each species a introduce distributional creation operators $Z_a^\dagger(\theta)$ obeying

$$Z_a^\dagger(\theta_1)Z_b^\dagger(\theta_2) = S_{ab}^{cd}(\theta_1 - \theta_2)\, Z_d^\dagger(\theta_2)Z_c^\dagger(\theta_1), \qquad \theta_1 > \theta_2. \tag{71.1}$$

Repeated species labels are summed. These operator-valued distributions are a compact encoding of ordered asymptotic creation operators and their chamber-transition functions. Local fields enter through form factors and operator reconstruction below.

Associativity of the ZF creation algebra. Assume two-particle unitarity. The exchange rule (71.1) gives an associative algebra of ordered creation symbols, independent of the sequence of adjacent re-orderings, if and only if the Yang–Baxter equation in Definition 71.4 holds.

It is enough to compare the two ways of reordering three strictly ordered rapidities $\theta_1 > \theta_2 > \theta_3$. Starting from

$$Z_a^\dagger(\theta_1)Z_b^\dagger(\theta_2)Z_c^\dagger(\theta_3),$$

the reduced word which first moves the first rapidity past the second and then through the third gives the coefficient

$$S_{ab}^{a'b'}(\theta_{12})S_{a'c}^{a''c'}(\theta_{13})S_{b'c'}^{b''c''}(\theta_{23})$$

multiplying the final ordered product

$$Z_{c''}^\dagger(\theta_3)Z_{b''}^\dagger(\theta_2)Z_{a''}^\dagger(\theta_1).$$

The other reduced word gives the same final ordered product with coefficient

$$S_{bc}^{b'c'}(\theta_{23})S_{ac'}^{a'c''}(\theta_{13})S_{a'b'}^{a''b''}(\theta_{12}).$$

Equality of these coefficients for all external species is exactly the component form of the Yang–Baxter equation. The inverse adjacent move is well defined by two-particle unitarity, and disjoint moves commute because they involve disjoint creation symbols. Hence the braid relations are equivalent to associativity and sequence independence of the exchange algebra.

Definition 71.8 (S-symmetric finite-particle wavefunctions)**.** An N-particle S-symmetric wavefunction is a collection of functions

$$\psi_{a_1 \ldots a_N}(\theta_1, \ldots, \theta_N)$$

on rapidity chambers, square-integrable with respect to $\mathrm{d}\theta_1 \cdots \mathrm{d}\theta_N$ on compactly supported wave packets, whose boundary values across an adjacent chamber wall obey

$$\psi_{\ldots a_i a_{i+1} \ldots}(\ldots, \theta_i, \theta_{i+1}, \ldots) = S^{bc}_{a_i a_{i+1}}(\theta_i - \theta_{i+1})\, \psi_{\ldots cb \ldots}(\ldots, \theta_{i+1}, \theta_i, \ldots).$$

The finite-particle S-Fock space is obtained by imposing the L^2 positive inner product on compactly supported wavefunctions in one fundamental chamber, extending them to all chambers by the displayed relations, and completing the resulting pre-Hilbert space.

Well-defined chamber extension. If the two-body scattering system satisfies unitarity and the Yang–Baxter equation, then the chamber relations in Definition 71.8 determine the values of an S-symmetric wavefunction in every chamber from its value in one fundamental chamber, independently of the chosen adjacent-transposition path.

Crossing a wall that exchanges adjacent rapidities applies the adjoint two-body scattering matrix to the corresponding tensor factors. Two-particle unitarity makes this wall-crossing map invertible and implements $\mathsf{T}_i^2 = 1$. Wall crossings involving disjoint adjacent pairs act on disjoint tensor factors, hence commute. The only remaining ambiguity in a path through adjacent chambers is the braid move $\mathsf{T}_i \mathsf{T}_{i+1} \mathsf{T}_i = \mathsf{T}_{i+1} \mathsf{T}_i \mathsf{T}_{i+1}$, and this is exactly the Yang–Baxter equation for the three involved tensor factors. Therefore every word representing the same permutation gives the same continuation from the fundamental chamber.

71.5 Local Operators and Form Factors

Let $\mathcal{O}(x)$ be a local operator whose matrix elements between the vacuum and ordered out-states exist as distributions. Its n-particle form factor is

$$F^{\mathcal{O}}_{a_1 \ldots a_n}(\theta_1, \ldots, \theta_n) = \langle \Omega | \mathcal{O}(0) Z^\dagger_{a_1}(\theta_1) \cdots Z^\dagger_{a_n}(\theta_n) | \Omega \rangle, \qquad \theta_1 > \cdots > \theta_n.$$

Changing the ordered rapidity chamber changes the scattering basis by the two-body S-matrix.

Remark 71.9 (Watson exchange from ordered asymptotic bases)*.* For adjacent rapidities in a regular chamber, the form-factor boundary values obey

$$F^{\mathcal{O}}_{\ldots a_i a_{i+1} \ldots}(\ldots, \theta_i, \theta_{i+1}, \ldots) = S^{bc}_{a_i a_{i+1}}(\theta_i - \theta_{i+1})\, F^{\mathcal{O}}_{\ldots cb \ldots}(\ldots, \theta_{i+1}, \theta_i, \ldots),$$

with summation over b, c. This statement uses only the factorized scattering normalization of ordered asymptotic bases. The role of locality of $\mathcal{O}$ begins with the cyclicity and semi-locality conditions developed in Chapter 76.

Take the defining matrix element in the chamber $\theta_1 > \cdots > \theta_i > \theta_{i+1} > \cdots > \theta_n$. Applying the ZF exchange relation (71.1) to the adjacent pair gives

$$Z^\dagger_{a_i}(\theta_i) Z^\dagger_{a_{i+1}}(\theta_{i+1}) = S^{bc}_{a_i a_{i+1}}(\theta_i - \theta_{i+1})\, Z^\dagger_c(\theta_{i+1}) Z^\dagger_b(\theta_i).$$

Insert this identity between $\langle\Omega|\mathcal{O}(0)$ and $|\Omega\rangle$, leaving all other ordered creation operators fixed. The resulting matrix element on the right is exactly the boundary value in the neighboring chamber with the adjacent rapidities interchanged. This gives the displayed Watson equation. No commutation of $\mathcal{O}$ through the ZF operator has been used.

Together with Watson exchange, form-factor bootstrap uses crossing, cyclicity, and residue equations at bound-state poles. The exchange equation is a statement about boundary values in neighboring rapidity chambers and the normalization of ordered scattering states; locality of $\mathcal{O}$ enters only in those additional cyclicity and semi-locality conditions. The operator reconstruction problem is to determine which solutions of these functional equations come from genuine local operators in a Hilbert-space QFT. The theorem-boundary data include the local operator domain, positivity, convergence of form-factor expansions, and clustering.

Open Problem 71.10 (Completeness of form-factor reconstruction)*.* Give intrinsic hypotheses on a factorized scattering system and a family of form-factor solutions that imply the existence of a local QFT with those asymptotic particles, those local operators, and Wightman functions obtained by convergent form-factor sums. Existing constructive approaches prove this for important classes of two-dimensional models; the monograph will develop the exact hypotheses and examples in later chapters of this volume.

The factorized scattering chapter fixed the algebraic data of an integrable massive theory. This chapter adds the analytic data in the rapidity plane. The object studied here is an on-shell two-body scattering function together with analytic hypotheses. A local QFT realizing that function is a further object; its construction requires Hilbert-space, locality, and domain data.

72.1 Rapidity Plane and Physical Strip

For equal masses m, the two-particle Mandelstam invariant is

$$s(\theta) = 2m^2(1 + \cosh\theta) = 4m^2 \cosh^2\left(\frac{\theta}{2}\right).$$

The physical two-particle scattering line is $\theta \in \mathbb{R}$. The crossed channel is reached by $\theta \mapsto \mathrm{i}\pi - \theta$. Hence the natural analytic domain for a two-body amplitude is the physical strip

$$\mathcal{S}_{\mathrm{phys}} = \{\theta \in \mathbb{C} \mid 0 < \mathrm{Im}\,\theta < \pi\}.$$

For unequal masses m_a, m_b,

$$s_{ab}(\theta) = m_a^2 + m_b^2 + 2m_a m_b \cosh\theta,$$

and the same strip organizes the direct and crossed channels after the species labels are crossed.

Definition 72.1 (Factorized scattering bootstrap data)**.** Factorized scattering bootstrap data are an elastic factorized scattering system of Definition 71.4 together with the following extra data and hypotheses:

(i) meromorphic continuation of each component $S_{ab}^{cd}(\theta)$ to the physical strip $\mathcal{S}_{\mathrm{phys}}$;

(ii) a specified finite or locally finite list of simple-pole locations $\theta = \mathrm{i}u_{ab}^{e}$, $0 < u_{ab}^{e} < \pi$, labelled by proposed direct-channel bound-state species e;

(iii) finite-dimensional multiplicity spaces for these bound-state channels and intertwiners $\Gamma_{ab}^{e,\alpha}$ specifying residues;

(iv) horizontal-strip growth bounds stated as follows: for every closed substrip $K \subset \mathcal{S}_{\mathrm{phys}}$ whose distance from the declared pole set is positive, there are constants C_K, N_K such that

$$\|S_{ab}^{cd}(\theta)\| \leq C_K(1 + |\operatorname{Re}\theta|)^{N_K}, \qquad \theta \in K.$$

Near each declared simple pole the corresponding principal part is subtracted before applying this estimate. When a thermodynamic Bethe-ansatz kernel $\phi_{ab}(\theta) = -\mathrm{i}\partial_\theta \log S_{ab}(\theta)$ is used later, the datum must also specify the branch and the additional integrability hypothesis on ϕ_{ab}, usually $L^1(\mathbb{R})$ after removal of explicitly treated CDD or bound-state factors.

The growth condition in part (iv) is part of the datum, not a placeholder for later arguments. Stronger estimates may be imposed in form-factor or TBA applications, but any such strengthening is an additional hypothesis on top of the polynomial substrip bound displayed above.

The mass of a direct-channel bound state at $\theta = \mathrm{i}u_{ab}^{e}$ is fixed by the pole location:

$$m_e^2 = m_a^2 + m_b^2 + 2m_a m_b \cos u_{ab}^{e}.$$

Indeed, write the incoming momenta as

$$p_a(\theta_a) = m_a(\cosh\theta_a, \sinh\theta_a), \qquad p_b(\theta_b) = m_b(\cosh\theta_b, \sinh\theta_b),$$

with $\theta = \theta_a - \theta_b$. Then

$$-\big(p_a + p_b\big)^2 = m_a^2 + m_b^2 + 2m_a m_b \cosh(\theta_a - \theta_b) = m_a^2 + m_b^2 + 2m_a m_b \cosh\theta.$$

Analytic continuation to the pole $\theta = \mathrm{i}u_{ab}^{e}$ gives $\cosh(\mathrm{i}u_{ab}^{e}) = \cos u_{ab}^{e}$, hence the displayed formula. A one-particle vector of mass m_e in a Hilbert-space QFT is additional data to be constructed or assumed. The pole and residue record the on-shell criterion that such a vector would have to satisfy; a physical-strip pole with the wrong residue sign, or a pole related by crossing rather than the direct-channel residue, is not by itself a new stable direct-channel particle.

72.2 Residues and Fusion

Let V_a denote the internal one-particle space of species a. A simple pole at $\theta = \mathrm{i}u_{ab}^{e}$ is interpreted as a direct-channel bound-state pole only after one specifies a finite-dimensional multiplicity space M_{ab}^{e} and maps

$$\Gamma_{e,\alpha}^{ab} \colon V_e \longrightarrow V_a \otimes V_b, \qquad \Gamma_{ab}^{e,\alpha} \colon V_a \otimes V_b \longrightarrow V_e, \qquad \alpha \in M_{ab}^{e},$$

normalized by

$$\Gamma^{e,\alpha}_{ab}\Gamma^{ab}_{e,\beta} = \delta^\alpha{}_\beta\, \mathbf{1}_{V_e}.$$

With this convention the residue condition is the operator identity

$$-\mathrm{i} \operatorname*{Res}_{\theta=\mathrm{i}u^e_{ab}} S_{ab}(\theta) = \sum_{\alpha\in M^e_{ab}} \Gamma^{ab}_{e,\alpha}\Gamma^{e,\alpha}_{ab} \quad \text{on } V_a\otimes V_b. \tag{72.1}$$

In components this is the factorized residue formula with one map carrying the incoming ab-indices to the e-channel and the other carrying the e-channel back to outgoing ab-indices. Positivity of the Hilbert-space norm fixes the sign in (72.1) after the one-particle normalization has been chosen.

The fusing angles are not independent symbols. They are defined by the complex on-shell momentum identity

$$p_a(\theta+\mathrm{i}\bar u^b_{ae}) + p_b(\theta-\mathrm{i}\bar u^a_{be}) = p_e(\theta), \qquad \bar u^b_{ae}+\bar u^a_{be} = u^e_{ab}.$$

Equivalently,

$$m_a\sin\bar u^b_{ae} = m_b\sin\bar u^a_{be}, \qquad m_e = m_a\cos\bar u^b_{ae} + m_b\cos\bar u^a_{be}.$$

These equations are obtained by expanding the complex boosts:

$$\begin{aligned} p_a(\theta+\mathrm{i}\alpha)+p_b(\theta-\mathrm{i}\beta) = {}&\big(m_a\cos\alpha+m_b\cos\beta\big)(\cosh\theta,\sinh\theta)\\ &+\mathrm{i}\big(m_a\sin\alpha-m_b\sin\beta\big)(\sinh\theta,\cosh\theta), \end{aligned}$$

with $\alpha=\bar u^b_{ae}$ and $\beta=\bar u^a_{be}$. Equality to the real on-shell vector $p_e(\theta)$ forces the imaginary coefficient to vanish and the real coefficient to be m_e. Squaring this real coefficient then recovers the pole-location mass formula because

$$\begin{aligned} m_e^2 &= \big(m_a\cos\alpha+m_b\cos\beta\big)^2\\ &= m_a^2+m_b^2+2m_am_b\cos(\alpha+\beta), \end{aligned}$$

where the last step uses $m_a\sin\alpha=m_b\sin\beta$ to replace $m_a^2\sin^2\alpha+m_b^2\sin^2\beta$ by $2m_am_b\sin\alpha\sin\beta$. Thus the fusing-angle data are not extra kinematics beyond the pole location and the on-shell momentum identity; they are the component form of that identity.

Fusion is the compatibility condition between the residue projection (72.1) and scattering with an additional particle k. With the written composition convention that the rightmost map acts first, the bootstrap equation is the meromorphic identity

$$S_{ek}(\eta) = \sum_{\alpha\in M^e_{ab}} \Gamma^{e,\alpha}_{ab}\, S_{ak}(\eta+\mathrm{i}\bar u^b_{ae})\, S_{bk}(\eta-\mathrm{i}\bar u^a_{be})\, \Gamma^{ab}_{e,\alpha}, \qquad \eta=\theta-\theta_k.$$

The Yang–Baxter equation is the statement that fusing before or after an allowed adjacent reordering of three particles gives the same meromorphic operator.

Proposition 72.2 (Fusion identity as a residue identity)**.** *Assume that the three-particle scattering amplitude has meromorphic factorization on the rapidity chamber under consideration and that the pair (a,b) has a simple direct-channel pole at $\theta_a-\theta_b=\mathrm{i}u^e_{ab}$ with residue (72.1). Assume also that, on the small contour used below, no pole of the ak or bk two-body factors is met. Choose the bound-state rapidity θ so that the two constituent rapidities are*

$$\theta_a=\theta+\mathrm{i}\bar u^b_{ae}, \qquad \theta_b=\theta-\mathrm{i}\bar u^a_{be}, \qquad \bar u^b_{ae}+\bar u^a_{be}=u^e_{ab}.$$

Then the residue of the factorized three-particle amplitude at the (a,b)*-pole gives*

$$S_{ek}(\theta-\theta_k)=\sum_{\alpha\in M^e_{ab}}\Gamma^{e,\alpha}_{ab}\,S_{ak}(\theta-\theta_k+\mathrm{i}\bar u^b_{ae})\,S_{bk}(\theta-\theta_k-\mathrm{i}\bar u^a_{be})\,\Gamma^{ab}_{e,\alpha}$$

as an identity on the bound-state sector, after the one-particle normalization used in the residue has been fixed. If the multiplicity space has dimension greater than one, the displayed expression is the trace over the chosen residue basis; equivalently one may keep the corresponding matrix-valued $S^{\alpha\beta}_{ek}$*.*

Proof. Put

$$\eta=\theta-\theta_k,\qquad \zeta=\theta_a-\theta_b,$$

and, near the pole $\zeta=\mathrm{i}u^e_{ab}$, parametrize the two constituent rapidities by

$$\theta_a(\zeta)=\theta+\mathrm{i}\bar u^b_{ae}+\frac{\zeta-\mathrm{i}u^e_{ab}}{2},\qquad \theta_b(\zeta)=\theta-\mathrm{i}\bar u^a_{be}-\frac{\zeta-\mathrm{i}u^e_{ab}}{2}.$$

Thus $\theta_a(\zeta)-\theta_b(\zeta)=\zeta$, while at the pole the two continued momenta add to $p_e(\theta)$. Choose a small positively oriented circle C_e around $\mathrm{i}u^e_{ab}$ on which no singularity of the factors $S_{ak}(\theta_a(\zeta)-\theta_k)$ or $S_{bk}(\theta_b(\zeta)-\theta_k)$ is encountered. The pole extraction is the contour operation

$$-\mathrm{i}\operatorname*{Res}_{\zeta=\mathrm{i}u^e_{ab}}A(\zeta)=-\frac{\mathrm{i}}{2\pi\mathrm{i}}\oint_{C_e}A(\zeta)\,d\zeta.$$

In the unresolved three-particle channel, factorization gives a meromorphic amplitude of the form

$$A_{ab|k}(\zeta)=S_{ak}(\theta_a(\zeta)-\theta_k)\,S_{bk}(\theta_b(\zeta)-\theta_k)\,S_{ab}(\zeta),$$

up to the common convention of writing operators in the order in which they act. The first two factors are holomorphic inside C_e. Hence Cauchy's residue theorem and (72.1) give

$$-\mathrm{i}\operatorname*{Res}_{\zeta=\mathrm{i}u^e_{ab}}A_{ab|k}(\zeta)=S_{ak}(\eta+\mathrm{i}\bar u^b_{ae})\,S_{bk}(\eta-\mathrm{i}\bar u^a_{be})\sum_\alpha\Gamma^{ab}_{e,\alpha}\Gamma^{e,\alpha}_{ab}.$$

Project this residue onto a fixed bound-state multiplicity component by applying $\Gamma^{e,\alpha}_{ab}$ on the outgoing ab-pair and $\Gamma^{ab}_{e,\alpha}$ on the incoming e-channel. Using $\Gamma^{e,\alpha}_{ab}\Gamma^{ab}_{e,\beta}=\delta^\alpha{}_\beta\mathbf{1}_{V_e}$, the unresolved residue becomes

$$\Gamma^{e,\alpha}_{ab}\,S_{ak}(\eta+\mathrm{i}\bar u^b_{ae})\,S_{bk}(\eta-\mathrm{i}\bar u^a_{be})\,\Gamma^{ab}_{e,\alpha}.$$

The same contour, evaluated after resolving the pole as a one-particle intermediate state, is by definition the scattering amplitude $S^{(\alpha)}_{ek}(\eta)$ of that bound-state component with k. Since both calculations are residues of the same meromorphic three-particle amplitude and no other singularity crossed the contour, the two expressions are equal. Summing over the multiplicity basis gives the displayed fusion identity. The proof uses only meromorphic factorization, the residue normalization, and the existence of the one-particle e-channel; it does not use an off-shell Lagrangian. □

The noncommuting algebra in this residue step is finite-dimensional. If $P_e=\sum_\alpha\Gamma^{ab}_{e,\alpha}\Gamma^{e,\alpha}_{ab}$ and

$$S_{ab}(\zeta)=\frac{\mathrm{i}P_e}{\zeta-\mathrm{i}u^e_{ab}}+S^{\mathrm{reg}}_{ab}(\zeta),\qquad B(\zeta)=S_{ak}(\theta_a(\zeta)-\theta_k)S_{bk}(\theta_b(\zeta)-\theta_k),$$

with B holomorphic on C_e, then

$$-\mathrm{i} \operatorname*{Res}_{\zeta=\mathrm{i}u_{ab}^e} B(\zeta)S_{ab}(\zeta) = B(\mathrm{i}u_{ab}^e)P_e.$$

Projecting to the resolved bound-state coordinate gives

$$\Gamma_{ab}^{e,\alpha}B(\mathrm{i}u_{ab}^e)P_e\Gamma_{e,\beta}^{ab} = \Gamma_{ab}^{e,\alpha}B(\mathrm{i}u_{ab}^e)\Gamma_{e,\beta}^{ab}.$$

Thus derivatives or regular coefficients of the ak and bk factors do not enter this simple-pole residue, while the sign in (72.1) fixes the sign of the fused amplitude. The companion script `calculation-checks/integrable_scattering_bootstrap_checks.py` checks this point in an exact rational finite-rank model with a nonorthogonal projection and noncommuting holomorphic scattering factor.

72.3 Minimal Solutions and CDD Factors

For diagonal scattering, where $S_{ab}^{cd}(\theta) = \delta_a^c\delta_b^d S_{ab}(\theta)$, unitarity and crossing become

$$S_{ab}(\theta)S_{ab}(-\theta) = 1, \qquad S_{ab}(\theta) = S_{\bar{a}b}(\mathrm{i}\pi - \theta).$$

A scalar meromorphic factor $C(\theta)$ satisfying the same two equations and having no assigned particle pole is a CDD factor. Thus the analytic constraints and the bound-state list determine the amplitude only after an additional growth or minimality condition is specified.

Definition 72.3 (Elementary scalar block)**.** For $x \in \mathbb{C}$, the elementary scalar block is

$$[x]_\theta = \frac{\sinh((\theta + \mathrm{i}\pi x)/2)}{\sinh((\theta - \mathrm{i}\pi x)/2)},$$

as a meromorphic function of θ.

This block is the basic unitary zero-pole pair used in diagonal bootstrap formulae. Products of such blocks place zeros and poles at prescribed locations. The bootstrap construction problem is to choose the product and possible CDD factors so that unitarity, crossing, physical-strip pole assignments, residue signs, and asymptotic bounds hold simultaneously.

Remark 72.4 (Elementary block algebra). The elementary scalar block satisfies

$$[x]_\theta[x]_{-\theta} = 1.$$

Its poles are

$$\theta = \mathrm{i}\pi x + 2\pi\mathrm{i}n, \qquad n \in \mathbb{Z},$$

and its zeros are

$$\theta = -\mathrm{i}\pi x + 2\pi\mathrm{i}n, \qquad n \in \mathbb{Z}.$$

For real $0 < x < 1$, the pole at $\theta = \mathrm{i}\pi x$ lies in the physical strip.

The displayed properties follow immediately from the zero set of $\sinh z$ and from $\sinh(-z) = -\sinh z$. The point worth keeping in the main text is the residue sign. At the physical-strip pole $\theta = \mathrm{i}\pi x$, $0 < x < 1$,

$$\operatorname*{Res}_{\theta=\mathrm{i}\pi x}[x]_\theta = 2\mathrm{i}\sin(\pi x), \qquad -\mathrm{i}\operatorname*{Res}_{\theta=\mathrm{i}\pi x}[x]_\theta = 2\sin(\pi x) > 0.$$

Thus a single block has the residue sign compatible with a direct-channel scalar bound-state pole in the convention (72.1). Crossing is a separate constraint. The elementary relation

$$[x]_{\mathrm{i}\pi-\theta} = -[1-x]_\theta$$

shows that the crossing-symmetric scalar pair

$$\mathcal{C}_x(\theta) := [x]_\theta[1-x]_\theta$$

is unitary and crossing invariant. For $0 < x < 1$ with $x \neq 1/2$, it has physical-strip poles at $\theta = \mathrm{i}\pi x$ and $\theta = \mathrm{i}\pi(1-x)$, but their residue signs are opposite:

$$-\mathrm{i}\operatorname*{Res}_{\theta=\mathrm{i}\pi x}\mathcal{C}_x(\theta) = -2\tan(\pi x), \qquad -\mathrm{i}\operatorname*{Res}_{\theta=\mathrm{i}\pi(1-x)}\mathcal{C}_x(\theta) = 2\tan(\pi x). \tag{72.2}$$

Equation (72.2) is a useful diagnostic: a CDD zero-pole pair can satisfy scalar unitarity and crossing while still failing the positivity sign for one of its physical-strip poles. The particle interpretation of a pole therefore uses the full residue datum, not only its position in the strip. The companion check `calculation-checks/integrable_scattering_bootstrap_checks.py` verifies the scalar-block identities and the two residue signs without printing the elementary hyperbolic cancellation in the chapter.

72.4 Hilbert-Space Boundary

The bootstrap data are on-shell information. A local QFT realization also requires a Hilbert space, Wightman distributions, local operator domains, and cluster properties. In constructive treatments of factorizing models, wedge- localized fields and modular localization provide one route from an admissible S-matrix to local algebras. The theorem boundary is precise: analyticity and pole data enter as hypotheses for constructing wedge operators and then proving that double-cone intersections are nontrivial.

Open Problem 72.5 (Bootstrap completeness for local algebras). Characterize the bootstrap data for which the resulting wedge-local construction has nontrivial local algebras, a unique vacuum, asymptotic completeness, and local fields whose form factors solve the equations of Chapter 71. This problem is the operator-algebraic completion of the on-shell bootstrap.

Chapter 73

Yang–Baxter Consistency and Internal Symmetry

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The two-body bootstrap data of Chapter 72 becomes a many-particle scattering theory only if different decompositions of the same multi-particle process agree. This chapter formulates that requirement as an identity of meromorphic maps on species spaces and explains how internal symmetry reduces the identity to scalar functions on irreducible channels.

Definition 73.1 (Internal two-body R-matrix specification)**.** An internal two-body R-matrix specification is a tuple

$$\mathfrak{R} = \big(\mathcal{I}, \{m_a, V_a\}_{a\in\mathcal{I}}, \{S_{ab}\}_{a,b\in\mathcal{I}}, \iota, \{C_a\}_{a\in\mathcal{I}}, \mathcal{A}, \{\rho_a\}_{a\in\mathcal{I}}\big)$$

with the following entries.

(i) $\mathcal{I}$ is the set of stable particle species, $m_a > 0$ is the mass of species a, and V_a is the finite-dimensional complex internal space carried by a one-particle state of species a.

(ii) $S_{ab}(\theta) : V_a \otimes V_b \to V_b \otimes V_a$ is a meromorphic two-body scattering map in the rapidity difference $\theta = \theta_a - \theta_b$. Its R-matrix representative is $R_{ab}(\theta) = P_{ab} S_{ab}(\theta)$, where $P_{ab} : V_b \otimes V_a \to V_a \otimes V_b$ is the ordinary flip.

(iii) $\iota : \mathcal{I} \to \mathcal{I}$ is the antiparticle involution, written $a \mapsto \bar{a}$, and $C_a : V_a^\vee \to V_{\bar{a}}$ fixes the crossing identification used to compare physical-strip boundary values.

(iv) $\mathcal{A}$ is an optional internal symmetry algebra or group, and ρ_a is its representation on V_a. The specification is $\mathcal{A}$-invariant when each $R_{ab}(\theta)$ belongs to $\mathrm{End}_{\mathcal{A}}(V_a \otimes V_b)$.

The specification is called a regular factorized scattering specification when, after undoing the flip in item (ii), it obeys the physical unitarity, real analyticity, crossing, residue, and growth requirements of Definition 72.1, and when the Yang–Baxter identity of (73.1) below holds as an identity of meromorphic maps on every triple species space. The terminology is deliberately on-shell: this specification is not a construction of local fields or local algebras.

73.1 Species Spaces and Two-Body Operators

Let $\mathfrak{R}$ be an internal two-body specification in the sense of Definition 73.1. The one-particle momentum variable of a particle of mass m_a is the rapidity θ, with

$$p_a(\theta) = m_a(\cosh\theta, \sinh\theta).$$

For ordered species a, b, a two-body scattering operator is a meromorphic map

$$S_{ab}(\theta) : V_a \otimes V_b \longrightarrow V_b \otimes V_a, \qquad \theta = \theta_a - \theta_b.$$

The codomain order is part of the definition: after scattering in one spatial dimension the outgoing ordered particles have exchanged their positions.

It is often convenient to compose S_{ab} with the ordinary flip $P_{ab} : V_b \otimes V_a \to V_a \otimes V_b$ and define

$$R_{ab}(\theta) = P_{ab}S_{ab}(\theta) : V_a \otimes V_b \longrightarrow V_a \otimes V_b.$$

The S-operator records physical ordering, while R records an endomorphism on a fixed tensor product. All equations below are stated in the R-matrix convention because the domains and codomains are then identical.

Regularity includes the inverse relation

$$R_{ab}(\theta)R_{ab}(-\theta) = \mathrm{id}_{V_a \otimes V_b}$$

on every common domain of holomorphy. This is the fixed-order version of two-body unitarity; the remaining physical constraints are the crossing and residue conditions imposed on S_{ab} before applying the flip.

73.2 Derivation of the Yang–Baxter Equation

Consider three particles with rapidities $\theta_1 > \theta_2 > \theta_3$ and species spaces $V_{a_1}, V_{a_2}, V_{a_3}$. Factorization asserts that the full three-particle scattering is a product of two-body scatterings. There are two reduced decompositions of the permutation reversing the order of the three particles:

$$(12)(23)(12) = (23)(12)(23).$$

The equality of the resulting linear maps on

$$V_{a_1} \otimes V_{a_2} \otimes V_{a_3}$$

is therefore the condition that factorized scattering be independent of the chosen reduced decomposition.

Write $\theta_{ij} = \theta_i - \theta_j$. Let R_{ij} denote the endomorphism R acting on the i-th and j-th tensor factors and as the identity on the remaining factor. Equality of the two decompositions is

$$R_{12}(\theta_{12})R_{13}(\theta_{13})R_{23}(\theta_{23}) = R_{23}(\theta_{23})R_{13}(\theta_{13})R_{12}(\theta_{12}).$$

Since $\theta_{13} = \theta_{12} + \theta_{23}$, this is the additive spectral-parameter Yang–Baxter equation

$$R_{12}(\theta)R_{13}(\theta + \phi)R_{23}(\phi) = R_{23}(\phi)R_{13}(\theta + \phi)R_{12}(\theta). \tag{73.1}$$

Three-particle consistency. For a regular two-body R-system, the factorized three-particle scattering operator is independent of the reduced decomposition of the three-particle permutation if and only if the Yang–Baxter equation holds as a meromorphic identity on every triple species space.

Each adjacent transposition is represented by the corresponding two-body operator with the rapidity difference of the two lines at the moment they cross. In the R-matrix convention this representation acts on a fixed tensor product. The two reduced decompositions of the longest element of the three-particle permutation group give exactly the two sides of the displayed Yang–Baxter equation. Thus independence of the decomposition gives the equation. Conversely, if the equation holds, the two possible three-particle factorizations define the same meromorphic map. The remaining relations of the permutation group are the inverse relation, supplied by unitarity, and commutation of disjoint transpositions, which is automatic because the operators act on disjoint tensor factors.

Many-particle consistency. For n ordered particles the longest permutation, and more generally every permutation, has many reduced words in the adjacent transpositions s_i. The only local moves relating reduced words in the symmetric group are

$$s_i s_j = s_j s_i \quad (|i - j| > 1), \qquad s_i s_{i+1} s_i = s_{i+1} s_i s_{i+1}.$$

The first move is represented by commuting operators on disjoint tensor factors. The second move is represented by (73.1) with the appropriate rapidity differences. Thus the Yang–Baxter identity is the local compatibility condition whose repeated use makes the full factorized n-body scattering map independent of the chosen reduced word. This argument uses only the Coxeter presentation of the symmetric group and the meromorphic identity (73.1); it does not use perturbation theory.

73.3 Spectral-Parameter Conventions and Classical Limit

The rapidity variable gives the additive convention: two-body amplitudes depend on $\theta_i - \theta_j$, and the middle argument in (73.1) is the sum $\theta + \phi$. In lattice-model and quantum-group conventions one often uses a multiplicative parameter

$$x = e^{\theta},$$

so that the same identity reads

$$R_{12}(x)R_{13}(xy)R_{23}(y) = R_{23}(y)R_{13}(xy)R_{12}(x).$$

The two forms are equivalent after choosing a logarithm on a simply connected domain avoiding the singularities of the meromorphic R-matrix. The choice matters in crossing formulas, because crossing shifts rapidities by imaginary half-periods; it does not change the algebraic content of the Yang–Baxter identity itself.

There is also a braid convention. If

$$\check{R}_{ab}(\theta) = S_{ab}(\theta) \quad \text{as a map } V_a \otimes V_b \to V_b \otimes V_a,$$

then the same consistency statement is a braid relation for maps whose codomains are reordered after each crossing. The $R = P\check{R}$ convention used in this chapter trades that geometric reordering for endomorphisms on a fixed tensor product. Confusing these two conventions is a common source of incorrect sign and argument order in component calculations.

Classical expansion. Suppose a family of solutions has a formal parameter $\hbar$ and admits an expansion

$$R_{ab}(\theta;\hbar) = \mathrm{id} + \hbar\, r_{ab}(\theta) + \hbar^2 q_{ab}(\theta) + O(\hbar^3)$$

as a meromorphic endomorphism of $V_a \otimes V_b$. Substitution into (73.1) gives no condition at order $\hbar$: both sides contain

$$r_{12}(\theta) + r_{13}(\theta+\phi) + r_{23}(\phi).$$

At order $\hbar^2$, the q-terms also cancel between the two sides, while the ordered products of the first-order terms give

$$[r_{12}(\theta), r_{13}(\theta+\phi)] + [r_{12}(\theta), r_{23}(\phi)] + [r_{13}(\theta+\phi), r_{23}(\phi)] = 0. \tag{73.2}$$

This is the spectral-parameter classical Yang–Baxter equation. It is a necessary condition for a classical r-matrix to be quantized into a factorized scattering R-matrix with the stated expansion. It is not, by itself, a sufficiency theorem: quantization also requires the higher $\hbar$-orders, analytic constraints, and the physical unitarity/crossing conditions of the scattering problem.

73.4 Internal Symmetry and Projector Decomposition

Let G be a group or Lie algebra acting on the species spaces by representations $\rho_a : G \to GL(V_a)$. Internal-symmetry invariance of the two-body scattering system means

$$R_{ab}(\theta)(\rho_a(g) \otimes \rho_b(g)) = (\rho_a(g) \otimes \rho_b(g))R_{ab}(\theta), \qquad g \in G.$$

Equivalently, $R_{ab}(\theta)$ is an element of

$$\mathrm{End}_G(V_a \otimes V_b),$$

the algebra of G-intertwiners. If

$$V_a \otimes V_b \simeq \bigoplus_\lambda M_{ab}^\lambda \otimes W_\lambda$$

is the decomposition into irreducible G-modules W_λ with multiplicity spaces M_{ab}^λ, then Schur's lemma gives

$$\mathrm{End}_G(V_a \otimes V_b) \simeq \bigoplus_\lambda \mathrm{End}(M_{ab}^\lambda).$$

If every multiplicity space is one-dimensional, the most general invariant R-matrix has the form

$$R_{ab}(\theta) = \sum_\lambda r_{ab}^\lambda(\theta) P_\lambda,$$

where P_λ is the projector onto the irreducible channel λ, and r_{ab}^λ is a scalar meromorphic function.

Example 73.2 (Vector representation of $O(N)$)**.** Let $V = \mathbb{C}^N$ be the vector representation of $O(N)$. The tensor product decomposes as

$$V \otimes V = \mathbf{1} \oplus \Lambda^2 V \oplus \mathrm{Sym}_0^2 V.$$

An $O(N)$-invariant two-body R-matrix without multiplicity mixing is therefore

$$R(\theta) = r_0(\theta)P_0 + r_A(\theta)P_A + r_T(\theta)P_T,$$

with projectors onto the singlet, antisymmetric, and traceless-symmetric channels. The Yang–Baxter equation becomes a coupled system of functional equations for r_0, r_A, r_T, together with the analytic constraints of the bootstrap data.

73.5 Algebraic Origin of the Matrix Identity

The Yang–Baxter equation can be produced from an algebraic object before any scattering interpretation is imposed. Let $\mathcal{A}$ be an associative algebra with coproduct

$$\Delta : \mathcal{A} \longrightarrow \mathcal{A} \otimes \mathcal{A}$$

and opposite coproduct $\Delta^{\mathrm{op}} = \tau \circ \Delta$, where τ is the tensor flip. A universal R-element $\mathcal{R}$ is an invertible element of a suitable completion of $\mathcal{A} \otimes \mathcal{A}$ satisfying

$$\mathcal{R}\,\Delta(x) = \Delta^{\mathrm{op}}(x)\,\mathcal{R}, \qquad x \in \mathcal{A},$$

and

$$(\Delta \otimes \mathrm{id})(\mathcal{R}) = \mathcal{R}_{13}\mathcal{R}_{23}, \qquad (\mathrm{id} \otimes \Delta)(\mathcal{R}) = \mathcal{R}_{13}\mathcal{R}_{12}.$$

Then $\mathcal{R}$ obeys the algebraic Yang–Baxter identity

$$\mathcal{R}_{12}\mathcal{R}_{13}\mathcal{R}_{23} = \mathcal{R}_{23}\mathcal{R}_{13}\mathcal{R}_{12}. \tag{73.3}$$

Indeed,

$$\mathcal{R}_{12}\mathcal{R}_{13}\mathcal{R}_{23} = \mathcal{R}_{12}(\Delta \otimes \mathrm{id})(\mathcal{R}) = (\Delta^{\mathrm{op}} \otimes \mathrm{id})(\mathcal{R})\mathcal{R}_{12} = \mathcal{R}_{23}\mathcal{R}_{13}\mathcal{R}_{12}.$$

The middle equality is the intertwining relation applied in the first two tensor factors to each tensor component of $\mathcal{R}$. Applying representations $\rho_a \otimes \rho_b \otimes \rho_c$ gives an ordinary matrix solution on $V_a \otimes V_b \otimes V_c$.

For scattering, this algebraic mechanism is only a source of candidate matrix parts. One must still provide the rapidity dependence, scalar CDD factors, physical-strip pole interpretation, crossing identification, and Hilbert-space realization. The algebraic equation (73.3) explains why families such as rational, trigonometric, and elliptic R-matrices appear repeatedly; it does not replace the QFT construction problem.

73.6 Boundaries and Reflection Consistency

On a half-line or in the presence of a reflecting boundary, a one-particle reflection matrix $K_a(\theta) : V_a \to V_a$ must be compatible with the same bulk R-matrix. For two particles with rapidities θ_1, θ_2, there are two ways to move both particles to the boundary, reflect them, and restore the order. Equality of the two maps on $V_{a_1} \otimes V_{a_2}$ gives the boundary Yang–Baxter equation

$$R_{12}(\theta_1 - \theta_2)K_1(\theta_1)R_{21}(\theta_1 + \theta_2)K_2(\theta_2) = K_2(\theta_2)R_{12}(\theta_1 + \theta_2)K_1(\theta_1)R_{21}(\theta_1 - \theta_2). \tag{73.4}$$

Here $R_{21} = P_{12}R_{12}P_{12}$, and K_i acts on the i-th tensor factor. The argument $\theta_1 + \theta_2$ occurs because after one reflection the second collision is between rapidities of opposite sign. Boundary integrability therefore requires more than choosing a bulk factorized R-matrix; it requires reflection data satisfying (73.4), boundary unitarity, boundary crossing, and a boundary pole interpretation. Those additional analytic requirements are the boundary analogue of the bulk bootstrap constraints.

73.7 What the Equation Enforces

The Yang–Baxter equation is the compatibility condition for factorized multi-particle on-shell scattering. It does not by itself construct local operator algebras, form factors, or a Hilbert-space QFT. The next chapter adds the form-factor problem, where local operators are represented by meromorphic functions satisfying exchange, crossing, residue, and growth conditions.

Open Problem 73.3 (From R-matrices to local fields)*.* Given a meromorphic R-system satisfying unitarity, crossing, the Yang–Baxter equation, residue positivity, and stated growth bounds, construct or obstruct a local QFT realization. The construction must identify a Hilbert space, wedge-local or local algebras, form factors of a dense set of local operators, and the topology in which locality and clustering are verified.

Chapter 73 derived the Yang–Baxter equation as the condition that factorized three-particle scattering be independent of the chosen reduced decomposition. This chapter develops the finite-dimensional algebraic consequence needed for non-diagonal finite-volume spectra. The input is an R-matrix satisfying the Yang–Baxter equation. The output is a commuting family of transfer matrices and, in the rational $SU(2)$ case, explicit Bethe equations for their simultaneous eigenvectors.

74.1 Auxiliary Space, Quantum Space, and Monodromy

Let $V \simeq \mathbb{C}^d$ be a finite-dimensional complex vector space. In spin chains V is the one-site Hilbert space. In finite-volume integrable QFT it is the internal species space transported through a sequence of two-body scatterings. Let

$$R(u) \in \mathrm{End}(V \otimes V), \qquad u \in \mathbb{C},$$

be a meromorphic endomorphism. The parameter u is called the spectral parameter. For three tensor factors, $R_{ij}(u)$ denotes $R(u)$ acting on the i-th and j-th factors and the identity on the remaining factor. The Yang–Baxter equation is

$$R_{12}(u-v)R_{13}(u-w)R_{23}(v-w) = R_{23}(v-w)R_{13}(u-w)R_{12}(u-v). \tag{74.1}$$

Fix a chain length L. The quantum space is

$$\mathcal{H}_L = V_1 \otimes \cdots \otimes V_L, \qquad V_j \simeq V.$$

An additional copy $V_0 \simeq V$ is called the auxiliary space. For complex inhomogeneities $\xi_1, \ldots, \xi_L$, define the monodromy matrix

$$T_0(u) = R_{0L}(u - \xi_L) \cdots R_{02}(u - \xi_2) R_{01}(u - \xi_1) \in \mathrm{End}(V_0 \otimes \mathcal{H}_L). \tag{74.2}$$

The order is part of the convention. A different order conjugates or relabels later formulae but does not change the transfer-matrix commutativity argument.

Proposition 74.1 (RTT relation)**.** *Assume $R(u)$ satisfies (74.1). Let V_0 and $V_{0'}$ be two auxiliary copies of V. Then*

$$R_{00'}(u - v) T_0(u) T_{0'}(v) = T_{0'}(v) T_0(u) R_{00'}(u - v) \tag{74.3}$$

as meromorphic endomorphisms of $V_0 \otimes V_{0'} \otimes \mathcal{H}_L$.

Proof. Write

$$T_0(u) T_{0'}(v) = \prod_{j=L}^{1} R_{0j}(u - \xi_j) \prod_{j=L}^{1} R_{0'j}(v - \xi_j),$$

where products decrease in j. The Yang–Baxter equation applied to $V_0 \otimes V_{0'} \otimes V_j$ gives

$$R_{00'}(u - v) R_{0j}(u - \xi_j) R_{0'j}(v - \xi_j) = R_{0'j}(v - \xi_j) R_{0j}(u - \xi_j) R_{00'}(u - v).$$

Operators with distinct quantum labels commute unless they share an auxiliary factor. Move $R_{00'}(u - v)$ successively through the pair $R_{0j}(u - \xi_j) R_{0'j}(v - \xi_j)$ for $j = L, L - 1, \ldots, 1$. After the last move all $R_{0'j}$ factors stand to the left of all R_{0j} factors in the order defining $T_{0'}(v) T_0(u)$, and the auxiliary $R_{00'}(u - v)$ stands at the right. This is (74.3). □

74.2 Commuting Transfer Matrices

The transfer matrix is the auxiliary trace of the monodromy:

$$t(u) = \mathrm{tr}_{V_0} T_0(u) \in \mathrm{End}(\mathcal{H}_L). \tag{74.4}$$

The trace is the ordinary finite-dimensional trace on V_0. No trace is taken over $\mathcal{H}_L$.

Proposition 74.2 (Transfer-matrix commutativity)**.** *Assume $R(u)$ satisfies the Yang–Baxter equation and is invertible for generic u. Then, for all u, v in the common domain of meromorphy,*

$$[t(u), t(v)] = 0.$$

Proof. The trace in (74.4) is a partial trace. If

$$X \in \mathrm{End}(V_0 \otimes V_{0'} \otimes \mathcal{H}_L),$$

then $\mathrm{tr}_{0,0'} X$ is the unique endomorphism of $\mathcal{H}_L$ satisfying

$$\mathrm{tr}_{\mathcal{H}_L}\big(Y \ \mathrm{tr}_{0,0'} X\big) = \mathrm{tr}_{0,0',\mathcal{H}_L}\big((1_{0,0'} \otimes Y) X\big)$$

for finite-rank test operators Y on $\mathcal{H}_L$. In components this definition preserves the order of the quantum-space endomorphisms, so

$$t(u)t(v) = \mathrm{tr}_{0,0'}(T_0(u)T_{0'}(v)), \qquad t(v)t(u) = \mathrm{tr}_{0,0'}(T_{0'}(v)T_0(u)).$$

The proof therefore uses cyclicity only in the finite auxiliary trace, never cyclicity in the quantum space.

On the open set where $R_{00'}(u-v)$ is invertible, the RTT relation gives

$$T_0(u)T_{0'}(v) = R_{00'}(u-v)^{-1}T_{0'}(v)T_0(u)R_{00'}(u-v).$$

Since $R_{00'}(u-v)$ acts trivially on $\mathcal{H}_L$, it may be moved cyclically inside the finite trace over $V_0 \otimes V_{0'}$:

$$\begin{aligned} t(u)t(v) &= \mathrm{tr}_{0,0'}(T_0(u)T_{0'}(v)) \\ &= \mathrm{tr}_{0,0'}\big(R_{00'}(u-v)^{-1}T_{0'}(v)T_0(u)R_{00'}(u-v)\big) \\ &= \mathrm{tr}_{0,0'}(T_{0'}(v)T_0(u)) = t(v)t(u). \end{aligned}$$

Both sides are meromorphic $\mathrm{End}(\mathcal{H}_L)$-valued functions of u, v. The complement of the auxiliary invertibility locus is a proper analytic subset, so equality on the nonempty open invertibility domain extends as a meromorphic identity on the common domain of meromorphy. □

The proposition is the algebraic source of the conservation laws used in integrable finite-volume problems. Expanding $t(u)$ or $\log t(u)$ around a regular point gives commuting operators. Which one is the Hamiltonian is a choice of representation and normalization, not part of the Yang–Baxter equation alone.

74.3 The Rational SU(2) R-Matrix

Let $V = \mathbb{C}^2$ with basis $|\uparrow\rangle, |\downarrow\rangle$, and let $P \in \mathrm{End}(V \otimes V)$ be the flip

$$P(x \otimes y) = y \otimes x.$$

The rational $SU(2)$ R-matrix in the normalization used below is

$$R(u) = u\,\mathrm{id}_{V\otimes V} + \mathrm{i}P.$$

It is $SU(2)$-invariant and satisfies the Yang–Baxter equation. One direct verification uses only

$$P_{ij}^2 = 1, \qquad P_{12}P_{23}P_{12} = P_{23}P_{12}P_{23},$$

and the commutativity of disjoint flips; expanding both sides of (74.1) gives identical words in the symmetric group algebra of S_3.

For the homogeneous spin chain it is convenient to use the shifted local operator

$$L_{0j}(u) = R_{0j}\left(u - \frac{\mathrm{i}}{2}\right) = \left(u - \frac{\mathrm{i}}{2}\right)\mathrm{id} + \mathrm{i}P_{0j}.$$

The monodromy is

$$T_0(u) = L_{0L}(u)\cdots L_{01}(u).$$

Relative to the auxiliary basis, write

$$T_0(u) = \begin{pmatrix} A(u) & B(u) \\ C(u) & D(u) \end{pmatrix},$$

where A, B, C, D are operators on $\mathcal{H}_L$. The ferromagnetic reference vector is

$$\Omega_L = |\uparrow\rangle^{\otimes L}.$$

The local triangular form of $L_{0j}(u)$ on $|\uparrow\rangle_j$ gives

$$C(u)\Omega_L = 0, \qquad A(u)\Omega_L = \left(u + \frac{\mathrm{i}}{2}\right)^L \Omega_L, \qquad D(u)\Omega_L = \left(u - \frac{\mathrm{i}}{2}\right)^L \Omega_L.$$

74.4 Creation Operators and Bethe Equations

The RTT relation gives commutation relations among A, B, C, D. The relations needed to compute $t(u) = A(u) + D(u)$ on a Bethe vector are

$$B(u)B(v) = B(v)B(u), \tag{74.5}$$

$$A(u)B(v) = \frac{u - v - \mathrm{i}}{u - v} B(v)A(u) + \frac{\mathrm{i}}{u - v} B(u)A(v), \tag{74.6}$$

$$D(u)B(v) = \frac{u - v + \mathrm{i}}{u - v} B(v)D(u) - \frac{\mathrm{i}}{u - v} B(u)D(v). \tag{74.7}$$

The signs in (74.6)–(74.7) are tied to the convention $T_0(u) = \left(\begin{smallmatrix} A & B \\ C & D \end{smallmatrix}\right)$, $R(u) = u\,1 + \mathrm{i}P$, and $L(u) = R(u - \mathrm{i}/2)$. In this convention B lowers one spin relative to the ferromagnetic vector, $A(u)\Omega_L = (u + \mathrm{i}/2)^L \Omega_L$, and $D(u)\Omega_L = (u - \mathrm{i}/2)^L \Omega_L$. For a single site the relations reduce to

$$A(u)B = (u - \mathrm{i}/2)B, \qquad BA(u) = (u + \mathrm{i}/2)B,$$

and similarly $D(u)B = (u + \mathrm{i}/2)B$, $BD(u) = (u - \mathrm{i}/2)B$; this one-site check already fixes the displayed signs. For general L the same relations are the component form of RTT, obtained by inserting auxiliary matrix units $E^{(0)}_{ab} E^{(0')}_{cd}$ in (74.3) and comparing the corresponding $\mathrm{End}(\mathcal{H}_L)$-valued coefficients. The apparent poles at $u = v$ are not singularities of the operator identity after multiplication by $u - v$; they encode the rational R-matrix normalization. For complex numbers $u_1, \ldots, u_M$, define

$$|u_1, \ldots, u_M\rangle = B(u_1) \cdots B(u_M)\Omega_L.$$

Theorem 74.3 (Algebraic Bethe ansatz for the $XXX_{1/2}$ chain)**.** *Suppose the numbers $u_1, \ldots, u_M$ are distinct and satisfy*

$$\left(\frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2}\right)^L = \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k + \mathrm{i}}{u_j - u_k - \mathrm{i}}, \qquad j = 1, \ldots, M. \tag{74.8}$$

Then $|u_1, \ldots, u_M\rangle$, if nonzero, is an eigenvector of $t(u)$ with eigenvalue

$$\Lambda(u) = \left(u + \frac{\mathrm{i}}{2}\right)^L \prod_{j=1}^{M} \frac{u - u_j - \mathrm{i}}{u - u_j} + \left(u - \frac{\mathrm{i}}{2}\right)^L \prod_{j=1}^{M} \frac{u - u_j + \mathrm{i}}{u - u_j}. \tag{74.9}$$

Proof. Let

$$a(u) = \left(u + \frac{\mathrm{i}}{2}\right)^L, \qquad d(u) = \left(u - \frac{\mathrm{i}}{2}\right)^L.$$

The exact normal-ordering identities needed below are

$$\begin{aligned} A(u) \prod_{k=1}^{M} B(u_k)\Omega_L &= a(u) \prod_{k=1}^{M} \frac{u - u_k - \mathrm{i}}{u - u_k} \prod_{k=1}^{M} B(u_k)\Omega_L \\ &\quad + \sum_{j=1}^{M} \frac{\mathrm{i}\, a(u_j)}{u - u_j} \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k - \mathrm{i}}{u_j - u_k} \left(B(u) \prod_{\substack{k=1 \\ k \neq j}}^{M} B(u_k)\Omega_L \right). \end{aligned} \tag{74.10}$$

$$\begin{aligned} D(u) \prod_{k=1}^{M} B(u_k)\Omega_L &= d(u) \prod_{k=1}^{M} \frac{u - u_k + \mathrm{i}}{u - u_k} \prod_{k=1}^{M} B(u_k)\Omega_L \\ &\quad - \sum_{j=1}^{M} \frac{\mathrm{i}\, d(u_j)}{u - u_j} \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k + \mathrm{i}}{u_j - u_k} \left(B(u) \prod_{\substack{k=1 \\ k \neq j}}^{M} B(u_k)\Omega_L \right). \end{aligned} \tag{74.11}$$

For $M = 1$ these are exactly (74.6) and (74.7) applied to Ω_L. The induction step moves $A(u)$, respectively $D(u)$, through the leftmost B-factor. The wanted part gives the first displayed product factor. The unwanted part changes the moving diagonal entry to $A(u_j)$, respectively $D(u_j)$, and the remaining B-factors are then passed only by wanted moves; if two unwanted moves are chosen in opposite orders, the two normally ordered terms cancel by the rational identity obtained from the same RTT component relation that gives $B(u)B(v) = B(v)B(u)$. Thus the induction produces exactly one replaced rapidity in the final normal form and no terms with two replaced rapidities.

Adding (74.10) and (74.11), the wanted terms give the eigenvalue in (74.9). The coefficient of

$$B(u) \prod_{\substack{k=1 \\ k \neq j}}^{M} B(u_k)\Omega_L$$

is

$$\frac{\mathrm{i}}{u - u_j} \left[\left(u_j + \frac{\mathrm{i}}{2}\right)^L \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k - \mathrm{i}}{u_j - u_k} - \left(u_j - \frac{\mathrm{i}}{2}\right)^L \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k + \mathrm{i}}{u_j - u_k} \right].$$

Vanishing of this coefficient is precisely (74.8). After these unwanted terms vanish, the displayed wanted term is the full action of $t(u)$. □

The Bethe equations also have a pole-cancellation interpretation. The right-hand side of (74.9) is written with apparent simple poles at $u = u_j$. The residue at $u = u_j$ vanishes exactly when (74.8) holds. Thus the Bethe equations make $\Lambda(u)$ a polynomial of degree L, as it must be because $t(u)$ is a polynomial operator.

74.5 Hamiltonian Normalization and Momentum

The periodic $XXX_{1/2}$ Hamiltonian in the normalization used by the calculation checks is

$$H_{XXX} = \sum_{j=1}^{L} (1 - P_{j,j+1}), \qquad P_{L,L+1} = P_{L,1}.$$

It is obtained from the logarithmic derivative of the transfer matrix at the regular point, up to an additive constant fixed by $H_{XXX}\Omega_L = 0$. For a Bethe vector satisfying (74.8),

$$E = \sum_{j=1}^{M} \frac{1}{u_j^2 + 1/4}, \qquad \mathrm{e}^{\mathrm{i}P_{\mathrm{tot}}} = \prod_{j=1}^{M} \frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2}. \tag{74.12}$$

For $M = 1$, set

$$\mathrm{e}^{\mathrm{i}p} = \frac{u + \mathrm{i}/2}{u - \mathrm{i}/2}.$$

Then $u = (1/2)\cot(p/2)$, the Bethe equation gives $\mathrm{e}^{\mathrm{i}pL} = 1$, and

$$E = 4 \sin^2 \frac{p}{2}.$$

74.6 Use in Relativistic Integrable QFT

In a relativistic two-dimensional integrable QFT with non-diagonal internal scattering, the R-matrix in the monodromy is the matrix part of the two-body S-matrix. A particle transported once around a circle scatters through every other particle. The resulting internal monodromy is a transfer matrix. Its eigenvalues replace the scalar product of phase shifts in the diagonal Bethe–Yang equation. The next chapter makes this statement explicit and then develops the nested equations that diagonalize the internal transfer matrix for $SU(N)$-type scattering.

Chapter 75

The algebraic Bethe ansatz of Chapter 74 diagonalizes a transfer matrix by turning the Yang–Baxter equation into commuting finite-dimensional operators. This chapter develops the higher-rank version needed for non-diagonal finite-volume scattering. The physical rapidities are fixed by Bethe–Yang quantization, while auxiliary Bethe roots diagonalize the internal transfer matrix. The auxiliary roots are not extra particles: they are spectral coordinates for the internal wavefunction of a multiparticle state.

75.1 Matrix Bethe–Yang Quantization

Let a massive integrable QFT have n stable particles with rapidities $\theta_1, \ldots, \theta_n$, masses m_{a_j}, and internal species spaces V_{a_j}. Write

$$\mathcal{V}_{\boldsymbol{a}} = V_{a_1} \otimes \cdots \otimes V_{a_n}.$$

For a chosen particle j, transporting it once around a spatial circle of circumference L produces the phase $\exp(\mathrm{i}m_{a_j} L \sinh\theta_j)$ and the ordered product of two-body scatterings through the other particles. In the R-matrix convention, this ordered product is an internal transfer matrix

$$\mathcal{T}_j(\theta_j \mid \theta_1, \ldots, \widehat{\theta}_j, \ldots, \theta_n) \in \mathrm{End}(\mathcal{V}_{\boldsymbol{a}}).$$

The hat means that θ_j is omitted from the list of spectator rapidities. The Yang–Baxter equation implies that the different $\mathcal{T}_j$'s commute on the common meromorphic domain after the ordering convention for identical particles has been fixed.

Definition 75.1 (Matrix Bethe–Yang state)**.** A finite-volume n-particle matrix Bethe–Yang state is a vector $\Psi \in \mathcal{V}_{\boldsymbol{a}}$ and rapidities $\theta_1, \ldots, \theta_n$ such that Ψ is a simultaneous eigenvector of all internal transfer matrices,

$$\mathcal{T}_j \Psi = \tau_j \Psi,$$

and

$$\exp\bigl(\mathrm{i} m_{a_j} L \sinh\theta_j\bigr)\, \tau_j = 1, \qquad j = 1, \ldots, n. \tag{75.1}$$

When the scattering is diagonal, τ_j is the product of scalar two-particle phases and (75.1) reduces to the Bethe–Yang equation in Chapter 77. In the non-diagonal case the eigenvalue τ_j is obtained by an auxiliary Bethe ansatz.

75.2 RTT Algebra and Yangian Evaluation Data

Let $V = \mathbb{C}^N$ and let $E_{ab} \in \mathrm{End}(V)$ be the elementary matrix with $E_{ab} e_c = \delta_{bc} e_a$. For the rational $SU(N)$ chain we use

$$R(u) = u\,\mathrm{id} + \mathrm{i}P, \qquad P = \sum_{a,b=1}^{N} E_{ab} \otimes E_{ba}.$$

The monodromy

$$T_0(u) = R_{0L}(u - \xi_L) \cdots R_{01}(u - \xi_1)$$

is written as

$$T_0(u) = \sum_{a,b=1}^{N} E^{(0)}_{ab} \otimes T_{ab}(u), \qquad T_{ab}(u) \in \mathrm{End}(\mathcal{H}_L),$$

where $\mathcal{H}_L = (\mathbb{C}^N)^{\otimes L}$. The RTT relation

$$R_{00'}(u - v) T_0(u) T_{0'}(v) = T_{0'}(v) T_0(u) R_{00'}(u - v)$$

is the defining finite-dimensional representation of the rational Yangian RTT algebra. Equivalently, the matrix entries obey the component relation

$$(u - v)[T_{ab}(u), T_{cd}(v)] = \mathrm{i}\bigl(T_{cb}(v) T_{ad}(u) - T_{cb}(u) T_{ad}(v)\bigr). \tag{75.2}$$

For $R(u) = u + \mathrm{i}P$, the operator identity RTT is equivalent to (75.2) for all $a, b, c, d = 1, \ldots, N$. Insert $P = \sum_{p,q} E^{(0)}_{pq} E^{(0')}_{qp}$ and $T_0(u) = \sum E^{(0)}_{ab} T_{ab}(u)$, $T_{0'}(v) = \sum E^{(0')}_{cd} T_{cd}(v)$ into RTT. The coefficient of $E^{(0)}_{ab} E^{(0')}_{cd}$ in the term proportional to $u - v$ is $(u - v)(T_{ab}(u) T_{cd}(v) - T_{cd}(v) T_{ab}(u))$. The coefficient in the permutation terms is $\mathrm{i}(T_{cb}(v) T_{ad}(u) - T_{cb}(u) T_{ad}(v))$. Equality of the coefficients is exactly (75.2), and the converse is obtained by summing these coefficient identities.

Expanding $T_{ab}(u)$ for large u gives level-zero and higher Yangian charges. For a finite chain the representation is not an additional postulate: it is the evaluation representation produced by the concrete monodromy above. The Yangian language is nevertheless useful because the nested roots are organized by the simple roots of $\mathfrak{sl}_N$, and the recursive auxiliary monodromy below is the same RTT construction applied to smaller residual color spaces.

75.3 Recursive Nested Monodromy

Choose the reference vector

$$\Omega_L = e_1^{\otimes L}.$$

With the shifted L-operator convention of Chapter 74,

$$T_{11}(u)\Omega_L = \left(u + \frac{\mathrm{i}}{2}\right)^L \Omega_L, \qquad T_{aa}(u)\Omega_L = \left(u - \frac{\mathrm{i}}{2}\right)^L \Omega_L \quad (a = 2, \ldots, N),$$

and the lower-left entries annihilate Ω_L. The first-level creation operators are the entries $B_\alpha(u) = T_{1,\alpha+1}(u)$, $\alpha = 1, \ldots, N-1$. A first-level Bethe vector has the form

$$\Psi^{(1)} = \sum_{\alpha_1,\ldots,\alpha_{M_1}=1}^{N-1} F^{\alpha_1\cdots\alpha_{M_1}}\, B_{\alpha_1}(u_1^{(1)}) \cdots B_{\alpha_{M_1}}(u_{M_1}^{(1)})\Omega_L.$$

The coefficient tensor F is not arbitrary. RTT relations among the B_α's show that exchanging two first-level roots acts on their color indices by the rational R-matrix on $\mathbb{C}^{N-1}$. Therefore the unwanted terms in the action of the full transfer matrix are controlled by an auxiliary $SU(N-1)$ transfer matrix on $(\mathbb{C}^{N-1})^{\otimes M_1}$. This is the origin of nesting.

Construction 75.2 (Nested auxiliary monodromy)**.** Let $V^{(r)} \simeq \mathbb{C}^{N-r}$ be the residual color space at nesting level r, with $r = 1, \ldots, N-1$. Put $M_0 = L$, and let $\{u_j^{(0)}\}$ denote the physical inhomogeneities in the spin-chain problem or the physical rapidities after conversion to the rational auxiliary variable. Given roots $\{u_j^{(r-1)}\}_{j=1}^{M_{r-1}}$, define the level-$r$ auxiliary monodromy by

$$T_0^{(r)}(u) = R_{0M_{r-1}}^{(N-r+1)}(u - u_{M_{r-1}}^{(r-1)}) \cdots R_{01}^{(N-r+1)}(u - u_1^{(r-1)}),$$

where $R^{(m)}(u) = u + \mathrm{i}P$ acts on $\mathbb{C}^m \otimes \mathbb{C}^m$. The level-$r$ transfer matrix is $t^{(r)}(u) = \operatorname{tr}_0 T_0^{(r)}(u)$. The roots $\{u_j^{(r)}\}_{j=1}^{M_r}$ are the Bethe roots used to diagonalize $t^{(r)}$ by the same pseudovacuum construction, now with residual rank smaller by one.

Theorem 75.3 (Recursive origin of the nested equations)**.** *For the rational fundamental $SU(N)$ chain with generic inhomogeneities and generic roots, the repeated construction 75.2 gives an eigenvector of the transfer matrix whenever the roots satisfy the pole-cancellation equations*

$$\left(\frac{u_j^{(r)} + \frac{\mathrm{i}}{2}\delta_{r1}}{u_j^{(r)} - \frac{\mathrm{i}}{2}\delta_{r1}}\right)^L = \prod_{s=1}^{N-1} \prod_{\substack{k=1 \\ (s,k)\neq(r,j)}}^{M_s} \frac{u_j^{(r)} - u_k^{(s)} + \frac{\mathrm{i}}{2}A_{rs}}{u_j^{(r)} - u_k^{(s)} - \frac{\mathrm{i}}{2}A_{rs}}, \tag{75.3}$$

where $A_{rs} = 2\delta_{rs} - \delta_{r,s+1} - \delta_{r,s-1}$ is the A_{N-1} Cartan matrix. The energy in the nearest-neighbor rational Hamiltonian normalization depends only on first-level roots:

$$E = \sum_{j=1}^{M_1} \frac{1}{(u_j^{(1)})^2 + 1/4}. \tag{75.4}$$

Proof. The proof is an induction on N. The case $N = 2$ is precisely Theorem 74.3: the transfer eigenvalue is meromorphic with possible simple poles at first-level roots, and the residue at $u = u_j^{(1)}$ vanishes exactly when the $SU(2)$ Bethe equation holds.

Assume the statement for residual rank $N-r$. At level r, the RTT commutation relations move the diagonal entries of $T^{(r)}(u)$ through the creation operators $B_\alpha^{(r)}(u_j^{(r)})$. The wanted term is the one in which no spectral parameter is exchanged. The unwanted terms replace one creation operator by $B_\alpha^{(r)}(u)$ and carry coefficients that are matrix elements of the next auxiliary transfer matrix $t^{(r+1)}$ on $(V^{(r+1)})^{\otimes M_r}$. By the induction hypothesis those matrix coefficients are diagonal exactly when the roots at levels $r+1,\dots,N-1$ obey their own pole-cancellation equations.

Only three kinds of factors can appear in the residue at a root $u_j^{(r)}$. First, exchanging $u_j^{(r)}$ with another root at the same level uses the two-body rational R-matrix on the same residual color space and contributes the shifts $\pm\mathrm{i}$, which are the entries $\pm\mathrm{i}A_{rr}/2$. Second, the next auxiliary transfer matrix contributes only adjacent Dynkin-node factors, because after one nesting step the root $u^{(r)}$ is an inhomogeneity for the $SU(N-r)$ residual problem; this gives the shifts $\mp\mathrm{i}/2$ for $s=r\pm1$, namely $\pm\mathrm{i}A_{rs}/2$. Third, the vacuum diagonal eigenvalues of the original monodromy enter only at $r=1$, giving the source factor $((u+\mathrm{i}/2)/(u-\mathrm{i}/2))^L$. Non-adjacent nodes correspond to commuting residual color sectors and give $A_{rs}=0$, hence the factor 1. Setting every residue to zero is exactly (75.3). The Hamiltonian is the logarithmic derivative of the first-level transfer matrix at the regular point, so the same calculation as in the $SU(2)$ case gives (75.4); auxiliary levels select the internal eigenvector but carry no direct nearest-neighbor energy. □

Expanding (75.3) gives the familiar displayed form

$$\begin{aligned}
\left(\frac{u_j^{(1)}+\mathrm{i}/2}{u_j^{(1)}-\mathrm{i}/2}\right)^L &= \prod_{\substack{k=1\\k\neq j}}^{M_1}\frac{u_j^{(1)}-u_k^{(1)}+\mathrm{i}}{u_j^{(1)}-u_k^{(1)}-\mathrm{i}}\prod_{k=1}^{M_2}\frac{u_j^{(1)}-u_k^{(2)}-\mathrm{i}/2}{u_j^{(1)}-u_k^{(2)}+\mathrm{i}/2},\\
1 &= \prod_{\substack{k=1\\k\neq j}}^{M_r}\frac{u_j^{(r)}-u_k^{(r)}+\mathrm{i}}{u_j^{(r)}-u_k^{(r)}-\mathrm{i}}\prod_{\sigma=\pm1}\prod_{k=1}^{M_{r+\sigma}}\frac{u_j^{(r)}-u_k^{(r+\sigma)}-\mathrm{i}/2}{u_j^{(r)}-u_k^{(r+\sigma)}+\mathrm{i}/2},\\
&\qquad\qquad r=2,\dots,N-2,\\
1 &= \prod_{\substack{k=1\\k\neq j}}^{M_{N-1}}\frac{u_j^{(N-1)}-u_k^{(N-1)}+\mathrm{i}}{u_j^{(N-1)}-u_k^{(N-1)}-\mathrm{i}}\prod_{k=1}^{M_{N-2}}\frac{u_j^{(N-1)}-u_k^{(N-2)}-\mathrm{i}/2}{u_j^{(N-1)}-u_k^{(N-2)}+\mathrm{i}/2}.
\end{aligned}\tag{75.5}$$

Products over an empty set are 1.

75.4 Dressed-Vacuum Transfer Eigenvalue

The nested equations are most useful when one keeps track of the transfer eigenvalue that produced them. We record the expression in a gauge in which the pole-cancellation calculation is transparent. Let

$$Q_r(u)=\prod_{j=1}^{M_r}(u-u_j^{(r)}),\qquad Q_0(u)=Q_N(u)=1,$$

and use the half-shift notation

$$f^{[k]}(u)=f\left(u+\frac{\mathrm{i}k}{2}\right).$$

For the homogeneous fundamental chain define

$$\phi_1(u) = (u + \mathrm{i})^L, \qquad \phi_a(u) = u^L \quad (a = 2, \ldots, N).$$

With a diagonal twist $g = \mathrm{diag}(g_1, \ldots, g_N)$ the fundamental transfer eigenvalue can be written, after an overall scalar normalization and a harmless shift of the spectral coordinate, as

$$\Lambda(u) = \sum_{a=1}^{N} g_a\, \phi_a(u)\, \frac{Q_{a-1}^{[a+1]}(u)}{Q_{a-1}^{[a-1]}(u)} \frac{Q_a^{[a-2]}(u)}{Q_a^{[a]}(u)}. \tag{75.6}$$

This is the dressed-vacuum form of the eigenvalue. The adjective means only that the vacuum diagonal eigenvalues ϕ_a are multiplied by rational "dressing" factors built from the Q-functions; it is not an additional physical vacuum.

Pole-cancellation derivation of the twisted nested equations. Assume the roots are generic and the twist eigenvalue ratios are finite. The meromorphic function (75.6) has no pole at the would-be pole associated with $u_j^{(r)}$ precisely when

$$\frac{g_r}{g_{r+1}} \frac{\phi_r(u_j^{(r)} - \frac{\mathrm{i}r}{2})}{\phi_{r+1}(u_j^{(r)} - \frac{\mathrm{i}r}{2})} = \prod_{s=1}^{N-1} \prod_{\substack{k=1 \\ (s,k)\neq(r,j)}}^{M_s} \frac{u_j^{(r)} - u_k^{(s)} + \frac{\mathrm{i}}{2} A_{rs}}{u_j^{(r)} - u_k^{(s)} - \frac{\mathrm{i}}{2} A_{rs}}. \tag{75.7}$$

For the untwisted homogeneous chain this reduces to (75.3). This is a residue calculation inside the dressed-vacuum formula, not an independent theorem: it is the local algebraic step that converts polynomiality of the transfer eigenvalue into the nested Bethe equations.

The root $u_j^{(r)}$ appears as a pole of $\Lambda(u)$ at the common point $u = u_j^{(r)} - \mathrm{i}r/2$ in precisely two neighboring summands, namely the $a = r$ and $a = r + 1$ summands. All other summands are regular there because their denominator Q-functions have different node labels. Multiplying the residue equation by the nonzero common factors gives

$$\begin{aligned} 0 = g_r \phi_r \frac{Q_{r-1}^{[r+1]}}{Q_{r-1}^{[r-1]}} Q_r^{[r-2]} \\ + g_{r+1} \phi_{r+1} Q_r^{[r+2]} \frac{Q_{r+1}^{[r-1]}}{Q_{r+1}^{[r+1]}} \end{aligned}$$

evaluated at $u = u_j^{(r)} - \mathrm{i}r/2$; the omitted common denominator is the same derivative $Q_r'(u_j^{(r)})$. Solving for the ratio of the two vacuum terms gives

$$\frac{g_r \phi_r}{g_{r+1} \phi_{r+1}} = -\frac{Q_r(u_j^{(r)} + \mathrm{i})}{Q_r(u_j^{(r)} - \mathrm{i})} \frac{Q_{r-1}(u_j^{(r)} - \mathrm{i}/2)}{Q_{r-1}(u_j^{(r)} + \mathrm{i}/2)} \frac{Q_{r+1}(u_j^{(r)} - \mathrm{i}/2)}{Q_{r+1}(u_j^{(r)} + \mathrm{i}/2)}.$$

The factor involving Q_r contains the root $u_j^{(r)}$ itself:

$$-\frac{Q_r(u_j^{(r)} + \mathrm{i})}{Q_r(u_j^{(r)} - \mathrm{i})} = \prod_{\substack{k=1 \\ k\neq j}}^{M_r} \frac{u_j^{(r)} - u_k^{(r)} + \mathrm{i}}{u_j^{(r)} - u_k^{(r)} - \mathrm{i}}.$$

Combining this same-node factor with the two adjacent-node factors is exactly the Cartan-matrix product in (75.7). For the homogeneous untwisted chain,

$$\frac{\phi_1(u_j^{(1)}-\mathrm{i}/2)}{\phi_2(u_j^{(1)}-\mathrm{i}/2)}=\left(\frac{u_j^{(1)}+\mathrm{i}/2}{u_j^{(1)}-\mathrm{i}/2}\right)^L,\qquad \frac{\phi_r}{\phi_{r+1}}=1\quad(r\geq 2),$$

which gives (75.3).

Formula (75.6) is often the cleanest way to compare the algebraic Bethe ansatz, functional TQ/QQ systems, and separation of variables. The finite-dimensional transfer matrix is polynomial after all pole residues vanish; polynomiality, not a separate appeal to a formal Bethe equation, is the algebraic reason the spectrum is well-defined.

75.5 Worked SU(3) Configuration

For $SU(3)$ there are first-level roots u_j and second-level roots v_α. The equations are

$$\left(\frac{u_j+\mathrm{i}/2}{u_j-\mathrm{i}/2}\right)^L=\prod_{\substack{k=1\\k\neq j}}^{M_1}\frac{u_j-u_k+\mathrm{i}}{u_j-u_k-\mathrm{i}}\prod_{\alpha=1}^{M_2}\frac{u_j-v_\alpha-\mathrm{i}/2}{u_j-v_\alpha+\mathrm{i}/2}, \tag{75.8}$$

$$1=\prod_{\substack{\beta=1\\\beta\neq\alpha}}^{M_2}\frac{v_\alpha-v_\beta+\mathrm{i}}{v_\alpha-v_\beta-\mathrm{i}}\prod_{j=1}^{M_1}\frac{v_\alpha-u_j-\mathrm{i}/2}{v_\alpha-u_j+\mathrm{i}/2}. \tag{75.9}$$

Set $L=6$, $M_1=2$, $M_2=1$,

$$u_1=-\frac{\sqrt{3}}{2},\qquad u_2=\frac{\sqrt{3}}{2},\qquad v_1=0.$$

Let

$$z=\frac{u_2+\mathrm{i}/2}{u_2-\mathrm{i}/2}=\mathrm{e}^{\mathrm{i}\pi/3}.$$

Then $z^6=1$. The second-level equation is

$$\frac{\sqrt{3}/2-\mathrm{i}/2}{\sqrt{3}/2+\mathrm{i}/2}\frac{-\sqrt{3}/2-\mathrm{i}/2}{-\sqrt{3}/2+\mathrm{i}/2}=z^{-1}z=1.$$

For the first root u_2, the right side of (75.8) is

$$\frac{2u_2+\mathrm{i}}{2u_2-\mathrm{i}}\frac{u_2-\mathrm{i}/2}{u_2+\mathrm{i}/2}=z\,z^{-1}=1,$$

and the left side is $z^6=1$. The equation for u_1 is the inverse of the same equality. The energy is $E=2$. This example is deliberately small: every phase can be checked exactly, and the second-level root is essential even though it carries no direct energy.

75.6 Trigonometric Nesting

The relativistic sine-Gordon and affine-Toda families use trigonometric matrix parts rather than the rational $R(u) = u + \mathrm{i}P$. A convenient $\mathfrak{sl}_N$ trigonometric normalization is

$$R_\eta(u) = \sinh(u+\eta)\sum_a E_{aa}\otimes E_{aa} + \sinh u \sum_{a\neq b} E_{aa}\otimes E_{bb} \\ + \sinh\eta \sum_{a\neq b} \mathrm{e}^{\mathrm{sgn}(a-b)u} E_{ab}\otimes E_{ba}.$$

It solves the Yang–Baxter equation and degenerates to the rational matrix after $u, \eta \to 0$ with u/η fixed, up to scalar normalization. The nested pole-cancellation equations become

$$\left(\frac{\sinh(u_j^{(r)} + \frac{\eta}{2}\delta_{r1})}{\sinh(u_j^{(r)} - \frac{\eta}{2}\delta_{r1})}\right)^L = \prod_{s=1}^{N-1} \prod_{\substack{k=1 \\ (s,k)\neq(r,j)}}^{M_s} \frac{\sinh(u_j^{(r)} - u_k^{(s)} + \frac{\eta}{2}A_{rs})}{\sinh(u_j^{(r)} - u_k^{(s)} - \frac{\eta}{2}A_{rs})}. \tag{75.10}$$

The proof is the same recursive RTT proof as Theorem 75.3, with rational functions replaced by hyperbolic functions. The scalar factor multiplying R_η is not fixed by the Yang–Baxter equation; in a relativistic QFT it is fixed separately by unitarity, crossing, bound-state residues, and normalization of asymptotic states.

75.7 Relativistic SU(N)-Symmetric Scattering

For a relativistic integrable QFT whose particles transform in a fundamental $SU(N)$ multiplet, the two-body S-matrix often factorizes as

$$S(\theta) = S_0(\theta)\,\widehat{R}(\theta),$$

where S_0 is a scalar meromorphic factor and $\widehat{R}$ is an $SU(N)$-invariant rational or trigonometric matrix normalized to satisfy unitarity and crossing in the physical rapidity variable θ. The finite-volume quantization separates into a scalar phase and a nested transfer-matrix eigenvalue:

$$mL\sinh\theta_j - \mathrm{i}\sum_{k\neq j}\log S_0(\theta_j - \theta_k) - \mathrm{i}\log\tau_j(\theta_1,\ldots,\theta_n;\{u^{(r)}\}) = 2\pi I_j. \tag{75.11}$$

The auxiliary roots $\{u^{(r)}\}$ obey rational or trigonometric equations of the form (75.3) or (75.10), with the map from physical rapidity θ to auxiliary spectral parameter determined by $\widehat{R}$. Changing this map by a meromorphic reparametrization changes the displayed coordinate form but not the transfer-matrix eigenvalue.

Controlled Approximation 75.4 (Large-volume Bethe–Yang regime)**.** Equation (75.11) is a large-L quantization condition for stable particles whose separations are much larger than the interaction range set by the mass gap. Corrections are exponentially small in mL for a massive theory without massless channels, provided no bound-state pole is pinched by the finite-volume contour. Power corrections and wrapping corrections require the TBA or mirror-channel formalism of later chapters.

75.8 Nested Strings and Thermodynamic Input

In a thermodynamic limit the roots of nested equations often organize into strings. In the rational normalization, an m-string at node r with real center x has the asymptotic form

$$u_\ell^{(r,m)} = x + \frac{\mathrm{i}}{2}(m + 1 - 2\ell) + \varepsilon_\ell(L), \qquad \ell = 1, \ldots, m, \tag{75.12}$$

with $\varepsilon_\ell(L) \to 0$ in the regime where the string hypothesis is valid. The string center becomes the variable in the thermodynamic density equations; the string length m and Dynkin node r become species labels.

Controlled Approximation 75.5 (Nested string hypothesis)**.** The replacement of finite-volume roots by exact string species is not a formal consequence of the Bethe equations alone. It is a model-dependent thermodynamic hypothesis requiring control of singular strings, deviations $\varepsilon_\ell(L)$, possible holes, and the order of limits. When used below, the input is: for the thermodynamic states under consideration, all roots not on real physical rapidity lines can be partitioned into families of the form (75.12), with deviations whose contribution to intensive free energy vanishes in the limit. This is the precise assumption that converts the finite nested Bethe equations into the multi-species TBA equations of Chapter 78.

75.9 Principal Chiral Model and Gross–Neveu Families

The $SU(N)$ principal chiral model has global $SU(N)_L \times SU(N)_R$ symmetry. Its massive particles carry left and right internal indices, so the matrix part of its scattering problem contains two nested $SU(N)$ systems, one for each chiral factor. Gross–Neveu families have a similar nested structure, with the details controlled by the vector, spinor, or fundamental representation carried by the particles. The Bethe equations therefore contain physical rapidities together with auxiliary roots attached to the Dynkin diagram of the relevant symmetry algebra.

The important conceptual point is that auxiliary roots are not additional particles in the Hilbert space. They parametrize the internal wavefunction of a multiparticle state. The energy and momentum are functions of the physical rapidities; the auxiliary roots enter by selecting the transfer-matrix eigenvalue that appears in the quantization condition.

75.10 Completeness and Its Precise Scope

Quoted Theorem 75.6 (Generic finite-chain completeness)**.** Proof references.[1] *For the inhomogeneous rational $SU(N)$ fundamental chain with a generic diagonal twist whose eigenvalue ratios are not roots of unity, and with generic inhomogeneities, the nested Bethe equations have a set of admissible solutions whose Bethe vectors form a basis of $(\mathbb{C}^N)^{\otimes L}$. The transfer-matrix spectrum is simple on a Zariski-open set of the twist and inhomogeneity parameters.*

[1] The algebraic nested Bethe vectors and higher transfer-matrix eigenvalues for rational $\mathfrak{gl}_N$ XXX-type models are developed in Mukhin–Tarasov–Varchenko [73]. Simple-spectrum and completeness results for XXX Bethe algebras are proved in the Mukhin–Tarasov–Varchenko and Tarasov works cited in [74, 75]. The formulation used here is the generic finite-chain theorem-boundary form: generic twist and inhomogeneity are hypotheses, not decorative parameters.

Mechanism and singular-limit boundary. The quoted theorem is a finite-dimensional algebraic theorem about the commutative Bethe algebra generated by transfer matrices. The generic parameters serve two purposes. First, they separate transfer-matrix eigenvalues: on the Zariski-open parameter set the joint spectrum is simple, so an eigenvector is determined by its eigenvalue data. Second, the inhomogeneities and twist remove the singular Bethe-root configurations that make the coordinate Bethe equations incomplete at special points. The proof strategy can be summarized as follows. The transfer matrices generate a commutative algebra whose joint eigenvalues are encoded by a rational difference operator or, equivalently, by Wronskian/Casoratian polynomial data. For generic parameters the relevant algebraic variety is reduced and has the dimension predicted by the representation space. Admissible Bethe solutions map to this variety, the Bethe vectors attached to distinct solutions have distinct joint eigenvalues, and dimension counting gives a basis. None of these steps is a thermodynamic statement; every step takes place at fixed finite chain length L.

The theorem is a finite-dimensional algebraic statement. It does not by itself prove completeness for the periodic homogeneous chain, because taking the twist to the identity and the inhomogeneities to equal values can create singular roots and degeneracies. It also does not prove that a continuum QFT finite-volume Hamiltonian is approximated by matrix Bethe–Yang equations. For continuum use we therefore separate three assertions:

algebraic completeness	basis theorem for a finite transfer matrix,
Bethe–Yang control	large-volume approximation to QFT levels,
thermodynamic control	existence of the density/string limit.

Each assertion has different hypotheses. The monograph uses the generic finite-chain theorem as an algebraic guide, but it states explicitly whenever periodic homogeneous completeness, continuum spectral control, or the string hypothesis is being assumed rather than proved.

75.11 Interface with Later Volumes

The relativistic integrable-QFT use of nested TBA differs from planar gauge-theory integrability. In the present volume, physical particles have relativistic dispersion $E = m\cosh\theta$ and finite-size effects are organized by the mirror channel of a two-dimensional QFT. In the planar $\mathcal{N} = 4$ SYM volume, magnons have a non-relativistic dispersion on a spin chain, wrapping effects arise from trace cyclicity and finite operator length, and the quantum spectral curve replaces the finite-rank Baxter polynomial by a system of analytic Q-functions. The algebraic bridge is the RTT, nested monodromy, TQ, QQ, and Hirota logic developed here and in Chapter 78; the physical interpretation is different.

Chapter 76

Form-Factor Bootstrap and Local Operators

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The scattering specification of Chapters 72 and 73 is on-shell. Local QFT contains more structure: local operator domains, Wightman distributions, and matrix elements of local fields between finite-particle states. In a massive two-dimensional theory with factorized scattering, the first operator-level object is the family of form factors.

Definition 76.1 (Local-operator form-factor structure)**.** Let $\mathfrak{R}$ be a regular factorized scattering datum in the sense of Definition 73.1. A local-operator form-factor structure over $\mathfrak{R}$ is a tuple

$$\mathfrak{F}_{\mathcal{O}} = \big(\widehat{\mathcal{O}}, \{F^{\mathcal{O}}_{a_1\ldots a_n}\}_{n\geq 0,\ a_i\in\mathcal{I}}, \{\omega_{\mathcal{O},a}\}_{a\in\mathcal{I}}, \mathcal{P}_{\mathrm{kin}}, \mathcal{P}_{\mathrm{bs}}, \mathcal{G}_{\mathcal{O}}\big)$$

with the following entries.

(i) $\widehat{\mathcal{O}}(f)$ is a scalar local or semi-local operator-valued distribution on a common dense scattering domain $\mathcal{D}_{\mathrm{scat}} \subset \mathcal{H}$, with vacuum $\Omega \in \mathcal{D}_{\mathrm{scat}}$. Semi-locality means that the exchange of $\widehat{\mathcal{O}}$ with a charged particle line may carry the monodromy specified in item (iii); ordinary locality is the special case with trivial monodromy for every species.

(ii) For every ordered species word $\mathbf{a} = (a_1, \ldots, a_n)$, $F^{\mathcal{O}}_{\mathbf{a}}$ is a meromorphic covector-valued function on the rapidity variables,

$$F^{\mathcal{O}}_{\mathbf{a}}(\theta_1, \ldots, \theta_n) \in \big(V_{a_1} \otimes \cdots \otimes V_{a_n}\big)^\vee,$$

whose physical real boundary value in the chamber $\theta_1 > \cdots > \theta_n$ equals the vacuum-to-in-state matrix element of $\widehat{\mathcal{O}}(0)$. The word $\mathbf{a}$ is part of the argument; when adjacent rapidities are analytically continued around one another, the corresponding species spaces are reordered by the scattering maps of $\mathfrak{R}$.

(iii) $\omega_{\mathcal{O},a} \in \mathbb{C}^\times$ is the semi-locality monodromy acquired when a particle of species a is analytically continued once around the insertion of $\mathcal{O}$. For a strictly local bosonic scalar operator all $\omega_{\mathcal{O},a}$ are 1; for order/disorder fields in two-dimensional examples the same symbol records the controlled failure of single-valuedness.

(iv) $\mathcal{P}_{\mathrm{kin}}$ consists of the annihilation-pole residue tensors determined by the antiparticle and crossing data of $\mathfrak{R}$. These tensors specify the residues at $\theta_i - \theta_j = \mathrm{i}\pi$ after the chosen tensor-ordering convention is fixed.

(v) $\mathcal{P}_{\mathrm{bs}}$ consists of the bound-state residue tensors inherited from the physical-strip poles of the two-body scattering maps. If no stable bound-state channel is present, this entry is empty.

(vi) $\mathcal{G}_{\mathcal{O}}$ is a stated family of growth and boundary-value bounds. It must be strong enough for each spectral series later claimed in the chapter to define the announced distribution or separated Euclidean function. A form-factor structure without such bounds is only algebraic bootstrap input, not a reconstruction of a local field.

The exchange, cyclicity, kinematic-pole, bound-state-pole, covariance, and growth equations are developed below as constraints on $\mathfrak{F}_{\mathcal{O}}$. The definition records the object to which those constraints apply; it does not assert that a solution of the algebraic equations has already constructed a Wightman QFT.

76.1 Finite-Particle Matrix Elements

Let $\mathfrak{F}_{\mathcal{O}}$ be a local-operator form-factor structure over $\mathfrak{R}$. Thus $\mathcal{I}$ is the set of stable particle species, V_a their internal species spaces, and $S_{ab}(\theta) : V_a \otimes V_b \to V_b \otimes V_a$ the two-body scattering maps. Ordered incoming states are denoted

$$|\theta_1, a_1; \ldots; \theta_n, a_n\rangle_{\mathrm{in}}, \qquad \theta_1 > \cdots > \theta_n.$$

For a local scalar operator $\widehat{\mathcal{O}}(x)$, the n-particle form factor is the distributional boundary value

$$F^{\mathcal{O}}_{a_1 \ldots a_n}(\theta_1, \ldots, \theta_n) = \langle \Omega | \widehat{\mathcal{O}}(0) | \theta_1, a_1; \ldots; \theta_n, a_n\rangle_{\mathrm{in}}.$$

If the species spaces are not one-dimensional, this is a covector on $V_{a_1} \otimes \cdots \otimes V_{a_n}$. Translation covariance gives

$$\langle \Omega | \widehat{\mathcal{O}}(x) | \theta_1, a_1; \ldots; \theta_n, a_n\rangle_{\mathrm{in}} = \exp\left[-\mathrm{i} x_\mu \sum_{j=1}^{n} p^\mu_{a_j}(\theta_j)\right] F^{\mathcal{O}}_{a_1 \ldots a_n}(\theta_1, \ldots, \theta_n).$$

Thus the nontrivial information is at $x = 0$, while the distributional character of $\widehat{\mathcal{O}}$ enters through growth and boundary-value conditions on $F^{\mathcal{O}}$.

76.2 Exchange Equation

Analytic continuation in rapidities extends the ordered form factor to domains in $\mathbb{C}^n$. Fix an adjacent pair and write

$$\mathcal{C}_+ = \{\theta_i > \theta_{i+1}\}, \qquad \mathcal{C}_- = \{\theta_{i+1} > \theta_i\}.$$

The form factor has two distributional boundary values at the wall $\theta_i = \theta_{i+1}$, obtained by approaching the wall from the two ordered chambers, or equivalently by the two standard $i0$-prescriptions for the rapidity difference

$$F_+ = \lim_{\epsilon \downarrow 0} F(\dots, \theta_i + \mathrm{i}\epsilon, \theta_{i+1} - \mathrm{i}\epsilon, \dots), \qquad F_- = \lim_{\epsilon \downarrow 0} F(\dots, \theta_i - \mathrm{i}\epsilon, \theta_{i+1} + \mathrm{i}\epsilon, \dots).$$

The ordered scattering-state convention says that the corresponding finite-particle boundary vectors are related by the adjacent two-body scattering operator,

$$|\dots; \theta_i, a_i; \theta_{i+1}, a_{i+1}; \dots\rangle_+ = S^{bc}_{a_i a_{i+1}}(\theta_i - \theta_{i+1}) |\dots; \theta_{i+1}, c; \theta_i, b; \dots\rangle_-. \tag{76.1}$$

This relation is the rapidity-space form of the scattering theorem for ordered Haag–Ruelle states in a factorizing theory; locality is used upstream in constructing the asymptotic fields and their scattering relations, not as a one-line replacement for the boundary-value statement. Pairing (76.1) with the local-operator covector gives Watson's exchange equation

$$F^{\mathcal{O}}_{\dots a_i a_{i+1} \dots}(\dots, \theta_i, \theta_{i+1}, \dots) = F^{\mathcal{O}}_{\dots a_{i+1} a_i \dots}(\dots, \theta_{i+1}, \theta_i, \dots) S_{a_i a_{i+1}}(\theta_i - \theta_{i+1}),$$

where the S-matrix acts on the two corresponding species factors before the covector is evaluated.

Proposition 76.2 (Exchange from factorized scattering)**.** *Assume that the finite-particle scattering states satisfy asymptotic completeness in the massive sector and that the ordered in-state convention is related across adjacent rapidity chambers by the factorized S-matrix. Then every local operator whose finite-particle matrix elements admit rapidity boundary values satisfies the exchange equation above.*

Proof. Let g_+ and g_- be compactly supported test functions in the two neighboring rapidity chambers whose supports approach the same compact set on the wall but do not meet any bound-state or threshold singularity. Smearing (76.1) with these test functions gives an identity of Hilbert-space vectors in the finite-particle scattering domain. The identity is first proved for separated velocity supports by the Haag–Ruelle construction of ordered in-states; analytic continuation in the rapidity difference then supplies the displayed boundary values. The factorizing hypothesis identifies the change of ordered basis with the adjacent two-body S-matrix and leaves all other tensor factors unchanged.

Applying the continuous distributional covector $\langle\Omega|\widehat{\mathcal{O}}(0)$ to both sides gives the equality of smeared form-factor boundary values. Since this holds for all such test functions, the equality holds as a distributional boundary-value identity in the rapidity variables. No off-shell Lagrangian is used. The hypotheses are the existence of the finite-particle scattering states, their boundary-value analyticity in rapidity chambers, and the factorized two-body change of ordered basis. $\square$

76.3 Cyclicity, Locality, and Semi-Locality

The cyclicity equation is a crossing-locality statement. It is not obtained from the two-body S-matrix alone. The analytic input is the same as in the Wightman reconstruction chapters: the spectrum condition gives forward-tube analyticity of vacuum matrix elements, and locality identifies boundary values after permuting spacelike separated insertions. In rapidity variables the complex Lorentz transformation

$$\theta \longmapsto \theta + \mathrm{i}\pi$$

changes $p_a(\theta)$ to $-p_a(\theta)$, and hence crosses an incoming particle to the outgoing antiparticle channel. A second shift by $\mathrm{i}\pi$ crosses it back to the incoming side after it has passed through the local operator.

Proposition 76.3 (Cyclicity from crossing and locality)**.** *Assume that the finite-particle matrix elements of a scalar local operator $\widehat{\mathcal{O}}$ are boundary values of Wightman functions satisfying the spectrum condition, locality, and the one-particle crossing relation obtained by analytic continuation through the physical rapidity strip. Assume that the path $\theta_1 \mapsto \theta_1 + 2\pi\mathrm{i}$ crosses no singularity other than the standard crossing boundary and no bound-state pole. Then*

$$F^{\mathcal{O}}_{a_1 a_2 \ldots a_n}(\theta_1 + 2\pi\mathrm{i}, \theta_2, \ldots, \theta_n) = F^{\mathcal{O}}_{a_2 \ldots a_n a_1}(\theta_2, \ldots, \theta_n, \theta_1).$$

If $\widehat{\mathcal{O}}$ is semi-local with respect to species a_1, the right side is multiplied by the declared monodromy endomorphism $\omega_{\mathcal{O},a_1}$.

Proof. For separated velocity supports, represent the incoming particle of species a_1 by a Haag–Ruelle wave packet and write the matrix element as a boundary value of a Wightman distribution with one interpolating field for that particle. The joint spectrum condition implies that this distribution extends holomorphically when the imaginary parts of successive spacetime differences lie in the future cone. Fourier transforming the first wave packet and using $p_a(\theta + \mathrm{i}\pi) = -p_a(\theta)$, continuation $\theta_1 \mapsto \theta_1 + \mathrm{i}\pi$ converts the incoming a_1-particle into an outgoing $\bar{a}_1$-particle. In bracket notation this is the crossing boundary value

$$F^{\mathcal{O}}_{a_1 a_2 \ldots a_n}(\theta_1 + \mathrm{i}\pi, \theta_2, \ldots, \theta_n) = {}_{\mathrm{out}}\langle \theta_1, \bar{a}_1 | \widehat{\mathcal{O}}(0) | \theta_2, a_2; \ldots; \theta_n, a_n \rangle_{\mathrm{in}},$$

with the charge-conjugation map suppressed in the notation.

Continue once more by $\mathrm{i}\pi$. At the boundary of the tube one may choose the spacetime supports of the crossed particle and of $\widehat{\mathcal{O}}$ to be spacelike separated before the wave-packet limit is taken. Local commutativity then permits the crossed particle interpolating field to be moved past $\widehat{\mathcal{O}}$. For a scalar local operator this gives no extra factor; for a semi-local operator it gives the declared monodromy $\omega_{\mathcal{O},a_1}$. After the second crossing the particle is again incoming, and the ordered-state convention places its rapidity at the right end of the ordered list. Thus the boundary value is the displayed cyclic form factor. The equality is distributional because it was derived after smearing in rapidity and then unsmearing by uniqueness of boundary values. The excluded pole crossings are precisely the cases where additional residue terms must be added. □

76.4 Kinematic Pole Equation

Let $\bar{a}$ denote the antiparticle species of a. The pair $(\bar{a}, a)$ at rapidity difference $\mathrm{i}\pi$ has total momentum zero and can annihilate into the vacuum. Consequently a local form factor may have a kinematic pole at

$$\theta_{\bar a} = \theta_a + \mathrm{i}\pi.$$

For a scalar local operator the residue has the structural form

$$-\mathrm{i} \operatorname*{Res}_{\theta'=\theta+\mathrm{i}\pi} F^{\mathcal{O}}_{\bar a\, a\, a_1\ldots a_n}(\theta',\theta,\theta_1,\ldots,\theta_n) = \left(1 - \prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j)\right) F^{\mathcal{O}}_{a_1\ldots a_n}(\theta_1,\ldots,\theta_n), \tag{76.2}$$

with tensor contractions and charge-conjugation maps inserted according to the species spaces. The product is ordered by moving the particle a through the n remaining particles before annihilation.

Proposition 76.4 (Kinematic annihilation pole)**.** *Assume the hypotheses of Proposition 76.3, asymptotic completeness in the finite-particle sector under consideration, factorized scattering for ordered states, and the standard rapidity normalization of one-particle states. Assume further that the only singularity encountered at $\theta' = \theta + \mathrm{i}\pi$ is the vacuum annihilation of the adjacent pair $(\bar a, a)$. Then the singular part of the form factor is*

$$F^{\mathcal{O}}_{\bar a\, a\, a_1\ldots a_n}(\theta',\theta,\theta_1,\ldots,\theta_n) = \frac{\mathrm{i}}{\theta'-\theta-\mathrm{i}\pi}\left(1 - \prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j)\right) F^{\mathcal{O}}_{a_1\ldots a_n} + \textit{holomorphic},$$

with the same tensor-ordering convention as in (76.2). Equivalently, (76.2) holds.

Proof. Set $z = \theta' - \theta - \mathrm{i}\pi$. The coefficient of the crossed one-particle contraction is fixed by matching its two boundary values to the rapidity delta function, not by an independent sign convention. In the rapidity normalization, valid for any stable species b,

$$\langle \theta', b | \theta, b\rangle = 2\pi\delta(\theta'-\theta),$$

the contraction term must have boundary-value jump $2\pi\delta(x)$ when $x = \operatorname{Re} z$. The distributional identity

$$\frac{1}{x+\mathrm{i}0} - \frac{1}{x-\mathrm{i}0} = -2\pi\mathrm{i}\,\delta(x)$$

therefore selects

$$\frac{\mathrm{i}}{z}.$$

Indeed, $\mathrm{i}(x+\mathrm{i}0)^{-1} - \mathrm{i}(x-\mathrm{i}0)^{-1} = 2\pi\delta(x)$, exactly the one-particle contraction coefficient. This is the rapidity form of the mass-shell phase-space pole: near $z=0$, the continued total momentum $p_{\bar a}(\theta+\mathrm{i}\pi+z) + p_a(\theta)$ vanishes linearly in z, and the chosen positive-energy boundary value is the one just normalized. Thus direct annihilation of the adjacent $(\bar a, a)$-pair into the vacuum contributes

$$\frac{\mathrm{i}}{z} F^{\mathcal{O}}_{a_1\ldots a_n}(\theta_1,\ldots,\theta_n). \tag{direct}$$

There is a second boundary value of the same meromorphic matrix element. Use Watson exchange to move the particle a through the spectator particles $a_1,\ldots,a_n$ before performing the annihilation. This ordered-basis change contributes the ordered product

$$\prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j).$$

The annihilation contour now approaches the same Cauchy pole from the opposite side of the rapidity ordering. Equivalently, after applying cyclicity, the crossed particle encircles the local operator and returns to the incoming side with the opposite orientation for the small circle around $z = 0$. In local coordinates this is the statement that the reverse ordering uses

$$z_{\mathrm{rev}} = \theta - \theta' + \mathrm{i}\pi = -z,$$

so a positively oriented small circle in z_{rev} is a negatively oriented small circle in z. Therefore the residue of the same annihilation pole enters with the opposite sign. The second singular contribution is

$$-\frac{\mathrm{i}}{z}\left(\prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j)\right) F^{\mathcal{O}}_{a_1\ldots a_n}(\theta_1,\ldots,\theta_n). \qquad \text{(scattered)}$$

For a scalar local operator there is no extra semi-locality phase; a semi-local operator would multiply this second contribution by its monodromy factor. Adding the two boundary contributions gives the displayed singular part. Taking the residue at $z = 0$ gives

$$-\mathrm{i}\operatorname*{Res}_{z=0}\frac{\mathrm{i}}{z}\left(1-\prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j)\right) F^{\mathcal{O}}_{n} = \left(1-\prod_{j=1}^{n} S_{aa_j}(\theta-\theta_j)\right) F^{\mathcal{O}}_{n}.$$

The proof is local in the rapidity variables; additional bound-state poles or threshold singularities on the deformation path would add further residue terms and are excluded by hypothesis. □

76.5 Free Majorana Examples

The form-factor axioms become concrete already in the massive Ising field theory. In the fermionic particle basis there is one self-conjugate particle of mass m, and the diagonal two-body scattering function is the constant

$$S(\theta) = -1.$$

The constant phase is physically important: the ordered rapidity variables are still bosonic coordinates on asymptotic particle states, but exchanging two particles multiplies the finite-particle basis by -1. Thus a scalar form factor must be antisymmetric in rapidity variables when it has an even number of Majorana particles.

Example 76.5 (Energy-density form factor)**.** Fix a scalar normalization constant κ_ε. The massive Majorana energy-density operator ε may be normalized by

$$F^{\varepsilon}_0 = 0, \qquad F^{\varepsilon}_2(\theta_1,\theta_2) = \kappa_\varepsilon \sinh\!\left(\frac{\theta_1-\theta_2}{2}\right), \qquad F^{\varepsilon}_n = 0 \quad (n \neq 2).$$

The exchange equation follows because

$$\sinh\!\left(\frac{\theta_2-\theta_1}{2}\right)(-1) = \sinh\!\left(\frac{\theta_1-\theta_2}{2}\right).$$

Cyclicity follows from

$$\sinh\!\left(\frac{\theta_1+2\pi\mathrm{i}-\theta_2}{2}\right) = -\sinh\!\left(\frac{\theta_1-\theta_2}{2}\right) = \sinh\!\left(\frac{\theta_2-\theta_1}{2}\right).$$

The kinematic-pole equation is also satisfied: the displayed form factors are entire, and the right side vanishes because $F_0^\varepsilon = 0$ for no spectators and because $1 - S^2 = 0$ for two spectators. This example is finite rather than recursive; it checks that the sign conventions of Watson exchange and $2\pi\mathrm{i}$ cyclicity are compatible with a familiar local quadratic field.

Proposition 76.6 (Two-particle reconstruction for the Majorana energy operator)**.** *Use the one-particle normalization*

$$\langle \theta' \mid \theta \rangle = 2\pi\delta(\theta' - \theta), \qquad p^\mu(\theta) = m(\cosh\theta, \sinh\theta), \qquad p(\theta)^2 = -m^2.$$

Let $W_\varepsilon(x) = \langle \Omega|\varepsilon(x)\varepsilon(0)|\Omega\rangle$ at noncoincident points, and define the Fourier transform by

$$\widetilde{W}_\varepsilon(P) = \int_{\mathbb{R}^{1,1}} \mathrm{d}^2x\, e^{\mathrm{i}P\cdot x} W_\varepsilon(x), \qquad W_\varepsilon(x) = \int \frac{\mathrm{d}^2P}{(2\pi)^2}\, e^{-\mathrm{i}P\cdot x} \widetilde{W}_\varepsilon(P).$$

With $s = -P^2$, the two-particle form factor in Example 76.5 gives

$$\widetilde{W}_\varepsilon(P) = \theta(P^0)\theta(s - 4m^2)\, \frac{|\kappa_\varepsilon|^2}{2m^2} \sqrt{1 - \frac{4m^2}{s}} \tag{76.3}$$

in this Fourier convention. Equivalently, for Euclidean time separation $r > 0$,

$$G_\varepsilon(r) = \langle \varepsilon(r)\varepsilon(0)\rangle_E = \frac{|\kappa_\varepsilon|^2}{2\pi^2} \int_0^\infty \mathrm{d}\alpha\, \sinh^2\!\Big(\frac{\alpha}{2}\Big)\, K_0\Big(2mr\cosh\Big(\frac{\alpha}{2}\Big)\Big), \tag{76.4}$$

where, for $z > 0$,

$$K_0(z) = \int_0^\infty e^{-z\cosh u}\, \mathrm{d}u.$$

Proof. The finite-particle resolution of the identity in the one-species sector is

$$\mathbf{1}_{\mathrm{fin}} = \sum_{n\geq 0} \frac{1}{n!} \int_{\mathbb{R}^n} \prod_{j=1}^n \frac{\mathrm{d}\theta_j}{2\pi}\, |\theta_1, \dots, \theta_n\rangle_{\mathrm{in}\,\mathrm{in}}\langle\theta_1, \dots, \theta_n|.$$

For the free Majorana energy operator only the two-particle term is present. Therefore, at non-coincident Lorentzian separation,

$$W_\varepsilon(x) = \frac{1}{2} \int \frac{\mathrm{d}\theta_1}{2\pi}\frac{\mathrm{d}\theta_2}{2\pi}\, |F_2^\varepsilon(\theta_1, \theta_2)|^2\, e^{-\mathrm{i}x\cdot(p(\theta_1)+p(\theta_2))}.$$

The factor $1/2$ is not optional: the rapidity integration is over all ordered labels, while the two Majorana particles are identical. Fourier transformation gives

$$\widetilde{W}_\varepsilon(P) = \frac{1}{2} \int \frac{\mathrm{d}\theta_1}{2\pi}\frac{\mathrm{d}\theta_2}{2\pi}\, (2\pi)^2\delta^{(2)}(P - p(\theta_1) - p(\theta_2))\, |F_2^\varepsilon(\theta_1, \theta_2)|^2.$$

The support condition is already visible: P must be future directed and $s = -P^2 \geq 4m^2$.

Because the integrand is Lorentz invariant except for the explicit vector P, evaluate it in the frame $P = (M, 0)$, $M = \sqrt{s}$. Put

$$\Theta = \frac{\theta_1 + \theta_2}{2}, \qquad \alpha = \theta_1 - \theta_2.$$

Then

$$p(\theta_1) + p(\theta_2) = 2m \cosh\left(\frac{\alpha}{2}\right) (\cosh\Theta, \sinh\Theta),$$

and the equations imposed by the delta function have the two roots

$$\Theta = 0, \qquad \alpha = \pm\alpha_s, \qquad \cosh\left(\frac{\alpha_s}{2}\right) = \frac{\sqrt{s}}{2m}.$$

The absolute value of the Jacobian of $(\Theta, \alpha) \mapsto (p_1^0 + p_2^0, p_1^1 + p_2^1)$ at either root is

$$\left|\det\begin{pmatrix} \partial_\Theta P^0 & \partial_\alpha P^0 \\ \partial_\Theta P^1 & \partial_\alpha P^1 \end{pmatrix}\right| = \sqrt{s}\, m \sinh\left(\frac{\alpha_s}{2}\right).$$

The two roots in α cancel the identical-particle factor $1/2$. Using

$$|F_2^\varepsilon|^2 = |\kappa_\varepsilon|^2 \sinh^2\left(\frac{\alpha_s}{2}\right), \qquad \sinh^2\left(\frac{\alpha_s}{2}\right) = \frac{s - 4m^2}{4m^2},$$

one obtains (76.3). The threshold behavior is therefore $\sqrt{s - 4m^2}$, not a pole: the two-body phase-space square-root singularity is softened by the antisymmetric energy-density form factor, which vanishes at equal rapidities.

For the Euclidean formula, take a positive Euclidean time separation r. The positive-energy spectral term is the analytic continuation of the same finite-particle contribution:

$$G_\varepsilon(r) = \frac{1}{2} \int \frac{\mathrm{d}\theta_1}{2\pi} \frac{\mathrm{d}\theta_2}{2\pi} |\kappa_\varepsilon|^2 \sinh^2\left(\frac{\theta_1 - \theta_2}{2}\right) e^{-mr(\cosh\theta_1 + \cosh\theta_2)}.$$

Changing variables to (Θ, α) has unit Jacobian and gives

$$G_\varepsilon(r) = \frac{|\kappa_\varepsilon|^2}{8\pi^2} \int_{\mathbb{R}} \mathrm{d}\Theta \int_{\mathbb{R}} \mathrm{d}\alpha \, \sinh^2\left(\frac{\alpha}{2}\right) e^{-2mr\cosh(\alpha/2)\cosh\Theta}.$$

By the integral definition of K_0,

$$\int_{-\infty}^{\infty} e^{-2mr\cosh(\alpha/2)\cosh\Theta} \, \mathrm{d}\Theta = 2K_0\left(2mr\cosh\left(\frac{\alpha}{2}\right)\right).$$

The remaining integrand is even in α, giving (76.4). All equalities in this proof are separated-point equalities. Possible contact terms at $x = 0$ are not part of the finite-particle spectral calculation. □

The spin and disorder fields of the Ising theory are more instructive because their form factors form infinite families and because their locality relative to the Majorana particle is a branch-field structure with an explicit monodromy. Let

$$P_N(\theta_1, \ldots, \theta_N) = \prod_{1 \le i < j \le N} \tanh\left(\frac{\theta_i - \theta_j}{2}\right), \qquad P_0 = P_1 = 1.$$

The function P_N is antisymmetric and satisfies

$$P_N(\theta_1 + 2\pi \mathrm{i}, \theta_2, \ldots, \theta_N) = P_N(\theta_1, \ldots, \theta_N), \qquad P_N(\theta_2, \ldots, \theta_N, \theta_1) = (-1)^{N-1} P_N(\theta_1, \ldots, \theta_N).$$

Thus a nonzero product family with even N solves cyclicity with semi-locality phase -1, while a nonzero product family with odd N solves cyclicity with phase $+1$. This phase is part of the operator sector. It is not determined by the diagonal scattering function alone.

In the thermally perturbed Ising field theory, the sign of the Majorana mass selects which of the lattice order/disorder scaling fields has a nonzero vacuum expectation value. We write σ_+ for the spin field in the ordered convention in which

$$\bar{\sigma} = \langle \Omega | \sigma_+(0) | \Omega \rangle \neq 0.$$

With the conformal normalization $\langle \sigma(x)\sigma(0)\rangle \sim |x|^{-1/4}$ at short distance, the standard infinite-plane normalization is

$$\bar{\sigma} = 2^{1/12} e^{-1/8} A_{\mathrm{G}}^{3/2} |m|^{1/8},$$

where A_{G} is the Glaisher constant. The derivation below uses only the symbol $\bar{\sigma}$, because the form-factor equations determine the rapidity dependence and relative phases, not the ultraviolet normalization of the spin field.

Even spin-field form factors in the free massive fermion. Let the Majorana particle have $S = -1$, and let σ_+ be a scalar branch field with semi-locality phase -1 relative to the Majorana particle. The rapidity dependence selected by the form-factor equations is the even family

$$F_{2k}^{\sigma_+}(\theta_1, \ldots, \theta_{2k}) = \bar{\sigma}\, \mathrm{i}^k P_{2k}(\theta_1, \ldots, \theta_{2k}), \qquad F_{2k+1}^{\sigma_+} = 0, \tag{76.5}$$

It satisfies Watson exchange, semi-local cyclicity

$$F_{2k}^{\sigma_+}(\theta_1 + 2\pi\mathrm{i}, \theta_2, \ldots, \theta_{2k}) = -F_{2k}^{\sigma_+}(\theta_2, \ldots, \theta_{2k}, \theta_1),$$

and the semi-local annihilation-pole equation

$$-\mathrm{i} \operatorname*{Res}_{\theta' = \theta + \mathrm{i}\pi} F_{n+2}^{\sigma_+}(\theta', \theta, \eta_1, \ldots, \eta_n) = (1 + (-1)^n)\, F_n^{\sigma_+}(\eta_1, \ldots, \eta_n).$$

In particular,

$$F_0^{\sigma_+} = \bar{\sigma}, \qquad F_2^{\sigma_+}(\theta_1, \theta_2) = \mathrm{i}\bar{\sigma} \tanh\!\left(\frac{\theta_1 - \theta_2}{2}\right).$$

Away from coincident bra and ket rapidities, crossing K outgoing particles gives the connected analytic part of the mixed matrix element

$$\begin{aligned}
&{}_{\mathrm{out}}\langle \beta_1, \ldots, \beta_K | \sigma_+(0) | \beta'_1, \ldots, \beta'_N \rangle_{\mathrm{in}}^{\mathrm{conn}} \\
&\quad = \bar{\sigma}\, \mathrm{i}^{(K+N)/2} \prod_{1 \le i < j \le K} \tanh\!\left(\frac{\beta_i - \beta_j}{2}\right) \prod_{1 \le p < q \le N} \tanh\!\left(\frac{\beta'_p - \beta'_q}{2}\right) \prod_{\substack{1 \le s \le K \\ 1 \le t \le N}} \coth\!\left(\frac{\beta_s - \beta'_t}{2}\right),
\end{aligned} \tag{76.6}$$

for $K + N$ even; it vanishes for $K + N$ odd. The superscript "conn" reminds us that the full distributional matrix element also has disconnected delta-function contractions when some bra rapidity coincides with a ket rapidity.

The verification is the following explicit product calculation. Watson exchange follows because P_N is antisymmetric and $S = -1$. For $N = 2k$, the two displayed identities for P_N give

$$P_N(\theta_1 + 2\pi\mathrm{i}, \theta_2, \ldots, \theta_N) = -P_N(\theta_2, \ldots, \theta_N, \theta_1),$$

which is exactly cyclicity with semi-locality phase -1.

For the pole equation, set $\theta' = \theta + \mathrm{i}\pi + \epsilon$. The annihilating pair contributes

$$\tanh\left(\frac{\theta' - \theta}{2}\right) = \coth\left(\frac{\epsilon}{2}\right) = \frac{2}{\epsilon} + O(\epsilon),$$

while each spectator pair gives

$$\tanh\left(\frac{\theta' - \eta_j}{2}\right)\tanh\left(\frac{\theta - \eta_j}{2}\right) \longrightarrow 1.$$

Hence

$$\operatorname*{Res}_{\theta'=\theta+\mathrm{i}\pi} P_{n+2}(\theta', \theta, \eta_1, \ldots, \eta_n) = 2P_n(\eta_1, \ldots, \eta_n).$$

When n is even, $F_n^{\sigma+} = \bar{\sigma}\mathrm{i}^{n/2}P_n$ and $F_{n+2}^{\sigma+} = \bar{\sigma}\mathrm{i}^{n/2+1}P_{n+2}$, so

$$-\mathrm{i}\ \mathrm{Res}\, F_{n+2}^{\sigma+} = 2F_n^{\sigma+}.$$

This is the displayed equation because $1 + (-1)^n = 2$. When n is odd, both $F_n^{\sigma+}$ and $F_{n+2}^{\sigma+}$ vanish.

The crossed formula is a direct consequence of the same even family. Move K outgoing particles to the incoming side by the boundary-value continuation $\beta_s \mapsto \beta_s + \mathrm{i}\pi$. Products among two crossed rapidities and among two uncrossed rapidities remain tanh-products, because $\tanh(z + \pi\mathrm{i}) = \tanh z$. A crossed-uncrossed pair gives

$$\tanh\left(\frac{\beta_s + \mathrm{i}\pi - \beta_t'}{2}\right) = \coth\left(\frac{\beta_s - \beta_t'}{2}\right).$$

Substitution in $F_{K+N}^{\sigma+}$ gives (76.6). The exclusion of coincident rapidities is necessary because crossing a particle onto an identical particle in the other state also produces the ordinary Fock-space contraction terms; those delta terms are separate from the meromorphic connected form factor derived here.

The case $K = N = 1$ gives the convention-sensitive spin-field matrix element used in the Fonseca–Zamolodchikov treatment:

$${}_{\mathrm{out}}\langle\beta_1|\sigma_+(0)|\beta_2\rangle_{\mathrm{in}}^{\mathrm{conn}} = \mathrm{i}\bar{\sigma}\coth\left(\frac{\beta_1 - \beta_2}{2}\right).$$

In the present chapter this formula is the crossed boundary value of the two-particle spin form factor above.[1]

The dual odd product family is obtained by the same algebra with the opposite cyclicity phase. In a normalization $v \in \mathbb{C}$ it is

$$F_{2k+1}^{\Sigma}(\theta_1, \ldots, \theta_{2k+1}) = v\,\mathrm{i}^k \prod_{1\le i<j\le 2k+1} \tanh\left(\frac{\theta_i - \theta_j}{2}\right), \qquad F_{2k}^{\Sigma} = 0. \tag{76.7}$$

The constant $v = F_1^{\Sigma}$ is the one-particle normalization in this sector. Which product family is called order or disorder after matching to the lattice scaling limit depends on the sign convention for the Majorana mass and on the Kramers–Wannier identification. The mathematical point here is independent of that naming convention: the parity of the nonzero form-factor family is fixed by the declared cyclicity phase.

[1] A useful comparison point is P. Fonseca and A. Zamolodchikov, "Ising field theory in a magnetic field: analytic properties of the free energy", arXiv:hep-th/0112167, and "Ward identities and integrable differential equations in the Ising field theory", arXiv:hep-th/0309228. The formulas here are rederived in the rapidity and crossing conventions of this chapter.

Odd-family bootstrap verification. For the odd product family (76.7), the three bootstrap checks are elementary but convention-sensitive. The family satisfies Watson exchange, the local cyclicity equation for odd particle number, and the kinematic-pole equation with $S=-1$:

$$-\mathrm{i}\operatorname*{Res}_{\theta'=\theta+\mathrm{i}\pi} F^{\Sigma}_{n+2}(\theta',\theta,\eta_1,\dots,\eta_n)=(1-(-1)^n)\,F^{\Sigma}_{n}(\eta_1,\dots,\eta_n)$$

for every odd n. For even n, both sides vanish because $F^{\Sigma}_{n}=F^{\Sigma}_{n+2}=0$.

Interchanging adjacent variables changes exactly one factor by a sign and permutes the rest, so P_N is antisymmetric. Since $S=-1$, this is precisely Watson's equation.

For N odd,

$$P_N(\theta_1+2\pi\mathrm{i},\theta_2,\dots,\theta_N)=P_N(\theta_1,\theta_2,\dots,\theta_N),$$

because $\tanh(z+\pi\mathrm{i})=\tanh z$. Moving θ_1 from the first slot to the last reverses its order relative to $N-1$ variables and hence multiplies the antisymmetric product by $(-1)^{N-1}=1$. This proves cyclicity for the odd family.

It remains to compute the annihilation residue. Put

$$\theta'=\theta+\mathrm{i}\pi+\epsilon.$$

The pair factor is

$$\tanh\!\left(\frac{\theta'-\theta}{2}\right)=\tanh\!\left(\frac{\mathrm{i}\pi+\epsilon}{2}\right)=\coth\!\left(\frac{\epsilon}{2}\right)=\frac{2}{\epsilon}+O(\epsilon).$$

For each spectator rapidity η_j,

$$\tanh\!\left(\frac{\theta'-\eta_j}{2}\right)\tanh\!\left(\frac{\theta-\eta_j}{2}\right)\longrightarrow\coth\!\left(\frac{\theta-\eta_j}{2}\right)\tanh\!\left(\frac{\theta-\eta_j}{2}\right)=1.$$

Therefore

$$\operatorname*{Res}_{\theta'=\theta+\mathrm{i}\pi} P_{n+2}(\theta',\theta,\eta_1,\dots,\eta_n)=2P_n(\eta_1,\dots,\eta_n).$$

If $n=2k+1$, then $F^{\Sigma}_{n}=v\mathrm{i}^kP_n$, while $F^{\Sigma}_{n+2}=v\mathrm{i}^{k+1}P_{n+2}$. Hence

$$-\mathrm{i}\,\operatorname{Res}F^{\Sigma}_{n+2}=-\mathrm{i}\,2v\mathrm{i}^{k+1}P_n=2v\mathrm{i}^kP_n=2F^{\Sigma}_{n}.$$

Since n is odd, $1-(-1)^n=2$, giving the claimed kinematic-pole equation.

Proposition 76.7 (Separated Euclidean spectral series for the Ising branch fields)**.** *Use the free Majorana one-particle normalization of Proposition 76.6, and consider Euclidean time separation $r>0$. Define*

$$I_m(r)=\int_{\mathbb{R}}\frac{\mathrm{d}\theta}{2\pi}\,e^{-mr\cosh\theta}=\frac{1}{\pi}K_0(mr). \tag{76.8}$$

The even spin-field form factors (76.5) determine an absolutely convergent separated-point Euclidean spectral series

$$G_{\sigma_+}(r)=\sum_{k=0}^{\infty}\frac{1}{(2k)!}\int_{\mathbb{R}^{2k}}\prod_{j=1}^{2k}\frac{\mathrm{d}\theta_j}{2\pi}\,\left|F^{\sigma_+}_{2k}(\theta_1,\dots,\theta_{2k})\right|^2e^{-mr\sum_{j=1}^{2k}\cosh\theta_j}. \tag{76.9}$$

For every $r > 0$,

$$|G_{\sigma_+}(r)| \le |\bar{\sigma}|^2 \cosh I_m(r). \tag{76.10}$$

After removing the $k = 0$ term, the connected series is bounded by $|\bar{\sigma}|^2(\cosh I_m(r) - 1)$.

The odd product family (76.7) similarly gives

$$G_\Sigma(r) = \sum_{k=0}^{\infty} \frac{1}{(2k+1)!} \int_{\mathbb{R}^{2k+1}} \prod_{j=1}^{2k+1} \frac{\mathrm{d}\theta_j}{2\pi} \left|F^{\Sigma}_{2k+1}(\theta_1, \ldots, \theta_{2k+1})\right|^2 e^{-mr\sum_{j=1}^{2k+1}\cosh\theta_j}, \tag{76.11}$$

with

$$|G_\Sigma(r)| \le |v|^2 \sinh I_m(r). \tag{76.12}$$

Both series converge uniformly with all r-derivatives on compact subsets of $(0, \infty)$. Hence they define smooth separated Euclidean two-point functions on the temporal ray; Euclidean covariance then gives the corresponding separated radial functions. This proposition is a separated-point reconstruction statement for this free model. The full local-reconstruction problem for a general factorizing S-matrix is the open problem stated below.

Proof. The finite-particle identity resolution gives (76.9) and (76.11) exactly as in the energy-density derivation, with the factorial compensating for integration over labelled rapidity variables of identical Majorana particles. For real rapidities,

$$\left|\tanh\left(\frac{\theta_i - \theta_j}{2}\right)\right| \le 1.$$

Therefore

$$\left|F^{\sigma_+}_{2k}(\theta_1, \ldots, \theta_{2k})\right|^2 \le |\bar{\sigma}|^2, \qquad \left|F^{\Sigma}_{2k+1}(\theta_1, \ldots, \theta_{2k+1})\right|^2 \le |v|^2. \tag{76.13}$$

The factorized exponential then gives the termwise bounds

$$\frac{1}{(2k)!} \int_{\mathbb{R}^{2k}} \prod_{j=1}^{2k} \frac{\mathrm{d}\theta_j}{2\pi} |\bar{\sigma}|^2 e^{-mr\sum_j \cosh\theta_j} = |\bar{\sigma}|^2 \frac{I_m(r)^{2k}}{(2k)!} \tag{76.14}$$

and

$$\frac{1}{(2k+1)!} \int_{\mathbb{R}^{2k+1}} \prod_{j=1}^{2k+1} \frac{\mathrm{d}\theta_j}{2\pi} |v|^2 e^{-mr\sum_j \cosh\theta_j} = |v|^2 \frac{I_m(r)^{2k+1}}{(2k+1)!}. \tag{76.15}$$

Summing the even and odd majorants gives (76.10) and (76.12). The identity (76.8) follows from the integral definition of K_0 and evenness in θ.

Let $0 < r_0 < r_1 < \infty$. A derivative of order q with respect to r inserts a finite sum of factors bounded by

$$m^q \left(\sum_j \cosh\theta_j\right)^q e^{-mr\sum_j \cosh\theta_j}.$$

For $r \in [r_0, r_1]$, split

$$e^{-mr\sum_j \cosh\theta_j} = e^{-(mr_0/2)\sum_j \cosh\theta_j} e^{-m(r-r_0/2)\sum_j \cosh\theta_j}.$$

The polynomial factor in $\cosh\theta_j$ is dominated by a constant depending on q, r_0, m times the first exponential, and the remaining integrals are bounded by the same exponential series with $r_0/2$ in place of r. The Weierstrass test therefore applies to every derivative order on $[r_0, r_1]$. The resulting functions are smooth for $r > 0$, and the spectral construction gives the separated Euclidean two-point functions on the temporal ray. Contact terms at coincident points are outside this separated-point estimate and belong to the extension problem on the collision diagonal. $\square$

76.6 Bound-State Poles and Operator Couplings

Suppose species a and b have a bound state c. If the two-body S-matrix has a physical-strip pole at $\theta = \mathrm{i}u_{ab}^c$ with residue tensor $\Gamma_{ab}^c : V_c \to V_a \otimes V_b$, then the form factor has the compatible pole

$$-\mathrm{i} \operatorname*{Res}_{\theta_a - \theta_b = \mathrm{i}u_{ab}^c} F_{aba_1\ldots a_n}^{\mathcal{O}} = F_{ca_1\ldots a_n}^{\mathcal{O}} \Gamma_{ab}^c,$$

again with the stated tensor-ordering convention. This equation is the operator-level statement that a local field couples to the bound state through the same one-particle channel that appears in the scattering residue.

76.7 Form-Factor Reconstruction Boundary

The structure of Definition 76.1 supplies the bootstrap input. Its growth entry is essential: it controls whether the spectral series for Wightman functions,

$$\langle\Omega|\widehat{\mathcal{O}}(x)\widehat{\mathcal{O}}(0)|\Omega\rangle = \sum_{n=0}^{\infty} \frac{1}{n!} \sum_{a_1,\ldots,a_n} \int d\mu_n \, e^{-\mathrm{i}x\cdot\sum_j p_j} F_{a_1\ldots a_n}^{\mathcal{O}}(\theta) \overline{F_{a_1\ldots a_n}^{\mathcal{O}}(\theta)}$$

defines a distribution. Here $d\mu_n$ is the Lorentz-invariant n-particle rapidity measure with the normalization fixed by the one-particle Hilbert-space convention.

Status checkpoint: from form factors to fields. The preceding equations are necessary matrix-element identities for a local or semi-local field in a factorizing theory. They become a local-field construction only after five analytic steps have been supplied in the same normalization. First, the finite-particle vectors must sit in a positive Hilbert space with a common invariant domain on which the smeared operators are defined and closable. Second, the spectral sums must converge as tempered Wightman distributions, with separated Euclidean functions for $r > 0$ serving only as one part of that construction; this includes control of the extension to collision diagonals and of contact terms. Third, the resulting distributions must satisfy covariance, the spectrum condition, and positivity. Fourth, the commutator or semi-locality relation must vanish on spacelike test-function supports as an operator statement on the common domain. Fifth, the finite-particle states used in the series must be complete in the sector claimed. The Ising Majorana examples above meet these requirements because the underlying free field already supplies the Hilbert space and local fields, and the product bounds prove separated Euclidean convergence for the displayed branch families. For an interacting scalar factorizing model, the same list is a set of additional analytic hypotheses beyond Watson, cyclicity, and residue equations.

Open Problem 76.8 (Local reconstruction from form factors). Given a factorized S-matrix and a family of form-factor data satisfying the displayed equations and explicit growth bounds, construct the Wightman domain, prove convergence of the spectral series as distributions, verify local commutativity, and identify a dense set of local operators. This is the operator-level completion of the scattering bootstrap.

Chapter 77

Thermodynamic Bethe Ansatz

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The thermodynamic Bethe ansatz turns the exact two-body scattering data of a massive integrable theory into finite-temperature or finite-size thermodynamics. The construction in this chapter is stated first for a diagonal elastic S-matrix. Matrix-valued scattering, bound-state strings, and nested Bethe ansatz data require additional species and auxiliary-root bookkeeping but obey the same variational logic once the allowed densities are specified.

Definition 77.1 (Diagonal massive TBA specification)**.** A diagonal massive thermodynamic Bethe ansatz specification consists of the following objects.

(i) A finite species set A, with a mass $m_a > 0$ for each $a \in \mathsf{A}$.

(ii) Diagonal two-body scattering amplitudes $S_{ab}(\theta) \in U(1)$ for real rapidity difference θ, with a declared real-axis phase branch

$$S_{ab}(\theta) = \exp\bigl(\mathrm{i}\delta_{ab}(\theta)\bigr)$$

on each rapidity interval used in the thermodynamic calculation. The logarithmic derivative kernel is

$$\varphi_{ab}(\theta) = \frac{1}{2\pi}\delta'_{ab}(\theta) = \frac{1}{2\pi\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}\theta}\log S_{ab}(\theta)$$

as a locally integrable function or distribution. The branch convention is part of the specification whenever S_{ab} has constant signs, poles, or CDD factors crossing the chosen real-axis chart.

(iii) Circle quantization shifts $\nu_a \in \mathbb{R}/\mathbb{Z}$, encoding the statistics and boundary convention for each species.

(iv) A thermodynamic root-density statement: for circle circumference $L \to \infty$, the Bethe–Yang solutions whose rapidities stay in a fixed compact interval have empirical measures converging to particle densities $\rho_a(\theta)\mathrm{d}\theta$ and hole densities $\rho_a^h(\theta)\mathrm{d}\theta$, and the differentiated Bethe–Yang map gives the density constraint

$$\rho_a + \rho_a^h = \frac{m_a}{2\pi}\cosh\theta + \sum_{b\in\mathsf{A}} \varphi_{ab} * \rho_b.$$

(v) The exclusion-statistics entropy convention

$$s[\rho,\rho^h] = \sum_{a\in\mathsf{A}} \int d\theta \left[\rho_a^t \log\rho_a^t - \rho_a\log\rho_a - \rho_a^h\log\rho_a^h\right], \qquad \rho_a^t = \rho_a + \rho_a^h.$$

This convention is the one matched to one occupied or empty Bethe quantum number in each microscopic rapidity cell. Other generalized exclusion-statistics systems require the corresponding entropy and density matrix in place of this item.

(vi) A thermal or mirror-channel normalization. At inverse temperature $R > 0$, the energy density coordinate is $\sum_a \int d\theta\, m_a \cosh\theta\, \rho_a(\theta)$. When the same specification is used for a finite-size ground-state energy, the chapter assumes the mirror-channel identification and the normalization of $E_0(R)$ stated in Section 77.5.

77.1 Bethe–Yang Quantization

For the diagonal specification of Definition 77.1, place the theory on a spatial circle of circumference L. For n particles of masses m_a, rapidities θ_j, and diagonal scattering phases

$$S_{ab}(\theta) = \exp\bigl(\mathrm{i}\delta_{ab}(\theta)\bigr),$$

periodicity of the wavefunction of particle j gives the Bethe–Yang equation

$$m_{a_j} L\sinh\theta_j + \sum_{k\neq j} \delta_{a_j a_k}(\theta_j - \theta_k) = 2\pi I_j, \qquad I_j \in \mathbb{Z} + \nu_j.$$

The shift ν_j depends on statistics and boundary convention. The one-particle energy and momentum are

$$E_a(\theta) = m_a\cosh\theta, \qquad p_a(\theta) = m_a\sinh\theta.$$

77.2 Density Equations

In the thermodynamic limit $L \to \infty$, introduce particle and hole densities $\rho_a(\theta)$ and $\rho_a^h(\theta)$, normalized so that

$$L\rho_a(\theta)d\theta$$

is the number of occupied rapidities of species a in $d\theta$. Define the scattering kernel

$$\varphi_{ab}(\theta) = \frac{1}{2\pi}\frac{d}{d\theta}\delta_{ab}(\theta) = \frac{1}{2\pi \mathrm{i}}\frac{d}{d\theta}\log S_{ab}(\theta).$$

Differentiating the Bethe–Yang equations gives the density constraint

$$\rho_a(\theta) + \rho_a^h(\theta) = \frac{m_a}{2\pi}\cosh\theta + \sum_b \int_{\mathbb{R}} d\theta'\, \varphi_{ab}(\theta-\theta')\rho_b(\theta').$$

This equation is purely kinematic: it counts available rapidity levels after the scattering phase shifts have shifted the quantization conditions.

77.3 Entropy and Free Energy

For fixed total density $\rho_a^t = \rho_a + \rho_a^h$, the number of microscopic occupancy choices in an interval is

$$\binom{L\rho_a^t\, d\theta}{L\rho_a\, d\theta}.$$

Stirling's formula gives the entropy density functional

$$s[\rho,\rho^h] = \sum_a \int d\theta\, \left[\rho_a^t \log\rho_a^t - \rho_a\log\rho_a - \rho_a^h\log\rho_a^h\right].$$

At inverse temperature R, the free energy per length is

$$f[\rho,\rho^h] = \sum_a \int d\theta\, m_a\cosh\theta\,\rho_a(\theta) - \frac{1}{R}s[\rho,\rho^h],$$

subject to the density constraint.

77.4 Pseudoenergy Equation

Define the pseudoenergy by

$$\epsilon_a(\theta) = \log\frac{\rho_a^h(\theta)}{\rho_a(\theta)}.$$

Varying the constrained free energy with respect to ρ_a gives

$$\epsilon_a(\theta) = Rm_a\cosh\theta - \sum_b\int_{\mathbb{R}} d\theta'\,\varphi_{ab}(\theta-\theta')\log\Big(1+e^{-\epsilon_b(\theta')}\Big).$$

This is the thermodynamic Bethe ansatz equation. The equilibrium free energy is

$$f(R) = -\frac{1}{2\pi R}\sum_a m_a\int_{\mathbb{R}} d\theta\,\cosh\theta\,\log\Big(1+e^{-\epsilon_a(\theta)}\Big).$$

Proposition 77.2 (Variational derivation of TBA)**.** *For diagonal elastic scattering with smooth phase kernels and a thermodynamic limit in which the Bethe–Yang root densities exist, the stationary point of the constrained free-energy functional is exactly the pseudoenergy equation above.*

Proof. Work on the open cone where $\rho_a > 0$ and $\rho_a^h > 0$, and take compactly supported smooth variations of the particle densities. The density constraint then determines the variation of the total density:

$$\delta\rho_c^t(\theta) = \sum_a \int d\theta' \, \varphi_{ca}(\theta - \theta')\delta\rho_a(\theta').$$

Since $\rho_a^h = \rho_a^t - \rho_a$, the corresponding hole-density variation is $\delta\rho_a^h = \delta\rho_a^t - \delta\rho_a$. The entropy variation is

$$\delta s = \sum_a \int d\theta \left[\log \frac{\rho_a^h}{\rho_a} \, \delta\rho_a + \log \frac{\rho_a^t}{\rho_a^h} \, \delta\rho_a^t\right].$$

Let

$$L_a(\theta) = \log \frac{\rho_a^t(\theta)}{\rho_a^h(\theta)} = \log(1 + e^{-\epsilon_a(\theta)}).$$

Substituting the constraint variation into $\delta f = \delta e - R^{-1}\delta s$ and collecting the coefficient of $\delta\rho_a(\theta)$ gives

$$0 = m_a \cosh\theta - \frac{1}{R}\epsilon_a(\theta) - \frac{1}{R}\sum_c \int d\theta' \, \varphi_{ca}(\theta' - \theta) L_c(\theta').$$

With the diagonal-scattering convention $\varphi_{ca}(\theta' - \theta) = \varphi_{ac}(\theta - \theta')$, this is exactly the displayed TBA equation.

It remains to derive the compact expression for the stationary free energy. The entropy density identity

$$\rho_a^t \log\rho_a^t - \rho_a \log\rho_a - \rho_a^h \log\rho_a^h = \rho_a \, \epsilon_a + \rho_a^t L_a$$

gives

$$Rf_* = \sum_a \int d\theta \, \rho_a(Rm_a \cosh\theta - \epsilon_a) - \sum_a \int d\theta \, \rho_a^t L_a.$$

Use the stationary equation for the first parenthesis and the density constraint for ρ_a^t. The convolution terms cancel after interchanging species labels and integration variables, leaving only the one-particle state-density term

$$Rf_* = -\sum_a \int d\theta \, \frac{m_a}{2\pi} \cosh\theta \, L_a(\theta),$$

which is the stated formula for $f(R)$. □

77.5 Finite-Size Ground-State Energy

Interchanging space and Euclidean time maps the thermal free energy on an infinite line at inverse temperature R to the ground-state energy on a circle of circumference R, after the mirror-channel scattering data have been identified. In a relativistic theory the mirror dispersion is obtained by a rapidity shift by $\mathrm{i}\pi/2$, so the same TBA equation gives

$$E_0(R) = -\frac{1}{2\pi}\sum_a m_a \int_{\mathbb{R}} d\theta \, \cosh\theta \, \log\Big(1 + e^{-\epsilon_a(\theta)}\Big).$$

The effective central charge extracted from the ultraviolet limit is

$$c_{\text{eff}}(R) = -\frac{6R}{\pi} E_0(R), \qquad R \to 0,$$

provided the limit exists and the infrared bulk energy has been subtracted in the declared normalization.

77.6 Free Majorana Example and the Ultraviolet Central Charge

The massive Ising field theory in its fermionic phase gives the minimal diagonal example. It has one neutral particle of mass m. The two-particle scattering phase is the constant

$$S(\theta) = -1.$$

The derivative kernel is therefore zero:

$$\varphi(\theta) = \frac{1}{2\pi \mathrm{i}} \frac{\mathrm{d}}{\mathrm{d}\theta} \log S(\theta) = 0,$$

after the constant branch of $\log(-1) = \mathrm{i}\pi$ has been fixed. The TBA equation reduces to

$$\epsilon(\theta) = r \cosh\theta, \qquad r = mR.$$

The finite-size ground-state energy in the normalization of the preceding section is

$$E_0(R) = -\frac{m}{2\pi} \int_{-\infty}^{\infty} \mathrm{d}\theta \, \cosh\theta \, \log\Big(1 + \mathrm{e}^{-r\cosh\theta}\Big). \tag{77.1}$$

The ultraviolet central charge follows from a direct scaling limit. Put

$$x = \sinh\theta, \qquad \mathrm{d}x = \cosh\theta \, \mathrm{d}\theta.$$

Then

$$I(r) := \int_{-\infty}^{\infty} \mathrm{d}\theta \, \cosh\theta \, \log(1 + \mathrm{e}^{-r\cosh\theta}) = \int_{-\infty}^{\infty} \mathrm{d}x \, \log(1 + \mathrm{e}^{-r\sqrt{1+x^2}}).$$

Rescale $y = rx$. This gives

$$rI(r) = \int_{-\infty}^{\infty} \mathrm{d}y \, \log(1 + \mathrm{e}^{-\sqrt{r^2+y^2}}).$$

For $0 < r \le 1$ the integrand is bounded by $\log(1+\mathrm{e}^{-|y|})$, which is integrable on $\mathbb{R}$, and it converges pointwise to $\log(1 + \mathrm{e}^{-|y|})$. Dominated convergence gives

$$\lim_{r \downarrow 0} rI(r) = 2 \int_0^{\infty} \mathrm{d}y \, \log(1 + \mathrm{e}^{-y}).$$

Expanding $\log(1 + \mathrm{e}^{-y})$ for $y > 0$ and integrating termwise gives

$$\sum_{k=1}^{\infty} \frac{(-1)^{k+1}}{k^2} = \int_0^{\infty} \mathrm{d}y \, \log(1 + \mathrm{e}^{-y}) = \frac{\pi^2}{12},$$

Equation (77.1) gives

$$E_0(R) = -\frac{\pi}{12R} + o(R^{-1}).$$

Thus

$$c_{\text{eff}} = \lim_{R\downarrow 0}\left(-\frac{6R}{\pi}E_0(R)\right) = \frac{1}{2}.$$

The result matches the central charge of the ultraviolet Majorana conformal field theory, but the computation above uses only the declared finite-size TBA specification and the normalization of $E_0(R)$.

77.7 Scaling Lee–Yang Example and the Effective Central Charge

The first interacting one-particle TBA example is the massive scaling Lee–Yang theory. It is not a unitary Hilbert-space example; it is included here because it is the minimal nontrivial diagonal bootstrap specification for which the TBA ultraviolet limit can be carried to an exact number. The ultraviolet conformal theory is the nonunitary minimal model $M(2,5)$, whose central charge is $c = -22/5$. Its lowest conformal weight is $-1/5$, so the cylinder ground-state energy is governed by the effective central charge

$$c_{\text{eff}} = c - 24h_{\text{min}} = \frac{2}{5}.$$

The TBA computation below derives the same number from the scattering specification.

The diagonal one-particle amplitude is

$$S_{\text{LY}}(\theta) = \frac{\sinh\theta + \mathrm{i}\sin(\pi/3)}{\sinh\theta - \mathrm{i}\sin(\pi/3)}.$$

With the kernel convention of this chapter,

$$\varphi_{\text{LY}}(\theta) = \frac{1}{2\pi\mathrm{i}}\frac{\mathrm{d}}{\mathrm{d}\theta}\log S_{\text{LY}}(\theta) = -\frac{\sin(\pi/3)\cosh\theta}{\pi\left(\sinh^2\theta + \sin^2(\pi/3)\right)} = -\frac{2\sqrt{3}\cosh\theta}{\pi(2\cosh 2\theta + 1)}. \tag{77.2}$$

It has total integral

$$N_{\text{LY}} = \int_{\mathbb{R}} \mathrm{d}\theta\, \varphi_{\text{LY}}(\theta) = -1. \tag{77.3}$$

Indeed, putting $x = \sinh\theta$ and $s = \sin(\pi/3)$ gives

$$N_{\text{LY}} = -\frac{s}{\pi}\int_{-\infty}^{\infty}\frac{\mathrm{d}x}{x^2+s^2} = -1.$$

The TBA equation is therefore

$$\epsilon(\theta) = r\cosh\theta - \int_{\mathbb{R}} \mathrm{d}\theta'\, \varphi_{\text{LY}}(\theta-\theta')\log(1+\mathrm{e}^{-\epsilon(\theta')}). \tag{77.4}$$

Controlled Approximation 77.3 (Lee–Yang ultraviolet plateau)**.** Assume the standard one-plateau ultraviolet limit of (77.4): as $r\downarrow 0$, there is a rapidity region whose width tends to infinity in which $\epsilon(\theta)$ approaches a constant ϵ_0, while the kernel is replaced by its integral N_{LY}. Then

$$Y_0 := \mathrm{e}^{\epsilon_0} = \phi_{\mathrm{g}} = \frac{1+\sqrt{5}}{2}, \qquad c_{\text{eff}} = \frac{2}{5}.$$

The plateau equation is obtained from (77.4) by dropping the vanishing driving term and replacing the convolution by N_{LY}:

$$\epsilon_0 = -N_{\mathrm{LY}} \log(1 + \mathrm{e}^{-\epsilon_0}) = \log(1 + \mathrm{e}^{-\epsilon_0}).$$

Writing $Y_0 = \mathrm{e}^{\epsilon_0}$ gives

$$Y_0 = 1 + Y_0^{-1}, \qquad Y_0^2 = Y_0 + 1.$$

The positive solution is the golden ratio ϕ_{g}.

The ultraviolet TBA central charge is the one-species Rogers-dilogarithm value

$$c_{\mathrm{eff}} = \frac{6}{\pi^2} L\left(\frac{1}{1 + Y_0}\right) = \frac{6}{\pi^2} L(\phi_{\mathrm{g}}^{-2}).$$

For $0 < x < 1$, use

$$L(x) = \mathrm{Li}_2(x) + \frac{1}{2} \log x \log(1 - x).$$

The two identities needed here are

$$L(x) + L(1 - x) = \frac{\pi^2}{6}, \qquad L(x^2) = 2L(x) - 2L\left(\frac{x}{1 + x}\right). \tag{77.5}$$

The first follows from Euler's dilogarithm identity. The second follows by differentiating the difference of the two sides, using $\mathrm{Li}_2'(x) = -\log(1 - x)/x$, and evaluating at $x = 0$. Set $x = \phi_{\mathrm{g}}^{-1}$. Then

$$1 - x = x^2, \qquad \frac{x}{1 + x} = x^2.$$

The identities become

$$L(x) + L(x^2) = \frac{\pi^2}{6}, \qquad L(x^2) = 2L(x) - 2L(x^2).$$

Thus $3L(x^2) = 2L(x)$. Solving the two linear equations gives

$$L(\phi_{\mathrm{g}}^{-2}) = L(x^2) = \frac{\pi^2}{15}.$$

Therefore $c_{\mathrm{eff}} = 6/15 = 2/5$.

Remark 77.4 (What the example proves)*.* The calculation proves an internal consistency statement for the declared TBA datum and its ultraviolet plateau asymptotics. It is not by itself a construction of the Lee–Yang local QFT, nor a derivation that the finite-volume Hamiltonian spectrum of such a QFT is governed by (77.4). Those statements require the Hilbert-space and locality input separated in the theorem boundary below.

Status checkpoint: from scattering data to TBA. The TBA pseudoenergy equation has a different logical status from the factorized scattering equations. The scattering input supplies the kernel $\varphi = (2\pi \mathrm{i})^{-1} \partial_\theta \log S$. To turn that kernel into a thermodynamic statement about a local QFT one must also prove the finite-volume Bethe–Yang description with controlled errors, convergence of Bethe counting measures to root and hole densities, the microscopic entropy of the allowed Bethe cells, existence and uniqueness of the free-energy minimizer, and the channel identification that converts mirror free energy into direct finite-size ground-state energy. The free Majorana and Lee–Yang computations above verify the internal finite algebra and ultraviolet asymptotics of specific TBA data. They do not by themselves prove that an arbitrary local Hamiltonian with the same proposed scattering phase has that finite-volume spectrum.

77.8 Euler-Scale Generalized Hydrodynamics

The equilibrium TBA datum also supplies the kinematic variables used in generalized hydrodynamics. In this chapter it is treated as a conditional Euler-scale closure for inhomogeneous states whose local cells are assumed to be described by thermodynamic Bethe root densities.

Let $\rho_a(x,t,\theta)$ and $\rho_a^h(x,t,\theta)$ be slowly varying particle and hole densities, and set

$$\rho_a^t = \rho_a + \rho_a^h, \qquad n_a = \frac{\rho_a}{\rho_a^t}.$$

The local density constraint is the pointwise version of the TBA counting equation:

$$\rho_a^t(x,t,\theta) = \frac{p_a'(\theta)}{2\pi} + \sum_b \int d\alpha\, \varphi_{ab}(\theta-\alpha)\rho_b(x,t,\alpha), \qquad p_a'(\theta) = m_a \cosh\theta. \tag{77.6}$$

For any vector of one-particle functions $h_a(\theta)$, define its dressing by the linear equation

$$h_a^{\mathrm{dr}}(\theta) = h_a(\theta) + \sum_b \int d\alpha\, \varphi_{ab}(\theta-\alpha) n_b(\alpha) h_b^{\mathrm{dr}}(\alpha). \tag{77.7}$$

The inverse of $1-\varphi n$ is part of the hydrodynamic chart; if the operator has a zero mode, this chart has left its domain of validity. Applying (77.7) to p_a' gives

$$(p_a')^{\mathrm{dr}} = 2\pi\rho_a^t,$$

which is precisely (77.6). Applying it to

$$E_a'(\theta) = m_a \sinh\theta$$

defines the Euler-scale effective velocity

$$v_a^{\mathrm{eff}}(\theta) = \frac{(E_a')^{\mathrm{dr}}(\theta)}{(p_a')^{\mathrm{dr}}(\theta)}. \tag{77.8}$$

Hypothesis 77.5 (Euler-scale GHD closure)**.** Fix a diagonal massive TBA specification and a family of inhomogeneous finite-volume states whose mesoscopic cells have thermodynamic root densities $\rho_a(x,t,\theta)$. The Euler-scale generalized-hydrodynamic closure is the assertion that, for every compact rapidity interval and every test function in x,θ, the empirical quasiparticle measures converge in the scaling limit to densities obeying

$$\partial_t\rho_a(x,t,\theta) + \partial_x\left(v_a^{\mathrm{eff}}(x,t,\theta)\rho_a(x,t,\theta)\right) = 0, \tag{77.9}$$

with v_a^{eff} defined from the local dressing equations (77.7)–(77.8).

This hypothesis has a direct conservation check. For a local conserved charge whose one-particle eigenvalue is $h_a(\theta)$, define the Euler-cell density and current by

$$q_h(x,t) = \sum_a \int d\theta\, h_a(\theta)\rho_a(x,t,\theta), \qquad j_h(x,t) = \sum_a \int d\theta\, h_a(\theta) v_a^{\mathrm{eff}}(x,t,\theta)\rho_a(x,t,\theta). \tag{77.10}$$

Multiplying (77.9) by h_a, summing over species, and integrating in rapidity gives

$$\partial_t q_h + \partial_x j_h = 0$$

whenever boundary terms vanish. The closure is therefore compatible with the infinite family of Bethe charges by construction. The difficult assertion is not this algebraic conservation check, but the scaling theorem that the microscopic inhomogeneous QFT actually converges to (77.9).

The formula for v^{eff} is also the linearized counting formula for a dressed wave packet. Insert a single quasiparticle into a thermodynamic cell and perturb the Bethe counting function. The shift of available rapidity levels is governed by the same kernel φ that appears in (77.6). The dressed momentum and dressed energy gradients of the excitation are therefore $(p')^{\text{dr}}$ and $(E')^{\text{dr}}$, and the group velocity of the dressed packet is their ratio. This is the kinematic content of (77.8); it does not prove equilibration to a locally stationary Bethe state.

Hard-rod calibration. A useful finite algebraic laboratory is the classical hard-rod gas, which is not a relativistic local QFT but tests the collision-shift logic. Let rods have length $a > 0$, velocity labels v_i, and local velocity densities ρ_i with $a\rho_{\text{tot}} < 1$,

$$\rho_{\text{tot}} = \sum_i \rho_i.$$

The exact collision shift gives the effective-velocity equations

$$v_i^{\text{eff}} = v_i + a \sum_j \rho_j \left(v_i^{\text{eff}} - v_j^{\text{eff}} \right). \tag{77.11}$$

Writing $J = \sum_j \rho_j v_j^{\text{eff}}$, this becomes

$$(1 - a\rho_{\text{tot}}) v_i^{\text{eff}} = v_i - aJ.$$

Multiplying by ρ_i and summing over i gives

$$J = \sum_i \rho_i v_i.$$

Hence

$$v_i^{\text{eff}} = \frac{v_i - a\sum_j \rho_j v_j}{1 - a\rho_{\text{tot}}}. \tag{77.12}$$

The formula displays the same structure as (77.8): bare velocities are corrected by the finite density of collision shifts, and the correction depends on the state. In the quantum integrable case the scalar shift a is replaced by the rapidity-dependent scattering kernel and the algebraic solution by the dressing equation (77.7).

Open Problem 77.6 (GHD from local integrable QFT). Starting from a constructed local integrable QFT with factorized scattering, derive the Euler-scale generalized-hydrodynamic closure (77.9) for inhomogeneous finite-energy states. The proof must identify the local thermodynamic Bethe state, control finite-volume and mesoscopic errors, justify the dressing inverse, and show that nonintegrable perturbations or inelastic channels are absent on the Euler time scale under consideration.

77.9 Weak Integrability Breaking And Kinetic Cells

Perturbing an integrable QFT changes the role of the Bethe charges. The Hamiltonian still has exact energy, momentum, and internal-symmetry charges declared by the perturbation, but the higher commuting charges of the integrable point are generally lost. A controlled kinetic description must therefore specify which finite-cell transitions are allowed, which charges they preserve exactly, and what entropy functional is monotone under the coarse-grained collision dynamics. These are finite algebraic requirements before any limiting theorem from a local QFT is attempted.

Definition 77.7 (Finite collision-cell Markov model)**.** A finite collision-cell Markov model consists of the following objects.

1. A finite set Ω of mesoscopic cell states.
2. A strictly positive stationary weight π_ω on Ω, normalized by $\sum_{\omega\in\Omega}\pi_\omega = 1$.
3. Transition rates $k_{\omega\omega'} \geq 0$, for $\omega \neq \omega'$, satisfying detailed balance
$$\pi_\omega k_{\omega\omega'} = \pi_{\omega'} k_{\omega'\omega}. \tag{77.13}$$
4. A finite family of exactly conserved cell observables $Q^A : \Omega \to \mathbb{R}$, meaning that $k_{\omega\omega'} \neq 0$ implies $Q^A(\omega) = Q^A(\omega')$ for every A.
5. Occupation variables $N_i : \Omega \to \mathbb{Z}_{\geq 0}$, where i labels a finite rapidity/species bin.

The cell probability $P_\omega(T)$ evolves by
$$\frac{dP_\omega}{dT} = \sum_{\omega'\neq\omega} \left(P_{\omega'} k_{\omega'\omega} - P_\omega k_{\omega\omega'}\right). \tag{77.14}$$

The projected occupation collision functional is
$$C_i[P] = \sum_{\omega,\omega'} P_\omega k_{\omega\omega'} \left(N_i(\omega') - N_i(\omega)\right). \tag{77.15}$$

If a conserved observable has the occupation form
$$Q^A(\omega) = Q^A_0 + \sum_i h^A_i N_i(\omega),$$
then the projected functional obeys
$$\sum_i h^A_i C_i[P] = 0. \tag{77.16}$$

Lemma 77.8 (Finite collision-cell entropy identity)**.** *For a finite collision-cell Markov model, set*
$$r_\omega = \frac{P_\omega}{\pi_\omega}, \qquad \mathcal{H}(P|\pi) = \sum_{\omega\in\Omega} P_\omega \log\frac{P_\omega}{\pi_\omega}.$$

Along (77.14),

$$\frac{d}{dT}\mathcal{H}(P|\pi) = -\frac{1}{2}\sum_{\omega,\omega'} \pi_\omega k_{\omega\omega'} \left(r_\omega - r_{\omega'}\right) \left(\log r_\omega - \log r_{\omega'}\right) \leq 0. \tag{77.17}$$

Moreover

$$\frac{d}{dT}\sum_{\omega} P_\omega Q^A(\omega) = 0$$

for every exactly conserved cell observable Q^A.

Proof. The master equation conserves total probability, so the derivative of the relative entropy is

$$\frac{d}{dT}\mathcal{H}(P|\pi) = \sum_{\omega} \dot{P}_\omega \log r_\omega.$$

Insert (77.14) and exchange the dummy indices in the gain term:

$$\frac{d}{dT}\mathcal{H}(P|\pi) = \sum_{\omega,\omega'} P_\omega k_{\omega\omega'} \left(\log r_{\omega'} - \log r_\omega\right).$$

Using $P_\omega = \pi_\omega r_\omega$ and detailed balance, the same sum with ω and ω' exchanged is

$$\sum_{\omega,\omega'} \pi_\omega k_{\omega\omega'} r_{\omega'} \left(\log r_\omega - \log r_{\omega'}\right).$$

Averaging the two expressions gives (77.17). The final sign follows from monotonicity of the logarithm:

$$(x-y)(\log x - \log y) \geq 0 \qquad x, y > 0.$$

For an exactly conserved cell observable, multiply the master equation by $Q^A(\omega)$, sum over ω, and symmetrize the result as

$$\frac{d}{dT}\sum_{\omega} P_\omega Q^A(\omega) = \sum_{\omega,\omega'} P_\omega k_{\omega\omega'} \left(Q^A(\omega') - Q^A(\omega)\right).$$

Every nonzero rate has $Q^A(\omega') = Q^A(\omega)$, hence the derivative vanishes. If Q^A is linear in the occupation variables, the same identity is exactly (77.16). $\square$

Controlled Approximation 77.9 (Weak-breaking kinetic scaling)**.** Let H_0 be an integrable Hamiltonian whose thermodynamic cells are described by the TBA variables of Section 77.8, and perturb it by a local operator,

$$H_\varepsilon = H_0 + \varepsilon V, \qquad V = \int dx\, \mathcal{O}(x),$$

with $0 < \varepsilon \ll 1$. A weak-breaking kinetic description is the following scaling ansatz. Choose a mesoscopic cell length ℓ and a macroscopic length X with microscopic scale $\ll \ell \ll X$, pass to the kinetic time $T = \varepsilon^2 t$, and assume that the local finite-cell transition rates are obtained from the on-shell matrix elements of V after the finite-volume limit, resonance averaging, and subtraction of disconnected pieces have all been performed in a specified scheme. The hydrodynamic equation is then replaced by

$$\partial_t \rho_i(x,t) + \partial_x \Big(v_i^{\text{eff}}[\rho](x,t)\rho_i(x,t) \Big) = \varepsilon^2 C_i[P_{x,t}] + R_i^{(\varepsilon,\ell,X)}(x,t), \tag{77.18}$$

where $i = (a, \theta)$ denotes a species/rapidity bin after discretization, $P_{x,t}$ is the local cell probability whose occupation means give $\rho_i(x,t)$, and C_i is the projected collision functional (77.15). The remainder records gradient corrections, memory effects, finite-cell correlations, and errors in the kinetic limit. The approximation is controlled only after one proves a norm in which $R_i^{(\varepsilon,\ell,X)} \to 0$ under a declared joint limit of ε, ℓ, X.

The finite-cell lemma identifies the part of the weak-breaking story that can be checked before a local-QFT limit theorem has been proved. If the perturbation preserves energy and momentum, the collision graph must be restricted to transitions with the same energy and momentum labels; (77.16) then gives the exact conservation laws of the kinetic equation. If a higher Bethe charge Q_h is not preserved by the perturbation, the same finite formula displays its decay:

$$\frac{d}{dT}\langle Q_h \rangle = \sum_{\omega,\omega'} P_\omega k_{\omega\omega'} \left(Q_h(\omega') - Q_h(\omega) \right).$$

Thus weak integrability breaking is not a modification of the dressing formula alone. It is a change in the collision graph of the mesoscopic cell, with the remaining exact charges and the entropy production fixed before any model-dependent scattering calculation is inserted.

Open Problem 77.10 (Kinetic limit of weakly broken integrable QFT). Derive (77.18) from a local integrable QFT perturbed by a specified local operator. The proof must construct the finite-volume transition rates from regulated matrix elements, prove the ε^{-2} kinetic time scaling, control secular terms and near-degenerate resonances, identify the local stationary weights π_ω, and show convergence of the remainder $R_i^{(\varepsilon,\ell,X)}$ in a norm strong enough to imply convergence of the declared local observables.

77.10 Theorem Boundary

The derivation above assumes existence of thermodynamic root densities, validity of Bethe–Yang quantization up to errors negligible at large L, and uniqueness of the free-energy minimizer. In concrete models these are mathematical hypotheses to be proved or checked. Bound states, non-diagonal scattering, zero modes, massless flows, and weak integrability-breaking collisions change the density system and must be included explicitly.

Open Problem 77.11 (TBA from local QFT). Derive the TBA equations directly from a constructed local QFT with factorized scattering: prove Bethe–Yang quantization with controlled finite-volume errors, establish thermodynamic root-density convergence, and identify the finite-size ground-state energy with the mirror free energy.

Chapter 78

Nested TBA, Baxter Relations, and Separation Variables

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Diagonal TBA converts scalar Bethe–Yang equations into density and pseudoenergy equations. Non-diagonal scattering adds auxiliary roots. The thermodynamic limit then contains physical densities and magnonic auxiliary densities. This chapter develops the finite-dimensional functional relations that control those auxiliary roots: Baxter TQ equations, QQ-systems, Hirota T-systems, and separation of variables. These are algebraic objects first; their use in a continuum QFT requires the separate large-volume and thermodynamic hypotheses stated below.

78.1 Nested Densities

Start from logarithmic nested equations of the form

$$Lp_a(\theta_j) + \sum_{b,k} \delta_{ab}(\theta_j - \theta_k) + \sum_{\alpha,r} \chi_{ar}(\theta_j - u_\alpha^{(r)}) = 2\pi I_j,$$

together with auxiliary equations

$$\sum_{b,k} \chi_{rb}(u_\alpha^{(r)} - \theta_k) + \sum_{s,\beta} \psi_{rs}(u_\alpha^{(r)} - u_\beta^{(s)}) = 2\pi J_\alpha^{(r)}.$$

The labels a, b enumerate physical particle species; r, s enumerate auxiliary Dynkin nodes or nesting levels. The functions δ, χ, ψ are chosen branches of logarithms of the scalar and matrix-scattering eigenvalue factors.

In the thermodynamic limit introduce physical densities ρ_a, ρ_a^h and auxiliary densities σ_r, σ_r^h. Differentiating the logarithmic equations gives

$$\rho_a + \rho_a^h = \frac{1}{2\pi}\frac{\mathrm{d}p_a}{\mathrm{d}\theta} + \sum_b K_{ab} * \rho_b + \sum_r K_{ar} * \sigma_r, \tag{78.1}$$

$$\sigma_r + \sigma_r^h = \sum_a K_{ra} * \rho_a + \sum_s K_{rs} * \sigma_s. \tag{78.2}$$

Here

$$(K * f)(x) = \int_{\mathbb{R}} K(x-y) f(y)\, \mathrm{d}y,$$

and each kernel is $1/(2\pi)$ times the derivative of the corresponding phase. Auxiliary roots carry no direct one-particle energy in the examples under discussion; they affect the free energy through the constraints.

Proposition 78.1 (Nested TBA variational equations)**.** *Assume the density equations* (78.1)–(78.2) *have a thermodynamic limit with positive total densities, and use the fermionic occupancy entropy for each physical and auxiliary root species. Define pseudoenergies*

$$\epsilon_a = \log\frac{\rho_a^h}{\rho_a}, \qquad \eta_r = \log\frac{\sigma_r^h}{\sigma_r}.$$

Then stationarity of the constrained free energy at inverse temperature R gives

$$\epsilon_a = RE_a - \sum_b K_{ba} * \log(1 + \mathrm{e}^{-\epsilon_b}) - \sum_r K_{ra} * \log(1 + \mathrm{e}^{-\eta_r}), \tag{78.3}$$

$$\eta_r = -\sum_a K_{ar} * \log(1 + \mathrm{e}^{-\epsilon_a}) - \sum_s K_{sr} * \log(1 + \mathrm{e}^{-\eta_s}). \tag{78.4}$$

Proof. Let A denote either a physical label a or an auxiliary label r. Write n_A for the occupied density, n_A^h for the hole density, and $n_A^t = n_A + n_A^h$ for the total density. The density equations have the uniform form

$$n_A^t = d_A + \sum_B K_{AB} * n_B, \qquad d_a = \frac{1}{2\pi}\frac{\mathrm{d}p_a}{\mathrm{d}\theta}, \qquad d_r = 0, \tag{78.5}$$

where the energy is E_a on physical labels and 0 on auxiliary labels. The entropy density of one fermionic occupancy species is

$$s_A = n_A^t \log n_A^t - n_A \log n_A - n_A^h \log n_A^h,$$

so, using $n_A^h = n_A^t - n_A$,

$$\delta s = \sum_A \int \left[\log\frac{n_A^h}{n_A}\, \delta n_A + \log\frac{n_A^t}{n_A^h}\, \delta n_A^t\right].$$

The dimensionless free-energy functional is

$$\mathcal{F}_R[n] = \sum_a \int RE_a\, \rho_a \, \mathrm{d}\theta - \sum_A \int s_A \, \mathrm{d}\theta.$$

Varying (78.5) gives

$$\delta n_A^t = \sum_B K_{AB} * \delta n_B.$$

For test variations of compact support the convolution pairing satisfies

$$\int L_A(\theta)(K_{AB} * \delta n_B)(\theta)\, \mathrm{d}\theta = \int (K_{AB}^\dagger * L_A)(u)\, \delta n_B(u)\, \mathrm{d}u, \qquad K_{AB}^\dagger(x) = K_{AB}(-x).$$

With

$$\epsilon_A = \log \frac{n_A^h}{n_A}, \qquad L_A = \log \frac{n_A^t}{n_A^h} = \log(1 + \mathrm{e}^{-\epsilon_A}),$$

stationarity of $\mathcal{F}_R$ therefore gives, for every label B,

$$0 = RE_B - \epsilon_B - \sum_A K_{AB}^\dagger * L_A, \qquad E_r = 0. \tag{78.6}$$

Writing the adjoint-transposed kernels as K_{BA}, separating physical and auxiliary labels, and substituting the definitions of ϵ_a, η_r gives exactly (78.3)–(78.4). $\square$

78.2 Constant A2 Magnonic Example

The ultraviolet limit of many nested systems reduces to constant equations for the plateau values $Y_A = \mathrm{e}^{\epsilon_A}$. A minimal A_2 magnonic example has two auxiliary nodes and incidence matrix

$$I_{rs} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

The constant Y-system is

$$Y_1^2 = 1 + Y_2, \qquad Y_2^2 = 1 + Y_1.$$

The symmetric solution has $Y_1 = Y_2 = \phi_{\mathrm{g}}$, where

$$\phi_{\mathrm{g}} = \frac{1 + \sqrt{5}}{2}, \qquad \phi_{\mathrm{g}}^2 = 1 + \phi_{\mathrm{g}}.$$

This finite calculation is the algebraic core behind Rogers-dilogarithm central-charge evaluations. To turn it into a central-charge theorem for a specific QFT one must also justify the scaling limit, the kernel reduction to the constant Y-system, and the absence or subtraction of bulk-energy terms.

78.3 An SU(3) Nested Density System

The finite $SU(3)$ equations (75.8)–(75.9) give a useful nontrivial density example. Define

$$\varphi_\alpha(u) = \mathrm{i}\log\frac{u+\mathrm{i}\alpha}{u-\mathrm{i}\alpha}, \qquad a_\alpha(u) = \frac{1}{2\pi}\varphi'_\alpha(u) = \frac{1}{2\pi}\frac{2\alpha}{u^2+\alpha^2}.$$

The logarithmic branches are fixed continuously along the real root lines. For first-level roots u_j and second-level roots v_α, the counting functions may be chosen as

$$Z_u(u) = L\varphi_{1/2}(u) - \sum_k \varphi_1(u-u_k) + \sum_\beta \varphi_{1/2}(u-v_\beta),$$
$$Z_v(v) = -\sum_\beta \varphi_1(v-v_\beta) + \sum_j \varphi_{1/2}(v-u_j).$$

Differentiating and passing to densities gives

$$\rho + \rho^h = a_{1/2} - a_1 * \rho + a_{1/2} * \sigma, \tag{78.7}$$
$$\sigma + \sigma^h = a_{1/2} * \rho - a_1 * \sigma. \tag{78.8}$$

The signs are not arbitrary: they are the logarithmic derivatives of the same-level scattering factors and adjacent-node inverse factors in (75.8)–(75.9). If $\widehat{f}(\omega) = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}\omega u} f(u)\,\mathrm{d}u$, then

$$\widehat{a}_\alpha(\omega) = \mathrm{e}^{-\alpha|\omega|},$$

so the coupled linear density constraints are diagonalized in Fourier space. This elementary calculation is the finite-rank shadow of the nested TBA kernel manipulations used in principal chiral and Gross–Neveu models: the Cartan matrix controls which auxiliary species couple, while the analytic input lies in the physical scalar factors and in the thermodynamic string hypothesis.

78.4 Baxter TQ Relation

For the $XXX_{1/2}$ transfer eigenvalue (74.9), define the Baxter polynomial

$$Q(u) = \prod_{j=1}^{M}(u-u_j).$$

Then the eigenvalue equation can be rewritten as the finite-difference relation

$$\Lambda(u)Q(u) = \left(u+\frac{\mathrm{i}}{2}\right)^L Q(u-\mathrm{i}) + \left(u-\frac{\mathrm{i}}{2}\right)^L Q(u+\mathrm{i}). \tag{78.9}$$

Let $Q(u) = \prod_j (u-u_j)$ have simple roots. Equation (78.9) is regular at the zeros of Q precisely when the roots u_j obey the $XXX_{1/2}$ Bethe equations (74.8). Evaluating the numerator at $u = u_j$ gives

$$\left(u_j+\frac{\mathrm{i}}{2}\right)^L Q(u_j-\mathrm{i}) + \left(u_j-\frac{\mathrm{i}}{2}\right)^L Q(u_j+\mathrm{i}) = 0.$$

Since

$$\frac{Q(u_j+\mathrm{i})}{Q(u_j-\mathrm{i})} = -\prod_{\substack{k=1\\k\neq j}}^{M} \frac{u_j-u_k+\mathrm{i}}{u_j-u_k-\mathrm{i}},$$

the displayed equality is precisely (74.8). Conversely, if the Bethe equations hold, the numerator on the right side of (78.9) vanishes at every root of Q, so division by Q produces a polynomial Λ.

78.5 Baxter Casoratian and the Second Solution

The scalar TQ relation is a second-order finite-difference equation. Its two independent solutions carry the same information as a rank-two Wronskian system. This elementary point becomes structurally important in higher rank and in the quantum spectral curve: a Q-system is not just a list of Bethe polynomials, but a family of finite-difference solutions tied together by Casoratian identities and boundary conditions.

Write the rank-one Baxter equation in the form

$$\Lambda(u)Q(u) = a(u)Q(u-\mathrm{i}) + d(u)Q(u+\mathrm{i}), \tag{78.10}$$

where a, d, Λ are meromorphic functions on a common shift domain. For two solutions Q_1, Q_2, define the half-shift Casoratian

$$\mathcal{W}[Q_1,Q_2](u) = Q_1\left(u+\frac{\mathrm{i}}{2}\right)Q_2\left(u-\frac{\mathrm{i}}{2}\right) - Q_1\left(u-\frac{\mathrm{i}}{2}\right)Q_2\left(u+\frac{\mathrm{i}}{2}\right). \tag{78.11}$$

Lemma 78.2 (Baxter Casoratian transport)**.** *If Q_1 and Q_2 solve (78.10) with the same a, d, Λ, then*

$$d(u)\,\mathcal{W}[Q_1,Q_2]\left(u+\frac{\mathrm{i}}{2}\right) = a(u)\,\mathcal{W}[Q_1,Q_2]\left(u-\frac{\mathrm{i}}{2}\right). \tag{78.12}$$

At a point where $a(u)d(u) \neq 0$, vanishing of the Casoratian on one adjacent half-shift is therefore transported to the other.

Proof. Multiply (78.10) for Q_1 by $Q_2(u)$, multiply the same equation for Q_2 by $Q_1(u)$, and subtract. The terms containing $\Lambda(u)Q_1(u)Q_2(u)$ cancel, leaving

$$a(u)\left(Q_1(u-\mathrm{i})Q_2(u) - Q_2(u-\mathrm{i})Q_1(u)\right) + d(u)\left(Q_1(u+\mathrm{i})Q_2(u) - Q_2(u+\mathrm{i})Q_1(u)\right) = 0.$$

The second bracket is

$$\mathcal{W}[Q_1,Q_2]\left(u+\frac{\mathrm{i}}{2}\right),$$

whereas the first bracket is

$$-\mathcal{W}[Q_1,Q_2]\left(u-\frac{\mathrm{i}}{2}\right).$$

Substitution gives (78.12). If $a(u)d(u) \neq 0$, the displayed equation is a nonzero scalar multiple relation between the two adjacent Casoratians, so either one vanishes exactly when the other does. □

For the homogeneous $XXX_{1/2}$ normalization of (78.9),

$$a(u) = \left(u + \frac{\mathrm{i}}{2}\right)^L, \qquad d(u) = \left(u - \frac{\mathrm{i}}{2}\right)^L,$$

so the Casoratian obeys

$$\frac{\mathcal{W}(u + \mathrm{i}/2)}{\mathcal{W}(u - \mathrm{i}/2)} = \left(\frac{u + \mathrm{i}/2}{u - \mathrm{i}/2}\right)^L. \tag{78.13}$$

The polynomial Bethe solution is only one member of the two-dimensional local solution space of the difference equation. The companion solution is usually meromorphic rather than polynomial; its poles and asymptotics encode the boundary condition that selected the Bethe state. Higher-rank Wronskian Q_A's generalize this rank-one Casoratian: the determinant formula in the next section is the multi-solution version of (78.11), and the QQ-relations are the corresponding Pluecker identities.

78.6 QQ-System and Bäcklund Flow

For higher-rank systems it is more efficient to work with a family of Q-functions indexed by subsets. Let $I = \{1, \ldots, N\}$. For every subset $A \subset I$ introduce a meromorphic function $Q_A(u)$, with $Q_\varnothing(u) = 1$. Write

$$f^\pm(u) = f\left(u \pm \frac{\mathrm{i}}{2}\right).$$

The rational $\mathfrak{gl}_N$ QQ-system is

$$Q_{Aab}(u)Q_A(u) = Q^+_{Aa}(u)Q^-_{Ab}(u) - Q^-_{Aa}(u)Q^+_{Ab}(u), \tag{78.14}$$

for $a, b \notin A$, $a \neq b$. Here $Aa = A \cup \{a\}$ and $Aab = A \cup \{a, b\}$. Repeated use of (78.14) reconstructs all multi-index Q-functions from a flag of one-index functions together with normalization data. Moving from Q_A to Q_{Aa} is the functional form of a Bäcklund step: one removes one simple color direction from the auxiliary problem, exactly as the nested monodromy removes one residual color space at each level.

Let $q_1(u), \ldots, q_N(u)$ be functions for which the determinants below are defined. For an ordered subset $A = \{a_1 < \cdots < a_m\}$, set

$$Q_A(u) = \det_{1 \le r,s \le m} q_{a_r}^{[m+1-2s]}(u), \qquad f^{[k]}(u) = f\left(u + \frac{\mathrm{i}k}{2}\right),$$

and $Q_\varnothing = 1$. Then the functions Q_A obey (78.14). Fix A of size m and two indices $a, b \notin A$. Form the $(m+2) \times (m+2)$ matrix whose columns are the shifted columns corresponding to A, a, b. Apply the Desnanot–Jacobi identity to the minor obtained by deleting the two columns associated with the outer shifts. With the shifts ordered as $m+2, m, \ldots, -m, -m-2$, the four minors are precisely $Q_{Aab}Q_A$, $Q^+_{Aa}Q^-_{Ab}$, and $Q^-_{Aa}Q^+_{Ab}$, with the relative sign fixed by the column order. This gives (78.14). The identity is purely determinant algebra; no analytic assumption on the q_i's is used beyond existence of the displayed values.

78.7 Bäcklund Elimination as Q-System Restriction

The Bäcklund language used in nested Bethe ansatz should be understood as a recursive statement about Q-system data, not as a separate dynamical principle. Let $I = \{1, \ldots, N\}$ and let $\{Q_A\}_{A \subset I}$ obey (78.14). Choose a color $c \in I$, and define an unnormalized restricted family on $I \setminus \{c\}$ by

$$Q_A^{(c)}(u) = Q_{A \cup \{c\}}(u), \qquad A \subset I \setminus \{c\}. \tag{78.15}$$

Then $Q^{(c)}$ obeys the same local QQ-relation on the smaller index set:

$$Q_{Aab}^{(c)}(u) Q_A^{(c)}(u) = \big(Q_{Aa}^{(c)}\big)^+(u)\big(Q_{Ab}^{(c)}\big)^-(u) - \big(Q_{Aa}^{(c)}\big)^-(u)\big(Q_{Ab}^{(c)}\big)^+(u), \tag{78.16}$$

for $a, b \notin A \cup \{c\}$, $a \neq b$. This is simply (78.14) applied to the subset $A \cup \{c\}$ and the two remaining indices a, b. The point of recording it is not the algebraic verification; the point is the interpretation. A Bäcklund step removes one auxiliary color direction by passing from the N-color Q-system to the subsystem of minors that contain the eliminated color. Repeating the operation along a flag

$$I = I_N \supset I_{N-1} \supset \cdots \supset I_1 \supset I_0 = \varnothing, \qquad |I_r| = r,$$

produces the chain of rank-reduced Q-systems that mirrors the recursive nested monodromy of Chapter 75.

The adjective "unnormalized" in (78.15) matters. The restricted empty function is $Q_\varnothing^{(c)} = Q_c$, not the constant 1. In a finite spin chain one often chooses a Q-gauge in which the new empty function is normalized away on a domain where Q_c has no zeros. In an analytic T-system or quantum spectral-curve problem this normalization is part of the analytic datum: zeros, cuts, asymptotics, and large-u powers cannot be divided out without recording what has happened to them. Thus Bäcklund elimination is a local algebraic operation on Q-systems, while the normalized physical presentation of the reduced problem requires the gauge and analytic data of Definition 78.4.

For $N = 3$, the first elimination already displays the nesting pattern. If $c = 3$, the restricted rank-two data are

$$Q_\varnothing^{(3)} = Q_3, \qquad Q_1^{(3)} = Q_{13}, \qquad Q_2^{(3)} = Q_{23}, \qquad Q_{12}^{(3)} = Q_{123}.$$

The smaller QQ-relation is

$$Q_{123} Q_3 = Q_{13}^+ Q_{23}^- - Q_{13}^- Q_{23}^+,$$

which is the original QQ-relation with base subset $\{3\}$. In nested Bethe ansatz this is the algebraic shadow of passing from the original three-color auxiliary problem to the residual two-color one; the Bethe roots of the reduced problem are zeros of the Q-functions that survive the restriction, together with the gauge convention used to interpret them as polynomials.

78.8 Fusion and the Hirota T-System

The transfer matrix with a fundamental auxiliary space is only the first member of a fused family. In a rational $SU(N)$ chain, one obtains commuting transfer matrices $T_{a,s}(u)$ by taking auxiliary spaces whose highest weights are rectangular Young diagrams: a rows and s columns, with $1 \leq$

$a \leq N-1$ and $s \geq 0$. Fusion is implemented by projecting products of fundamental monodromies at shifted spectral parameters onto the corresponding irreducible auxiliary component. The Yang–Baxter equation ensures that the projected transfer matrices commute.

The local functional identity is the Hirota equation

$$T^+_{a,s}(u)T^-_{a,s}(u) = T_{a+1,s}(u)T_{a-1,s}(u) + T_{a,s+1}(u)T_{a,s-1}(u), \tag{78.17}$$

with boundary data $T_{0,s} = T_{a,0} = 1$ in the simplest normalization and $T_{N,s}$ fixed by the quantum determinant. The precise boundary factors depend on twist, inhomogeneity, and representation; the local bilinear identity is the invariant content.

Suppose the fused eigenvalues $T_{a,s}$ are written in a Wronskian gauge as minors of a matrix of shifted Q-functions. Then (78.17) follows from the Pluecker relation among adjacent minors. In the Wronskian gauge, $T_{a,s}$ is an $a \times a$ minor whose columns are shifts separated by i. The shifts of $T^+_{a,s}$ and $T^-_{a,s}$ differ by moving the left and right boundary columns of this minor outward. The Desnanot–Jacobi identity for the corresponding $(a+1)\times(a+1)$ matrix states that the product of the two adjacent $a \times a$ minors equals the product of the inner and outer minors plus the product of the two side minors. These four minors are, respectively, $T^+_{a,s}T^-_{a,s}$, $T_{a+1,s}T_{a-1,s}$, and $T_{a,s+1}T_{a,s-1}$. This is exactly (78.17).

The associated Y-functions are gauge-invariant ratios of neighboring T-functions:

$$Y_{a,s}(u) = \frac{T_{a,s+1}(u)T_{a,s-1}(u)}{T_{a+1,s}(u)T_{a-1,s}(u)}. \tag{78.18}$$

Using Hirota gives the local Y-system identity

$$Y^+_{a,s}(u)Y^-_{a,s}(u) = \frac{(1+Y_{a,s+1})(1+Y_{a,s-1})}{(1+Y^{-1}_{a+1,s})(1+Y^{-1}_{a-1,s})}, \tag{78.19}$$

where all functions are evaluated at u unless shifted. This is an algebraic identity once the same Hirota gauge is used at the four adjacent nodes; analytic continuation, strip domains, source terms, and asymptotics are additional model-specific data.

78.9 T-Gauge and Analytic T-System Specifications

The Hirota equation is not by itself a spectral problem. It is a local bilinear relation on a two-dimensional lattice of functions. A transfer matrix, a relativistic TBA system, or a quantum spectral curve is obtained only after one adds the boundary conditions and analytic constraints that select a particular solution. The first such constraint is the gauge freedom of the T-system.

Definition 78.3 (T-gauge transformation)**.** Let g_1, g_2, g_3, g_4 be nowhere-vanishing meromorphic functions on a shift domain containing the arguments used below. For a family $T_{a,s}(u)$, set

$$\mathcal{G}_{a,s}(u) = g_1^{[a+s]}(u)\, g_2^{[a-s]}(u)\, g_3^{[-a+s]}(u)\, g_4^{[-a-s]}(u), \qquad \widetilde{T}_{a,s}(u) = \mathcal{G}_{a,s}(u)T_{a,s}(u). \tag{78.20}$$

This transformation is called a T-gauge transformation on the chosen (a,s)-domain.

The four factors in $\mathcal{G}_{a,s}$ are arranged so that every monomial in the Hirota equation receives the same multiplier:

$$\mathcal{G}_{a,s}^{+}\mathcal{G}_{a,s}^{-} = \mathcal{G}_{a+1,s}\mathcal{G}_{a-1,s} = \mathcal{G}_{a,s+1}\mathcal{G}_{a,s-1}. \tag{78.21}$$

For example, the g_1 arguments in the first product are $[a+s+1]$ and $[a+s-1]$; the g_1 arguments in the second and third products are the same two shifts in the opposite lattice directions. The same check applies to g_2, g_3, g_4. Thus a T-gauge transformation maps a solution of (78.17) to another solution. It also leaves the Y-functions (78.18) invariant, because the four g_i-shift pairs in the numerator and denominator cancel separately. Consequently the Y-system is a gauge-invariant shadow of the T-system, while the transfer matrices themselves retain gauge-dependent boundary factors.

This distinction matters in applications. The local Hirota relation says that adjacent rectangular representations, or adjacent Wronskian minors, fit together consistently. It does not specify:

1. the allowed (a, s)-domain;
2. the boundary factors $T_{0,s}$, $T_{N,s}$, $T_{a,0}$, and their zeros and poles;
3. the strip of meromorphy or cut structure in the spectral parameter;
4. asymptotic behavior at infinity or at distinguished singular points;
5. reality, crossing, twist, and quantum-determinant constraints;
6. source terms introduced by physical particles, holes, defects, or wrapping corrections.

These items are not decorative. They are the analytic and boundary conditions that turn the Hirota identity into a spectral problem with a discrete set, or a controlled continuum family, of solutions. Two T-systems related by (78.20) describe the same Y-system, but they may place boundary divisors in different T-functions. A statement about polynomiality, zero locations, or large-u normalization is therefore meaningful only after the gauge has been fixed.

Definition 78.4 (Analytic T-system specification)**.** An analytic T-system specification on a lattice domain $\mathfrak{D} \subset \mathbb{Z}^2$ consists of:

1. meromorphic functions $T_{a,s}$ on a specified shift-stable spectral domain, for $(a, s) \in \mathfrak{D}$, satisfying Hirota at interior lattice points;
2. a T-gauge equivalence class, together with a chosen gauge when polynomiality or asymptotics are asserted;
3. boundary functions and quantum-determinant factors on $\partial\mathfrak{D}$;
4. the allowed zero, pole, branch-cut, and asymptotic conditions;
5. the map from this analytic specification to physical charges or transfer eigenvalues.

In finite spin chains the analytic specification is often polynomial: the inhomogeneities, twist, representation labels, and quantum determinant fix the boundary factors, and Bethe equations enforce cancellation of unwanted poles. In relativistic integrable QFT, the same local Hirota/Y-system algebra must be supplemented by strip analyticity, source terms, and large-rapidity asymptotics before it becomes a TBA problem. In planar gauge-theory integrability, the quantum spectral curve replaces the finite polynomial condition by a Riemann–Hilbert type problem: sheets, cuts, asymptotics, gluing conditions, and quantization of charges. The determinant identities in this chapter supply the local algebraic skeleton; the analytic T-system specification turns that skeleton into a physical spectral problem.

78.10 Q-Operators

A Q-operator is an operator-valued function $Q(u)$ commuting with the transfer matrix and satisfying an operator TQ relation whose eigenvalue version is (78.9). Operator construction requires an auxiliary representation in which the trace, or a regulated trace, is defined. In rank one this can be described as follows.

Construction 78.5 (Rank-one Baxter operator construction)**.** Let $\mathcal{A}$ be an auxiliary representation of the RTT algebra for the same R-matrix, not necessarily finite dimensional. Let $\mathcal{L}_{\mathcal{A},j}(u) \in \mathrm{End}(\mathcal{A} \otimes \mathbb{C}^2_j)$ satisfy the mixed RTT relation with the fundamental L-operator. If the regularized auxiliary trace

$$Q(u) = \mathrm{Tr}^{\mathrm{reg}}_{\mathcal{A}}\big(\mathcal{L}_{\mathcal{A},L}(u) \cdots \mathcal{L}_{\mathcal{A},1}(u)\big)$$

exists and is cyclic on the products used in the RTT proof, then $[Q(u), t(v)] = 0$. If the tensor product of the fundamental auxiliary space with $\mathcal{A}$ has a short exact sequence whose quotient and submodule shift the spectral parameter by $\pm\mathrm{i}$, the transfer-matrix trace over that sequence gives the operator TQ relation.

Exact-sequence derivation of an operator TQ relation. Assume the data of Construction 78.5. Assume further that, for every spectral parameter u, there is a short exact sequence of auxiliary RTT modules

$$0 \longrightarrow \mathcal{A}(u - \mathrm{i}) \xrightarrow{\iota} \mathbb{C}^2(u) \otimes \mathcal{A}(u) \xrightarrow{\pi} \mathcal{A}(u + \mathrm{i}) \longrightarrow 0, \tag{78.22}$$

and that the corresponding monodromy on $\mathbb{C}^2(u) \otimes \mathcal{A}(u) \otimes \mathcal{H}_L$ is block triangular in a basis adapted to ι, π, with diagonal blocks $a(u)\, M_{\mathcal{A}}(u - \mathrm{i})$ and $d(u)\, M_{\mathcal{A}}(u + \mathrm{i})$. Then

$$t(u)\, Q(u) = a(u)Q(u - \mathrm{i}) + d(u)Q(u + \mathrm{i}) \tag{78.23}$$

as operators on the quantum chain.

The product $t(u)Q(u)$ is the regularized trace over $\mathbb{C}^2(u) \otimes \mathcal{A}(u)$ of the product monodromy, because the mixed RTT relation permits the fundamental and auxiliary monodromies to be ordered inside one common auxiliary trace. Adapt the auxiliary vector space to the short exact sequence (78.22). The monodromy matrix is block triangular, hence its trace is the sum of the traces of the two diagonal blocks. The scalar diagonal factors are exactly the vacuum propagation factors $a(u)$ and $d(u)$, while the remaining block traces are the regularized traces defining $Q(u-\mathrm{i})$ and $Q(u+\mathrm{i})$. Cyclicity of the regularized trace is the only analytic input in this finite-chain argument. This gives (78.23).

The construction displays the logical ingredients rather than hiding them in the phrase "Baxter operator": a mixed RTT relation, a trace functional with cyclicity, and an exact sequence of auxiliary representations. In rational finite chains one may realize $\mathcal{A}$ as a limiting highest-weight module. In trigonometric rank-one chains one uses a q-oscillator Fock module. For $q \in \mathbb{C}^\times$ not a root of unity, one convenient q-oscillator algebra is generated by $D, \mathsf{a}, \mathsf{a}^\dagger$ with

$$q^D \mathsf{a} q^{-D} = q^{-1}\mathsf{a}, \qquad q^D \mathsf{a}^\dagger q^{-D} = q\mathsf{a}^\dagger, \qquad \mathsf{a}^\dagger \mathsf{a} = 1 - q^{2D}, \qquad \mathsf{a}\mathsf{a}^\dagger = 1 - q^{2D+2}.$$

On the Fock module $\mathcal{F} = \bigoplus_{n\ge 0} \mathbb{C}|n\rangle$,

$$D|n\rangle = n|n\rangle, \qquad \mathsf{a}|n\rangle = (1-q^{2n})|n-1\rangle, \qquad \mathsf{a}^\dagger|n\rangle = |n+1\rangle.$$

This convention is related to the Borel q-oscillator generators $\mathcal{H}, \mathcal{E}_\pm$ by

$$\mathcal{H} = 2D, \qquad \mathcal{E}_+ = \frac{\mathsf{a}^\dagger}{q-q^{-1}}, \qquad \mathcal{E}_- = \frac{\mathsf{a}}{q-q^{-1}}.$$

Indeed

$$[\mathcal{H}, \mathcal{E}_\pm] = \pm 2\mathcal{E}_\pm, \qquad q\mathcal{E}_+\mathcal{E}_- - q^{-1}\mathcal{E}_-\mathcal{E}_+ = \frac{1}{q-q^{-1}}, \tag{78.24}$$

where the second identity follows from

$$q\mathsf{a}^\dagger\mathsf{a} - q^{-1}\mathsf{a}\mathsf{a}^\dagger = q(1-q^{2D}) - q^{-1}(1-q^{2D+2}) = q - q^{-1}.$$

The local trigonometric q-oscillator L-operator. Let $V = \mathbb{C}e_+ \oplus \mathbb{C}e_-$. In the six-vertex normalization used in this paragraph, $R(x) \in \mathrm{End}(V \otimes V)$ has non-zero entries

$$\begin{aligned} &R^{++}_{++}(x) = R^{--}_{--}(x) = q + q^{-1}x, && R^{+-}_{+-}(x) = R^{-+}_{-+}(x) = 1 + x, \\ &R^{+-}_{-+}(x) = q - q^{-1}, && R^{-+}_{+-}(x) = -(q-q^{-1})x. \end{aligned} \tag{78.25}$$

The q-oscillator auxiliary L-operator is the following element of $\mathrm{End}(V \otimes \mathcal{F})$, written as a 2×2 matrix in the ordered basis e_+, e_-:

$$L^{(+)}_{\mathcal{F}}(x) = \begin{pmatrix} q^D & \mathsf{a} \\ -x\,\mathsf{a}^\dagger & q^{-D} + xq^{D+1} \end{pmatrix}. \tag{78.26}$$

Equivalently, before choosing the Fock realization,

$$\begin{aligned} L^{(+)}_{\mathcal{F}}(x) = q^{\mathcal{H}\otimes\sigma^z/2} &+ (q-q^{-1})(\mathcal{E}_- \otimes \sigma^+ - x\mathcal{E}_+ \otimes \sigma^-) \\ &+ x(q-q^{-1})q^{-\mathcal{H}/2}(\mathcal{E}_+\mathcal{E}_- - \mathcal{E}_-\mathcal{E}_+) \otimes \sigma^-\sigma^+, \end{aligned} \tag{78.27}$$

with $\sigma^z e_\pm = \pm e_\pm$, $\sigma^+ e_- = e_+$, $\sigma^- e_+ = e_-$. Substituting (78.24) gives (78.26); the bottom-right entry uses

$$\mathcal{E}_+\mathcal{E}_- - \mathcal{E}_-\mathcal{E}_+ = \frac{q^{2D+1}}{q-q^{-1}}.$$

Proposition 78.6 (Local q-oscillator RLL identity)**.** *For $q \in \mathbb{C}^\times$ not a root of unity, the operators* (78.25) *and* (78.26) *satisfy*

$$R_{12}(-x/y)\, L^{(+)}_{\mathcal{F},13}(x)\, L^{(+)}_{\mathcal{F},23}(y) = L^{(+)}_{\mathcal{F},23}(y)\, L^{(+)}_{\mathcal{F},13}(x)\, R_{12}(-x/y) \tag{78.28}$$

as an identity in $\mathrm{End}(V \otimes V \otimes \mathcal{F})$.

Proof. Write $N = q^D$. The q-oscillator relations are

$$N\mathsf{a} = q^{-1}\mathsf{a}N, \qquad N\mathsf{a}^\dagger = q\mathsf{a}^\dagger N, \qquad \mathsf{a}^\dagger\mathsf{a} = 1 - N^2, \qquad \mathsf{a}\mathsf{a}^\dagger = 1 - q^2N^2. \tag{78.29}$$

Both sides of (78.28) are finite sums of monomials in $N^{\pm1}, \mathsf{a}, \mathsf{a}^\dagger$. Moving every $N^{\pm1}$ to the middle and reducing every adjacent $\mathsf{a}^\dagger\mathsf{a}$ and $\mathsf{a}\mathsf{a}^\dagger$ by (78.29) gives a normal form with at most one creation or annihilation operator on either side of a Laurent polynomial in N. Therefore it is enough to compare the four spin-input sectors $e_{\epsilon_1} \otimes e_{\epsilon_2} \otimes |n\rangle$, $n \geq 0$.

Let

$$\begin{aligned} N_n &= q^n, & \alpha_n &= 1 - q^{2n}, & A_n &= N_n^2 - 1, & \Delta &= x - q^2 y, \\ B_x &= N_n^2 qx + 1, & B_y &= N_n^2 qy + 1, & G_y &= N_n^2 y + q. \end{aligned}$$

For the mixed sector below also write

$$\begin{aligned} C_{+-} &= N_n^2 q^2 y^2 - N_n^2 xy - q^2 xy - qx + qy + xy, \\ D_{+-} &= N_n^2 q^3 y - N_n^2 qx + q^2 + qx - qy - 1. \end{aligned}$$

In the sector $e_+ \otimes e_+$, both sides of (78.28) act as

$$\begin{aligned} e_+ \otimes e_+ \otimes |n\rangle \mapsto \; & -\frac{\Delta}{qy} N_n^2 \, e_+ \otimes e_+ \otimes |n\rangle + \frac{\Delta}{q} N_n \, e_+ \otimes e_- \otimes |n+1\rangle \\ & + \frac{x\Delta}{y} N_n \, e_- \otimes e_+ \otimes |n+1\rangle - \frac{x\Delta}{q} \, e_- \otimes e_- \otimes |n+2\rangle. \end{aligned} \tag{78.30}$$

In the sector $e_- \otimes e_-$, applying the same reductions gives

$$\begin{aligned} e_- \otimes e_- \otimes |n\rangle \mapsto \; & \frac{(q - N_n)(N_n + q) A_n \Delta}{q^3 y} \, e_+ \otimes e_+ \otimes |n-2\rangle + \frac{A_n G_y \Delta}{q N_n y} \, e_+ \otimes e_- \otimes |n-1\rangle \\ & + \frac{A_n \Delta B_x}{q N_n y} \, e_- \otimes e_+ \otimes |n-1\rangle - \frac{\Delta B_x B_y}{q N_n^2 y} \, e_- \otimes e_- \otimes |n\rangle. \end{aligned} \tag{78.31}$$

The terms with $|n-1\rangle$ or $|n-2\rangle$ vanish automatically when the displayed ket is outside the Fock module, because $\alpha_0 = 0$. The mixed sectors are the only places where the off-diagonal six-vertex weights enter. For $e_+ \otimes e_-$, both sides give

$$\begin{aligned} & -\frac{\Delta \alpha_n N_n}{q^2 y} \, e_+ \otimes e_+ \otimes |n-1\rangle + \frac{C_{+-}}{qy} \, e_+ \otimes e_- \otimes |n\rangle \\ & + \frac{x D_{+-}}{qy} \, e_- \otimes e_+ \otimes |n\rangle + \frac{x \Delta B_y}{q N_n y} \, e_- \otimes e_- \otimes |n+1\rangle. \end{aligned} \tag{78.32}$$

The $e_- \otimes e_+$ formula is obtained from (78.32) by interchanging $(x, e_1) \leftrightarrow (y, e_2)$ together with the asymmetric normalization of R_{+-}^{-+} in (78.25); the resulting coefficients are exactly those obtained by expanding the two sides. These four sector computations exhaust the basis of $V \otimes V \otimes \mathcal{F}$, hence (78.28) follows. $\square$

The regularized trace is first defined by

$$\operatorname{Tr}_{\mathcal{F}}^{\mathrm{reg}}(X) = \underset{z=1}{\text{mer. cont.}} \operatorname{Tr}_{\mathcal{F}}(z^D X), \qquad |z| < 1,$$

whenever the meromorphic continuation exists and is finite after the scalar normalization of the Q-operator has been fixed. Proposition 78.6 supplies the local algebraic input for the trigonometric rank-one Q-operator. The remaining analytic inputs are separate: cyclicity of the regularized trace on the monodromy products and the short exact sequence (78.22). Once these are checked, the operator identity (78.23) is a consequence of block-triangular algebra plus the stated trace regularization. The eigenvalue statement used in this chapter is the consequence of this construction, not its replacement.

78.11 Separation of Variables

Separation of variables uses a different complete set of commuting objects. For the 2×2 monodromy

$$T(u) = \begin{pmatrix} A(u) & B(u) \\ C(u) & D(u) \end{pmatrix},$$

RTT implies $[B(u), B(v)] = 0$. Suppose we are in a finite-dimensional representation for which the commuting coefficients of $B(u)$ are simultaneously diagonalizable with simple joint spectrum. On a joint right or left eigenline the B-eigenvalue has the polynomial form

$$B(u) = B_0 \prod_{\alpha=1}^{L-1} (u - x_\alpha).$$

The numbers x_α are separated coordinates.

Local RTT shift algebra. The separated-coordinate shift is an operator statement before it is a wavefunction equation. In the rational RTT normalization compatible with (78.9), the components involving A, D, and B are understood as identities after multiplication by $u - v$:

$$A(u)B(v) = \frac{u - v - \mathrm{i}}{u - v} B(v)A(u) + \frac{\mathrm{i}}{u - v} B(u)A(v), \tag{78.33}$$

$$D(u)B(v) = \frac{u - v + \mathrm{i}}{u - v} B(v)D(u) - \frac{\mathrm{i}}{u - v} B(u)D(v). \tag{78.34}$$

Let $\langle \boldsymbol{x}|$ be a simultaneous left eigenvector of the commuting coefficients of B:

$$\langle \boldsymbol{x}| B(v) = B_0 \prod_{\beta=1}^{L-1} (v - x_\beta) \langle \boldsymbol{x}|.$$

Set $u = x_\alpha$ in (78.33)–(78.34). The terms proportional to $B(x_\alpha)$ vanish on the left eigenvector, so

$$\langle \boldsymbol{x}| A(x_\alpha) B(v) = B_0 (v - x_\alpha + \mathrm{i}) \prod_{\beta \neq \alpha} (v - x_\beta) \langle \boldsymbol{x}| A(x_\alpha), \tag{78.35}$$

$$\langle \boldsymbol{x}| D(x_\alpha) B(v) = B_0 (v - x_\alpha - \mathrm{i}) \prod_{\beta \neq \alpha} (v - x_\beta) \langle \boldsymbol{x}| D(x_\alpha). \tag{78.36}$$

Thus, whenever the resulting covector is nonzero and the joint spectrum is simple, $\langle \boldsymbol{x}|A(x_\alpha)$ lies on the eigenline with the single coordinate x_α replaced by $x_\alpha - \mathrm{i}$, while $\langle \boldsymbol{x}|D(x_\alpha)$ lies on the eigenline with x_α replaced by $x_\alpha + \mathrm{i}$. A choice of SoV covector normalization fixes the scalar coefficients. In the normalization used in the scalar Baxter equation,

$$\langle \boldsymbol{x}| A(x_\alpha) = a(x_\alpha) \langle \boldsymbol{x} - \mathrm{i} e_\alpha|, \qquad \langle \boldsymbol{x}| D(x_\alpha) = d(x_\alpha) \langle \boldsymbol{x} + \mathrm{i} e_\alpha|. \tag{78.37}$$

Equations (78.35)–(78.37) are the finite-chain construction behind the separated Baxter equation below. The shift is not an analogy with classical separated coordinates; it is the residue of the RTT algebra at a zero of B.

Finite-chain SoV reduction under simple-spectrum hypotheses. Assume the coefficients of $B(u)$ have a simple joint eigenbasis $\{\langle \boldsymbol{x}|\}$ normalized as in (78.37). Then a transfer-matrix eigenvector with separated wavefunction $\Psi(\boldsymbol{x}) = \langle \boldsymbol{x}|\Psi\rangle$ satisfies, for each $\alpha = 1, \dots, L-1$, a one-variable Baxter equation

$$\Lambda(x_\alpha)\Psi(\boldsymbol{x}) = a(x_\alpha)\Psi(\boldsymbol{x} - \mathrm{i}e_\alpha) + d(x_\alpha)\Psi(\boldsymbol{x} + \mathrm{i}e_\alpha), \tag{78.38}$$

where $a(u)$ and $d(u)$ are the vacuum diagonal eigenvalue functions of $A(u)$ and $D(u)$, and e_α shifts only the coordinate x_α.

Act with $t(u) = A(u)+D(u)$ on a transfer eigenvector Ψ and evaluate the left covector equation at $u = x_\alpha$. The two summands are evaluated by (78.37), giving exactly (78.38). The simple-spectrum hypothesis ensures that the shifted covectors are identified by their separated coordinates rather than by a nontrivial Jordan block or multiplicity space.

When both the algebraic Bethe ansatz and SoV are valid, the Bethe polynomial $Q(u)$ is the one-variable factor whose values solve (78.38) at every separated coordinate. The pseudovacuum construction builds eigenvectors from zeros of Q; SoV builds the same spectral problem by diagonalizing $B(u)$. Their equality is not a slogan about roots: it is a comparison statement between two bases of the same finite-dimensional representation.

Finite-chain ABA–Q–SoV comparison under explicit hypotheses. For a finite rational $SU(2)$ chain with generic diagonal twist and generic inhomogeneities, assume the following finite-dimensional properties:

1. the transfer matrix has simple spectrum;
2. the algebraic Bethe ansatz produces one nonzero Bethe vector for every transfer eigenvalue;
3. a Baxter Q-operator satisfying the operator TQ relation exists;
4. the coefficients of $B(u)$ have a simple SoV spectrum.

Then the ABA Bethe roots, the zeros of the Q-operator eigenvalue, and the one-variable SoV Baxter wavefunction determine the same transfer-matrix eigenline.

The justification uses only these finite-chain inputs. By the operator TQ relation, the eigenvalue $Q_\Psi(u)$ of $Q(u)$ on a transfer eigenvector Ψ satisfies (78.9) with the same $\Lambda(u)$. Regularity of the scalar TQ relation at the simple zeros of Q_Ψ gives the ABA Bethe equations. Assumption 2 then gives an ABA vector with the same transfer eigenvalue Λ. Simplicity of the transfer spectrum identifies the two vectors up to scalar. The SoV wavefunction satisfies (78.38); the polynomial Q_Ψ gives a solution of each one-coordinate equation by evaluation at x_α. Simplicity of the SoV joint spectrum identifies the resulting wavefunction with the same eigenline. Thus all three constructions label the same line, under the stated hypotheses.

78.12 The SoV Measure Is Part of the Construction

The word "measure" in finite-chain SoV does not mean a Borel measure on a classical configuration space. It is the weight in the resolution of the identity for a finite-dimensional joint spectral problem. Let $\mathcal{X}$ be the finite joint spectrum of the commuting coefficients of $B(u)$, and let $|\boldsymbol{x}\rangle$, $\langle\widetilde{\boldsymbol{x}}|$ be right and left eigenvectors normalized so that

$$\langle\widetilde{\boldsymbol{x}} \mid \boldsymbol{y}\rangle = 0 \qquad (\boldsymbol{x} \neq \boldsymbol{y}).$$

If the joint spectrum is simple and complete, define

$$\mu(\boldsymbol{x}) = \langle\widetilde{\boldsymbol{x}} \mid \boldsymbol{x}\rangle^{-1}.$$

Then

$$\mathrm{id}_{\mathcal{H}} = \sum_{\boldsymbol{x}\in\mathcal{X}} \mu(\boldsymbol{x})|\boldsymbol{x}\rangle\langle\widetilde{\boldsymbol{x}}|. \tag{78.39}$$

For two vectors Φ, Ψ, their scalar product is therefore

$$\langle\Phi \mid \Psi\rangle = \sum_{\boldsymbol{x}\in\mathcal{X}} \mu(\boldsymbol{x})\,\langle\Phi \mid \boldsymbol{x}\rangle\langle\widetilde{\boldsymbol{x}} \mid \Psi\rangle,$$

with the obvious conjugations when the left basis is chosen as the Hermitian dual of the right basis in a unitary representation. In concrete inhomogeneous spin chains this weight can be written as a determinant or Vandermonde-type product. That explicit formula is representation-dependent, but (78.39) is the invariant finite-dimensional statement.

Under the simple-spectrum SoV hypotheses above, suppose a function $Q(u)$ solves the one-variable Baxter equation at every separated coordinate value appearing in $\mathcal{X}$. Then

$$\Psi_Q(\boldsymbol{x}) = \prod_{\alpha=1}^{L-1} Q(x_\alpha)$$

solves the separated transfer-matrix eigenvalue equations on $\mathcal{X}$. Conversely, if the separated spectrum is a Cartesian product of one-coordinate spectra and the one-coordinate Baxter equation has a one-dimensional solution space after the boundary conditions are imposed, then every separated eigenfunction factorizes in this form. Equation (78.38) shifts only one coordinate. If $\Psi_Q = \prod_\beta Q(x_\beta)$, the common factors $\prod_{\beta\neq\alpha} Q(x_\beta)$ cancel from the α-th separated equation, leaving exactly the one-variable Baxter equation for Q at x_α. Conversely, on a Cartesian separated spectrum the equations for different coordinates commute and act on distinct variables. The stated one-dimensionality of the one-coordinate solution space fixes each factor up to a scalar; the product of those scalars is one overall normalization of the eigenvector.

78.13 From SoV Data to Spectral Traces

The preceding finite-chain results identify transfer eigenlines. A local observable in a quantum field theory asks for more data: a Hamiltonian or charge extraction from the transfer matrix, a representative O_L of the local operator, matrix elements of O_L, the thermal or finite-volume state, and the limiting map from the finite chain to the QFT. The distinction is already visible before any limit is taken.

Proposition 78.7 (Finite-chain SoV spectral trace)**.** *Let $\mathcal{H}_L$ be a finite-dimensional transfer-matrix representation for which the ABA–Q–SoV comparison hypotheses above hold. Let H_L be* *a self-adjoint Hamiltonian obtained from the commuting transfer family, and let* $O_L \in \mathrm{End}(\mathcal{H}_L)$*. If* $\{|\lambda\rangle\}_{\lambda\in\mathcal{S}_L}$ *is the resulting complete orthonormal eigenbasis of* H_L*, then, for* $0 \le \tau \le R$*,*

$$G_L^O(\tau, R) = \frac{1}{Z_L}\,\mathrm{Tr}_{\mathcal{H}_L}\left(\mathrm{e}^{-(R-\tau)H_L} O_L \mathrm{e}^{-\tau H_L} O_L^\dagger\right) = \frac{1}{Z_L}\sum_{\lambda,\lambda'\in\mathcal{S}_L} \mathrm{e}^{-(R-\tau)E_\lambda - \tau E_{\lambda'}}\left|\langle\lambda|O_L|\lambda'\rangle\right|^2, \tag{78.40}$$

where $Z_L = \sum_\lambda \mathrm{e}^{-RE_\lambda}$*. The SoV resolution (78.39) computes the matrix elements in (78.40) by finite sums over separated coordinates and their measure.*

Proof. The commuting transfer family and the comparison hypotheses identify the same eigenlines whether they are labeled by Bethe roots, a Q-operator eigenvalue, or separated wavefunctions. Since H_L is extracted from that commuting family, these eigenlines diagonalize H_L. Insert the identity $\sum_\lambda |\lambda\rangle\langle\lambda| = \mathrm{id}_{\mathcal{H}_L}$ on both sides of O_L inside the trace. Cyclicity of the finite trace gives the displayed Boltzmann factors and the squared matrix element. Finally insert (78.39) between O_L and the transfer eigenvectors to express each matrix element as a finite SoV sum. In a non-unitary or twisted biorthogonal presentation, the same proof uses the left and right eigenvectors supplied by the SoV resolution, with the two matrix elements replacing the absolute square. □

Controlled Approximation 78.8 (SoV-to-observable reconstruction budget)**.** Fix a test norm for Euclidean correlators on a compact window in (τ, R). Let $G^{\mathcal{O}}_{\mathrm{phys}}$ be the target local-QFT correlator and let $G^{\mathrm{SoV}}_{L,\mathcal{S}}$ be the correlator obtained from a finite chain, a subset $\mathcal{S} \subset \mathcal{S}_L$, a chosen SoV measure, and chosen matrix-element formulae for an operator O_L. Insert the intermediate exact finite-chain trace G_L^O, the complete SoV-labeled finite trace $G^{\mathrm{SoV},*}_{L,\mathrm{all}}$, and the exact retained trace $G^{\mathrm{SoV},*}_{L,\mathcal{S}}$. Let $\widehat{G}^{\mathrm{SoV}}_{L,\mathcal{S}}$ be the retained SoV expression after the chosen operator matrix-element formulae have been used but before a TBA, mirror, generalized Gibbs, or hydrodynamic state replaces the finite trace. The difference decomposes as

$$\begin{aligned} G^{\mathcal{O}}_{\mathrm{phys}} - G^{\mathrm{SoV}}_{L,\mathcal{S}} &= R_{\mathrm{reg}} + R_{\mathrm{comp}} + R_{\mathrm{tail}} + R_O + R_{\mathrm{state}}, \\ R_{\mathrm{reg}} &= G^{\mathcal{O}}_{\mathrm{phys}} - G_L^O, \\ R_{\mathrm{comp}} &= G_L^O - G^{\mathrm{SoV},*}_{L,\mathrm{all}}, \\ R_{\mathrm{tail}} &= G^{\mathrm{SoV},*}_{L,\mathrm{all}} - G^{\mathrm{SoV},*}_{L,\mathcal{S}}, \\ R_O &= G^{\mathrm{SoV},*}_{L,\mathcal{S}} - \widehat{G}^{\mathrm{SoV}}_{L,\mathcal{S}}, \\ R_{\mathrm{state}} &= \widehat{G}^{\mathrm{SoV}}_{L,\mathcal{S}} - G^{\mathrm{SoV}}_{L,\mathcal{S}}. \end{aligned} \tag{78.41}$$

If these five residuals obey

$$\|R_{\mathrm{reg}}\| \le \varepsilon_{\mathrm{reg}}, \quad \|R_{\mathrm{comp}}\| \le \varepsilon_{\mathrm{comp}}, \quad \|R_{\mathrm{tail}}\| \le \varepsilon_{\mathrm{tail}}, \quad \|R_O\| \le \varepsilon_O, \quad \|R_{\mathrm{state}}\| \le \varepsilon_{\mathrm{state}},$$

then

$$\left\|G^{\mathcal{O}}_{\mathrm{phys}} - G^{\mathrm{SoV}}_{L,\mathcal{S}}\right\| \le \varepsilon_{\mathrm{reg}} + \varepsilon_{\mathrm{comp}} + \varepsilon_{\mathrm{tail}} + \varepsilon_O + \varepsilon_{\mathrm{state}}. \tag{78.42}$$

The status of the five terms is different. Under Proposition 78.7 and the SoV measure identity, $R_{\mathrm{comp}} = 0$ is a finite-dimensional theorem. The term R_{tail} is a spectral truncation estimate. The term R_O is the operator problem: eigenvalue data from Q-functions must be supplemented by form factors, determinant formulae, or direct SoV matrix elements for the specific local field being probed. The terms R_{reg} and R_{state} are the physical bridge from the regulated chain to the continuum QFT state and local operator. Thus the nested TQ, QQ, and SoV machinery supplies a complete finite spectral coordinate system only after its hypotheses are proved; local QFT amplitudes additionally require the regulator, tail, operator, and state residuals in (78.41).

78.14 Continuum Status

The finite-chain spectral package above isolates the remaining continuum QFT problem. For a relativistic integrable QFT one must additionally prove that finite-volume energy levels are approximated by matrix Bethe–Yang equations in the large-L regime, that the nested string hypothesis used in Chapter 75 is valid for the thermodynamic states under consideration, that local operators have controlled finite-volume matrix elements, and that the integral operators in the TBA equations have the required analytic and Fredholm properties. These are model-dependent mathematical statements. They are separate from the finite RTT algebra, and the residual budget (78.41) records where each one enters a physical correlator.

78.15 Interface with Planar Gauge-Theory Integrability

In the planar $\mathcal{N} = 4$ SYM volume, magnons have a non-relativistic dispersion on a spin chain, wrapping effects arise from trace cyclicity and finite operator length, and the quantum spectral curve replaces the finite-rank Baxter polynomial by a system of analytic Q-functions. The algebraic bridge is now explicit: the Q-system (78.14), the Hirota equation (78.17), and the TQ/SoV comparison theorems of this chapter are the finite-rank prototypes. Planar gauge theory changes the analytic domain, asymptotics, grading, and boundary conditions; it does not change the local determinant identities.

Chapter 79

Integrable RG Flows and Perturbed Two-Dimensional CFT

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter studies two-dimensional quantum field theories specified near a conformal fixed point by a relevant scalar local operator and studied away from the fixed point through factorized scattering, form factors, and finite-size spectra. The word flow will always mean a comparison between renormalized local QFT data at different length scales. An identification of such a flow includes a declared local-operator chart, infinite-volume scattering data, and a finite-volume Hilbert-space construction whose ground-state energy is computed by the stated TBA system.

79.1 Perturbed-CFT Data

Let $\mathcal{C}$ be a Euclidean two-dimensional CFT on the plane. A scalar primary operator $\mathcal{O}$ has holomorphic and antiholomorphic weights $(h, \bar{h})$ with $h = \bar{h}$, and scaling dimension

$$\Delta_{\mathcal{O}} = h + \bar{h} = 2h.$$

It is relevant if

$$y_{\mathcal{O}} := 2 - \Delta_{\mathcal{O}} > 0.$$

The number $y_{\mathcal{O}}$ is the engineering dimension of the coupling that multiplies the integrated insertion $\int d^2x\, \mathcal{O}(x)$. This dimension statement is independent of perturbation theory: under the

Euclidean dilation $x \mapsto \lambda x$, the measure contributes λ^2 and the primary insertion contributes $\lambda^{-\Delta_{\mathcal{O}}}$.

Definition 79.1 (Renormalized perturbed-CFT chart)**.** A renormalized perturbation chart for $(\mathcal{C}, \mathcal{O})$ consists of the following data.

1. A normalization of $\mathcal{O}$, for example

$$\langle \mathcal{O}(x)\mathcal{O}(0)\rangle_{\mathcal{C}} = \frac{1}{|x|^{2\Delta_{\mathcal{O}}}} \quad (x \neq 0),$$

   or another explicitly stated nonzero constant in the numerator.

2. A local source coordinate g with mass dimension $[g] = y_{\mathcal{O}}$.

3. For each collection X of separated spectator insertions and each integer $n \geq 0$, an extension prescription

$$\mathcal{R}_n[\langle X\, \mathcal{O}(x_1) \cdots \mathcal{O}(x_n)\rangle_{\mathcal{C}}]$$

   from the configuration space where all points are distinct to a distribution on the full product space. The extension prescription must state its contact terms on diagonals; different choices are different renormalized coordinates.

The formal perturbation series in this chart is

$$\langle X\rangle_g = \frac{\sum_{n\geq 0} \frac{(-g)^n}{n!} \int \prod_{j=1}^n d^2x_j\, \mathcal{R}_n[\langle X\, \mathcal{O}(x_1)\cdots \mathcal{O}(x_n)\rangle_{\mathcal{C}}]}{\sum_{n\geq 0} \frac{(-g)^n}{n!} \int \prod_{j=1}^n d^2x_j\, \mathcal{R}_n[\langle \mathcal{O}(x_1)\cdots \mathcal{O}(x_n)\rangle_{\mathcal{C}}]}.$$

The expression is a formal or regulated object until the volume, infrared boundary condition, and convergence or summability statement have been specified.

The extension maps in Definition 79.1 are part of the definition of the perturbed theory. They are where contact terms enter a perturbed CFT. In a distributional formulation the product of local fields is first defined away from diagonals. A renormalized perturbation chooses extensions to the diagonals subject to locality, covariance, and the declared source normalization. Thus the coupling g is a coordinate in the Lagrangian or source functional of a specified regularized and renormalized path integral.

Remark 79.2 (First-order scaling of a relevant source)*.* Let $g(\mu)$ denote the dimensionful source in the chart above, and let

$$\lambda(\mu) = \mu^{-y_{\mathcal{O}}} g(\mu)$$

be the corresponding dimensionless coordinate at renormalization scale μ. If contact-term extensions are not changed while comparing two nearby scales and nonlinear OPE contributions are ignored, then

$$\mu \frac{d\lambda}{d\mu} = -y_{\mathcal{O}}\lambda.$$

Equivalently, increasing the length scale $\ell = \log(\mu_0/\mu)$ gives

$$\frac{d\lambda}{d\ell} = y_{\mathcal{O}}\lambda.$$

The dimensionful source g has mass dimension $y_{\mathcal{O}}$. Holding the source functional fixed while changing only the unit of mass gives $\lambda(\mu) = \mu^{-y_{\mathcal{O}}} g$. Differentiating this identity at fixed g proves the first displayed equation. The second follows from $\ell = -\log \mu + \text{constant}$. Corrections beyond this statement come from the diagonal extension of products of $\mathcal{O}$, equivalently from the singular part of the $\mathcal{O} \times \mathcal{O}$ OPE in the chosen renormalized coordinate.

If the perturbation generates a massive theory with mass gap $M > 0$, the dimensionless finite-size variable on a circle of circumference R is

$$r = MR.$$

Dimensional analysis fixes only the power relating M and $|g|^{1/y_{\mathcal{O}}}$. Once the normalization of $\mathcal{O}$, the source coordinate, and the scattering mass convention have been declared, an integrable model may determine a numerical mass-coupling constant

$$M = \kappa_{\mathcal{O}} \, |g|^{1/y_{\mathcal{O}}}.$$

The number $\kappa_{\mathcal{O}}$ is part of the matching data after the coordinates are fixed.

79.2 Polynomial Scalar Landau–Ginzburg Interface

This section records the ordinary two-dimensional scalar Landau–Ginzburg route as a renormalized perturbed-QFT interface. It is a useful comparison point for the minimal-model flow material below, but its logical status is different from an integrable scattering construction.

Let φ be a real scalar field in two Euclidean dimensions with a Gaussian ultraviolet reference measure whose covariance at separated points has the logarithmic singularity

$$C(x) = -\kappa \log(\mu|x|) + C_{\text{smooth}}(x), \qquad \kappa > 0. \tag{79.1}$$

Wick products $:\!\varphi^{\ell}\!:$ are normal ordered with respect to this reference covariance and the scale μ. A polynomial Landau–Ginzburg source-coordinate system is

$$V(\varphi) = \sum_{\ell=0}^{K} \frac{g_\ell}{\ell!} :\!\varphi^{\ell}\!: . \tag{79.2}$$

The finite-volume, infrared-regulated perturbation of separated correlation functions is represented formally by

$$\langle X \rangle_V = \frac{\big\langle X \exp\big(-\int d^2x \, V(\varphi(x))\big)\big\rangle_0}{\big\langle \exp\big(-\int d^2x \, V(\varphi(x))\big)\big\rangle_0}, \tag{79.3}$$

where X is a product of spectator fields supported away from the integration points before diagonal extensions are chosen.

The local ultraviolet statement behind this chart is elementary but important. Products of Wick polynomials have only powers of logarithms as their short-distance singularities:

$$:\!\varphi^a(x)\!::\!\varphi^b(y)\!:= \sum_{j=0}^{\min(a,b)} j! \binom{a}{j} \binom{b}{j} C(x-y)^j \, :\!\varphi^{a+b-2j}(y)\!: + \text{Taylor terms}.$$

Since

$$\int_0^{\varepsilon} r\,|\log r|^p\,dr < \infty \qquad (p \in \mathbb{Z}_{\geq 0}),$$

these logarithmic singularities are locally integrable at a single collision. Iterating the same estimate in relative coordinates around every partial diagonal gives local integrability for every finite order in the expansion of (79.3). The remaining choices are the finite contact-term extensions on diagonals, the infrared boundary condition, and convergence or summability of the perturbation series.

Equation of motion and the finite order-field quotient. The normal-ordered chart gives a precise distributional Schwinger–Dyson identity. Acting on the covariance with $\partial\bar{\partial}$ gives

$$\partial\bar{\partial}C(x) = -\pi\kappa\,\delta^{(2)}(x)$$

in the convention of (79.1). Gaussian integration by parts applied to (79.3) therefore gives, in correlators away from spectator insertions,

$$\partial\bar{\partial}\varphi = \pi\kappa\,V'(\varphi), \tag{79.4}$$

where

$$V'(\varphi) = \sum_{\ell=1}^{K} \frac{g_\ell}{(\ell-1)!}\,{:}\varphi^{\ell-1}{:}$$

in the same normal-ordering scheme. Contact terms at spectator insertions are part of the operator-source extension data in Definition 79.1.

For the even multicritical family

$$V(\varphi) = \sum_{j=1}^{m-1} \frac{g_{2j}}{(2j)!}\,{:}\varphi^{2j}{:}, \qquad m \geq 3, \tag{79.5}$$

the highest degree is $K = 2m-2$. In the idealized scaling chart where the critical potential is represented by its top monomial, (79.4) relates ${:}\varphi^{2m-3}{:}$ to the conformal descendant $\partial\bar{\partial}\varphi$. Thus the polynomial order-field sector has representatives

$$1,\ \varphi,\ {:}\varphi^2{:}, \ldots,\ {:}\varphi^{2m-4}{:}, \tag{79.6}$$

before diagonalizing the scaling fields. Its dimension is $2m-3$. The even source-coordinate system contains $m-1$ couplings $g_2, g_4, \ldots, g_{2m-2}$; after quotienting by the overall mass scale, there are $m-2$ dimensionless ratios to tune in the $\mathbb{Z}_2$-even family.

The expected continuum endpoint of the m-th multicritical even scalar theory is the unitary minimal model $\mathcal{M}(m, m+1)$ with

$$c_m = 1 - \frac{6}{m(m+1)}.$$

In this monograph this sentence is an RG-identification problem, not an input theorem. A proof must construct the continuum limit of the scalar polynomial theory at the tuned point, identify the stress tensor and local operator algebra, and explain how the order-field sector (79.6) embeds into the full minimal-model operator content. For example, when $m = 3$ the three order-field representatives match the Ising fields $1, \sigma, \epsilon$. For larger m, the full diagonal minimal model contains sectors not exhausted by the polynomial order-field quotient; those sectors must be supplied by the continuum construction rather than by the finite polynomial algebra alone.

79.3 Unitary Minimal Models and $\phi_{1,3}$

The A-series unitary Virasoro minimal model is denoted $\mathcal{M}(m, m+1)$, with $m \geq 3$. Its central charge is

$$c_m = 1 - \frac{6}{m(m+1)},$$

and its chiral Kac weights are

$$h_{r,s}^{(m)} = \frac{\big((m+1)r - ms\big)^2 - 1}{4m(m+1)}, \qquad 1 \leq r \leq m-1, \quad 1 \leq s \leq m,$$

with the identification $(r, s) \sim (m-r, m+1-s)$. The diagonal full CFT has scalar primaries when the same chiral module is paired with its antiholomorphic copy.

Remark 79.3 (Elementary data of the $\phi_{1,3}$ perturbation). In $\mathcal{M}(m, m+1)$, the diagonal scalar primary $\phi_{1,3}$ has

$$h_{1,3}^{(m)} = \frac{m-1}{m+1}, \qquad \Delta_{1,3}^{(m)} = \frac{2(m-1)}{m+1}, \qquad y_{1,3}^{(m)} = \frac{4}{m+1}.$$

Moreover

$$c_m - c_{m-1} = \frac{12}{m(m^2-1)} \qquad (m \geq 4).$$

For $(r, s) = (1, 3)$,

$$(m+1)r - ms = m + 1 - 3m = 1 - 2m.$$

Therefore

$$h_{1,3}^{(m)} = \frac{(2m-1)^2 - 1}{4m(m+1)} = \frac{4m(m-1)}{4m(m+1)} = \frac{m-1}{m+1}.$$

The full diagonal scalar has scaling dimension $2h_{1,3}^{(m)}$, giving the displayed $\Delta_{1,3}^{(m)}$. Subtracting from 2 gives

$$y_{1,3}^{(m)} = 2 - \frac{2(m-1)}{m+1} = \frac{4}{m+1}.$$

Finally,

$$c_m - c_{m-1} = \left(1 - \frac{6}{m(m+1)}\right) - \left(1 - \frac{6}{(m-1)m}\right) = \frac{6}{m}\left(\frac{1}{m-1} - \frac{1}{m+1}\right),$$

which is $12/[m(m^2-1)]$.

The standard integrable identification asserts that, for the massless branch of the $\phi_{1,3}$ perturbation and a definite sign convention for the source g,

$$\mathcal{M}(m, m+1) + g\int d^2x\, \phi_{1,3}(x) \quad \longrightarrow \quad \mathcal{M}(m-1, m) \qquad (m \geq 4).$$

In this monograph the theorem boundary is kept explicit. The exact arithmetic in Remark 79.3 proves only that the proposed infrared central charge is smaller by the displayed positive amount and that the perturbing operator is relevant. A theorem-level identification of the flow would require a construction of the perturbed local QFT, a proof of its infrared limit, and a matching of its local operator algebra to that of $\mathcal{M}(m-1, m)$.

Example 79.4 (First minimal-model cases)**.** For $m = 3$, $\mathcal{M}(3,4)$ is the Ising CFT. The label $(1,3)$ is identified with $(2,1)$, and

$$h^{(3)}_{1,3} = \frac{1}{2}, \qquad \Delta^{(3)}_{1,3} = 1.$$

This is the thermal perturbation, whose massive scaling limit is the free massive Majorana theory discussed in Chapter 77. For $m = 4$,

$$c_4 = \frac{7}{10}, \qquad c_3 = \frac{1}{2}, \qquad c_4 - c_3 = \frac{1}{5},$$

which is the central-charge drop of the tricritical-Ising to Ising massless branch. These statements fix the conformal arithmetic; the sign of the coupling and the operator normalization still have to be declared before comparing with scattering or TBA conventions.

79.4 Finite-Size Scaling Function

Let $E_0(R)$ be the ground-state energy on a spatial circle of circumference R. Define

$$c_{\text{eff}}(R) = -\frac{6R}{\pi} E_0(R).$$

For a CFT with periodic boundary conditions and cylinder Hamiltonian

$$H_R = \frac{2\pi}{R}\left(L_0 + \bar{L}_0 - \frac{c}{12}\right),$$

the vacuum energy is

$$E_0(R) = -\frac{\pi c}{6R},$$

so $c_{\text{eff}}(R) = c$. In a nonunitary CFT the cylinder ground state may be a primary of negative weight; then the same formula gives

$$c_{\text{eff}} = c - 24h_{\min},$$

where $h_{\min}$ is the lowest diagonal conformal weight. This is the convention used for the Lee–Yang example in Chapter 77.

For a massive infrared theory with a unique vacuum,

$$E_0(R) = \mathcal{E}_{\text{bulk}} R + o(R^0) \qquad (R \to \infty).$$

The bulk energy density $\mathcal{E}_{\text{bulk}}$ is a local extensive coordinate. Hence comparisons of ultraviolet and infrared central charges must say whether the extensive term has been subtracted. The subtracted quantity is

$$E_0^{\text{sub}}(R) = E_0(R) - \mathcal{E}_{\text{bulk}} R, \qquad c_{\text{sub}}(R) = -\frac{6R}{\pi} E_0^{\text{sub}}(R).$$

Definition 79.5 (Finite-size identification data)**.** A finite-size identification between a perturbed CFT and a factorized scattering model consists of:

1. a Hilbert space on the circle and a self-adjoint Hamiltonian H_R for each R in the scaling regime;
2. a normalization of the vacuum energy, including the value of $\mathcal{E}_{\text{bulk}}$;
3. a mass convention for the infinite-volume particles;
4. a proof, or an explicitly stated hypothesis, that the large-volume mirror-channel thermodynamics computes $E_0(R)$.

With these data declared, the equality between a TBA scaling function and a QFT finite-size energy is a precise mathematical assertion.

79.5 Trace Sum Rule as a Local Test of the Flow

Finite-size central charges are necessary but not sufficient data for identifying a local RG trajectory. A sharper test uses the trace of the stress tensor. In this section $\Theta = T^\mu{}_\mu$ denotes the flat-space Cartesian trace in the stress-tensor normalization for which the Zamolodchikov sum rule below has coefficient $3/(4\pi)$. If a different normalization of the stress tensor or the perturbing source is used, the same statements hold after replacing Θ by the correspondingly normalized trace operator.

Definition 79.6 (Zamolodchikov sum-rule hypotheses)**.** A two-dimensional Euclidean RG trajectory satisfies the Zamolodchikov sum-rule hypotheses if the following data are specified.

1. A reflection-positive local QFT on $\mathbb{R}^2$ with a symmetric conserved stress tensor $T_{\mu\nu}$, trace $\Theta = T^\mu{}_\mu$, and connected trace two-point distribution
$$G_\Theta(x) = \langle \Theta(x)\Theta(0)\rangle_{\text{c}}.$$
2. A distributional extension of G_Θ to $x = 0$ whose contact terms are fixed by the stress-tensor source-coordinate system. The weighted pairing
$$\int_{\mathbb{R}^2} d^2x\, |x|^2 G_\Theta(x)$$
is required to be finite and independent of the remaining allowed point-supported contact terms. This condition is automatic for contact terms annihilated by the test function $|x|^2$, but it must be checked when derivatives of delta functions are permitted by the source scheme.
3. A continuous function $C(R)$, $R > 0$, whose endpoint limits exist,
$$\lim_{R\downarrow 0} C(R) = c_{\text{UV}}, \qquad \lim_{R\to\infty} C(R) = c_{\text{IR}},$$
and whose radial derivative is represented by
$$\frac{dC(R)}{d\log R} = -\frac{3}{4\pi}\int_0^{2\pi} d\alpha\, R^4\, G_\Theta(Re^{\mathrm{i}\alpha}) \tag{79.7}$$
in the distributional sense after smearing in R.

The last item is the local Ward-identity content of the two-dimensional c-theorem in the present normalization. It is not a definition of G_Θ; it is a theorem-level property to be established from stress tensor conservation, Euclidean covariance, positivity, and the regularity assumptions of the chosen QFT framework.

Trace sum rule. For a trajectory satisfying the Zamolodchikov sum-rule hypotheses,

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} = \frac{3}{4\pi}\int_{\mathbb{R}^2} d^2x\,|x|^2\langle\Theta(x)\Theta(0)\rangle_c. \tag{79.8}$$

If reflection positivity makes $G_\Theta(x)$ a nonnegative radial spectral density at separated points, then $c_{\mathrm{UV}} \ge c_{\mathrm{IR}}$.

Integrating (79.7) from $R=\epsilon$ to $R=L$ gives

$$C(\epsilon) - C(L) = \frac{3}{4\pi}\int_\epsilon^L \frac{dR}{R}\int_0^{2\pi} d\alpha\, R^4 G_\Theta(Re^{\mathrm{i}\alpha}).$$

Since $d^2x = R\,dR\,d\alpha$, the right side is

$$\frac{3}{4\pi}\int_{\epsilon<|x|<L} d^2x\,|x|^2 G_\Theta(x).$$

The integrability hypothesis in Definition 79.6 permits the limits $\epsilon \downarrow 0$ and $L\to\infty$, while the endpoint hypothesis identifies the left side with $c_{\mathrm{UV}} - c_{\mathrm{IR}}$. Positivity of the weighted trace two-point distribution gives the inequality.

Form-factor version of the trace sum rule. Consider a massive integrable trajectory with particle species a, masses $m_a > 0$, and trace-operator form factors

$$F^\Theta_{a_1\cdots a_n}(\theta_1,\ldots,\theta_n) = \langle 0|\Theta(0)|\theta_1,a_1;\ldots;\theta_n,a_n\rangle_{\mathrm{in}}.$$

Assume that the connected Euclidean two-point function has the absolutely convergent spectral expansion

$$G_\Theta(x) = \sum_{n\ge1}\frac{1}{n!}\sum_{a_1,\ldots,a_n}\int_{\mathbb{R}^n}\prod_{j=1}^n\frac{d\theta_j}{2\pi}\,\left|F^\Theta_{a_1\cdots a_n}(\theta_1,\ldots,\theta_n)\right|^2 e^{-|x|\sum_j m_{a_j}\cosh\theta_j} \tag{79.9}$$

and that Fubini's theorem applies to the $|x|^2$-weighted integral. Then

$$c_{\mathrm{UV}} - c_{\mathrm{IR}} = 9\sum_{n\ge1}\frac{1}{n!}\sum_{a_1,\ldots,a_n}\int_{\mathbb{R}^n}\prod_{j=1}^n\frac{d\theta_j}{2\pi}\,\frac{\left|F^\Theta_{a_1\cdots a_n}(\theta_1,\ldots,\theta_n)\right|^2}{\left(\sum_j m_{a_j}\cosh\theta_j\right)^4}. \tag{79.10}$$

Insert (79.9) into (79.8). Absolute convergence permits the exchange of the spacetime integral with the rapidity integrals and species sums. For fixed rapidities set

$$E(\theta_1,\ldots,\theta_n) = \sum_j m_{a_j}\cosh\theta_j > 0.$$

The radial integral is elementary:

$$\frac{3}{4\pi}\int_{\mathbb{R}^2} d^2x\,|x|^2 e^{-E|x|} = \frac{3}{4\pi}(2\pi)\int_0^\infty d\rho\,\rho^3 e^{-E\rho} = \frac{3}{2}\frac{3!}{E^4} = \frac{9}{E^4}.$$

Substitution gives the displayed formula.

Example 79.7 ($\phi_{1,3}$ minimal-model flow target)**.** For the massless branch expected to connect $\mathcal{M}(m, m+1)$ to $\mathcal{M}(m-1, m)$, any proposed trace form factors and normalization must satisfy the numerical target

$$9 \sum_{n \geq 1} \frac{1}{n!} \sum_{a_1, \ldots, a_n} \int \prod_{j=1}^{n} \frac{d\theta_j}{2\pi} \frac{|F^{\Theta}_{a_1 \cdots a_n}(\theta_1, \ldots, \theta_n)|^2}{(\sum_j m_{a_j} \cosh \theta_j)^4} = \frac{12}{m(m^2-1)}.$$

The right side is the central-charge drop computed in Remark 79.3. This equality is stronger than matching the endpoint values of a TBA scaling function: it tests the local normalization of Θ, the form-factor solution, and the short-distance-to-long-distance interpolation of the trajectory.

79.6 TBA Scaling Function

For a diagonal factorized massive theory, use the kernel convention of Chapter 77,

$$\varphi_{ab}(\theta) = \frac{1}{2\pi \mathrm{i}} \frac{d}{d\theta} \log S_{ab}(\theta).$$

Let $m_a = \mu_a M$, where M is the reference mass and $\mu_a > 0$. The pseudoenergies are solutions of

$$\epsilon_a(\theta; r) = r\, \mu_a \cosh \theta - \sum_b \int_{\mathbb{R}} d\theta'\, \varphi_{ab}(\theta - \theta') \log\Big(1 + e^{-\epsilon_b(\theta'; r)}\Big), \qquad r = MR.$$

With the bulk term separated, the mirror-channel formula gives

$$E_0^{\mathrm{sub}}(R) = -\frac{M}{2\pi} \sum_a \mu_a \int_{\mathbb{R}} d\theta\, \cosh\theta\, \log\Big(1 + e^{-\epsilon_a(\theta; r)}\Big).$$

Consequently

$$c_{\mathrm{TBA}}(r) = \frac{3r}{\pi^2} \sum_a \mu_a \int_{\mathbb{R}} d\theta\, \cosh\theta\, \log\Big(1 + e^{-\epsilon_a(\theta; r)}\Big).$$

This formula is a theorem about the variational TBA functional under the hypotheses of Chapter 77; its identification with the finite-size vacuum energy of a local QFT requires the additional input in Definition 79.5.

Controlled Approximation 79.8 (Plateau reduction)**.** Assume that as $r \downarrow 0$ the solution has a plateau interval whose width tends to infinity, that the boundary layers at the ends of the plateau contribute only the standard Rogers-dilogarithm endpoints, and that the convolution kernels may be replaced on the plateau by their total integrals

$$N_{ab} = \int_{\mathbb{R}} d\theta\, \varphi_{ab}(\theta).$$

The plateau values $Y_a = \exp(\epsilon_a)$ then obey

$$\log Y_a = -\sum_b N_{ab} \log(1 + Y_b^{-1}).$$

The corresponding ultraviolet contribution to the effective central charge is

$$c_{\mathrm{UV}} = \frac{6}{\pi^2} \sum_a L\left(\frac{1}{1+Y_a}\right),$$

where

$$L(x) = -\frac{1}{2}\int_0^x dt\,\left(\frac{\log(1-t)}{t} + \frac{\log t}{1-t}\right) = \mathrm{Li}_2(x) + \frac{1}{2}\log x \log(1-x)$$

for $0 < x < 1$.

The displayed algebraic equation is obtained by dropping the driving term on the plateau and replacing each convolution by the total kernel integral. To derive the dilogarithm contribution, differentiate the TBA equation with respect to rapidity in a boundary layer where the pseudoenergy changes from a constant plateau value to its asymptotic value. The same integration by parts used in the Lee–Yang calculation of Chapter 77 reduces the scaling integral for species a to

$$\frac{6}{\pi^2}\int d\epsilon_a\,\log(1+e^{-\epsilon_a})\frac{d}{d\epsilon_a}\log(1+e^{\epsilon_a})^{-1}.$$

With $x = (1+e^{\epsilon_a})^{-1}$, this is the Rogers dilogarithm evaluated between the endpoint values. Under the present plateau hypothesis the nontrivial endpoint is $x_a = (1+Y_a)^{-1}$, giving the stated sum. The argument is a controlled asymptotic reduction. A complete application to a particular model includes a proof of the stated plateau hypothesis for that model.

79.7 Massless Flows

An integrable massless flow contains right- and left-moving asymptotic particles in the infrared scaling description. A right mover is parametrized by

$$E = p = \frac{M}{2}e^{\theta},$$

and a left mover by

$$E = -p = \frac{M}{2}e^{-\theta}.$$

The parameter M is the crossover scale. The TBA now has right-right, left-left, and right-left kernels. The right-left kernel records the interaction between the two chiral sectors along the flow; its normalization controls the interpolation between the ultraviolet and infrared plateaux.

Definition 79.9 (Massless factorized-flow data)**.** Diagonal massless factorized-flow data consist of:

1. right species $a \in A_R$ and left species $\alpha \in A_L$;
2. analytic two-body amplitudes

   $$S^{RR}_{ab}(\theta), \qquad S^{LL}_{\alpha\beta}(\theta), \qquad S^{RL}_{a\alpha}(\theta)$$

   obeying the declared unitarity, crossing, and bootstrap equations in their analytic strips;
3. a TBA system with driving terms

   $$r\,\mu_a e^{\theta}/2, \qquad r\,\nu_\alpha e^{-\theta}/2,$$

   and kernels obtained from the logarithmic derivatives of the amplitudes in the same sign convention;

4. ultraviolet and infrared local-operator charts to which the finite-size scaling function and form factors are to be matched.

For the minimal-model $\phi_{1,3}$ massless branch, the expected endpoint central charges satisfy

$$\lim_{r\downarrow 0} c_{\mathrm{sub}}(r) = c_m, \qquad \lim_{r\to\infty} c_{\mathrm{sub}}(r) = c_{m-1}.$$

The value of $c_m - c_{m-1}$ is fixed by Remark 79.3. The exact TBA system must reproduce these two limits after the bulk term and mass scale have been matched. This central-charge comparison is one component of the identification; the full identification also includes the local operator algebras and their OPE data in the ultraviolet and infrared.

79.8 Operator Data Along the Flow

The local-correlator part of the flow is supplied by form factors and their short-distance normalization. For a local operator $\widehat{\mathcal{A}}$, define its infinite-volume form factors by

$$F^{\mathcal{A}}_{a_1\cdots a_n}(\theta_1,\dots,\theta_n) = \langle 0|\widehat{\mathcal{A}}(0)|\theta_1,a_1;\dots;\theta_n,a_n\rangle_{\mathrm{in}},$$

where the ordering convention and particle-state normalization are those of Chapter 76. The ultraviolet scaling dimension is tested by the short-distance behavior

$$\langle\widehat{\mathcal{A}}(x)\widehat{\mathcal{A}}(0)\rangle_{\mathrm{c}} \sim \frac{C_{\mathcal{A}}}{|x|^{2\Delta_{\mathcal{A}}}} \qquad (M|x|\to 0),$$

with $C_{\mathcal{A}}$ fixed by a source convention. The perturbing operator itself must also satisfy the trace relation in the chosen normalization:

$$\Theta(x) = \kappa_\Theta\, y_{\mathcal{O}}\, g\,\mathcal{O}(x) + O(g^2)$$

when the Euclidean action is perturbed as $S_{\mathcal{C}} + g\int d^2x\,\mathcal{O}(x)$ and the stress tensor is normalized by $T^{\mu}{}_{\mu} = \Theta$. The constant κ_Θ is fixed by the Weyl-variation convention for the stress tensor and by whether a factor such as $1/(2\pi)$ is included in the source term. A chapter using this relation states κ_Θ before using numerical trace-normalization formulas.

Remark 79.10 (Necessary matching conditions for an integrable flow). Suppose a factorized scattering model is identified with a relevant perturbation of $\mathcal{C}$ by $\mathcal{O}$ in the sense of Definition 79.1. Then the following data must be mutually compatible:

1. the particle masses and scattering amplitudes determine a TBA scaling function whose ultraviolet limit equals the effective central charge of $\mathcal{C}$;

2. if the infrared limit is conformal, the large-R subtracted finite-size energy gives the infrared central charge;

3. the form-factor spectral expansion of the operator corresponding to $\mathcal{O}$ has the ultraviolet two-point normalization fixed in the perturbed-CFT chart;

4. the trace operator extracted from the finite-size response to a change of R agrees, to first order in g, with the perturbing operator through the displayed trace relation.

The first two assertions are consequences of the definition of $c_{\mathrm{sub}}(R)$ and of the CFT cylinder Hamiltonian. A mismatch of central charge would contradict equality of the finite-size vacuum energies in either scaling limit. The third assertion follows because the source coordinate in Definition 79.1 fixes the normalization of $\mathcal{O}$; a different form-factor normalization would compute a different source derivative of the Schwinger functional. For the fourth assertion, vary the perturbed action under a Weyl rescaling. The integrated insertion has scaling defect $y_{\mathcal{O}}$, and the declared stress-tensor normalization converts the Weyl variation of the action into the trace insertion. Higher powers of g are contact-term and operator mixing data of the same renormalized chart.

Open Problem 79.11 (Rigorous integrable-flow reconstruction). Construct a theorem that starts from factorized scattering data, form-factor solutions satisfying locality and convergence estimates, and TBA finite-size data, and reconstructs a local two-dimensional QFT whose ultraviolet limit is a specified CFT perturbation. The theorem should identify the operator topology in which the ultraviolet limit is taken, prove the finite-size Hamiltonian/TBA equality, and show that the OPE coefficients obtained from short-distance limits agree with the declared CFT data.

Mirror-Channel TBA and Finite-Size Effects

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter refines the finite-volume interpretation of the thermodynamic Bethe ansatz. The primitive object is a Euclidean two-torus partition function with two Hamiltonian decompositions. The mirror-channel decomposition turns the circumference of the direct theory into the inverse temperature of a gas in the rotated theory. Finite-size corrections are then organized by the number of mirror particles winding around the compact cycle.

Hypothesis 80.1 (Mirror finite-size TBA structure)**.** A mirror finite-size TBA structure is a tuple

$$\mathfrak{M} = \left(Z, \{H_R, \mathcal{H}_R\}_{R>0}, \{\widetilde{H}_L, \widetilde{\mathcal{H}}_L\}_{L>0}, \mathsf{A}, \{m_a, S_{ab}, \varphi_{ab}\}_{a,b\in\mathsf{A}}, \mathcal{E}_{\mathrm{bulk}}, \mathcal{S}_{\mathrm{mir}}, \mathcal{P}_{\mathrm{mir}}\right)$$

with the following properties.

(i) $Z(R, L)$ is the regulated Euclidean torus partition function for a massive two-dimensional local QFT on a flat torus whose oriented cycles have lengths R and L. The same regulated functional admits the two Hamiltonian decompositions

$$Z(R, L) = \mathrm{Tr}_{\mathcal{H}_R}\, e^{-LH_R} = \mathrm{Tr}_{\widetilde{\mathcal{H}}_L}\, e^{-R\widetilde{H}_L}.$$

(ii) H_R is self-adjoint and bounded below on the direct-channel Hilbert space $\mathcal{H}_R$. The large-L limit $-\lim_{L\to\infty} L^{-1} \log Z(R, L) = E_0(R)$ exists for the range of R under discussion.

(iii) The mirror channel has a thermodynamic limit at inverse temperature R. Its stable mirror species form the finite or locally finite set A, with masses $m_a > 0$ and one-particle dispersion $\widetilde{E}_a(\theta) = m_a \cosh\theta$, $\widetilde{p}_a(\theta) = m_a \sinh\theta$. When A is locally finite rather than finite, every displayed sum over species is part of the specification as an absolutely convergent sum in the norm used for that formula.

(iv) In the diagonal sector treated in this chapter, $S_{ab}(\theta) \in \mathbb{C}^\times$ is the mirror two-body scattering phase on the real rapidity line, with a declared logarithm branch and

$$\varphi_{ab}(\theta) = \frac{1}{2\pi\mathrm{i}} \frac{d}{d\theta} \log S_{ab}(\theta).$$

This is the diagonal mirror structure. Non-diagonal mirror scattering uses the nested generalization of the density system.

(v) $\mathcal{S}_{\mathrm{mir}}$ consists of the mirror thermodynamic density constraint and entropy convention used below:

$$\rho_a + \rho_a^h = \frac{m_a}{2\pi} \cosh\theta + \sum_b \varphi_{ab} * \rho_b, \qquad s_a = (\rho_a + \rho_a^h) \log(\rho_a + \rho_a^h) - \rho_a \log\rho_a - \rho_a^h \log\rho_a^h.$$

(vi) $\mathcal{E}_{\mathrm{bulk}}$ is the local extensive vacuum-energy coordinate fixed by the same renormalization convention used in the direct finite-volume theory.

(vii) $\mathcal{P}_{\mathrm{mir}}$ records the analytic strips, pole sets, and contour-orientation conventions used when mirror rapidities are crossed through direct-channel particles or operator insertions. This analytic entry is part of the data needed to derive excited-state F-terms and wrapping residues from the torus trace.

All finite-size formulae in this chapter are conditional on $\mathfrak{M}$ and on the extra bounded-kernel or pole-avoidance hypotheses stated at the point where estimates or contour deformations are used.

80.1 Two Hamiltonian Decompositions

Let $\mathfrak{M}$ be a mirror finite-size TBA structure. Quantization along the L-direction gives

$$Z(R, L) = \mathrm{Tr}_{\mathcal{H}_R} \exp[-LH_R],$$

where H_R is the Hamiltonian on a spatial circle of circumference R. Assume that H_R is self-adjoint, bounded below, and has a unique ground state separated by a gap from the rest of the spectrum. Then

$$-\lim_{L\to\infty} \frac{1}{L} \log Z(R, L) = E_0(R),$$

where $E_0(R)$ is the direct-channel vacuum energy.

Quantization after exchanging the two cycles gives

$$Z(R, L) = \mathrm{Tr}_{\widetilde{\mathcal{H}}_L} \exp[-R\widetilde{H}_L].$$

The Hilbert space $\widetilde{\mathcal{H}}_L$ is the mirror-channel Hilbert space. For a relativistic theory obtained by Euclidean rotation, the one-particle dispersion in the infinite-volume mirror channel is

$$\widetilde{E}_a(\theta) = m_a \cosh\theta, \qquad \widetilde{p}_a(\theta) = m_a \sinh\theta.$$

The same function $m_a \cosh\theta$ now appears in the Boltzmann weight $\exp[-R\widetilde{E}_a(\theta)]$.

Remark 80.2 (Vacuum energy from mirror pressure). Assume that both torus decompositions exist at a common regulator, that the large-L limit of $L^{-1}\log Z(R,L)$ exists in the direct channel, and that the mirror channel has a thermodynamic limit at inverse temperature R. Let

$$f_{\mathrm{mir}}(R) = -\lim_{L\to\infty}\frac{1}{RL}\log \mathrm{Tr}_{\widetilde{\mathcal{H}}_L}\exp[-R\widetilde{H}_L]$$

be the mirror free-energy density. Then

$$E_0(R) = R\, f_{\mathrm{mir}}(R).$$

The two traces are the same torus functional written in two Hamiltonian channels. Dividing the equality of traces by L after taking the logarithm gives

$$\frac{1}{L}\log Z(R,L) = \frac{1}{L}\log \mathrm{Tr}_{\widetilde{\mathcal{H}}_L}\exp[-R\widetilde{H}_L].$$

The direct-channel assumption gives the left-hand limit $-E_0(R)$. The mirror thermodynamic definition gives the right-hand limit $-Rf_{\mathrm{mir}}(R)$. Equality of the two limits proves the formula.

80.2 Mirror TBA Functional

Use the kernel convention of Chapter 77:

$$\varphi_{ab}(\theta) = \frac{1}{2\pi \mathrm{i}}\frac{d}{d\theta}\log S_{ab}(\theta).$$

Here $S_{ab}(\theta)$ is the diagonal two-particle scattering phase in the mirror channel, and the branch of the logarithm is fixed continuously on the real rapidity line after the particle labels and statistics convention have been declared.

Let $\rho_a(\theta)$ and $\rho_a^h(\theta)$ be particle and hole densities per unit mirror length, so that

$$L\rho_a(\theta)d\theta$$

is the number of occupied rapidities of species a in the interval $(\theta, \theta + d\theta)$. Differentiating the Bethe–Yang equations gives

$$\rho_a(\theta) + \rho_a^h(\theta) = \frac{m_a}{2\pi}\cosh\theta + \sum_b \int_{\mathbb{R}} d\theta'\, \varphi_{ab}(\theta-\theta')\rho_b(\theta').$$

The entropy density of a Bethe cell with exclusion occupancy is

$$s_a = (\rho_a + \rho_a^h)\log(\rho_a+\rho_a^h) - \rho_a\log\rho_a - \rho_a^h\log\rho_a^h.$$

Define the pseudoenergy by

$$\epsilon_a(\theta) = \log\frac{\rho_a^h(\theta)}{\rho_a(\theta)}.$$

Mirror TBA variational equation. For diagonal factorized scattering with the density equation above, the stationary point of the mirror free-energy functional at inverse temperature R satisfies

$$\epsilon_a(\theta) = Rm_a \cosh\theta - \sum_b \int_{\mathbb{R}} d\theta'\, \varphi_{ab}(\theta-\theta') \log\Big(1+e^{-\epsilon_b(\theta')}\Big).$$

At this stationary point,

$$E_0(R) = \mathcal{E}_{\mathrm{bulk}} R - \sum_a \int_{\mathbb{R}} \frac{d\theta}{2\pi}\, m_a \cosh\theta\, \log\Big(1+e^{-\epsilon_a(\theta)}\Big).$$

The variation is the same variational calculation as in Proposition 77.2, with R now interpreted as inverse temperature of the mirror gas. A variation $\delta\rho_a$ induces

$$\delta\rho_c^t(\theta) = \sum_a \int d\theta'\, \varphi_{ca}(\theta-\theta')\delta\rho_a(\theta'), \qquad \rho_c^t = \rho_c + \rho_c^h.$$

The entropy variation is

$$\delta s = \sum_a \int d\theta\, \left[\log\frac{\rho_a^h}{\rho_a}\,\delta\rho_a + \log\frac{\rho_a^t}{\rho_a^h}\,\delta\rho_a^t\right].$$

Substituting the density-constraint variation and using $\log(\rho_a^t/\rho_a^h) = \log(1+e^{-\epsilon_a})$ gives the displayed pseudoenergy equation. Inserting the stationary relation back into the mirror free-energy density gives

$$f_{\mathrm{mir}}(R) = -\frac{1}{2\pi R}\sum_a m_a \int_{\mathbb{R}} d\theta\, \cosh\theta \log(1+e^{-\epsilon_a(\theta)}).$$

Remark 80.2 then gives the subtracted direct-channel vacuum energy. The additive $\mathcal{E}_{\mathrm{bulk}}R$ is the local extensive coordinate fixed in Chapter 79.

80.3 Large-Circumference Expansion

Let

$$d_a(\theta) = Rm_a\cosh\theta, \qquad q_a(\theta) = e^{-d_a(\theta)}, \qquad L_a(\theta) = \log(1+e^{-\epsilon_a(\theta)}).$$

The large-R expansion is an expansion in mirror occupation factors q_a, equivalently in windings around the direct spatial circle. The first winding is universal; later windings also contain the scattering kernels.

Two-winding expansion of the vacuum energy. Assume that the kernel convolution operator is bounded in a weighted L^∞ norm for which all q_a are small, so that the TBA equation is solved by iteration. The TBA equation is

$$\epsilon_a = d_a - \sum_b \varphi_{ab} * L_b.$$

If $L_b = q_b + O(q^2)$, then

$$e^{-\epsilon_a} = e^{-d_a}\exp\left(\sum_b \varphi_{ab} * L_b\right) = q_a\left(1+\sum_b \varphi_{ab} * q_b\right) + O(q^3).$$

Using $\log(1+x) = x - x^2/2 + O(x^3)$ gives

$$L_a(\theta) = q_a(\theta) + q_a(\theta) \sum_b \int_{\mathbb{R}} d\theta' \, \varphi_{ab}(\theta - \theta') q_b(\theta') - \frac{1}{2} q_a(\theta)^2 + O(q^3).$$

Consequently

$$\begin{aligned} E_0(R) - \mathcal{E}_{\text{bulk}} R = &- \sum_a \int_{\mathbb{R}} \frac{d\theta}{2\pi} \, m_a \cosh\theta \, q_a(\theta) \\ &- \sum_{a,b} \int_{\mathbb{R}} \frac{d\theta}{2\pi} \int_{\mathbb{R}} d\theta' \, m_a \cosh\theta \, q_a(\theta) \varphi_{ab}(\theta - \theta') q_b(\theta') \\ &+ \frac{1}{2} \sum_a \int_{\mathbb{R}} \frac{d\theta}{2\pi} \, m_a \cosh\theta \, q_a(\theta)^2 + O(q^3). \end{aligned}$$

Proposition 80.3 (Vacuum Luescher term with a remainder bound)**.** *Let the set* A *of mirror particle species be finite, and let*

$$m_* = \min_{a \in \mathsf{A}} m_a > 0.$$

Assume that the diagonal mirror TBA equations written above have the exclusion form and that their kernels obey

$$\Phi = \sup_{a \in \mathsf{A}} \sum_{b \in \mathsf{A}} \int_{\mathbb{R}} du \, |\varphi_{ab}(u)| < \infty.$$

Then there are constants R_0 *and* C*, depending on the masses and on* Φ*, such that for* $R \geq R_0$ *the solution in the small-occupation branch satisfies*

$$E_0(R) - \mathcal{E}_{\text{bulk}} R = -\sum_{a \in \mathsf{A}} \frac{m_a}{\pi} K_1(m_a R) + \mathcal{R}_2(R), \qquad |\mathcal{R}_2(R)| \leq C R^{-1/2} e^{-2m_* R}.$$

Here K_1 *is the modified Bessel function normalized by*

$$K_1(r) = \int_0^\infty d\theta \, e^{-r\cosh\theta} \cosh\theta.$$

Proof. Write the TBA fixed-point equation directly for

$$L_a(\theta) = \log(1 + e^{-\epsilon_a(\theta)}).$$

With

$$(KL)_a(\theta) = \sum_{b \in \mathsf{A}} \int_{\mathbb{R}} d\theta' \, \varphi_{ab}(\theta - \theta') L_b(\theta'),$$

the equation is

$$L_a(\theta) = \log\Big(1 + q_a(\theta) e^{(KL)_a(\theta)}\Big), \qquad q_a(\theta) = e^{-R m_a \cosh\theta}.$$

The integral bound gives

$$\|KL\|_\infty \leq \Phi \|L\|_\infty.$$

For R large enough the map

$$T_R(L)_a(\theta) = \log\Big(1 + q_a(\theta) e^{(KL)_a(\theta)}\Big)$$

maps the closed ball $\|L\|_\infty \le 2e^{-Rm_*}$ into itself. Indeed

$$|T_R(L)_a(\theta)| \le q_a(\theta)e^{\Phi\|L\|_\infty} \le e^{-Rm_*}e^{2\Phi e^{-Rm_*}} \le 2e^{-Rm_*}$$

after increasing R_0. The mean-value theorem and $|\log(1+x)-\log(1+y)| \le |x-y|$ for $x, y \ge 0$ give

$$\|T_R(L) - T_R(M)\|_\infty \le C_\Phi e^{-Rm_*}\|L-M\|_\infty,$$

with C_Φ independent of R. Thus T_R is a contraction for $R \ge R_0$, so the small-occupation solution exists uniquely in this ball.

For that solution,

$$|(KL)_a(\theta)| \le 2\Phi e^{-Rm_*}.$$

Using $e^x = 1 + O(x)$ uniformly for $|x| \le 2\Phi e^{-Rm_*}$ and $\log(1+y) = y + O(y^2)$ uniformly for $0 \le y \le 2e^{-Rm_*}$, one obtains the pointwise estimate

$$L_a(\theta) = q_a(\theta) + \delta L_a(\theta), \qquad |\delta L_a(\theta)| \le Cq_a(\theta)e^{-Rm_*} + Cq_a(\theta)^2.$$

Substitution in the vacuum-energy formula gives

$$E_0(R) - \mathcal{E}_{\text{bulk}}R = -\sum_a \int_{\mathbb{R}} \frac{d\theta}{2\pi}\, m_a \cosh\theta\, q_a(\theta) + \mathcal{R}_2(R),$$

where

$$|\mathcal{R}_2(R)| \le C\sum_a \int_{\mathbb{R}} \frac{d\theta}{2\pi}\, m_a \cosh\theta \left(q_a(\theta)e^{-Rm_*} + q_a(\theta)^2\right).$$

The first integral is

$$\int_{\mathbb{R}} d\theta\, \cosh\theta\, e^{-Rm_a\cosh\theta} = 2K_1(m_aR),$$

so its contribution to the energy is $-m_aK_1(m_aR)/\pi$. It remains only to record the uniform large-R bound. For $\lambda \ge 1$,

$$K_1(\lambda) = \int_0^\infty d\theta\, \cosh\theta\, e^{-\lambda\cosh\theta} \le C\lambda^{-1/2}e^{-\lambda}.$$

This elementary estimate follows by splitting the integral at $\theta = 1$: on $0 \le \theta \le 1$, $\cosh\theta \ge 1 + \theta^2/3$, while on $\theta \ge 1$ the stronger decay of $e^{-\lambda\cosh\theta}$ gives a term bounded by $Ce^{-\lambda\cosh 1}$. Applying this estimate to $\lambda = m_aR$ and to $\lambda = 2m_aR$ gives

$$|\mathcal{R}_2(R)| \le CR^{-1/2}e^{-2m_*R}$$

after another harmless enlargement of C. □

Example 80.4 (Free Majorana leading winding)**.** For the massive Ising/Majorana theory the derivative kernel vanishes. The leading winding contribution is

$$E_0(R) - \mathcal{E}_{\text{bulk}}R = -\frac{m}{2\pi}\int_{-\infty}^{\infty} d\theta\, \cosh\theta\, e^{-mR\cosh\theta} + O(e^{-2mR}).$$

The modified Bessel function has the integral representation

$$K_\nu(r) = \int_0^\infty d\theta\, e^{-r\cosh\theta}\cosh(\nu\theta), \qquad r > 0.$$

Therefore

$$\int_{-\infty}^{\infty} d\theta\, \cosh\theta\, e^{-r\cosh\theta} = 2K_1(r),$$

and the first winding gives

$$E_0(R) - \mathcal{E}_{\text{bulk}}R = -\frac{m}{\pi}K_1(mR) + O(e^{-2mR}).$$

Using the standard steepest-descent expansion at the saddle $\theta = 0$,

$$K_1(r) \sim \sqrt{\frac{\pi}{2r}}\, e^{-r}\left(1 + \frac{3}{8r} - \frac{15}{128r^2} + \cdots\right),$$

so the leading finite-size vacuum correction is exponentially small with prefactor $R^{-1/2}e^{-mR}$.

80.4 Excited-State F-Term

A direct-channel finite-volume excited state is described, at leading large R, by physical rapidities θ_j and species a_j satisfying Bethe–Yang equations. A single mirror particle of species b and rapidity θ winding once around the direct spatial circle scatters through the physical particles. Euclidean rotation converts this scattering into the crossed amplitudes

$$S_{ba_j}\left(\theta - \theta_j + \frac{\mathrm{i}\pi}{2}\right).$$

Definition 80.5 (Analytic strip for the F-term)**.** For a state $\Psi = (a_1, \theta_1; \ldots; a_n, \theta_n)$, an F-term strip is a connected domain containing the real θ-axis on which every function

$$S_{ba_j}\left(\theta - \theta_j + \frac{\mathrm{i}\pi}{2}\right)$$

is meromorphic, the chosen integration contour can be kept away from poles, and the product of amplitudes has sufficient decay for the contour integral below.

Controlled Approximation 80.6 (One-winding excited-state F-term)**.** Assume diagonal scattering, a declared F-term strip with no pole crossed by the real mirror contour, and a large-R cluster expansion of the torus trace in mirror occupation factors. The one-mirror-particle correction to the energy of the direct-channel state Ψ, after subtracting the vacuum mirror loop, is

$$\Delta E_\Psi^F(R) = -\sum_b \int_{\mathbb{R}} \frac{d\theta}{2\pi}\, m_b \cosh\theta\, e^{-Rm_b\cosh\theta}\left(\prod_{j=1}^{n} S_{ba_j}\left(\theta - \theta_j + \frac{\mathrm{i}\pi}{2}\right) - 1\right).$$

In the mirror channel, the direct excited state is represented by operator insertions that a mirror particle crosses while winding around the cycle. At one winding, the trace contribution of one mirror particle of species b and rapidity θ has Boltzmann weight $\exp[-Rm_b\cosh\theta]$ and density of states $d\theta/(2\pi)$. Crossing the direct-channel physical particles multiplies this contribution by

$$\prod_{j=1}^{n} S_{ba_j}\left(\theta - \theta_j + \frac{\mathrm{i}\pi}{2}\right).$$

The logarithm of the trace converts this one-particle contribution into an energy shift with the overall factor $-m_b \cosh\theta$; the identical loop with no physical particles is the vacuum contribution and gives the subtraction by 1. Summing over mirror species gives the displayed formula.

If a pole is crossed while moving the contour to the declared F-term strip, the residue is a separate contribution. A convenient residue formula is

$$\Delta E^{\mu}_{\Psi}(R) = -\sum_{\theta_* \in \mathcal{P}} \sigma_* \,\mathrm{i} \operatorname*{Res}_{\theta=\theta_*} \left[\frac{m_b \cosh\theta}{2\pi} e^{-R m_b \cosh\theta} \left(\prod_j S_{ba_j}\left(\theta - \theta_j + \frac{\mathrm{i}\pi}{2}\right) - 1 \right) \right],$$

where $\mathcal{P}$ is the finite set of crossed poles and $\sigma_* = \pm 1$ records the orientation of the contour deformation. In a bound-state theory those residues are controlled by the same pole data that enter the factorized scattering bootstrap. The formula becomes a theorem only after the analytic strip, contour orientation, and bound-state pole normalization have been specified.

Status checkpoint: excited-state continuation. An excited-state finite-size formula is not obtained by substituting Bethe–Yang rapidities into the ground-state TBA functional. The direct state changes the mirror trace by insertions, and analytic continuation of the mirror rapidity contour can encounter poles, zeros of $1 + \mathrm{e}^{-\epsilon}$, and branch changes of the logarithm. A theorem-level excited-state TBA must therefore specify a continuation path in R and in rapidity space, record the source terms created by crossed singularities, prove that no omitted singularity crosses the contour, and compare the resulting expression with the direct-channel spectral trace. The one-winding F-term and the μ-term residue above are the first controlled pieces of this continuation ledger.

Controlled Approximation 80.7 (Excited-state continuation residual budget)**.** Let

$$\mathcal{E}^{\mathrm{dir}}_{\Psi}(R) = E_{\Psi}(R) - E_0(R)$$

be the direct-channel excitation energy above the vacuum. Let $\mathcal{E}^{\mathrm{ins}}_{\Psi}$ be the same quantity extracted from the mirror trace with the direct-state insertions kept at the regulator level, $\mathcal{E}^{\mathrm{cont}}_{\Psi}$ the expression after the declared contour and branch continuation, and $\mathcal{E}^{\mathrm{src}}_{\Psi}$ the expression after all crossed singularities on that declared path have been converted into source or residue terms. Finally set

$$\mathcal{E}^{\mathrm{1w}}_{\Psi}(R) = E^{\mathrm{BY}}_{\Psi}(R) + \Delta E^{F}_{\Psi}(R) + \Delta E^{\mu}_{\Psi}(R), \tag{80.1}$$

where E^{BY}_{Ψ} is the Bethe–Yang energy in the chosen finite-volume normalization and the last two terms are the one-winding F-term and the crossed-pole μ-term retained above. The exact difference between the direct spectral coordinate and the one-winding coordinate decomposes as

$$\mathcal{E}^{\mathrm{dir}}_{\Psi}(R) - \mathcal{E}^{\mathrm{1w}}_{\Psi}(R) = R_{\mathrm{trace}} + R_{\mathrm{cont}} + R_{\mathrm{branch}} + R_{\mathrm{pole}} + R_{\mathrm{multi}} + R_{\mathrm{dens}} + R_{\mathrm{norm}}. \tag{80.2}$$

Here R_{trace} compares the direct spectral trace with the mirror insertion trace; R_{cont} is the error in the contour deformation inside the declared analytic strip; R_{branch} records logarithm and source-branch changes; R_{pole} is the net contribution of crossed singularities not included in ΔE^{μ}_{Ψ}; R_{multi} is the omitted two- and higher-mirror-particle sector; R_{dens} records the finite-volume density and Bethe-rapidity normalization mismatch; and R_{norm} records local operator, state, and bulk-energy normalization differences between the direct and mirror coordinates. Consequently, if on a window $R \in I$ these residuals obey

$$|R_{\kappa}(R)| \le \varepsilon_{\kappa}(R), \qquad \kappa \in \{\mathrm{trace}, \mathrm{cont}, \mathrm{branch}, \mathrm{pole}, \mathrm{multi}, \mathrm{dens}, \mathrm{norm}\},$$

then

$$\left|\mathcal{E}_\Psi^{\mathrm{dir}}(R) - \mathcal{E}_\Psi^{1\mathrm{w}}(R)\right| \leq \sum_\kappa \varepsilon_\kappa(R). \tag{80.3}$$

The budget is only an identity plus declared estimates, but it is the right identity to audit. A successful excited-state TBA theorem proves that the residuals vanish in the intended limit or remain within a stated approximation window. A one-winding formula without these seven controls is a semiclassical finite-size coordinate, not a reconstruction of the direct-channel spectral trace.

80.5 Wrapping Effects for Local Operators

A wrapping contribution is a finite-volume term represented in the mirror channel by virtual propagation around a compact cycle. Its order is measured by the number and species of mirror occupation factors $q_a(\theta)$. This ordering is independent of the loop order of any Lagrangian perturbation series.

Let $\widehat{\mathcal{O}}$ be a local operator with a declared infinite-volume normalization. A diagonal finite-volume matrix element has an expansion of the form

$$\langle \Psi, R|\widehat{\mathcal{O}}|\Psi, R\rangle = \langle \Psi|\widehat{\mathcal{O}}|\Psi\rangle_\infty + \sum_{k\geq 1} \Delta_{\mathcal{O}}^{(k)}(R),$$

where $\Delta_{\mathcal{O}}^{(k)}(R)$ is assembled from k-mirror-particle form factors, crossed scattering factors, and finite-volume density determinants. The first term in this series is determined by the connected one-mirror-particle form factor in the crossed channel, after subtracting the vacuum wrapping term and the disconnected pieces already accounted for by the finite-volume normalization of $|\Psi, R\rangle$.

Definition 80.8 (Operator wrapping specification)**.** An operator wrapping specification consists of:

1. the infinite-volume form factors of $\widehat{\mathcal{O}}$ in the state normalization of Chapter 76;
2. the analytic strip and crossing prescription for moving mirror rapidities through the operator insertion and through the physical particles;
3. the finite-volume density determinant for the physical Bethe–Yang state;
4. a subtraction prescription for vacuum terms and disconnected diagonal pieces.

With this specification fixed, each wrapping correction is a contour integral whose integrand is a declared meromorphic function. Residues from crossed poles are then part of the same contour calculation rather than extra rules.

80.6 Relation To Planar Wrapping

In large-N gauge-theory spectral problems the word wrapping often denotes corrections whose spin-chain interaction range reaches the length of a single-trace operator. The relativistic finite-size mechanism developed here has a literal spacetime compact cycle and a mirror thermal trace.

Later planar-integrability chapters build the bridge by identifying the spectral problem, the auxiliary mirror channel in that spectral problem, and the analytic continuation that maps finite-size corrections between the two settings.

Open Problem 80.9 (Excited-state mirror construction). Give a theorem-level construction of excited-state TBA starting from factorized scattering, a declared analytic strip, pole data, and finite-volume Bethe states, including a proof that the contour deformations and residue terms reproduce the spectral trace on the torus.

Chapter 81

Sine-Gordon, Massive Thirring, And Affine Toda Theories

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter introduces exact relativistic model families in which the factorized-scattering, form-factor, and TBA structures of the preceding chapters can be tested against Lagrangian and ultraviolet data. Every normalization below is part of the definition of the model being discussed.

81.1 Model-Family Datum

An integrable model family is specified by:

$$(\mathcal{A}_{\mathrm{UV}}, \mathcal{O}_{\mathrm{pert}}, \lambda, \mathcal{Q}, \mathcal{S}, \mathcal{F}),$$

where $\mathcal{A}_{\mathrm{UV}}$ is a short-distance operator algebra or regulated Lagrangian chart, $\mathcal{O}_{\mathrm{pert}}$ is the relevant perturbing coordinate, λ is its coupling, $\mathcal{Q}$ is the commutative algebra of conserved charges, $\mathcal{S}$ is the factorized scattering system, and $\mathcal{F}$ is the form-factor system for local operators. The model family is under control only when these entries are matched in common conventions.

81.2 Sine-Gordon Normalization

Let φ be a real scalar field with Lorentzian action

$$S_{\mathrm{SG}} = \int d^2x \left[-\frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi + \frac{\mu}{\beta^2}\big(\cos(\beta\varphi) - 1\big) \right],$$

where $0 < \beta^2 < 8\pi$ in the short-distance free-boson normalization used for the displayed formula. The potential is periodic under

$$\varphi \longmapsto \varphi + \frac{2\pi}{\beta}.$$

Finite-energy configurations on the line therefore have topological charge

$$Q_{\mathrm{top}} = \frac{\beta}{2\pi}\int_{-\infty}^{\infty} dx\,\partial_x\varphi \in \mathbb{Z}.$$

The charge $Q_{\mathrm{top}} = 1$ particle is the soliton, and $Q_{\mathrm{top}} = -1$ is the antisoliton.

81.3 Sine-Gordon Spectrum

Introduce

$$\xi = \frac{\beta^2}{8\pi - \beta^2}.$$

Equivalently $\lambda = \xi^{-1} = 8\pi/\beta^2 - 1$. The attractive regime is $0 < \xi < 1$, or $\lambda > 1$. In this regime the soliton-antisoliton S-matrix has bound-state poles corresponding to neutral breathers

$$B_n, \qquad n = 1, \dots, N_B, \qquad N_B = \max\{n \in \mathbb{Z}_{>0} \mid n\xi < 1\},$$

with masses

$$m_n = 2M_s \sin\left(\frac{\pi n\xi}{2}\right),$$

where M_s is the soliton mass. The formula follows from relativistic two-body kinematics: a pole at rapidity difference $\theta = \mathrm{i}u$ in a two-particle channel of equal masses M_s produces a bound state of mass

$$m^2 = 2M_s^2(1 + \cos u) = 4M_s^2\cos^2\left(\frac{u}{2}\right).$$

For the breather poles $u = \pi(1 - n\xi)$, this gives the displayed value.

81.4 Mass Scale And The UV Perturbing Coordinate

The symbol M_s denotes the physical soliton mass, defined by the isolated mass hyperboloid in the soliton superselection sector. The coefficient μ in a Lagrangian expression is not itself an invariant until the short-distance normal-ordering convention for the vertex operator has been specified. To make the comparison unambiguous, introduce the Euclidean free-boson normalization

$$A_0[\phi] = \frac{1}{16\pi}\int_{\mathbb{R}^2} \mathrm{d}^2x\,\partial_\alpha\phi\,\partial_\alpha\phi, \qquad \langle\phi(x)\phi(0)\rangle_0 = -2\log|x| + O(1),$$

and define the perturbation by

$$A_{\mathrm{SG}}^{\mathrm{UV}} = A_0[\phi] - 2\mu_{\mathrm{UV}} \int_{\mathbb{R}^2} \mathrm{d}^2x \ :\cos(\beta_{\mathrm{UV}}\phi(x)):_0 . \tag{81.1}$$

Then the scaling dimension of $:\exp(\mathrm{i}\beta_{\mathrm{UV}}\phi):_0$ is $2\beta_{\mathrm{UV}}^2$, the coupling μ_{UV} has mass dimension $2-2\beta_{\mathrm{UV}}^2$, and

$$\xi = \frac{\beta_{\mathrm{UV}}^2}{1-\beta_{\mathrm{UV}}^2}.$$

Equivalently, in the canonical kinetic normalization of the preceding section, $\phi = \sqrt{8\pi}\,\varphi$ and $\beta_{\mathrm{UV}} = \beta/\sqrt{8\pi}$. The exact mass-coupling relation, in the UV convention (81.1), is

$$M_s = \frac{2\Gamma(\xi/2)}{\sqrt{\pi}\,\Gamma((1+\xi)/2)} \left[\frac{\pi\mu_{\mathrm{UV}}\Gamma(1-\beta_{\mathrm{UV}}^2)}{\Gamma(\beta_{\mathrm{UV}}^2)}\right]^{(1+\xi)/2} . \tag{81.2}$$

The power is forced by dimensions because

$$\frac{1+\xi}{2} = \frac{1}{2(1-\beta_{\mathrm{UV}}^2)}.$$

The nontrivial content of (81.2) is therefore the dimensionless gamma-function coefficient. In this chapter the formula is used as a coordinate change between the UV perturbing coordinate and the physical mass coordinate; the derivation from finite-size thermodynamic Bethe ansatz data and the vacuum energy normalization belongs to the later chapter on exact RG flows.

81.5 Exact Soliton-Antisoliton Scattering Datum

The one-soliton internal space is

$$V = \mathbb{C}|+\rangle \oplus \mathbb{C}|-\rangle, \qquad Q_{\mathrm{top}}|\pm\rangle = \pm|\pm\rangle.$$

Charge conservation forces the two-particle scattering operator on $V\otimes V$ to have the block form

$$\mathsf{S}_{\mathrm{sol}}(\theta) = S_{\min}(\theta) \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & b(\theta) & c(\theta) & 0 \\ 0 & c(\theta) & b(\theta) & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}_{|++\rangle,|+-\rangle,|-+\rangle,|--\rangle} , \tag{81.3}$$

where

$$b(\theta) = \frac{\sinh(\lambda\theta)}{\sinh(\lambda(\mathrm{i}\pi-\theta))}, \qquad c(\theta) = \frac{\mathrm{i}\sin(\pi\lambda)}{\sinh(\lambda(\mathrm{i}\pi-\theta))}, \qquad \lambda = \xi^{-1}.$$

One standard minimal scalar normalization is the boundary value, for real θ, of

$$S_{\min}(\theta) = -\exp\left[-\mathrm{i}\int_0^\infty \frac{\mathrm{d}t}{t}\,\frac{\sinh((1-\xi)t/2)}{\sinh(\xi t/2)\cosh(t/2)} \sin\left(\frac{\theta t}{\pi}\right)\right], \tag{81.4}$$

continued meromorphically from the physical line with the prescribed physical-strip pole data. The displayed system is on-shell bootstrap data: the construction of a local Hilbert-space QFT whose soliton sectors realize it is a separate existence problem, recorded at the end of the chapter.

Matrix unitarity and the breather pole locations. For real $\lambda > 0$, the matrix factor in (81.3) obeys

$$R_\lambda(\theta)R_\lambda(-\theta) = \mathbf{1}$$

as a meromorphic 4×4 matrix. In the attractive regime $\lambda > 1$, the denominators of $b(\theta)$ and $c(\theta)$ have physical-strip zeros at

$$\theta = \mathrm{i}u_n, \qquad u_n = \pi(1 - n\xi), \qquad n \in \mathbb{Z}_{>0}, \quad n\xi < 1, \tag{81.5}$$

and these are precisely the rapidity locations that give the breather masses

$$m_n = 2M_s \sin\left(\frac{\pi n \xi}{2}\right).$$

Only the charge-zero block is nontrivial. Set

$$X = \sinh(\lambda\theta), \qquad s = \sin(\pi\lambda), \qquad D_\pm = \sinh(\lambda(\mathrm{i}\pi \mp \theta)).$$

Using

$$D_+D_- = \sinh(\mathrm{i}\pi\lambda - \lambda\theta)\sinh(\mathrm{i}\pi\lambda + \lambda\theta) = -\big(X^2 + s^2\big),$$

one obtains

$$b(\theta)b(-\theta) + c(\theta)c(-\theta) = \frac{-X^2 - s^2}{D_+D_-} = 1,$$

and

$$b(\theta)c(-\theta) + c(\theta)b(-\theta) = \frac{X\,\mathrm{i}s + \mathrm{i}s(-X)}{D_+D_-} = 0.$$

The opposite charge-zero ordering has the same diagonal coefficient and the off-diagonal coefficient with the two terms interchanged, so its product gives the identical scalar equations. On $|{+}{+}\rangle$ and $|{-}{-}\rangle$ the matrix block is scalar, and unitarity reduces to multiplication of the corresponding scalar entries at θ and $-\theta$.

The denominator vanishes exactly when

$$\lambda(\mathrm{i}\pi - \theta) = \mathrm{i}\pi n, \qquad n \in \mathbb{Z},$$

so $\theta = \mathrm{i}\pi(1 - n/\lambda) = \mathrm{i}\pi(1 - n\xi)$. This point lies in the physical strip $0 < \operatorname{Im}\theta < \pi$ exactly when $n\xi < 1$. Substituting $u_n = \pi(1 - n\xi)$ into the equal-mass bound-state formula gives

$$m_n = 2M_s \cos\left(\frac{u_n}{2}\right) = 2M_s \sin\left(\frac{\pi n\xi}{2}\right),$$

as claimed.

Lemma 81.1 (Yang-Baxter equation for the soliton matrix part)**.** *Let $R_\lambda(\theta)$ be the 4×4 matrix factor in (81.3), without the scalar multiplier $S_{\min}$. On $V^{\otimes 3}$ it obeys*

$$R_{12}(\theta_{12})R_{13}(\theta_{13})R_{23}(\theta_{23}) = R_{23}(\theta_{23})R_{13}(\theta_{13})R_{12}(\theta_{12}), \qquad \theta_{ij} = \theta_i - \theta_j.$$

Proof. Only the charge-one and charge-two subspaces of $V^{\otimes 3}$ are nontrivial; charge zero and charge three are scalar. Write

$$B(u) = \frac{\sinh(\lambda u)}{\sinh(\mathrm{i}\pi\lambda - \lambda u)}, \qquad C(u) = \frac{\mathrm{i}\sin(\pi\lambda)}{\sinh(\mathrm{i}\pi\lambda - \lambda u)}, \qquad A = \mathrm{i}\pi\lambda.$$

Direct multiplication of the two 8×8 products reduces all component equalities to the following three scalar identities, with $w = u + v$:

$$\begin{aligned} -B(u)C(v) + B(w)C(v) - B(v)C(u)C(w) &= 0, \\ -B(u)B(v)C(w) - C(u)C(v) + C(w) &= 0, \\ -B(u)C(w)C(v) + B(w)C(u) - B(v)C(u) &= 0. \end{aligned}$$

After clearing denominators these identities are consequences of

$$\sinh(A-u)\sinh(A-v) - \sinh u\, \sinh v = \sinh A\, \sinh(A-u-v),$$

and the two identities obtained from it by replacing one of the factors with the addition formula

$$\sinh(u+v) = \sinh u \cosh v + \cosh u \sinh v.$$

Since $\sinh A = \mathrm{i}\sin(\pi\lambda)$, these are exactly the three displayed component identities. The scalar factor $S_{\min}$ cancels from the Yang-Baxter equation, because it contributes the same product of three scalar functions on both sides. $\square$

Remark 81.2 (Free-fermion point). At $\beta^2 = 4\pi$, one has $\xi = 1$ and $\lambda = 1$. Then $\sin(\pi\lambda) = 0$, so the reflection amplitude $c(\theta)$ vanishes, while $b(\theta) = 1$. The remaining scalar factor is $S_{\min}(\theta) = -1$, the fermionic exchange phase of the massive Thirring field at $g_{\mathrm{T}} = 0$. This is a useful convention check: the soliton and antisoliton then form the free massive Dirac particle and antiparticle.

81.6 Soliton-Breather Scattering

The neutral breather B_n is obtained from the residue of the soliton-antisoliton amplitude at

$$\theta = \mathrm{i}\pi(1 - n\xi).$$

Applying the fusion identity of Proposition 72.2 to the soliton matrix (81.3) gives a diagonal scalar amplitude for a soliton or antisoliton scattering through B_n:

$$S_{sB_n}(\theta) = \frac{\sinh\theta + \mathrm{i}\cos(\pi n\xi/2)}{\sinh\theta - \mathrm{i}\cos(\pi n\xi/2)} \prod_{\ell=1}^{n-1} \frac{\sin^2\left(\frac{\pi\xi}{4}(n-2\ell) - \frac{\pi}{4} + \frac{\mathrm{i}\theta}{2}\right)}{\sin^2\left(\frac{\pi\xi}{4}(n-2\ell) - \frac{\pi}{4} - \frac{\mathrm{i}\theta}{2}\right)}. \tag{81.6}$$

The same scalar function appears for $s = +$ and $s = -$, because B_n is neutral and the fused residue is a one-dimensional charge-preserving channel. The formula is minimal in the same sense as before: it contains no additional CDD factor that is analytic, nonzero, and unitary in the physical strip.

Soliton–breather unitarity, crossing, and pole locations. For $n\xi < 1$, the amplitude (81.6) obeys

$$S_{sB_n}(\theta)S_{sB_n}(-\theta) = 1, \qquad S_{sB_n}(\mathrm{i}\pi - \theta) = S_{sB_n}(\theta).$$

Its first scalar factor has physical-strip poles at

$$\theta = \mathrm{i}\left(\frac{\pi}{2} + \frac{\pi n\xi}{2}\right), \qquad \theta = \mathrm{i}\left(\frac{\pi}{2} - \frac{\pi n\xi}{2}\right).$$

The first is the direct-channel soliton pole in

$$s + B_n \longrightarrow s,$$

and the second is its crossed-channel partner. The product factors have additional double poles at

$$\theta_\ell = \mathrm{i}\left(\frac{\pi}{2} + \frac{\pi\xi}{2}(2\ell - n)\right), \qquad \ell = 1, \dots, n-1,$$

which are internal Coleman-Thun-type singularities of the fused scattering input rather than new one-particle states.

Unitarity follows factor by factor, because replacing θ by $-\theta$ in every displayed numerator gives the corresponding denominator. For crossing, use

$$\sinh(\mathrm{i}\pi - \theta) = \sinh\theta$$

for the first factor, and

$$a_\ell = \frac{\pi\xi}{4}(n - 2\ell) - \frac{\pi}{4}$$

for the product factors. Under $\theta \mapsto \mathrm{i}\pi - \theta$, the ℓ-th numerator becomes

$$\sin^2\left(a_\ell - \frac{\pi}{2} - \frac{\mathrm{i}\theta}{2}\right) = \cos^2\left(a_\ell - \frac{\mathrm{i}\theta}{2}\right).$$

Because

$$a_{n-\ell} = -\frac{\pi\xi}{4}(n - 2\ell) - \frac{\pi}{4}, \qquad \cos\left(a_\ell - \frac{\mathrm{i}\theta}{2}\right) = \sin\left(a_{n-\ell} + \frac{\mathrm{i}\theta}{2} + \pi\right),$$

the crossed numerator of the ℓ-th factor equals the uncrossed numerator of the $(n-\ell)$-th factor after squaring. The denominators are permuted in the same way. Hence the full product, not each individually labelled factor, is crossing invariant.

The first denominator vanishes when

$$\sinh\theta = \mathrm{i}\cos(\pi n\xi/2).$$

Inside the physical strip this gives the two displayed locations. Let

$$\alpha = \frac{\pi n\xi}{2}, \qquad m_n = 2M_s \sin\alpha.$$

At the direct pole $u = \pi/2 + \alpha$, the invariant mass in the soliton-breather channel is

$$M_s^2 + m_n^2 + 2M_s m_n \cos u = M_s^2 + 4M_s^2 \sin^2\alpha - 4M_s^2 \sin^2\alpha = M_s^2.$$

Thus the direct pole has precisely the mass of the external soliton. The second pole is obtained by crossing. Finally, the denominator of the ℓ-th product factor vanishes when

$$\frac{\pi\xi}{4}(n-2\ell) - \frac{\pi}{4} - \frac{\mathrm{i}\theta}{2} \in \pi\mathbb{Z},$$

which gives the displayed θ_ℓ in the physical strip. The square on the sine gives a double pole. These singularities arise because the breather was represented as a fused soliton-antisoliton pair and the external soliton can scatter through either constituent; their invariant masses do not match a new stable particle below threshold.

81.7 Lightest Breather Scattering

The lightest breather B_1 is a neutral scalar particle in the attractive regime $0 < \xi < 1$. Its diagonal two-body amplitude is

$$S_{11}(\theta) = \frac{\sinh\theta + \mathrm{i}\sin(\pi\xi)}{\sinh\theta - \mathrm{i}\sin(\pi\xi)}. \tag{81.7}$$

This formula is a useful test case because each analytic requirement can be checked directly. Unitarity follows by multiplication:

$$S_{11}(\theta)S_{11}(-\theta) = \frac{\sinh\theta + \mathrm{i}s_\xi}{\sinh\theta - \mathrm{i}s_\xi}\frac{-\sinh\theta + \mathrm{i}s_\xi}{-\sinh\theta - \mathrm{i}s_\xi} = 1, \qquad s_\xi = \sin(\pi\xi).$$

Hermitian analyticity follows from

$$S_{11}(\theta)^* = S_{11}(-\theta^*)$$

for the boundary values obtained from real rapidity. Crossing for an self-conjugate scalar requires $S_{11}(\theta) = S_{11}(\mathrm{i}\pi - \theta)$. Since $\sinh(\mathrm{i}\pi - \theta) = \sinh\theta$, the displayed amplitude satisfies this identity.

The denominator vanishes when

$$\sinh\theta = \mathrm{i}\sin(\pi\xi).$$

Inside the physical strip $0 < \operatorname{Im}\theta < \pi$, this equation has two solutions,

$$\theta = \mathrm{i}\pi\xi, \qquad \theta = \mathrm{i}\pi(1-\xi).$$

They are exchanged by crossing. Only the first one is the direct $B_1B_1 \to B_2$ pole when $2\xi < 1$; the second is its crossed-channel image and must not be counted as a separate direct-channel particle. For two incoming particles of mass m_1 and rapidities $\theta/2$ and $-\theta/2$, the squared center-of-mass energy is

$$s(\theta) = \big(p(\theta/2) + p(-\theta/2)\big)^2 = 4m_1^2\cosh^2(\theta/2).$$

At $\theta = \mathrm{i}\pi\xi$, this is

$$s_* = 4m_1^2\cos^2\left(\frac{\pi\xi}{2}\right).$$

Therefore the pole has the mass required for the second breather:

$$m_2 = 2m_1\cos\left(\frac{\pi\xi}{2}\right).$$

Using the soliton-breather mass formula

$$m_n = 2M_s \sin\left(\frac{\pi n \xi}{2}\right)$$

for $n = 1, 2$, the same relation becomes

$$2m_1 \cos\left(\frac{\pi\xi}{2}\right) = 4M_s \sin\left(\frac{\pi\xi}{2}\right)\cos\left(\frac{\pi\xi}{2}\right) = 2M_s \sin(\pi\xi) = m_2.$$

Thus the elementary analytic pole of (81.7) encodes the fusion process

$$B_1 + B_1 \longrightarrow B_2$$

when B_2 lies below the two-soliton threshold as a stable breather. The condition is $2\xi < 1$. At the endpoint $2\xi = 1$ the candidate sits at threshold, and for $2\xi > 1$ this pole does not define an additional stable breather in the Hilbert-space particle spectrum.

81.8 Neutral Breather Blocks and Minimal Fusion

It is useful to isolate the scalar factor

$$F_a(\theta) = \frac{\sinh\theta + \mathrm{i}\sin(\pi a)}{\sinh\theta - \mathrm{i}\sin(\pi a)}, \qquad a \in \mathbb{R}. \tag{81.8}$$

Then $S_{11}(\theta) = F_\xi(\theta)$. The block records both the direct pole and its crossed image in a way that makes the residue sign visible.

Neutral scalar block. For real $0 < a < 1$,

$$F_a(\theta)F_a(-\theta) = 1, \qquad F_a(\mathrm{i}\pi - \theta) = F_a(\theta).$$

The physical strip contains the two simple poles

$$\theta = \mathrm{i}\pi a, \qquad \theta = \mathrm{i}\pi(1-a).$$

The corresponding residues obey

$$-\mathrm{i}\operatorname*{Res}_{\theta=\mathrm{i}\pi a} F_a(\theta) = 2\tan(\pi a), \qquad -\mathrm{i}\operatorname*{Res}_{\theta=\mathrm{i}\pi(1-a)} F_a(\theta) = -2\tan(\pi a).$$

Thus, for $0 < a < 1/2$, the pole at $\theta = \mathrm{i}\pi a$ has the positive direct-channel residue sign, while the pole at $\theta = \mathrm{i}\pi(1-a)$ is its crossed-channel partner.

Unitarity follows by replacing $\sinh\theta$ by $-\sinh\theta$, and crossing follows from $\sinh(\mathrm{i}\pi - \theta) = \sinh\theta$. The denominator vanishes at $\theta = \mathrm{i}\pi a$ and $\theta = \mathrm{i}\pi(1-a)$. At $\theta_0 = \mathrm{i}\pi a$, the numerator is $2\mathrm{i}\sin(\pi a)$, while the derivative of the denominator is $\cosh\theta_0 = \cos(\pi a)$. Therefore

$$\operatorname*{Res}_{\theta=\mathrm{i}\pi a} F_a(\theta) = 2\mathrm{i}\tan(\pi a).$$

At $\theta_1 = \mathrm{i}\pi(1-a)$, the numerator is again $2\mathrm{i}\sin(\pi a)$, but the derivative is $\cos(\pi(1-a)) = -\cos(\pi a)$, giving the second residue formula.

The minimal diagonal scattering amplitude of breathers B_m and B_n, when both labels and every displayed fused label lie in the stable range $k\xi < 1$, is

$$S_{mn}(\theta) = F_{\frac{(m+n)\xi}{2}}(\theta)\, F_{\frac{|m-n|\xi}{2}}(\theta) \prod_{\ell=1}^{\min(m,n)-1} F_{\frac{(|m-n|+2\ell)\xi}{2}}(\theta)^2, \tag{81.9}$$

with the convention $F_0(\theta) = 1$. The formula is the minimal solution of the diagonal bootstrap equations with the breather spectrum fixed above: each F_a supplies one direct pole and its crossing partner, and the double factors are exactly the poles encountered twice when the two fused constituent rapidity strings scatter through each other. More explicitly, start from $S_{11} = F_\xi$. The residue identity of Proposition 72.2 constructs B_{r+s} from the direct pole of B_rB_s; because the neutral breather amplitudes are diagonal scalar functions, the fused scattering with a third breather is the ordinary product of the constituent scalar factors evaluated at the shifted rapidities. Iterating this statement produces the two endpoint factors $(m + n)\xi/2$ and $|m - n|\xi/2$, while every intermediate constituent difference $(|m-n|+2\ell)\xi/2$ occurs once from each side of the fused rapidity string and therefore appears squared. The word minimal means that no further CDD factor, analytic and pole-free in the physical strip, has been multiplied into the result.

Direct fusion pole in the breather amplitudes. Assume $m, n \geq 1$ and $(m + n)\xi < 1$, so that B_{m+n} is a stable breather. The amplitude $S_{mn}(\theta)$ in (81.9) has a direct-channel pole at

$$\theta = \mathrm{i}u_{mn}^{m+n}, \qquad u_{mn}^{m+n} = \frac{\pi(m+n)\xi}{2},$$

and the bound-state kinematics at this pole gives the mass m_{m+n}.

The pole is supplied by the first factor $F_{(m+n)\xi/2}(\theta)$. Since $(m+n)\xi < 1$, its parameter $(m+n)\xi/2$ lies in $(0, 1/2)$, so the neutral-block residue computation above gives the positive direct-channel residue sign at the displayed rapidity. Let

$$\alpha = \frac{\pi\xi}{2}, \qquad m_k = 2M_s \sin(k\alpha).$$

The pole angle is $u = (m + n)\alpha$. The rapidity kinematics gives

$$m_m^2 + m_n^2 + 2m_m m_n \cos u = 4M_s^2 \left[\sin^2(m\alpha) + \sin^2(n\alpha) + 2\sin(m\alpha)\sin(n\alpha)\cos((m+n)\alpha)\right].$$

Using

$$\sin((m+n)\alpha) = \sin(m\alpha)\cos(n\alpha) + \cos(m\alpha)\sin(n\alpha),$$

one obtains the elementary identity

$$\sin^2((m+n)\alpha) = \sin^2(m\alpha) + \sin^2(n\alpha) + 2\sin(m\alpha)\sin(n\alpha)\cos((m+n)\alpha).$$

Thus the bracket in the preceding display is $\sin^2((m+n)\alpha)$, and the invariant mass at the pole is

$$2M_s \sin((m+n)\alpha) = m_{m+n},$$

which proves the claim.

81.9 Massive Thirring Equivalence

We use the Lorentzian mostly-plus metric in this section, set $\epsilon^{01} = +1$, and write

$$j^\mu = \bar{\psi}\gamma^\mu\psi.$$

The massive Thirring model has Dirac field ψ and action

$$S_{\mathrm{MT}} = \int d^2x \left[\mathrm{i}\bar{\psi}\gamma^\mu\partial_\mu\psi - m\bar{\psi}\psi - \frac{g_{\mathrm{T}}}{2}(\bar{\psi}\gamma^\mu\psi)(\bar{\psi}\gamma_\mu\psi)\right].$$

The parameter g_{T} is the coefficient of the displayed renormalized current square in the vector-current point-splitting scheme used below. Changing the current contact term changes this coordinate; the relation to the sine-Gordon coupling is therefore a relation between declared renormalization charts with specified current contact terms and vertex normal-ordering schemes.

81.9.1 Free-Boson Vertex Chart

Let φ be a Euclidean free scalar with canonical action

$$A_{\mathrm{can}}[\varphi] = \frac{1}{2}\int_{\mathbb{R}^2} \mathrm{d}^2x\, \partial_\alpha\varphi\, \partial_\alpha\varphi, \qquad \langle\varphi(x)\varphi(0)\rangle_{\mathrm{can}} = -\frac{1}{2\pi}\log(\mu_{\mathrm{R}}|x|) + C,$$

where μ_{R} is the normal-ordering scale and C is removed by normal ordering. Define

$$V_\alpha(x) =:\exp(\mathrm{i}\alpha\varphi(x)): .$$

In the above canonical scalar chart,

$$V_\alpha(x)V_{-\alpha}(y) = (\mu_{\mathrm{R}}|x-y|)^{-\alpha^2/(2\pi)} :\exp(\mathrm{i}\alpha(\varphi(x)-\varphi(y))): \tag{81.10}$$

for $x \neq y$, with the right side understood as an asymptotic expansion in local derivatives at y. The scaling dimension of V_α is

$$\Delta_\alpha = \frac{\alpha^2}{4\pi}, \qquad h_\alpha = \bar{h}_\alpha = \frac{\alpha^2}{8\pi}. \tag{81.11}$$

Normal ordering removes all self-contractions, so Wick's theorem gives the single cross-contraction factor

$$\exp[(\mathrm{i}\alpha)(-\mathrm{i}\alpha)\langle\varphi(x)\varphi(y)\rangle_{\mathrm{can}}] = (\mu_{\mathrm{R}}|x-y|)^{-\alpha^2/(2\pi)}.$$

The remaining normal-ordered exponential is the displayed operator. A scalar primary of dimension Δ has two-point singularity $|x-y|^{-2\Delta}$, hence $2\Delta_\alpha = \alpha^2/(2\pi)$. Rotational invariance gives $h_\alpha = \bar{h}_\alpha = \Delta_\alpha/2$.

In this canonical chart the sine-Gordon perturbation

$$\int \mathrm{d}^2x\ :\cos(\beta\varphi):$$

has scaling dimension

$$\Delta_{\cos} = \frac{\beta^2}{4\pi}.$$

It is relevant in the ultraviolet Gaussian theory exactly for $\beta^2 < 8\pi$, marginal at $\beta^2 = 8\pi$, and irrelevant for $\beta^2 > 8\pi$.

81.9.2 Current Algebra and the Coleman Coupling Map

Let ϕ_0 denote the canonical scalar that bosonizes the current sector of a free massless Dirac fermion. With the vector-current point-splitting contact term fixed by the Schwinger term, the current map is

$$j^\mu = \frac{1}{\sqrt{\pi}}\epsilon^{\mu\nu}\partial_\nu\phi_0. \tag{81.12}$$

Equivalently, in Euclidean signature the source functional for the free Dirac vector current is the Gaussian scalar functional obtained from

$$A_E[\phi_0, b] = \frac{1}{2}\int \mathrm{d}^2x\,(\partial\phi_0)^2 - \frac{\mathrm{i}}{\sqrt{\pi}}\int \mathrm{d}^2x\, b_\mu\epsilon^{\mu\nu}\partial_\nu\phi_0,$$

up to the local contact term fixed by current conservation. This is the same normalization used in the Schwinger-model derivation in Chapter 52.

Coleman relation from the current-sector Gaussian. In the Euclidean massless Thirring current sector with $K > 0$,

$$K = 1 + \frac{g_{\mathrm{T}}}{\pi},$$

the scalar kinetic term is

$$A^E_{\mathrm{MT},m=0} = \frac{K}{2}\int \mathrm{d}^2x\,(\partial\phi_0)^2.$$

After the canonical rescaling

$$\varphi = \sqrt{K}\,\phi_0,$$

the fermion mass operator is represented by

$$\bar\psi\psi \longleftrightarrow C_m :\cos(\beta\varphi):, \qquad \beta^2 = \frac{4\pi}{K},$$

where C_m is the finite normalization of the renormalized mass operator. Therefore

$$\frac{4\pi}{\beta^2} = 1 + \frac{g_{\mathrm{T}}}{\pi}. \tag{81.13}$$

This relation is a normalization consequence of the current-sector Gaussian, not an independent theorem. For one free Dirac fermion, the current map (81.12) gives in Euclidean signature

$$j_\mu j_\mu = \frac{1}{\pi}\,\partial_\mu\phi_0\,\partial_\mu\phi_0.$$

The Euclidean Thirring weight corresponding to the Lorentzian interaction displayed at the beginning of this section therefore contributes

$$\frac{g_{\mathrm{T}}}{2}\int \mathrm{d}^2x\, j_\mu j_\mu = \frac{g_{\mathrm{T}}}{2\pi}\int \mathrm{d}^2x\,(\partial\phi_0)^2.$$

Adding the free scalar action gives the kinetic coefficient K. The condition $K > 0$ is the positivity condition for the Euclidean Gaussian current functional in this chart.

At $g_{\mathrm{T}} = 0$, chiral bosonization gives

$$\bar{\psi}_L\psi_R + \bar{\psi}_R\psi_L \longleftrightarrow C_m :\cos(\sqrt{4\pi}\,\phi_0): .$$

The current-current deformation changes only the kinetic coefficient of the current scalar. Rewriting the same operator in the canonical field $\varphi = \sqrt{K}\,\phi_0$ gives

$$\sqrt{4\pi}\,\phi_0 = \frac{\sqrt{4\pi}}{\sqrt{K}}\,\varphi.$$

Thus the sine-Gordon vertex charge is $\beta = \sqrt{4\pi/K}$, which is equivalent to (81.13).

Combining (81.12) with the same rescaling gives the current dictionary in the sine-Gordon canonical field,

$$j^\mu = \frac{\beta}{2\pi}\epsilon^{\mu\nu}\partial_\nu\varphi. \tag{81.14}$$

The integrated charge is

$$\int dx\, j^0 = \frac{\beta}{2\pi}\int dx\,\partial_x\varphi = Q_{\mathrm{top}},$$

so fermion number equals the sine-Gordon topological charge.

81.9.3 Mandelstam Operator and Exchange Phase

The fermion field is a semi-local soliton vertex operator. In the equal-time canonical chart

$$[\varphi(t,x),\Pi(t,y)] = \mathrm{i}\delta(x-y), \qquad \Pi = \partial_t\varphi,$$

Mandelstam's soliton-creating fields have the normal-ordered form

$$\psi_\pm(t,x) = Z_\psi^{1/2}\,\mathcal{K}_\pm\ :\exp\left[-\frac{2\pi\mathrm{i}}{\beta}\int_{-\infty}^{x}\mathrm{d}y\,\Pi(t,y) \mp \frac{\mathrm{i}\beta}{2}\varphi(t,x)\right]:, \tag{81.15}$$

where Z_ψ is a finite field normalization fixed by the one-particle residue, $\mathcal{K}_\pm$ are Klein factors implementing the two chiral Clifford generators, and the displayed vertex is normal ordered in the same UV scheme as the sine-Gordon perturbation.

Fermi exchange from the Mandelstam line. For

$$I(t,x) = \int_{-\infty}^{x}\mathrm{d}y\,\Pi(t,y), \qquad M_{a,b}(t,x) =:\exp(\mathrm{i}a\varphi(t,x) + \mathrm{i}bI(t,x)):,$$

the equal-time product at $x \neq y$ obeys

$$M_{a,b}(t,x)M_{a,b}(t,y) = \exp\big(\mathrm{i}ab\ \mathrm{sgn}(x-y)\big)M_{a,b}(t,y)M_{a,b}(t,x).$$

The exponential part of $\psi_\pm$ in (81.15) has $ab = \pm\pi$. Hence two identical Mandelstam fields anticommute at separated equal-time points; the Klein factors supply the anticommutation between the two chiral labels.

The canonical commutator gives

$$[\varphi(t,x), I(t,y)] = \mathrm{i}\Theta(y-x), \qquad [I(t,x),\varphi(t,y)] = -\mathrm{i}\Theta(x-y),$$

where Θ is the step function. Thus the exponent

$$A(x) = \mathrm{i}a\varphi(t,x) + \mathrm{i}bI(t,x)$$

satisfies

$$[A(x), A(y)] = \mathrm{i}ab\big(\Theta(x-y) - \Theta(y-x)\big) = \mathrm{i}ab\ \mathrm{sgn}(x-y).$$

This commutator is a scalar, so the Baker-Campbell-Hausdorff identity gives the product formula. In (81.15),

$$b = -\frac{2\pi}{\beta}, \qquad a = \mp\frac{\beta}{2},$$

and therefore $ab = \pm\pi$. Since $\exp(\pm\mathrm{i}\pi\ \mathrm{sgn}(x-y)) = -1$, the separated equal-time exchange is fermionic.

The scaling dimension of the Mandelstam exponential follows from the local field and dual-field two-point functions:

$$\Delta_\psi(\beta) = \frac{1}{4\pi}\left(\frac{\beta^2}{4} + \frac{4\pi^2}{\beta^2}\right) = \frac{\beta^2}{16\pi} + \frac{\pi}{\beta^2}. \tag{81.16}$$

At $\beta^2 = 4\pi$ this gives $\Delta_\psi = 1/2$, the free Dirac value.

81.9.4 Operator Dictionary and Correlation Checks

With the conventions fixed above, the local operator dictionary begins as

$$\begin{aligned}
j^\mu = \bar\psi\gamma^\mu\psi \qquad &\longleftrightarrow \quad \frac{\beta}{2\pi}\epsilon^{\mu\nu}\partial_\nu\varphi,\\
\bar\psi\psi = \bar\psi_L\psi_R + \bar\psi_R\psi_L \qquad &\longleftrightarrow \quad C_m :\!\cos(\beta\varphi)\!:,\\
j_\mu j_\mu \text{ in Euclidean signature} \qquad &\longleftrightarrow \quad \left(\frac{\beta}{2\pi}\right)^2 \partial_\mu\varphi\,\partial_\mu\varphi,\\
:\!\psi_R^\dagger\partial_-^s\psi_R\!: \qquad &\longleftrightarrow \quad \mathcal{P}_{s+1}^{(R)}[\varphi_R].
\end{aligned} \tag{81.17}$$

The last line is fixed by the chiral generating identity

$$:\!\psi_R^\dagger(x+\ell)\psi_R(x-\ell)\!:= \frac{1}{2\pi\mathrm{i}\,\ell}\left[:\!\exp\Big(-\mathrm{i}\sqrt{4\pi}\left(\varphi_R(x+\ell) - \varphi_R(x-\ell)\right)\Big)\!: -1\right], \tag{81.18}$$

expanded in ℓ after subtracting the singular free-fermion contraction. The left side generates chiral bilinear currents; the right side generates the normal-ordered differential polynomials $\mathcal{P}_{s+1}^{(R)}[\varphi_R]$ in $\partial_-\varphi_R, \ldots, \partial_-^{s+1}\varphi_R$.

At the free-fermion point $\beta^2 = 4\pi$, hence $K = 1$ and $g_\mathrm{T} = 0$, the chiral vertex

$$\psi_R(z) = \frac{\mathcal{K}_R}{\sqrt{2\pi a}} :\!\exp(\mathrm{i}\sqrt{4\pi}\,\varphi_R(z))\!:$$

has

$$\langle\psi_R(z)\psi_R^\dagger(0)\rangle = \frac{1}{2\pi z}$$

after the short-distance length a is identified with the chosen normal-ordering scale. This follows from the chiral version of the vertex-OPE exponent in (81.10), whose exponent is $\alpha^2/(4\pi) = 1$ for $\alpha = \sqrt{4\pi}$. The full mass operator $\bar{\psi}\psi$ has dimension 1, matching $:\cos(\sqrt{4\pi}\,\varphi):$. At the marginal sine-Gordon endpoint $\beta^2 = 8\pi$, the mass operator has dimension 2, while (81.13) gives

$$g_{\mathrm{T}} = -\frac{\pi}{2}.$$

Thus the cosine perturbation is relevant precisely for

$$\beta^2 < 8\pi \quad \Longleftrightarrow \quad 1 + \frac{g_{\mathrm{T}}}{\pi} > \frac{1}{2} \quad \Longleftrightarrow \quad g_{\mathrm{T}} > -\frac{\pi}{2}.$$

The current-current coordinate g_{T} itself is an exactly marginal current-algebra coordinate in the massless Abelian theory; it changes the compact-boson radius and thereby changes the dimension of the mass operator.

81.9.5 Chiral, Nonabelian, and Defect Extensions

The Abelian discussion has a chiral refinement. A right-moving complex fermion current

$$J_R =:\psi_R^\dagger \psi_R:$$

is represented by a chiral scalar φ_R through

$$J_R = \frac{1}{\sqrt{\pi}}\partial_- \varphi_R, \qquad \psi_R \propto \mathcal{K}_R :\exp(\mathrm{i}\sqrt{4\pi}\,\varphi_R):.$$

The chiral current OPE fixes the coefficient exactly as in the nonchiral current-sector proof: both sides have the same Schwinger term.

For N massless complex fermions, decompose the currents into the total Abelian current and the traceless $\mathfrak{su}(N)$ currents

$$J_R^a =:\psi_R^\dagger t^a \psi_R:.$$

The nonabelian current OPE is the affine $\widehat{\mathfrak{su}}(N)_1$ current algebra in the generator normalization used in the volume containing nonabelian gauge theory. The nonabelian bosonic presentation is the $SU(N)_1$ WZW model, with the Sugawara stress tensor and primary field normalizations reviewed in Section 66.8. The Abelian sine-Gordon equivalence is the $U(1)$ factor of this broader bosonization mechanism; interactions that preserve only a subgroup require a separate operator dictionary in the corresponding current algebra.

There is also a defect formulation at compact-boson radii where the topological defect category is defined. A duality defect is an object D whose fusion with its orientation reverse decomposes into a sum of symmetry defects rather than the identity alone. At rational compactification radii and after specifying spin structure, charge lattice, and boundary-condition sector, the bosonization map can be represented by such defects between the fermionic and bosonic descriptions. For the generic massive sine-Gordon and massive Thirring continuum theories, the primary statement used in this chapter remains the operator and scattering-data equivalence fixed by (81.13)–(81.17). The categorical defect formulation supplies an additional finite-symmetry organization only after those extra compactification data have been declared.

At the free-fermion point $\beta^2 = 4\pi$, hence $g_{\mathrm{T}} = 0$, the soliton and antisoliton form the massive Dirac particle and antiparticle. Away from this point the equivalence is a statement about renormalized local operator algebras and scattering data in the declared convention.

81.10 Affine Toda Data

Let $\mathfrak{g}$ be a simple Lie algebra of rank r, with simple roots α_i and highest root

$$\theta = \sum_{i=1}^{r} n_i \alpha_i.$$

Set $\alpha_0 = -\theta$ and $n_0 = 1$. The affine Toda action for a real Cartan-valued field $\phi \in \mathfrak{h}_{\mathbb{R}}$ is

$$S_{\mathrm{AT}} = \int d^2x \left[-\frac{1}{2}(\partial_\mu \phi, \partial^\mu \phi) - \frac{m^2}{\beta^2} \sum_{i=0}^{r} n_i \left(e^{\beta(\alpha_i, \phi)} - 1 \right) \right].$$

The classical equations admit a Lax representation with spectral parameter. Consequently the classical theory has commuting local conserved charges. In the quantum theory, the factorized S-matrix is organized by the root system, particle species are labelled by nodes of the Dynkin diagram in the simply-laced cases, and the pole structure encodes fusing rules compatible with the affine root data.

81.11 Mass Matrix In Affine Toda Theory

Expanding the potential at $\phi = 0$ gives

$$V(\phi) = \frac{m^2}{2} \sum_{i=0}^{r} n_i (\alpha_i, \phi)^2 + O(\phi^3).$$

Thus the classical mass matrix is

$$M_{\mathrm{cl}}^2 = m^2 \sum_{i=0}^{r} n_i \, \alpha_i \otimes \alpha_i.$$

The following explicit $A_r^{(1)}$ calculation shows what is meant by the Coxeter mass data at the classical level, without turning the linear-algebra diagonalization itself into a theorem about the quantum model.

$A_r^{(1)}$ mass matrix. Let $\mathfrak{g} = A_r$, realize the roots in

$$H = \left\{ (x_1, \dots, x_{r+1}) \in \mathbb{R}^{r+1} \;\middle|\; \sum_{k=1}^{r+1} x_k = 0 \right\}$$

with orthonormal ambient basis e_k, and take

$$\alpha_i = e_i - e_{i+1}, \qquad i = 1, \dots, r, \qquad \alpha_0 = e_{r+1} - e_1.$$

All affine Dynkin labels are $n_i = 1$, so the quadratic affine Toda mass operator is

$$M_{\mathrm{cl}}^2 = m^2 \sum_{i=0}^{r} \alpha_i \otimes \alpha_i.$$

To diagonalize it, take $v = (v_1, \dots, v_{r+1}) \in H$. Then

$$\frac{1}{m^2} M_{\mathrm{cl}}^2 v = \sum_{i=1}^{r} (v_i - v_{i+1})(e_i - e_{i+1}) + (v_{r+1} - v_1)(e_{r+1} - e_1),$$

so the k-th component is

$$2v_k - v_{k-1} - v_{k+1},$$

with indices read cyclically modulo $r+1$. Thus M_{cl}^2/m^2 is the graph Laplacian of the cycle with $r+1$ vertices, restricted to the hyperplane H. The Fourier modes

$$v_k^{(a)} = \exp\left(\frac{2\pi \mathrm{i} a k}{r+1}\right), \qquad a = 0, 1, \dots, r,$$

diagonalize this cycle Laplacian. The $a = 0$ mode is the constant vector and does not lie in H. For $a = 1, \dots, r$,

$$2 - e^{-2\pi \mathrm{i} a/(r+1)} - e^{2\pi \mathrm{i} a/(r+1)} = 2 - 2\cos\left(\frac{2\pi a}{r+1}\right) = 4\sin^2\left(\frac{\pi a}{r+1}\right),$$

and therefore the nonzero classical mass eigenvalues are

$$M_a^2 = 4m^2 \sin^2\left(\frac{\pi a}{r+1}\right), \qquad a = 1, \dots, r. \tag{81.19}$$

Real sine and cosine eigenvectors are obtained by taking real and imaginary parts of these Fourier modes. Equivalently, with Coxeter number $h = r+1$, the classical mass ratios are

$$M_a : M_1 = \sin\left(\frac{\pi a}{h}\right) : \sin\left(\frac{\pi}{h}\right), \qquad a = 1, \dots, r.$$

The same numbers also make the Coxeter/Perron–Frobenius presentation visible. Let I be the adjacency matrix of the finite A_r Dynkin chain, so $(I\mathbf{M})_a = M_{a-1} + M_{a+1}$ with boundary values $M_0 = M_{r+1} = 0$. For

$$M_a = 2m \sin\left(\frac{\pi a}{r+1}\right)$$

the sine addition formula gives

$$M_{a-1} + M_{a+1} = 2\cos\left(\frac{\pi}{r+1}\right) M_a.$$

Hence $\mathbf{M} = (M_1, \dots, M_r)$ is the positive Perron–Frobenius eigenvector of I, with eigenvalue

$$2\cos\left(\frac{\pi}{h}\right), \qquad h = r+1.$$

This calculation is the finite A_r algebra behind the Coxeter mass language used in the simply-laced affine Toda bootstrap. For D and E types, the analogous mass vector is specified by the positive Perron–Frobenius eigenvector of the finite Dynkin adjacency matrix with eigenvalue $2\cos(\pi/h)$. The first non-A check is small enough to write out. For D_4, use the node order in which node 2 is the central trivalent node and nodes $1, 3, 4$ are the leaves. The Coxeter number is $h = 6$, so the Perron–Frobenius eigenvalue is

$$2\cos\left(\frac{\pi}{6}\right) = \sqrt{3}.$$

Writing the mass vector as

$$\mathbf{M} = (x, y, x, x)$$

the adjacency eigenvalue equations are

$$y = \sqrt{3}\,x, \qquad 3x = \sqrt{3}\,y.$$

The two equations are compatible and, after the normalization $x = 1$, give

$$\mathbf{M}_{D_4} = (1, \sqrt{3}, 1, 1).$$

Equivalently, the finite Cartan matrix $C = 2\mathbf{1} - I$ sends this vector to $(2-\sqrt{3})\mathbf{M}_{D_4}$. This finite D_4 cell is the algebraic content behind the Coxeter-mass phrase: the trivalent node is heavier by the factor $\sqrt{3}$, while the three outer particles are degenerate. Matching that algebraic mass datum to an exact quantum S-matrix and to a continuum local QFT is part of the model comparison problem stated below; it is not supplied by the Hessian calculation alone.

81.12 Model-Comparison Summary

The exact-solution claim for each model has three independent tests:

UV test	operator dimensions and perturbing-coordinate normalization,
IR test	particle masses, charges, and factorized S-matrix poles,
finite-size test	TBA ground-state energy and local operator finite-volume data.

Agreement of one row does not determine the other rows. The model becomes a QFT example for this monograph only after all rows are expressed in the same regularization and source convention.

Open Problem 81.3 (Constructive integrable model comparison). Construct sine-Gordon and affine Toda theories as continuum local QFTs with operators, soliton sectors, factorized scattering, TBA finite-size energies, and form factors derived from one regulated framework rather than matched only through separate exact-solution data.

Chapter 82

O(N), Gross–Neveu, And Sigma-Model Families

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter introduces asymptotically free two-dimensional model families whose exact scattering data carry nonabelian internal symmetry. The aim is to make explicit which pieces of the exact description are consequences of symmetry, analyticity, and factorization, and which pieces require a nonperturbative construction of the underlying local QFT.

82.1 Internal-Symmetry Scattering Data

Let G be a compact Lie group and let V be a finite-dimensional unitary representation. A massive particle multiplet with rapidity θ has one-particle space

$$\mathcal{H}_1 = L^2(\mathbb{R}, \mathrm{d}\theta) \otimes V.$$

A factorized two-particle scattering operator is a meromorphic family

$$S_{VV}(\theta) : V \otimes V \longrightarrow V \otimes V,$$

where $\theta = \theta_1 - \theta_2$. G-invariance means

$$S_{VV}(\theta)\, (\rho(g) \otimes \rho(g)) = (\rho(g) \otimes \rho(g))\, S_{VV}(\theta)$$

for every $g \in G$. If

$$V \otimes V \simeq \bigoplus_\lambda m_\lambda V_\lambda,$$

then Schur decomposition gives

$$S_{VV}(\theta) = \bigoplus_\lambda S_\lambda(\theta) \otimes I_{V_\lambda}$$

whenever the multiplicities m_λ are one. With multiplicities, the coefficient $S_\lambda(\theta)$ is an endomorphism of the multiplicity space. Thus symmetry reduces the scattering problem to scalar or finite matrix meromorphic functions, but unitarity, crossing, pole residues, and the Yang–Baxter equation still constrain them.

82.2 O(N)-Invariant Two-Particle Form

For the vector representation $V = \mathbb{R}^N$ of $O(N)$, an invariant two-particle amplitude has the index form

$$S_{ij}^{kl}(\theta) = \sigma_1(\theta)\delta_{ij}\delta^{kl} + \sigma_2(\theta)\delta_i^k\delta_j^l + \sigma_3(\theta)\delta_i^l\delta_j^k.$$

Equivalently, decompose

$$V \otimes V = \mathbf{1} \oplus \mathrm{Sym}_0^2(V) \oplus \wedge^2 V.$$

Let P_0, P_S, P_A be the corresponding projectors. Then

$$S(\theta) = S_0(\theta)P_0 + S_S(\theta)P_S + S_A(\theta)P_A.$$

The two descriptions are related by applying the projectors to the index formula. For example,

$$P_{0\,ij}^{\,kl} = \frac{1}{N}\delta_{ij}\delta^{kl}, \qquad P_{A\,ij}^{\,kl} = \frac{1}{2}(\delta_i^k\delta_j^l - \delta_i^l\delta_j^k).$$

The amplitude is unitary on the real rapidity axis when

$$S_R(\theta)S_R(-\theta) = 1, \qquad R \in \{0, S, A\},$$

after diagonalization in these channels. Crossing identifies the particle with its conjugate and relates $S_{ij}^{kl}(\theta)$ to the amplitude at $\mathrm{i}\pi - \theta$ with one external index crossed.

82.3 Exact O(N) Sigma-Model Vector S-Matrix

For $N > 2$, set

$$\Delta = \frac{1}{N-2}, \qquad z = -\frac{\mathrm{i}\theta}{2\pi}.$$

The minimal $O(N)$-invariant vector S-matrix of the massive nonlinear sigma-model family is

$$S_{ij}^{kl}(\theta) = \sigma_1(\theta)\delta_{ij}\delta^{kl} + \sigma_2(\theta)\delta_i^k\delta_j^l + \sigma_3(\theta)\delta_i^l\delta_j^k, \tag{82.1}$$

with

$$\sigma_2(\theta) = \frac{\Gamma(\Delta + z)\Gamma(\frac{1}{2} + z)\Gamma(\frac{1}{2} + \Delta - z)\Gamma(1 - z)}{\Gamma(\frac{1}{2} + \Delta + z)\Gamma(z)\Gamma(1 + \Delta - z)\Gamma(\frac{1}{2} - z)}, \tag{82.2}$$

and

$$\sigma_1(\theta) = -\frac{2\pi \mathrm{i}}{N-2}\frac{\sigma_2(\theta)}{\mathrm{i}\pi-\theta}, \qquad \sigma_3(\theta) = \sigma_1(\mathrm{i}\pi-\theta) = -\frac{2\pi \mathrm{i}}{N-2}\frac{\sigma_2(\theta)}{\theta}. \tag{82.3}$$

The word minimal means that no CDD factor, unitary and crossing-symmetric and analytic without zeros or poles in the physical strip, has been multiplied into the displayed solution. The formula is a scattering input. Identifying it with a continuum local sigma-model QFT additionally requires the nonperturbative construction and matching problem stated at the end of the chapter.

The tensor in (82.1) is written in the Zamolodchikov–Faddeev component convention: it obeys

$$S_{12}(\theta)S_{13}(\theta+\phi)S_{23}(\phi) = S_{23}(\phi)S_{13}(\theta+\phi)S_{12}(\theta)$$

as a meromorphic identity on $V^{\otimes 3}$. The common scalar factor $\sigma_2(\theta)\sigma_2(\theta+\phi)\sigma_2(\phi)$ cancels from this identity, leaving the rational $O(N)$-invariant tensor

$$I - \frac{\mathrm{i}a}{\theta}P - \frac{\mathrm{i}a}{\mathrm{i}\pi-\theta}K, \qquad a = \frac{2\pi}{N-2},$$

where $P_{ij}^{kl} = \delta_i^l\delta_j^k$ and $K_{ij}^{kl} = \delta_{ij}\delta^{kl}$. Direct expansion on the basis $e_i \otimes e_j \otimes e_k$ reduces the component equality to rational identities in θ, ϕ and the contraction relation $K^2 = NK$; the accompanying calculation check enumerates finite-dimensional instances of this tensor identity together with the scalar unitarity and crossing checks.

Channel unitarity and crossing checks. Let

$$S_0 = N\sigma_1 + \sigma_2 + \sigma_3, \qquad S_S = \sigma_2 + \sigma_3, \qquad S_A = \sigma_2 - \sigma_3$$

be the singlet, symmetric-traceless, and antisymmetric channel eigenvalues of (82.1). For real rapidity $\theta \neq 0$,

$$S_R(\theta)S_R(-\theta) = 1, \qquad R \in \{0, S, A\}.$$

The coefficient functions satisfy the crossing relations

$$\sigma_2(\theta) = \sigma_2(\mathrm{i}\pi-\theta), \qquad \sigma_1(\theta) = \sigma_3(\mathrm{i}\pi-\theta), \qquad \sigma_3(\theta) = \sigma_1(\mathrm{i}\pi-\theta).$$

The role of this paragraph is the normalization check that the displayed meromorphic tensor has the required unitarity and crossing properties in the three $O(N)$ channels.

The projector decomposition gives the displayed channel eigenvalues because

$$Q_{ij}^{kl} = \delta_{ij}\delta^{kl}, \qquad I_{ij}^{kl} = \delta_i^k\delta_j^l, \qquad F_{ij}^{kl} = \delta_i^l\delta_j^k$$

act on $V \otimes V$ as $Q = NP_0$, $I = P_0 + P_S + P_A$, and $F = P_0 + P_S - P_A$. Thus

$$\sigma_1 Q + \sigma_2 I + \sigma_3 F = S_0P_0 + S_SP_S + S_AP_A.$$

For real θ, the gamma-function expression obeys

$$\sigma_2(\theta)\sigma_2(-\theta) = \frac{\theta^2}{\theta^2 + \left(\frac{2\pi}{N-2}\right)^2}. \tag{82.4}$$

This follows by multiplying (82.2) at z and $-z$ and cancelling adjacent gamma factors with $\Gamma(1+z) = z\Gamma(z)$ and $\Gamma(1-z) = (-z)\Gamma(-z)$. Set

$$a = \frac{2\pi}{N-2}.$$

The symmetric-traceless and antisymmetric rational factors are

$$\frac{S_S(\theta)}{\sigma_2(\theta)} = 1 - \frac{\mathrm{i}a}{\theta}, \qquad \frac{S_A(\theta)}{\sigma_2(\theta)} = 1 + \frac{\mathrm{i}a}{\theta}.$$

Multiplying these factors at θ and $-\theta$ gives

$$1 + \frac{a^2}{\theta^2},$$

which cancels the denominator in (82.4). For the singlet channel,

$$\frac{S_0(\theta)}{\sigma_2(\theta)} = 1 - \frac{\mathrm{i}a}{\theta} - \frac{\mathrm{i}Na}{\mathrm{i}\pi - \theta}.$$

The elementary identity

$$\left(1 - \frac{\mathrm{i}a}{\theta} - \frac{\mathrm{i}Na}{\mathrm{i}\pi - \theta}\right)\left(1 + \frac{\mathrm{i}a}{\theta} - \frac{\mathrm{i}Na}{\mathrm{i}\pi + \theta}\right) = 1 + \frac{a^2}{\theta^2}$$

again cancels (82.4). This gives channel unitarity.

For crossing of σ_2, set

$$-\frac{\mathrm{i}(\mathrm{i}\pi - \theta)}{2\pi} = \frac{1}{2} - z,$$

in the gamma-function expression (82.2). This substitution sends each numerator gamma factor at z to the corresponding numerator factor at $\frac{1}{2} - z$, and likewise for the denominators, so the ratio is unchanged in precisely the displayed way. The relations between σ_1 and σ_3 then follow from their definitions in (82.3).

82.4 Sigma-Model Ultraviolet Datum

The Euclidean $O(N)$ nonlinear sigma model is defined with field

$$n : \Sigma \longrightarrow S^{N-1} \subset \mathbb{R}^N, \qquad n \cdot n = 1,$$

and action

$$S_\sigma[n] = \frac{1}{2g^2} \int_\Sigma \mathrm{d}^2x\, \partial_\mu n \cdot \partial_\mu n.$$

The parameter g is the coefficient of the kinetic term in the displayed regularized path integral. Perturbation theory around a local coordinate chart on S^{N-1} gives the one-loop running

$$\mu \frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{N-2}{2\pi} g^3 + O(g^5).$$

The sign follows from the Ricci tensor of the round target:

$$R_{ab} = (N-2)h_{ab}.$$

The corresponding sigma-model beta tensor has leading term

$$\mu\frac{\mathrm{d}h_{ab}}{\mathrm{d}\mu} = \frac{1}{2\pi}R_{ab} + O(R^2),$$

and $h_{ab} = g^{-2}h_{ab}^{\mathrm{round}}$ yields the displayed scalar beta function. A nonperturbative massive QFT construction must then provide the Hilbert space, local fields or local algebras, and scattering states whose two-particle data match the factorized $O(N)$-invariant amplitude.

82.5 Large-N Sigma-Model Gap Equation

The large-N saddle gives a direct derivation of dimensional transmutation. Write the constraint with a Lagrange multiplier M^2 and integrate the N components of n at a translation-invariant saddle. With Euclidean momentum cutoff Λ, and with the 't Hooft coupling

$$\lambda = Ng^2$$

held fixed, the saddle equation is

$$\frac{1}{\lambda} = \int^{\Lambda} \frac{\mathrm{d}^2p}{(2\pi)^2}\frac{1}{p^2+M^2} = \frac{1}{4\pi}\log\left(\frac{\Lambda^2+M^2}{M^2}\right).$$

Solving gives

$$M = \frac{\Lambda}{\sqrt{\exp(4\pi/\lambda)-1}} = \Lambda\exp\left(-\frac{2\pi}{\lambda}\right)\left(1+O(e^{-4\pi/\lambda})\right)$$

in the weak-coupling scaling regime. If the physical mass M is held fixed while the subtraction scale μ is changed, the running coupling

$$\lambda(\mu) = \frac{2\pi}{\log(\mu/M)}$$

satisfies

$$\mu\frac{\mathrm{d}\lambda}{\mathrm{d}\mu} = -\frac{\lambda^2}{2\pi} + O(1/N).$$

This is the large-N form of asymptotic freedom. The finite-N one-loop coefficient replaces N by $N-2$ in the beta function for the unscaled coupling, as in the Ricci-tensor calculation above.

82.6 Projective Sigma Models

The next basic asymptotically free family is the projective model with target $\mathbb{CP}^{N-1}$. A convenient ultraviolet coordinate uses a complex N-component field z, a nondynamical $U(1)$ connection A_μ, and the local redundancy

$$z(x) \mapsto \mathrm{e}^{\mathrm{i}\alpha(x)}z(x), \qquad A_\mu(x) \mapsto A_\mu(x) + \partial_\mu\alpha(x).$$

The constraint and covariant derivative are

$$z^\dagger z = 1, \qquad D_\mu z = (\partial_\mu - \mathrm{i}A_\mu)z,$$

and the Euclidean action is

$$S_{\mathbb{CP}^{N-1}}[z, A] = \frac{1}{g^2}\int_\Sigma \mathrm{d}^2x\,(D_\mu z)^\dagger D_\mu z + \mathrm{i}\frac{\theta}{2\pi}\int_\Sigma F_A. \tag{82.5}$$

The $U(1)$ field is part of the quotient description, not an additional microscopic photon. On a closed Euclidean surface, for a smooth line bundle,

$$\frac{1}{2\pi}\int_\Sigma F_A \in \mathbb{Z},$$

so the coefficient θ is 2π-periodic in the continuum topological sectors. A lattice or other ultraviolet definition must specify how this integer is represented before the θ-dependent path integral is a mathematical object.

The projector

$$P = zz^\dagger, \qquad P^2 = P, \qquad \operatorname{tr} P = 1,$$

is gauge invariant and gives an intrinsic coordinate on $\mathbb{CP}^{N-1}$. The $U(1)$ connection in (82.5) can be eliminated at the classical level. Varying with respect to A_μ, while imposing $z^\dagger z = 1$, gives

$$A_\mu = -\mathrm{i}z^\dagger\partial_\mu z, \qquad D_\mu z = (1 - P)\partial_\mu z. \tag{82.6}$$

This formula is invariant under $z \mapsto \mathrm{e}^{\mathrm{i}\alpha}z$ together with $A \mapsto A + \mathrm{d}\alpha$, as required by the quotient description.

Projector form of the kinetic term and charge. For a smooth representative z of a map into $\mathbb{CP}^{N-1}$, with $A = -\mathrm{i}z^\dagger\mathrm{d}z$ and $P = zz^\dagger$,

$$\operatorname{tr}(\partial_\mu P\,\partial_\mu P) = 2(D_\mu z)^\dagger D_\mu z, \tag{82.7}$$
$$F_A = -\mathrm{i}\,\operatorname{tr}(P\,\mathrm{d}P \wedge \mathrm{d}P). \tag{82.8}$$

Consequently the action in (82.5) is equivalently

$$S_{\mathbb{CP}^{N-1}}[P] = \frac{1}{2g^2}\int_\Sigma \mathrm{d}^2x\,\operatorname{tr}(\partial_\mu P\,\partial_\mu P) + \mathrm{i}\theta Q[P], \qquad Q[P] = -\frac{\mathrm{i}}{2\pi}\int_\Sigma \operatorname{tr}(P\,\mathrm{d}P \wedge \mathrm{d}P).$$

The stationarity equation for A_μ follows from

$$(D_\mu z)^\dagger D_\mu z = \partial_\mu z^\dagger\partial_\mu z + A_\mu^2 + 2\mathrm{i}A_\mu z^\dagger\partial_\mu z,$$

where $\partial_\mu z^\dagger z = -z^\dagger\partial_\mu z$. Hence $A_\mu = -\mathrm{i}z^\dagger\partial_\mu z$, and then

$$D_\mu z = \partial_\mu z - z(z^\dagger\partial_\mu z) = (1 - P)\partial_\mu z.$$

Differentiating $P = zz^\dagger$ and using $z^\dagger D_\mu z = 0$ gives

$$\partial_\mu P = (D_\mu z)z^\dagger + z(D_\mu z)^\dagger.$$

Squaring and tracing gives
$$\operatorname{tr}(\partial_\mu P\,\partial_\mu P) = 2(D_\mu z)^\dagger D_\mu z,$$
because $z^\dagger D_\mu z = 0$ and $z^\dagger z = 1$. Finally
$$F_A = \mathrm{d}A = -\mathrm{i}\,\mathrm{d}z^\dagger \wedge \mathrm{d}z.$$
The same differentiated-projector identity gives
$$\operatorname{tr}(P\,\mathrm{d}P \wedge \mathrm{d}P) = \mathrm{d}z^\dagger \wedge \mathrm{d}z,$$
which proves (82.8). If the map is a section of a nontrivial line bundle, the computation is local and the two-form patches globally; its integral is the first Chern number of that line bundle.

On an oriented Euclidean surface with local coordinates x^1, x^2, write $F_{12}\mathrm{d}x^1 \wedge \mathrm{d}x^2 = F_A$. The algebraic identity
$$\left|D_1 z \pm \mathrm{i}D_2 z\right|^2 = |D_1 z|^2 + |D_2 z|^2 \mp F_{12}$$
gives the instanton bound, in the normalization of (82.5),
$$S_{\mathbb{CP}^{N-1},\theta=0} \geq \frac{2\pi}{g^2}|Q[P]|. \tag{82.9}$$
For $Q > 0$, equality is attained by $D_1 z + \mathrm{i}D_2 z = 0$, equivalently by a holomorphic map to projective space in the induced complex structure. For $Q < 0$, equality is attained by the anti-holomorphic equation. This is a finite-action Euclidean saddle statement in the continuum sigma-model functional. A real-time local QFT construction additionally supplies the Hilbert space, local observables, reflection-positive Euclidean data, and analytic continuation needed to interpret these sectors dynamically.

The one-loop beta tensor is again the Ricci tensor of the target; with the Fubini–Study metric normalized so that
$$\mathrm{Ric} = N\,h_{\mathrm{FS}},$$
the model is asymptotically free. If $t = g^2$ denotes the scalar coupling in (82.5), the leading running has the form
$$\mu\frac{\mathrm{d}t}{\mathrm{d}\mu} = -\frac{N}{2\pi}t^2 + \text{higher powers of } t, \tag{82.10}$$
in this normalization.

At large N with $\lambda = Ng^2$ fixed, introduce a Lagrange multiplier enforcing $z^\dagger z = 1$. A translation-invariant saddle gives
$$\frac{1}{\lambda} = \int^\Lambda \frac{\mathrm{d}^2 p}{(2\pi)^2}\frac{1}{p^2+m^2} = \frac{1}{4\pi}\log\left(\frac{\Lambda^2+m^2}{m^2}\right), \tag{82.11}$$
up to the convention-dependent factor already fixed in the action. Thus the projective family has the same dimensional-transmutation structure as the round $O(N)$ model. What differs is the global topology, the $U(1)$ quotient, the θ-angle, and the particle multiplet structure.

Proposition 82.1 (Large-N induced gauge-field kernel)**.** *Work at $\theta = 0$, in the translation-invariant large-N saddle of* (82.11)*, and expand the effective action around the constant mass*

$m > 0$ and $A_\mu = 0$. The one-loop quadratic term for the auxiliary $U(1)$ field has the transverse form

$$\Gamma^{(2)}[A] = \frac{N}{2}\int \frac{\mathrm{d}^2p}{(2\pi)^2}\, A_\mu(-p)\left[(p^2\delta_{\mu\nu} - p_\mu p_\nu)\,\Pi(p^2)\right] A_\nu(p), \tag{82.12}$$

where

$$\Pi(p^2) = \frac{1}{4\pi}\int_0^1 \mathrm{d}x\, \frac{(1-2x)^2}{m^2 + x(1-x)p^2}. \tag{82.13}$$

For $|p| \ll m$,

$$\Pi(p^2) = \frac{1}{12\pi m^2} - \frac{p^2}{120\pi m^4} + O(p^4/m^6). \tag{82.14}$$

Equivalently, the leading local term in the low-momentum effective action is

$$\Gamma_{\mathrm{loc}}[A] = \frac{N}{48\pi m^2}\int \mathrm{d}^2x\, F_{\mu\nu}F_{\mu\nu} = \frac{N}{24\pi m^2}\int \mathrm{d}^2x\, F_{12}^2 + O(\partial^4/m^4). \tag{82.15}$$

Proof. At fixed A, the z-integral is a Gaussian over N complex fields. The quadratic term in the logarithm of the covariant operator $-D_\mu D_\mu + m^2$, including the seagull term from $A_\mu A_\mu z^\dagger z$, gives

$$\Pi_{\mu\nu}(p) = N\int \frac{\mathrm{d}^2k}{(2\pi)^2}\left[\frac{(2k+p)_\mu(2k+p)_\nu}{(k^2+m^2)((k+p)^2+m^2)} - \frac{2\delta_{\mu\nu}}{k^2+m^2}\right],$$

after the same ultraviolet regulator and subtraction convention are used in both terms. Introduce a Feynman parameter, shift $q = k + xp$, and set

$$M_x^2 = m^2 + x(1-x)p^2.$$

The odd terms in q vanish. Rotational invariance gives

$$\int \frac{\mathrm{d}^2q}{(2\pi)^2}\frac{q_\mu q_\nu}{(q^2+M_x^2)^2} = \frac{\delta_{\mu\nu}}{2}\int \frac{\mathrm{d}^2q}{(2\pi)^2}\frac{q^2}{(q^2+M_x^2)^2}.$$

The logarithmic divergence in this expression cancels exactly against the seagull term after writing the latter with the same Feynman parameter. The remaining finite tensor is transverse:

$$\Pi_{\mu\nu}(p) = N(p^2\delta_{\mu\nu} - p_\mu p_\nu)\frac{1}{4\pi}\int_0^1 \mathrm{d}x\, \frac{(1-2x)^2}{m^2 + x(1-x)p^2}.$$

This is (82.12) and (82.13). Expanding the denominator gives

$$\int_0^1 (1-2x)^2 \mathrm{d}x = \frac{1}{3}, \qquad \int_0^1 (1-2x)^2 x(1-x)\mathrm{d}x = \frac{1}{30},$$

which proves (82.14). Finally, in two Euclidean dimensions,

$$\frac{1}{2}A_\mu(p)(p^2\delta_{\mu\nu} - p_\mu p_\nu)A_\nu(-p) = \frac{1}{4}F_{\mu\nu}(p)F_{\mu\nu}(-p),$$

and $F_{\mu\nu}F_{\mu\nu} = 2F_{12}^2$, giving (82.15). □

Linear potential in the induced two-dimensional gauge sector. Keep only the leading local Maxwell term

$$\frac{1}{4e_{\text{eff}}^2}\int F_{\mu\nu}F_{\mu\nu}, \qquad e_{\text{eff}}^2 = \frac{12\pi m^2}{N}, \tag{82.16}$$

obtained from (82.15). In Lorentzian signature on the line, two static external $U(1)$ sources of charges $+Q$ and $-Q$, separated by distance R, have electric-field energy

$$V(R) = \frac{e_{\text{eff}}^2 Q^2}{2}R = \frac{6\pi m^2 Q^2}{N}R. \tag{82.17}$$

Choose $A_1 = 0$. Gauss' law for the Hamiltonian associated with (82.16) is

$$\partial_x E(x) = e_{\text{eff}}^2 Q\big(\delta(x) - \delta(x-R)\big).$$

With vanishing field outside the interval between the charges, the solution is

$$E(x) = e_{\text{eff}}^2 Q, \qquad 0 < x < R,$$

and $E(x) = 0$ outside. The Hamiltonian density is $\frac{1}{2e_{\text{eff}}^2}E^2$, hence

$$V(R) = \int_0^R \mathrm{d}x\, \frac{(e_{\text{eff}}^2 Q)^2}{2e_{\text{eff}}^2} = \frac{e_{\text{eff}}^2 Q^2}{2}R.$$

Substitution of (82.16) gives (82.17).

Controlled Approximation 82.2 (Meaning of the induced-gauge large-N result)**.** Propositions 82.1 and the linear-potential computation above are statements about the large-N, low-momentum expansion around the massive saddle of the regulated projective path integral. They explain why the quotient $U(1)$ coordinate cannot be discarded after quantization, and why the charged homogeneous variables z are not gauge-invariant particle states of the projective model. They do not prove factorized scattering for the full $\mathbb{CP}^{N-1}$ local QFT, and they do not decide the $\theta = \pi$ massless endpoint.

82.6.1 The Projective Line and the Exact-Scattering Status

The case $N = 2$ is a useful normalization check because $\mathbb{CP}^1$ is the two-sphere. Let σ_a, $a = 1, 2, 3$, be Pauli matrices with

$$\operatorname{tr}(\sigma_a\sigma_b) = 2\delta_{ab}, \qquad \operatorname{tr}(\sigma_a\sigma_b\sigma_c) = 2\mathrm{i}\epsilon_{abc}.$$

For a unit vector $n : \Sigma \to S^2 \subset \mathbb{R}^3$, set

$$P_n = \frac{1}{2}(I + n_a\sigma_a). \tag{82.18}$$

$\mathbb{CP}^1$ **as the** $O(3)$ **sigma model.** The map $n \mapsto P_n$ identifies S^2 with the rank-one Hermitian projectors in $\mathbb{C}^2$ and obeys

$$\operatorname{tr}(\partial_\mu P_n\, \partial_\mu P_n) = \frac{1}{2}\,\partial_\mu n \cdot \partial_\mu n, \tag{82.19}$$

$$-\mathrm{i}\,\operatorname{tr}(P_n\,\mathrm{d}P_n \wedge \mathrm{d}P_n) = \frac{1}{2}\,\epsilon_{abc}n_a\,\mathrm{d}n_b \wedge \mathrm{d}n_c. \tag{82.20}$$

Consequently the $\mathbb{CP}^1$ action

$$\frac{1}{2g^2}\int_\Sigma \operatorname{tr}(\partial_\mu P\,\partial_\mu P) + \mathrm{i}\theta Q[P]$$

is the $O(3)$ action

$$\frac{1}{2g^2_{O(3)}}\int_\Sigma \partial_\mu n\cdot\partial_\mu n + \mathrm{i}\theta\,\deg(n), \qquad g^2_{O(3)} = 2g^2, \tag{82.21}$$

where

$$\deg(n) = \frac{1}{8\pi}\int_\Sigma \epsilon_{abc} n_a\,\mathrm{d}n_b\wedge\mathrm{d}n_c.$$

The matrix P_n is Hermitian and

$$P_n^2 = \frac{1}{4}(I + 2n_a\sigma_a + n_a n_b\sigma_a\sigma_b) = \frac{1}{2}(I + n_a\sigma_a) = P_n,$$

because $n_a n_b \epsilon_{abc} = 0$ and $n_a n_a = 1$. Its trace is one. Conversely every rank-one Hermitian projector in $\mathbb{C}^2$ has the form (82.18), since Hermitian 2×2 matrices are spanned by $I, \sigma_1, \sigma_2, \sigma_3$, the trace-one condition fixes the coefficient of I, and $P^2 = P$ fixes $n\cdot n = 1$.

Differentiating gives $\partial_\mu P_n = \frac{1}{2}(\partial_\mu n_a)\sigma_a$. Thus

$$\operatorname{tr}(\partial_\mu P_n\,\partial_\mu P_n) = \frac{1}{4}\,\partial_\mu n_a\partial_\mu n_b\operatorname{tr}(\sigma_a\sigma_b) = \frac{1}{2}\,\partial_\mu n\cdot\partial_\mu n.$$

For the curvature form,

$$\operatorname{tr}(P_n\,\mathrm{d}P_n\wedge\mathrm{d}P_n) = \frac{1}{8} n_a\,\mathrm{d}n_b\wedge\mathrm{d}n_c\ \operatorname{tr}(\sigma_a\sigma_b\sigma_c),$$

because the term with $\operatorname{tr}(\sigma_b\sigma_c)$ is symmetric in (b, c) and hence vanishes after wedging. The Pauli trace identity gives (82.20). Substituting (82.19) into the projector action gives the coupling match, and substituting (82.20) into $Q[P]$ gives the degree formula.

For $N = 2$, the exact massive scattering problem is therefore the $O(3)$ case of the vector sigma-model scattering problem described earlier in this chapter. For $N > 2$, one must keep a sharper distinction. The classical $\mathbb{CP}^{N-1}$ target is a compact symmetric space and has a classical zero-curvature description. A quantum factorization theorem for the bosonic projective model requires additional data: quantum conserved charges or an equivalent factorizing construction, the particle spectrum, the scalar normalization, the crossed particle-antiparticle amplitudes, and the matching map from the regulator-defined model (82.5) to the bootstrap mass coordinate.

The $N = (2, 2)$ supersymmetric $\mathbb{CP}^{N-1}$ model is a different local QFT. Its scattering proposal factorizes an $SU(N)$ chiral Gross–Neveu tensor part with an additional supersymmetric minimal factor and has an antisymmetric bound-state tower. Those statements use the extra fermionic fields and supercharges of the supersymmetric theory; the bosonic projective action (82.5) requires its own factorization and matching data.

82.6.2 Projective-Model Crossing Data

The minimal scattering language for the massive projective family contains particles in the defining representation $V = \mathbb{C}^N$ of $SU(N)$ and antiparticles in the dual representation $V^\vee$. Fix a basis $\{e_i\}_{i=1}^N$ of V and the dual basis $\{e^i\}_{i=1}^N$ of $V^\vee$. On $V\otimes V$, define

$$I_{VV}(e_i\otimes e_j) = e_i\otimes e_j, \qquad P_{VV}(e_i\otimes e_j) = e_j\otimes e_i.$$

On $V \otimes V^\vee$, define

$$I_{V\bar{V}}(e_i \otimes e^j) = e_i \otimes e^j, \qquad E_{V\bar{V}}(e_i \otimes e^j) = \delta_i^j \Omega, \qquad \Omega = \sum_{m=1}^{N} e_m \otimes e^m. \tag{82.22}$$

The operator $E_{V\bar{V}}$ is the invariant cap-cup tensor; it obeys

$$E_{V\bar{V}}^2 = N E_{V\bar{V}}. \tag{82.23}$$

Thus $N^{-1}E_{V\bar{V}}$ projects onto the singlet line $\mathbb{C}\Omega$, while

$$\Pi_{\mathrm{adj}} = I_{V\bar{V}} - \frac{1}{N} E_{V\bar{V}} \tag{82.24}$$

projects onto the adjoint summand in $V \otimes V^\vee$.

Definition 82.3 (Projective crossing system)**.** A rank-one projective bootstrap system consists of meromorphic functions $A(\theta)$, $B(\theta)$, $C(\theta)$, and $D(\theta)$, together with the operators

$$S_{VV}(\theta) = A(\theta) I_{VV} + B(\theta) P_{VV}, \tag{82.25}$$

$$S_{V\bar{V}}(\theta) = C(\theta) I_{V\bar{V}} + D(\theta) E_{V\bar{V}}. \tag{82.26}$$

The chosen charge-conjugation pairing identifies $V^\vee$ with the crossed outgoing V-leg. In this convention, crossing in the second leg is the meromorphic relation

$$C(\theta) = A(\mathrm{i}\pi - \theta), \qquad D(\theta) = B(\mathrm{i}\pi - \theta). \tag{82.27}$$

Crossing of the invariant tensors. With the convention of Definition 82.3, the crossed tensor of S_{VV} is exactly $S_{V\bar{V}}$ with coefficients (82.27).

Write matrix elements of S_{VV} as

$$(S_{VV})_{ij}^{k\ell}(\theta) = A(\theta)\delta_i^k \delta_j^\ell + B(\theta)\delta_i^\ell \delta_j^k. \tag{82.28}$$

Crossing the second outgoing leg to an incoming antiparticle replaces the pair (j, ℓ) by (ℓ, j) and evaluates the rapidity at $\mathrm{i}\pi - \theta$:

$$(S_{V\bar{V}})_{i\bar{j}}^{k\bar{\ell}}(\theta) = (S_{VV})_{i\ell}^{kj}(\mathrm{i}\pi - \theta). \tag{82.29}$$

Substitution into (82.28) gives

$$A(\mathrm{i}\pi - \theta)\delta_i^k \delta_\ell^j + B(\mathrm{i}\pi - \theta)\delta_i^j \delta_\ell^k.$$

The first tensor is $I_{V\bar{V}}$, and the second tensor is $E_{V\bar{V}}$, with the component convention in (82.22). This proves (82.27).

Let

$$S_\pm(\theta) = A(\theta) \pm B(\theta), \qquad S_{\mathrm{adj}}(\theta) = C(\theta), \qquad S_{\mathrm{sing}}(\theta) = C(\theta) + ND(\theta). \tag{82.30}$$

Then braiding unitarity on $V \otimes V$ is equivalent to

$$S_+(\theta)S_+(-\theta) = 1, \qquad S_-(\theta)S_-(-\theta) = 1, \tag{82.31}$$

and braiding unitarity on $V \otimes V^\vee$ is equivalent to

$$S_{\mathrm{adj}}(\theta)S_{\mathrm{adj}}(-\theta) = 1, \qquad S_{\mathrm{sing}}(\theta)S_{\mathrm{sing}}(-\theta) = 1. \tag{82.32}$$

The flip P_{VV} has eigenvalue $+1$ on $\mathrm{Sym}^2 V$ and eigenvalue -1 on $\wedge^2 V$. Therefore S_{VV} has eigenvalues S_+ and S_- on the two irreducible summands, and unitarity reduces to (82.31). For $V \otimes V^\vee$, (82.23) gives eigenvalue N on $\mathbb{C}\Omega$ and eigenvalue 0 on the adjoint summand. The two eigenvalues of $S_{V\bar{V}}$ are therefore S_{sing} and S_{adj}, giving (82.32).

Remark 82.4 (Pole assignment in the projective rank-one block). Suppose the VV tensor part is the rational block $\mathcal{R}_N(\theta)$ of (82.57), multiplied by a scalar factor $X_{\mathbb{CP}}(\theta)$. If the projective bootstrap system assigns no stable direct-channel particle in $\wedge^2 V$, then

$$X_{\mathbb{CP}}(\theta)$$

has a zero at $\theta = 2\pi\mathrm{i}/N$ of at least the order of the pole of $\mathcal{R}_N$ there. If instead that pole is assigned to a listed stable bound state, the residue must be projected onto $\wedge^2 V$ and must obey the positive-residue convention of the Hilbert-space normalization.

The symmetric and antisymmetric eigenvalues of $\mathcal{R}_N$ are

$$1, \qquad \frac{\theta + \frac{2\pi\mathrm{i}}{N}}{\theta - \frac{2\pi\mathrm{i}}{N}}.$$

The second eigenvalue has a simple pole at $\theta = 2\pi\mathrm{i}/N$, inside the physical strip for $N > 2$, and the corresponding eigenspace is $\wedge^2 V$. A meromorphic scattering amplitude can contain such a pole in the physical strip only as declared scattering data. If the spectrum assigns no stable direct-channel state to that tensor channel, the pole of the matrix block must be canceled by a zero of the scalar factor. If the pole is kept, its residue is precisely the projection onto the stated bound-state channel, with its normalization fixed by the Hilbert-space inner product.

Controlled Approximation 82.5 (Projective scattering status)**.** The preceding tensor constructions give finite-dimensional bootstrap infrastructure for the projective family. They specify the invariant channels, their crossing relation, and the pole-assignment rule before any scalar factor is chosen. A completed projective-model S-matrix further specifies the scalar functions, their physical-strip singularities, the CDD normalization, and the map from the regulator-defined model (82.5) to the bootstrap mass coordinate. The $\theta = \pi$ infrared behavior is a separate dynamical question; for some families it is expected to land on a level-one WZW fixed point, but that statement belongs to a specified continuum limit and cannot be read off from the perturbative beta function alone.

82.7 Principal Chiral Models and WZW Endpoints

Let G be a compact simple Lie group with invariant positive form κ on its Lie algebra $\mathfrak{g}$. The principal chiral model has field $U : \Sigma \to G$, current $j_\mu = U^{-1}\partial_\mu U$, and action

$$S_{\mathrm{PCM}}[U] = \frac{1}{2g^2}\int_\Sigma \mathrm{d}^2x\, \kappa(j_\mu, j_\mu). \tag{82.33}$$

The global symmetry is $G_L \times G_R$, acting by

$$U \mapsto g_L\, U\, g_R^{-1}.$$

The equations of motion and Maurer–Cartan identity in light-cone coordinates are

$$\partial_+ j_- + \partial_- j_+ = 0, \qquad \partial_+ j_- - \partial_- j_+ + [j_+, j_-] = 0. \tag{82.34}$$

Define

$$L_+(\zeta) = \frac{j_+}{1-\zeta}, \qquad L_-(\zeta) = \frac{j_-}{1+\zeta}. \tag{82.35}$$

Then the flatness condition

$$\partial_+ L_-(\zeta) - \partial_- L_+(\zeta) + [L_+(\zeta), L_-(\zeta)] = 0$$

for all complex ζ away from ± 1 is equivalent to the two relations in (82.34). Multiplying the curvature by $1-\zeta^2$ gives

$$(1-\zeta)\partial_+ j_- - (1+\zeta)\partial_- j_+ + [j_+, j_-] = \big(\partial_+ j_- - \partial_- j_+ + [j_+, j_-]\big) - \zeta(\partial_+ j_- + \partial_- j_+).$$

Vanishing for all ζ is therefore equivalent to the vanishing of the constant and linear coefficients, which are precisely the Maurer–Cartan identity and the equation of motion. Conversely, if those two relations hold, both coefficients vanish and the curvature of $L_\pm(\zeta)$ vanishes for all $\zeta \neq \pm 1$. The poles at $\zeta = \pm 1$ are part of the auxiliary spectral-parameter family and do not add additional equations of motion.

The Wess–Zumino deformation is defined by extending U to a three-manifold B with $\partial B = \Sigma$ and setting

$$\Gamma[U] = \frac{1}{24\pi} \int_B \kappa(U^{-1}\mathrm{d}U, [U^{-1}\mathrm{d}U, U^{-1}\mathrm{d}U]). \tag{82.36}$$

The quantum functional

$$S_{k,\lambda}[U] = \frac{1}{2\lambda^2} \int_\Sigma \kappa(j_\mu, j_\mu) + \mathrm{i}k\,\Gamma[U] \tag{82.37}$$

is single-valued only when the normalization of κ and the integer level k make the change of $k\Gamma$ under a different extension a multiple of 2π.

Polyakov–Wiegmann identity in the chapter normalization. Let $U, V : \Sigma \to G$ be smooth maps that admit extensions to a common three-manifold B with $\partial B = \Sigma$. Put

$$\Theta_U = U^{-1}\mathrm{d}U, \qquad \overline{\Theta}_V = \mathrm{d}V\, V^{-1}.$$

With Γ normalized as in (82.36),

$$\Gamma[UV] = \Gamma[U] + \Gamma[V] - \frac{1}{4\pi} \int_\Sigma \kappa(\Theta_U, \overline{\Theta}_V), \tag{82.38}$$

up to the integral periods already fixed by the level quantization of the WZ term. Here $\kappa(\Theta_U, \overline{\Theta}_V)$ denotes the scalar two-form obtained by wedging the one-forms and pairing their Lie-algebra values by κ. Let

$$H(g) = \frac{1}{24\pi} \kappa(g^{-1}\mathrm{d}g, [g^{-1}\mathrm{d}g, g^{-1}\mathrm{d}g])$$

be the closed three-form integrated in $\Gamma[g]$. The bracket of Lie-algebra-valued one-forms is the wedge bracket, so that the displayed normalization agrees with (82.36). Since

$$(UV)^{-1}\mathrm{d}(UV) = V^{-1}\Theta_U V + V^{-1}\mathrm{d}V,$$

invariance of κ and the Maurer–Cartan equations

$$\mathrm{d}\Theta_U + \frac{1}{2}[\Theta_U, \Theta_U] = 0, \qquad \mathrm{d}\overline{\Theta}_V - \frac{1}{2}[\overline{\Theta}_V, \overline{\Theta}_V] = 0$$

give the differential identity

$$H(UV) = H(U) + H(V) - \frac{1}{4\pi}\mathrm{d}\,\kappa(\Theta_U, \overline{\Theta}_V). \tag{82.39}$$

To see the coefficient, expand the cubic expression for $H(UV)$: the pure Θ_U and pure $V^{-1}\mathrm{d}V$ terms give $H(U)$ and $H(V)$, and the three mixed cyclic placements combine with the two Maurer–Cartan equations into the exterior derivative in (82.39). Integrating this identity over B and applying Stokes' theorem gives (82.38). Changing the extensions shifts the three bulk terms by integral periods; the quantization condition on k is exactly the condition that $\exp(-S_{k,\lambda})$ be independent of that choice.

82.7.1 Current Algebra at the WZW Endpoint

The conformal endpoint is specified by its local current algebra, positive energy representation space, stress tensor, and Ward identities. We record the construction here in the sigma-model normalization used in this chapter; Volume V develops the same object from the broader two-dimensional CFT point of view.

Let $(\,\cdot\,,\,\cdot\,)$ be the basic invariant form on $\mathfrak{g}$, normalized so that long roots have squared length 2. Choose an orthonormal basis T_a, write

$$[T_a, T_b] = f_{ab}{}^{c}T_c, \qquad f_{abc} = f_{ab}{}^{d}\delta_{dc},$$

and define the dual Coxeter number by

$$f_{acd}f_{bcd} = 2h^\vee \delta_{ab}. \tag{82.40}$$

With this convention the adjoint quadratic Casimir is $2h^\vee$. At a positive integer level k, the holomorphic and antiholomorphic currents have separated-point OPEs

$$J^a(z)J^b(0) \sim \frac{k\delta^{ab}}{z^2} + \frac{f_{ab}{}^{c}J^c(0)}{z}, \qquad \bar{J}^a(\bar{z})\bar{J}^b(0) \sim \frac{k\delta^{ab}}{\bar{z}^2} + \frac{f_{ab}{}^{c}\bar{J}^c(0)}{\bar{z}}. \tag{82.41}$$

The mixed $J\bar{J}$ OPE is regular at separated points. If

$$J^a(z) = \sum_{n\in\mathbb{Z}} J^a_n z^{-n-1},$$

then (82.41) is equivalent to

$$[J^a_m, J^b_n] = f_{ab}{}^{c}J^c_{m+n} + km\,\delta^{ab}\delta_{m+n,0}. \tag{82.42}$$

The integer k is therefore both the Wess–Zumino level and the central extension of the loop algebra. This equality is a theorem of the canonical quantization of the WZW functional or, equivalently, of the current Ward identity derived from the Polyakov–Wiegmann identity; it is not a separate postulate appended to the sigma model.

Lemma 82.6 (Sugawara tensor at the WZW endpoint)**.** *Assume $k + h^\vee \neq 0$. The holomorphic stress tensor is*

$$T_G(z) = \frac{1}{2(k + h^\vee)} \sum_a : J^a J^a : (z), \tag{82.43}$$

and has central charge

$$c(G, k) = \frac{k \, \dim \mathfrak{g}}{k + h^\vee}. \tag{82.44}$$

Each current J^a is a primary field of weight 1.

Proof. The coefficient in (82.43) is forced by the OPE $T_G(z)J^b(0)$. Contracting one of the two currents in $: J^a J^a :$ with J^b, the central term in (82.41) contributes $2kJ^b/z^2$ before the overall coefficient. The simple-pole contraction gives two adjoint actions. When the resulting current is normal ordered past the remaining current, the adjoint Casimir contributes $2h^\vee J^b/z^2$, by (82.40). Hence the numerator of the second-order pole is $2(k + h^\vee)J^b$, and the unique coefficient making the current have weight 1 is $1/[2(k + h^\vee)]$. The first-order pole is then $\partial J^b/z$, because the zero mode of T_G implements translations of the current field.

For the $T_G T_G$ OPE, the fourth-order pole is obtained from double contractions of the two quadratic normal-ordered products. The central central contractions give $2k^2 \dim \mathfrak{g}$, and the contractions containing two structure constants give $2kh^\vee \dim \mathfrak{g}$. After division by $[2(k + h^\vee)]^2$, comparison with

$$T_G(z)T_G(0) \sim \frac{c/2}{z^4} + \frac{2T_G(0)}{z^2} + \frac{\partial T_G(0)}{z}$$

gives (82.44). The lower-order poles agree with the Virasoro action because the coefficient was already fixed by the current-primary condition. □

Let P^+ be the dominant integral weights of G, let θ be the highest root, and let ρ be the Weyl vector. The compact unitary WZW endpoint at positive integral level k uses the integrable highest weights

$$P_k^+ = \{\lambda \in P^+ \mid (\lambda, \theta) \leq k\}. \tag{82.45}$$

The corresponding affine highest-weight Hilbert spaces are denoted $\mathcal{H}_\lambda$. A primary with horizontal highest weight λ has conformal weight

$$h_\lambda = \frac{(\lambda, \lambda + 2\rho)}{2(k + h^\vee)}. \tag{82.46}$$

The diagonal compact theory has Hilbert space

$$\mathcal{H}_{G,k}^{\mathrm{diag}} = \bigoplus_{\lambda \in P_k^+} \mathcal{H}_\lambda \otimes \overline{\mathcal{H}_\lambda}. \tag{82.47}$$

Other modular invariants change the pairing of left and right integrable modules and are therefore extra global data of the full CFT. They do not alter the local affine OPE (82.41).

Proposition 82.7 (KZ equations from WZW Ward identities)**.** *Let V_{λ_i} be finite-dimensional $\mathfrak{g}$-modules with $\lambda_i \in P_k^+$, and let $\mathcal{F}(z_1, \ldots, z_n)$ be a genus-zero chiral block with primary insertions of horizontal types V_{λ_i}. Write t_i^a for the action of T_a on the i-th tensor factor and*

$$\Omega_{ij} = \sum_a t_i^a t_j^a.$$

Then

$$(k+h^\vee)\,\partial_{z_i}\mathcal{F} = \mathcal{F}\circ\sum_{j\neq i}\frac{\Omega_{ij}}{z_i-z_j}, \qquad i=1,\dots,n. \tag{82.48}$$

Proof. For a primary field $\Phi_{\lambda_i}(v_i,z_i)$, the current OPE is

$$J^a(\zeta)\Phi_{\lambda_i}(v_i,z_i)\sim\frac{\Phi_{\lambda_i}(t_i^a v_i,z_i)}{\zeta-z_i}.$$

The translation Ward identity gives

$$\partial_{z_i}\Phi_{\lambda_i}(v_i,z_i)=\Phi_{\lambda_i}(L_{-1}v_i,z_i).$$

Applying (82.43) to an affine-primary state, all modes in

$$L_{-1}=\frac{1}{2(k+h^\vee)}\sum_{a,m}:J^a_{-1-m}J^a_m:$$

annihilate the state except the two terms with $m=0$ and $m=-1$. Their sum is

$$L_{-1}v_i=\frac{1}{k+h^\vee}\sum_a J^a_{-1}t_i^a v_i,$$

because $\sum_a[J_0^a,J_{-1}^a]=0$. The insertion of J^a_{-1} is the contour integral

$$\oint_{z_i}\frac{\mathrm{d}\zeta}{2\pi\mathrm{i}}\,\frac{J^a(\zeta)}{\zeta-z_i}.$$

Deforming this contour away from z_i gives the sum of the residues at the other insertions. The residue at z_j is $(z_i-z_j)^{-1}t_j^a$. Substitution gives (82.48). No crossing or modular-invariance input enters this derivation; it is a consequence of the local current OPE, primary-field OPE, and Sugawara translation operator. □

Let $H\subset G$ be a compact connected subgroup with Lie algebra $\mathfrak{h}$. If the basic forms satisfy

$$(X,Y)_{\mathfrak{g}}=x_e(X,Y)_{\mathfrak{h}}, \qquad X,Y\in\mathfrak{h},$$

then the induced H-current algebra inside G_k has level $k_H=kx_e$. The coset stress tensor

$$T_{G/H}=T_G-T_H \tag{82.49}$$

has central charge

$$c(G_k/H_{k_H})=\frac{k\dim\mathfrak{g}}{k+h^\vee_{\mathfrak{g}}}-\frac{k_H\dim\mathfrak{h}}{k_H+h^\vee_{\mathfrak{h}}}. \tag{82.50}$$

It has regular OPE with the embedded $\mathfrak{h}$-currents. The level rescales by the embedding index because the central term in the current OPE is the invariant form evaluated on the embedded Lie algebra. Both T_G and T_H make the same embedded H-currents primary fields of weight 1. Their difference therefore has no singular OPE with those currents. The central charge is the difference of the two Sugawara central charges in Lemma 82.6, with the H-level set to k_H.

Free-field realizations such as Wakimoto charts are useful computational coordinates on particular affine modules. They are not part of the definition of the sigma-model endpoint, and they require a separate development of bosonic first-order systems and screening charges. In this volume we use only the current algebra, integrable modules, KZ connection, and coset stress tensor, which are the endpoint structures needed for the principal chiral and current-current perturbations below.

82.8 Nonabelian Bosonization and Chiral Gross–Neveu Bridges

The relation between sigma models, WZW models, and fermionic Gross–Neveu models should be stated at the level of current algebras, not as a slogan about replacing fermions by bosons. Let

$$\psi_{L\,a}^{\,i}(x^+), \qquad \psi_{R\,a}^{\,i}(x^-), \qquad a = 1, \dots, N_c, \quad i = 1, \dots, N_f,$$

be free complex chiral fermions. The index a is acted on by $SU(N_c)$, the index i by $SU(N_f)$. The left-moving bilinears

$$J_c^A =: \psi_{L\,a}^{\,i\dagger}(T_c^A)^a{}_b \psi_{L\,b}^{\,i} :, \qquad J_f^B =: \psi_{L\,a}^{\,i\dagger}(T_f^B)^i{}_j \psi_{L\,a}^{\,j} :, \qquad J_u =: \psi_{L\,a}^{\,i\dagger}\psi_{L\,a}^{\,i} :$$

generate affine

$$\widehat{\mathfrak{su}}(N_c)_{N_f} \oplus \widehat{\mathfrak{su}}(N_f)_{N_c} \oplus \widehat{\mathfrak{u}}(1)$$

inside the free-fermion chiral algebra. The level is the number of spectator fermion flavors in the trace of the short-distance contraction: for example, the color-current two-point singularity receives N_f identical flavor contractions and hence has level N_f.

Remark 82.8 (Central-charge check for nonabelian bosonization). With the current normalization in which

$$c\big(\widehat{\mathfrak{su}}(N)_k\big) = \frac{k(N^2-1)}{k+N},$$

the chiral algebra generated by the bilinears above has the same central charge as N_cN_f free complex left-moving fermions:

$$\frac{N_f(N_c^2-1)}{N_f+N_c} + \frac{N_c(N_f^2-1)}{N_c+N_f} + 1 = N_cN_f. \tag{82.51}$$

Bring the two nonabelian terms to the common denominator $N_c + N_f$:

$$\frac{N_fN_c^2 - N_f + N_cN_f^2 - N_c}{N_c+N_f} = \frac{N_cN_f(N_c+N_f) - (N_c+N_f)}{N_c+N_f} = N_cN_f - 1.$$

Adding the $\widehat{\mathfrak{u}}(1)$ boson gives N_cN_f. The identity is only the central-charge compatibility check; the operator equivalence also requires equality of the affine OPEs, the stress tensor, and the compact $U(1)$ radius.

For $N_f = 1$ the flavor affine factor is absent and a set of N_c complex fermions decomposes into $SU(N_c)_1$ WZW data plus a compact $U(1)$ boson. Perturbing the WZW model by the marginal current-current operator

$$\delta S = \lambda \int \mathrm{d}^2x \sum_A J_L^A(x^+) J_R^A(x^-) \tag{82.52}$$

is the bosonic current-algebra presentation of the chiral Gross–Neveu family, once the $U(1)$ sector and discrete quotient data have been fixed. The exact massive $SU(N)$ chiral Gross–Neveu scattering theory is then the rapidity-space description of the current-current perturbation, while the WZW model is the ultraviolet fixed point described by the affine algebra. The statement is not that every fermionic model is identical to a principal chiral model; the dictionary is a statement about local current algebras and perturbations with specified global quotients. In the abelian rank-one subcase this reduces to the sine-Gordon/massive-Thirring bridge of Chapter 81; in the nonabelian case the replacement of the compact boson by a WZW field is the essential new structure.

82.9 SU(N) Bootstrap Spectrum and Matrix Blocks

The exact scattering descriptions of the $SU(N)$ chiral Gross–Neveu and principal-chiral families contain a common representation-theoretic skeleton. Let $V = \mathbb{C}^N$ be the defining representation of $SU(N)$, and write

$$V_a = \wedge^a V, \qquad a = 1, \dots, N-1.$$

The conjugate of V_a is V_{N-a}. A bootstrap spectrum of sine-law type assigns masses

$$m_a = M\,\frac{\sin(\pi a/N)}{\sin(\pi/N)}, \qquad a = 1, \dots, N-1, \tag{82.53}$$

for a single positive mass scale $M = m_1$. In the chiral Gross–Neveu family these multiplets are the antisymmetric tensor particles. In the principal chiral model the corresponding particles carry left and right indices, with one common convention taking the rank-a multiplet to transform in $V_a \otimes V_a^*$ under $SU(N)_L \times SU(N)_R$. The choice of the global form of the symmetry and the quotient by common centers is part of the family specification; it affects which line operators and twisted sectors exist, although not the local sine-mass formula itself.

Remark 82.9 (Fusing-angle consistency of the sine spectrum). For $1 \le a, b$ and $a + b < N$, the mass formula (82.53) is compatible with a direct-channel bound state $V_a \otimes V_b \to V_{a+b}$ at rapidity

$$\theta = \mathrm{i}u_{ab}^{a+b}, \qquad u_{ab}^{a+b} = \frac{\pi(a+b)}{N}. \tag{82.54}$$

Indeed,

$$m_{a+b}^2 = m_a^2 + m_b^2 + 2m_a m_b \cos u_{ab}^{a+b}. \tag{82.55}$$

Set $A = \pi a/N$, $B = \pi b/N$, and suppress the common positive factor $M/\sin(\pi/N)$. The required identity is

$$\sin^2(A+B) = \sin^2 A + \sin^2 B + 2\sin A \sin B \cos(A+B). \tag{82.56}$$

Using $\cos(A+B) = \cos A \cos B - \sin A \sin B$, the right-hand side becomes

$$\sin^2 A + \sin^2 B + 2\sin A \sin B \cos A \cos B - 2\sin^2 A \sin^2 B.$$

Since

$$\sin^2(A+B) = \sin^2 A \cos^2 B + \cos^2 A \sin^2 B + 2\sin A \sin B \cos A \cos B,$$

and $\cos^2 A = 1 - \sin^2 A$, $\cos^2 B = 1 - \sin^2 B$, the two expressions agree. The restriction $a+b < N$ selects the antisymmetric tensor before conjugation; fusion channels with $a + b \ge N$ are equivalently described after replacing V_c^* by V_{N-c} and keeping track of crossed-channel conventions.

The fundamental rational $SU(N)$ matrix block acts on $V \otimes V$. Let

$$P(v \otimes w) = w \otimes v, \qquad \lambda_N = \frac{2\pi}{N},$$

and define

$$\mathcal{R}_N(\theta) = \frac{\theta\, I - \mathrm{i}\lambda_N P}{\theta - \mathrm{i}\lambda_N}. \tag{82.57}$$

This normalization makes the symmetric-channel eigenvalue equal to 1, and the antisymmetric-channel eigenvalue equal to

$$\frac{\theta + \mathrm{i}\lambda_N}{\theta - \mathrm{i}\lambda_N}.$$

Thus the pole of the matrix block at $\theta = \mathrm{i}\lambda_N$ lies in the antisymmetric channel, matching the rank-two entry of (82.53). The scalar factor multiplying $\mathcal{R}_N$ is not optional: it fixes crossing, removes or adds CDD ambiguities, and supplies the complete pole-residue normalization. The matrix block records the tensor part of the exact S-matrix; the scalar minimality and the regulator-to-bootstrap matching are additional data.

Rational-block unitarity and Yang–Baxter equation. The block $\mathcal{R}_N$ obeys

$$\mathcal{R}_N(\theta)\mathcal{R}_N(-\theta) = I$$

as an operator on $V \otimes V$. Its unnormalized numerator

$$R_N(\theta) = \theta I - \mathrm{i}\lambda_N P$$

obeys the Yang–Baxter equation

$$R_{12}(\theta)R_{13}(\theta+\phi)R_{23}(\phi) = R_{23}(\phi)R_{13}(\theta+\phi)R_{12}(\theta) \tag{82.58}$$

on $V^{\otimes 3}$.

The permutation P satisfies $P^2 = I$, so the numerator product is

$$(\theta I - \mathrm{i}\lambda_N P)(-\theta I - \mathrm{i}\lambda_N P) = -(\theta^2 + \lambda_N^2)I = (\theta - \mathrm{i}\lambda_N)(-\theta - \mathrm{i}\lambda_N)I.$$

For the Yang–Baxter equation, expand both sides of (82.58) as polynomials in θ, ϕ and λ_N. The constant, linear, and quadratic terms reduce to the relations of the symmetric group acting on tensor factors:

$$P_{12}^2 = P_{23}^2 = I, \qquad P_{12}P_{23}P_{12} = P_{23}P_{12}P_{23}.$$

The mixed P_{13} terms are written as $P_{13} = P_{12}P_{23}P_{12} = P_{23}P_{12}P_{23}$. After this substitution the two expanded polynomials coincide coefficient by coefficient. The calculation companion checks this equality by finite-dimensional matrix multiplication for representative N and rapidities.

82.10 SU(N) Scalar Factors and CDD Conventions

The rational matrix block is only the tensor part of the scattering problem. The scalar factor fixes the analytic normalization. Let

$$\mathcal{P} = \{\theta \in \mathbb{C} : 0 < \operatorname{Im}\theta < \pi\}$$

be the physical rapidity strip for equal-mass relativistic scattering. In a scalar channel, unitarity is the meromorphic identity

$$X(\theta)X(-\theta) = 1,$$

and self-conjugate crossing is the identity $X(\theta) = X(\mathrm{i}\pi - \theta)$. For non-self-conjugate multiplets, crossing relates a particle-particle amplitude to a particle-antiparticle amplitude; the scalar factor must be specified together with the charge-conjugation convention.

Definition 82.10 (CDD factor in one scalar channel)**.** A scalar CDD factor is a meromorphic function $C(\theta)$, nonzero on the real rapidity axis, such that

$$C(\theta)C(-\theta) = 1$$

and such that the appropriate crossing equation of the channel is preserved. It is an allowed ambiguity only after its zeros and poles in $\mathcal{P}$ have been declared either absent or assigned to specified bound states, Coleman–Thun singularities, or other explicitly stated on-shell mechanisms. A scalar factor is called minimal relative to a listed bootstrap spectrum when it has no additional zeros or poles in $\mathcal{P}$ beyond those listed.

The elementary self-conjugate block

$$C_\alpha(\theta) = \frac{\sinh\theta + \mathrm{i}\sin\alpha}{\sinh\theta - \mathrm{i}\sin\alpha} \tag{82.59}$$

obeys $C_\alpha(\theta)C_\alpha(-\theta) = 1$ and $C_\alpha(\mathrm{i}\pi - \theta) = C_\alpha(\theta)$. Its denominator vanishes at $\theta = \mathrm{i}u$ when $\sin u = \sin\alpha$. Thus, for $0 < \alpha < \pi$, it has physical-strip singularities at $u = \alpha$ and $u = \pi - \alpha$, with coincidences at $\alpha = \pi/2$. Such a block is therefore not a harmless convention unless those singularities have been assigned. This is the reason that "multiply by a CDD factor" is not a mathematical conclusion; it is new scattering data.

For the $SU(N)$ chiral Gross–Neveu family, $N \geq 3$, put

$$x = \frac{\theta}{2\pi\mathrm{i}}, \qquad \lambda_N = \frac{2\pi}{N},$$

and define the rank-one scalar transmission eigenvalue

$$A_N(\theta) = -\frac{\Gamma(1-x)\Gamma(1-\frac{1}{N}+x)}{\Gamma(1+x)\Gamma(1-\frac{1}{N}-x)}. \tag{82.60}$$

In the Zamolodchikov–Faddeev component convention with outgoing order reversed,

$$S^{\delta\gamma}_{\alpha\beta}(\theta) = \delta^\gamma_\alpha\delta^\delta_\beta\, b_N(\theta) + \delta^\delta_\alpha\delta^\gamma_\beta\, c_N(\theta), \qquad c_N(\theta) = -\frac{\mathrm{i}\lambda_N}{\theta} b_N(\theta), \tag{82.61}$$

with

$$A_N(\theta) = b_N(\theta) + c_N(\theta), \qquad b_N(\theta) = \frac{A_N(\theta)}{1 - \mathrm{i}\lambda_N/\theta}.$$

Equivalently, if the outgoing permutation is pulled out explicitly, this is

$$S^{(1,1)}_{\mathrm{CGN}}(\theta) = A_N(\theta)\, P\, \mathcal{R}_N(\theta), \tag{82.62}$$

with $\mathcal{R}_N$ defined in (82.57). The matrix pole at $\theta = \mathrm{i}\lambda_N$ is then the first antisymmetric bound-state pole, while A_N itself supplies the minimal gamma-function normalization in this convention.

Gross–Neveu scalar unitarity identity. As meromorphic identities in θ,

$$A_N(\theta)A_N(-\theta) = 1,$$

and the component matrix (82.61) obeys

$$S(\theta)S(-\theta) = I$$

on $V \otimes V$, away from its poles.

In (82.60), replacing x by $-x$ interchanges the two gamma-function products: the factors $\Gamma(1-x)\Gamma(1/N+x)$ in $A_N(\theta)$ become the denominator factors of $A_N(-\theta)$, and the denominator factors $\Gamma(1+x)\Gamma(1/N-x)$ become the numerator factors. The two explicit minus signs multiply to 1. Thus $A_N(\theta)A_N(-\theta) = 1$. For the component matrix, write $S = bP + cI$ with $c = -(\mathrm{i}\lambda_N/\theta)b$. At $-\theta$,

$$c(-\theta) = \frac{\mathrm{i}\lambda_N}{\theta} b(-\theta).$$

Since $A = b(1 - \mathrm{i}\lambda_N/\theta)$ and

$$A(-\theta) = b(-\theta)(1 + \mathrm{i}\lambda_N/\theta),$$

the scalar identity gives

$$b(\theta)b(-\theta)\left(1 + \frac{\lambda_N^2}{\theta^2}\right) = 1.$$

Using $P^2 = I$,

$$(bP + cI)(b_-P + c_-I) = (bb_- + cc_-)I + (bc_- + cb_-)P,$$

where $b_- = b(-\theta)$ and $c_- = c(-\theta)$. The P-coefficient vanishes, and the I-coefficient is the scalar displayed above. This proves matrix unitarity.

For the $SU(N)$ principal chiral model, the fundamental particle carries left and right indices. It is convenient to distinguish the normalized block $\mathcal{R}_N$ from the unnormalized rational block

$$\widetilde{\mathcal{R}}_N(\theta) = I - \frac{\mathrm{i}\lambda_N}{\theta} P = \frac{\theta - \mathrm{i}\lambda_N}{\theta}\, \mathcal{R}_N(\theta).$$

One standard particle-particle bootstrap convention is

$$S^{(1,1)}_{\mathrm{PCM}}(\theta) = W_N(\theta)\, \widetilde{\mathcal{R}}_{N,L}(\theta) \otimes \widetilde{\mathcal{R}}_{N,R}(\theta), \tag{82.63}$$

where

$$W_N(\theta) = \frac{\sinh(\theta/2 - \pi\mathrm{i}/N)}{\sinh(\theta/2 + \pi\mathrm{i}/N)} \left[\frac{\Gamma(1-x)\Gamma(x-\frac{1}{N})}{\Gamma(1-x-\frac{1}{N})\Gamma(x)}\right]^2, \qquad x = \frac{\theta}{2\pi\mathrm{i}}. \tag{82.64}$$

In the normalized block convention used in (82.66) below, the scalar factor is

$$X_{\mathrm{PCM}}(\theta) = W_N(\theta)\left(\frac{\theta - \mathrm{i}\lambda_N}{\theta}\right)^2. \tag{82.65}$$

Thus

$$S^{(1,1)}_{\mathrm{PCM}}(\theta) = X_{\mathrm{PCM}}(\theta)\, \mathcal{R}_{N,L}(\theta) \otimes \mathcal{R}_{N,R}(\theta). \tag{82.66}$$

The sine-law tower (82.53) is generated by fusion at (82.54); higher-rank scattering is obtained by projecting tensor products onto the corresponding antisymmetric representations and taking residues at the listed poles. The CDD convention is part of the statement: multiplying W_N or X_{PCM} by any additional factor satisfying Definition 82.10 changes the bootstrap theory unless the extra singularity data are also specified.

Principal-chiral scalar unitarity identity. The scalar factor (82.64) obeys

$$W_N(\theta)W_N(-\theta) = \left(1 + \frac{\lambda_N^2}{\theta^2}\right)^{-2}. \tag{82.67}$$

Consequently $X_{\mathrm{PCM}}(\theta)X_{\mathrm{PCM}}(-\theta) = 1$, and (82.66) is unitary on the real rapidity axis away from poles.

Let $a = 1/N$ and $x = \theta/(2\pi\mathrm{i})$. The hyperbolic prefactor in (82.64) has product 1 under $\theta \mapsto -\theta$, because sinh is odd. For the gamma ratio

$$G(x) = \frac{\Gamma(1-x)\Gamma(x-a)}{\Gamma(1-x-a)\Gamma(x)},$$

use $\Gamma(1+x) = x\Gamma(x)$, $\Gamma(1-x) = -x\Gamma(-x)$, $\Gamma(1-x-a) = (-x-a)\Gamma(-x-a)$, and $\Gamma(1+x-a) = (x-a)\Gamma(x-a)$. These identities give

$$G(x)G(-x) = \frac{x^2}{(x-a)(x+a)}.$$

Since $\lambda_N = 2\pi a$ and $\theta = 2\pi\mathrm{i}x$,

$$1 + \frac{\lambda_N^2}{\theta^2} = 1 - \frac{a^2}{x^2} = \frac{(x-a)(x+a)}{x^2}.$$

Squaring the gamma-ratio product proves (82.67). Multiplying by

$$\left(\frac{\theta - \mathrm{i}\lambda_N}{\theta}\right)^2 \left(\frac{-\theta - \mathrm{i}\lambda_N}{-\theta}\right)^2 = \left(1 + \frac{\lambda_N^2}{\theta^2}\right)^2$$

then gives $X_{\mathrm{PCM}}(\theta)X_{\mathrm{PCM}}(-\theta) = 1$. The normalized matrix blocks are unitary by the rational-block calculation above, so the full particle-particle PCM matrix is unitary.

Equations (82.62) and (82.66) are exact bootstrap data with the displayed scalar convention. They become statements about the continuum sigma models only after the ultraviolet definitions of the preceding sections are matched to the factorizing QFT: one must construct the Hilbert space, local or graded-local fields, conserved currents, Haag–Ruelle scattering states, and the map between the regulator mass scale and the bootstrap mass coordinate.

82.11 Nested String Data for Gross–Neveu and PCM

The nested Bethe ansatz of Chapter 78 becomes concrete only after the physical representation carried by each particle and the number of independent internal symmetry nests are specified. For the $SU(N)$ chiral Gross–Neveu family there is one A_{N-1} nest. For the $SU(N)$ principal chiral model there are two nests, one for $SU(N)_L$ and one for $SU(N)_R$. This distinction is not a cosmetic doubling: it is the finite-volume origin of the two rational blocks in (82.66).

Let α_r, $r = 1, \ldots, N-1$, be the simple roots of A_{N-1}, and let ω_r be the fundamental weights, normalized by $\langle \alpha_r^\vee, \omega_s \rangle = \delta_{rs}$. Since A_{N-1} is simply laced,

$$\alpha_r = \sum_{s=1}^{N-1} C_{rs}\omega_s, \qquad C_{rs} = 2\delta_{rs} - \delta_{r,s+1} - \delta_{r,s-1}. \tag{82.68}$$

The inverse Cartan matrix is

$$(C^{-1})_{rs} = \frac{\min(r,s)\big(N - \max(r,s)\big)}{N}, \qquad 1 \le r, s \le N-1. \tag{82.69}$$

The quotient of the weight lattice by the root lattice is

$$P_{\mathrm{wt}}/Q_{\mathrm{rt}} \cong \mathbb{Z}_N, \qquad \omega_a \longmapsto a \pmod N.$$

This is the center charge, or N-ality, of the corresponding antisymmetric-tensor representation $V_a = \wedge^a \mathbb{C}^N$.

Nested root-count constraints. Consider a finite-volume chiral Gross–Neveu multiparticle state containing M_a particles in V_a, $a = 1, \ldots, N-1$. In the algebraic nested Bethe ansatz, an auxiliary root of Dynkin color r lowers the total highest weight by α_r. If m_r is the total number of auxiliary roots of color r, counted with string length, then the Dynkin-label vector after nesting is

$$\ell_s = M_s - \sum_{r=1}^{N-1} C_{rs} m_r, \qquad s = 1, \ldots, N-1. \tag{82.70}$$

Consequently a state in the trivial $SU(N)$ representation must satisfy

$$m_r = \sum_{s=1}^{N-1} (C^{-1})_{rs} M_s. \tag{82.71}$$

The vector on the right-hand side is integral if and only if

$$\sum_{a=1}^{N-1} a\, M_a \equiv 0 \pmod N. \tag{82.72}$$

Verification. The reference tensor product has highest weight $\Lambda_{\mathrm{ref}} = \sum_a M_a \omega_a$. The nested creation operator of color r has Cartan weight $-\alpha_r$: in the RTT presentation this follows from commuting the Cartan part of the monodromy through the off-diagonal entry that creates the root; in the representation-theoretic language it is exactly the elementary lowering by the simple root associated to the adjacent pair of colors in the A_{N-1} Dynkin diagram. After m_r such roots, the total weight is

$$\Lambda_{\mathrm{ref}} - \sum_r m_r \alpha_r = \sum_s \left(M_s - \sum_r m_r C_{rs} \right) \omega_s,$$

which is (82.70). Trivial representation forces all Dynkin labels to vanish, hence $M = Cm$ and (82.71).

It remains to identify when $C^{-1}M$ is integral. The equality $\sum_s M_s \omega_s = \sum_r m_r \alpha_r$ with $m_r \in \mathbb{Z}$ is precisely the condition that the reference weight lies in the root lattice Q_{rt}. For $SU(N)$, the map $P_{\mathrm{wt}} \to P_{\mathrm{wt}}/Q_{\mathrm{rt}} \cong \mathbb{Z}_N$ sends ω_a to a. Therefore $\sum_s M_s \omega_s \in Q_{\mathrm{rt}}$ exactly when (82.72) holds. Since the simple roots form an integral basis of Q_{rt}, the coordinates m_r in the simple-root basis are then integers; conversely, integral m_r makes the weight a root lattice element and hence gives zero N-ality.

This is only weight-space bookkeeping. It does not replace the Bethe equations, the string hypothesis, or a proof that a particular solution exists. It does, however, fix the source vector and the number of nests before any TBA kernel is written. If $M^{\rm aux}_{r,k}$ is the number of auxiliary strings of Dynkin color r and length k, then

$$m_r = \sum_{k\geq 1} k\, M^{\rm aux}_{r,k}. \tag{82.73}$$

Thus the thermodynamic limit replaces M_a/L by physical particle densities and $M^{\rm aux}_{r,k}/L$ by auxiliary string densities, while preserving the Cartan constraint

$$\frac{M_s}{L} - \sum_{r,k} k\, C_{rs}\frac{M^{\rm aux}_{r,k}}{L} \longrightarrow \ell_s/L.$$

The energy and momentum driving terms come only from the physical particles:

$$E = \sum_{a=1}^{N-1}\sum_{j=1}^{M_a} m_a \cosh\theta_{a,j}, \qquad P = \sum_{a=1}^{N-1}\sum_{j=1}^{M_a} m_a \sinh\theta_{a,j}, \tag{82.74}$$

with m_a given in (82.53). Auxiliary strings carry no independent relativistic energy; they encode internal polarization and enter the TBA through the logarithmic derivatives of the rational matrix blocks and their fused descendants.

Worked chiral Gross–Neveu root counts. For $SU(3)$,

$$C^{-1} = \frac{1}{3}\begin{pmatrix} 2 & 1\\ 1 & 2\end{pmatrix}.$$

One V_1 particle and one V_2 particle have $M=(1,1)$, zero N-ality, and require $m=(1,1)$. Three fundamental particles have $M=(3,0)$ and require $m=(2,1)$. A single fundamental particle has $M=(1,0)$, nonzero N-ality, and $C^{-1}M=(2/3,1/3)$, so it cannot be a singlet-sector Bethe state. For $SU(4)$, four fundamentals have $m=(3,2,1)$, while two rank-two particles have $m=(1,2,1)$. These numbers are the total color-root counts; for example, $m=(3,2,1)$ may be refined into three length-one strings at node 1, two at node 2, and one at node 3, or into any string distribution whose length-weighted totals are the displayed integers and which solves the finite-volume Bethe equations.

Principal-chiral doubling. A rank-a principal-chiral particle transforms as $V_a\otimes V_a^*\cong V_a\otimes V_{N-a}$ under $SU(N)_L\times SU(N)_R$. For a state with physical counts M_a, the two source vectors are therefore

$$M^L_s = M_s, \qquad M^R_s = M_{N-s}, \qquad s=1,\dots,N-1, \tag{82.75}$$

and a two-sided singlet constraint has

$$m^L = C^{-1}M^L, \qquad m^R = C^{-1}M^R. \tag{82.76}$$

The two integrality conditions are equivalent because

$$\sum_s sM^R_s = \sum_s sM_{N-s} \equiv -\sum_a aM_a \pmod N.$$

Thus the PCM has the same center obstruction as the chiral Gross–Neveu family, but the auxiliary-string sector is doubled. This is the finite-volume reason that the principal-chiral TBA has left and right magnonic towers attached to the same physical sine-law particles, whereas the chiral Gross–Neveu TBA has only one such tower. The calculation companion verifies (82.69)–(82.76) exactly for representative N, including the $SU(3)$ and $SU(4)$ root counts above.

82.12 Symmetric-Space and Deformed-Sphere Families

Many integrable sigma models are organized by a homogeneous target G/H. Let $\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}$ be a reductive split and write

$$g^{-1}\mathrm{d}g = A + P, \qquad A \in \mathfrak{h}, \quad P \in \mathfrak{m}.$$

The bosonic coset action is

$$S_{G/H}[g] = \frac{1}{2g^2}\int_\Sigma \kappa(P_\mu, P_\mu), \tag{82.77}$$

with local H redundancy $g(x) \mapsto g(x)h(x)$. If G/H is a symmetric space,

$$[\mathfrak{h}, \mathfrak{h}] \subset \mathfrak{h}, \qquad [\mathfrak{h}, \mathfrak{m}] \subset \mathfrak{m}, \qquad [\mathfrak{m}, \mathfrak{m}] \subset \mathfrak{h},$$

the equations admit a Lax representation that is slightly different from the principal-chiral one because the H gauge connection must remain in the auxiliary connection. Write $A_\pm$ and $P_\pm$ for the light-cone components of A and P, and let

$$D_\pm X = \partial_\pm X + [A_\pm, X]$$

be the H-covariant derivative on $\mathfrak{m}$-valued fields.

Lemma 82.11 (Symmetric-space Lax equivalence)**.** *For the bosonic symmetric-space action (82.77), the Euler–Lagrange equation together with the two $\mathfrak{h}$- and $\mathfrak{m}$-components of the Maurer–Cartan identity is equivalent to flatness, for every $\zeta \in \mathbb{C}^\times$, of the connection*

$$\mathcal{L}_+(\zeta) = A_+ + \zeta P_+, \qquad \mathcal{L}_-(\zeta) = A_- + \zeta^{-1} P_-. \tag{82.78}$$

Proof. The Maurer–Cartan equation for $g^{-1}\mathrm{d}g = A+P$ splits, using the symmetric-space brackets, into

$$F_{+-}(A) + [P_+, P_-] = 0, \tag{82.79}$$
$$D_+P_- - D_-P_+ = 0. \tag{82.80}$$

Varying g by a compactly supported $\mathfrak{m}$-valued field gives the field equation

$$D_+P_- + D_-P_+ = 0. \tag{82.81}$$

Conversely, (82.80) and (82.81) are equivalent to

$$D_+P_- = 0, \qquad D_-P_+ = 0.$$

The curvature of (82.78) is

$$\partial_+\mathcal{L}_- - \partial_-\mathcal{L}_+ + [\mathcal{L}_+, \mathcal{L}_-] = F_{+-}(A) + [P_+, P_-] + \zeta^{-1}D_+P_- - \zeta D_-P_+.$$

If (82.79), (82.80), and (82.81) hold, this curvature vanishes for all ζ. If the curvature vanishes for all $\zeta \in \mathbb{C}^\times$, the coefficients of ζ^{-1}, ζ^0, and ζ give $D_+P_- = 0$, $F_{+-}(A) + [P_+, P_-] = 0$, and $D_-P_+ = 0$, which imply the Maurer–Cartan identities and the equation of motion. This proves the equivalence. □

Projective space is the example

$$\mathbb{CP}^{N-1} = SU(N)/S(U(N-1) \times U(1)).$$

82.13 Supergroup and Supersphere Sigma-Model Families

Supergroup sigma models require the same locally super-ringed-space discipline as fermionic path integrals. A supertarget is not a set of ordinary maps. Locally it is described by even coordinate functions and odd coordinate generators in a structure sheaf; the odd coordinates are integrated by Berezin rules, not by a Borel measure. This distinction matters in sigma-model examples because cancellations in beta functions are supertrace cancellations, not cancellations between two positive measures.

Let $E = E_{\bar{0}} \oplus E_{\bar{1}}$ be a finite-dimensional real super vector space, with

$$\operatorname{sdim} E = \dim E_{\bar{0}} - \dim E_{\bar{1}}.$$

For $m, n \geq 0$, the orthosymplectic supersphere

$$S^{m-1|2n} = OSp(m|2n)/OSp(m-1|2n)$$

is the supermanifold cut out in $\mathbb{R}^{m|2n}$ by

$$X \cdot X = 1.$$

Here $X \cdot X$ uses a positive quadratic form on the even coordinates and a nondegenerate symplectic pairing on the $2n$ odd coordinates. The Euclidean sigma-model functional is

$$S_{S^{m-1|2n}}[X] = \frac{1}{2g^2} \int_\Sigma \mathrm{d}^2x\, \partial_\mu X \cdot \partial_\mu X, \qquad X \cdot X = 1, \tag{82.82}$$

understood as a local expression in the supercoordinate sheaf. The ordinary round sphere is recovered at $n = 0$, $m = N$.

Supersphere Ricci coefficient. In the standard constant-curvature normalization of (82.82), the Ricci tensor entering the one-loop sigma-model beta tensor is

$$\mathrm{Ric}_{ab} = (m - 2n - 2)h_{ab}. \tag{82.83}$$

Thus the scalar coupling has leading perturbative running

$$\mu \frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{m - 2n - 2}{2\pi} g^3 + O(g^5). \tag{82.84}$$

The family $S^{2n+1|2n} = OSp(2n+2|2n)/OSp(2n+1|2n)$ has vanishing one-loop coefficient.

For a bosonic round sphere S^{m-1}, the constant-curvature tensor gives $\mathrm{Ric} = (m-2)h$: the tangent space has $m-1$ dimensions and the Ricci contraction counts all tangent directions except the distinguished one in the two-plane used by the curvature operator. In the supersphere, the same normal-coordinate computation uses the graded contraction

$$\mathrm{Ric}_{ab} = (-1)^{|c|} R^{c}{}_{acb}, \tag{82.85}$$

where $|c| = 0$ on even tangent directions and $|c| = 1$ on odd tangent directions. The tangent superdimension is

$$\operatorname{sdim} TS^{m-1|2n} = m - 1 - 2n.$$

The same constant-curvature contraction therefore replaces the bosonic count $(m-1)-1$ by the graded count

$$(m - 1 - 2n) - 1 = m - 2n - 2,$$

which gives (82.83). Substitution into the one-loop sigma-model beta tensor

$$\mu \frac{\mathrm{d}h_{ab}}{\mathrm{d}\mu} = \frac{1}{2\pi} \mathrm{Ric}_{ab} + O(R^2)$$

and $h_{ab} = g^{-2} h^{\mathrm{unit}}_{ab}$ gives (82.84). Setting $m = 2n + 2$ gives zero.

The projective supermodel is the quotient analogue. Let

$$Z = (z^1, \dots, z^{p+1}; \eta^1, \dots, \eta^q)$$

be a complex supervector, with z^i even and η^α odd. The superprojective target

$$\mathbb{CP}^{p|q}$$

is obtained by imposing a nonzero homogeneous coordinate and quotienting by the even $\mathbb{C}^\times$ rescaling. In the unitary coordinate used for the sigma model, one writes a $U(1)$ redundancy

$$Z(x) \mapsto \mathrm{e}^{\mathrm{i}\alpha(x)} Z(x), \qquad A_\mu \mapsto A_\mu + \partial_\mu \alpha,$$

and

$$S_{\mathbb{CP}^{p|q}}[Z, A] = \frac{1}{g^2} \int_\Sigma \mathrm{d}^2x \, (D_\mu Z)^\dagger D_\mu Z + \mathrm{i}\frac{\theta}{2\pi} \int_\Sigma F_A, \qquad D_\mu Z = (\partial_\mu - \mathrm{i}A_\mu) Z, \tag{82.86}$$

with the constraint $Z^\dagger Z = 1$ interpreted in the superalgebra of local functions. The gauge-invariant superprojector is

$$\mathcal{P} = ZZ^\dagger, \qquad \mathcal{P}^2 = \mathcal{P}, \qquad \operatorname{str} \mathcal{P} = 1,$$

where str is the supertrace.

Projective-supermodel one-loop identity. For the Fubini–Study supermetric on $\mathbb{CP}^{p|q}$, the one-loop Ricci coefficient is

$$\mathrm{Ric} = (p + 1 - q) \, h_{\mathrm{FS}}. \tag{82.87}$$

Consequently $\mathbb{CP}^{N-1|N}$ has zero one-loop beta coefficient in this normalization, while the ordinary $\mathbb{CP}^{N-1}$ coefficient is N.

In a holomorphic coordinate patch, the Fubini–Study Kähler potential is the even function

$$K = \log(1 + w^\dagger w + \eta^\dagger \eta),$$

where w has p even components and η has q odd components. The Ricci form of a Kähler supermetric is computed by the Berezinian:

$$\rho = -\mathrm{i}\,\partial\bar{\partial} \log \mathrm{Ber}(g_{A\bar{B}}). \tag{82.88}$$

For the Fubini–Study metric, the Berezinian is proportional to

$$(1 + w^\dagger w + \eta^\dagger \eta)^{-(p+1-q)}.$$

The exponent is the ordinary projective homogeneous-coordinate count $p+1$ minus the number q of odd homogeneous coordinates, because the odd block enters the Berezinian inversely. Applying $-\mathrm{i}\partial\bar{\partial}\log$ gives (82.87). The two special cases follow by setting $q = 0$, $p = N-1$, and by setting $p = N-1$, $q = N$.

Finally, let G be a Lie supergroup whose Lie superalgebra $\mathfrak{g}$ carries a nondegenerate even invariant bilinear form κ. The principal supergroup sigma-model action is

$$S_{\mathrm{PSG}}[U] = \frac{1}{2g^2} \int_\Sigma \mathrm{d}^2 x\, \kappa(U^{-1}\partial_\mu U, U^{-1}\partial_\mu U). \tag{82.89}$$

The one-loop counterterm is proportional to the Killing form

$$K(X, Y) = \mathrm{str}_{\mathfrak{g}}(\mathrm{ad}_X\, \mathrm{ad}_Y). \tag{82.90}$$

Thus supergroups with $K = 0$, such as the projective special linear family $\mathfrak{psl}(N|N)$ and the dual-Coxeter-zero orthosymplectic family $\mathfrak{osp}(2n+2|2n)$, are distinguished perturbatively. This is a statement about the first local counterterm in a regularized superfield path integral. Construction of the Hilbert space, locality, and exact factorized scattering theory requires additional data.

Controlled Approximation 82.12 (Supercoset status)**.** The supersphere actions, projective supermodels, and principal supergroup actions above are ultraviolet family data. Their perturbative cancellations explain why $OSp(2n+2|2n)$, $\mathbb{CP}^{N-1|N}$, and $\mathfrak{psl}(N|N)$-type examples recur in the integrable and logarithmic two-dimensional literature. A theorem-level identification with a local QFT requires the same ingredients demanded in Open Problem 82.26: a regulator, Hilbert space or graded state space, local observables, conserved currents, and matching between ultraviolet and bootstrap coordinates. For supertargets, one must additionally specify the real form, the positivity or graded replacement of positivity, and the interpretation of logarithmic sectors if Jordan blocks appear.

82.14 Deformed-Sphere and Sausage Family

The sausage family should be treated as a controlled deformation of the round S^2 sigma model with a stated metric and RG trajectory before any comparison to cigar or parafermion cosets is made. The sign of the deformation parameter is part of the specification: the elongated physical sausage is the negative branch of the real parameter used below.

Definition 82.13 (Sausage metric)**.** The two-dimensional deformed-sphere, or sausage, target used in the semiclassical description is the $U(1)$-invariant Riemannian metric

$$\mathrm{d}s^2_{h,q} = h\left[\frac{\mathrm{d}r^2}{(1-r^2)(1+qr^2)} + \frac{1-r^2}{1+qr^2}\,\mathrm{d}\phi^2\right], \qquad -1 < r < 1, \quad \phi \sim \phi + 2\pi, \tag{82.91}$$

with $h > 0$ and $q > -1$. The undeformed value $q = 0$ is the round sphere of radius $\sqrt{h}$: setting $r = \cos\vartheta$ gives

$$\mathrm{d}s^2_{h,0} = h(\mathrm{d}\vartheta^2 + \sin^2\vartheta\,\mathrm{d}\phi^2).$$

For $q \neq 0$ the metric preserves only the axial $U(1)$ isometry. The pair (h,q) is therefore a metric coordinate for the sigma model; an exact quantum S-matrix proposal for the sausage family is a separate rapidity-space object that must be matched to this coordinate choice.

Curvature of the sausage target. For the metric (82.91), the scalar curvature is

$$R_{h,q}(r) = \frac{2(1+q)(1-qr^2)}{h(1+qr^2)}. \tag{82.92}$$

In particular $R_{h,0} = 2/h$, as required for the round two-sphere of radius $\sqrt{h}$.

Write the metric as $E(r)\mathrm{d}r^2 + G(r)\mathrm{d}\phi^2$, where

$$E(r) = \frac{h}{(1-r^2)(1+qr^2)}, \qquad G(r) = h\frac{1-r^2}{1+qr^2}.$$

For any diagonal two-dimensional metric of this form, direct computation from the Christoffel symbols gives

$$R = -\frac{G''}{EG} + \frac{(G')^2}{2EG^2} + \frac{E'G'}{2E^2G}. \tag{82.93}$$

Substitution of E and G into (82.93) gives (82.92). At $q = 0$, the formula becomes the constant $2/h$, agreeing with the standard scalar curvature of the round sphere.

Closure under one-loop Ricci flow. Let $g_{h,q}$ denote the metric (82.91). Under the geometric Ricci flow

$$\partial_\tau g_{ij} = -\,\mathrm{Ric}_{ij}, \tag{82.94}$$

the family $g_{h,q}$ is closed. The induced parameter equations are

$$\frac{\mathrm{d}h}{\mathrm{d}\tau} = -(1+q), \qquad \frac{\mathrm{d}q}{\mathrm{d}\tau} = -\frac{2q(1+q)}{h}. \tag{82.95}$$

Equivalently, for the physical sausage branch $q = -\kappa^2$, $0 \le \kappa < 1$,

$$\frac{\mathrm{d}h}{\mathrm{d}\tau} = -(1-\kappa^2), \qquad \frac{\mathrm{d}\kappa}{\mathrm{d}\tau} = -\frac{\kappa(1-\kappa^2)}{h}. \tag{82.96}$$

The ratio q/h^2 is constant along (82.95).

In two dimensions $\mathrm{Ric}_{ij} = \frac{1}{2}Rg_{ij}$. Write

$$g_{rr} = \frac{h}{(1-r^2)(1+qr^2)}, \qquad g_{\phi\phi} = h\frac{1-r^2}{1+qr^2}.$$

The logarithmic variation of either component under a parameter change is

$$\frac{\partial_\tau g_{ij}}{g_{ij}} = \frac{\dot h}{h} - \frac{\dot q\, r^2}{1+qr^2}. \tag{82.97}$$

The right side of (82.94), using (82.92), gives the common logarithmic factor

$$-\frac{1}{2}R_{h,q}(r) = -\frac{(1+q)(1-qr^2)}{h(1+qr^2)}. \tag{82.98}$$

Equating (82.97) and (82.98) as rational functions of r^2 gives the constant term

$$\dot h = -(1+q)$$

and the coefficient of r^2,

$$q\frac{\dot h}{h} - \dot q = \frac{q(1+q)}{h}.$$

Substituting $\dot h = -(1+q)$ gives $\dot q = -2q(1+q)/h$. The κ-form follows from $q = -\kappa^2$. Finally,

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{q}{h^2}\right) = \frac{\dot q}{h^2} - \frac{2q\dot h}{h^3} = 0.$$

Integrated sausage Ricci trajectory. Fix a solution of (82.95) with initial value (h_0, q_0) at $\tau = \tau_0$. If $q_0 = 0$, then

$$h(\tau) = h_0 - (\tau - \tau_0), \qquad q(\tau) = 0. \tag{82.99}$$

On the physical sausage branch $q < 0$, write the invariant as

$$\frac{q}{h^2} = -\alpha^2, \qquad \alpha > 0, \tag{82.100}$$

so that $\kappa(\tau) = \alpha h(\tau)$. While $0 < \alpha h(\tau) < 1$,

$$h(\tau) = \frac{1}{\alpha}\tanh(\operatorname{arctanh}(\alpha h_0) - \alpha(\tau - \tau_0)), \qquad q(\tau) = -\alpha^2 h(\tau)^2. \tag{82.101}$$

On the positive branch $q > 0$, write $q/h^2 = \beta^2$, $\beta > 0$. Then

$$h(\tau) = \frac{1}{\beta}\tan(\arctan(\beta h_0) - \beta(\tau - \tau_0)), \qquad q(\tau) = \beta^2 h(\tau)^2, \tag{82.102}$$

up to the first zero or pole of the tangent chart.

The preceding Ricci-flow calculation gives the invariant q/h^2. For $q_0 = 0$, the equation for h reduces to $\dot h = -1$, which gives (82.99).

On the negative branch, substitute $q = -\alpha^2 h^2$ into (82.95). The scalar equation is

$$\dot h = -(1 - \alpha^2 h^2). \tag{82.103}$$

Since

$$\frac{\mathrm{d}}{\mathrm{d}h}\operatorname{arctanh}(\alpha h) = \frac{\alpha}{1-\alpha^2 h^2},$$

(82.103) is equivalent to

$$\frac{\mathrm{d}}{\mathrm{d}\tau}\operatorname{arctanh}(\alpha h(\tau)) = -\alpha.$$

Integrating from τ_0 to τ gives (82.101). The relation $q = -\alpha^2 h^2$ then supplies the second coordinate. The condition $\alpha h < 1$ is exactly $q > -1$, the Riemannian domain of Definition 82.13.

On the positive branch, substitute $q = \beta^2 h^2$. Then

$$\dot{h} = -(1 + \beta^2 h^2),$$

and

$$\frac{\mathrm{d}}{\mathrm{d}h}\arctan(\beta h) = \frac{\beta}{1 + \beta^2 h^2}.$$

Thus $\frac{\mathrm{d}}{\mathrm{d}\tau}\arctan(\beta h(\tau)) = -\beta$, and integration gives (82.102).

Remark 82.14 (Round and cylindrical endpoints of the metric family). The branch $q = -\kappa^2$, $0 \leq \kappa < 1$, interpolates at the metric level between the round two-sphere and a flat cylinder. More precisely, $\kappa = 0$ gives S^2 of radius $\sqrt{h}$, while the limiting metric as $\kappa \to 1$ is

$$\mathrm{d}s^2_{h,-1} = h(\mathrm{d}\rho^2 + \mathrm{d}\phi^2), \qquad r = \tanh\rho, \quad \rho \in \mathbb{R}. \tag{82.104}$$

The case $\kappa = 0$ is the calculation already displayed in Definition 82.13. For $\kappa \to 1$, set $q = -1$ in (82.91). Then

$$\frac{\mathrm{d}r^2}{(1-r^2)^2} + \mathrm{d}\phi^2$$

is obtained. The change of variable $r = \tanh\rho$ gives $\mathrm{d}r = (1 - \tanh^2\rho)\mathrm{d}\rho = (1 - r^2)\mathrm{d}\rho$, hence $\mathrm{d}r^2/(1-r^2)^2 = \mathrm{d}\rho^2$. This proves (82.104).

82.14.1 Repulsive-Domain Fateev–Onofri–Zamolodchikov Sausage Scattering

The metric/RG data above are not themselves a factorized scattering theory. The Fateev–Onofri–Zamolodchikov massive sausage scattering proposal is a one-parameter $U(1)$-invariant deformation of the $O(3)$ triplet scattering theory. We record the repulsive-domain version because it is the exact rapidity-space object against which any regulator-defined sausage sigma model must be matched.

Definition 82.15 (Repulsive massive sausage scattering proposal)**.** Let $0 \leq \lambda < \frac{1}{2}$. The one-particle labels are

$$a \in \{+, 0, -\}, \qquad Q(+) = 1, \quad Q(0) = 0, \quad Q(-) = -1,$$

all with the same mass $m > 0$. The two-particle scattering matrix preserves the total $U(1)$ charge. In the Zamolodchikov–Faddeev convention used in Section 82.1, the nonzero entries generated from charge conjugation and exchange by the following formulae are

$$S_{++}^{++}(\theta) = S_{+-}^{+-}(\mathrm{i}\pi - \theta) = \frac{\sinh\lambda(\theta - \mathrm{i}\pi)}{\sinh\lambda(\theta + \mathrm{i}\pi)}, \tag{82.105}$$

$$S_{+0}^{0+}(\theta) = S_{+-}^{00}(\mathrm{i}\pi - \theta) = \frac{-\mathrm{i}\sin(2\pi\lambda)}{\sinh\lambda(\theta - 2\mathrm{i}\pi)} S_{++}^{++}(\theta), \tag{82.106}$$

$$S_{+0}^{+0}(\theta) = \frac{\sinh(\lambda\theta)}{\sinh\lambda(\theta - 2\mathrm{i}\pi)} S_{++}^{++}(\theta), \tag{82.107}$$

$$S_{+-}^{-+}(\theta) = -\frac{\sin(\pi\lambda)\sin(2\pi\lambda)}{\sinh\lambda(\theta - 2\mathrm{i}\pi)\,\sinh\lambda(\theta + \mathrm{i}\pi)}, \tag{82.108}$$

$$S_{00}^{00}(\theta) = S_{+0}^{+0}(\theta) + S_{-+}^{+-}(\theta). \tag{82.109}$$

Here $S_{-+}^{+-} = S_{+-}^{-+}$ and the remaining charge-conjugate entries are fixed by the simultaneous replacement $+ \leftrightarrow -$. No other matrix element is nonzero in this scattering proposal. At $\lambda = 0$ the formula is understood as the meromorphic limit. The parameter λ is a bootstrap coordinate. A comparison with a metric-coordinate deformation such as (h, q) in Definition 82.13 requires a separate matching map; the semiclassical and TBA/NLIE analyses suggest using a coordinate ν satisfying

$$\frac{\nu}{4\pi} = \frac{\lambda}{1 - 2\lambda}, \tag{82.110}$$

but in this monograph (82.110) is a matching coordinate relation, not a theorem identifying a constructed local QFT.

Repulsive-sausage strip analyticity and block unitarity checks. For $0 \le \lambda < \frac{1}{2}$, the displayed denominator factors in (82.105)–(82.108) have no zeros in the open physical strip

$$\mathcal{S}_{\mathrm{phys}} = \{\theta \in \mathbb{C} : 0 < \operatorname{Im}\theta < \pi\}.$$

Moreover, the charge $+2$, charge $+1$, and charge 0 blocks obey two-particle unitarity on the real rapidity axis. Explicitly, for real $\theta \neq 0$,

$$S_{++}^{++}(\theta) S_{++}^{++}(-\theta) = 1,$$

and, in the ordered charge-$+1$ basis $(|+0\rangle, |0+\rangle)$, the matrix

$$S_{+1}(\theta) = \begin{pmatrix} A(\theta) & B(\theta) \\ B(\theta) & A(\theta) \end{pmatrix},$$

where

$$A(\theta) = S_{+0}^{+0}(\theta), \qquad B(\theta) = S_{+0}^{0+}(\theta),$$

satisfies

$$S_{+1}(\theta) S_{+1}(-\theta) = I_2.$$

In the ordered charge-zero basis $(|+-\rangle, |00\rangle, |-+\rangle)$, write

$$S_{Q=0}(\theta) = \begin{pmatrix} E(\theta) & F(\theta) & G(\theta) \\ F(\theta) & H(\theta) & F(\theta) \\ G(\theta) & F(\theta) & E(\theta) \end{pmatrix},$$

where

$$E = S_{+-}^{+-}, \qquad F = S_{+-}^{00}, \qquad G = S_{+-}^{-+}, \qquad H = S_{00}^{00}.$$

Then

$$S_{Q=0}(\theta)S_{Q=0}(-\theta) = I_3.$$

These are explicit bootstrap consistency checks for the written repulsive-sausage scattering proposal. The constructive question of whether this proposal is realized by a regulator-defined local sigma model is stated separately in Controlled Approximation 82.21.

The possible zeros of $\sinh \lambda(\theta + \mathrm{i}\pi)$ occur at

$$\theta = \mathrm{i}\pi \left(\frac{n}{\lambda} - 1\right), \qquad n \in \mathbb{Z},$$

when $\lambda > 0$. For $n \leq 0$ the imaginary part is at most $-\pi$; for $n \geq 1$ it is at least $\pi(1/\lambda - 1) > \pi$. Hence there is no zero in the open physical strip. The possible zeros of $\sinh \lambda(\theta - 2\mathrm{i}\pi)$ occur at

$$\theta = \mathrm{i}\pi \left(\frac{n}{\lambda} + 2\right).$$

For $n \geq 0$ the imaginary part is at least 2π; for $n \leq -1$ it is at most $2\pi - \pi/\lambda \leq 0$. Thus these denominators also have no physical-strip zeros. At $\lambda = 0$ the statement follows from the meromorphic limiting rational functions.

Set $x = \lambda\theta$ and $a = \pi\lambda$. The highest-charge block is

$$D(x) = \frac{\sinh(x - \mathrm{i}a)}{\sinh(x + \mathrm{i}a)}.$$

Since $D(-x) = D(x)^{-1}$, the charge $+2$ unitarity relation follows. For the charge $+1$ block,

$$A(x) = \frac{\sinh x}{\sinh(x - 2\mathrm{i}a)} D(x), \qquad B(x) = \frac{-\mathrm{i}\sin(2a)}{\sinh(x - 2\mathrm{i}a)} D(x).$$

Using $D(-x) = D(x)^{-1}$,

$$A(-x) = \frac{\sinh x}{\sinh(x + 2\mathrm{i}a)} D(x)^{-1}, \qquad B(-x) = \frac{\mathrm{i}\sin(2a)}{\sinh(x + 2\mathrm{i}a)} D(x)^{-1}.$$

Therefore

$$A(x)A(-x) + B(x)B(-x) = \frac{\sinh^2 x + \sin^2(2a)}{\sinh(x - 2\mathrm{i}a)\sinh(x + 2\mathrm{i}a)} = 1,$$

because $\sinh(x - 2\mathrm{i}a)\sinh(x + 2\mathrm{i}a) = \sinh^2 x + \sin^2(2a)$. Similarly

$$A(x)B(-x) + B(x)A(-x) = 0.$$

These two scalar identities are exactly $S_{+1}(\theta)S_{+1}(-\theta) = I_2$.

It remains to check the charge-zero block. With the same notation $x = \lambda\theta$, $a = \pi\lambda$, set

$$s_k = \sinh(x + \mathrm{i}ka), \qquad u = \sin a, \qquad v = \sin(2a).$$

The entries of $S_{Q=0}$ are

$$E = \frac{s_0}{s_{-2}}, \qquad F = \frac{\mathrm{i}vs_0}{s_{-2}s_1}, \qquad G = -\frac{uv}{s_{-2}s_1}, \qquad H = \frac{s_0 s_{-1} - uv}{s_{-2}s_1}. \tag{82.111}$$

At rapidity $-\theta$, the replacement is $s_k \mapsto -s_{-k}$. The antisymmetric vector $(1,0,-1)$ has eigenvalue $E-G$, while the symmetric subspace spanned by $(1,0,1)$ and $(0,1,0)$ has matrix

$$\begin{pmatrix} E+G & \sqrt{2}F \\ \sqrt{2}F & H \end{pmatrix}.$$

Thus $S_{Q=0}(\theta)S_{Q=0}(-\theta) = I_3$ is equivalent to the four scalar identities

$$(E-G)(E_- - G_-) = 1, \tag{82.112}$$

$$(E+G)(E_- + G_-) + 2FF_- = 1, \tag{82.113}$$

$$(E+G)F_- + FH_- = 0, \tag{82.114}$$

$$2FF_- + HH_- = 1, \tag{82.115}$$

where $E_- = E(-\theta)$, and similarly for F, G, H. Substituting (82.111), using $s_k(-x) = -s_{-k}(x)$, and repeatedly applying

$$\sinh(y + \mathrm{i}b)\sinh(y - \mathrm{i}b) = \sinh^2 y + \sin^2 b$$

reduces the left sides of (82.112)–(82.115) exactly to $1, 1, 0, 1$, respectively. This gives the charge-zero unitarity block.

Definition 82.16 (Full sausage triplet matrix)**.** Let V_s be the three-dimensional vector space with ordered basis (e_+, e_0, e_-) and charges $Q(e_\pm) = \pm 1$, $Q(e_0) = 0$. The entries in Definition 82.15 define a meromorphic endomorphism

$$S_\lambda(\theta) : V_\mathrm{s} \otimes V_\mathrm{s} \longrightarrow V_\mathrm{s} \otimes V_\mathrm{s}$$

by declaring all charge-nonconserving matrix elements to vanish and by using charge conjugation $+ \leftrightarrow -$ for the negative-charge blocks. In the ordered two-particle bases

$$Q = 2: \ (++), \qquad Q = 1: \ (+0, 0+), \qquad Q = 0: \ (+-, 00, -+),$$

the nontrivial blocks are respectively

$$(S^{++}_{++}), \qquad \begin{pmatrix} S^{+0}_{+0} & S^{0+}_{+0} \\ S^{0+}_{+0} & S^{+0}_{+0} \end{pmatrix}, \qquad \begin{pmatrix} S^{+-}_{+-} & S^{00}_{+-} & S^{-+}_{+-} \\ S^{00}_{+-} & S^{00}_{00} & S^{00}_{+-} \\ S^{-+}_{+-} & S^{00}_{+-} & S^{+-}_{+-} \end{pmatrix}.$$

The $Q = -1, -2$ blocks are obtained by simultaneous charge conjugation.

Example 82.17 (Exact Yang–Baxter verification for the displayed sausage matrix)**.** For $0 \le \lambda < \frac{1}{2}$, the meromorphic matrix $S_\lambda(\theta)$ of Definition 82.16 satisfies the Zamolodchikov–Faddeev Yang–Baxter equation

$$S_{\lambda,12}(\theta)S_{\lambda,13}(\theta+\phi)S_{\lambda,23}(\phi) = S_{\lambda,23}(\phi)S_{\lambda,13}(\theta+\phi)S_{\lambda,12}(\theta) \tag{82.116}$$

as a meromorphic identity on $V_\mathrm{s}^{\otimes 3}$.

This is a finite algebraic identity. We give the reduction because a sampled numerical Yang–Baxter check would not be evidence for the meromorphic statement. Put

$$q = e^{\mathrm{i}\pi\lambda}, \qquad u = e^{\lambda\theta}, \qquad v = e^{\lambda\phi},$$

and, for an integer k, abbreviate

$$[z]_k = \frac{1}{2}\left(zq^k - z^{-1}q^{-k}\right) = \sinh(\lambda\vartheta + \mathrm{i}k\pi\lambda) \quad \text{when } z = e^{\lambda\vartheta}.$$

In these variables the highest-charge entry is the rational function

$$D(z) = \frac{[z]_{-1}}{[z]_1},$$

the charge-one entries are

$$A(z) = \frac{[z]_0}{[z]_{-2}} D(z), \qquad B(z) = -\frac{q^2 - q^{-2}}{2[z]_{-2}} D(z),$$

and the charge-zero exchange entry is

$$G(z) = \frac{(q - q^{-1})(q^2 - q^{-2})}{4[z]_{-2}[z]_1}.$$

The crossed charge-zero entries are obtained by replacing z with q/z:

$$E(z) = D(q/z), \qquad F(z) = B(q/z), \qquad H(z) = A(z) + G(z).$$

Thus every entry of $S_\lambda(\theta)$, $S_\lambda(\phi)$, and $S_\lambda(\theta + \phi)$ is an element of the rational function field $\mathbb{Q}(q, u, v)$, with $z = u, v, uv$, respectively. After substituting these entries into (82.116), charge conservation leaves 141 possibly nonzero scalar component equations. Clearing the common denominators in each component gives 141 Laurent polynomial identities in q, u, v. Multiplication by a sufficiently large monomial $q^a u^b v^c$ turns each into an ordinary polynomial identity over $\mathbb{Q}$. Direct expansion and collection gives the zero polynomial in every component.

The companion file `calculation-checks/sigma_model_family_checks.py` implements exactly this reduction in sparse tensor notation. It constructs the 19 nonzero two-particle components, forms the two sides of (82.116) on $V_{\mathrm{s}}^{\otimes 3}$, and verifies the 141 numerator polynomials symbolically in $\mathbb{Q}(q, u, v)$, with no floating-point specialization of q, u, v. Since the two sides are meromorphic functions, equality of all cleared numerators proves equality away from the union of their pole divisors, and therefore proves the meromorphic identity.

Example 82.17 is an algebraic bootstrap identity for the displayed meromorphic matrix. It is not a construction of the local sausage sigma model, nor a proof that the regulator-defined metric family has scattering matrix S_λ.

Remark 82.18 (Rational $O(3)$ limit of the repulsive sausage matrix)*.* At fixed rapidity away from the displayed poles, the limit $\lambda \to 0$ of the repulsive sausage matrix exists. The highest-charge and charge-$+1$ entries become

$$S_{++}^{++}(\theta) \longrightarrow \frac{\theta - \mathrm{i}\pi}{\theta + \mathrm{i}\pi}, \tag{82.117}$$

$$S_{+0}^{+0}(\theta) \longrightarrow \frac{\theta}{\theta - 2\mathrm{i}\pi}\frac{\theta - \mathrm{i}\pi}{\theta + \mathrm{i}\pi}, \tag{82.118}$$

$$S_{+0}^{0+}(\theta) \longrightarrow \frac{-2\mathrm{i}\pi}{\theta - 2\mathrm{i}\pi}\frac{\theta - \mathrm{i}\pi}{\theta + \mathrm{i}\pi}. \tag{82.119}$$

The charge-zero block has the corresponding charge-conjugate rational limit obtained by the crossing relations in Definition 82.15. Thus the repulsive deformation is normalized so that its $\lambda = 0$ endpoint is the same rational $O(3)$ triplet block used in the round sigma-model bootstrap coordinate.

Use

$$\sinh(\lambda z) = \lambda z + O(\lambda^3) \quad \text{and} \quad \sin(2\pi\lambda) = 2\pi\lambda + O(\lambda^3).$$

Substitution in (82.105) gives (82.117). Substitution in (82.107) and (82.106), using the already computed highest-charge limit, gives (82.118) and (82.119). The charge-zero entries are generated by the same meromorphic crossing prescriptions that define them at nonzero λ, so their limits follow by applying those prescriptions to the three displayed rational functions.

Definition 82.19 (Massless $\theta = \pi$ endpoint problem)**.** A massless endpoint statement for the S^2 or sausage family at topological angle $\theta_{\text{top}} = \pi$ is a statement about a scaling limit of regulator-defined local QFTs, not a statement about the massive repulsive matrix S_λ by itself. A precise endpoint claim consists of:

1. a sequence of regularized sigma models with target metric g_ϵ, topological term $\mathrm{i}\theta_{\text{top},\epsilon}Q$, and local operator algebra $\mathcal{A}_\epsilon$;
2. a correlation-length scale $\xi_\epsilon \to \infty$ and a rule for holding finite renormalized distances as $\epsilon \to 0$;
3. candidate limiting stress tensor and current operators, obtained as renormalized limits of local fields in $\mathcal{A}_\epsilon$;
4. convergence of finite-volume energies or Euclidean correlation functions to the $SU(2)_1$ WZW conformal data, including $c = 1$, affine currents of level 1, and the allowed primary dimensions;
5. a statement of which global form of the $SO(3)$ or $SU(2)$ symmetry acts faithfully on the limiting Hilbert space.

The Haldane–Affleck picture supplies a powerful physical route to this endpoint, but the endpoint assertion is not identical to the massive factorized scattering proposal in Definition 82.15.

Open Problem 82.20 (Constructive massless endpoint for the sausage family)*.* Give a regulator-level proof of the massless $\theta_{\text{top}} = \pi$ endpoint for a declared branch of the round or deformed S^2 sigma model, including reflection-positive Euclidean correlators, the limiting stress tensor, the $SU(2)_1$ current algebra, and the convergence of finite-volume spectra. A satisfactory proof would also identify how the massive repulsive bootstrap coordinate λ, if used as an analytic continuation device, is related to the endpoint scaling coordinates.

Controlled Approximation 82.21 (Sausage bootstrap matching)**.** Equations (82.91), (82.95), and (82.104) are metric and one-loop RG data, while Definition 82.15 is a rapidity-space scattering proposal satisfying the bootstrap consistency tests above. A theorem identifying the two requires a regulator-defined local sigma model, conserved charges or an equivalent factorization construction, Haag–Ruelle scattering states, and a matching map from the regulator-defined couplings to the bootstrap coordinate λ. This matching is especially delicate near the cylindrical endpoint, where the target develops an asymptotic circle and the relation to compact parafermion or noncompact cigar descriptions depends on the precise scaling limit. The elementary strip-analyticity and block-unitarity checks above are necessary bootstrap consistency tests, and Example 82.17 is the factorization identity for the meromorphic matrix; neither replaces the missing constructive identification. In attractive analytic continuations, physical-strip poles must be accompanied by declared bound-state particles and residue normalizations before one can speak of a complete spectrum. The repulsive domain treated here has no such denominator poles by the strip-analyticity check above. A massless $\theta_{\text{top}} = \pi$ endpoint statement requires the separate scaling data of Definition 82.19.

Definition 82.22 (Sigma-model family specification)**.** A sigma-model family specification consists of:

1. a target, quotient, or supertarget X, including its global and local redundancy groups;
2. a regulator definition of maps $\Sigma \to X$ and of the functional measure or Berezin functional;
3. coupling coordinates in the metric, B-field, Wess–Zumino, and θ-angle sectors;
4. classical integrability structures, such as a Lax connection, when present;
5. ultraviolet beta functions or a nonperturbative mass-generation calculation;
6. a proposed bootstrap spectrum and S-matrix, with CDD choices and bound state poles specified;
7. a matching statement between the regulator construction and bootstrap specification.

The families discussed in this chapter are the round $O(N)$ model, $\mathbb{CP}^{N-1}$, principal chiral models, WZW endpoints, symmetric-space cosets, supergroup variants, and deformed-sphere trajectories.

82.15 Gross–Neveu Ultraviolet Action

Let ψ^i, $i = 1, \dots, N$, be Majorana fermions in two Lorentzian dimensions. The $O(N)$ Gross–Neveu action is

$$S_{\text{GN}} = \int \mathrm{d}^2x \left[\frac{\mathrm{i}}{2}\psi^i\gamma^\mu\partial_\mu\psi^i + \frac{g^2}{8}(\bar{\psi}^i\psi^i)^2\right].$$

Introducing an auxiliary scalar σ gives the equivalent finite-cutoff functional

$$S_{\text{GN}}[\psi,\sigma] = \int \mathrm{d}^2x \left[\frac{\mathrm{i}}{2}\psi^i\gamma^\mu\partial_\mu\psi^i - \frac{1}{2}\sigma\,\bar{\psi}^i\psi^i - \frac{1}{2g^2}\sigma^2\right],$$

because the Gaussian equation of motion is

$$\sigma = -\frac{g^2}{2}\bar{\psi}^i\psi^i.$$

Substitution returns the quartic interaction. The auxiliary-field form makes the large-N mass gap equation explicit: for a constant saddle $\sigma = m$,

$$\frac{m}{g^2} = Nm\int^\Lambda \frac{\mathrm{d}^2p_E}{(2\pi)^2}\frac{1}{p_E^2 + m^2}.$$

For $m \neq 0$,

$$\frac{1}{Ng^2} = \frac{1}{4\pi}\log\left(\frac{\Lambda^2 + m^2}{m^2}\right).$$

Thus a fixed physical mass m requires logarithmic dependence of g on the regulator scale. Equivalently, with $\lambda_{\mathrm{GN}} = Ng^2$,

$$m = \frac{\Lambda}{\sqrt{\exp(4\pi/\lambda_{\mathrm{GN}}) - 1}} \sim \Lambda \exp\left(-\frac{2\pi}{\lambda_{\mathrm{GN}}}\right).$$

This derivation is a saddle calculation in a specified regularized functional integral; the exact finite-N factorized QFT is a separate construction.

82.16 Regulator-to-Bootstrap Matching

The preceding sections deliberately separated three kinds of statements. First, a sigma model can be specified by ultraviolet local structures: a target or quotient, a regularized functional integral, coupling coordinates, global symmetries, and local composite fields. Second, integrability can be stated by classical Lax equations or by finite-dimensional Yang–Baxter identities for rapidity-space matrices. Third, an exact scattering proposal becomes a statement about a local QFT only after the Hilbert space, one-particle subspaces, scattering states, and local observables have been constructed from the same regulator.

Definition 82.23 (Bootstrap specification for a massive factorizing family)**.** A massive factorizing bootstrap specification consists of:

1. a finite list of one-particle species a, with masses $m_a > 0$, internal Hilbert spaces V_a, charge conjugates $\bar{a}$, and a positive inner product on each V_a;
2. meromorphic two-particle matrices

$$S_{ab}(\theta) : V_a \otimes V_b \longrightarrow V_b \otimes V_a$$

satisfying real-rapidity unitarity, the appropriate crossing equations, and the Yang–Baxter equation as identities of meromorphic operators;
3. a physical-strip pole assignment that assigns each pole either to a stable bound-state multiplet with a positive residue in the Hilbert-space convention, to a specified on-shell composite singularity, or to a zero of the scalar factor that cancels an unphysical matrix pole;
4. CDD declaration, namely a statement that no additional physical-strip zeros or poles are present except those just assigned;
5. form-factor residues for the local currents and stress tensor, or an equivalent construction of the local operator algebra;
6. a finite-volume spectral prescription, such as a Bethe–Yang or TBA system, with kernels defined from the channel eigenvalues by

$$K_R(\theta) = \frac{1}{2\pi \mathrm{i}} \partial_\theta \log S_R(\theta)$$

wherever a diagonal channel R is being used.

The word "exact" refers to this whole specification, not only to the displayed matrix part of S_{ab}.

Definition 82.24 (Regulator realization of a bootstrap specification)**.** Let $\mathcal{B}$ be a bootstrap specification in the sense of Definition 82.23. A regulator realization of $\mathcal{B}$ is a sequence of regularized local theories $\mathfrak{R}_\epsilon$, $\epsilon \downarrow 0$, together with a choice of renormalized coupling coordinates, such that:

1. the Euclidean Schwinger functions or Lorentzian Wightman functions of local observables converge, after renormalization, to distributions obeying the positivity, covariance, spectral, and locality properties needed for Haag–Ruelle scattering in the neutral massive sector under discussion;
2. the limiting mass operator has isolated one-particle subspaces $\mathcal{H}_{1,a} \simeq V_a \otimes L^2(H^+_{m_a}, \mathrm{d}\mu_{m_a})$, with the same masses and symmetry representations as $\mathcal{B}$;
3. the local currents, stress tensor, and any topological or Noether charges obtained from the regulator act on these one-particle subspaces in the representations assigned by $\mathcal{B}$;
4. Haag–Ruelle wave operators exist for the stable species and the two-particle scattering kernel in rapidity variables is the boundary value of a meromorphic function on the domain used by the bootstrap specification;
5. this meromorphic scattering kernel, including scalar factors and residue normalizations, equals the S_{ab} of $\mathcal{B}$;
6. finite-volume energies and local form factors computed from the regulator converge to the Bethe–Yang/TBA and form-factor structures specified in $\mathcal{B}$, with the same mass coordinate.

The matching map includes the relation between the regulator mass scale, renormalized couplings, θ-angle or WZ level, and the rapidity-space bootstrap parameter. Without this map, a bootstrap matrix and a sigma-model action are two compatible coordinate systems, not yet one constructed QFT.

Analytic uniqueness after regulator matching. Assume a regulator realization supplies Haag–Ruelle two-particle scattering for species a, b, and that the resulting two-particle kernel $S^{\mathrm{HR}}_{ab}(\theta)$ and a bootstrap matrix $S^{\mathrm{boot}}_{ab}(\theta)$ are meromorphic operator-valued functions on a connected domain $\Omega \subset \mathbb{C}$ containing a nonempty real rapidity interval I in its boundary-value set. Suppose their boundary values on I exist as tempered distribution kernels and agree there as operators

$$V_a \otimes V_b \longrightarrow V_b \otimes V_a.$$

Assume also that the difference carries no boundary-supported contact term in the two-particle rapidity variable. These hypotheses imply the meromorphic identity

$$S^{\mathrm{HR}}_{ab}(\theta) = S^{\mathrm{boot}}_{ab}(\theta), \qquad \theta \in \Omega.$$

Here is the complete analytic step. Choose bases of V_a and V_b. For each matrix entry set

$$F(\theta) = (S^{\mathrm{HR}}_{ab})^{\alpha'\beta'}_{\beta\alpha}(\theta) - (S^{\mathrm{boot}}_{ab})^{\alpha'\beta'}_{\beta\alpha}(\theta).$$

On any relatively compact subdomain avoiding accumulation of pole divisors, multiply by the finite product of local factors that cancel the poles met in that subdomain. The result is a holomorphic function $\widetilde{F}$ on a connected open set whose boundary still contains a real interval $I_0 \subset I$. The equality of distributional boundary values on I_0, together with the stated exclusion of a boundary-supported term, says that the boundary distribution of $\widetilde{F}$ vanishes on I_0. Fix

$x_0 \in I_0$ and a disc D centered at x_0 whose upper half lies in the holomorphy domain. Define $G = \widetilde{F}$ on the upper half-disc and $G = 0$ on the lower half-disc. For a triangle $T \subset D$ crossing the diameter, replace T by $T \cap \{\Im z > \varepsilon\}$ and let $\varepsilon \downarrow 0$. The holomorphic integral over the truncated triangle is zero, and the only limiting contribution from the diameter is the vanishing boundary distribution paired with the test density induced by the edge of T. Hence $\int_{\partial T} G \, \mathrm{d}z = 0$ for every such triangle; Morera's theorem makes G holomorphic across the interval. Since G vanishes on the lower half-disc, the identity theorem gives $\widetilde{F} = 0$ in the upper half-disc. Analytic continuation then carries the vanishing through the connected component. Dividing by the pole-cancelling factors gives $F = 0$ away from the removed divisors, and meromorphic continuation extends the equality across them.

The mathematical burden in a sigma-model bootstrap comparison is therefore the construction of the continuum regulator realization: existence of the neutral Haag–Ruelle scattering theory, control of the meromorphic boundary values, identification of poles and residues, and matching of the finite-volume and form-factor structures in Definition 82.23. The paragraph above is only the final uniqueness step once those structures have already been obtained.

Definition 82.25 (Family status summary for this chapter)**.** The families developed in this chapter have the following status in the terminology above.

1. The $O(N)$ sigma model has a regulator action, asymptotic freedom, large-N mass generation, and a vector bootstrap matrix with the standard tensor decomposition. The chapter records the bootstrap consistency data; a fully constructive realization remains an open problem.

2. The $O(N)$ Gross–Neveu model has the auxiliary-field ultraviolet action, the large-N gap equation, and the same factorizing-scattering logic in the fermionic representation. The bosonic WZW/current-current bridge is the nonabelian-bosonization coordinate on the same local current algebra, after the $U(1)$ and quotient data are fixed.

3. The $\mathbb{CP}^{N-1}$ family is specified by the constrained complex field, auxiliary $U(1)$ quotient connection, projector action, topological charge, instanton bound, large-N gap equation, induced Maxwell kernel, and projective tensor/crossing data. For $N = 2$, the projector identifies the model with the $O(3)$ target with the coupling conversion derived above. For $N > 2$, the chapter treats exact projective scattering as a bootstrap and construction problem rather than importing a scalar factor without a regulator-level proof.

4. Principal chiral models are developed through their $G_L \times G_R$ action, Lax equivalence, Wess–Zumino deformation, Polyakov–Wiegmann identity, WZW endpoint current algebra, KZ equations, GKO cosets, and the $SU(N)$ sine-law/bootstrap matrix and scalar-factor conventions. The matrix and scalar unitarity identities are proved in the displayed convention; the constructive matching to a regulator remains a separate construction problem.

5. Symmetric-space sigma models are developed through the reductive quotient G/H, local H redundancy, and the Lax equivalence for symmetric spaces. This proves the classical integrability statement used by the family classification.

6. Supersphere, projective-super, and principal-supergroup examples are defined as locally superringed target theories. Their one-loop cancellations are supertrace/Berezinian statements, not statements about positive Borel measures. Positivity, logarithmic sectors, and exact scattering require separate constructions.

7. The deformed-sphere sausage family is specified by its metric, scalar curvature, one-loop

Ricci trajectory, round and cylindrical metric limits, the repulsive-domain triplet scattering proposal, real-rapidity unitarity, and the algebraic Yang–Baxter identity for the displayed meromorphic matrix. The massless $\theta_{\mathrm{top}} = \pi$ endpoint and the regulator-to-λ matching are separate scaling problems.

Open Problem 82.26 (Constructive factorizing sigma-model families). Construct the massive factorizing sigma-model families discussed in this chapter as local QFTs with Hilbert spaces or graded state spaces, local algebras, conserved currents, mass gaps, Haag–Ruelle scattering states, and exact S-matrices in one framework where the ultraviolet regulator definitions, bootstrap specifications, form factors, and finite-volume spectra are proved to match. At present the chapter supplies the regulator definitions, classical integrability identities, large-N controls, algebraic bootstrap checks, and scalar-factor consistency checks that such a theorem must connect; the constructive identification remains a genuine theorem-level problem.

Chapter 83

Bridges To Nonintegrable Two-Dimensional QFT And CFT

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Exact integrability supplies unusually explicit coordinates on a local QFT: asymptotic particles, factorized scattering, form factors, finite-volume Bethe–Yang spectra, and TBA vacuum energies. A nearby nonintegrable theory is studied by deforming these data through a declared regulator and local operator chart. The bridge developed in this chapter is local and finite-volume first; infinite-volume resonance poles and decay widths are defined as limits of finite-volume matrix elements.

83.1 Integrability-Breaking Datum

Let $\mathcal{Q}_0$ be a massive integrable two-dimensional QFT with Hilbert space $\mathcal{H}_0$, Hamiltonian H_0, local operator algebra $\mathcal{A}_0$, and commuting conserved charges

$$Q_s, \qquad s \in \mathcal{S} \subset \mathbb{Z}.$$

The charge Q_s acts diagonally on an asymptotic multiparticle state

$$\alpha = (a_1, \theta_1; \ldots; a_n, \theta_n)$$

with eigenvalue

$$q_s(\alpha) = \sum_{j=1}^{n} q_s^{(a_j)}(\theta_j),$$

where $q_s^{(a)}(\theta)$ is the one-particle charge eigenvalue. For ordinary energy and momentum,

$$q_1^{(a)}(\theta) = m_a \cosh\theta, \qquad \widetilde{q}_1^{(a)}(\theta) = m_a \sinh\theta.$$

Definition 83.1 (Regulated integrability-breaking deformation)**.** A regulated deformation of $\mathcal{Q}_0$ is a family of finite-volume Hamiltonians

$$H(\epsilon, L, \Lambda) = H_0(L, \Lambda) + \epsilon V_b(L, \Lambda) + \sum_A c_A(\epsilon, \Lambda)\, V_A(L, \Lambda),$$

where

$$V_b(L, \Lambda) = \int_0^L dx\, \mathcal{O}_b(x)_\Lambda, \qquad V_A(L, \Lambda) = \int_0^L dx\, \mathcal{O}_A(x)_\Lambda.$$

Here L is the spatial circumference, Λ is a UV cutoff, $\mathcal{O}_b$ is the declared perturbing local operator, and the finite set of local coordinates c_A is fixed by the chosen regularization and renormalization condition. The continuum deformation is the limit of this family in matrix elements or Schwinger functions after these local coordinates have been specified.

The deformation parameter ϵ has engineering dimension

$$[\epsilon] = 2 - \Delta_b$$

when $\mathcal{O}_b$ has scaling dimension Δ_b at a conformal short-distance fixed point. Away from a CFT, the same symbol denotes the coordinate multiplying the integrated local operator in the regulated Hamiltonian.

83.2 Broken Conservation Laws

Let $V_b = \int dx\, \mathcal{O}_b(x)$ in infinite volume, with a finite-volume regulator understood. At $\epsilon = 0$,

$$[H_0, Q_s] = 0.$$

The deformed time derivative of Q_s is

$$\frac{dQ_s}{dt} = \mathrm{i}[H(\epsilon), Q_s] = \mathrm{i}\epsilon[V_b, Q_s] + O(\epsilon^2).$$

If $Q_s = \int dx\, j_s^0(x)$, this is the integrated form of

$$\partial_\mu j_s^\mu(x) = \epsilon\, \mathcal{B}_s(x) + O(\epsilon^2),$$

where $\mathcal{B}_s$ is the local operator representing the charge-breaking density in the chosen operator chart.

Broken-charge matrix element identity. Let α and β be finite-particle scattering states of the integrable theory on which Q_s has eigenvalues $q_s(\alpha)$ and $q_s(\beta)$. Then the first-order broken-charge matrix element obeys

$$\langle\beta|\mathrm{i}[V_b, Q_s]|\alpha\rangle = \mathrm{i}\big(q_s(\alpha) - q_s(\beta)\big)\langle\beta|V_b|\alpha\rangle.$$

Since $Q_s|\alpha\rangle = q_s(\alpha)|\alpha\rangle$ and $\langle\beta|Q_s = q_s(\beta)\langle\beta|$,

$$\langle\beta|V_b Q_s|\alpha\rangle = q_s(\alpha)\langle\beta|V_b|\alpha\rangle, \qquad \langle\beta|Q_s V_b|\alpha\rangle = q_s(\beta)\langle\beta|V_b|\alpha\rangle.$$

Subtracting the two identities and multiplying by i gives the formula.

The equation is useful because the integrable charges give many independent kinematic tests. A matrix element that changes any higher-spin charge eigenvalue is a direct channel through which the deformation breaks factorized scattering. Energy and momentum remain conserved when the deformed Hamiltonian is translation invariant; higher charges typically do not.

83.3 Form-Factor Perturbation Theory

Let $|A_a(\theta)\rangle$ denote a one-particle state of species a and rapidity θ in the integrable theory. The Lorentzian normalization used in this volume is

$$\langle A_a(\theta')|A_b(\theta)\rangle = 2\pi\,\delta_{ab}\delta(\theta' - \theta).$$

For a scalar perturbing operator $\mathcal{O}_b$, define the connected diagonal crossed form factor by

$$F^{b,\mathrm{conn}}_{a\bar{a}}(\theta + \mathrm{i}\pi, \theta) = {}_{\mathrm{out}}\langle A_a(\theta)|\mathcal{O}_b(0)|A_a(\theta)\rangle_{\mathrm{in,conn}}.$$

Lorentz invariance makes this connected diagonal matrix element independent of θ for a scalar operator; denote it by F^b_a.

Controlled Approximation 83.2 (First-order mass shift from a diagonal form factor)**.** Assume that the one-particle state remains an isolated stable particle under the deformation, and that the diagonal connected form factor F^b_a is finite in the declared crossing prescription. For

$$H = H_0 + \epsilon \int dx\, \mathcal{O}_b(x) + O(\epsilon^2),$$

the first-order shift of the squared mass is

$$\delta m_a^2 = 2\epsilon F^b_a.$$

Place the theory on a circle of circumference L. The one-particle Bethe–Yang density is

$$\rho_1(\theta) = m_a L \cosh\theta.$$

The finite-volume diagonal form-factor formula of Chapter 84 gives, after the vacuum term is separated into the bulk energy coordinate,

$${}_L\langle A_a(\theta)|\mathcal{O}_b(0)|A_a(\theta)\rangle^{\mathrm{conn}}_L = \frac{F^b_a}{m_a L\cosh\theta} + O(e^{-\mu L}).$$

Thus the connected first-order energy shift is

$$\delta E_a(\theta) = \epsilon L_L \langle A_a(\theta)|\mathcal{O}_b(0)|A_a(\theta)\rangle_L^{\mathrm{conn}} = \epsilon \frac{F_a^b}{m_a \cosh\theta} + O(e^{-\mu L}).$$

If the shifted dispersion remains relativistic,

$$E_a(\theta)^2 - p_a(\theta)^2 = m_a^2 + \delta m_a^2 + O(\epsilon^2),$$

then at fixed momentum

$$\delta E_a(\theta) = \frac{\delta m_a^2}{2E_a(\theta)} = \frac{\delta m_a^2}{2m_a \cosh\theta}.$$

Comparing the two expressions gives $\delta m_a^2 = 2\epsilon F_a^b$.

Definition 83.3 (Form-factor perturbation data)**.** First-order form-factor perturbation data consist of:

1. the perturbing operator normalization in the local operator chart;
2. the crossing prescription for diagonal form factors and kinematic-pole subtractions;
3. the vacuum-energy subtraction convention;
4. the finite-volume normalization used to take the infinite-volume limit;
5. the stability hypothesis specifying which isolated particles remain asymptotic states.

The stability hypothesis is part of the data because an integrable particle may become a resonance or may be confined after the deformation. The finite diagonal form factor then supplies a mass counterterm or a pole displacement only after the relevant analytic continuation has been declared.

83.4 Semi-Locality and Confinement Diagnostics

Let $\mathcal{O}_b$ be semi-local with respect to particle species a. The semi-locality phase $\omega_{b,a} \in U(1)$ is the monodromy acquired when the particle-creating field for a is moved once around $\mathcal{O}_b$. The kinematic pole equation of the form-factor chapter then gives the two-particle diagonal pole

$$-\mathrm{i} \operatorname*{Res}_{\theta'=\theta+\mathrm{i}\pi} F^b_{\bar{a}a}(\theta', \theta) = (1-\omega_{b,a})\,\langle \mathcal{O}_b \rangle.$$

Remark 83.4 (Semi-local pole obstruction to a particle mass shift)*.* If $\omega_{b,a} \neq 1$ and $\langle \mathcal{O}_b \rangle \neq 0$, the first-order diagonal form factor entering Controlled Approximation 83.2 has a kinematic pole at the required crossing point. The perturbative one-particle mass shift is therefore replaced by a confinement or resonance problem in the deformed theory.

The displayed residue is nonzero under the stated hypotheses. Hence the crossed two-particle form factor has a pole at $\theta' = \theta + \mathrm{i}\pi$, which is exactly the diagonal point used to define the connected one-particle matrix element. The finite value F_a^b in Controlled Approximation 83.2 is absent. Thus the assumption that the original one-particle state admits an ordinary first-order mass shift fails. The deformed spectral problem must be formulated with the appropriate long-distance force, resonance pole, or finite-volume mixing included.

Example 83.5 (Ising magnetic perturbation and kink confinement)**.** In the ordered phase of the thermally perturbed Ising model there are two vacua $|+\rangle$ and $|-\rangle$ with

$$\langle +|\sigma|+\rangle = v, \qquad \langle -|\sigma|-\rangle = -v.$$

Perturb the Hamiltonian by

$$\delta H = -h \int dx\, \sigma(x).$$

The two vacuum energy densities shift by $-hv$ and $+hv$. A kink–antikink pair separated by distance R encloses a segment of the higher-energy vacuum. The leading long-distance potential is therefore

$$V_{\mathrm{conf}}(R) = 2|hv|\, R.$$

For two heavy kinks of mass m, the leading nonrelativistic meson equation for the relative coordinate is

$$\left[-\frac{1}{m}\frac{d^2}{dR^2} + 2|hv|\,|R|\right]\psi(R) = (M-2m)\psi(R).$$

This equation is an infrared consequence of the vacuum energy splitting. The operator-level warning sign is the semi-local kinematic pole of the spin-field form factor with respect to the kink.

83.5 Finite-Volume Transition Rates

Let

$$V_b(L) = \int_0^L dx\, \mathcal{O}_b(x)$$

and let $|A, L\rangle$ be an eigenstate of $H_0(L)$. Let $|n, L\rangle$ be finite-volume eigenstates with energies $E_n(L)$. First order time-dependent perturbation theory gives

$$P_{A\to n}(T, L) = \epsilon^2 \left| \int_0^T dt\, e^{\mathrm{i}(E_n - E_A)t} \langle n, L|V_b(L)|A, L\rangle \right|^2 + O(\epsilon^3).$$

The elementary distributional limit is

$$\frac{1}{T}\left|\int_0^T dt\, e^{\mathrm{i}\Delta E t}\right|^2 = \frac{4\sin^2(\Delta E T/2)}{T(\Delta E)^2} \longrightarrow 2\pi\delta(\Delta E).$$

This last arrow is not a pointwise limit at finite volume. If L is fixed, the spectrum is discrete: away from exact degeneracies the expression oscillates with total weight $O(T^{-1})$, while exact degeneracies give terms growing linearly in T. The delta function notation means weak convergence of the kernels

$$K_T(\omega) = \frac{4\sin^2(\omega T/2)}{T\omega^2}$$

against smooth spectral test functions:

$$\lim_{T\to\infty} \int_{\mathbb{R}} d\omega\, K_T(\omega) f(\omega) = 2\pi f(0), \qquad f \in C_c^\infty(\mathbb{R}).$$

For a finite-volume regulator this weak limit must be paired with the $L \to \infty$ limit that turns the discrete Bethe–Yang spectrum into an absolutely continuous rapidity measure.

Finite-volume golden-rule limit. For each L, let $\nu_{A,L}$ be the finite positive spectral measure obtained from the unperturbed finite-volume states by

$$\int F(\omega,p)\,d\nu_{A,L}(\omega,p)=\sum_n |\langle n,L|V_b(L)|A,L\rangle|^2 F(E_n(L)-E_A(L),P_n(L)-P_A(L)).$$

Assume that, after inserting the Bethe–Yang state-counting measure and the finite-volume form-factor normalization, $\nu_{A,L}$ converges weakly on smooth compactly supported test functions in the channel under consideration to the absolutely continuous rapidity measure determined by the connected crossed form factors. Assume also that the crossed form factors are regular on the joint energy-momentum conserving contour. For a channel

$$\beta=(b_1,\theta_1;\ldots;b_n,\theta_n)$$

use the momentum-conserving rapidity measure

$$d\Phi_\beta=2\pi\delta\left(P_A-\sum_{j=1}^n m_{b_j}\sinh\theta_j\right)\prod_{j=1}^n\frac{d\theta_j}{2\pi}.$$

Then the leading inclusive decay rate out of A is

$$\Gamma_A=2\pi\epsilon^2\sum_\beta\int d\Phi_\beta\,\delta\left(E_A-\sum_{j=1}^n m_{b_j}\cosh\theta_j\right)|\langle\beta|\mathcal{O}_b(0)|A\rangle_{\rm conn}|^2\,,$$

At finite L, the transition probability per time is the finite sum over normalizable states

$$\frac{P_A(T,L)}{T}=\epsilon^2\sum_n\frac{4\sin^2((E_n-E_A)T/2)}{T(E_n-E_A)^2}|\langle n,L|V_b(L)|A,L\rangle|^2+O(\epsilon^3).$$

The continuum golden-rule rate is the iterated weak limit

$$\Gamma_A=\epsilon^2\lim_{T\to\infty}\lim_{L\to\infty}\int K_T(\omega)\,d\nu_{A,L}(\omega,p),$$

with the momentum component restricted by the spatial integral in $V_b(L)$. Equivalently, one may use a joint large-L, large-T limit in which the time window is long compared with microscopic scales but does not resolve the finite-volume recurrence structure before the continuum spectral measure has formed. The spatial integral in $V_b(L)$ gives finite-volume momentum conservation; in the infinite-volume limit this becomes the delta function contained in $d\Phi_\beta$. The finite-volume matrix-element normalization converges to the connected crossed form factor by the same Gaudin-density cancellation used in Chapter 84. Applying the weak kernel limit $K_T\to2\pi\delta$ to the limiting absolutely continuous spectral measure gives the displayed inclusive rate.

83.6 Two-Particle Phase Space In Two Dimensions

The finite-volume formula becomes especially sharp for the first allowed decay channel. Let the unstable particle A have mass M_A, and study the contribution of two stable particles r,s of masses m_r,m_s. In the rest frame of A, energy-momentum conservation has a real solution precisely when

$$M_A>m_r+m_s.$$

Define the Kallen polynomial

$$\lambda(x,y,z)=x^2+y^2+z^2-2xy-2xz-2yz$$

and the relative momentum

$$p_*=\frac{\sqrt{\lambda(M_A^2,m_r^2,m_s^2)}}{2M_A}.$$

The two on-shell energies at the decay point are

$$E_r^*=\frac{M_A^2+m_r^2-m_s^2}{2M_A},\qquad E_s^*=\frac{M_A^2+m_s^2-m_r^2}{2M_A}.$$

For each orientation $\sigma=\pm1$, let

$$m_r\sinh\theta_r^\sigma=\sigma p_*,\qquad m_s\sinh\theta_s^\sigma=-\sigma p_*.$$

Two-particle decay width in $1+1$ dimensions. Use the state normalization and golden-rule convention above. Suppose A is at rest, $M_A>m_r+m_s$, and the crossed connected form factor

$$\mathcal{F}_{rs;A}(\theta_r,\theta_s)=\langle A_r(\theta_r)A_s(\theta_s)|\mathcal{O}_b(0)|A\rangle_{\text{conn}}$$

has a finite boundary value at the two energy-conserving rapidity pairs $(\theta_r^\sigma,\theta_s^\sigma)$. If the channel sum is over labelled ordered particles, the rs contribution to the leading width is

$$\Gamma_{A\to rs}=\frac{\epsilon^2}{M_Ap_*}\sum_{\sigma=\pm1}|\mathcal{F}_{rs;A}(\theta_r^\sigma,\theta_s^\sigma)|^2\,.$$

If instead the channel is counted as an unordered physical channel, the right-hand side must be divided by 2 when $r=s$, and is unchanged when $r\neq s$.

Start from the finite-volume golden-rule formula with $P_A=0$ and with a two-particle labelled channel:

$$\Gamma_{A\to rs}=2\pi\epsilon^2\int\frac{d\theta_r}{2\pi}\frac{d\theta_s}{2\pi}2\pi\delta(p_r+p_s)\delta(M_A-E_r-E_s)|\mathcal{F}_{rs;A}(\theta_r,\theta_s)|^2,$$

where

$$p_i=m_i\sinh\theta_i,\qquad E_i=m_i\cosh\theta_i.$$

Change variables from rapidities to momenta. Since $d\theta_i=dp_i/E_i$, the phase-space integral without the exterior factor $2\pi\epsilon^2$ is

$$\int_{\mathbb{R}^2}\frac{dp_r\,dp_s}{2\pi E_rE_s}\,\delta(p_r+p_s)\,\delta(M_A-E_r-E_s)\,|\mathcal{F}_{rs;A}|^2.$$

The momentum delta function sets $p_r=p$ and $p_s=-p$. Therefore

$$E_r(p)=\sqrt{m_r^2+p^2},\qquad E_s(p)=\sqrt{m_s^2+p^2}.$$

The equation $E_r(p)+E_s(p)=M_A$ has the two roots $p=\sigma p_*$, $\sigma=\pm1$, because solving it gives

$$E_r^*=\frac{M_A^2+m_r^2-m_s^2}{2M_A},\qquad (E_r^*)^2-m_r^2=\frac{\lambda(M_A^2,m_r^2,m_s^2)}{4M_A^2}.$$

At either root,

$$\left|\frac{d}{dp}(E_r(p)+E_s(p))\right| = |p_*|\left(\frac{1}{E_r^*}+\frac{1}{E_s^*}\right) = \frac{|p_*|M_A}{E_r^*E_s^*}.$$

Thus each root contributes

$$\frac{1}{2\pi E_r^*E_s^*}\,\frac{E_r^*E_s^*}{|p_*|M_A}|\mathcal{F}_{rs;A}(\theta_r^\sigma,\theta_s^\sigma)|^2.$$

Multiplication by the exterior $2\pi\epsilon^2$ gives the displayed formula. If $r=s$ and the physical channel is unlabelled, the two labels of the identical particles describe the same basis of final states twice; dividing by 2 implements the chosen unordered channel convention.

The factor $1/p_*$ is the one-dimensional threshold singularity of the two-particle density of states. It is not by itself a physical divergence in an observable statement: at threshold the perturbative decay problem must be examined with the form-factor boundary value, finite-volume level spacing, and possible near-threshold bound or virtual-state poles kept in the same scaling limit.

83.7 CFT-Deformation Regulator Interface

Let $\mathcal{C}$ be a two-dimensional CFT on a circle of circumference L. The CFT Hamiltonian is

$$H_{\mathrm{CFT}} = \frac{2\pi}{L}\left(L_0+\bar{L}_0-\frac{c}{12}\right).$$

Perturbing by relevant scalar operators $\mathcal{O}_i$ gives

$$H = H_{\mathrm{CFT}} + \sum_i \lambda_i\left(\frac{2\pi}{L}\right)^{\Delta_i-1}\int_0^{2\pi} d\theta\,\mathcal{O}_i(\theta).$$

Equivalently,

$$\frac{L}{2\pi}H = L_0+\bar{L}_0-\frac{c}{12}+\sum_i g_i(L)\int_0^{2\pi} d\theta\,\mathcal{O}_i(\theta), \qquad g_i(L)=\lambda_i\left(\frac{L}{2\pi}\right)^{2-\Delta_i}.$$

The displayed Hamiltonian is a coordinate chart for relevant deformations, not a numerical calculation. A truncated conformal-space regulator may be used to approximate such a deformation only after one has chosen a CFT sector, cutoff subspaces, perturbing-operator matrix elements, counterterm coordinates, and an order of limits. Those choices, together with the Rayleigh–Ritz and finite-matrix error controls, are developed in Chapter 145. This chapter does not expose the TCSA machinery further, because no concrete nonintegrable finite-volume spectrum is extracted here. The information needed for the present bridge is only that a CFT-deformation regulator must match the same local operator normalizations and counterterm coordinates that enter the form-factor perturbation theory around an integrable massive point.

83.8 Comparison Objects

A bridge between integrable and nonintegrable two-dimensional QFT compares declared observables:

finite-volume spectra, local-operator matrix elements,
resonance pole positions and residues, thermal or hydrodynamic late-time data.

An integrable point controls nearby data through form-factor perturbation theory in ϵ. A CFT point controls nearby data through relevant deformations and Hamiltonian truncation. The two coordinate systems meet when the finite-volume regulator, local counterterms, operator normalization, and infinite-volume continuation are matched.

Open Problem 83.6 (Nonintegrable deformation). Construct a nonintegrable two-dimensional QFT near an integrable point with a finite-volume regulator, local counterterm coordinates, form-factor perturbation theory, resonance pole analysis, and a proof of convergence to a local continuum QFT in a specified scaling domain.

Chapter 84

Finite-Volume Form Factors And Spectral Expansions

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Exact scattering data become QFT data only after they are connected to local operator matrix elements and to correlation functions. A spatial circle of circumference L is the cleanest intermediate regulator in massive two-dimensional integrable theories: rapidities become discrete, scattering states become normalizable vectors, matrix elements have honest Hilbert-space normalizations, and the infinite-volume spectral expansion is recovered as a controlled limit. This chapter develops that bridge for diagonal scattering sectors. Non-diagonal scattering requires replacing scalar phase functions by eigenvalues of transfer matrices and is treated in the nested Bethe-ansatz chapters.

84.1 Finite-Volume Hilbert Space And Bethe–Yang Quantization

Let the infinite-volume theory have stable particle species

$$a \in \mathcal{I}, \qquad p_a^\mu(\theta) = m_a(\cosh\theta, \sinh\theta),$$

with diagonal two-body scattering eigenvalues

$$S_{ab}(\theta) = \exp(\mathrm{i}\delta_{ab}(\theta)).$$

The phase convention is fixed by unitarity and real analyticity on the real rapidity axis:

$$S_{ab}(\theta)S_{ba}(-\theta) = 1, \qquad \delta_{ab}(\theta) + \delta_{ba}(-\theta) \in 2\pi\mathbb{Z}.$$

We choose a continuous branch on the rapidity interval under consideration and define

$$\varphi_{ab}(\theta) = \partial_\theta \delta_{ab}(\theta).$$

The branch of δ changes the Bethe integers, while φ and the Gaudin density below are branch-independent.

For a multiparticle state with ordered rapidities

$$\theta_1, \ldots, \theta_n$$

and species $a_1, \ldots, a_n$, the Bethe–Yang equations are

$$Q_j(\theta) = m_{a_j} L \sinh\theta_j + \sum_{k\neq j} \delta_{a_j a_k}(\theta_j - \theta_k) = 2\pi I_j, \qquad j = 1, \ldots, n. \tag{84.1}$$

The I_j are integers or half-integers depending on particle statistics, twists, and branch choices. The finite-volume energy and momentum at Bethe–Yang order are

$$E_L(\theta) = \sum_{j=1}^{n} m_{a_j} \cosh\theta_j, \qquad P_L(\theta) = \sum_{j=1}^{n} m_{a_j} \sinh\theta_j.$$

The neglected effects are exponentially small in $m_* L$, where

$$m_* = \min_{a\in\mathcal{I}} m_a,$$

provided no massless channel, threshold singularity, or nearby bound-state pole invalidates the contour deformation used to wrap virtual particles around the circle.

Construction 84.1 (Bethe–Yang phase from diagonal finite-volume monodromy)**.** Assume the n-particle wave function is described away from collision hyperplanes by ordered plane waves, and that crossing a hyperplane $x_j = x_k$ multiplies the ordered amplitude by the diagonal scattering phase $S_{a_j a_k}(\theta_j - \theta_k)$. Periodicity of particle j around the circle gives (84.1).

Indeed, moving particle j once around the spatial circle while keeping the other particles fixed contributes the free propagation phase

$$\exp(\mathrm{i} p_j L), \qquad p_j = m_{a_j} \sinh\theta_j.$$

During the circuit it crosses each other particle once, so in the diagonal sector the ordered amplitude is multiplied by

$$\prod_{k\neq j} S_{a_j a_k}(\theta_j - \theta_k) = \exp\left(\mathrm{i} \sum_{k\neq j} \delta_{a_j a_k}(\theta_j - \theta_k)\right).$$

Single-valuedness of the wave function demands that the total phase be one. Taking the logarithm on the chosen branch gives

$$m_{a_j} L \sinh\theta_j + \sum_{k\neq j} \delta_{a_j a_k}(\theta_j - \theta_k) = 2\pi I_j.$$

84.2 Gaudin Density And Normalization

The density of Bethe–Yang states is the Jacobian of the map

$$\theta \longmapsto Q(\theta).$$

Define the Gaudin matrix

$$G_{ij}(\theta) = \frac{\partial Q_i}{\partial \theta_j}, \qquad \rho_n(\theta) = \det G(\theta). \tag{84.2}$$

Explicitly,

$$G_{ii} = m_{a_i} L \cosh\theta_i + \sum_{k\neq i} \varphi_{a_i a_k}(\theta_i - \theta_k), \qquad G_{ij} = -\varphi_{a_i a_j}(\theta_i - \theta_j) \quad (i \neq j).$$

For one particle,

$$\rho_1(\theta) = m_a L \cosh\theta.$$

For two particles, using $\varphi_{a_2 a_1}(\theta_2 - \theta_1) = \varphi_{a_1 a_2}(\theta_1 - \theta_2)$, one obtains

$$\rho_2(\theta_1, \theta_2) = m_{a_1} m_{a_2} L^2 \cosh\theta_1 \cosh\theta_2 + \varphi_{a_1 a_2}(\theta_{12}) L\big(m_{a_1}\cosh\theta_1 + m_{a_2}\cosh\theta_2\big), \tag{84.3}$$

where $\theta_{12} = \theta_1 - \theta_2$.

Proposition 84.2 (State-counting measure)**.** *Let $U \subset \mathbb{R}^n$ be a bounded rapidity region with piecewise C^1 boundary, and suppose that on a neighborhood of $\overline{U}$ the Bethe–Yang map Q_L is a C^2 diffeomorphism onto its image and $\rho_{n,L} = \det(\partial Q_{L,i}/\partial\theta_j) > 0$. Assume also that, for $r = 0, 1, 2$,*

$$\|\partial^r Q_L\|_{C^0(\overline{U})} \le C_r L, \qquad \|(\partial Q_L)^{-1}\|_{C^0(\overline{U})} \le C_{-1} L^{-1},$$

with constants independent of L. For every $f \in C_c^1(U)$,

$$\sum_{I:\,\theta(I)\in U} f(\theta(I)) = \int_U \frac{\mathrm{d}^n\theta}{(2\pi)^n}\, \rho_{n,L}(\theta) f(\theta) + O(L^{n-1})$$

as $L \to \infty$. The implicit constant depends on U, the displayed uniform bounds for Q_L, and $\|f\|_{C^1}$, but not on L.

Proof. The Bethe integers form a translate of the lattice $(2\pi)\mathbb{Z}^n$ in Q-space. Since Q_L is one-to-one on U, summing over Bethe solutions in U is summing the function

$$h_L(Q) = f(\theta_L(Q)), \qquad \theta_L = Q_L^{-1},$$

over lattice points in $Q_L(U)$. Cover $Q_L(U)$ by closed lattice cubes of side 2π. For a cube C contained in $Q_L(U)$ with lattice corner Q_C,

$$\left| (2\pi)^n h_L(Q_C) - \int_C h_L(Q)\, \mathrm{d}^n Q \right| \le C_n \sup_C |\nabla_Q h_L|.$$

By the chain rule and the inverse-derivative bound,

$$|\nabla_Q h_L(Q)| \le \|(\partial Q_L)^{-1}\|\, |\nabla_\theta f(\theta_L(Q))| \le C L^{-1} \|f\|_{C^1}.$$

The number of cubes meeting $Q_L(\operatorname{supp} f)$ is $O(L^n)$, because Q_L has $O(L)$ diameter on the fixed region U. Hence the interior Riemann-sum error is $O(L^{n-1})$. Cubes crossing the boundary of $Q_L(U)$ also contribute $O(L^{n-1})$: the piecewise C^1 boundary and the C^1 bound on Q_L give $(n-1)$-dimensional boundary measure $O(L^{n-1})$, hence only $O(L^{n-1})$ fixed-size cubes meet the boundary. Therefore

$$\sum_I f(\theta(I)) = \int_{Q_L(U)} \frac{\mathrm{d}^n Q}{(2\pi)^n}\, h_L(Q) + O(L^{n-1}).$$

Changing variables from Q back to θ gives

$$\mathrm{d}^n Q = \det\left(\frac{\partial Q_i}{\partial \theta_j}\right) \mathrm{d}^n\theta = \rho_{n,L}(\theta)\mathrm{d}^n\theta,$$

which proves the formula. □

The same determinant normalizes finite-volume states. If

$$|\theta_1, a_1; \ldots; \theta_n, a_n\rangle_\infty$$

is an infinite-volume rapidity state normalized by delta functions, then the corresponding unit finite-volume vector has leading normalization

$$|I_1, \ldots, I_n\rangle_L = \rho_n(\theta)^{-1/2} |\theta_1, a_1; \ldots; \theta_n, a_n\rangle_\infty + O(\mathrm{e}^{-\mu L})$$

in matrix elements of local operators. The statement compares normalized matrix elements through the finite-volume regulator; the infinite-volume delta-normalized state and the finite-volume unit vector live in different Hilbert-space normalizations.

84.3 Off-Diagonal Matrix Elements

Let $\widehat{\mathcal{O}}$ be a local scalar operator. The infinite-volume crossed form factor for an outgoing m-particle state and incoming n-particle state is written

$$F^{\mathcal{O}}_{b_1 \ldots b_m, a_1 \ldots a_n}(\theta'_1 + \mathrm{i}\pi, \ldots, \theta'_m + \mathrm{i}\pi, \theta_1, \ldots, \theta_n),$$

with the branch specified by the rapidity ordering and by the crossing prescription of Chapter 76.

Controlled Approximation 84.3 (Off-diagonal finite-volume form-factor formula)**.** Assume the incoming and outgoing Bethe–Yang rapidity sets have no coincident rapidities after crossing, and assume that the crossed form factor is regular at the corresponding point. Then

$$_L\langle J_1, \ldots, J_m | \widehat{\mathcal{O}}(0) | I_1, \ldots, I_n\rangle_L = \frac{F^{\mathcal{O}}_{b_1 \ldots b_m, a_1 \ldots a_n}(\theta'_1 + \mathrm{i}\pi, \ldots, \theta'_m + \mathrm{i}\pi, \theta_1, \ldots, \theta_n)}{\sqrt{\rho_m(\theta')\rho_n(\theta)}} + O(\mathrm{e}^{-\mu L}). \quad (84.4)$$

The derivation is a matching argument, not a theorem independent of the finite-volume construction. Smear the finite-volume Bethe states by packets whose rapidity widths are large compared with the level spacing L^{-1} and small compared with the distance to any kinematic or bound-state pole. In that window the finite-volume packet is approximated by the infinite-volume packet with the state-counting measure of Proposition 84.2. The unit normalization of the finite-volume packet therefore supplies one factor $\rho_n^{-1/2}$ for the incoming state and one factor $\rho_m^{-1/2}$ for the outgoing state. The local operator matrix element between the corresponding infinite-volume packets is the crossed form factor by the crossing prescription. Since the form factor is regular at the chosen point, shrinking the packets to the Bethe rapidities gives (84.4). Virtual particles wrapping around the circle give the exponentially small correction when the corresponding contour deformation is valid with a positive mass scale μ.

Remark 84.4 (Cancellation in the infinite-volume two-point sum). For vacuum-to-n-particle matrix elements of a scalar operator,

$$\sum_I \left| {}_L\langle \Omega_L|\widehat{\mathcal{O}}(0)|I\rangle_L \right|^2 f(\theta(I)) \longrightarrow \int \frac{\mathrm{d}^n\theta}{(2\pi)^n} |F_n^{\mathcal{O}}(\theta)|^2 f(\theta)$$

on rapidity regions with no singularities, after the usual $1/n!$ quotient for identical unordered particles.

By Controlled Approximation 84.3, the squared matrix element contributes

$$|F_n^{\mathcal{O}}(\theta(I))|^2/\rho_n(\theta(I))$$

up to exponentially small corrections. Summing over Bethe integers and using Proposition 84.2 supplies the measure

$$\rho_n(\theta)\mathrm{d}^n\theta/(2\pi)^n.$$

The Gaudin determinant cancels. If the rapidity ordering was used to label states, the ordered chamber gives one copy; if integration is over all $\mathbb{R}^n$ for identical particles, the $n!$ permutations must be divided out.

84.4 Diagonal Matrix Elements

Diagonal matrix elements require subtracting kinematic poles. Let

$$F_{2n,c}^{\mathcal{O}}(\theta_1, \ldots, \theta_n)$$

denote the connected diagonal form factor obtained as the finite part of

$$F_{\bar{a}_n\ldots\bar{a}_1a_1\ldots a_n}^{\mathcal{O}}(\theta_n + \mathrm{i}\pi + \epsilon_n, \ldots, \theta_1 + \mathrm{i}\pi + \epsilon_1, \theta_1, \ldots, \theta_n)$$

after removing all terms singular in the ϵ_j as $\epsilon_j \to 0$. The order of the crossed rapidities is part of the definition. In diagonal theories the connected finite part is symmetric in the rapidities after the same branch convention is used throughout.

Definition 84.5 (Principal minors of the Gaudin matrix)**.** For $A \subset \{1, \ldots, n\}$, let G_A be the principal submatrix of the Gaudin matrix with rows and columns in A, and set

$$\rho_A(\theta) = \det G_A, \qquad \rho_\emptyset = 1.$$

When the complement of A is denoted $\bar{A}$, the symbol $\rho_{\bar{A}}$ means the determinant of the principal minor on that complement, not the Gaudin density of an isolated smaller-volume theory.

Controlled Approximation 84.6 (Diagonal finite-volume matrix element)**.** Under the same massive diagonal assumptions and away from accidental degeneracies,

$$ {}_L\langle I_1, \ldots, I_n | \widehat{\mathcal{O}}(0) | I_1, \ldots, I_n \rangle_L = \frac{1}{\rho_n(\theta)} \sum_{A \subset \{1,\ldots,n\}} F^{\mathcal{O}}_{2|A|,c}(\theta_A)\, \rho_{\bar{A}}(\theta) + O(\mathrm{e}^{-\mu L}). \tag{84.5} $$

Here $F^{\mathcal{O}}_{0,c}$ is the infinite-volume vacuum expectation value $\langle \mathcal{O} \rangle$.

The formula is obtained by a finite-volume subtraction of the kinematic poles. Start from the off-diagonal formula with outgoing rapidities θ'_j distinct from the incoming rapidities, then approach $\theta'_j = \theta_j$. The crossed form factor develops kinematic poles. Each singular contraction identifies one crossed particle with one incoming particle and produces the finite-volume delta contribution associated with the corresponding Bethe quantum number. In the finite-volume regularization these delta contributions are replaced by derivatives of the quantization conditions, namely entries and minors of the Gaudin matrix.

After all possible disconnected contractions are grouped by the subset $\bar{A}$ of particles that contract through the finite-volume normalization, the remaining particles A contribute the connected diagonal finite part $F^{\mathcal{O}}_{2|A|,c}(\theta_A)$, while the contracted particles contribute the principal minor $\rho_{\bar{A}}$. The overall normalization of the bra and ket contributes $1/\rho_n$. Summing over all subsets gives (84.5). The only analytic input beyond the off-diagonal case is the kinematic-pole residue equation of Chapter 76, which ensures that the disconnected pieces are exactly the contractions enumerated by the subsets.

For one particle this gives

$$ {}_L\langle I | \mathcal{O} | I \rangle_L = \langle \mathcal{O} \rangle + \frac{F^{\mathcal{O}}_{2,c}(\theta)}{\rho_1(\theta)} + O(\mathrm{e}^{-\mu L}). $$

For two particles,

$$ \begin{aligned} {}_L\langle I_1, I_2 | \mathcal{O} | I_1, I_2 \rangle_L = \frac{1}{\rho_{12}} \Big[&\langle \mathcal{O} \rangle \rho_{12} + F^{\mathcal{O}}_{2,c}(\theta_1) \rho_{\{2\}} + F^{\mathcal{O}}_{2,c}(\theta_2) \rho_{\{1\}} \\ &+ F^{\mathcal{O}}_{4,c}(\theta_1, \theta_2) \Big] + O(\mathrm{e}^{-\mu L}). \end{aligned} $$

This explicit formula is often the first place where the distinction between connected diagonal form factors and symmetric finite parts matters.

84.5 Zero-Temperature Spectral Expansion

For a finite-volume two-point function

$$ C_L(x,t) = \langle \Omega_L | \widehat{\mathcal{O}}(x,t) \widehat{\mathcal{O}}(0,0) | \Omega_L \rangle, $$

insert the finite-volume identity operator:

$$ \mathbf{1}_L = \sum_\alpha |\alpha, L\rangle \langle \alpha, L|. $$

Translation covariance gives

$$C_L(x,t) = \sum_{\alpha} \big|\langle \Omega_L|\widehat{\mathcal{O}}(0)|\alpha, L\rangle\big|^2 \exp(-\mathrm{i}E_\alpha t + \mathrm{i}P_\alpha x).$$

Using the cancellation mechanism of Remark 84.4 in each particle-number sector gives the infinite-volume Wightman expansion

$$C(x,t) = \sum_{n=0}^{\infty} \frac{1}{n!} \sum_{a_1,\dots,a_n} \int_{\mathbb{R}^n} \prod_{j=1}^{n} \frac{\mathrm{d}\theta_j}{2\pi} \big|F^{\mathcal{O}}_{a_1\dots a_n}(\theta_1,\dots,\theta_n)\big|^2 e^{-\mathrm{i}\sum_j m_{a_j} t\cosh\theta_j + \mathrm{i}\sum_j m_{a_j} x \sinh\theta_j}. \quad (84.6)$$

The Euclidean Schwinger function at separation

$$r = \sqrt{\tau^2 + x^2} > 0$$

is obtained by analytic continuation $t = -\mathrm{i}\tau$. Lorentz invariance allows the exponent to be written, in a frame where the separation is purely Euclidean time, as

$$\exp\left[-r\sum_{j=1}^{n} m_{a_j}\cosh\theta_j\right].$$

The following comparison estimate is a practical convergence criterion rather than a theorem about any particular integrable model. Fix $r > 0$. If there are constants $A, B, c \geq 0$, with $c < m_* r$, such that the absolute n-particle term satisfies

$$\frac{1}{n!} \sum_{a_1,\dots,a_n} \int_{\mathbb{R}^n} \prod_{j=1}^{n} \frac{\mathrm{d}\theta_j}{2\pi} |F^{\mathcal{O}}_{a_1\dots a_n}(\theta)|^2 e^{-r\sum_j m_{a_j}\cosh\theta_j} \leq \frac{AB^n}{n!} e^{cn}.$$

for every n, then the sum of absolute values is bounded by

$$\sum_{n=0}^{\infty} \frac{A(Be^c)^n}{n!} = A\exp(Be^c).$$

This proves absolute convergence by comparison. The analytic work in a specific model lies in estimating the joint large-rapidity and large-particle-number behavior of the form factors strongly enough to obtain such a bound, or a sharper model-specific replacement for it.

84.6 Example: Free Majorana Energy Density

In the massive Ising field theory without magnetic perturbation, the free Majorana scattering phase is

$$S = -1.$$

For the energy-density operator ε, the only nonzero vacuum-to-particle form factor in the even sector needed for the first spectral term is the two-particle form factor

$$F_2^{\varepsilon}(\theta_1,\theta_2) = \kappa \sinh\left(\frac{\theta_1-\theta_2}{2}\right),$$

with normalization κ fixed by the convention for ε. The two-particle contribution to the Euclidean two-point function is

$$C_2^{\varepsilon}(r) = \frac{1}{2}\int_{\mathbb{R}^2} \frac{\mathrm{d}\theta_1 \mathrm{d}\theta_2}{(2\pi)^2} \left|\kappa \sinh \frac{\theta_1 - \theta_2}{2}\right|^2 e^{-mr(\cosh\theta_1 + \cosh\theta_2)}. \tag{84.7}$$

Introduce center and relative rapidities

$$\Theta = \frac{\theta_1 + \theta_2}{2}, \qquad \alpha = \theta_1 - \theta_2.$$

Then

$$\cosh\theta_1 + \cosh\theta_2 = 2\cosh\Theta \cosh\frac{\alpha}{2}, \qquad \mathrm{d}\theta_1 \mathrm{d}\theta_2 = \mathrm{d}\Theta\, \mathrm{d}\alpha.$$

Using

$$\int_{-\infty}^{\infty} e^{-z\cosh\Theta}\, \mathrm{d}\Theta = 2K_0(z),$$

(84.7) becomes

$$C_2^{\varepsilon}(r) = \frac{|\kappa|^2}{(2\pi)^2}\int_{-\infty}^{\infty} \mathrm{d}\alpha\, \sinh^2\frac{\alpha}{2}\, K_0\Big(2mr\cosh\frac{\alpha}{2}\Big).$$

Since the integrand is even,

$$C_2^{\varepsilon}(r) = \frac{2|\kappa|^2}{(2\pi)^2}\int_{0}^{\infty} \mathrm{d}\alpha\, \sinh^2\frac{\alpha}{2}\, K_0\Big(2mr\cosh\frac{\alpha}{2}\Big).$$

This example displays the finite-volume logic in its simplest form: the finite-volume matrix element contains the inverse Gaudin determinant, the sum over Bethe integers contains the Gaudin determinant, and the infinite-volume answer contains only the invariant rapidity measure and the form factor.

84.7 Thermal Traces And Connected Diagonal Series

At finite temperature, the Gibbs trace is organized by the thermodynamic limit at fixed rapidity density. The pseudoenergy $\varepsilon_a(\theta)$ is determined by the TBA equations in the same scattering convention used to define the form factors. For fermionic Bethe quantization conventions, the occupation factor is

$$n_a(\theta) = \frac{1}{1 + e^{\varepsilon_a(\theta)}}.$$

The Leclair–Mussardo type one-point series has the form

$$\langle \mathcal{O}\rangle_R = \sum_{n=0}^{\infty} \frac{1}{n!} \sum_{a_1,\dots,a_n} \int \prod_{j=1}^{n} \frac{\mathrm{d}\theta_j}{2\pi} \prod_{j=1}^{n} n_{a_j}(\theta_j)\, F^{\mathcal{O}}_{2n,c}(\theta_1,\dots,\theta_n), \tag{84.8}$$

where R is inverse temperature. Other quantization conventions move statistical signs between the occupation factor and the connected diagonal form factor. The formula is meaningful only with a fixed prescription for the TBA kernel, the connected diagonal finite part, and the convergence domain.

84.8 Reconstruction Boundary

The finite-volume form-factor formalism supplies a computable chain

$$S\text{-matrix} \longrightarrow F_n^{\mathcal{O}} \longrightarrow {}_L\langle\beta|\mathcal{O}|\alpha\rangle_L \longrightarrow \text{correlation functions.}$$

Each arrow has its own status. The first arrow is on-shell scattering data. The second is the operator bootstrap and crossing prescription. The third is a finite-volume normalization statement with normalizable Bethe states and Gaudin densities. The last arrow is a reconstruction step: it asks that the regulated matrix-element sums converge to distributions with positivity, covariance, locality or wedge-locality with a local subalgebra, clustering, and compatibility with the scattering theory used at the beginning. Thus the finite-volume regulator is valuable precisely because each pre-limit step has a declared Hilbert space and normalizable vectors, but removing the regulator is still an analytic theorem, not a bookkeeping identity. The free Majorana energy-density example realizes the chain inside an already constructed local theory. For an interacting regular factorizing model, the same chain is a conditional reconstruction program until convergence, domains, and locality have been proved.

Controlled Approximation 84.7 (Separated Euclidean reconstruction package)**.** Fix a separated Euclidean test space $\mathcal{T}_{r_0,r_1}$ whose tests are supported at distances $r_0 \le r \le r_1$, with $0 < r_0 < r_1 < \infty$. A form-factor reconstruction claim for a local scalar operator $\mathcal{O}$ on this window consists of the following data:

1. a finite-volume approximation $G^{\mathcal{O}}_{L,N}[\psi]$, $\psi \in \mathcal{T}_{r_0,r_1}$, built from normalizable Bethe states and Gaudin-normalized matrix elements through particle number N;
2. a finite-volume-to-rapidity-integral error for taking $L \to \infty$ on the retained sectors;
3. a particle-number tail estimate for the omitted sectors $n > N$;
4. a collision/contact extension controlling coincident rapidities, diagonal finite parts, and possible $r = 0$ contact coordinates;
5. a common-domain and positivity statement strong enough for the tested Schwinger functions to define a Hilbert-space operator or local algebra;
6. a locality or wedge-locality-with-local-subalgebra statement;
7. a sector-completeness statement comparing the scattering states used in the expansion with the physical Hilbert-space sectors under study.

The separated window removes the ultraviolet contact point from the tested observable, but it does not remove the domain, positivity, locality, or completeness obligations. Those are additional reconstruction inputs, not consequences of Bethe–Yang normalization.

Proposition 84.8 (Finite form-factor reconstruction residual budget)**.** *In the setting of Controlled Approximation 84.7, let $G^{\mathcal{O}}_{\mathrm{loc}}[\psi]$ denote the target separated Euclidean functional of a local QFT, and suppose that, for a fixed L, N,*

$$G^{\mathcal{O}}_{\mathrm{loc}}[\psi] = G^{\mathcal{O}}_{L,N}[\psi] + \Delta_{\mathrm{FV}}[\psi] + \Delta_{\mathrm{tail}}[\psi] + \Delta_{\mathrm{diag}}[\psi] + \Delta_{\mathrm{dom}}[\psi] + \Delta_{\mathrm{loc}}[\psi] + \Delta_{\mathrm{comp}}[\psi]. \tag{84.9}$$

Assume each residual is bounded in the dual test norm,

$$|\Delta_a[\psi]| \le \epsilon_a(L, N; r_0, r_1)\, \|\psi\|_{\mathcal{T}}, \qquad a \in \{\mathrm{FV}, \mathrm{tail}, \mathrm{diag}, \mathrm{dom}, \mathrm{loc}, \mathrm{comp}\}. \tag{84.10}$$

Then

$$\left|G_{\mathrm{loc}}^{\mathcal{O}}[\psi] - G_{L,N}^{\mathcal{O}}[\psi]\right| \le (\epsilon_{\mathrm{FV}} + \epsilon_{\mathrm{tail}} + \epsilon_{\mathrm{diag}} + \epsilon_{\mathrm{dom}} + \epsilon_{\mathrm{loc}} + \epsilon_{\mathrm{comp}})\, \|\psi\|_{\mathcal{T}}. \tag{84.11}$$

In particular, exact Gaudin-density cancellation and exact finite-volume matrix-element normalization control only the retained pre-limit coordinate $G_{L,N}^{\mathcal{O}}$. They do not prove local-QFT reconstruction unless the six residual budgets are driven to zero, or are retained as declared approximation errors, in the stated test topology.

Proof. Subtract $G_{L,N}^{\mathcal{O}}[\psi]$ from (84.9) and apply the triangle inequality together with (84.10). The final statement follows because the Gaudin cancellation and finite-volume normalization enter only in the definition of the retained approximant $G_{L,N}^{\mathcal{O}}$. The other terms measure analytic and operator properties that are invisible to finite state-counting algebra. □

Open Problem 84.9 (Form-factor construction)*.* Construct an interacting factorizing QFT from bootstrap scattering and form-factor data by proving convergence of the spectral expansions, locality of reconstructed fields or algebras, and agreement of finite-volume matrix elements with the Hilbert-space scattering limit.

Part VII

Supersymmetric Quantum Field Theory

Chapter 85

Supersymmetry Algebras and Representation Data

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Supersymmetry is an extension of spacetime symmetry by odd generators. The word "odd" refers to a $\mathbb{Z}_2$-graded algebra: even generators commute by ordinary commutators, odd generators anticommute with odd generators, and mixed brackets are ordinary commutators. This chapter fixes the representation-theoretic data before introducing superfields or Lagrangians.

85.1 Particle Multiplets and Field-Variable Multiplets

Definition 85.1 (Particle supersymmetry representation)**.** A particle representation of supersymmetry is a positive-energy unitary representation of the real super-Poincare algebra on a $\mathbb{Z}_2$-graded Hilbert space, or on a one-particle spectral subspace of such a Hilbert space. The odd generators are closed operators whose anticommutators are understood on a common invariant domain. A particle supermultiplet is an irreducible representation after the mass orbit, spin or helicity data, internal charges, and central charges have been fixed.

Definition 85.2 (Field-variable supersymmetry representation)**.** A field-variable representation of supersymmetry is an action of the super-Poincare algebra, or of its supertranslation subalgebra, by derivations on a space of classical field variables, superfields, antifields, or local functionals. It is off shell when the algebra closes without imposing Euler–Lagrange equations. It is on shell when closure holds only modulo equations of motion, gauge transformations, or both. Auxiliary fields are field variables added to obtain off-shell closure; they are not particle states by that fact alone.

The two notions of multiplet have different ambient categories. Particle multiplets live in Hilbert-space representation theory and are constrained by positivity of the supercharge anticommutator. Off-shell field multiplets live in a coordinate description of local dynamics. A relation between them is a derived statement: one must choose an action or equations of motion, impose constraints, quotient gauge redundancy if present, quantize or reconstruct the state space, and then identify the resulting one-particle spectral subspaces. Counting component fields in an off-shell superfield is therefore not a proof of the number or spin content of physical particles.

On-shell particle multiplets. Let $\mathcal{V}$ be a finite-dimensional linear space of component field variables on which the supertranslation algebra acts by linear differential operators in spacetime, and let S_{cl} be a quadratic supersymmetric action. The physical one-particle multiplet is determined by the positive-frequency solution space of the Euler–Lagrange equations modulo linearized gauge transformations and null vectors of the symplectic form; it is not determined by $\mathcal{V}$ alone. In particular, an auxiliary field whose equation of motion is algebraic contributes no independent one-particle oscillator in the free theory. The free one-particle space is obtained from the space of classical solutions by the standard linear quantization construction: one restricts to solutions of the linear equations, quotients pure-gauge directions if present, equips the quotient with the conserved Hermitian form coming from the quadratic action, and completes the positive-frequency part. None of these operations is encoded in the representation of the supertranslation algebra on the ambient coordinate space $\mathcal{V}$ alone.

If a component $F \in \mathcal{V}$ is auxiliary, the quadratic action contains no time derivative of F and the Euler–Lagrange equation has the form

$$AF + B(\Phi) = 0,$$

where A is an invertible algebraic operator and Φ denotes the other linearized fields. Thus $F = -A^{-1}B(\Phi)$ on the solution space. The initial data of F are fixed by the initial data of Φ, and the symplectic form has no independent F-oscillator. Consequently the auxiliary component may be necessary for off-shell closure, but it is absent from the particle Hilbert-space multiplet.

85.2 Graded Lie Algebra

Definition 85.3 (Four-dimensional $\mathcal{N} = 1$ supertranslation algebra)**.** Let P_μ be the translation generators in the convention $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$. The complexified $\mathcal{N} = 1$ supertranslation algebra is generated by P_μ, odd Weyl spinors Q_α, $\bar{Q}_{\dot\alpha}$, and the identity, with

$$[P_\mu, P_\nu] = [P_\mu, Q_\alpha] = [P_\mu, \bar{Q}_{\dot\alpha}] = 0,$$

$$\{Q_\alpha, Q_\beta\} = 0, \qquad \{\bar{Q}_{\dot\alpha}, \bar{Q}_{\dot\beta}\} = 0, \qquad \{Q_\alpha, \bar{Q}_{\dot\beta}\} = 2\sigma^\mu_{\alpha\dot\beta} P_\mu.$$

The matrices $\sigma^\mu_{\alpha\dot\beta}$ and the raising/lowering conventions are those of Section 40.16. A real form is obtained by a choice of adjoint operation for which P_μ is Hermitian and $(Q_\alpha)^\dagger = \bar{Q}_{\dot\alpha}$ after the stated spinor identifications.

The Poincare generators $M_{\mu\nu}$ act on Q and $\bar{Q}$ by the two Weyl spinor representations. This action is part of the full super-Poincare algebra and fixes the Lorentz covariance of the anticommutator above.

85.3 Haag–Łopuszański–Sohnius Classification

The super-Poincare algebra is not introduced as an arbitrary formal gadget. Its distinguished status in four-dimensional particle physics comes from a classification theorem about possible symmetries of a massive scattering theory. The theorem is conditional. It assumes the same kind of scattering framework as the Coleman–Mandula theorem: a positive-energy Hilbert space, an S-matrix on an asymptotic particle space, analyticity of matrix elements in the relevant variables, a finite number of one-particle species below each mass, and nontrivial scattering. These assumptions exclude massless conformal theories without an ordinary particle S-matrix, integrable two-dimensional theories with infinitely many higher-spin charges, and gauge-theory charged sectors whose asymptotic states require nonlocal dressings. They are therefore hypotheses of a classification result, not axioms of QFT.

Definition 85.4 (Finite graded scattering symmetry)**.** In the setting of a massive Haag–Ruelle scattering theory, a finite graded scattering symmetry is a finite-dimensional real Lie superalgebra

$$\mathfrak{g} = \mathfrak{g}_{\bar{0}} \oplus \mathfrak{g}_{\bar{1}}$$

represented by densely defined operators on a common invariant domain in the asymptotic Hilbert space, with the following properties.

1. The even subalgebra contains the Poincare algebra generated by P_μ and $M_{\mu\nu}$.
2. The even generators preserve fermion parity and the odd generators reverse it.
3. The generators commute with the scattering operator S on the common domain, after acting by the corresponding graded Leibniz rule on tensor-product asymptotic states.
4. The action on one-particle states has finite multiplicity at fixed mass and spin, and no generator creates a continuum of new particle species from one species.

The word "finite" refers to the symmetry algebra and to particle-species multiplicity; it does not assert that the Hilbert space is finite-dimensional.

Quoted Theorem 85.5 (Haag–Łopuszański–Sohnius form in four dimensions)**.** *Under the usual analyticity, finite-species, positive-energy, and nontrivial massive scattering hypotheses of the Coleman–Mandula and Haag–Łopuszański–Sohnius theorems, any finite graded scattering symmetry of a four-dimensional theory is, after quotienting possible ideals acting trivially on the S-matrix, a super-Poincare algebra with compact internal even symmetries. More explicitly, the even generators are*

$$P_\mu, \qquad M_{\mu\nu}, \qquad B_A,$$

where B_A generate a compact internal Lie algebra commuting with P_μ and $M_{\mu\nu}$. The odd generators are Weyl spinors

$$Q^I_\alpha, \qquad \bar{Q}_{\dot{\alpha} I}, \qquad I = 1, \ldots, \mathcal{N}, \quad \alpha, \dot{\alpha} = 1, 2,$$

possibly transforming in a unitary representation of the internal algebra. In a basis compatible with the positive inner product, the nonzero brackets may be written

$$[M_{\mu\nu}, Q^I_\alpha] = (\sigma_{\mu\nu})_\alpha{}^\beta Q^I_\beta, \qquad [M_{\mu\nu}, \bar{Q}_{\dot\alpha I}] = (\bar\sigma_{\mu\nu})_{\dot\alpha}{}^{\dot\beta}\bar{Q}_{\dot\beta I}, \tag{85.1}$$

$$[B_A, Q^I_\alpha] = (T_A)^I{}_J Q^J_\alpha, \qquad [B_A, \bar{Q}_{\dot\alpha I}] = -\bar{Q}_{\dot\alpha J}(T_A)^J{}_I, \tag{85.2}$$

$$\{Q^I_\alpha, \bar{Q}_{\dot\beta J}\} = 2\delta^I{}_J \sigma^\mu_{\alpha\dot\beta} P_\mu, \tag{85.3}$$

$$\{Q^I_\alpha, Q^J_\beta\} = 2\epsilon_{\alpha\beta} Z^{IJ}, \qquad \{\bar{Q}_{\dot\alpha I}, \bar{Q}_{\dot\beta J}\} = 2\epsilon_{\dot\alpha\dot\beta}\bar{Z}_{IJ}. \tag{85.4}$$

Here $Z^{IJ} = -Z^{JI}$ are central charges invariant under whatever internal symmetry is kept as a simultaneous symmetry of the fixed algebra:

$$(T_A)^I{}_K Z^{KJ} + (T_A)^J{}_K Z^{IK} = 0. \tag{85.5}$$

No odd Lorentz tensors of spin $3/2$ or higher, and no additional even spacetime-tensor charges, occur under these hypotheses.

Remark 85.6 (Status of the theorem in this monograph). The quoted theorem is a classification theorem about symmetries of a class of massive scattering theories. It is not a construction theorem for supersymmetric QFTs. It also does not apply without modification to superconformal theories, theories without an ordinary particle S-matrix, two-dimensional factorized theories with infinitely many higher-spin charges, or gauge-theory charged sectors requiring Wilson-line dressings. The algebraic consequences used below, however, are finite-dimensional representation-theoretic statements and are proved directly.

Lorentz covariance of the mixed supercharge anticommutator. Assume the odd generators transform as left- and right-handed Weyl spinors and commute with translations. Under the HLS scattering hypotheses excluding new independent even spacetime-vector charges, Lorentz covariance and positivity put the mixed anticommutator in the form

$$\{Q^I_\alpha, \bar{Q}_{\dot\beta J}\} = 2\delta^I{}_J \sigma^\mu_{\alpha\dot\beta} P_\mu$$

after a nonsingular change of basis in the index I. The tensor product of the left Weyl representation $(\frac{1}{2}, 0)$ with the right Weyl representation $(0, \frac{1}{2})$ is the vector representation $(\frac{1}{2}, \frac{1}{2})$. Therefore Lorentz covariance requires

$$\{Q^I_\alpha, \bar{Q}_{\dot\beta J}\} = A^I{}_J \sigma^\mu_{\alpha\dot\beta} V_\mu$$

for some even vector generator V_μ, up to possible sums of such vector generators. The Coleman–Mandula part of the HLS hypotheses rules out a new independent even vector symmetry acting nontrivially on the S-matrix; the only available spacetime vector generator is P_μ. Thus

$$\{Q^I_\alpha, \bar{Q}_{\dot\beta J}\} = A^I{}_J \sigma^\mu_{\alpha\dot\beta} P_\mu.$$

Hermitian conjugation gives $A = A^\dagger$. In a timelike positive-energy state with momentum p, the expectation value of $\{u^\alpha_I Q^I_\alpha, (u^\beta_J Q^J_\beta)^\dagger\}$ is a norm and is nonnegative for every u. Hence A is positive semidefinite on the subspace of nontrivially acting supercharges. Quotienting zero-norm supercharges and choosing an orthonormal basis in the remaining internal index diagonalizes A to a positive diagonal matrix. Rescaling each nonzero Q^I fixes the diagonal entries to 2, giving the displayed normalization.

Central-charge tensor structure. Under the same HLS hypotheses, the anticommutator of two left-handed supercharges has only the Lorentz-scalar central part

$$\{Q^I_\alpha, Q^J_\beta\} = 2\epsilon_{\alpha\beta} Z^{IJ}, \qquad Z^{IJ} = -Z^{JI},$$

with the conjugate formula for two right-handed supercharges. If an internal generator B_A is retained as an actual symmetry of the same algebra, then Z obeys the invariance condition (85.5).

The product of two left Weyl representations decomposes as

$$\left(\frac{1}{2}, 0\right) \otimes \left(\frac{1}{2}, 0\right) = (0, 0) \oplus (1, 0).$$

The scalar summand is obtained by contracting the spinor indices with $\epsilon_{\alpha\beta}$, while the $(1, 0)$ summand is a self-dual two-form spin representation. An even self-dual tensor charge would be an additional spacetime-tensor symmetry; the HLS hypotheses exclude such charges in the particle S-matrix setting. The remaining scalar term is therefore $2\epsilon_{\alpha\beta} Z^{IJ}$. The factor 2 is part of the central charge convention used below: it makes the rest-frame positivity block have eigenvalues $2(m \pm z_s)$ when z_s is a singular value of Z.

The graded anticommutator is symmetric under exchange of the combined labels $(I, \alpha) \leftrightarrow (J, \beta)$. Since $\epsilon_{\beta\alpha} = -\epsilon_{\alpha\beta}$, this symmetry requires

$$2\epsilon_{\alpha\beta} Z^{IJ} = 2\epsilon_{\beta\alpha} Z^{JI} = -2\epsilon_{\alpha\beta} Z^{JI},$$

and hence $Z^{IJ} = -Z^{JI}$. Finally, apply the graded Jacobi identity to $(B_A, Q^I_\alpha, Q^J_\beta)$. Using $[B_A, Q^I_\alpha] = (T_A)^I{}_K Q^K_\alpha$, the Jacobi identity gives

$$[B_A, Z^{IJ}] = (T_A)^I{}_K Z^{KJ} + (T_A)^J{}_K Z^{IK}.$$

For Z^{IJ} to be a numerical central element in the algebra, the left side vanishes; this is exactly (85.5). If this condition fails for a proposed internal generator, that generator is an automorphism of a family of algebras or is broken in the sector with the fixed central charge, not a simultaneous internal symmetry of that fixed algebra.

85.4 Positivity and Multiplet Size

For a one-particle state of mass $m > 0$, go to its rest frame $P^\mu = (m, 0, 0, 0)$. The supercharge anticommutator becomes

$$\{Q_\alpha, Q^\dagger_\beta\} = 2m\, \delta_{\alpha\beta}$$

after choosing the rest-frame spinor basis. Thus

$$a_\alpha = \frac{1}{\sqrt{2m}} Q_\alpha, \qquad a^\dagger_\alpha = \frac{1}{\sqrt{2m}} Q^\dagger_\alpha$$

generate a two-mode fermionic oscillator algebra.

Massive $\mathcal{N} = 1$ oscillator module. Fix a massive one-particle orbit of mass $m > 0$, and fix an irreducible spin-j representation V_j of the massive little group $SU(2)$. The corresponding irreducible rest-frame supertranslation module is, as a $\mathbb{Z}_2$-graded vector space,

$$V_j \otimes \Lambda^\bullet \mathbb{C}^2.$$

It has total dimension $4(2j+1)$, bosonic dimension $2(2j+1)$, and fermionic dimension $2(2j+1)$. Under the diagonal little-group action the fermionic one-oscillator sector carries

$$V_j \otimes \mathbb{C}^2 \cong V_{j+1/2} \oplus V_{j-1/2}, \tag{85.6}$$

with the $V_{j-1/2}$ summand omitted when $j = 0$, while the zero- and two-oscillator sectors are two copies of V_j with opposite fermion number parity from the one-oscillator sector. The normalized operators $a_\alpha, a_\alpha^\dagger$ satisfy

$$\{a_\alpha, a_\beta^\dagger\} = \delta_{\alpha\beta}, \qquad \{a_\alpha, a_\beta\} = \{a_\alpha^\dagger, a_\beta^\dagger\} = 0.$$

The irreducible representation of this Clifford algebra with a cyclic vector annihilated by the a_α is the exterior algebra $\Lambda^\bullet \mathbb{C}^2$. Tensoring with the chosen little-group representation gives the stated vector space and dimension. The two creation operators transform as a spin-1/2 doublet, so the one-oscillator sector is $V_j \otimes V_{1/2}$, which decomposes by the Clebsch–Gordan rule into (85.6). The zero-oscillator sector $\Lambda^0\mathbb{C}^2$ and the two-oscillator sector $\Lambda^2\mathbb{C}^2$ are both little-group scalars, giving two copies of V_j. Fermion parity is exterior degree modulo 2, hence the even and odd dimensions are both $2(2j+1)$.

Remark 85.7 (Equal bosonic and fermionic dimensions). Let $F = (-1)^{N_F}$ be the fermion-parity operator of the massive rest-frame $\mathcal{N} = 1$ oscillator algebra. For a two-mode fermionic Fock space,

$$\operatorname{Tr} F = (1-1)^2 = 0.$$

Tensoring with a little-group representation multiplies the trace by its dimension, so the trace remains zero. Since F has eigenvalue $+1$ on bosonic states and -1 on fermionic states, $\operatorname{Tr} F = 0$ is exactly equality of the two dimensions.

85.5 Massless Representations

For a massless momentum $p^\mu = (E, 0, 0, E)$, the matrix $\sigma^\mu p_\mu$ has rank one. Only one complex linear combination of the supercharges acts with nonzero norm on a positive-energy representation; the null combination is quotiented. The remaining creation operator changes helicity by 1/2. Hence a massless irreducible representation is built from a Clifford algebra with one fermionic oscillator, and its helicities come in adjacent pairs $(h, h+1/2)$ before CPT completion.

Massless $\mathcal{N} = 1$ helicity pair. Let $E > 0$ and $p^\mu = (E, 0, 0, E)$. In a spinor basis where $\sigma^\mu p_\mu$ is diagonal, positivity sets one complex supercharge combination to zero on the Hilbert space and leaves one normalized fermionic oscillator. An irreducible massless $\mathcal{N} = 1$ representation generated from a helicity-h state therefore has two helicity states,

$$h, \qquad h + \frac{1}{2},$$

before imposing CPT. For the chosen momentum, $\sigma^\mu p_\mu$ is a positive semidefinite 2×2 Hermitian matrix of rank one. A unitary change of spinor basis therefore puts the supercharge norm matrix into the form

$$\{Q_a, Q_b^\dagger\} = \begin{pmatrix} cE & 0 \\ 0 & 0 \end{pmatrix}_{ab}, \qquad c > 0.$$

If ψ is any vector in the common invariant domain, then

$$0 = \langle \psi, \{Q_2, Q_2^\dagger\}\psi\rangle = \|Q_2\psi\|^2 + \|Q_2^\dagger\psi\|^2$$

because the second diagonal entry is zero. Positivity of the inner product therefore forces $Q_2\psi = Q_2^\dagger\psi = 0$ for all vectors in the domain, equivalently the null supercharge combination acts trivially after quotienting zero-norm vectors. The remaining normalized operator

$$b = (cE)^{-1/2}Q_1, \qquad b^\dagger = (cE)^{-1/2}Q_1^\dagger$$

satisfies $\{b, b^\dagger\} = 1$. Because a Weyl supercharge has helicity $\pm 1/2$, the nontrivial creation operator shifts helicity by one half in the chosen convention. Thus the irreducible Clifford module has precisely the two displayed helicities.

85.6 Central Charges and BPS Bounds

For extended supersymmetry, odd generators carry an index $I = 1, \ldots, N$. The algebra may contain antisymmetric central charges,

$$\{Q_\alpha^I, Q_\beta^J\} = 2\epsilon_{\alpha\beta}Z^{IJ}, \qquad Z^{IJ} = -Z^{JI}.$$

In a rest frame, positivity of the matrix of anticommutators gives lower bounds on the mass in terms of the singular values of Z. A state saturating such a bound is annihilated by a nonzero linear combination of supercharges; its multiplet is shorter because the corresponding fermionic oscillator is absent in the quotient representation.

Proposition 85.8 (Rest-frame BPS bound from singular values)**.** *In a massive rest frame for extended supersymmetry, suppose the central-charge matrix has singular values $z_s \geq 0$ after skew-diagonalization of the antisymmetric matrix Z^{IJ}. Positivity of the Hilbert-space representation implies*

$$m \geq z_s \qquad \text{for every singular value } z_s.$$

If $m = z_s$ for some s, then a nonzero linear combination of supercharges has zero norm and annihilates the shortened representation.

Proof. The linear-algebra input is the skew Takagi factorization for a complex antisymmetric matrix: there is a unitary matrix U such that

$$(UZU^T)^{2s-1,2s} = z_s, \qquad (UZU^T)^{2s,2s-1} = -z_s, \qquad z_s \geq 0,$$

with all other entries inside the displayed 2×2 block zero, and with additional zero blocks if the number of supercharges is odd. Replacing Q_α^I by $U^I{}_J Q_\alpha^J$ preserves the mixed anticommutator

$$\{Q_\alpha^I, (Q_\beta^J)^\dagger\} = 2m\,\delta_{\alpha\beta}\delta^{IJ}$$

in the rest frame and puts the central term into these blocks.

Fix one nonzero block and write it as $I = 1, 2$, $Z^{12} = z$. Since $(Q^I_\alpha)^\dagger = \bar{Q}_{\dot{\alpha} I}$, the two-dimensional subspace spanned by the operators Q^1_1 and $\bar{Q}_{\dot{2}\,2}$ has Hermitian anticommutator matrix

$$\begin{pmatrix} \{Q^1_1, \bar{Q}_{\dot{1}\,1}\} & \{Q^1_1, Q^2_2\} \\ \{\bar{Q}_{\dot{2}\,2}, \bar{Q}_{\dot{1}\,1}\} & \{\bar{Q}_{\dot{2}\,2}, Q^2_2\} \end{pmatrix} = 2 \begin{pmatrix} m & z \\ z & m \end{pmatrix},$$

after the phase of the block has been absorbed into the unitary Takagi basis. The companion pair $Q^1_2, -\bar{Q}_{\dot{1}\,2}$ gives the same matrix. Thus the normalized combinations

$$R_\pm = \frac{1}{\sqrt{2}} \left(Q^1_1 \pm \bar{Q}_{\dot{2}\,2} \right)$$

have anticommutators

$$\{R_\pm, R^\dagger_\pm\} = 2(m \pm z).$$

The same computation applies independently to every skew block and to each multiplicity space for a repeated singular value.

In a Hilbert-space representation, $\langle \psi, \{R, R^\dagger\} \psi \rangle = \|R^\dagger \psi\|^2 + \|R\psi\|^2$ is nonnegative for every vector in the common invariant domain of the supercharges. Therefore every eigenvalue of each block must be nonnegative, and in particular $2(m - z_s) \geq 0$. This gives $m \geq z_s$ for every singular value. If $m = z_s$, the operator R_- for that block has zero norm on every vector; after quotienting zero-norm vectors and closing the operator, R_- acts trivially. The associated fermionic oscillator is absent, which is the representation-theoretic shortening mechanism. This proves only the algebraic BPS inequality and shortening criterion; whether a QFT contains states saturating it is separate dynamical information. □

Open Problem 85.9 (Nonperturbative realization of supersymmetric QFT data). For a proposed supersymmetric QFT, one must construct the Hilbert space or Euclidean/functorial object, the supercharges as operators or Ward identities, the stress tensor and supercurrent, and the required positivity structure. Perturbative superfield expressions and protected-index calculations are powerful coordinates on such data, but a nonperturbative construction requires separate control of the regulator, local operator domains, anomalies, and possible supersymmetry-breaking effects.

Chapter 86

Superspace, Superfields, and Local Actions

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Superspace is a supermanifold, understood as a locally super-ringed space. Its odd coordinates are algebraic generators of local structure sheaves, not points of an ordinary set. This distinction is essential for a precise relation between fermionic path-integral variables, component fields, and operator-valued fermion fields.

Two-component spinor conventions are those of Section 40.16. In this chapter the supersymmetry variation is written with odd constant parameters $\epsilon^\alpha, \bar{\epsilon}_{\dot{\alpha}}$. Thus $\delta_\epsilon = \epsilon^\alpha Q_\alpha + \bar{\epsilon}_{\dot{\alpha}} \bar{Q}^{\dot{\alpha}}$ is an even derivation of the supercommutative algebra of field variables. This convention is convenient for component calculations because all signs are obtained from the same Koszul rule as for the odd coordinates. If one instead uses commuting spinor parameters to label transformations of operator fields, the displayed component formulae are the same after the parameters are moved outside the graded algebra, but closure signs must be translated accordingly. We use

$$\theta^2 = \theta^\alpha \theta_\alpha, \qquad \bar{\theta}^2 = \bar{\theta}_{\dot{\alpha}} \bar{\theta}^{\dot{\alpha}}, \qquad \epsilon\psi = \epsilon^\alpha \psi_\alpha.$$

Thus, with $\epsilon^{12} = \epsilon_{12} = 1$, $\theta^2 = 2\theta^1\theta^2$ as a top monomial. The Berezin measure below is normalized against this θ^2, not against the unordered monomial $\theta^1\theta^2$.

86.1 Superfields as Field-Variable Data

Definition 86.1 (Off-shell superfield multiplet)**.** An off-shell superfield multiplet is a finite collection of superfields and constraints on them such that the supertranslation derivations act without using Euler–Lagrange equations. Its component fields are coordinates on a space of field variables. They are not, by definition, particle states in a Hilbert space.

If an action is supplied, the Euler–Lagrange equations may remove auxiliary fields or impose differential constraints. If gauge symmetry is present, the physical field configurations are further quotients or cohomology classes. Only after these operations and a Hilbert-space or Euclidean reconstruction has been specified can one compare the resulting one-particle spectrum with the particle representations of Chapter 85. This chapter therefore uses the word *multiplet* only for field-variable packages unless explicitly stated otherwise.

86.2 Affine Superspace

Four-dimensional $\mathcal{N} = 1$ affine superspace has underlying ordinary manifold $\mathbb{M}^4$ and structure sheaf

$$\mathcal{O}_{\mathbb{M}^{4|4}}(U) = C^\infty(U) \otimes \Lambda(\theta^1, \theta^2, \bar{\theta}^{\dot{1}}, \bar{\theta}^{\dot{2}})$$

for open $U \subset \mathbb{M}^4$. A superfield is a section of this sheaf or of a vector bundle tensored with it. In local coordinates,

$$F(x, \theta, \bar{\theta}) = f(x) + \theta^\alpha f_\alpha(x) + \bar{\theta}_{\dot{\alpha}} \bar{f}^{\dot{\alpha}}(x) + \cdots + \theta^2 \bar{\theta}^2 f_{\mathrm{top}}(x),$$

where the expansion terminates because the odd coordinate algebra is finite.

The supertranslation generators act as derivations of the structure sheaf:

$$Q_\alpha = \frac{\partial}{\partial\theta^\alpha} - \mathrm{i}\sigma^\mu_{\alpha\dot{\alpha}} \bar{\theta}^{\dot{\alpha}} \partial_\mu, \qquad \bar{Q}_{\dot{\alpha}} = -\frac{\partial}{\partial\bar{\theta}^{\dot{\alpha}}} + \mathrm{i}\theta^\alpha \sigma^\mu_{\alpha\dot{\alpha}} \partial_\mu.$$

The covariant derivatives are

$$D_\alpha = \frac{\partial}{\partial\theta^\alpha} + \mathrm{i}\sigma^\mu_{\alpha\dot{\alpha}} \bar{\theta}^{\dot{\alpha}} \partial_\mu, \qquad \bar{D}_{\dot{\alpha}} = -\frac{\partial}{\partial\bar{\theta}^{\dot{\alpha}}} - \mathrm{i}\theta^\alpha \sigma^\mu_{\alpha\dot{\alpha}} \partial_\mu.$$

They anticommute with the supercharges and obey

$$\{D_\alpha, \bar{D}_{\dot{\beta}}\} = -2\mathrm{i}\sigma^\mu_{\alpha\dot{\beta}} \partial_\mu.$$

86.3 Chiral Superfields

Definition 86.2 (Chiral superfield)**.** A chiral superfield is a superfield Φ satisfying

$$\bar{D}_{\dot{\alpha}} \Phi = 0.$$

Equivalently, in chiral coordinates

$$y^\mu = x^\mu + \mathrm{i}\theta\sigma^\mu\bar{\theta},$$

it has the component expansion

$$\Phi(y, \theta) = \phi(y) + \sqrt{2}\,\theta^\alpha \psi_\alpha(y) + \theta^2 F(y).$$

Here ϕ is an even scalar field, ψ_α an odd Weyl spinor field, and F an even auxiliary field.

Component transformations of a chiral multiplet. With the supertranslation derivations displayed above and the odd-parameter convention fixed at the beginning of the chapter, the components of a chiral superfield transform as

$$\delta\phi = \sqrt{2}\,\epsilon\psi, \tag{86.1}$$
$$\delta\psi_\alpha = \sqrt{2}\,\epsilon_\alpha F + \mathrm{i}\sqrt{2}\,\sigma^\mu_{\alpha\dot\alpha}\bar\epsilon^{\dot\alpha}\partial_\mu\phi, \tag{86.2}$$
$$\delta F = \mathrm{i}\sqrt{2}\,\bar\epsilon_{\dot\alpha}\bar\sigma^{\mu\dot\alpha\alpha}\partial_\mu\psi_\alpha. \tag{86.3}$$

The commutator of two such even variations is the translation

$$[\delta_{\epsilon_1}, \delta_{\epsilon_2}] = a^\mu\partial_\mu, \qquad a^\mu = 2\mathrm{i}\left(\epsilon_1\sigma^\mu\bar\epsilon_2 - \epsilon_2\sigma^\mu\bar\epsilon_1\right),$$

on each of ϕ, ψ_α, F, without imposing equations of motion.

Use left derivatives with respect to odd variables. In the chiral coordinate system $(y^\mu, \theta, \bar\theta)$, the chiral condition removes the $\bar\theta$-dependence of Φ, while the supercharges restrict to

$$Q_\alpha = \frac{\partial^L}{\partial\theta^\alpha}, \qquad \bar Q_{\dot\alpha} = 2\mathrm{i}\,\theta^\beta\sigma^\mu_{\beta\dot\alpha}\partial_\mu$$

on chiral superfields. Hence

$$\delta\Phi = \epsilon^\alpha\frac{\partial^L}{\partial\theta^\alpha}\big(\phi + \sqrt{2}\,\theta^\beta\psi_\beta + \theta^2 F\big) + 2\mathrm{i}\,\bar\epsilon_{\dot\alpha}\theta^\beta\sigma_\beta^{\mu\dot\alpha}\partial_\mu\big(\phi + \sqrt{2}\,\theta^\gamma\psi_\gamma + \theta^2 F\big).$$

The coefficient of 1 is $\sqrt{2}\,\epsilon^\alpha\psi_\alpha$, giving (86.1). The coefficient of θ^α is $\sqrt{2}\,\delta\psi_\alpha$. Since $\partial^L\theta^2/\partial\theta^\alpha = 2\theta_\alpha$, the ϵQ part contributes $2\epsilon_\alpha F$ to the coefficient of θ^α. Dividing by the $\sqrt{2}$ in the component expansion gives the displayed $\sqrt{2}\,\epsilon_\alpha F$. The $\bar\epsilon\bar Q$ part contributes $\mathrm{i}\sqrt{2}\,\sigma^\mu_{\alpha\dot\alpha}\bar\epsilon^{\dot\alpha}\partial_\mu\phi$, giving (86.2).

The coefficient of θ^2 gives δF. The ϵQ part has no θ^2 contribution because $\partial^L(\theta^2 F)/\partial\theta^\alpha$ is only linear in θ. The remaining term is

$$2\mathrm{i}\sqrt{2}\,\bar\epsilon_{\dot\alpha}\theta^\beta\theta^\gamma\sigma_\beta^{\mu\dot\alpha}\partial_\mu\psi_\gamma.$$

Using $\theta^\beta\theta^\gamma = -\frac{1}{2}\epsilon^{\beta\gamma}\theta^\rho\theta_\rho$ and the spinor-index conventions of Section 40.16, this coefficient is precisely (86.3).

For closure, it is shortest to return to the supertranslation algebra. Since δ_{ϵ_i} are even derivations with odd coefficients,

$$[\delta_{\epsilon_1}, \delta_{\epsilon_2}] = \epsilon_1^\alpha\bar\epsilon_{2\dot\beta}\{Q_\alpha, \bar Q^{\dot\beta}\} - \epsilon_2^\alpha\bar\epsilon_{1\dot\beta}\{Q_\alpha, \bar Q^{\dot\beta}\},$$

and the anticommutator of the differential operators is $2\mathrm{i}\sigma_\alpha^{\mu\dot\beta}\partial_\mu$. This gives the displayed translation. The computation used only the component expansion and the auxiliary field F; no Euler–Lagrange equation was invoked.

86.4 Berezin Integration and Local Superspace Actions

Berezin integration is the projection functional onto the top odd coefficient of the exterior algebra:

$$\int d^2\theta\, \theta^2 = 1, \qquad \int d^2\bar\theta\, \bar\theta^2 = 1.$$

As a linear functional on the odd coordinate algebra, it is the integration operation intrinsic to the locally super-ringed-space description. A local superspace action for chiral fields has the form

$$S = \int d^4x\, d^4\theta\, K(\Phi^i, \bar\Phi^{\bar j}) + \left[\int d^4x\, d^2\theta\, W(\Phi^i) + \text{h.c.}\right],$$

where K is a real function of superfields and W is holomorphic in the chiral superfields. The $d^4\theta$ term is a D-term; the $d^2\theta$ term is an F-term.

Nilpotent Taylor coefficient of a chiral F-term. Let

$$\Phi^i = \phi^i + \sqrt{2}\,\theta^\alpha\psi^i_\alpha + \theta^2 F^i, \qquad i = 1, \dots, n,$$

with the θ^2 convention fixed above, and let W be holomorphic in the even variables ϕ^i. The θ^2 coefficient of $W(\Phi)$ is

$$[W(\Phi)]_{\theta^2} = F^i\,\partial_i W(\phi) - \frac{1}{2}\,\partial_i\partial_j W(\phi)\,\psi^{i\alpha}\psi^j_\alpha. \tag{86.4}$$

The repeated flavor indices are summed, and $\psi^{i\alpha}\psi^j_\alpha$ is symmetric in i, j because the spinor contraction and the odd field variables both change sign under exchange.

Set

$$\Xi^i = \sqrt{2}\,\theta^\alpha\psi^i_\alpha + \theta^2 F^i.$$

Since there are only two undotted θ-coordinates, all terms of degree higher than two in Ξ have zero θ^2 coefficient. Thus

$$W(\phi + \Xi) = W(\phi) + \partial_i W(\phi)\Xi^i + \frac{1}{2}\partial_i\partial_j W(\phi)\Xi^i\Xi^j$$

for the purpose of extracting the F-term. The linear term contributes $\theta^2 F^i \partial_i W$. In the quadratic term the only possible θ^2 contribution comes from the one-θ pieces. The monograph's spinor and odd-variable conventions give the identity

$$(\theta\psi^i)(\theta\psi^j) = -\frac{1}{2}\,\theta^2\,\psi^{i\alpha}\psi^j_\alpha. \tag{86.5}$$

Therefore

$$\frac{1}{2}\partial_i\partial_j W\big(\sqrt{2}\,\theta\psi^i\big)\big(\sqrt{2}\,\theta\psi^j\big) = -\frac{1}{2}\theta^2\partial_i\partial_j W\,\psi^{i\alpha}\psi^j_\alpha.$$

Combining the linear and quadratic contributions proves (86.4). No equation of motion or integration by parts has been used.

For one chiral field with $K = \bar\Phi\Phi$, the component expansion gives

$$\mathcal{L} = -\partial_\mu\bar\phi\,\partial^\mu\phi - \mathrm{i}\bar\psi\bar\sigma^\mu\partial_\mu\psi + \bar F F + \left[F W'(\phi) - \frac{1}{2}W''(\phi)\psi^\alpha\psi_\alpha + \text{h.c.}\right]$$

in the mostly-plus convention. Eliminating F by its algebraic Euler–Lagrange equation gives $F = -\overline{W'(\phi)}$ and potential

$$V(\phi, \bar\phi) = |W'(\phi)|^2.$$

Component form of the Wess–Zumino model. Let Φ^i, $i = 1, \ldots, n$, be chiral superfields with canonical Kahler potential $K = \sum_i \bar{\Phi}^{\bar{i}} \Phi^i$ and holomorphic superpotential $W(\Phi)$. Up to total derivatives, the superspace action

$$S_{\rm WZ} = \int d^4x\, d^4\theta\, \bar{\Phi}^{\bar{i}} \Phi^i + \left[\int d^4x\, d^2\theta\, W(\Phi) + \text{h.c.} \right]$$

has Lagrangian density

$$\begin{aligned} \mathcal{L}_{\rm WZ} = &-\partial_\mu \bar{\phi}^{\bar{i}} \partial^\mu \phi^i - \mathrm{i} \bar{\psi}^{\bar{i}} \bar{\sigma}^\mu \partial_\mu \psi^i + \bar{F}^{\bar{i}} F^i \\ &+ F^i\, \partial_i W(\phi) + \bar{F}^{\bar{i}}\, \partial_{\bar{i}} \bar{W}(\bar{\phi}) - \frac{1}{2}\, \partial_i \partial_j W(\phi)\, \psi^i \psi^j - \frac{1}{2}\, \partial_{\bar{i}} \partial_{\bar{j}} \bar{W}(\bar{\phi})\, \bar{\psi}^{\bar{i}} \bar{\psi}^{\bar{j}}. \end{aligned} \tag{86.6}$$

The auxiliary Euler–Lagrange equations are

$$F^i = -\partial_{\bar{i}} \bar{W}(\bar{\phi}), \qquad \bar{F}^{\bar{i}} = -\partial_i W(\phi),$$

and the on-shell scalar potential is

$$V(\phi, \bar{\phi}) = \sum_i |\partial_i W(\phi)|^2.$$

For the D-term, expand $\bar{\Phi}^{\bar{i}} \Phi^i$ in ordinary $(x, \theta, \bar{\theta})$ coordinates and extract the $\theta^2 \bar{\theta}^2$ coefficient. The $y = x + \mathrm{i}\theta\sigma\bar{\theta}$ dependence of Φ and the conjugate $\bar{y} = x - \mathrm{i}\theta\sigma\bar{\theta}$ dependence of $\bar{\Phi}$ give

$$[\bar{\Phi}^{\bar{i}} \Phi^i]_{\theta^2\bar{\theta}^2} = -\partial_\mu \bar{\phi}^{\bar{i}} \partial^\mu \phi^i - \mathrm{i} \bar{\psi}^{\bar{i}} \bar{\sigma}^\mu \partial_\mu \psi^i + \bar{F}^{\bar{i}} F^i + \partial_\mu(\cdots).$$

The total derivative is discarded in the action. For the F-term, apply (86.4). The θ^2 coefficient is

$$F^i \partial_i W(\phi) - \frac{1}{2} \partial_i \partial_j W(\phi) \psi^i \psi^j.$$

Adding the conjugate gives (86.6). The equations for $F^i, \bar{F}^{\bar{i}}$ are algebraic because no derivatives of auxiliary fields occur. Substitution gives

$$\bar{F}^{\bar{i}} F^i + F^i W_i + \bar{F}^{\bar{i}} \bar{W}_{\bar{i}} = -\sum_i |W_i|^2,$$

so the Lagrangian has the standard form kinetic minus potential, with $V = \sum_i |W_i|^2$.

For the elementary Wess–Zumino model one takes one chiral superfield and

$$W(\Phi) = \frac{1}{2} m \Phi^2 + \frac{1}{3} y \Phi^3.$$

The parameters m and y are coordinates in the chosen supersymmetric regularization scheme; later nonrenormalization arguments concern how these coordinates enter Wilsonian F-terms, not an undefined all-purpose "effective potential".

86.5 Real Vector Superfields and Wess–Zumino Gauge

Gauge multiplets require a separate superfield because a connection is not a gauge-invariant local field variable. A real vector superfield is a Lie-algebra-valued superfield $V = V^\dagger$. In a representation of the gauge group, a chiral gauge parameter Λ acts by

$$e^V \longmapsto e^{-\bar\Lambda} e^V e^{-\Lambda}, \qquad \bar D_{\dot\alpha}\Lambda = 0.$$

For an Abelian gauge group this reduces to

$$V \longmapsto V - \Lambda - \bar\Lambda.$$

The lowest scalar, spinor, and complex auxiliary components of a general real superfield are therefore gauge representatives, not physical fields.

Wess–Zumino gauge as a representative. Locally in field space and perturbatively in the non-Abelian case, the chiral gauge freedom can put a real vector superfield in the representative

$$V_{\mathrm{WZ}} = -\theta\sigma^\mu\bar\theta\, A_\mu + \mathrm{i}\theta^2\bar\theta_{\dot\alpha}\bar\lambda^{\dot\alpha} - \mathrm{i}\bar\theta^2\theta^\alpha\lambda_\alpha + \frac{1}{2}\theta^2\bar\theta^2 D. \tag{86.7}$$

The remaining gauge freedom is the ordinary gauge transformation of $A_\mu, \lambda, \bar\lambda, D$. A supersymmetry transformation of V_{WZ} does not preserve the representative (86.7); it must be followed by a field-dependent chiral gauge transformation. Thus Wess–Zumino gauge is a gauge-fixed coordinate choice on field variables, not a gauge-invariant realization of the supersymmetry algebra.

A general real superfield has the finite expansion

$$V = C + \theta\chi + \bar\theta\bar\chi + \theta^2 M + \bar\theta^2\bar M + \theta\sigma^\mu\bar\theta\, v_\mu + \theta^2\bar\theta\bar\rho + \bar\theta^2\theta\rho + \theta^2\bar\theta^2 E.$$

The chiral parameter has the expansion

$$\Lambda(y,\theta) = a(y) + \sqrt{2}\,\theta\zeta(y) + \theta^2 f(y).$$

In the Abelian transformation $V \mapsto V - \Lambda - \bar\Lambda$, the real part of a removes C, ζ removes χ, and f removes M. The imaginary part of a remains and acts on v_μ by the ordinary gauge transformation $v_\mu \mapsto v_\mu + \partial_\mu\alpha$ after the $y, \bar y$ expansion is written in x-coordinates. Renaming the remaining components with the normalization in (86.7) gives $(A_\mu, \lambda, \bar\lambda, D)$.

For a non-Abelian group, the same elimination is performed order by order using the Baker–Campbell–Hausdorff expansion of $e^{-\bar\Lambda}e^V e^{-\Lambda}$. Since the components removed by Λ are algebraic superfield coordinates and the identity transformation has invertible linearization on them, the formal implicit function theorem gives the local gauge representative. Supersymmetry changes the removed components because Q and $\bar Q$ do not commute with the gauge-slice condition; the compensating chiral gauge transformation is therefore necessary.

In Abelian Wess–Zumino gauge the chiral field strength

$$W_\alpha = -\frac{1}{4}\bar D^2 D_\alpha V$$

has component expansion

$$W_\alpha(y,\theta) = -\mathrm{i}\lambda_\alpha + \theta_\alpha D - \mathrm{i}(\sigma^{\mu\nu}\theta)_\alpha F_{\mu\nu} + \theta^2\sigma^\mu_{\alpha\dot\alpha}\partial_\mu\bar\lambda^{\dot\alpha}.$$

The non-Abelian formula replaces $D_\alpha V$ by $e^{-V}D_\alpha e^V$ and ordinary derivatives by covariant derivatives, as in Chapter 87.

Gauge kinetic coefficient in Wess–Zumino gauge. Let $\eta = \mathrm{diag}(-,+,+,+)$, $\epsilon^{0123} = +1$, and

$$\sigma^{\mu\nu} = \frac{1}{4}\left(\sigma^\mu\bar{\sigma}^\nu - \sigma^\nu\bar{\sigma}^\mu\right)$$

with the two-component blocks fixed by Section 40.16. Interpret repeated antisymmetric pairs in the displayed W_α formula as summation over all μ, ν; equivalently, in a sum over $\mu < \nu$, replace $(\sigma^{\mu\nu}\theta)_\alpha F_{\mu\nu}$ by $2(\sigma^{\mu\nu}\theta)_\alpha F_{\mu\nu}$. Then the bosonic chiral top coefficient is

$$[W^\alpha W_\alpha]_{\theta^2,\mathrm{bos}} = D^2 - \frac{1}{2}F_{\mu\nu}F^{\mu\nu} - \frac{\mathrm{i}}{4}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}. \tag{86.8}$$

Consequently, for real g,

$$\frac{1}{4g^2}\int d^2\theta\, W^\alpha W_\alpha + \mathrm{h.c.} = -\frac{1}{4g^2}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2g^2}D^2 + \mathrm{fermions}. \tag{86.9}$$

For a complex holomorphic gauge coupling the imaginary part of (86.8) instead contributes to the topological θ-angle term, with the normalization matched in Chapter 87.

Only the terms of W_α that are linear in θ can contribute to the bosonic θ^2 coefficient of $W^\alpha W_\alpha$. Thus set

$$L_\alpha = \theta_\alpha D - 2\mathrm{i}\sum_{\mu<\nu}(\sigma^{\mu\nu}\theta)_\alpha F_{\mu\nu}.$$

The factor 2 converts the unrestricted antisymmetric summation in the component formula to a sum over ordered pairs $\mu < \nu$. Since $\epsilon^{12} = \epsilon_{12} = 1$, lowering is $\theta_1 = \theta^2$, $\theta_2 = -\theta^1$, and the inverse operation on a lowered spinor is $\chi^\alpha = -\epsilon^{\alpha\beta}\chi_\beta$. Hence

$$\theta^\alpha\theta_\alpha = \theta^2, \qquad \theta^\alpha\theta_\beta = \frac{1}{2}\delta^\alpha{}_\beta\,\theta^2. \tag{86.10}$$

The pure D-term in $L^\alpha L_\alpha$ gives D^2. The mixed D-F term is proportional to $\mathrm{tr}\,\sigma^{\mu\nu} = 0$, and therefore vanishes. The remaining finite matrix identity, obtained by multiplying the displayed $\sigma^{\mu\nu}$ blocks and using (86.10), is

$$[(\sigma^{\mu\nu}\theta)^\alpha(\sigma^{\rho\sigma}\theta)_\alpha]_{\theta^2} = \frac{1}{4}\left(\eta^{\mu\rho}\eta^{\nu\sigma} - \eta^{\mu\sigma}\eta^{\nu\rho}\right) + \frac{\mathrm{i}}{4}\epsilon^{\mu\nu\rho\sigma}, \qquad \mu<\nu,\ \rho<\sigma. \tag{86.11}$$

Substitution gives

$$[L^\alpha L_\alpha]_{\theta^2} = D^2 - 4\sum_{\mu<\nu,\rho<\sigma} F_{\mu\nu}F_{\rho\sigma}\left[(\sigma^{\mu\nu}\theta)^\alpha(\sigma^{\rho\sigma}\theta)_\alpha\right]_{\theta^2}.$$

The real part of this sum is $-\sum_{\mu<\nu}\eta^{\mu\mu}\eta^{\nu\nu}F_{\mu\nu}^2 = -\frac{1}{2}F_{\mu\nu}F^{\mu\nu}$. The oriented part uses

$$\sum_{\mu<\nu,\rho<\sigma}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = \frac{1}{4}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma},$$

where the expression on the right has unrestricted repeated indices. This proves (86.8). Adding the Hermitian conjugate with real coefficient $1/(4g^2)$ doubles the real part and cancels the imaginary topological term, giving (86.9).

The companion Python calculation check in `calculation-checks/` verifies (86.10), (86.11), and the final gauge-kinetic coefficient by exact finite exterior algebra. With the trace and gauge-coupling normalization fixed in Chapter 87, the non-Abelian superspace term

$$\frac{1}{4g^2}\int d^2\theta\ \mathrm{tr}(W^\alpha W_\alpha) + \mathrm{h.c.}$$

contains $-\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$.

86.6 Operator Fields and Grassmann Variables

Fermionic component fields in a Hilbert-space QFT are operator-valued distributions satisfying graded locality. Fermionic variables in a superspace or path-integral expression are elements of odd pieces of a Grassmann algebra. The bridge between them is the correlation functional: Grassmann sources and Berezin integration encode antisymmetric multilinear forms that represent vacuum or Euclidean correlation functions of the operator-valued fermion fields after reconstruction or perturbative definition.

86.7 Supersymmetric Wilsonian Schemes

The later dynamics of four-dimensional $\mathcal{N} = 1$ and $\mathcal{N} = 2$ gauge theories will use Wilsonian effective actions. Such statements require a scheme, not only a formal superspace expression.

Definition 86.3 (Supersymmetric Wilsonian scheme)**.** A supersymmetric Wilsonian scheme on a scale interval $\Lambda_{\mathrm{IR}} < \Lambda < \Lambda_{\mathrm{UV}}$ consists of the following data:

(i) a regulated space of field variables $\mathfrak{F}_\Lambda$, including ordinary fields, superfields, ghosts, antifields, and background sources when they are part of the construction;

(ii) an integration prescription with Lagrangian functional S_Λ: for gauge theories this means either a BV finite-cutoff integral with bracket, Laplacian, half-density, and master action specified, or a lattice construction with gauge-invariant link-variable data and blocking maps;

(iii) odd derivations or Ward operators representing the supersymmetry algebra on the regulated variables, with a stated closure relation: off shell, on shell, modulo gauge transformations, or modulo the BV differential;

(iv) a coarse-graining map from scale Λ_2 to scale Λ_1 for $\Lambda_{\mathrm{IR}} < \Lambda_1 < \Lambda_2 < \Lambda_{\mathrm{UV}}$, satisfying a composition law up to finite local coordinate changes;

(v) a coordinate chart on local and quasilocal functionals, including the separation of D-terms, F-terms, gauge kinetic terms, theta terms, and local counterterms allowed by the regulator;

(vi) a prescription for composite operator insertions and background-field variations, stated separately from the regularization of the functional integral itself.

The scheme is called supersymmetric if the regulated Ward identity is exact at finite Λ, or if the failure is a local breaking functional with a specified restoration prescription and anomaly class.

Holomorphic or nonrenormalization statements are statements about coordinates in such a scheme. They are not statements about an undefined path-integral symbol, nor are they automatically statements about the one-particle irreducible effective action. A physical statement extracted from a Wilsonian action must be invariant under the finite coordinate changes allowed by the scheme, or the coordinate dependence must be part of the statement. This distinction is essential in the exact dynamics of four-dimensional supersymmetric gauge theories.

There is a second distinction which will be used repeatedly. The BV formalism can encode gauge symmetry and supersymmetry on a space of fields, ghosts, antifields, and background superfields, and it can express a symmetry-preserving coarse-graining step as a canonical or quantum-canonical operation once a regulator has been supplied. This does not by itself produce an ultraviolet regularization. A regulated BV Laplacian, a finite field-variable space, a cutoff propagator, an integration cycle, and a proof that the regulated quantum master equation and Ward identities hold are additional data. Thus an off-shell-superfield BV description is a natural language for supersymmetric Wilsonian integration, but it is not identical to a manifestly supersymmetric regulator.

For supersymmetric gauge theories, the Wilsonian effective theory is therefore formulated through BV data unless a lattice construction is explicitly available. The BV data must include the regulated odd symplectic structure, normal half-density, BV Laplacian, integration cycle, master action, and coarse-graining map. Lattice data must include the finite gauge-field configuration space, fermion and auxiliary-field regulator, exact gauge symmetry, reflection or Hilbert-space positivity status when needed, and the blocking map for observables. Holomorphic coordinates, moduli-space coordinates, and exact superpotential arguments are verified only relative to one of these gauge-compatible finite-cutoff frameworks.

For four-dimensional supersymmetric gauge theories we shall not assume the existence of a completely satisfactory manifestly supersymmetric regularization scheme. Dimensional reduction is a perturbative prescription: loop momenta are analytically continued away from four dimensions while spinor and gauge algebra are partly kept four-dimensional. A calculation performed with this prescription is therefore verified only after the algebraic rules used at the relevant loop order have been stated and checked, including identities involving $\epsilon_{\mu\nu\rho\sigma}$, chiral matrices, and evanescent tensor structures. Higher-covariant-derivative or heat-kernel regulators supplemented by Pauli–Villars-type fields are likewise candidate schemes, not axioms: one must state the regulator fields, statistics, masses, gauge and supersymmetry transformations, BV pairing, decoupling limit, local counterterm freedom, and anomaly class before using such a construction as a proved input.

Open Problem 86.4 (Regulators preserving supersymmetry). Classify regulator schemes for supersymmetric QFT by the exact symmetries they preserve, the Ward identities they realize before removing the regulator, and the local counterterms required to restore the remaining identities. Dimensional reduction must be treated as a formal perturbative scheme whose consistency is checked at the loop order being used, rather than as a mathematical definition of a supersymmetric continuum theory. Higher-derivative heat-kernel schemes, Pauli–Villars completions, lattice constructions, and BV-compatible exact-RG schemes must be compared at the level of their regulated master equations or finite lattice Ward identities, locality of counterterms, decoupling limits, and anomaly cohomology before nonrenormalization or anomaly statements are used.

Open Problem 86.5 (Wilsonian foundations for four-dimensional supersymmetric gauge dynamics). Develop the exact dynamics of four-dimensional $\mathcal{N} = 1$ and $\mathcal{N} = 2$ gauge theories inside explicitly defined supersymmetric Wilsonian schemes. The target is to formulate holomorphic couplings, effective superpotentials, quantum moduli spaces, Seiberg-Witten effective actions, anomaly matching, decoupling, and duality tests as statements about specified Wilsonian coordinates and scheme-invariant observables, with the relation to 1PI effective actions stated separately.

Open Problem 86.6 (Supersymmetric examples across dimensions). Develop the main classes of supersymmetric QFTs in dimensions other than four with the same separation of algebra, field-variable realization, regulator, Wilsonian coordinate, and observable. In two dimensions this includes $\mathcal{N} = (2, 2)$ Landau–Ginzburg models, nonlinear sigma models with Calabi–Yau target, and gauged linear sigma models, where the relation among UV superpotential data, Kähler data, chiral rings, RG flow, and infrared CFT must be stated as a theorem, construction, controlled argument, or open problem rather than as an undeveloped phase label. In three dimensions this includes supersymmetric Chern–Simons–matter theories, where level quantization, framing, parity anomalies, boundary conditions, monopole operators, and the meaning of Wilsonian coordinates for topological terms must be part of the definition. In six dimensions this includes superconformal theories for which a conventional Lagrangian may not be part of the data; the tensor-branch effective theory, anomaly polynomial, BPS strings, compactifications, and extended operators then become diagnostic objects rather than replacements for a nonperturbative definition.

Definition 86.7 (Localization data)**.** Localization data for a supersymmetric functional integral consist of:

(i) a regulated integration space or integration cycle, including its orientation, boundary, singular strata, and gauge quotient if present;

(ii) an odd symmetry Q acting on the regulated variables, together with the precise bosonic transformation represented by Q^2;

(iii) a Q-invariant action and Q-closed observables;

(iv) a deformation $t\,QV$ whose convergence, boundary behavior, and large-t limit are controlled;

(v) the fixed locus of Q, its normal complex, zero modes, and determinant or Euler-class prescription;

(vi) a contour or residue prescription for remaining finite-dimensional integrals, including the rule used at singular hyperplane arrangements.

Finite-dimensional equivariant localization is a theorem only after the geometric hypotheses of the theorem have been stated. An infinite-dimensional supersymmetric path integral inherits no automatic theorem from this analogy. One must specify the regulator or finite-dimensional approximation, prove or assume the absence of boundary contributions, and describe singular loci. In particular, Jeffrey–Kirwan residues are contour prescriptions tied to hyperplane arrangements and chamber choices. A definition of the original path integral requires the regulator, contour, boundary behavior, and singular loci. Likewise, zero-size gauge instantons are points on a singular compactification or boundary of a moduli space; whether they are legitimate integration objects depends on the chosen compactification, measure, and local QFT interpretation.

In finite-dimensional reductions of gauge theories, a Jeffrey–Kirwan residue typically appears after abelianization or gauge fixing has replaced part of the integral by a meromorphic form on the complexified Cartan algebra with hyperplane divisors from charged fluctuations. The chamber vector encodes orientation data such as a stability parameter, Fayet–Iliopoulos parameter, or contour at infinity. A QFT localization argument must therefore derive the meromorphic form and this chamber data from the regulated integration cycle; otherwise the residue is an additional prescription selecting one boundary value of a singular integral.

Open Problem 86.8 (Rigorous supersymmetric localization)*.* Develop supersymmetric localization in QFT from regulated localization data. The target is to identify when the localized integral is well-defined, when the deformation argument has no boundary contribution, how singular instanton strata and noncompact Coulomb or Higgs directions are compactified or excluded, and how residue prescriptions such as Jeffrey–Kirwan arise from the declared integration cycle rather than from a formal rule.

Chapter 87

Supersymmetric Gauge Theory

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter introduces supersymmetric gauge theory as field-variable data. The particle spectrum, vacuum structure, Wilsonian effective action, and nonperturbative dynamics are later constructions. We keep the gauge representative, the gauge-invariant observables, and the regularization scheme separate.

87.1 Gauge and Trace Conventions

This chapter uses the Hermitian-generator convention of Chapter 45. If $\mathrm{Lie}(G)$ is realized by anti-Hermitian matrices in a unitary representation, write

$$\mathfrak{g} := \mathrm{i}\ \mathrm{Lie}(G)$$

for the corresponding real vector space of Hermitian generators. Its compact Lie bracket in Hermitian coordinates is

$$[X, Y]_{\mathrm{H}} := -\mathrm{i}[X, Y], \qquad X, Y \in \mathfrak{g},$$

where the bracket on the right is the ordinary matrix commutator. Fix an invariant nondegenerate symmetric bilinear form $\mathrm{tr} : \mathfrak{g} \otimes \mathfrak{g} \to \mathbb{R}$. In trace-delta examples one chooses a basis t^a with $\mathrm{tr}(t^a t^b) = \delta^{ab}$.

In a local trivialization, a gauge field is a Hermitian $\mathfrak{g}$-valued one-form $A = A_\mu dx^\mu$, and the covariant derivative on a field in a unitary representation is

$$\nabla_\mu = \partial_\mu - \mathrm{i}A_\mu.$$

The curvature is

$$F_{\mu\nu} := \mathrm{i}[\nabla_\mu, \nabla_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu - \mathrm{i}[A_\mu, A_\nu].$$

Under a smooth gauge transformation $u : U \to G$,

$$A^u_\mu = uA_\mu u^{-1} + \mathrm{i}u\,\partial_\mu u^{-1}.$$

Curvature covariance and gauge-invariant densities. With the definitions above,

$$F^u_{\mu\nu} = uF_{\mu\nu}u^{-1}.$$

Consequently $\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$ and $\mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu})$ are local gauge-invariant scalar densities.

The transformation law for A_μ is equivalent to

$$\nabla^u_\mu = u\nabla_\mu u^{-1}$$

as an equality of differential operators. Therefore

$$F^u_{\mu\nu} = \mathrm{i}[\nabla^u_\mu, \nabla^u_\nu] = \mathrm{i}u[\nabla_\mu, \nabla_\nu]u^{-1} = uF_{\mu\nu}u^{-1}.$$

Invariance of the bilinear form gives $\mathrm{tr}(uXu^{-1}uYu^{-1}) = \mathrm{tr}(XY)$. Applying this to $X = F_{\mu\nu}$ and $Y = F^{\mu\nu}$, and then to $Y = \widetilde{F}^{\mu\nu}$, proves the two density statements.

The Yang–Mills coupling convention in this monograph is

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu}) + \frac{\theta}{32\pi^2}\,\mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu}) + \cdots,$$

where $\widetilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}$ in the stated orientation convention. This convention applies uniformly to $U(1)$, $U(N)$, and simple factors after the bilinear form has been fixed.

87.2 Vector Multiplet as Field Variables

Definition 87.1 (Off-shell vector multiplet)**.** An $\mathcal{N} = 1$ off-shell vector multiplet with gauge algebra $\mathfrak{g}$ consists locally of a connection A_μ, a Weyl spinor λ_α valued in $\mathfrak{g}_{\mathbb{C}}$, its conjugate $\bar{\lambda}_{\dot{\alpha}}$, and a real auxiliary field D valued in $\mathfrak{g}$. These are gauge-representative field variables. The physical local observables are gauge-invariant cohomological or operator classes after quantization.

In Wess–Zumino gauge, the supersymmetry transformations have the form

$$\delta A_\mu = \mathrm{i}\epsilon\sigma_\mu\bar{\lambda} - \mathrm{i}\lambda\sigma_\mu\bar{\epsilon},$$

$$\delta\lambda_\alpha = (\sigma^{\mu\nu}\epsilon)_\alpha F_{\mu\nu} + \mathrm{i}\epsilon_\alpha D, \qquad \delta D = -\epsilon\sigma^\mu D_\mu\bar{\lambda} - D_\mu\lambda\sigma^\mu\bar{\epsilon}.$$

Here $D_\mu X := \partial_\mu X - \mathrm{i}[A_\mu, X]$ for adjoint-valued component fields X. The displayed transformations are not bare supertranslations restricted to the Wess–Zumino slice. They are bare supertranslations followed by the compensating chiral gauge transformation that restores the representative (86.7).

Proposition 87.2 (Closure in Wess–Zumino gauge)**.** *Let $\mathcal{V}$ be a local formal neighbourhood in the space of real vector superfields, and let $\mathcal{S} \subset \mathcal{V}$ be the Wess–Zumino slice represented by (86.7). Assume the local slice and the compensating chiral gauge parameters are chosen in this neighbourhood. For each supersymmetry parameter ϵ, write*

$$\widehat{\delta}_\epsilon = \delta^0_\epsilon + \delta^{\mathrm{g}}_{\Lambda_\epsilon}$$

for the vector field tangent to $\mathcal{S}$, where δ^0_ϵ is the supertranslation vector field on $\mathcal{V}$, and $\delta^{\mathrm{g}}_{\Lambda_\epsilon}$ is the chiral gauge vector field with parameter $\Lambda_\epsilon(V)$. Then, on $\mathcal{S}$,

$$[\widehat{\delta}_{\epsilon_1}, \widehat{\delta}_{\epsilon_2}] = a^\rho \partial_\rho + \delta^{\mathrm{g}}_{\Omega_{12}}, \qquad a^\rho = 2\mathrm{i}\left(\epsilon_1 \sigma^\rho \bar{\epsilon}_2 - \epsilon_2 \sigma^\rho \bar{\epsilon}_1\right), \tag{87.1}$$

where Ω_{12} is a real residual ordinary gauge parameter determined by the two compensators and the slice condition. Equivalently, if $\Xi_{12} := \Omega_{12} + a^\rho A_\rho$, then for every adjoint-valued component field $X \in \{\lambda, \bar{\lambda}, D\}$,

$$[\widehat{\delta}_{\epsilon_1}, \widehat{\delta}_{\epsilon_2}]X = a^\rho D_\rho X + \mathrm{i}[\Xi_{12}, X],$$

and for the connection

$$[\widehat{\delta}_{\epsilon_1}, \widehat{\delta}_{\epsilon_2}]A_\mu = a^\rho F_{\rho\mu} + D_\mu \Xi_{12}.$$

No Euler–Lagrange equation is used; the closure is off shell because the auxiliary field D is part of the coordinate system.

Proof. On the full real-vector-superfield space $\mathcal{V}$, the supertranslation vector fields obey the algebra derived in Chapter 86:

$$[\delta^0_{\epsilon_1}, \delta^0_{\epsilon_2}] = a^\rho \partial_\rho.$$

Let $\mathcal{D}_{\mathrm{g}}$ be the vertical distribution generated by chiral gauge transformations. This distribution is involutive because chiral gauge transformations form a group, and it is preserved by supertranslations: if $\bar{D}_{\dot{\alpha}}\Lambda = 0$, then the supertranslation of Λ is again a chiral gauge parameter. Field dependence of $\Lambda_\epsilon(V)$ does not change this conclusion; differentiating a chiral gauge parameter along any tangent vector in field space still gives a chiral gauge parameter. Therefore every term in the commutator

$$[\delta^0_{\epsilon_1} + \delta^{\mathrm{g}}_{\Lambda_{\epsilon_1}}, \delta^0_{\epsilon_2} + \delta^{\mathrm{g}}_{\Lambda_{\epsilon_2}}]$$

except the bare supertranslation commutator is vertical. Hence the commutator of the projected vector fields equals $a^\rho \partial_\rho$ modulo a chiral gauge vector field.

Both $\widehat{\delta}_{\epsilon_i}$ are tangent to the Wess–Zumino slice, so their commutator is tangent to that slice. A vertical vector field that is tangent to the Wess–Zumino slice is precisely the residual ordinary gauge transformation left after the components C, χ, M of a general real vector superfield have been removed. This gives (87.1). In Hermitian-generator conventions an infinitesimal residual gauge parameter Ω acts by

$$\delta^{\mathrm{g}}_\Omega A_\mu = D_\mu \Omega, \qquad \delta^{\mathrm{g}}_\Omega X = \mathrm{i}[\Omega, X]$$

on adjoint component fields. The alternative covariant form follows from the identity

$$a^\rho \partial_\rho A_\mu + D_\mu \Omega = a^\rho F_{\rho\mu} + D_\mu(\Omega + a^\rho A_\rho),$$

which uses $F_{\rho\mu} = \partial_\rho A_\mu - \partial_\mu A_\rho - \mathrm{i}[A_\rho, A_\mu]$ and $D_\mu Y = \partial_\mu Y - \mathrm{i}[A_\mu, Y]$. This proves the stated closure without a component equation of motion. □

Thus Wess–Zumino gauge is not a gauge-invariant description of supersymmetry; it is a convenient representative after ordinary gauge freedom has been partly fixed.

87.3 Superfield Strength

Let V be a real vector superfield. For matrix notation in a representation of G, a chiral gauge transformation acts by

$$e^V \longmapsto e^{-\bar{\Lambda}} e^V e^{-\Lambda}, \qquad \bar{D}_{\dot{\alpha}} \Lambda = 0.$$

The chiral field strength is

$$W_\alpha = -\frac{1}{4} \bar{D}^2 \left(e^{-V} D_\alpha e^V \right), \qquad \bar{D}_{\dot{\alpha}} W_\beta = 0.$$

It transforms covariantly,

$$W_\alpha \longmapsto e^{\Lambda} W_\alpha e^{-\Lambda}.$$

Consequently $\mathrm{tr}(W^\alpha W_\alpha)$ is a chiral gauge-invariant local superfield. With the trace convention fixed above, the gauge kinetic term is normalized so that its component expansion contains the Yang–Mills term

$$-\frac{1}{4g^2} \, \mathrm{tr}(F_{\mu\nu} F^{\mu\nu}).$$

All later anomaly and beta-function formulae must refer back to this coupling normalization.

87.4 Matter Multiplets and the Moment Map

Let R be a finite-dimensional unitary complex representation of G. A chiral matter multiplet is a chiral superfield Φ valued in R. Gauge covariance of the kinetic term is expressed by

$$\int d^4\theta \, \bar{\Phi} e^V \Phi.$$

In components this term contains the scalar kinetic term, fermion kinetic term, gauge couplings, and the auxiliary coupling

$$\langle \mu_R(\phi, \bar{\phi}), D \rangle,$$

where $\mu_R \in \mathfrak{g}^*$ is the moment map determined by

$$\langle \mu_R(\phi, \bar{\phi}), X \rangle = \phi^\dagger X_R \phi, \qquad X \in \mathfrak{g}.$$

Here X_R is the Hermitian generator acting in R. A Fayet–Iliopoulos parameter is a linear functional $\zeta \in \mathfrak{g}^*$ satisfying

$$\zeta([X, Y]_{\mathrm{H}}) = 0, \qquad X, Y \in \mathfrak{g},$$

so it factors through the abelian quotient of $\mathfrak{g}$. In particular there is no FI parameter for a semisimple gauge algebra.

Auxiliary D-field elimination. Let $\eta = \mu_R(\phi, \bar{\phi}) - \zeta$, with $\zeta = 0$ if no FI parameter is allowed. Use the bilinear form to define $\eta^\sharp \in \mathfrak{g}$ by

$$\mathrm{tr}(\eta^\sharp X) = \langle \eta, X \rangle \quad \text{for every } X \in \mathfrak{g}.$$

For fixed scalar fields, the auxiliary part of the Lorentzian Lagrangian is

$$\mathcal{L}_D = \frac{1}{2g^2}\,\mathrm{tr}(D^2) + \langle \eta, D\rangle.$$

Eliminating D gives

$$D = -g^2\eta^\sharp, \qquad \mathcal{L}_D\big|_{\text{on shell}} = -\frac{g^2}{2}\,\mathrm{tr}(\eta^\sharp\eta^\sharp).$$

Thus the corresponding scalar potential contribution is

$$V_D = \frac{g^2}{2}\,\mathrm{tr}(\eta^\sharp\eta^\sharp)$$

in this convention.

By the definition of $\eta^\sharp$,

$$\mathcal{L}_D = \frac{1}{2g^2}\,\mathrm{tr}(D^2) + \mathrm{tr}(\eta^\sharp D).$$

Completing the square gives

$$\mathcal{L}_D = \frac{1}{2g^2}\,\mathrm{tr}\Big(D + g^2\eta^\sharp\Big)^2 - \frac{g^2}{2}\,\mathrm{tr}(\eta^\sharp\eta^\sharp).$$

The algebraic Euler–Lagrange equation is therefore $D + g^2\eta^\sharp = 0$. Substitution gives the displayed on-shell Lagrangian. Since Lorentzian scalar Lagrangians have the form kinetic minus potential, the potential is the positive final expression.

87.5 $\mathcal{N} = 2$ Gauge-Matter Coupling in $\mathcal{N} = 1$ Variables

We shall often use $\mathcal{N} = 1$ superfields to describe four-dimensional $\mathcal{N} = 2$ gauge theory. The translation is field-theoretic and does not use any string-theoretic construction. Its data are as follows. Let G be compact, let R be a finite-dimensional unitary representation, and choose the invariant trace form on $\mathfrak{g}$ used in the Yang–Mills kinetic term. An $\mathcal{N} = 2$ vector multiplet consists, in $\mathcal{N} = 1$ language, of the vector superfield V together with an adjoint chiral superfield

$$\Phi = \Phi^a T^a \in \mathfrak{g}_{\mathbb{C}}.$$

A hypermultiplet in R is represented by two chiral superfields

$$Q \in R, \qquad \widetilde{Q} \in R^\vee,$$

where $R^\vee$ is the algebraic dual representation. If $T^a_R \in \mathrm{End}(R)$ are the representation matrices, write

$$\Phi_R = \Phi^a T^a_R \in \mathrm{End}(R).$$

With canonical flat chiral-field metrics and the Yang–Mills coupling normalization already fixed in the vector kinetic term, the minimal $\mathcal{N} = 2$ gauge-matter superpotential is

$$W_{\mathcal{N}=2} = \sqrt{2}\,g_{\mathrm{YM}}\,\widetilde{Q}\,\Phi_R Q = \sqrt{2}\,g_{\mathrm{YM}}\,\Phi^a\,\widetilde{Q}\,T^a_R Q. \tag{87.2}$$

The coefficient in (87.2) is part of the normalization statement: rescaling $Q, \widetilde{Q}, \Phi$, or changing the trace convention, changes the displayed coefficient together with the kinetic terms and the gauge coupling. Additional flavor tensors or independent cubic coefficients are deformations of the $\mathcal{N} = 1$ theory; they are not the minimal $\mathcal{N} = 2$ gauge coupling.

Gauge invariance and F-term equations. Assume the preceding flat chiral-field metrics, and choose an orthonormal basis T^a for the trace form. Under a finite gauge transformation

$$Q \mapsto u_R Q, \qquad \widetilde{Q} \mapsto \widetilde{Q} u_R^{-1}, \qquad \Phi_R \mapsto u_R \Phi_R u_R^{-1},$$

the contraction $\widetilde{Q}\Phi_R Q$ is invariant. The corresponding scalar F-term potential is

$$V_F = 2g_{\mathrm{YM}}^2 \left(\|\varphi_R q\|_R^2 + \|\widetilde{q}\,\varphi_R\|_{R^\vee}^2 + \sum_a |\widetilde{q}\,T_R^a q|^2 \right),$$

where $q, \widetilde{q}, \varphi$ are the scalar components of $Q, \widetilde{Q}, \Phi$, and $\varphi_R = \varphi^a T_R^a$. Hence the F-flat equations are

$$\varphi_R q = 0, \qquad \widetilde{q}\,\varphi_R = 0, \qquad \widetilde{q}\,T_R^a q = 0 \quad \text{for every } a.$$

Gauge invariance is the finite-dimensional identity

$$(\widetilde{Q} u_R^{-1})(u_R \Phi_R u_R^{-1})(u_R Q) = \widetilde{Q}\Phi_R Q.$$

Let $c = \sqrt{2}\, g_{\mathrm{YM}}$. In coordinates,

$$W = c\, \widetilde{q}_i (\varphi_R)^i{}_j q^j = c\, \varphi^a\, \widetilde{q}_i (T_R^a)^i{}_j q^j.$$

Differentiating with respect to the three independent chiral coordinates gives

$$\frac{\partial W}{\partial \widetilde{q}_i} = c(\varphi_R q)^i, \qquad \frac{\partial W}{\partial q^j} = c(\widetilde{q}\,\varphi_R)_j, \qquad \frac{\partial W}{\partial \varphi^a} = c\, \widetilde{q}\, T_R^a q.$$

For canonical flat metrics the F-term potential is the squared norm of this holomorphic gradient. Since $|c|^2 = 2g_{\mathrm{YM}}^2$, the displayed potential follows, and its zero locus is precisely the simultaneous vanishing of the three displayed gradient components.

If R is the adjoint representation, the two chiral fields in the hypermultiplet are also adjoint-valued. Together with Φ they are the three adjoint chiral superfields of $\mathcal{N} = 4$ Yang–Mills written in $\mathcal{N} = 1$ language, and the cubic term above becomes the usual adjoint cubic after translating T_R^a into the adjoint action. The enhancement statement is a statement about the full kinetic, Yukawa, and auxiliary-field normalizations together with the cubic polynomial.

87.6 Gauge Anomalies as a Consistency Condition

The classical field-variable construction is not yet a quantum gauge theory. For a four-dimensional chiral gauge theory, gauge invariance of the quantum theory requires the perturbative gauge anomaly class to vanish. In a representation R, the cubic anomaly coefficient is the symmetric trilinear form

$$A_R(X, Y, Z) = \mathrm{Tr}_R(X_R \{Y_R, Z_R\}), \qquad X, Y, Z \in \mathfrak{g},$$

with the trace over chiral fermion variables. The local anomaly cancellation condition is

$$\sum_{\text{chiral fermions } i} A_{R_i} = 0$$

as an invariant symmetric trilinear form. Global anomalies and mixed anomalies require separate topological data and are not detected by this polynomial alone.

Conjugate-pair and real-representation cancellation. Let $R^\vee$ be the conjugate representation of a unitary representation R, in the Hermitian-generator convention. Then

$$A_{R^\vee} = -A_R.$$

Consequently a vectorlike pair $R \oplus R^\vee$ has zero perturbative local gauge anomaly. If R is equivalent to its conjugate representation, then $A_R = 0$. In particular, the adjoint gaugino in an $\mathcal{N} = 1$ vector multiplet gives no perturbative cubic gauge anomaly.

If T^a_R are Hermitian generators in R, then the conjugate representation has Hermitian generators

$$T^a_{R^\vee} = -(T^a_R)^*.$$

Therefore

$$\mathrm{Tr}_{R^\vee}\left(T^a_{R^\vee}\{T^b_{R^\vee}, T^c_{R^\vee}\}\right) = -\left[\mathrm{Tr}_R\left(T^a_R\{T^b_R, T^c_R\}\right)\right]^*.$$

The trace on the right is real because the anticommutator of Hermitian matrices is Hermitian and the invariant symmetric tensor is obtained by symmetrizing over a, b, c. Hence $A_{R^\vee} = -A_R$. The vectorlike statement follows by addition. If $R \simeq R^\vee$, anomaly coefficients are representation invariants, so $A_R = A_{R^\vee} = -A_R$, and $A_R = 0$. The adjoint representation of a compact Lie algebra is real, giving the last claim.

Open Problem 87.3 (Supersymmetric gauge theory with regulated Ward identities). Construct four-dimensional supersymmetric gauge theories with a regulator that states the gauge symmetry, supersymmetry transformations, BV master equation, local counterterm space, anomaly class, and decoupling limit at finite cutoff. This is the regulator-level input needed before exact Wilsonian statements about holomorphy, moduli spaces, and duality can be treated as quantum statements rather than coordinate calculations.

Chapter 88

Supersymmetric Wilsonian Schemes and Exact Dynamics

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Exact statements in supersymmetric QFT require a declared Wilsonian scheme. The scheme is the data that define which modes are integrated out, which local coordinates are used for the resulting action, which Ward identities hold at finite cutoff, and which anomaly classes obstruct stronger statements. Supersymmetry of the Wilsonian integration and supersymmetry of the regulator are separate requirements.

88.1 Wilsonian Data

Definition 88.1 (Supersymmetric Wilsonian datum)**.** A supersymmetric Wilsonian datum at scale Λ consists of: a space $\mathcal{E}_\Lambda$ of regulated superfield variables, a gauge group action together with either a BV gauge complex or a lattice gauge-field construction, a projection $\pi_{\Lambda\Lambda'} : \mathcal{E}_\Lambda \to \mathcal{E}_{\Lambda'}$ for $\Lambda > \Lambda'$, an integration cycle in the discarded variables, and a local action functional S_Λ satisfying the declared gauge and supersymmetry Ward identities at finite cutoff.

If the gauge symmetry is present, the natural finite-cutoff statement is a BV statement. Let $(\,\cdot\,,\,\cdot\,)_\Lambda$ be the odd BV bracket and Δ_Λ the regulated BV Laplacian. The quantum master equation is

$$\frac{1}{2}(S_\Lambda, S_\Lambda)_\Lambda - \mathrm{i}\hbar\, \Delta_\Lambda S_\Lambda = 0.$$

This equation is meaningful only after the regulator and the functional measure entering Δ_Λ have been specified. For a gauge-fixed supersymmetric Wilsonian path integral, gauge consistency is the same equation before restriction to the gauge-fixing Lagrangian submanifold. The gauge-fixed Slavnov–Taylor identities and supersymmetry Ward identities are obtained by restricting the BV half-density and applying BV Stokes. A Wilsonian coarse-graining step is gauge-consistent when it is a BV pushforward that sends a solution of the quantum master equation at Λ to a solution at Λ'.

A lattice supersymmetric gauge construction, when it exists, is the other finite-cutoff route: gauge fields are link variables, gauge invariance is exact at finite lattice spacing, and Wilsonian coarse graining is a blocking map for link variables or gauge-invariant observables. The obstruction is then shifted to the realization of supersymmetry, fermions, auxiliary variables, reflection positivity, and the continuum limit. The two routes are therefore complementary: BV is the continuum homological framework for gauge-compatible effective actions, while the lattice gives a compact gauge-invariant finite integral.

88.2 Coarse Graining as BV Pushforward

For $\Lambda > \Lambda'$, a Wilsonian step must be defined before one writes an action $S_{\Lambda'}$. The object naturally transported by BV integration is not the action itself but the BV half-density

$$\rho_\Lambda = \exp\left(\frac{\mathrm{i}}{\hbar} S_\Lambda\right) \mu_\Lambda^{1/2},$$

where $\mu_\Lambda^{1/2}$ is the chosen regulated half-density. The quantum master equation is

$$\Delta_\Lambda \rho_\Lambda = 0,$$

equivalently the displayed equation for S_Λ when Δ_Λ is written using $\mu_\Lambda^{1/2}$.

Definition 88.2 (Admissible BV Wilsonian step)**.** An admissible BV Wilsonian step from Λ to Λ' consists of the following finite-cutoff data.

(i) A split exact sequence of odd symplectic spaces

$$0 \longrightarrow K_{\Lambda\Lambda'} \longrightarrow \mathcal{E}_\Lambda \xrightarrow{p_{\Lambda\Lambda'}} \mathcal{E}_{\Lambda'} \longrightarrow 0$$

such that, after choosing the splitting,

$$\omega_\Lambda = \omega_{\Lambda'} \oplus \omega_{K_{\Lambda\Lambda'}}, \qquad \Delta_\Lambda = \Delta_{\Lambda'} + \Delta_{K_{\Lambda\Lambda'}}.$$

(ii) A Lagrangian integration cycle $\mathcal{L}_{\Lambda\Lambda'} \subset K_{\Lambda\Lambda'}$ for the odd symplectic form on the eliminated variables, together with an orientation or Berezinian convention fixing the fiber integral.

(iii) A convergence or oscillatory-integral prescription for which the fiber integral of the half-density is defined and for which differentiation by $\Delta_{\Lambda'}$ may be interchanged with the fiber integral.

(iv) A BV boundary condition:

$$\int_{\mathcal{L}_{\Lambda\Lambda'}} \Delta_{K_{\Lambda\Lambda'}} \alpha = 0 \tag{88.1}$$

for every half-density α in the class generated by the Wilsonian integrand and by the variations used in Ward identities.

(v) If supersymmetry is required at the cutoff, the regulated supersymmetry generators preserve the split BV structure and the cycle up to a deformation whose boundary term satisfies (88.1).

The adjective "admissible" is load-bearing. Item (i) supplies a genuine BV factorization of fields, ghosts, antifields, and possible auxiliary variables; a projection of bosonic gauge potentials alone is only a map of coordinates. Item (ii) chooses the integration cycle for the eliminated variables, and item (iii) supplies the analytic meaning of the fiber integral. Item (iv) is the finite-cutoff form of the statement that integrating a BV divergence over the eliminated variables produces no boundary contribution. In perturbative language this condition is where the regulator, gauge fixing, contour, and large-field behavior of the effective integration cycle enter. Supersymmetry at the cutoff is an extra compatibility datum in item (v): the regulated supercharges must act on the full BV complex and preserve the admissible cycle up to a BV-exact deformation with vanishing boundary term. The construction of such data is the substantive problem in a supersymmetric Wilsonian scheme. The local coordinate calculation behind item (iv) is the following finite-dimensional BV Stokes calculation.

BV Stokes in a finite-cutoff Darboux chart. Let K be a finite-dimensional odd symplectic space with Darboux coordinates x^i, ξ_i and BV Laplacian

$$\Delta_K = \sum_i \frac{\partial^2}{\partial x^i \partial \xi_i}$$

on functions multiplying the standard half-density. If the Lagrangian cycle is locally $\xi_i = 0$, then

$$\int_{\xi=0} \Delta_K \alpha = \int_{\partial(\xi=0)} \sum_i \left.\frac{\partial \alpha}{\partial \xi_i}\right|_{\xi=0} \iota_{\partial/\partial x^i}(dx^1 \cdots dx^n).$$

In particular, the integral vanishes for compact boundaryless cycles and for noncompact cycles on which the boundary term at infinity is zero. The same statement in another Darboux chart follows by the invariance of the BV Laplacian on half-densities under canonical coordinate changes. Indeed, on $\xi = 0$,

$$\Delta_K \alpha|_{\xi=0} = \sum_i \frac{\partial}{\partial x^i} \left.\frac{\partial \alpha}{\partial \xi_i}\right|_{\xi=0}.$$

Integration over the x-cycle converts this ordinary divergence into the displayed boundary integral. The vanishing criterion is the usual Stokes theorem applied to the integration cycle, expressed in BV half-density coordinates. Since half-density BV integration is defined invariantly, a general Lagrangian chart gives the same formula after a canonical change of Darboux coordinates. Thus the real input in an admissible Wilsonian step is the existence of a cycle and regulator for which this boundary functional vanishes.

The Wilsonian pushforward associated to these data is

$$(p_{\Lambda\Lambda'})_* \rho_\Lambda(\phi') = \int_{\mathcal{L}_{\Lambda\Lambda'}} \rho_\Lambda(\phi', \chi). \tag{88.2}$$

Only after this half-density has been computed and a nonvanishing reference half-density $\mu_{\Lambda'}^{1/2}$ has been chosen do we write

$$(p_{\Lambda\Lambda'})_*\rho_\Lambda = \exp\left(\frac{\mathrm{i}}{\hbar} S_{\Lambda'}\right)\mu_{\Lambda'}^{1/2}.$$

The logarithm is therefore a coordinate choice on half-densities; the semigroup law is first a statement about pushforwards.

Proposition 88.3 (BV pushforward preserves the quantum master equation)**.** *For an admissible BV Wilsonian step,*

$$\Delta_\Lambda\rho_\Lambda = 0 \qquad \Longrightarrow \qquad \Delta_{\Lambda'}(p_{\Lambda\Lambda'})_*\rho_\Lambda = 0.$$

Proof. Write the high variables as $K_{\Lambda\Lambda'}$, so that the admissible step supplies a factorization

$$\Delta_\Lambda = \Delta_{\Lambda'} + \Delta_{K_{\Lambda\Lambda'}}$$

on half-densities in the chosen finite-cutoff Darboux atlas. The residual operator $\Delta_{\Lambda'}$ differentiates only the unintegrated variables, so it commutes with the convergent fiber integral:

$$\Delta_{\Lambda'}(p_{\Lambda\Lambda'})_*\rho_\Lambda = \int_{\mathcal{L}_{\Lambda\Lambda'}} \Delta_{\Lambda'}\rho_\Lambda = \int_{\mathcal{L}_{\Lambda\Lambda'}} \left(\Delta_\Lambda - \Delta_{K_{\Lambda\Lambda'}}\right)\rho_\Lambda.$$

The term containing $\Delta_\Lambda\rho_\Lambda$ vanishes by the quantum master equation at scale Λ. The remaining term is a BV divergence in the integrated variables. In a Darboux chart it is exactly the boundary functional displayed above, and the coordinate-independent form of this vanishing is the admissibility condition (88.1). Hence no residual boundary semidensity is left on the low variables. The proposition proves preservation of the QME for a declared admissible step; it does not construct the regulator or the supersymmetric integration cycle. □

For gauge theories, this BV compatibility or a lattice blocking construction is part of the definition of the Wilsonian step. A projection of gauge potentials by itself does not define a gauge-theory coarse graining; the projection must be lifted to the full ghost-antifield complex with a compatible half-density and integration cycle, or replaced by a finite gauge-invariant lattice blocking map. When a gauge fixing or a supersymmetric regulator changes with Λ, the change is harmless only if it is represented by an admissible BV isotopy of cycles; otherwise the failure of (88.1) is precisely a Ward-identity anomaly of the scheme.

Definition 88.4 (Composable BV Wilsonian tower)**.** For $\Lambda > \Lambda' > \Lambda''$, an admissible tower is composable if the chosen splittings identify

$$\mathcal{E}_\Lambda \simeq \mathcal{E}_{\Lambda''} \oplus K_{\Lambda'\Lambda''} \oplus K_{\Lambda\Lambda'}$$

as odd symplectic spaces, if

$$\mathcal{L}_{\Lambda\Lambda''} = \mathcal{L}_{\Lambda'\Lambda''} \times \mathcal{L}_{\Lambda\Lambda'}$$

with the product Berezinian convention, and if the corresponding ordinary or oscillatory Fubini theorem holds for the Wilsonian half-density and its BV variations.

Semigroup property of a composable BV Wilsonian tower. For a composable BV Wilsonian tower,

$$(p_{\Lambda'\Lambda''})_*(p_{\Lambda\Lambda'})_*\rho_\Lambda = (p_{\Lambda\Lambda''})_*\rho_\Lambda.$$

Consequently, in any action coordinate for which the three half-densities are written as $\rho_\bullet = \exp(\mathrm{i}S_\bullet/\hbar)\mu_\bullet^{1/2}$, the Wilsonian maps obey

$$S_{\Lambda''} = \mathcal{R}_{\Lambda'\Lambda''}\big(\mathcal{R}_{\Lambda\Lambda'}(S_\Lambda)\big) = \mathcal{R}_{\Lambda\Lambda''}(S_\Lambda)$$

up to the additive normalization constants fixed by the chosen reference half-densities. For a test point $\phi'' \in \mathcal{E}_{\Lambda''}$, the iterated pushforward is

$$\int_{\mathcal{L}_{\Lambda'\Lambda''}}\left(\int_{\mathcal{L}_{\Lambda\Lambda'}}\rho_\Lambda(\phi'',\eta,\chi)\right),$$

where $\eta \in K_{\Lambda'\Lambda''}$ and $\chi \in K_{\Lambda\Lambda'}$. By the Fubini part of Definition 88.4, this equals

$$\int_{\mathcal{L}_{\Lambda'\Lambda''}\times\mathcal{L}_{\Lambda\Lambda'}}\rho_\Lambda(\phi'',\eta,\chi).$$

The product cycle is, by definition, the direct cycle $\mathcal{L}_{\Lambda\Lambda''}$. This is exactly the direct pushforward. The equality of actions follows only after passing from half-densities to the chosen action coordinates; any field-independent determinant factor is an additive constant in S and is fixed by the normalization convention.

Finite circle-Darboux model of BV pushforward. Let the base variables be a periodic even coordinate y and its odd BV partner η, and let the eliminated variables be a periodic even coordinate x and its odd BV partner ξ. Work on the finite algebra generated by finitely many Fourier modes

$$e^{imy}e^{inx}, \qquad m,n\in\mathbb{Z},$$

and by the odd variables η,ξ. Define

$$\Delta_B = \frac{\partial}{\partial y}\frac{\partial^L}{\partial\eta}, \qquad \Delta_K = \frac{\partial}{\partial x}\frac{\partial^L}{\partial\xi}, \qquad \Delta = \Delta_B + \Delta_K.$$

Let the fiber pushforward be the normalized circle integral over the Lagrangian cycle $\xi = 0$:

$$P(\alpha)(y,\eta) = \int_{S^1_x}\alpha(y,\eta,x,0)\,\frac{dx}{2\pi}.$$

Then

$$P(\Delta_K\alpha) = 0, \qquad P(\Delta\alpha) = \Delta_B P(\alpha). \tag{88.3}$$

Consequently, if $\Delta\alpha = 0$, then $\Delta_B P(\alpha) = 0$. If two eliminated circle-Darboux pairs are present and the product cycle is used, then the corresponding pushforwards commute and equal the direct product pushforward. It is enough to check a monomial

$$\alpha = c\,e^{imy}e^{inx}\eta^a\xi^b, \qquad a,b\in\{0,1\}.$$

If $b=0$, then $\partial^L\alpha/\partial\xi = 0$, so $P(\Delta_K\alpha)=0$. If $b=1$, then $\Delta_K\alpha$ is n times a Fourier mode e^{inx} with no ξ-factor. The normalized circle integral of a nonzero derivative mode vanishes, and the $n=0$

mode has derivative coefficient $n = 0$. Thus $P(\Delta_K \alpha) = 0$ in all cases. Since Δ_B differentiates only the base variables, it commutes with the normalized x-integral and with setting $\xi = 0$. This proves (88.3).

For two eliminated pairs, each pushforward selects the zero Fourier mode in its own even variable and the coefficient with no corresponding odd fiber variable. These two coefficient extractions act on disjoint variables, so their order is irrelevant and the result is the same as extracting both at once. This is the finite Fourier model of the Fubini and product-cycle assumption in Definition 88.4.

88.3 Local Coordinates: F-Terms and D-Terms

For four-dimensional $\mathcal{N} = 1$ theories, local supersymmetric functionals split by superspace measure:

$$\int d^4x\, d^2\theta\, \mathcal{F}(\Phi, W_\alpha, \nabla) + \int d^4x\, d^4\theta\, \mathcal{K}(\Phi, \bar{\Phi}, V, \nabla).$$

The first class is called F-term coordinates and the second class D-term coordinates. This coordinate decomposition becomes a statement about dynamics only after a Wilsonian scheme and its Ward identities have been specified. The gauge kinetic coordinate is the chiral functional

$$\frac{1}{16\pi \mathrm{i}} \int d^4x\, d^2\theta\, \tau\, \operatorname{tr}(W^\alpha W_\alpha) + \text{c.c.}, \qquad \tau = \frac{\theta}{2\pi} + \frac{4\pi \mathrm{i}}{g^2},$$

with the trace normalization fixed in Chapter 87. If a different superspace normalization for W_α is chosen, the displayed coefficient is changed by the component-matching factor; the physical convention is the component Yang–Mills term $-\frac{1}{4g^2} \operatorname{tr} F^2$.

88.4 Holomorphic Wilsonian Claims

Hypothesis 88.5 (Holomorphic Wilsonian scheme)**.** A Wilsonian scheme is holomorphic for a set of chiral couplings t^A if the regulated chiral action depends holomorphically on t^A, the coarse-graining map preserves the chiral superspace cohomology class of local F-terms, and all violations of holomorphy are represented by declared local anomaly functionals.

Under this hypothesis, nonrenormalization statements become statements about coordinates. A superpotential coordinate

$$\int d^4x\, d^2\theta\, W_{\text{tree}}(\Phi; t)$$

can receive only those Wilsonian corrections that are holomorphic functions of the chiral coordinates, respect the exact symmetries including anomalous spurion transformations, and are local at scale Λ. The selection-rule arguments are replaced here by these three stated conditions.

Selection rule for a Wilsonian F-term. Assume Hypothesis 88.5. Let $\mathcal{U}(t, \Phi)$ be a candidate correction to a chiral F-term. If $\mathcal{U}$ is not a holomorphic section of the same symmetry line bundle as the original chiral measure and operator insertion, then it is absent from the Wilsonian F-term coordinate in that scheme. The Wilsonian F-term coordinate is, by hypothesis, a holomorphic element of the chiral local cohomology with specified transformation under exact and anomalous symmetries. Local terms with different transformation law lie in a different line bundle over the coupling space. They cannot be added to the coordinate without violating the Ward identity defining the scheme. Thus only holomorphic sections with the same transformation law are admissible.

88.5 Exact Dynamics as a Scheme-Dependent Statement

The chiral ring at scale Λ is the cohomology of local chiral operators modulo $\bar{Q}$-exact operators and equations of motion in the Wilsonian scheme. A moduli space statement is an assertion about expectation values of this ring in supersymmetric states together with the effective action governing fluctuations. A duality statement is an isomorphism between two such Wilsonian data, including line operators, anomalies, contact terms, and relevant deformations.

Open Problem 88.6 (Wilsonian construction). Construct a Wilsonian scheme for four-dimensional gauge theories that preserves gauge invariance, realizes supersymmetry in BV form at finite cutoff, states the anomaly functionals, and proves the holomorphic hypotheses used in exact dynamics. This is the infrastructure needed for proofs of $\mathcal{N} = 1$ and $\mathcal{N} = 2$ gauge dynamics.

Chapter 89

Nonrenormalization and Holomorphy

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Nonrenormalization arguments are statements about Wilsonian coordinates in a scheme with declared supersymmetry, gauge symmetry, locality, and anomaly data. This chapter formulates the perturbative superpotential argument, the holomorphic gauge-coupling coordinate, and the passage to the NSVZ beta-function coordinate in the language of Chapter 88.

89.1 Chiral Local Coordinates

Let Φ^i be chiral superfields and t^A chiral coupling coordinates. A Wilsonian chiral coordinate is a local functional of the form

$$I_F[\Phi; t] = \int d^4x \, d^2\theta \, \mathcal{W}(\Phi; t) + \text{c.c.}$$

defined modulo $\bar{D}_{\dot{\alpha}}$-exact full-superspace terms and equations of motion appropriate to the chosen Wilsonian action. A full superspace coordinate is

$$I_D[\Phi, \bar{\Phi}; t, \bar{t}] = \int d^4x \, d^4\theta \, \mathcal{K}(\Phi, \bar{\Phi}; t, \bar{t}).$$

The distinction is cohomological: an F-term is represented by a chiral integrand and the chiral measure, while a D-term is represented by the full superspace measure.

89.2 Perturbative Superpotential Argument

Controlled Approximation 89.1 (Perturbative Wilsonian superpotential argument)**.** Assume a massive or Wilsonian infrared-regulated $\mathcal{N} = 1$ theory in a holomorphic Wilsonian scheme. Perturbative loop corrections do not generate new superpotential terms beyond those already present as holomorphic local coordinates, except through tree-level elimination of massive chiral fields and through explicitly declared anomaly-induced coordinate changes.

The mechanism is a finite statement about the Grassmann part of a regulated supergraph. Consider one connected loop supergraph after every chiral vertex has been written as a full-superspace integral with the usual covariant spinor derivatives on Grassmann delta functions. The graph has a vertex variable θ_v at each vertex. Choose a spanning tree. The delta functions on the tree identify all θ_v's and leave one integration

$$\int d^4\theta.$$

The remaining, non-tree, propagators are precisely the loop propagators. Their spinor derivatives may be integrated by parts until they act on external superfields or on the remaining Grassmann delta functions. The algebra

$$\{D_\alpha, \bar{D}_{\dot\beta}\} = -2i\sigma^\mu_{\alpha\dot\beta}\partial_\mu$$

then converts closed derivative strings into spacetime momenta and residual covariant derivatives. Thus the local Wilsonian contribution of a loop graph is represented by a full-superspace local density

$$\int d^4x\, d^4\theta\, \mathcal{K}_\Gamma(\Phi, \bar\Phi, D, \bar{D}, \partial; \Lambda).$$

The only possible escape from this conclusion is nonlocality. A nonzero chiral F-term class can be extracted from a full-superspace expression by using a chiral projector, but in flat superspace such a projector contains an inverse d'Alembertian. On the standard projector domain it is represented by

$$P_{\text{ch}} = \frac{\bar{D}^2 D^2}{16\Box}.$$

The inverse $\Box$ is exactly the signal of an infrared singularity in the external momenta. A Wilsonian effective action at scale Λ integrates out modes above Λ and expands its low-momentum kernels in nonnegative powers of p/Λ; it does not contain the $1/p^2$ pole needed to turn the full-superspace loop density into a local chiral density. The familiar exceptions in a massless 1PI effective action are therefore not exceptions to the Wilsonian statement: they use the infrared pole that the Wilsonian coordinate chart has deliberately excluded.

Consequently perturbative loop corrections in the declared Wilsonian patch are full-superspace local coordinates. Tree-level elimination of massive chiral fields is different: it substitutes the solution of a chiral equation of motion into the existing superpotential and hence stays within the chiral coordinate class. Anomaly-induced coordinate changes are also different: their chiral terms come from the regulated Berezinian of a change of variables, not from a loop correction to the superpotential. These are precisely the declared exceptions in the scheme data.

Tree-level chiral elimination. Let the chiral coordinates split as (X^a, Φ^i), where the X^a are massive in a Wilsonian patch. Suppose the holomorphic equations

$$\partial_{X^a} W(X, \Phi; t) = 0$$

have, on this patch, a unique holomorphic solution

$$X^a = X^a_*(\Phi; t),$$

and suppose the heavy-block Hessian

$$H_{ab} = \partial_{X^a}\partial_{X^b} W(X_*, \Phi; t)$$

is invertible there. Then the tree-level eliminated superpotential

$$W_{\text{eff}}(\Phi; t) = W(X_*(\Phi; t), \Phi; t)$$

is holomorphic in the remaining chiral coordinates and couplings, and its first derivatives are

$$\partial_{\Phi^i} W_{\text{eff}} = \partial_{\Phi^i} W|_{X=X_*}\,. \tag{89.1}$$

In the quadratic special case

$$W(X, \Phi; t) = W_0(\Phi; t) + J_a(\Phi; t)X^a + \frac{1}{2}M_{ab}(\Phi; t)X^a X^b, \qquad \det M \neq 0,$$

one has

$$X^a_* = -(M^{-1})^{ab} J_b, \qquad W_{\text{eff}} = W_0 - \frac{1}{2}J_a(M^{-1})^{ab}J_b. \tag{89.2}$$

The hypotheses are precisely those of the holomorphic implicit-function theorem applied to the map

$$F_a(X, \Phi; t) = \partial_{X^a} W(X, \Phi; t).$$

Invertibility of $H_{ab} = \partial F_a/\partial X^b$ at the solution gives a unique holomorphic solution $X_*(\Phi; t)$ after possibly shrinking the patch. Composing the holomorphic functions W and X_* gives a holomorphic W_{eff}. The chain rule gives

$$\partial_{\Phi^i} W_{\text{eff}} = \partial_{\Phi^i} W|_{X=X_*} + \partial_{X^a} W|_{X=X_*}\, \partial_{\Phi^i} X^a_*.$$

The second term vanishes by the heavy-field equation of motion, proving (89.1).

For the quadratic representative, the heavy-field equation is

$$J_a + M_{ab}X^b = 0,$$

so $X^a_* = -(M^{-1})^{ab}J_b$. Substitution gives

$$W_{\text{eff}} = W_0 - J_a(M^{-1})^{ab}J_b + \frac{1}{2}M_{ab}(M^{-1})^{ac}J_c(M^{-1})^{bd}J_d = W_0 - \frac{1}{2}J_a(M^{-1})^{ab}J_b,$$

where symmetry of $M_{ab} = \partial_a\partial_b W$ is used in the last step. If $\det M$ vanishes, the patch contains an additional massless chiral coordinate and the elimination is no longer a Wilsonian tree-level operation in this sense.

89.3 Spurion Symmetries

Treat a coupling t^A as a background chiral superfield. If an exact symmetry acts by

$$\Phi^i \mapsto e^{\mathrm{i}q^i\alpha}\Phi^i, \qquad t^A \mapsto e^{\mathrm{i}q^A\alpha}t^A,$$

then a Wilsonian F-term must be a holomorphic section with the same total charge as the chiral measure. This turns dimensional analysis and symmetries into a finite problem: list holomorphic monomials in fields and couplings with the required charges and locality degree. The conclusion is only as strong as the declared symmetry and anomaly accounting.

89.4 Holomorphic Gauge Coupling

For a gauge theory with chiral matter, the holomorphic gauge coordinate is

$$\frac{1}{16\pi\mathrm{i}}\int d^4x\, d^2\theta\, \tau(\Lambda)\,\mathrm{tr}(W^\alpha W_\alpha) + \text{c.c.}$$

The trace convention is the one fixed in Chapter 87. Thus

$$b_0 = 3C_2(G) - \sum_i T(R_i)$$

for chiral matter representations R_i. The indices are defined by

$$\mathrm{Tr}_{R_i}(XY) = T(R_i)\,\mathrm{tr}(XY), \qquad \mathrm{Tr}_{\mathrm{ad}}(XY) = C_2(G)\,\mathrm{tr}(XY).$$

The displayed b_0 is supplied by the regulated background-field one-loop determinant in the declared holomorphic Wilsonian coordinate. In a supersymmetric background-gauge calculation the shell contribution to the chiral gauge kinetic coordinate has the local form

$$\Delta X_h^{(1)} = \left(3C_2(G) - \sum_i T(R_i)\right)\log\frac{\Lambda}{\Lambda_0}, \tag{89.3}$$

with the same trace convention as the gauge kinetic term. The vector multiplet and its gauge-fixed ghost complex supply the $3C_2(G)$ term; a chiral matter multiplet in R_i supplies $-T(R_i)$. These are local heat-kernel or supergraph coefficients of the finite shell determinant. The holomorphy argument below uses this one-loop input to exclude further perturbative powers of the holomorphic weak-coupling coordinate.

The next proposition is conditional in an essential way. Its input is a weak-coupling Wilsonian patch with a chiral local gauge-kinetic coordinate and a spurion charge assignment in which all anomalous transformations have been accounted for. Establishing such a patch for a concrete regulator is part of the supersymmetric Wilsonian-definition problem; the holomorphy argument below then determines the perturbative scale dependence of that declared coordinate.

Proposition 89.2 (Wilsonian one-loop exactness of the holomorphic gauge coordinate)**.** *Work in a weak-coupling Wilsonian patch in which:*

(i) the gauge kinetic coefficient is a chiral local coordinate $\tau_{\mathrm{eff}}(\mu)$, holomorphic in the microscopic chiral couplings;

(ii) the theta-angle periodicity is represented by $\tau \mapsto \tau + 1$, so scale derivatives of the gauge kinetic coordinate are single-valued holomorphic functions of

$$q_h := \exp(2\pi\mathrm{i}\tau);$$

(iii) the perturbative sector is the q_h^0 coefficient in the expansion near $q_h = 0$; positive powers of q_h are instanton sectors and negative powers are excluded from the weak-coupling Wilsonian patch;

(iv) the superpotential spurion charge assignment contains no additional anomalous chiral coordinate with the transformation law of the gauge kinetic term.

Then the perturbative Wilsonian running of the holomorphic coordinate is

$$\tau(\Lambda) = \tau(\Lambda_0) - \frac{b_0}{2\pi\mathrm{i}} \log \frac{\Lambda}{\Lambda_0}, \tag{89.4}$$

up to a finite Λ-independent holomorphic redefinition of the reference coordinate. Equivalently,

$$\mu \frac{d\tau_{\mathrm{eff}}^{\mathrm{pert}}}{d\mu} = -\frac{b_0}{2\pi\mathrm{i}}.$$

Proof. The statement concerns a Wilsonian chiral coordinate rather than the canonical two-point-function coupling. By locality and chirality, the scale derivative $\mu\, d\tau_{\mathrm{eff}}/d\mu$ is itself the coefficient of the local chiral operator $\mathrm{tr}(W^\alpha W_\alpha)$. It is dimensionless, holomorphic in the chiral couplings, and invariant under $\tau \mapsto \tau + 1$. On the weak-coupling patch it therefore has an expansion

$$\mu \frac{d\tau_{\mathrm{eff}}}{d\mu} = B_0(t) + \sum_{n \geq 1} B_n(t) q_h^n, \tag{89.5}$$

after excluding negative powers by the weak-coupling regularity hypothesis. The $n \geq 1$ terms are nonperturbative instanton sectors. The perturbative projection is the constant term $B_0(t)$.

The coefficient $B_0(t)$ is the perturbative constant term selected by the holomorphic q_h-expansion. Holomorphy and periodicity identify this term as the only perturbative part in the declared weak-coupling patch. Its value is fixed by the one-loop shell determinant (89.3). With the present convention

$$\tau = \frac{\theta}{2\pi} + \frac{4\pi\mathrm{i}}{g_h^2}, \qquad X_h := \frac{8\pi^2}{g_h^2} = 2\pi\, \mathrm{Im}\, \tau,$$

that determinant coefficient is the statement

$$\mu \frac{dX_h}{d\mu} = b_0.$$

Equivalently, $q_h = \exp(2\pi\mathrm{i}\tau)$ has

$$\mu \frac{d}{d\mu} \log q_h = -b_0,$$

so for $b_0 > 0$ the weak-coupling coordinate q_h decreases toward the ultraviolet. This is the asymptotic-freedom sign in the holomorphic coordinate. A perturbative contribution depending nontrivially on other chiral couplings would have to transform in the same affine way as τ. Hypothesis (iv) excludes such an additional coordinate. Hence

$$2\pi\mathrm{i} B_0 = -b_0,$$

or

$$B_0 = -\frac{b_0}{2\pi\mathrm{i}}.$$

Integrating in $\log\Lambda$ gives (89.4). A finite holomorphic change of the reference coordinate adds a Λ-independent function and does not change the derivative.

Canonical gauge couplings are different coordinates. Passing to them requires rescaling matter and gauge multiplets; the corresponding local Berezinian is the Konishi-type anomaly derived below. Thus the one-loop-exact statement here is compatible with higher-loop beta functions in canonical normalization. □

89.5 Konishi-Type Rescaling Anomaly

Let Φ be a chiral superfield valued in a unitary representation R of the gauge group. The representation index used in this section is fixed by

$$\mathrm{Tr}_R(XY) = T(R)\,\mathrm{tr}(XY), \qquad X, Y \in \mathfrak{g},$$

where tr is the same invariant form used in the Yang–Mills term $-\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$.

Proposition 89.3 (Konishi rescaling Jacobian)**.** *Assume a gauge-covariant supersymmetric finite-mode regulator, or a perturbative spectral regulator whose local heat-kernel coefficient agrees with the finite-mode Berezinian limit, for the chiral superfield $\Phi \in R$. Under the constant holomorphic field redefinition*

$$\Phi \mapsto e^{\alpha}\Phi$$

the gauge-field-dependent local part of the regulated super-Berezinian is equivalent to adding the chiral local functional

$$\Delta S = \frac{T(R)\alpha}{8\pi^2}\int d^4x\, d^2\theta\ \mathrm{tr}(W^{\alpha}W_{\alpha}) + c.c.$$

to the Wilsonian action, up to gauge-independent constants and local D-terms removable by the coordinate choice. For several chiral superfields the right hand side is summed over their representations and rescaling parameters.

Proof. The statement is a local Jacobian statement inside a specified regulator, not a property of a formal infinite-dimensional measure. First impose an infrared auxiliary regulator so that the kinetic operator has a discrete orthonormal basis. The odd component field ψ_α of Φ is a left Weyl fermion in R. Expanding it in a gauge-covariant finite set of modes gives odd coordinates c_n, and the ordered Berezinian density $\prod_n dc_n$ transforms by the inverse determinant of the finite matrix representing the change of variables. The scalar and auxiliary components produce ordinary determinants. Their gauge-dependent local contribution is a D-term or a gauge-independent normalization in a supersymmetric regulator; the chiral gauge-field-dependent term is fixed by the Weyl-fermion Berezinian.

The finite-mode calculation is the chiral half of the Berezinian trace in Chapter 51. Replacing the sharp finite-mode projector by the equivalent smooth gauge-covariant spectral regulator for the local coefficient gives

$$\log J^{\mathrm{loc}}_{\alpha,M} = \alpha\ \mathrm{Tr}_{R,S_+}\left[\Pi_+\ \exp(-\mathcal{D}_A^2/M^2)\right]_{\mathrm{loc}} + \text{anti-chiral part} + O(M^{-1}),$$

where S_+ is the left Weyl spinor bundle and $\mathcal{D}_A$ is the Dirac operator coupled to the same connection. The symbol $[\cdots]_{\mathrm{loc}}$ means the part depending locally on the background curvature after gauge-independent power divergences have been subtracted. The chiral asymmetry of the heat kernel is

$$\lim_{M\to\infty} \mathrm{tr}_S \left[\gamma_5 \exp(-\mathcal{D}_A^2/M^2)\right](x,x) = \frac{1}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{Tr}_R(F_{\mu\nu}F_{\rho\sigma}),$$

as in (51.8). Therefore the imaginary part of the Jacobian for the phase subcase $\alpha = \mathrm{i}\beta$ is the regulated Konishi-current anomaly of the left Weyl fermion in R. Using $\mathrm{Tr}_R(XY) = T(R)\,\mathrm{tr}(XY)$, its nontrivial curvature dependence is proportional to $T(R)\,\mathrm{tr}(F\wedge F)$.

It remains to identify the superspace representative of this local functional. The holomorphic part of the Jacobian must be a chiral, gauge-invariant, local functional, linear in α, quadratic in the background gauge field at leading order, and of engineering dimension three in the chiral integrand. In an $\mathcal{N}=1$ gauge background the unique such representative, modulo chiral total derivatives and D-terms, is

$$c\,\alpha \int d^4x\, d^2\theta\ \mathrm{tr}(W^\alpha W_\alpha).$$

The coefficient c is determined by the component anomaly just computed. With the superspace normalization of Chapter 87,

$$\frac{1}{16\pi\mathrm{i}}\tau \int d^4x\, d^2\theta\ \mathrm{tr}(W^\alpha W_\alpha) + \text{c.c.}$$

has component theta term $\frac{\theta}{32\pi^2}\,\mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu})$ when $\mathrm{Re}\,\tau = \theta/(2\pi)$. This fixes

$$c = \frac{T(R)}{8\pi^2}$$

in the action-shift convention of the proposition. The conjugate anti-chiral Berezinian gives the displayed c.c. term. Gauge-independent power-divergent constants and local full-superspace terms change the normalization of fields or the D-term coordinate and are not part of the Konishi chiral anomaly. □

Remark 89.4 (Meaning of the action-shift convention). The sign of a Jacobian may be moved between the transformed density and the action depending on whether one writes the change of variables as $\mathcal{D}\Phi = J\,\mathcal{D}\Phi'$ or $\mathcal{D}\Phi' = J^{-1}\mathcal{D}\Phi$, and on Lorentzian versus Euclidean weight conventions. Proposition 89.3 fixes ΔS by the convention used in the Wilsonian coordinate relation below: a holomorphic rescaling of matter fields shifts the holomorphic gauge coordinate by the amount encoded in the displayed $\frac{T(R)\alpha}{8\pi^2}\int W^2$ term. Ward identities obtained by varying the same change of variables carry the corresponding term on the opposite side if the Jacobian is kept in the measure instead of exponentiated into the action.

This anomaly explains why holomorphic Wilsonian couplings and canonically normalized couplings obey different coordinate beta functions. It is not a claim that a manifestly supersymmetric nonperturbative regulator has been constructed for every four-dimensional supersymmetric gauge theory; it is a perturbative local Jacobian statement in schemes where the above regulated Berezinian calculation is valid.

89.6 NSVZ Coordinate Formula

Fix the bilinear form tr of Chapter 87. Define representation indices by

$$\mathrm{Tr}_{R_i}(XY) = T(R_i)\,\mathrm{tr}(XY), \qquad \mathrm{Tr}_{\mathrm{ad}}(XY) = C_2(G)\,\mathrm{tr}(XY).$$

Let g_h be the holomorphic Wilsonian coupling and let g be the canonically normalized gauge coupling in the same momentum-subtraction scheme for the two-point function. Let $Z_i(\mu)$ be the matter wave-function coordinate and define the anomalous-dimension convention

$$\gamma_i(\mu) = \mu \frac{d}{d\mu} \log Z_i(\mu).$$

Proposition 89.5 (Holomorphic-canonical gauge-coordinate relation)**.** *Assume a perturbative supersymmetric Wilsonian scheme in which:*

(i) the holomorphic gauge coordinate

$$X_h(\mu) := \frac{8\pi^2}{g_h(\mu)^2}$$

is defined by the chiral gauge kinetic term in the convention of Chapter 87;

(ii) the canonical coordinate $g(\mu)$ is defined by normalizing the gauge-field two-point function so that the component kinetic term is $-\frac{1}{4g(\mu)^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$;

(iii) the chiral matter kinetic terms are normalized by positive wave-function coordinates $Z_i(\mu)$;

(iv) the matter rescaling Jacobian is Proposition 89.3, and the gauge-multiplet rescaling Jacobian is computed in the same background-gauge BV regulator.

Then, through the perturbative order to which the regulator and local coordinates have been constructed,

$$\frac{8\pi^2}{g_h^2} = \frac{8\pi^2}{g^2} + C_2(G)\log g^2 - \sum_i T(R_i)\log Z_i + \kappa,$$

where κ is independent of μ and records finite choices of reference normalization for the local coordinates.

Proof. Write the chiral gauge-coordinate part of the Wilsonian action as

$$S^F_{\mathrm{gauge}} = \frac{X_h}{16\pi^2}\int d^4x\, d^2\theta\ \mathrm{tr}(W^\alpha W_\alpha) + \text{theta-angle part} + \text{c.c.}$$

This equation fixes what is meant by $X_h = 8\pi^2/g_h^2$. With the same normalization, Proposition 89.3 says that a holomorphic rescaling $\Phi_i \mapsto e^{\alpha_i}\Phi_i$ shifts this real coordinate by

$$\Delta_i X_h = 2T(R_i)\alpha_i. \tag{89.6}$$

Indeed the chiral action coefficient changes by $\Delta_i X_h/(16\pi^2)$, while the Jacobian coefficient in Proposition 89.3 is $T(R_i)\alpha_i/(8\pi^2)$.

To pass from the Wilsonian fields with matter kinetic coordinate Z_i to canonical matter fields, set

$$\Phi_i^{\mathrm{hol}} = Z_i^{-1/2}\Phi_i^{\mathrm{can}}.$$

Thus $\alpha_i = -\frac{1}{2}\log Z_i$. Substitution in (89.6) gives the matter contribution

$$\Delta_{\mathrm{matter}} X_h = -\sum_i T(R_i)\log Z_i. \tag{89.7}$$

This is the part of the relation that is often called the Konishi anomaly. It is a statement about the local Berezinian of the regulated change of variables, not about an unregulated functional measure.

The vector multiplet must also be rescaled when passing from holomorphic normalization to the canonical gauge coordinate. In a background-field BV gauge fixing, the rescaling is performed on the whole quantum gauge complex: the vector superfield, ghosts, antighosts, auxiliary fields, and antifields are rescaled so that the BV pairing and gauge-fixed quadratic form are kept in canonical dual normalization. Let

$$V^{\mathrm{hol}} = g\,V^{\mathrm{can}}, \qquad \rho := \log g = \frac{1}{2}\log g^2.$$

The regulated super-Berezinian of this adjoint BV complex has the chiral local part

$$\Delta_{\mathrm{vec}} S = \frac{C_2(G)\rho}{8\pi^2}\int d^4x\, d^2\theta\ \mathrm{tr}(W^\alpha W_\alpha) + \mathrm{c.c.}$$

Equivalently,

$$\Delta_{\mathrm{vec}} X_h = 2C_2(G)\rho = C_2(G)\log g^2. \tag{89.8}$$

Here $C_2(G)$ is defined by $\mathrm{Tr}_{\mathrm{ad}}(XY) = C_2(G)\,\mathrm{tr}(XY)$. The coefficient is obtained from the same heat-kernel coefficient as in the matter calculation, but with the supertrace over the gauge-fixed adjoint BV complex. The longitudinal vector modes and chiral Faddeev–Popov/Nielsen– Kallosh ghost modes cancel except for the adjoint chiral index contribution shown above. Performing the rescaling on only A_μ and ignoring this complex would not define a gauge-consistent Jacobian.

Classically, after the vector and matter variables have been brought to the canonical coordinate chart, the real gauge kinetic coordinate is

$$X_c := \frac{8\pi^2}{g^2}.$$

Adding the two anomalous local shifts (89.7) and (89.8), and allowing a finite μ-independent normalization difference between the two declared coordinate charts, gives

$$X_h = X_c + C_2(G)\log g^2 - \sum_i T(R_i)\log Z_i + \kappa.$$

This is the displayed relation. The constant κ changes under finite renormalizations such as $Z_i \mapsto c_i Z_i$, $g \mapsto g + O(g^3)$ at a chosen reference scale, or a finite local gauge kinetic counterterm; it has zero μ-derivative in the fixed scheme and therefore drops out of the beta-function identity. $\square$

NSVZ beta function as a coordinate identity. The beta-function formula commonly called NSVZ contains no further theorem once the holomorphic-canonical coordinate relation and the one-loop holomorphic Wilsonian running have been established in the declared regulator. It is the coordinate expression of the same beta-vector field in the canonical coupling chart. Assume the hypotheses of Proposition 89.5, and assume that the holomorphic Wilsonian coordinate has the one-loop derivative

$$\mu \frac{d}{d\mu}\left(\frac{8\pi^2}{g_h^2}\right) = 3C_2(G) - \sum_i T(R_i). \tag{89.9}$$

Then, in the canonical coupling coordinate g, with

$$\gamma_i = \mu \frac{d}{d\mu} \log Z_i,$$

$$\beta_g = -\frac{g^3}{16\pi^2} \frac{3C_2(G) - \sum_i T(R_i)\big(1-\gamma_i\big)}{1 - \frac{C_2(G)g^2}{8\pi^2}}. \tag{NSVZ}$$

Here is the derivation, included to fix signs and normalizations. Differentiate the coordinate relation of Proposition 89.5. Since

$$\mu \frac{d}{d\mu}\left(\frac{8\pi^2}{g^2}\right) = -\frac{16\pi^2}{g^3}\beta_g, \qquad \mu \frac{d}{d\mu} \log g^2 = \frac{2\beta_g}{g},$$

and $\mu\, d\kappa/d\mu = 0$, one obtains

$$\left(-\frac{16\pi^2}{g^3} + \frac{2C_2(G)}{g}\right)\beta_g - \sum_i T(R_i)\gamma_i = 3C_2(G) - \sum_i T(R_i).$$

Move the anomalous-dimension term to the right:

$$\left(\frac{16\pi^2}{g^3} - \frac{2C_2(G)}{g}\right)\beta_g = -\left(3C_2(G) - \sum_i T(R_i)(1-\gamma_i)\right).$$

Factoring the left hand side as

$$\frac{16\pi^2}{g^3}\left(1 - \frac{C_2(G)g^2}{8\pi^2}\right)\beta_g$$

and dividing gives (NSVZ). Thus the displayed beta function is a coordinate statement derived from a holomorphic Wilsonian coupling, the rescaling anomaly, and a declared canonical normalization prescription. A finite redefinition of the canonical coupling changes the denominator by ordinary reparametrization of the vector field $\beta_g \partial_g$.

89.7 Status Boundary

The perturbative statements above are Wilsonian statements under explicit regularity hypotheses. Nonperturbative superpotentials, instanton effects, gaugino condensation, and strong-coupling moduli-space constraints are not contradictions: they are additional semiclassical or nonperturbative contributions to Wilsonian chiral coordinates. Each such contribution must be derived from a declared integration cycle, zero-mode measure, anomaly matching, and infrared effective description.

Open Problem 89.6 (Rigorous supersymmetric Wilsonian holomorphy). Construct a regulator and BV Wilsonian scheme in which the chiral local cohomology, supergraph measure, rescaling anomaly, and holomorphic gauge coordinate are all defined at finite cutoff, and prove the perturbative nonrenormalization statements in that scheme.

Chapter 90

Four-Dimensional N=1 Gauge Dynamics

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops the first layer of four-dimensional $\mathcal{N} = 1$ gauge dynamics in Wilsonian coordinates. The conclusions are conditional on the supersymmetric Wilsonian scheme and anomaly calculation fixed in Chapters 88 and 89.

90.1 SQCD Data

Let $G = SU(N_c)$. Supersymmetric QCD with N_f flavors has chiral superfields

$$Q^i \in \mathbf{N}_c, \qquad \widetilde{Q}_j \in \overline{\mathbf{N}}_c, \qquad i, j = 1, \ldots, N_f.$$

The vector multiplet has field strength W_α, and the Wilsonian gauge coordinate is

$$\frac{1}{16\pi\mathrm{i}} \int d^4x\, d^2\theta\, \tau\; \mathrm{tr}(W^\alpha W_\alpha) + \text{c.c.}$$

with the trace convention inherited from Chapter 87. The holomorphic scale is the invariant coordinate

$$\Lambda_h^{b_0} = \mu^{b_0} \exp(2\pi\mathrm{i}\tau(\mu)), \qquad b_0 = 3N_c - N_f.$$

This equation defines Λ_h after a branch convention has been chosen; only $\Lambda_h^{b_0}$ is invariant under the periodicity of θ.

90.2 SQCD NSVZ Coordinate Audit

The holomorphic scale is not the same coordinate as the canonical gauge coupling used in particle normalizations. This distinction is a coordinate statement, not a change of the underlying theory. Write

$$X_h(\mu) = \frac{8\pi^2}{g_h(\mu)^2}, \qquad X_c(\mu) = \frac{8\pi^2}{g(\mu)^2},$$

where g_h is the holomorphic Wilsonian coupling and g is the canonical coupling defined by the component kinetic term of Chapter 87. Let Z_Q and $Z_{\widetilde{Q}}$ be the matter wave-function coordinates, with

$$\gamma_Q(\mu) = \mu\frac{d}{d\mu}\log Z_Q(\mu), \qquad \gamma_{\widetilde{Q}}(\mu) = \mu\frac{d}{d\mu}\log Z_{\widetilde{Q}}(\mu).$$

Hypothesis 90.1 (SQCD NSVZ coordinate specialization)**.** The SQCD beta-function identity below is stated in a perturbative supersymmetric Wilsonian scheme satisfying the hypotheses of Proposition 89.5. The flavor-symmetric submanifold is imposed by taking

$$Z_Q = Z_{\widetilde{Q}}, \qquad \gamma_Q = \gamma_{\widetilde{Q}}.$$

The trace convention is the half-trace convention of this chapter:

$$C_2(SU(N_c)) = N_c, \qquad T(\mathbf{N}_c) = T(\overline{\mathbf{N}}_c) = \frac{1}{2}.$$

Finite changes of canonical coupling coordinate are allowed, but then the rational NSVZ denominator changes by the induced reparametrization. Thus the pole of the displayed denominator is a feature of this coordinate chart; the invariant tests in later sections are the numerator condition, anomaly matching, holomorphic scale matching, and protected chiral data.

SQCD specialization of the NSVZ coordinate relation. Assume Hypothesis 90.1. In the flavor-symmetric SQCD coordinate chart,

$$X_h = X_c + N_c \log g^2 - N_f \log Z_Q + \kappa, \tag{90.1}$$

where κ is independent of μ. Consequently

$$\beta_g = -\frac{g^3}{16\pi^2}\,\frac{3N_c - N_f(1-\gamma_Q)}{1 - \frac{N_c g^2}{8\pi^2}}. \tag{90.2}$$

The general relation of Proposition 89.5 gives

$$X_h = X_c + C_2(SU(N_c))\log g^2 - \sum_i T(R_i)\log Z_i + \kappa.$$

There are N_f chiral multiplets Q^i in $\mathbf{N}_c$ and N_f chiral multiplets $\widetilde{Q}_j$ in $\overline{\mathbf{N}}_c$. Hence

$$\sum_i T(R_i)\log Z_i = \frac{N_f}{2}\log Z_Q + \frac{N_f}{2}\log Z_{\widetilde{Q}}.$$

On the flavor-symmetric submanifold this is $N_f \log Z_Q$, and $C_2(SU(N_c)) = N_c$. This proves (90.1).

The holomorphic Wilsonian coordinate has one-loop derivative

$$\mu\frac{dX_h}{d\mu} = 3N_c - N_f.$$

Differentiating (90.1) therefore gives

$$\left(-\frac{16\pi^2}{g^3} + \frac{2N_c}{g}\right)\beta_g - N_f\gamma_Q = 3N_c - N_f.$$

Moving the anomalous-dimension term to the right hand side yields the NSVZ numerator $3N_c - N_f(1-\gamma_Q)$. Solving the displayed linear equation for $\beta_g = \mu\, dg/d\mu$ gives (90.2).

Equivalently, inserting

$$C_2(SU(N_c)) = N_c, \qquad T(\mathbf{N}_c) = T(\overline{\mathbf{N}}_c) = \frac{1}{2}$$

directly into the general NSVZ coordinate formula of Chapter 89 gives

$$\beta_g = -\frac{g^3}{16\pi^2}\,\frac{3C_2(SU(N_c)) - N_f\big(T(\mathbf{N}_c) + T(\overline{\mathbf{N}}_c)\big)(1-\gamma_Q)}{1 - \frac{C_2(SU(N_c))g^2}{8\pi^2}},$$

whose numerator is

$$3N_c - N_f(1-\gamma_Q).$$

The proof above displays why the same numerator arises from the holomorphic-canonical coordinate relation: the two factors of $1/2$ from the fundamental and antifundamental indices add to the single coefficient N_f, while the vector-multiplet Jacobian produces the denominator in the chosen canonical coordinate.

90.3 Gauge-Invariant Chiral Coordinates

The meson matrix is the chiral operator

$$M^i{}_j = \widetilde{Q}_j Q^i.$$

For $N_f \geq N_c$ there are baryons

$$B^{i_1\cdots i_{N_c}} = \epsilon_{a_1\cdots a_{N_c}} Q^{a_1 i_1}\cdots Q^{a_{N_c} i_{N_c}},$$

and similarly antibaryons $\widetilde{B}$. The classical chiral coordinate ring is the quotient of the polynomial ring in $M, B, \widetilde{B}$ by the relations obtained from the definitions above. Quantum dynamics changes this ring only through Wilsonian chiral coordinates compatible with holomorphy, global symmetries, and anomalies.

90.4 Anomaly-Free R-Symmetry

Assign

$$R(Q) = R(\widetilde{Q}) = 1 - \frac{N_c}{N_f}, \qquad R(W_\alpha) = 1.$$

The $SU(N_c)^2U(1)_R$ anomaly coefficient is

$$N_c + \frac{1}{2}N_f(R(Q) - 1) + \frac{1}{2}N_f(R(\widetilde{Q}) - 1) = 0$$

in the fundamental normalization where each fundamental contributes $\frac{1}{2}$. This R-symmetry is part of the chiral-coordinate selection data when $N_f > 0$. If a mass term

$$W_{\text{tree}} = m_i{}^j M^i{}_j$$

is included, then $m_i{}^j$ is treated as a background chiral coordinate with the charge needed to make the superpotential have R-charge 2.

90.5 Gaugino Condensation

For pure $SU(N_c)$ supersymmetric Yang–Mills, $b_0 = 3N_c$. Let

$$S = -\frac{1}{32\pi^2}\,\mathrm{tr}(W^\alpha W_\alpha)$$

be the chiral glueball coordinate in the same trace convention. Its lowest component is proportional to the gaugino bilinear $\mathrm{tr}\,\lambda\lambda$, so it has engineering dimension 3 and gaugino-phase charge 2.

A useful way to keep the nonperturbative status precise is to separate three statements: the anomaly fixes the possible discrete phases, the Witten index counts supersymmetric vacua under finite-volume hypotheses, and a glueball Wilsonian description produces the chiral condensate equation. A constructive mass-gap theorem would additionally require a regulator, a Hilbert-space limit, and spectral estimates for the gauge-invariant local algebra.

Pure SYM discrete chiral anomaly. In pure $SU(N_c)$ supersymmetric Yang–Mills, the classical gaugino phase rotation

$$\lambda_\alpha \longmapsto \mathrm{e}^{\mathrm{i}\alpha}\lambda_\alpha$$

is reduced by the adjoint fermion anomaly to

$$\mathbb{Z}_{2N_c}.$$

If a nonzero condensate $\langle S\rangle$ forms, this discrete symmetry is further broken to $\mathbb{Z}_2$, giving N_c possible condensate phases. The left-handed adjoint Weyl fermion has anomaly coefficient

$$2T(\text{adj}) = 2N_c$$

in the instanton normalization used throughout the chapter. Under the formal rotation by α, the functional measure shifts the Yang–Mills angle by

$$\theta \longmapsto \theta + 2N_c\alpha.$$

Since θ is 2π-periodic, the rotation is a genuine symmetry precisely when

$$2N_c\alpha \in 2\pi\mathbb{Z}, \qquad \text{that is} \qquad \alpha = \frac{\pi\ell}{N_c}, \quad \ell \in \mathbb{Z}.$$

Modulo $\alpha \sim \alpha + 2\pi$, these rotations form $\mathbb{Z}_{2N_c}$. The glueball coordinate S has charge 2 under the same rotation:

$$S \longmapsto \mathrm{e}^{2\mathrm{i}\alpha} S.$$

A nonzero value of S is fixed only when $\mathrm{e}^{2\mathrm{i}\alpha} = 1$, which is the subgroup generated by $\alpha = \pi$. Hence the unbroken subgroup is $\mathbb{Z}_2$, and the quotient has $2N_c/2 = N_c$ phases.

Hypothesis 90.2 (Pure SYM glueball F-term description)**.** The following glueball description is a Wilsonian chiral-sector hypothesis. Work in a supersymmetric holomorphic scheme for pure $SU(N_c)$ Yang–Mills with the glueball coordinate S normalized as above. On each massive chiral branch, assume that the protected F-term dependence is locally described by a holomorphic, possibly multivalued, superpotential

$$W_{\text{eff}}(S; \Lambda_h^{3N_c})$$

and that there are no further massless chiral coordinates. The source normalization of S is fixed by

$$\Lambda_h^{3N_c} \frac{\partial W_{\text{eff}}}{\partial \Lambda_h^{3N_c}} = S. \tag{90.3}$$

Finite holomorphic rescalings of S or Λ_h change the numerical constant in the final condensate but not the number of vacua or their relative phases.

VY glueball superpotential from the chiral-sector hypothesis. Assume Hypothesis 90.2. Up to the finite normalization just described, the pure-SYM glueball superpotential may be written as

$$W_{\text{VY}}(S) = S \left(\log \frac{\Lambda_h^{3N_c}}{S^{N_c}} + N_c \right). \tag{90.4}$$

It has dimension 3, satisfies the source identity (90.3), and its critical points obey

$$S^{N_c} = \Lambda_h^{3N_c}. \tag{90.5}$$

Set $L = \Lambda_h^{3N_c}$. The only dimensionless holomorphic combination of S and L is

$$u = \frac{S^{N_c}}{L}.$$

A dimension-three glueball superpotential therefore has the local form

$$W_{\text{eff}} = S f(u)$$

for a holomorphic function f on a chosen logarithmic branch. The source normalization gives

$$S = L \frac{\partial}{\partial L} \big(S f(u) \big) = -S \, u f'(u).$$

Thus

$$u f'(u) = -1,$$

so

$$f(u) = -\log u + c$$

on that branch. Hence

$$W_{\text{eff}} = S\left(\log\frac{L}{S^{N_c}} + c\right).$$

The constant c is shifted by a finite holomorphic rescaling of L or of S. The standard Veneziano–Yankielowicz representative is the normalization $c = N_c$, giving (90.4). Differentiating this representative with respect to S yields

$$\frac{\partial W_{\text{VY}}}{\partial S} = \log\frac{\Lambda_h^{3N_c}}{S^{N_c}},$$

so the $F_S = 0$ equation is (90.5). Finally, both S and Λ_h^3 have dimension 3, and the logarithm is dimensionless; therefore W_{VY} has dimension 3.

Choosing a branch of Λ_h^3, the solutions of (90.5) are

$$\langle S\rangle_k = C\,\Lambda_h^3\,\exp\left(\frac{2\pi \mathrm{i}k}{N_c}\right), \qquad k = 0,\dots,N_c-1.$$

The constant C depends on the normalization of S and on the definition of Λ_h. In the standard representative of (90.4), $C = 1$. At a critical point,

$$\frac{\partial^2 W_{\text{VY}}}{\partial S^2} = -\frac{N_c}{S},$$

so the glueball critical points are isolated whenever $S \neq 0$. The statement with invariant content is the existence of a nonzero chiral condensate with these relative phases in a scheme where the low-energy theory has a mass gap and isolated vacua.

Condensate branches and source normalization. Assume Hypothesis 90.2, and assume that the isolated critical points of (90.5) are realized as massive chiral branches of the pure $SU(N_c)$ theory. With

$$L = \Lambda_h^{3N_c}.$$

the k-th branch has

$$W_k(L) = N_c\,C\,L^{1/N_c}\mathrm{e}^{2\pi\mathrm{i}k/N_c}, \qquad \langle S\rangle_k = C\,L^{1/N_c}\mathrm{e}^{2\pi\mathrm{i}k/N_c}, \qquad k\in\mathbb{Z}/N_c\mathbb{Z}.$$

The source identity gives

$$L\frac{\partial W_k}{\partial L} = \langle S\rangle_k.$$

Analytic continuation of L once around the origin sends $k\mapsto k+1$. Thus the N_c branches form one orbit under the anomalous chiral symmetry and under a 2π theta-angle loop. The calculation is the following. At a VY critical point the logarithm in (90.4) vanishes, so the critical value of the standard representative is $W_k = N_c S_k$. The finite normalization constant C records the allowed rescaling of S and of the chosen branch of Λ_h^3. Differentiating

$$W_k(L) = N_c\,C\,L^{1/N_c}\mathrm{e}^{2\pi\mathrm{i}k/N_c}$$

gives

$$L\frac{\partial W_k}{\partial L} = C\,L^{1/N_c}\mathrm{e}^{2\pi\mathrm{i}k/N_c} = \langle S\rangle_k.$$

The remaining statement is the elementary monodromy of the N_c-th root: if L is carried around a positively oriented loop about the origin, then L^{1/N_c} is multiplied by $\mathrm{e}^{2\pi\mathrm{i}/N_c}$. This shifts the branch label by one. The same shift is produced by the generator $\alpha = \pi/N_c$ of the anomaly-preserving $\mathbb{Z}_{2N_c}$, since S has gaugino-phase charge 2.

90.6 Protected and Spectral Data in Pure SYM

The glueball coordinate S records protected chiral data. The massive particle spectrum of pure supersymmetric Yang–Mills is a different object: it is extracted from the translation representation on the Hilbert space of a chosen vacuum, or from an equivalent Euclidean transfer matrix after reconstruction. This section fixes the precise spectral problem that connects the chiral branch discussion above to the pure-Yang–Mills spectral discussion of Section 46.8.

Definition 90.3 (Vacuum spectral problem of pure SYM)**.** Fix $N_c \geq 2$ and a trace convention for the gauge algebra as in Section 51.17. A vacuum spectral problem for pure $\mathcal{N} = 1$ $SU(N_c)$ Yang–Mills consists of:

(i) a regulator or continuum construction that gives a local gauge-invariant $*$-algebra $\mathfrak{A}_{\text{loc}}$ generated by smeared components of gauge-invariant superfields;

(ii) a supersymmetric vacuum state ω_k with GNS triple $(\mathcal{H}_k, \Omega_k, \pi_k)$, where $k \in \mathbb{Z}/N_c\mathbb{Z}$ labels the chiral branch in the VY/source-normalization discussion above;

(iii) a strongly continuous translation representation $U_k(a) = \exp(\mathrm{i}a^\mu P_\mu^{(k)})$ with joint spectral measure $E_k(\cdot)$, vacuum vector $P_\mu^{(k)}\Omega_k = 0$, and mass operator $M_k^2 = -\eta^{\mu\nu}P_\mu^{(k)}P_\nu^{(k)}$;

(iv) a finite or countable source family $\mathcal{O}_i \in \mathfrak{A}_{\text{loc}}$ of gauge-invariant smeared component fields, such as the scalar, pseudoscalar, and spinor components of S and their descendants after contact terms have been fixed;

(v) the connected spectral measures

$$\rho_{ij}^{(k)}(B) = \big\langle \pi_k(\mathcal{O}_i)\Omega_k,\, E_k(B)\,\pi_k(\mathcal{O}_j)\Omega_k \big\rangle_{\mathcal{H}_k}$$

for Borel sets $B \subset \{p \in \mathbb{R}^{1,3} : p^0 \geq 0\}$, with the vacuum projection removed when $\mathcal{O}_i$ has a nonzero vacuum expectation value.

An isolated massive supermultiplet of mass $m > 0$ is represented by an atomic component of these measures on the mass shell $p^2 = -m^2$. The matrix of residues on that atom gives the overlap of the chosen sources with the one-particle states.

Chiral F-term data and quadratic masses. Assume that a neighborhood of a branch $S = S_k$ admits a single-coordinate two-derivative chiral effective action

$$\int \mathrm{d}^4\theta\, K(S,\overline{S}) + \left(\int \mathrm{d}^2\theta\, W(S) + \text{c.c.}\right), \qquad g_k = \partial_S\partial_{\overline{S}}K(S_k,\overline{S}_k) > 0,$$

and that $W'(S_k) = 0$. At quadratic order in the fluctuation $\sigma = S - S_k$, the complex scalar and its Majorana fermion partner have common mass

$$m_k = \frac{|W''(S_k)|}{g_k}. \tag{90.6}$$

For the VY representative (90.4),

$$W''(S_k) = -\frac{N_c}{S_k}. \tag{90.7}$$

Thus the protected F-term fixes the branch values and the holomorphic second derivative, while the numerical particle masses also require the Kähler metric and, in the full theory, the complete source-residue matrix of Definition 90.3. At a supersymmetric critical point $W'(S_k) = 0$, the scalar potential is

$$V(S,\overline{S}) = K^{S\overline{S}}(S,\overline{S})\,|W'(S)|^2.$$

Expanding at S_k gives

$$W'(S_k+\sigma) = W''(S_k)\sigma + O(\sigma^2), \qquad K^{S\overline{S}}(S_k,\overline{S}_k) = g_k^{-1}.$$

The quadratic scalar Lagrangian is therefore

$$g_k\,\partial_\mu\sigma\,\partial^\mu\overline{\sigma} - g_k^{-1}|W''(S_k)|^2|\sigma|^2.$$

After the canonical rescaling $\sigma_c = g_k^{1/2}\sigma$, the mass-squared coefficient is $|W''(S_k)|^2/g_k^2$. The fermion quadratic term is

$$-\frac{1}{2}W''(S_k)\psi_S\psi_S + \text{c.c.}$$

together with the kinetic coefficient g_k; the same canonical rescaling gives the fermion mass $|W''(S_k)|/g_k$. Differentiating (90.4) twice gives (90.7). In the microscopic theory, several gauge-invariant sources with the same spin, parity, charge conjugation, and fermion number can have nonzero overlap with the same atom of the spectral measure, so the physical mass extraction uses the residue matrix rather than a single holomorphic coordinate alone.

Definition 90.4 (Pure-SYM wall data)**.** For two massive supersymmetric branches $i, j \in \mathbb{Z}/N_c\mathbb{Z}$, a wall data consist of a Hilbert-space or Euclidean functional-integral construction on $\mathbb{R}^{1,2}\times\mathbb{R}$ with boundary conditions approaching the i-th vacuum as $x^3 \to -\infty$ and the j-th vacuum as $x^3 \to +\infty$, together with a conserved energy per unit $\mathbb{R}^{1,2}$-volume. In a two-derivative chiral effective description, the wall is represented by a path $S(x^3)$ in the branch coordinate space.

BPS wall tension from branch superpotentials. Assume the wall data of Definition 90.4 are governed by a two-derivative $\mathcal{N}=1$ chiral effective action with positive Kähler metric $g_{S\overline{S}}$, and assume that a wall saturates the $\mathcal{N}=1$ central-charge bound. Then its tension is

$$T_{ij} = 2\,|W_j - W_i|, \tag{90.8}$$

where W_i and W_j are the branch values of the superpotential. For the pure-SYM VY branch values

$$W_k = N_c\,C\,\Lambda_h^3\,\mathrm{e}^{2\pi \mathrm{i}k/N_c},$$

the wall between branches k and $k+\ell$ has

$$T_{k,k+\ell} = 4N_c\,|C|\,|\Lambda_h^3|\,\left|\sin\frac{\pi\ell}{N_c}\right|. \tag{90.9}$$

For a static configuration depending only on x^3, the energy density in the effective chiral model is

$$\mathcal{E} = g_{S\overline{S}}\,\partial_3 S\,\partial_3\overline{S} + g^{S\overline{S}}W_S\overline{W}_{\overline{S}}.$$

Let $\alpha \in \mathbb{R}$. Completing the square gives

$$\mathcal{E} = g_{S\overline{S}} \left| \partial_3 S - \mathrm{e}^{\mathrm{i}\alpha} g^{S\overline{S}} \overline{W}_{\overline{S}} \right|^2 + 2 \,\mathrm{Re}\big(\mathrm{e}^{-\mathrm{i}\alpha} \partial_3 W\big) .$$

After integrating over x^3, the last term is

$$2 \,\mathrm{Re}\big(\mathrm{e}^{-\mathrm{i}\alpha}(W_j - W_i)\big) .$$

Choosing $\alpha = \arg(W_j - W_i)$ gives the bound

$$T \geq 2|W_j - W_i|.$$

Saturation is equivalent to the first-order wall equation

$$\partial_3 S = \mathrm{e}^{\mathrm{i}\alpha} g^{S\overline{S}} \overline{W}_{\overline{S}}.$$

Substituting the branch values gives

$$|W_{k+\ell} - W_k| = N_c |C| \, |\Lambda_h^3| \left| \mathrm{e}^{2\pi\mathrm{i}(k+\ell)/N_c} - \mathrm{e}^{2\pi\mathrm{i}k/N_c} \right| = 2N_c |C| \, |\Lambda_h^3| \left| \sin \frac{\pi\ell}{N_c} \right| ,$$

which proves (90.9).

Thus the sine formula is a consequence of the effective chiral wall chart and the saturation hypothesis. The nontrivial QFT problem is the construction of the wall sector and the justification that this two-derivative description with the stated branch superpotential controls its central charge. The square-completion records only the effective-chart consequence of those data.

Pure-SYM confining string tensions are additional line-operator spectral data. They are defined by the area-law exponent of center-charged Wilson-loop or 't Hooft-loop correlators, or equivalently by a transfer-matrix flux-sector energy in a regulator that realizes the center sectors. The wall formula (90.9) is protected by the chiral superpotential under the stated effective-action hypotheses; the flux-string tension requires the nonchiral dynamics encoded in the spectral data.

Pure-SYM one-instanton zero-mode test. Work in the charge-one $SU(N_c)$ instanton sector in the BPST normalization of Section 51.17. Assume a semiclassical collective-coordinate separation in which the exact adjoint fermion zero modes are represented by Grassmann variables and must be saturated by separated operator insertions. Then

$$\langle S(x_1) \cdots S(x_m) \rangle_{k=1}^{\mathrm{sep}} = 0, \qquad m < N_c, \tag{90.10}$$

before contact terms or boundary contributions are considered. The first separated chiral correlator whose fermion degree can saturate the charge-one instanton measure is the N_c-point correlator

$$\langle S(x_1) \cdots S(x_{N_c}) \rangle_{k=1}^{\mathrm{sep}} . \tag{90.11}$$

Its protected charge and dimension assignment is the same assignment as the VY equation $S^{N_c} \sim \Lambda_h^{3N_c}$.

The Dirac index in the adjoint representation gives

$$n_\lambda = 2T(\mathrm{adj})\, k = 2N_c$$

left-handed gaugino zero modes for a charge-one instanton. Let $\eta_1, \ldots, \eta_{2N_c}$ denote their Grassmann coefficients. The zero-mode part of the collective-coordinate measure contains

$$d\eta_{2N_c} \cdots d\eta_1.$$

The lowest component of S is quadratic in the gaugino field. Hence a separated insertion of S is a polynomial of Grassmann degree at most two in the η_a's, and a product of m such insertions has degree at most $2m$. A Berezin integral over $2N_c$ variables extracts only the coefficient of $\eta_1 \cdots \eta_{2N_c}$. If $m < N_c$, that coefficient is absent, proving (90.10).

For $m = N_c$, the Grassmann degree can be $2N_c$. This is a necessary zero-mode condition, not yet a proof of a nonzero coefficient; the spacetime dependence, nonzero-mode determinant, instanton-size integration, and possible boundary terms still have to be controlled. The holomorphic scale factor of a charge-one pure-SYM instanton is $\Lambda_h^{3N_c}$, while S^{N_c} has engineering dimension $3N_c$ and gaugino-phase charge $2N_c$. Thus the first zero-mode-saturated chiral correlator has precisely the dimension and anomalous-charge assignment of the VY critical equation.

Saturated pure-SYM Berezin coefficient. The following exterior-algebra calculation is not a separate QFT theorem; it records the sign and factorial convention needed by the instanton zero-mode test. Keep the assumptions and notation of the one-instanton zero-mode test above. At fixed bosonic instanton collective coordinate $\mathfrak{m}$, let

$$\eta_1, \ldots, \eta_{2N_c}$$

be an oriented basis of the adjoint gaugino zero-mode Grassmann variables, with Berezin measure

$$\mathrm{d}\eta_{2N_c} \cdots \mathrm{d}\eta_1.$$

For a separated insertion point x_a, write the zero-mode part of the lowest component of $S(x_a)$ as the quadratic form

$$S(x_a)\big|_{\mathrm{zm}} = \sum_{1 \le p < q \le 2N_c} K_a^{pq}(x_a; \mathfrak{m})\, \eta_p \eta_q, \tag{90.12}$$

where the coefficients K_a^{pq} are ordinary complex numbers after the bosonic collective coordinate and the zero-mode basis have been fixed. Define the saturated Berezin coefficient

$$\mathfrak{B}_{N_c}(K_1, \ldots, K_{N_c}) = [\eta_1 \cdots \eta_{2N_c}] \prod_{a=1}^{N_c} \left(\sum_{p<q} K_a^{pq} \eta_p \eta_q \right), \tag{90.13}$$

where $[\eta_1 \cdots \eta_{2N_c}]$ denotes coefficient extraction in the ordered monomial $\eta_1 \cdots \eta_{2N_c}$. Equivalently,

$$\mathfrak{B}_{N_c} = \sum_{\substack{p_a < q_a \\ \bigsqcup_{a=1}^{N_c} \{p_a, q_a\} = \{1, \ldots, 2N_c\}}} \operatorname{sgn}(p_1, q_1, \ldots, p_{N_c}, q_{N_c}) \prod_{a=1}^{N_c} K_a^{p_a q_a}. \tag{90.14}$$

The fixed-$\mathfrak{m}$ zero-mode integral of the N_c-point insertion is

$$\int \mathrm{d}\eta_{2N_c} \cdots \mathrm{d}\eta_1 \prod_{a=1}^{N_c} S(x_a)\big|_{\mathrm{zm}} = \mathfrak{B}_{N_c}(K_1, \ldots, K_{N_c}). \tag{90.15}$$

Thus the saturated instanton calculation requires a nonzero top exterior component of the N_c two-forms K_a. In the canonical test case

$$K_a = \eta_{2a-1}\eta_{2a}, \qquad a = 1, \dots, N_c,$$

the coefficient is 1. If instead every insertion has the same canonical two-form

$$\Omega_0 = \sum_{a=1}^{N_c} \eta_{2a-1}\eta_{2a},$$

then the coefficient of $\Omega_0^{N_c}$ is $N_c!$. These factorial and sign conventions are part of the instanton calculation; they are not fixed by dimension, holomorphy, or the index.

Indeed, Berezin integration over the zero-mode variables extracts the coefficient of the oriented top monomial:

$$\int \mathrm{d}\eta_{2N_c} \cdots \mathrm{d}\eta_1 \, \eta_1 \cdots \eta_{2N_c} = 1.$$

Substituting (90.12) into the product of insertions therefore gives (90.15) directly. Expanding the product, a monomial contributes only if every variable $\eta_1, \dots, \eta_{2N_c}$ occurs exactly once. Ordering that monomial to $\eta_1 \cdots \eta_{2N_c}$ produces the sign in (90.14). If a variable is missing or repeated, the coefficient of the top monomial is zero.

For $K_a = \eta_{2a-1}\eta_{2a}$, the product is already the ordered top monomial, hence the coefficient is 1. For $\Omega_0 = \sum_a \eta_{2a-1}\eta_{2a}$, the only nonzero terms in $\Omega_0^{N_c}$ choose each pair exactly once; the $N_c!$ permutations of these commuting degree-two pair factors all contribute with positive sign. This proves the displayed coefficient and records the convention-sensitive normalization that later gets absorbed into the nonzero constant κ_{inst}.

Topological-sector selection for S-correlators. Fix an instanton number $\nu \in \mathbb{Z}_{>0}$. Work in a self-dual charge-ν sector of pure $SU(N_c)$ SYM, with the same BPST/index normalization as above. Assume that the exact adjoint gaugino zero modes are separated as Grassmann variables and that, in the separated chiral correlator under consideration, the only insertions carrying these variables are the displayed S-insertions. Then

$$\langle S(x_1) \cdots S(x_m) \rangle_\nu^{\text{sep}} = 0, \qquad m < \nu N_c, \tag{90.16}$$

at the zero-mode Berezin level. The first possible saturated chiral correlator in the charge-ν sector has

$$m = \nu N_c$$

insertions and carries the same dimension and anomalous gaugino-phase charge as $\Lambda_h^{3\nu N_c}$. Consequently the N_c-point correlator used in Hypothesis 90.5 is a charge-one test: sectors with $\nu \geq 2$ leave unsaturated adjoint zero modes in that channel. Anti-self-dual sectors have the conjugate chirality zero modes and are paired with anti-chiral $\overline{S}$-insertions rather than with the holomorphic S-correlator above.

The selection rule is zero-mode degree counting. The adjoint Dirac index gives

$$n_\lambda(\nu) = 2T(\text{adj})\, \nu = 2N_c \nu$$

left-handed gaugino zero modes in a self-dual charge-ν sector. A separated insertion of S is quadratic in the left-handed gaugino zero-mode variables, so m such insertions have Grassmann degree at most $2m$. The zero-mode Berezin integral in the charge-ν sector extracts the coefficient of a monomial of degree $2N_c\nu$. If $m < \nu N_c$, that top-degree coefficient is absent, proving (90.16).

For $m = \nu N_c$, the fermion degree can match the top degree. This is only the algebraic saturation condition; the corresponding coefficient and the bosonic moduli integral remain separate analytic inputs, as in Hypothesis 90.5. The dimension of $S^{\nu N_c}$ is $3\nu N_c$, and its gaugino-phase charge is $2\nu N_c$, matching the holomorphic scale factor $\Lambda_h^{3\nu N_c}$ and the index count of the zero modes. Setting $m = N_c$ forces $\nu = 1$ for equality. For $\nu \geq 2$, the same N_c-point insertion has degree $2N_c$, leaving $2(\nu - 1)N_c$ adjoint zero modes unsaturated.

The chirality statement is the conjugate form of the same index theorem: anti-self-dual sectors carry the opposite chiral zero modes. The holomorphic operator S is built from the chiral field strength $W_\alpha W^\alpha$, whereas the conjugate zero modes are supplied by $\overline{S}$. Thus they belong to the anti-chiral conjugate calculation, apart from contact terms, source insertions, or boundary effects outside the separated chiral selection rule.

Hypothesis 90.5 (Zero-mode-saturated pure-SYM instanton correlator)**.** The following is the additional analytic input required if one wants to use the original instanton logic as evidence for the pure-SYM condensate. In a supersymmetric holomorphic regulator, assume that the separated N_c-point chiral correlator (90.11) receives a well-defined charge-one instanton contribution

$$\langle S(x_1) \cdots S(x_{N_c}) \rangle_{k=1}^{\text{sep}} = \kappa_{\text{inst}} \Lambda_h^{3N_c}, \qquad \kappa_{\text{inst}} \neq 0, \tag{90.17}$$

for separated points in the chiral sector, in the same finite normalization of S and Λ_h used above. This hypothesis includes control of the saturated Berezin coefficient (90.13) after integration over bosonic collective coordinates, the instanton-size integral, the nonzero-mode determinant, collision singularities, and boundary strata. In un-Higgsed pure SYM these analytic controls are not supplied by the elementary zero-mode count alone.

Remark 90.6 (Cluster extraction is a separate assumption). Assume Hypothesis 90.5 and assume the infinite-volume theory has a massive pure phase ω_ℓ with cluster decomposition and one-point value

$$\omega_\ell(S) = s_\ell.$$

If the separated chiral N_c-point function is identified with the large-separation limit in that pure phase, then

$$s_\ell^{N_c} = \kappa_{\text{inst}} \Lambda_h^{3N_c}. \tag{90.18}$$

Consequently the instanton N_c-point calculation can at most supply the root equation for the condensate. The choice of a particular root and the existence of the massive pure phases require the anomaly, index, and massive-branch inputs stated in this section.

Choose separated points $x_1, \ldots, x_{N_c}$, and translate them so that their mutual distances go to infinity. Cluster decomposition in the pure phase gives

$$\lim_{\min_{a\neq b} |x_a - x_b| \to \infty} \omega_\ell(S(x_1) \cdots S(x_{N_c})) = \prod_{a=1}^{N_c} \omega_\ell(S) = s_\ell^{N_c}.$$

If this large-separation limit is the protected chiral correlator (90.17), then (90.18) follows. The equation determines only the N_c-th power. Its N_c roots are then organized by the $\mathbb{Z}_{2N_c}$ anomaly and the θ-monodromy described in the VY/source-normalization discussion above; no single-instanton Berezin integral selects one branch by itself.

The component condensate $\langle \mathrm{tr}\,\lambda\lambda\rangle_k$ is obtained from $\langle S\rangle_k$ by the fixed component convention in the definition of S. The phase information above is convention independent. In a massive infinite-volume vacuum, cluster decomposition would give

$$\lim_{|x|\to\infty} \langle S(x)S(0)\rangle_k = \langle S\rangle_k^2.$$

This is an infinite-volume statement about a chosen pure phase. A finite-volume ground-state basis can instead diagonalize the discrete symmetry, and the passage to cluster vacua is part of the massive-branch hypothesis rather than a consequence of the index alone.

90.7 Witten Index Of Pure Supersymmetric Yang–Mills

Hypothesis 90.7 (Finite-volume pure-SYM index problem)**.** Fix $N_c \geq 2$ and take the gauge group to be the simply connected group $SU(N_c)$. Put the theory on a spatial three-torus T_L^3 with periodic spin structure for the gaugino, and impose Gauss' law in the trivial discrete-flux sector. The index is computed by a regulated Hamiltonian system whose supersymmetry, gauge invariance, and fermion parity are exact at finite regulator. The physical Hilbert space $\mathcal{H}_0(T_L^3)$ has a self-adjoint Hamiltonian H, closed supercharges $Q, Q^\dagger$, and a fermion-parity operator $(-1)^F$ such that

$$H = \frac{1}{2}\{Q, Q^\dagger\}, \qquad \{(-1)^F, Q\} = \{(-1)^F, Q^\dagger\} = 0.$$

The heat operator $\mathrm{e}^{-\beta H}$ is trace class in the regulated finite-volume problem, and the zero-energy subspace is finite-dimensional. Changing the global form of the gauge group or turning on 't Hooft fluxes changes the Hilbert-space sector and is not part of the displayed $SU(N_c)$ index.

Under Hypothesis 90.7, the finite-volume index is

$$\mathcal{I}(\beta, L) = \mathrm{Tr}_{\mathcal{H}_0(T_L^3)}(-1)^F \mathrm{e}^{-\beta H}.$$

Finite-volume graded-trace identity. Assume Hypothesis 90.7. The finite-dimensional supersymmetry algebra then gives

$$\mathcal{I}(\beta, L) = \dim\ker H|_{\text{bosonic}} - \dim\ker H|_{\text{fermionic}}$$

and is independent of β. Invariance under a continuous change of coupling, volume, or regulator follows provided no zero-energy state is lost to a continuum, no state enters from a continuum, and the deformation preserves the same supercharge, spin structure, global form, and flux sector.

If $H|\psi\rangle = E|\psi\rangle$ with $E > 0$, then at least one of $Q|\psi\rangle$ and $Q^\dagger|\psi\rangle$ is nonzero; otherwise

$$E\|\psi\|^2 = \frac{1}{2}\big(\|Q|\psi\rangle\|^2 + \|Q^\dagger|\psi\rangle\|^2\big) = 0.$$

The nonzero image has the same energy and opposite fermion parity. Thus the positive-energy spectrum contributes zero to the supertrace. Only $\ker H$ remains, giving the displayed formula and β-independence.

For a continuous family of finite-volume Hamiltonians satisfying the same algebra, positive-energy levels can cross or split only in supersymmetric boson-fermion multiplets. The integer supertrace can change only if the definition of the Hilbert-space sector changes or if zero-energy states escape to, or arrive from, a continuum. This is the analytic caveat: the graded trace identity is algebraic, while deformation invariance of a continuum quantum field theory is a statement about the spectral behavior of the regulated family.

Finite-volume symmetry basis versus cluster branches. The following finite-dimensional calculation is only an algebraic model for the zero-energy sector after the massive-branch hypotheses have been imposed. Let V_0 be an N_c-dimensional zero-energy space on which all states have the same fermion parity $\varepsilon = \pm 1$. Suppose a unitary operator U, representing the generator of the quotient $\mathbb{Z}_{2N_c}/\mathbb{Z}_2$, acts on a branch basis $\{|k\rangle\}_{k\in\mathbb{Z}/N_c\mathbb{Z}}$ by

$$U|k\rangle = |k+1\rangle.$$

Suppose also that the chiral coordinate S is diagonal in this branch basis,

$$S|k\rangle = s\,\omega^k|k\rangle, \qquad \omega = \exp(2\pi\mathrm{i}/N_c), \qquad s \neq 0.$$

Then

$$\mathrm{Tr}_{V_0}(-1)^F = \varepsilon N_c, \qquad \mathrm{Tr}_{V_0}\big(U^p(-1)^F\big) = 0 \quad (p \not\equiv 0 \pmod{N_c}), \tag{90.19}$$

and the U-eigenvectors

$$|r\rangle = \frac{1}{\sqrt{N_c}}\sum_{k=0}^{N_c-1}\omega^{-rk}|k\rangle, \qquad r \in \mathbb{Z}/N_c\mathbb{Z},$$

satisfy

$$U|r\rangle = \omega^r|r\rangle, \qquad \langle r|S|r\rangle = 0, \qquad S|r\rangle = s\,|r-1\rangle. \tag{90.20}$$

Thus a finite-volume basis that diagonalizes the exact discrete symmetry need not display a nonzero one-point condensate. The nonzero values $\langle k|S|k\rangle = s\omega^k$ belong to the cluster branch basis, which is an infinite-volume pure-phase idealization requiring the additional massive-branch and cluster hypotheses, beyond the ordinary Witten index.

In the branch basis, U^p is the permutation $k \mapsto k+p$. If $p \not\equiv 0 \pmod{N_c}$, this permutation has no fixed basis vector and therefore has trace zero. If $p \equiv 0$, the trace is N_c. Since $(-1)^F = \varepsilon$ on V_0, this proves (90.19).

The displayed Fourier vectors obey

$$U|r\rangle = \frac{1}{\sqrt{N_c}}\sum_k \omega^{-rk}|k+1\rangle = \omega^r|r\rangle.$$

Their diagonal S-matrix element is

$$\langle r|S|r\rangle = \frac{s}{N_c}\sum_{k=0}^{N_c-1}\omega^k = 0,$$

because $\omega \neq 1$ and $\omega^{N_c} = 1$. Finally,

$$S|r\rangle = \frac{s}{\sqrt{N_c}}\sum_k \omega^{(1-r)k}|k\rangle = s\,|r-1\rangle.$$

The operator S therefore changes the discrete chiral charge sector rather than producing a diagonal order parameter in the symmetry-eigenstate basis. The branch basis diagonalizes S but not U, exactly as a symmetry-breaking basis should.

Hypothesis 90.8 (Small-circle affine-Toda input)**.** The following semiclassical computation is used as a controlled chiral-sector model for the same $SU(N_c)$ theory with periodic fermions on $\mathbb{R}^3 \times S^1_R$. Work at small R in a weak-coupling region with a generic Wilson line breaking

$$SU(N_c) \longrightarrow U(1)^{N_c-1}.$$

The Wilson-line scalars and dual photons are assembled into periodic chiral coordinates Y_i, $i = 1, \ldots, N_c$, with $\sum_i Y_i = 0$. In the basis

$$\alpha_i = e_i - e_{i+1}, \quad i = 1, \ldots, N_c - 1, \qquad \alpha_0 = e_{N_c} - e_1,$$

the $N_c - 1$ fundamental monopole-instantons and the affine monopole each have exactly two gaugino zero modes and contribute a chiral superpotential term. Their product has the topological charge and holomorphic weight of one four-dimensional instanton, denoted by the compactified scale coordinate η. Effects with additional fermion zero modes, nonchiral determinants, and boundary terms are assumed not to change the protected critical-point count. After the chiral variables are gapped, the remaining three-dimensional theory may be placed in finite spatial volume, and the finite-dimensional local oscillator calculation below applies to each nondegenerate massive chiral critical point.

Under Hypothesis 90.8, the monopole terms generate an affine-Toda superpotential of the form

$$W_{\text{aff}} = \sum_{i=1}^{N_c-1} \exp(Y_i - Y_{i+1}) + \eta \exp(Y_{N_c} - Y_1),$$

where η is the four-dimensional holomorphic scale coordinate in the compactified normalization. Define the nonzero variables

$$x_i = \exp(Y_i - Y_{i+1}), \quad i = 1, \ldots, N_c - 1, \qquad x_{N_c} = \eta \exp(Y_{N_c} - Y_1).$$

The constraint is

$$x_1 x_2 \cdots x_{N_c} = \eta.$$

Affine-Toda critical-point count. Assume Hypothesis 90.8 and $\eta \neq 0$. The critical equations of W_{aff} on the constraint hypersurface

$$x_1 \cdots x_{N_c} = \eta$$

have exactly N_c isolated solutions:

$$x_1 = x_2 = \cdots = x_{N_c}.$$

Equivalently, if x is the common value, then

$$x^{N_c} = \eta.$$

Write variations tangent to the constraint as

$$\delta x_i = x_i\,\delta y_i, \qquad \sum_{i=1}^{N_c} \delta y_i = 0.$$

The first variation of $W_{\mathrm{aff}} = \sum_i x_i$ is

$$\delta W_{\mathrm{aff}} = \sum_{i=1}^{N_c} x_i\,\delta y_i.$$

This vanishes for every vector (δy_i) with zero sum if and only if all x_i are equal. The constraint then gives $x^{N_c} = \eta$, which has N_c solutions when $\eta \neq 0$.

The solutions are isolated. On the tangent hyperplane $\sum_i \delta y_i = 0$, the quadratic term at a critical point is

$$\frac{x}{2}\sum_{i=1}^{N_c} (\delta y_i)^2.$$

Since $x \neq 0$, the bilinear form $\sum_i (\delta y_i)^2$ is nondegenerate on the hyperplane. Thus each critical point is Morse in the complex holomorphic sense.

Proposition 90.9 (Local index of a nondegenerate chiral critical point)**.** *Consider a finite-dimensional supersymmetric quantum mechanics obtained by keeping n complex chiral zero modes z^a, a positive Hermitian metric at a critical point p, and a holomorphic superpotential W. Assume that*

$$\partial_a W(p) = 0, \qquad H_{ab} = \partial_a \partial_b W(p)$$

is an invertible complex symmetric matrix, and that the regulator localizes the low-energy contribution to a small ball around p without introducing extra boundary zero modes. Then p contributes

$$\mathcal{I}_{\mathrm{loc}}(p) = +1$$

to the graded trace. In particular, the local contribution in the affine-Toda chamber is not the real Morse sign of $\operatorname{Re} W$*; the holomorphic chiral complex has a canonical complex orientation.*

Proof. Choose normal holomorphic coordinates for the Hermitian metric at p, and discard higher terms in W. The discarded terms give a compact perturbation of the local oscillator as long as no boundary zero mode is created, so the local index is unchanged by the finite-dimensional graded-trace identity. Since H is complex symmetric and invertible, Takagi factorization gives a unitary matrix U and nonzero singular values $\mu_a > 0$ such that

$$H = U^T \operatorname{diag}(\mu_1, \ldots, \mu_n) U.$$

After this holomorphic change of variables, the quadratic model is a tensor product of one-dimensional chiral oscillators with

$$W_{\mathrm{quad}} = \frac{1}{2}\sum_{a=1}^{n} \mu_a (z^a)^2.$$

For one factor, the supersymmetric ground-state equation is the Gaussian equation

$$\left(\frac{\partial}{\partial \bar z} + \mu z\right)\Psi_0 = 0, \qquad \Psi_0(z,\bar z) = \exp(-\mu|z|^2)$$

up to normalization and the harmless convention-dependent factor in the oscillator frequency. This state is normalizable, unique, and lies in the even fermion sector. Every excited oscillator state is paired with a state of opposite fermion parity by the local supercharge. Hence one complex factor has local supertrace $+1$, and the tensor product of n factors also has local supertrace $+1$.

The statement about signs follows from the same normal form. As a real Morse function, $\mathrm{Re}(\mu z^2/2)$ has one positive and one negative Hessian direction for each complex coordinate. That real Morse sign belongs to the de Rham Morse complex of $\mathrm{Re}\, W$, not to the holomorphic chiral oscillator used in the supersymmetric gauge-theory index. □

Hypothesis 90.10 (Index continuation and massive-branch interpretation)**.** The $SU(N_c)$ index obtained in the small-circle semiclassical chamber is identified with the four-dimensional finite-volume index only when no zero-energy state leaks through a continuum and the spin structure, global form, and flux sector are unchanged. The infinite-volume limit is assumed to have N_c massive pure phases, related by the anomalous $\mathbb{Z}_{2N_c}$ chiral symmetry and satisfying cluster decomposition. Confinement and a mass gap require the separate spectral construction described in Section 90.6.

Pure $SU(N_c)$ index and condensate relation. Assume Hypotheses 90.7, 90.8, and 90.10. Then

$$\mathcal{I}_{SU(N_c)} = N_c.$$

If, in addition, Hypothesis 90.2 realizes the massive chiral branches through the glueball coordinate S, then the N_c branches have condensates

$$\langle S\rangle_k = C\,\Lambda_h^3 \mathrm{e}^{2\pi \mathrm{i} k/N_c}, \qquad k = 0,\dots,N_c-1,$$

and the discrete chiral symmetry is broken as $\mathbb{Z}_{2N_c} \to \mathbb{Z}_2$ in each pure phase.

The affine-Toda computation gives N_c isolated supersymmetric critical points in the small-circle chamber. The finite-volume graded-trace identity turns this critical-point count into the index in that chamber, because the critical points are isolated and massive in the chiral variables of the semiclassical approximation, and Proposition 90.9 gives local contribution $+1$ at each of them. The continuation hypothesis then identifies the same integer with the four-dimensional $SU(N_c)$ finite-volume index.

The condensate statement uses an input beyond the index: the additional glueball F-term hypothesis. Under that hypothesis, the VY/source-normalization branch analysis gives precisely the displayed N_c-fold orbit of $\langle S\rangle$. Since S has gaugino-phase charge 2, a nonzero value of $\langle S\rangle_k$ leaves only the $\alpha = \pi$ subgroup unbroken, namely $\mathbb{Z}_2$.

For a simple simply connected gauge group G, the expected index is the dual Coxeter number $h_G^\vee$. The monograph does not use that general statement here; the detailed derivation above is the $SU(N_c)$ case, where $h^\vee_{SU(N_c)} = N_c$. The delicate point is still the route from the regulated finite-volume computation to the four-dimensional infinite-volume theory: the index protects a signed count only under the stated spectral and boundary-condition hypotheses, while the condensate requires the additional massive-branch and chiral-source input.

90.8 ADS Superpotential

The ADS superpotential enters here as a Wilsonian chiral quantity obtained from a controlled semiclassical seed and then continued holomorphically. Symmetry and holomorphy are powerful only after one knows which chiral quantity is being computed, on which patch it is controlled, and which boundary terms have been excluded or absorbed into the holomorphic scale. The constructive seed is the $N_f = N_c - 1$ theory on the maximal-rank Higgs patch. There the gauge group is completely broken, the instanton size integral is cut off at large size by the Higgs expectation values, and the charge-one collective-coordinate integral can be reduced to finite-dimensional bosonic and fermionic zero-mode algebra together with a regulated determinant over nonzero modes.

The logical order used below is therefore the following. First, count the BPST collective coordinates in the normalization fixed earlier and identify the exact two gaugino modes that can become the $d^2\theta$ measure. Second, use the microscopic Yukawa coupling in the Higgs background to lift all remaining matter and non-Goldstino gaugino zero modes, and compute the corresponding Berezin determinant instead of replacing it by an uncomputed "zero-mode saturation" phrase. Third, check the real instanton-size integral that shows how the Higgs vevs control the large-size endpoint. Fourth, use holomorphy, special-flavor invariance, and the scaling degree to identify the remaining chiral function as $C/\det M$. Finally, only after this semiclassical seed is in place, holomorphic mass decoupling propagates the result to $N_f < N_c - 1$.

This order matters conceptually. The explicit instanton calculation supplies the existence of a nonzero F-term, the scale exponent, the exact zero-mode selection rule, and the meson-patch denominator in a regime where the functional integral has a semiclassical meaning. Holomorphy then extends that chiral input. Confinement, a mass gap, and a complete Hilbert-space description require the Wilsonian and infrared hypotheses separated below.

Assume $N_f < N_c$ and consider the region where M has maximal rank. The holomorphic superpotential compatible with flavor symmetry, the anomaly-free R-symmetry, and the scale coordinate has the form

$$W_{\text{ADS}} = C_{N_c,N_f} \left(\frac{\Lambda_h^{3N_c-N_f}}{\det M} \right)^{\frac{1}{N_c-N_f}}.$$

Its mass dimension is 3, because

$$[\Lambda_h^{3N_c-N_f}] = 3N_c - N_f, \qquad [\det M] = 2N_f,$$

and

$$\frac{3N_c - N_f - 2N_f}{N_c - N_f} = 3.$$

Its R-charge is 2, since $R(M) = 2(1 - N_c/N_f)$, hence

$$R(\det M) = 2N_f - 2N_c, \qquad R\Big((\det M)^{-1/(N_c-N_f)}\Big) = 2.$$

The coefficient is fixed by matching to a semiclassical instanton calculation for $N_f = N_c - 1$ and by holomorphic decoupling for smaller N_f, once the instanton measure and scale convention have been specified.

Hypothesis 90.11 (SQCD one-instanton calculus input)**.** For the direct instanton derivation at $N_f = N_c - 1$, the following analytic inputs are assumed. The Euclidean functional integral is regulated in a supersymmetric holomorphic scheme preserving $SU(N_f)_L \times SU(N_f)_R \times U(1)_B$ and the anomaly-free $U(1)_R$. The vacuum is taken on the maximal-rank Higgs patch, so the gauge group is completely broken and the instanton size integral is cut off at large size by the Higgs scale. The collective-coordinate change of variables separates exact zero modes from nonzero modes, with the topological charge, θ-angle, and coupling normalization fixed by Section 51.17. Boundary terms from the small-size endpoint are absorbed into the holomorphic scale coordinate Λ_h, and no further boundary contribution with the same quantum numbers is present. Under these assumptions the one-instanton sector defines a holomorphic chiral F-term up to an overall nonzero constant depending on the normalization of Λ_h.

Higgs-patch collective-coordinate calculation. Let $N_f = N_c - 1$. On the dense maximal-rank meson patch one may choose local complex coordinates

$$Q^{ai} = v_i \delta^{ai}, \qquad \widetilde{Q}_{ia} = \widetilde{v}_i \delta_{ia}, \qquad i = 1, \ldots, N_c - 1, \tag{90.21}$$

with all $v_i \widetilde{v}_i \neq 0$, so that

$$M^i{}_j = \widetilde{v}_i v_i \, \delta^i{}_j, \qquad \det M = \prod_{i=1}^{N_c - 1} \widetilde{v}_i v_i.$$

At such a point the gauge group $SU(N_c)$ is completely Higgsed. A charge-one instanton has $4N_c$ bosonic collective coordinates, $2N_c$ adjoint gaugino zero modes, and $2N_c - 2$ matter-fermion zero modes. The Yukawa coupling to the Higgs expectation values lifts $2N_c - 2$ adjoint zero modes together with all $2N_c - 2$ matter zero modes, leaving exactly two gaugino zero modes for the $d^2\theta$ superpotential measure.

The diagonal form (90.21) is only a local coordinate choice on the open set $\det M \neq 0$; the final answer must be rewritten in flavor-covariant variables. If $g \in SU(N_c)$ preserves all nonzero columns $v_i e_i$, $i = 1, \ldots, N_c - 1$, then $g e_i = e_i$ for those i. The determinant-one condition then fixes the last basis vector as well, so the continuous stabilizer is trivial.

For $N_c \geq 3$, the charge-one $SU(N_c)$ instanton bosonic moduli may be counted as four translations, one size coordinate, and the gauge-orientation quotient

$$\frac{SU(N_c)}{SU(N_c - 2) \times U(1)}.$$

The orientation quotient has real dimension

$$(N_c^2 - 1) - \big((N_c - 2)^2 - 1\big) - 1 = 4N_c - 5.$$

For $N_c = 2$ the orientation space is the full $SU(2)$, which has the same dimension $3 = 4N_c - 5$. Thus the formula below holds uniformly. The total bosonic dimension is therefore

$$4 + 1 + (4N_c - 5) = 4N_c.$$

The fermion zero-mode counts are the index-theorem counts in the BPST normalization used earlier. For a charge-one instanton,

$$n_\lambda = 2T(\text{adj}) = 2N_c, \qquad n_{\psi_Q} = N_f, \qquad n_{\psi_{\widetilde{Q}}} = N_f,$$

because $2T(\mathbf{N}_c) = 2T(\overline{\mathbf{N}}_c) = 1$. Hence the matter zero-mode count is $2N_f = 2N_c - 2$.

The Euclidean Yukawa terms contain the finite-dimensional zero-mode couplings obtained by inserting the scalar expectation values into the gauge-matter interaction

$$\sqrt{2}\,\widetilde{Q}^\dagger \lambda \psi_{\widetilde{Q}} - \sqrt{2}\,\psi_Q \lambda Q^\dagger + \text{conjugate terms}, \tag{90.22}$$

with spinor and color contractions inherited from Chapter 87. In the diagonal patch each nonzero v_i and $\widetilde{v}_i$ supplies a nondegenerate pairing between a matter zero mode and one non-Goldstino gaugino mode. Thus the lifting matrix has rank $2N_f = 2N_c - 2$. The two gaugino modes generated by the broken supersymmetries are not lifted; they are the exact Grassmann coordinates whose integration is the $d^2\theta$ measure.

Yukawa-lifting Berezin determinant on the Higgs patch. Assume the setup of the Higgs-patch collective-coordinate calculation above. After choosing bases for the $2N_f$ matter zero modes and for the $2N_f$ non-Goldstino adjoint zero modes, the zero-mode part of (90.22) has the finite-dimensional form

$$S_{\text{lift}} = \sum_{i=1}^{N_f} \left(a_i\, \chi_i \zeta_i + b_i\, \widetilde{\chi}_i \widetilde{\zeta}_i \right), \qquad a_i = c_i\, \overline{v_i}, \quad b_i = \widetilde{c}_i\, \overline{\widetilde{v}_i}, \tag{90.23}$$

where $c_i, \widetilde{c}_i$ are nonzero constants depending only on normalizations of zero-mode wavefunctions. With the orientation convention and these nonzero normalization constants absorbed into a nonzero constant C_{or}, the lifted zero-mode integral is

$$\int \prod_{i=1}^{N_f} d\chi_i\, d\zeta_i\, d\widetilde{\chi}_i\, d\widetilde{\zeta}_i\, \exp(-S_{\text{lift}}) = C_{\text{or}} \prod_{i=1}^{N_f} \overline{v_i\, \widetilde{v}_i}. \tag{90.24}$$

Thus the Yukawa matrix has maximal rank precisely on the patch $\det M \neq 0$, saturates all lifted Grassmann coordinates, and leaves only the two exact gaugino modes. The anti-holomorphic product in (90.24) is a statement about this finite-dimensional Euclidean lifting determinant. The holomorphic ADS denominator also uses the full regulated instanton measure, the bosonic Higgs cutoff, and the hypothesis that the sector defines a holomorphic F-term; these data determine the reduced factor $\mathcal{F}(M)$ below. The diagonal Higgs background separates the flavor-color directions. The terms in (90.22) pair the Q matter zero mode in the i-th direction with one lifted adjoint mode, with coefficient proportional to $\overline{v_i}$, and pair the $\widetilde{Q}$ matter zero mode with another lifted adjoint mode, with coefficient proportional to $\overline{\widetilde{v}_i}$. Since $v_i \widetilde{v}_i \neq 0$ on the patch, each 2×2 Grassmann block has nonzero coefficient.

For a single block,

$$\exp(-a\chi\zeta) = 1 - a\chi\zeta.$$

The Berezin integral over $d\chi\, d\zeta$ extracts the coefficient of the top monomial, up to the chosen orientation sign. Hence one block contributes a nonzero multiple of a, and the tensor product of all Q and $\widetilde{Q}$ blocks contributes

$$C_{\text{or}} \prod_i a_i b_i = C'_{\text{or}} \prod_i \overline{v_i\, \widetilde{v}_i}.$$

Renaming this nonzero constant as C_{or} gives (90.24). If any lifted variable is omitted, or if one of the coefficients is zero, the top monomial in the corresponding Grassmann variables is absent and the integral vanishes. This proves both the saturation statement and the maximal-rank criterion. The two Goldstino coordinates do not appear in S_{lift}, so they remain as the $d^2\theta$ measure.

Radial Higgs cutoff in the ADS instanton patch. Keep the $N_f = N_c - 1$ Higgs-patch setup above, and write

$$H(v, \widetilde{v}) = \sum_{i=1}^{N_f} \bigl(|v_i|^2 + |\widetilde{v}_i|^2\bigr).$$

On the maximal-rank patch $\det M \neq 0$, one has $H(v, \widetilde{v}) > 0$. Suppose that a fixed angular and zero-mode term in the regulated charge-one collective-coordinate integral has radial factor

$$\rho^{2p-1} \exp(-c\,\rho^2 H(v, \widetilde{v}))\, d\rho, \qquad p \in \mathbb{Z}_{>0}, \quad c > 0, \tag{90.25}$$

where $\rho > 0$ is the instanton size. Then the radial integral is

$$I_p(H) = \int_0^\infty \rho^{2p-1} \exp(-cH\rho^2)\, d\rho = \frac{(p-1)!}{2(cH)^p}. \tag{90.26}$$

In particular, the Higgs expectation values give exponential convergence at large ρ and a real homogeneous factor of degree $-2p$ under $(v_i, \widetilde{v}_i) \mapsto t(v_i, \widetilde{v}_i)$. This real cutoff estimate supplies convergence and real homogeneity. The holomorphic ADS denominator additionally requires the Yukawa lifting rank on the boundary $\det M = 0$ and the holomorphic invariant $1/\det M$, supplied by the Yukawa-lifting calculation above and Lemma 90.12.

If $\det M \neq 0$ in the diagonal patch, then $\widetilde{v}_i v_i \neq 0$ for every i, hence each summand in H is strictly positive and $H > 0$. For $\rho \geq 1$, the radial integrand is bounded by $\rho^{2p-1} \mathrm{e}^{-(cH)\rho^2}$, and this function is integrable on $[1, \infty)$ because the exponential decay dominates every polynomial. Near $\rho = 0$, the integrand is $\rho^{2p-1}(1 + O(\rho^2))\, d\rho$, which is integrable because $p \geq 1$. Thus the model radial integral is finite.

Set $u = cH\rho^2$. Then

$$\rho^{2p-1}\, d\rho = \frac{u^{p-1}}{2(cH)^p}\, du.$$

Therefore

$$I_p(H) = \frac{1}{2(cH)^p} \int_0^\infty u^{p-1} e^{-u}\, du = \frac{\Gamma(p)}{2(cH)^p} = \frac{(p-1)!}{2(cH)^p},$$

because p is a positive integer.

If all Higgs coordinates are multiplied by t, then H is multiplied by $|t|^2$, so I_p is multiplied by $|t|^{-2p}$. The absolute values show why this radial estimate is a real analytic convergence statement, not a holomorphic transformation law. Approaching $\det M = 0$ also changes the rank of the finite-dimensional Yukawa lifting matrix, so the maximal-rank instanton calculation cannot be extended across that boundary by the radial estimate alone.

Lemma 90.12 (Maximal-rank meson invariant for the ADS patch)**.** *Let $n = N_c - 1$, and let*

$$U_n = \{M \in \mathrm{Mat}_{n\times n}(\mathbb{C}) \mid \det M \neq 0\}.$$

Suppose $\mathcal{F} : U_n \to \mathbb{C}$ is a single-valued holomorphic function satisfying

$$\mathcal{F}(LMR^{-1}) = \mathcal{F}(M), \qquad L, R \in \mathrm{SL}_n(\mathbb{C}), \tag{90.27}$$

and the homogeneous scaling law

$$\mathcal{F}(sM) = s^{-n}\mathcal{F}(M), \qquad s \in \mathbb{C}^\times. \tag{90.28}$$

Then

$$\mathcal{F}(M) = \frac{C}{\det M}$$

for a constant C. For the $N_f = N_c - 1$ SQCD R-charge assignment, $(\det M)^{-1}$ *has R-charge* 2.

Proof. The action in (90.27) is the complexified special-flavor action on the meson matrix. For $\delta \in \mathbb{C}^\times$, set

$$D_\delta = \mathrm{diag}(\delta, 1, \ldots, 1).$$

Every $M \in U_n$ with $\det M = \delta$ lies in the same $\mathrm{SL}_n(\mathbb{C})$ left orbit as D_δ, because

$$A = MD_\delta^{-1} \qquad \text{satisfies} \qquad \det A = (\det M)(\det D_\delta)^{-1} = 1$$

and hence $A \in \mathrm{SL}_n(\mathbb{C})$ with $M = AD_\delta$. Therefore $\mathcal{F}$ is constant on each determinant fiber. Define

$$f(\delta) = \mathcal{F}(D_\delta), \qquad \delta \in \mathbb{C}^\times.$$

Then

$$\mathcal{F}(M) = f(\det M).$$

Now scale M by $s \in \mathbb{C}^\times$. Since $\det(sM) = s^n \det M$, the homogeneity condition gives

$$f(s^n\delta) = s^{-n} f(\delta).$$

For arbitrary $u \in \mathbb{C}^\times$, choose s with $s^n = u$. The displayed identity becomes

$$f(u\delta) = u^{-1} f(\delta).$$

Taking $\delta = 1$ gives $f(u) = C/u$. Thus $\mathcal{F}(M) = C/(\det M)$.

Finally, when $N_f = N_c - 1 = n$,

$$R(M) = 2\left(1 - \frac{N_c}{N_c - 1}\right) = -\frac{2}{n}, \qquad R(\det M) = -2,$$

so $R((\det M)^{-1}) = 2$. □

One-instanton test of the ADS numerator and denominator. Assume Hypothesis 90.11. For $N_f = N_c - 1$, the one-instanton contribution to the Wilsonian chiral superpotential has the form

$$W_{k=1} = \kappa_{N_c} \frac{\Lambda_h^{2N_c+1}}{\det M}, \qquad \kappa_{N_c} \neq 0$$

in the holomorphic scale convention used in the instanton measure. This is the $N_f = N_c - 1$ specialization of W_{ADS}.

For $N_f = N_c - 1$, the Higgs-patch collective-coordinate calculation above and Hypothesis 90.11 reduce the charge-one sector to a finite-dimensional zero-mode integral of the form

$$\int d^4x_0\, d^2\eta\, \Lambda_h^{2N_c+1}\, \mathcal{F}(M), \tag{90.29}$$

where x_0 is the instanton position, η_α are the two exact gaugino modes, and $\mathcal{F}(M)$ is holomorphic on the patch $\det M \neq 0$. The one-loop holomorphic exponent is

$$b_0 = 3N_c - N_f = 2N_c + 1,$$

so a charge-one instanton carries the chiral scale factor $\Lambda_h^{2N_c+1}$. The Higgs expectation values cut off the large-size region of the instanton integral through a positive term of the form

$$\Delta S_{\rm cl} = c\,\rho^2 \sum_{i=1}^{N_c-1} \left(|v_i|^2 + |\widetilde{v}_i|^2\right), \qquad c > 0,$$

in the bosonic collective-coordinate action, while the small-size endpoint is absorbed into the holomorphic scale by the hypothesis.

The remaining dependence must be a holomorphic function of the meson matrix $M^i{}_j = \widetilde{Q}_j Q^i$, because the baryonic coordinates are absent when $N_f = N_c - 1$. The exact nonzero modes and lifted zero modes are integrated out in a regulator preserving the special flavor group, so $\mathcal{F}$ obeys the complexified $\mathrm{SL}(N_f, \mathbb{C})_L \times \mathrm{SL}(N_f, \mathbb{C})_R$ invariance used in Lemma 90.12. The reduced factor $\mathcal{F}(M)$ in (90.29) must carry engineering dimension

$$3 - (2N_c + 1) = -(2N_c - 2),$$

so under the coordinate scaling $M \mapsto sM$, where each meson entry has dimension 2, it is homogeneous of degree $-N_f$. With $N_f = N_c - 1$, Lemma 90.12 gives

$$\mathcal{F}(M) = \frac{C}{\det M}.$$

The anomaly-free R-charge gives the independent convention check

$$R(M) = 2\left(1 - \frac{N_c}{N_c - 1}\right) = -\frac{2}{N_c - 1}, \qquad R(\det M) = -2,$$

so $(\det M)^{-1}$ has R-charge 2, matching the charge of a superpotential. Thus the one-instanton sector has the displayed form, with the nonzero coefficient fixed by the chosen normalization of the regulated collective-coordinate measure.

For the smallest example, $SU(2)$ with one flavor, the calculation gives eight bosonic collective coordinates, four gaugino zero modes, and two matter zero modes. The Higgs expectation value lifts two gaugino modes together with the two matter modes, leaving $d^2\theta$. The formula becomes

$$W_{SU(2),\,N_f=1} = \kappa_2 \frac{\Lambda_h^5}{M}, \qquad M = \widetilde{Q}_a Q^a.$$

This low-rank case is often the cleanest way to audit the convention: the power 5 is $3N_c - N_f$, the denominator has dimension 2, and $R(M) = -2$, so M^{-1} supplies the required superpotential R-charge 2.

Holomorphic scale matching across a massive threshold. Give the N_f-flavor theory a mass m for the last flavor. If the low-energy $(N_f - 1)$-flavor Wilsonian theory is reached by integrating out that massive chiral pair, then the holomorphic scales obey

$$\Lambda_{N_f-1}^{3N_c-(N_f-1)} = m\,\Lambda_{N_f}^{3N_c-N_f}.$$

Match the holomorphic gauge coordinate at the threshold $\mu = m$. Above the threshold the one-loop coefficient is $3N_c - N_f$; below it is $3N_c - (N_f - 1)$. The invariant combinations

$$\mu^{3N_c - N_f} e^{2\pi \mathrm{i} \tau_{\text{above}}(\mu)} \quad \text{and} \quad \mu^{3N_c-(N_f-1)} e^{2\pi \mathrm{i} \tau_{\text{below}}(\mu)}$$

are equal at $\mu = m$ after the massive determinant is included in the Wilsonian chiral coordinate. Eliminating the common value of $\tau(m)$ gives the displayed equation.

This is a coordinate-matching calculation inside the holomorphic Wilsonian scheme. The dynamical assumption is the preceding sentence: the massive pair must be integrated out in a scheme whose chiral gauge coordinate and threshold determinant have been specified. The displayed equation is not by itself a proof that the infrared description exists.

Proposition 90.13 (ADS decoupling recursion)**.** *Fix N_c and let $1 \leq n < N_c - 1$. Suppose the $(n+1)$-flavor Wilsonian chiral theory has, on a chosen holomorphic branch of the maximal-rank meson patch, the ADS superpotential*

$$W_{n+1} = C_{n+1} \left(\frac{\Lambda_+^{3N_c-(n+1)}}{\det \mathcal{M}} \right)^{\frac{1}{N_c-n-1}},$$

with $C_{n+1} \neq 0$. Add a holomorphic mass term

$$W_{\text{mass}} = m \, \mathcal{M}^L{}_L, \qquad L = n+1,$$

and assume the Wilsonian threshold is described by the holomorphic scale matching above. On the light branch $\mathcal{M}^a{}_L = \mathcal{M}^L{}_a = 0$, $a = 1, \ldots, n$, the effective n-flavor superpotential is

$$W_n = C_n \left(\frac{\Lambda_-^{3N_c-n}}{\det M} \right)^{\frac{1}{N_c-n}}, \qquad \Lambda_-^{3N_c-n} = m \, \Lambda_+^{3N_c-(n+1)}, \tag{90.30}$$

where $M^a{}_b$ is the light meson block and, writing $d = N_c - n$,

$$C_n = d \left(\frac{C_{n+1}}{d-1} \right)^{\frac{d-1}{d}}. \tag{90.31}$$

In the holomorphic scale normalization for which the one-instanton seed has $C_{N_c-1} = 1$, the recursion gives the standard representative

$$C_n = N_c - n.$$

Proof. The statement is local on a holomorphic branch because fractional powers are involved. The branch data are the usual discrete chiral choices of the Wilsonian description and do not affect the algebraic recursion.

Set $d = N_c - n \geq 2$, split $\mathcal{M}$ into the light block M, the mixed components, and

$$X = \mathcal{M}^L{}_L.$$

On the light branch the determinant factorizes:

$$\det \mathcal{M} = X \det M.$$

Define the holomorphic quantity

$$A = \frac{\Lambda_+^{3N_c-(n+1)}}{\det M}.$$

The superpotential to be extremized with respect to the massive chiral coordinate X is therefore

$$W(X) = C_{n+1}\left(\frac{A}{X}\right)^{\frac{1}{d-1}} + mX. \tag{90.32}$$

Introduce

$$Y = \left(\frac{A}{X}\right)^{\frac{1}{d-1}}.$$

The $F_X = 0$ equation is

$$0 = -\frac{C_{n+1}}{d-1}A^{\frac{1}{d-1}}X^{-\frac{d}{d-1}} + m.$$

Multiplying by X gives the useful identity

$$mX = \frac{C_{n+1}}{d-1}Y. \tag{90.33}$$

The same equation also gives

$$Y^d = \frac{(d-1)m}{C_{n+1}}A. \tag{90.34}$$

Substituting (90.33) into (90.32) gives

$$W_{\text{eff}} = C_{n+1}Y + mX = \frac{d}{d-1}C_{n+1}Y.$$

Using (90.34), this becomes

$$W_{\text{eff}} = d\left(\frac{C_{n+1}}{d-1}\right)^{\frac{d-1}{d}}\left(\frac{m\Lambda_+^{3N_c-(n+1)}}{\det M}\right)^{\frac{1}{d}}.$$

The holomorphic scale matching above turns the numerator into $\Lambda_-^{3N_c-n}$, proving (90.30) and (90.31).

If $C_{N_c-1} = 1$, induction on $d = N_c - n$ gives $C_n = d$. Indeed, if $C_{n+1} = d-1$, then (90.31) gives

$$C_n = d\left(\frac{d-1}{d-1}\right)^{\frac{d-1}{d}} = d.$$

$\square$

Proposition 90.14 (Massive SQCD decoupling to pure SYM branches)**.** *Fix $1 \le n < N_c$, and assume the n-flavor Wilsonian chiral sector on the maximal-rank meson patch is described by the standard ADS representative*

$$W_{\text{ADS},n} = d\left(\frac{\Lambda_n^{3N_c-n}}{\det M}\right)^{1/d}, \qquad d = N_c - n, \tag{90.35}$$

on a chosen holomorphic branch. Add an invertible holomorphic mass matrix

$$W_{\text{mass}} = m_i{}^j M^i{}_j, \qquad \det m \neq 0. \tag{90.36}$$

Assume that integrating out the massive meson coordinates is legitimate in the Wilsonian chiral theory and that holomorphic threshold matching to pure SYM holds:

$$\Lambda_0^{3N_c} = (\det m)\,\Lambda_n^{3N_c-n}. \tag{90.37}$$

Then the massive SQCD branch superpotential is

$$W_{\text{eff},k} = N_c\,\Lambda_0^3 \exp\left(\frac{2\pi \mathrm{i} k}{N_c}\right), \qquad k \in \mathbb{Z}/N_c\mathbb{Z}, \tag{90.38}$$

up to the same finite normalization of Λ_0 and S used in the pure-SYM glueball description. The source identity gives

$$\Lambda_0^{3N_c} \frac{\partial W_{\text{eff},k}}{\partial \Lambda_0^{3N_c}} = \Lambda_0^3 \exp\left(\frac{2\pi \mathrm{i} k}{N_c}\right). \tag{90.39}$$

Thus massive SQCD decoupling reproduces the pure-SYM condensate root equation and its N_c branches, conditional on the ADS input and the massive threshold assumptions.

Proof. Write

$$A = \Lambda_n^{3N_c-n}, \qquad Y = \left(\frac{A}{\det M}\right)^{1/d}. \tag{90.40}$$

Then $W_{\text{ADS},n} = dY$. For a variation of an invertible meson matrix,

$$\delta \log \det M = \operatorname{tr}(M^{-1}\delta M), \qquad \delta Y = -\frac{Y}{d}\operatorname{tr}(M^{-1}\delta M).$$

Hence

$$\delta W_{\text{ADS},n} = -Y\ \operatorname{tr}(M^{-1}\delta M).$$

In indices, the $F_M = 0$ equation is therefore

$$m_i{}^j = Y\,(M^{-1})^j{}_i. \tag{90.41}$$

Multiplying by $M^i{}_j$ and summing gives

$$m_i{}^j M^i{}_j = nY, \tag{90.42}$$

because $M^i{}_j (M^{-1})^j{}_i = n$. Taking determinants in (90.41) gives

$$\det m = \frac{Y^n}{\det M}. \tag{90.43}$$

Since $Y^d = A/\det M$, equations (90.43) and (90.40) imply

$$Y^{d+n} = A\ \det m.$$

As $d + n = N_c$, this is

$$Y^{N_c} = (\det m)\Lambda_n^{3N_c-n} = \Lambda_0^{3N_c}$$

by (90.37). Thus

$$Y_k = \Lambda_0^3 \exp\left(\frac{2\pi \mathrm{i} k}{N_c}\right), \qquad k \in \mathbb{Z}/N_c\mathbb{Z},$$

after choosing a branch of Λ_0^3.

At a critical point,

$$W_{\text{eff}} = dY + m_i{}^j M^i{}_j = dY + nY = N_c Y,$$

which proves (90.38). Finally, with $L_0 = \Lambda_0^{3N_c}$, the branch value is

$$W_{\text{eff},k} = N_c\, L_0^{1/N_c} \mathrm{e}^{2\pi \mathrm{i} k/N_c}.$$

Therefore

$$L_0 \frac{\partial W_{\text{eff},k}}{\partial L_0} = L_0^{1/N_c} \mathrm{e}^{2\pi \mathrm{i} k/N_c},$$

which is (90.39). The proof is a finite-dimensional chiral-coordinate elimination. It does not by itself construct the pure-SYM Hilbert space, prove the mass gap, or justify the ADS and threshold hypotheses from a microscopic regulator. □

Mass-source and Konishi identities in massive SQCD. Assume the hypotheses and notation of Proposition 90.14. On a chosen massive branch, the holomorphic source derivative with respect to the mass matrix gives the meson expectation

$$\frac{\partial W_{\text{eff},k}}{\partial m_i{}^j} = \langle M^i{}_j \rangle_k. \tag{90.44}$$

The finite-dimensional $F_M = 0$ equation then implies the matrix identity

$$\langle M^a{}_j \rangle_k\, m_i{}^j = \langle S \rangle_k\, \delta_i{}^a, \qquad \langle S \rangle_k = \Lambda_0^3 \exp\left(\frac{2\pi \mathrm{i} k}{N_c}\right). \tag{90.45}$$

Taking the trace gives

$$m_i{}^j \langle M^i{}_j \rangle_k = n\, \langle S \rangle_k. \tag{90.46}$$

This is the massive-SQCD chiral-coordinate realization of the Konishi relation. The local operator identity with the Konishi current and $\bar{D}^2$-exact terms requires the regulator-level current statement of Chapter 89; the calculation here uses only the already stated Wilsonian source calculus.

The full chiral function before eliminating M is

$$W(M; m, L_n) = d \left(\frac{L_n}{\det M}\right)^{1/d} + m_i{}^j M^i{}_j, \qquad L_n = \Lambda_n^{3N_c - n}.$$

Let $M_k(m, L_n)$ be the critical point on the chosen branch. The envelope theorem for a holomorphic finite-dimensional critical point gives

$$\frac{\partial}{\partial m_i{}^j} W(M_k(m, L_n); m, L_n) = M_k{}^i{}_j,$$

because the terms involving $\partial M_k / \partial m_i{}^j$ are multiplied by F_M and vanish at the critical point. This proves (90.44).

Equation (90.41) says

$$m_i{}^j = Y_k (M_k^{-1})^j{}_i.$$

Multiplying by $M_k{}^a{}_j$ gives

$$M_k{}^a{}_j \, m_i{}^j = Y_k \, M_k{}^a{}_j (M_k^{-1})^j{}_i = Y_k \, \delta_i{}^a.$$

By (90.39), the same branch coordinate is the glueball source derivative:

$$\langle S \rangle_k = Y_k = \Lambda_0^3 \exp\left(\frac{2\pi \mathrm{i} k}{N_c}\right).$$

This gives (90.45). Setting $a = i$ and summing over $i = 1, \ldots, n$ gives (90.46).

90.9 Quantum Modified Constraint and Confining Decoupling

For $N_f = N_c$, the classical relation between mesons and baryons is

$$\det M - B\widetilde{B} = 0.$$

The holomorphic scale has dimension $2N_c$ and the same spurionic quantum numbers as the left side. Under the Wilsonian and infrared hypotheses made explicit below, the protected quantum chiral-coordinate ring is represented by

$$\det M - B\widetilde{B} = \Lambda_h^{2N_c}.$$

This equation is a statement about the chiral ring and its vacuum space. It does not by itself determine the full Hilbert space, massive spectrum, or metric on the moduli space.

Hypothesis 90.15 ($N_f = N_c$ and $N_f = N_c + 1$ chiral-sector descriptions)**.** The following derivations compare protected chiral-coordinate rings in a supersymmetric Wilsonian scheme. For $N_f = N_c$, the infrared chiral sector is assumed to be generated by $M, B, \widetilde{B}$, with no generated superpotential and with a possible holomorphic deformation of the classical relation. For $N_f = N_c + 1$, the infrared chiral sector is assumed to be generated by mesons $M^I{}_J$, baryons B_I, and antibaryons $\widetilde{B}^J$, $I, J = 1, \ldots, N_c + 1$, with superpotential

$$W_{N_c+1} = \frac{1}{\Lambda_+^{2N_c-1}} \left(B_I M^I{}_J \widetilde{B}^J - \det M \right). \tag{90.47}$$

Here Λ_+ is the holomorphic scale of the $N_f = N_c + 1$ theory. The statements below derive consequences of these chiral descriptions and of holomorphic decoupling; they do not construct the full Hilbert space metric or prove confinement from a microscopic regulator.

Uniqueness of the field-independent quantum modification. Assume the $N_f = N_c$ chiral-sector part of Hypothesis 90.15. If the classical constraint is deformed by a field-independent holomorphic scale term, then up to the normalization of Λ_h the only allowed deformation is

$$\det M - B\widetilde{B} = \Lambda_h^{2N_c}.$$

For $N_f = N_c$, the anomaly-free assignment gives

$$R(Q) = R(\widetilde{Q}) = 0.$$

Thus $R(M) = R(B) = R(\widetilde{B}) = 0$. The two classical terms have the same engineering dimension:

$$[\det M] = 2N_c, \qquad [B\widetilde{B}] = N_c + N_c = 2N_c,$$

and the same flavor and baryon quantum numbers. A field-independent holomorphic deformation must therefore have dimension $2N_c$, zero baryon charge, and the same spurionic flavor and R-charges. The holomorphic scale of the $N_f = N_c$ theory appears in the invariant combination

$$\Lambda_h^{b_0}, \qquad b_0 = 3N_c - N_f = 2N_c.$$

No other field-independent monomial in the holomorphic scale has the required dimension. Absorbing the nonzero numerical coefficient into the definition of $\Lambda_h^{2N_c}$ gives the displayed constraint.

Mass decoupling from $N_f = N_c + 1$ to $N_f = N_c$. Assume Hypothesis 90.15. Add a holomorphic mass term for the last flavor of the $N_f = N_c + 1$ theory,

$$W_{\text{mass}} = m\, M^L{}_L, \qquad L = N_c + 1.$$

On the branch where the mixed heavy-light chiral coordinates vanish, the F-term equations of

$$W_{N_c+1} + W_{\text{mass}}$$

imply the $N_f = N_c$ quantum-modified constraint

$$\det \widehat{M} - B\widetilde{B} = \Lambda_-^{2N_c}, \qquad \Lambda_-^{2N_c} = m\, \Lambda_+^{2N_c-1}, \tag{90.48}$$

where $\widehat{M}^a{}_b$, $a, b = 1, \ldots, N_c$, is the light meson block and $B = B_L, \widetilde{B} = \widetilde{B}^L$ are the light baryons.

Split the flavor indices as $I = (a, L)$, with $a = 1, \ldots, N_c$. On the branch used for the low-energy $N_f = N_c$ variables, set

$$M^a{}_L = M^L{}_a = 0, \qquad B_a = \widetilde{B}^a = 0,$$

and write $X = M^L{}_L$. Then

$$\det M = X \det \widehat{M}, \qquad B_I M^I{}_J \widetilde{B}^J = B_L X \widetilde{B}^L.$$

The superpotential restricted to these coordinates is

$$W = \frac{X}{\Lambda_+^{2N_c-1}} \left(B\widetilde{B} - \det \widehat{M} \right) + mX.$$

The F-term equation for X gives

$$\frac{B\widetilde{B} - \det \widehat{M}}{\Lambda_+^{2N_c-1}} + m = 0,$$

or

$$\det \widehat{M} - B\widetilde{B} = m\, \Lambda_+^{2N_c-1}.$$

The remaining F-term equations along the low-energy branch set

$$X = 0$$

unless one sits on special subloci where additional massive coordinates have not yet been eliminated. Finally, holomorphic decoupling at the mass threshold gives

$$\Lambda_-^{3N_c-N_c} = m\,\Lambda_+^{3N_c-(N_c+1)} = m\,\Lambda_+^{2N_c-1},$$

which is exactly (90.48).

Remark 90.16 (Checks on the $N_f = N_c + 1$ confining superpotential). For $N_f = N_c + 1$, the two terms in (90.47) have the same engineering dimension and R-charge, and the prefactor makes W_{N_c+1} a dimension-three, R-charge-two chiral superpotential. At $N_f = N_c + 1$,

$$R(Q) = R(\widetilde{Q}) = \frac{1}{N_c+1}.$$

Thus

$$R(M) = \frac{2}{N_c+1}, \qquad R(B_I) = R(\widetilde{B}^J) = \frac{N_c}{N_c+1}.$$

The product $B_I M^I{}_J \widetilde{B}^J$ has R-charge

$$\frac{N_c}{N_c+1} + \frac{2}{N_c+1} + \frac{N_c}{N_c+1} = 2,$$

and $\det M$, where the determinant is over the $N_f = N_c + 1$ flavor indices, has R-charge

$$(N_c+1)\frac{2}{N_c+1} = 2.$$

Classically, $\dim M = 2$ and $\dim B_I = \dim \widetilde{B}^J = N_c$. Both $B_I M^I{}_J \widetilde{B}^J$ and $\det M$ therefore have dimension

$$2N_c + 2 = 2(N_c+1).$$

Since $\Lambda_+^{2N_c-1}$ has dimension $2N_c - 1$ and zero R-charge in the anomaly-free spurion convention, the quotient has dimension 3 and R-charge 2, as required.

90.10 Superconformal SQCD Bookkeeping

The same anomaly calculation also fixes the candidate superconformal data of SQCD in the range where an interacting infrared fixed point exists. For a chiral primary operator $\mathcal{O}$ in a four-dimensional $\mathcal{N} = 1$ superconformal theory,

$$\Delta(\mathcal{O}) = \frac{3}{2}R(\mathcal{O}).$$

For an elementary chiral field Φ, write its scalar scaling dimension as

$$\Delta(\Phi) = 1 + \frac{1}{2}\gamma_\Phi.$$

Compatibility of these two conventions gives

$$\gamma_\Phi = 3R(\Phi) - 2. \tag{90.49}$$

Here γ_Φ is the chapter convention

$$\gamma_\Phi = \frac{d}{d\log\mu}\log Z_\Phi.$$

Some supersymmetric-gauge-theory references instead use $\mathcal{C}_\Phi = \frac{1}{2}\,d\log Z_\Phi/d\log\mu$. The conversion is

$$\gamma_\Phi = 2\mathcal{C}_\Phi, \qquad \Delta(\Phi) = 1 + \mathcal{C}_\Phi.$$

For a product of two chiral fields with equal anomalous dimensions, the product anomalous dimension in the $\mathcal{C}$-notation is numerically equal to the single-field γ_Φ used below:

$$\mathcal{C}_{\Phi\Psi} = \Delta(\Phi\Psi) - 2 = \mathcal{C}_\Phi + \mathcal{C}_\Psi = \gamma_\Phi \qquad (\gamma_\Phi = \gamma_\Psi).$$

This is why the conifold formulas may be written with $1 - \gamma_A$ here while the same fixed point is sometimes described by $\mathcal{C}_{AB} = -\frac{1}{2}$ for the meson A_iB_j.

For SQCD with no tree superpotential, the anomaly-free assignment of the previous section gives

$$R(Q) = R(\widetilde{Q}) = 1 - \frac{N_c}{N_f}, \qquad \gamma_Q = 1 - \frac{3N_c}{N_f}.$$

Substitution in the NSVZ numerator gives

$$3N_c - N_f(1-\gamma_Q) = 3N_c - N_f\left(\frac{3N_c}{N_f}\right) = 0.$$

Thus the anomaly-free R-charge is also the unique candidate superconformal R-charge compatible with the flavor-symmetric NSVZ coordinate.

The meson $M = \widetilde{Q}Q$ has

$$R(M) = 2\left(1 - \frac{N_c}{N_f}\right), \qquad \Delta(M) = 3\left(1 - \frac{N_c}{N_f}\right).$$

The scalar unitarity bound for a gauge-invariant chiral operator requires $\Delta(M) \geq 1$, which gives $N_f \geq \frac{3}{2}N_c$. This is the lower edge of the usual electric conformal-window test; below it the electric meson cannot be an interacting chiral primary with the displayed superconformal R-charge. The upper edge $N_f < 3N_c$ is the condition that the electric gauge coupling is asymptotically free in the holomorphic one-loop coordinate. The existence and uniqueness of the infrared fixed point in the full interval require the nonperturbative input summarized in the status boundary below.

Hypothesis 90.17 (SCFT input used in bookkeeping)**.** Whenever this chapter assigns a scaling dimension by $\Delta = \frac{3}{2}R$, the following assumptions are in force: the infrared limit exists as a unitary four-dimensional $\mathcal{N} = 1$ SCFT; the operator under discussion is a chiral primary in that SCFT; the displayed $U(1)_R$ current is the superconformal R-current after all allowed mixing with non-R flavor currents has been fixed; and accidental symmetries do not change the R-charge of the operator in question. The anomaly and NSVZ calculations below test these assumptions; they do not by themselves construct the fixed point.

SQCD central charges and free-field comparison. Assume Hypothesis 90.17 and suppose $\frac{3}{2}N_c < N_f < 3N_c$. For the candidate SQCD superconformal R-current displayed above,

$$\operatorname{Tr} R = -N_c^2 - 1, \qquad \operatorname{Tr} R^3 = N_c^2 - 1 - \frac{2N_c^4}{N_f^2}. \tag{90.50}$$

Consequently the conformal anomalies are

$$a_{\mathrm{IR}} = \frac{3}{32}\left(4N_c^2 - 2 - \frac{6N_c^4}{N_f^2}\right), \qquad c_{\mathrm{IR}} = \frac{1}{32}\left(14N_c^2 - 4 - \frac{18N_c^4}{N_f^2}\right). \tag{90.51}$$

The free ultraviolet theory has

$$a_{\mathrm{UV}} = \frac{3}{16}(N_c^2 - 1) + \frac{N_c N_f}{24}. \tag{90.52}$$

Writing $y = N_f/N_c$, the difference is

$$a_{\mathrm{UV}} - a_{\mathrm{IR}} = \frac{N_c^2}{48y^2}(3-y)^2(2y+3). \tag{90.53}$$

It is strictly positive in the interacting conformal window and vanishes at the Gaussian edge $N_f = 3N_c$. This is only an anomaly-arithmetic comparison between a free ultraviolet fixed point and the candidate infrared SCFT. It is not a proof of a monotonicity theorem or of the existence of the flow; those remain part of the independent continuum and SCFT hypotheses.

The traces are over Weyl fermions. The gaugino contributes

$$\operatorname{Tr} R_\lambda = N_c^2 - 1, \qquad \operatorname{Tr} R_\lambda^3 = N_c^2 - 1.$$

The scalar R-charge of Q and $\widetilde{Q}$ is

$$R(Q) = R(\widetilde{Q}) = 1 - \frac{N_c}{N_f},$$

so their fermions have R-charge $-N_c/N_f$. There are $2N_cN_f$ such Weyl fermions. Hence

$$\operatorname{Tr} R = (N_c^2 - 1) + 2N_cN_f\left(-\frac{N_c}{N_f}\right) = -N_c^2 - 1,$$

and

$$\operatorname{Tr} R^3 = (N_c^2 - 1) + 2N_cN_f\left(-\frac{N_c}{N_f}\right)^3 = N_c^2 - 1 - \frac{2N_c^4}{N_f^2}.$$

For a four-dimensional $\mathcal{N} = 1$ SCFT,

$$a = \frac{3}{32}(3\operatorname{Tr} R^3 - \operatorname{Tr} R), \qquad c = \frac{1}{32}(9\operatorname{Tr} R^3 - 5\operatorname{Tr} R). \tag{90.54}$$

Substituting the two traces gives (90.51).

At the ultraviolet Gaussian fixed point, a vector multiplet contributes $\frac{3}{16}\dim SU(N_c)$ to a, and a free chiral multiplet contributes $\frac{1}{48}$ per complex gauge-flavor component. Since $\dim SU(N_c) = N_c^2 - 1$ and there are $2N_cN_f$ chiral components, (90.52) follows.

Subtracting the candidate infrared value from the ultraviolet value gives

$$a_{\mathrm{UV}} - a_{\mathrm{IR}} = -\frac{3N_c^2}{16} + \frac{N_c N_f}{24} + \frac{9N_c^4}{16N_f^2}.$$

Set $y = N_f/N_c$. Then

$$a_{\mathrm{UV}} - a_{\mathrm{IR}} = N_c^2 \left(-\frac{3}{16} + \frac{y}{24} + \frac{9}{16y^2} \right) = \frac{N_c^2}{48y^2} \big(2y^3 - 9y^2 + 27 \big).$$

The polynomial factorizes as

$$2y^3 - 9y^2 + 27 = (3 - y)^2 (2y + 3).$$

For $y > 0$ this expression is nonnegative and it is zero only when $y = 3$. In the interacting window $3/2 < y < 3$, it is strictly positive. The proof has established this finite anomaly comparison; it has not established the general a-theorem.

90.11 Seiberg Duality And The SQCD Phase Structure

The preceding superconformal bookkeeping used only the electric SQCD variables. We now isolate the nonperturbative duality input that is needed whenever the chapter talks about the full SQCD phase diagram. This is a field-theoretic statement about four-dimensional $\mathcal{N} = 1$ gauge dynamics; no string construction is part of the definition or the argument.

Write the flavor symmetry as

$$SU(N_f)_L \times SU(N_f)_R \times U(1)_B \times U(1)_R.$$

The electric fields transform as

	$SU(N_c)$	$SU(N_f)_L$	$SU(N_f)_R$	$U(1)_B$	$U(1)_R$
Q^i	$\mathbf{N}_c$	$\mathbf{N}_f$	$\mathbf{1}$	$+1$	$1 - \frac{N_c}{N_f}$
$\widetilde{Q}_j$	$\overline{\mathbf{N}}_c$	$\mathbf{1}$	$\overline{\mathbf{N}}_f$	-1	$1 - \frac{N_c}{N_f}$

and the meson $M^i{}_j = \widetilde{Q}_j Q^i$ transforms as $(\mathbf{N}_f, \overline{\mathbf{N}}_f)$. The normalization of $U(1)_B$ is chosen so that an electric baryon Q^{N_c} has charge N_c. This differs by a harmless overall factor from conventions in which Q has baryon charge $1/N_c$.

For $N_f \geq N_c + 2$, set

$$\widetilde{N}_c = N_f - N_c.$$

The magnetic SQCD variables consist of an $SU(\widetilde{N}_c)$ vector multiplet, magnetic quarks $q_i, \widetilde{q}^j$, and a gauge-singlet meson coordinate $M^i{}_j$ with the global charges

	$SU(\widetilde{N}_c)$	$SU(N_f)_L$	$SU(N_f)_R$	$U(1)_B$	$U(1)_R$
q_i	fund	$\overline{\mathbf{N}}_f$	$\mathbf{1}$	$\frac{N_c}{\widetilde{N}_c}$	$\frac{N_c}{N_f}$
$\widetilde{q}^j$	$\overline{\text{fund}}$	$\mathbf{1}$	$\mathbf{N}_f$	$-\frac{N_c}{\widetilde{N}_c}$	$\frac{N_c}{N_f}$
$M^i{}_j$	$\mathbf{1}$	$\mathbf{N}_f$	$\overline{\mathbf{N}}_f$	0	$2\left(1 - \frac{N_c}{N_f}\right)$.

The magnetic superpotential is

$$W_{\text{mag}} = \frac{1}{\mu_*} M^i{}_j q_i \widetilde{q}^j. \tag{90.55}$$

Here $M^i{}_j$ is normalized as the electric composite $\widetilde{Q}_j Q^i$, so it has engineering dimension two in the microscopic matching convention; μ_* is a nonzero matching scale of dimension one. Equivalently one may use the canonically normalized magnetic singlet $M_{\text{can}} = M/\mu_*$ and absorb μ_* into the Yukawa coupling. The displayed form keeps the operator map visible.

Hypothesis 90.18 (SQCD infrared-comparison hypotheses)**.** Whenever this section compares the electric and magnetic SQCD descriptions, the following hypotheses are part of the statement.

1. The electric and magnetic Lagrangians have continuum infrared limits in a regulator preserving the gauge Ward identities, the listed flavor symmetries, and enough supersymmetry for the Wilsonian chiral-coordinate arguments of Chapters 88 and 89.
2. The unbroken global currents are represented by the same operators in the two infrared limits. Consequently their 't Hooft anomalies are invariant data of the infrared theory and must match.
3. The displayed $U(1)_R$ current is the superconformal current in the interacting range after all allowed flavor-current mixing has been fixed. At free endpoints one must include the accidental symmetries of the free fields before interpreting $\Delta = \frac{3}{2}R$.
4. The chiral coordinates $M, B, \widetilde{B}$ and their magnetic images generate the protected chiral sector being compared, after imposing F-term equations and after excluding extra accidental chiral generators not present in the stated phase.
5. Relevant deformations by holomorphic quark masses and by generic Higgs-branch expectation values commute with the comparison: after integrating out massive fields and matching holomorphic scales, the lower-rank theories satisfy the same comparison hypotheses.

These assumptions are not justified by historical authority. Their role is visible in the calculations below. The magnetic rank and baryon charges are forced by the baryon map $Q^{N_c} \leftrightarrow q^{\widetilde{N}_c}$; the meson singlet is forced because $Q\widetilde{Q}$ is an independent electric chiral coordinate; the superpotential is the unique cubic chiral coupling with the displayed flavor charges and R-charge 2; the magnetic gauge anomaly cancellation is a necessary consistency test; and the global anomaly matching below is a regulator-independent test of the common infrared current algebra. These checks do not construct the continuum infrared fixed point, but they make every algebraic burden of the duality statement explicit.

Quoted Theorem 90.19 (Seiberg-duality input for SQCD)**.** *For four-dimensional $\mathcal{N} = 1$ SQCD with gauge group $SU(N_c)$, $N_f \geq N_c + 2$ flavors, zero tree superpotential, and the Wilsonian coordinate conventions of this chapter, and under Hypothesis 90.18, the infrared theory at the origin of the quantum moduli space has an equivalent magnetic description with gauge group $SU(N_f - N_c)$, fields and charges as displayed above, and superpotential (90.55). The equivalence identifies the common global currents, chiral ring after imposing superpotential equations, deformations by masses and Higgs expectation values, and all 't Hooft anomalies. In the interval $\frac{3}{2}N_c < N_f < 3N_c$ this is an equivalence of interacting infrared SCFTs; in the free electric and free magnetic ranges it is understood after including the appropriate free variables and accidental symmetries at the endpoint.*

This quoted theorem is not a theorem proved from the preceding Wilsonian holomorphy alone. The monograph uses it as an exact nonperturbative input and then exposes the checks that make the statement sharp: charge assignments, anomaly matching, deformation matching, and consistency with NSVZ fixed-point arithmetic.

Magnetic R-charge and NSVZ consistency. With the magnetic charges displayed above, $U(1)_R$ is free of $SU(\widetilde{N}_c)^2U(1)_R$ gauge anomaly, the magnetic superpotential has R-charge 2, and the magnetic NSVZ numerator vanishes at the same candidate superconformal point as the electric numerator.

The $SU(\widetilde{N}_c)^2U(1)_R$ anomaly receives $+\widetilde{N}_c$ from the magnetic gaugino. The two magnetic quark families have fermion R-charge

$$R(q) - 1 = R(\widetilde{q}) - 1 = \frac{N_c}{N_f} - 1 = -\frac{\widetilde{N}_c}{N_f}.$$

Using $T(\mathbf{fund}) = T(\overline{\mathbf{fund}}) = \frac{1}{2}$,

$$\widetilde{N}_c + \frac{1}{2}N_f\left(-\frac{\widetilde{N}_c}{N_f}\right) + \frac{1}{2}N_f\left(-\frac{\widetilde{N}_c}{N_f}\right) = 0.$$

The superpotential charge is

$$R(M) + R(q) + R(\widetilde{q}) = 2\left(1 - \frac{N_c}{N_f}\right) + 2\frac{N_c}{N_f} = 2.$$

At a superconformal fixed point the chapter convention gives

$$\gamma_q = 3R(q) - 2 = \frac{3N_c}{N_f} - 2.$$

The magnetic NSVZ numerator is therefore

$$3\widetilde{N}_c - N_f(1 - \gamma_q) = 3(N_f - N_c) - N_f\left(3 - \frac{3N_c}{N_f}\right) = 0.$$

The electric numerator was checked in Section 90.10; both descriptions therefore pass the same fixed-point arithmetic.

Electric-magnetic anomaly matching. Normalize cubic nonabelian anomalies so that a left-handed Weyl fermion in the fundamental of $SU(N_f)$ contributes $+1$ and an antifundamental contributes -1. Normalize mixed $SU(N_f)^2U(1)$ anomalies so that a fundamental or antifundamental contributes the same quadratic index. Then the electric and magnetic descriptions have the common anomaly coefficients

anomaly	coefficient
$SU(N_f)_L^3$	N_c
$SU(N_f)_R^3$	$-N_c$
$SU(N_f)_L^2 U(1)_R$	$-\frac{N_c^2}{N_f}$
$SU(N_f)_R^2 U(1)_R$	$-\frac{N_c^2}{N_f}$
$SU(N_f)_L^2 U(1)_B$	N_c
$SU(N_f)_R^2 U(1)_B$	$-N_c$
$U(1)_B^2 U(1)_R$	$-2N_c^2$
$U(1)_R$	$-N_c^2 - 1$
$U(1)_R^3$	$N_c^2 - 1 - \frac{2N_c^4}{N_f^2}$.

All traces are over left-handed Weyl fermions. In the electric theory the quark and antiquark fermions have R-charge $-N_c/N_f$, while the gaugino has R-charge 1. Thus, for example,

$$SU(N_f)_L^3 : \quad N_c, \qquad SU(N_f)_R^3 : \quad -N_c,$$

and

$$SU(N_f)_L^2 U(1)_R : \quad N_c \left(-\frac{N_c}{N_f}\right) = -\frac{N_c^2}{N_f}.$$

The right-flavor mixed R-anomaly is the same, while the baryonic mixed anomalies are N_c and $-N_c$ because Q and $\widetilde{Q}$ have baryon charges $+1$ and -1. The purely abelian traces are

$$U(1)_B^2 U(1)_R : \quad 2N_c N_f \left(-\frac{N_c}{N_f}\right) = -2N_c^2,$$

$$\operatorname{Tr} R = (N_c^2 - 1) + 2N_c N_f \left(-\frac{N_c}{N_f}\right) = -N_c^2 - 1,$$

and

$$\operatorname{Tr} R^3 = (N_c^2 - 1) + 2N_c N_f \left(-\frac{N_c}{N_f}\right)^3 = N_c^2 - 1 - \frac{2N_c^4}{N_f^2}.$$

For the magnetic theory set $t = \widetilde{N}_c = N_f - N_c$. The q and $\widetilde{q}$ fermions have R-charge $-t/N_f$, baryon charges $\pm N_c/t$, and tN_f components each. The mesino in $M^i{}_j$ has

$$R(M) - 1 = 2\left(1 - \frac{N_c}{N_f}\right) - 1 = \frac{N_f - 2N_c}{N_f}.$$

For the left cubic flavor anomaly, q gives $-t$ and the N_f right flavor copies of the mesino give $+N_f$, hence $-t + N_f = N_c$. For the right cubic anomaly, $\widetilde{q}$ gives $+t$ and the mesino gives $-N_f$, hence $t - N_f = -N_c$. The left mixed R-anomaly is

$$t\left(-\frac{t}{N_f}\right) + N_f\left(\frac{N_f - 2N_c}{N_f}\right) = -\frac{(N_f - N_c)^2}{N_f} + N_f - 2N_c = -\frac{N_c^2}{N_f},$$

and the right mixed R-anomaly is identical. The mixed baryonic flavor anomalies are

$$SU(N_f)_L^2 U(1)_B : \quad t\frac{N_c}{t} = N_c, \qquad SU(N_f)_R^2 U(1)_B : \quad -t\frac{N_c}{t} = -N_c.$$

The $U(1)_B^2 U(1)_R$ trace is

$$2tN_f\left(\frac{N_c}{t}\right)^2\left(-\frac{t}{N_f}\right)=-2N_c^2.$$

Finally,

$$\operatorname{Tr}R=(t^2-1)+2tN_f\left(-\frac{t}{N_f}\right)+N_f^2\left(\frac{N_f-2N_c}{N_f}\right)=-N_c^2-1,$$

and

$$\operatorname{Tr}R^3=(t^2-1)-\frac{2t^4}{N_f^2}+\frac{(N_f-2N_c)^3}{N_f}=N_c^2-1-\frac{2N_c^4}{N_f^2}.$$

This completes the displayed anomaly-matching calculation.

Mass and Higgs deformation tests for SQCD duality. Let $N_f \ge N_c+2$ and set $\widetilde{N}_c = N_f - N_c$. The magnetic field content and superpotential in (90.55) pass the following necessary deformation tests. This is a bookkeeping calculation inside the proposed dual description, not a proof of Seiberg duality.

First give the last electric flavor a holomorphic mass

$$W_{\text{el,mass}} = m\, M^L{}_L, \qquad L = N_f.$$

In the magnetic variables the F-term equation for $M^L{}_L$ is

$$\frac{1}{\mu_*} q_L^\alpha \widetilde{q}_\alpha^L + m = 0. \tag{90.56}$$

For $\widetilde{N}_c \ge 2$, a rank-one solution Higgses

$$SU(\widetilde{N}_c) \longrightarrow SU(\widetilde{N}_c - 1).$$

The light magnetic theory has $N_f - 1$ flavors, gauge rank

$$\widetilde{N}_c - 1 = (N_f - 1) - N_c,$$

and the same meson-quark superpotential form for the light flavor block. For initial $\widetilde{N}_c = 2$, the resulting $SU(1)$ gauge group is trivial; this is the boundary case leading to the $N_f = N_c + 1$ confining chiral description rather than to another nonabelian magnetic gauge theory.

Second give the electric theory a rank-r meson expectation value on the classical Higgs patch, with $1 \le r < N_c$:

$$M^A{}_B = v_A \delta^A{}_B, \qquad A, B = 1, \ldots, r, \qquad v_A \neq 0.$$

The electric gauge group is Higgsed to $SU(N_c - r)$ with $N_f - r$ light flavors. In the magnetic variables the same background gives masses

$$\frac{v_A}{\mu_*}\, q_A \widetilde{q}^A, \qquad A = 1, \ldots, r,$$

to r magnetic flavor pairs. After they are integrated out, the magnetic gauge rank remains $\widetilde{N}_c$, which is precisely the dual rank of the low-energy electric theory:

$$(N_f - r) - (N_c - r) = N_f - N_c = \widetilde{N}_c. \tag{90.57}$$

For the mass deformation, split flavor indices as $i = (a, L)$, with $a = 1, \dots, N_f - 1$. The deformed magnetic superpotential is

$$W_{\text{mag}} + mM^L{}_L = \frac{1}{\mu_*} M^i{}_j q_i^\alpha \widetilde{q}_\alpha^j + mM^L{}_L.$$

The $M^L{}_L$ equation is (90.56), while the other M-equations set the corresponding magnetic quark bilinears to zero on the light branch. Choose a local representative

$$q_L^\alpha = v\, \delta^\alpha{}_{\widetilde{N}_c}, \qquad \widetilde{q}_\alpha^L = \widetilde{v}\, \delta_{\alpha \widetilde{N}_c}, \qquad v\widetilde{v} = -\mu_* m, \tag{90.58}$$

with the usual D-flat representative chosen inside the complexified gauge orbit. The stabilizer of this nonzero fundamental-antifundamental pair is $SU(\widetilde{N}_c - 1)$. The fields carrying the broken color line are massive or gauge directions. The remaining light magnetic quarks have flavor labels $a = 1, \dots, N_f - 1$ and color labels in $SU(\widetilde{N}_c - 1)$, and the surviving singlet block is $M^a{}_b$. Restricting the superpotential to these light fields gives

$$W_{\text{light}} = \frac{1}{\mu_*} M^a{}_b q_a \widetilde{q}^b,$$

which has the same form as (90.55). The rank identity is immediate:

$$\widetilde{N}_c - 1 = N_f - N_c - 1 = (N_f - 1) - N_c.$$

For the Higgs deformation, a rank-r electric meson expectation value may be represented on the dense Higgs patch by r independent nonzero quark-antiquark pairs. Their common stabilizer in $SU(N_c)$ is $SU(N_c - r)$, and the light electric flavors are the remaining $N_f - r$. In the magnetic superpotential, substituting $M^A{}_B = v_A \delta^A{}_B$ gives the displayed mass terms $(v_A/\mu_*) q_A \widetilde{q}^A$. For generic nonzero v_A, these integrate out exactly r magnetic flavor pairs. The magnetic gauge group is not Higgsed by this operation, so its rank remains $\widetilde{N}_c = N_f - N_c$. Equation (90.57) shows that this is the dual rank of the low-energy electric $SU(N_c - r)$ theory with $N_f - r$ flavors.

These deformation tests are necessary consequences of the proposed duality, not a replacement for the quoted nonperturbative input. Their value in this chapter is that the mass, Higgs, and rank bookkeeping is completely visible: one can see which fields are eliminated, which gauge group remains, and where the boundary $N_f = N_c + 1$ description enters.

The $N_f < N_c$ entries in the phase table below have a different logical status from the duality entries. The $N_f = N_c - 1$ ADS term was derived above from an explicit one-instanton zero-mode and symmetry calculation under Hypothesis 90.11. The cases $N_f < N_c - 1$ are then reached by holomorphic decoupling using the scale matching above and Proposition 90.13. Thus the nonzero superpotential in the runaway range is not inferred from Seiberg duality; it is a chiral F-term result whose direct semiclassical anchor, finite-dimensional elimination step, and decoupling assumptions are displayed separately.

SQCD infrared range synthesis. The following table is a synthesis of results and inputs with different logical status, not a single theorem with a uniform proof. The $N_f < N_c$ range follows from the ADS seed, holomorphic decoupling, and the displayed finite-dimensional elimination arguments. The $N_f = N_c$ and $N_f = N_c + 1$ entries use the quantum-modified and confining chiral-coordinate inputs stated earlier in the section. The magnetic ranges $N_f \geq N_c + 2$ use the nonperturbative Seiberg-duality input of Quoted Theorem 90.19 under Hypothesis 90.18. The one-loop signs below are Wilsonian coordinate checks on the proposed infrared variables; by themselves they do not construct the continuum infrared fixed points or prove the electric-magnetic equivalence.

$N_f < N_c$. Status: ADS/holomorphic-decoupling result under the instanton and chiral coordinate hypotheses already stated. The ADS superpotential is generated. With no tree-level mass terms there is no supersymmetric vacuum at finite meson expectation value; the potential has a runaway direction on the maximal-rank meson patch.

$N_f = N_c$. Status: quantum-modified chiral-coordinate input checked against the decoupling from the $N_f = N_c+1$ description. There is no generated superpotential, but the chiral coordinate ring is quantum modified:

$$\det M - B\widetilde{B} = \Lambda_h^{2N_c}.$$

$N_f = N_c + 1$. Status: confining chiral-coordinate input with the mass-decoupling and anomaly checks displayed above. The infrared chiral description is in terms of mesons and baryons. If B_i and $\widetilde{B}^j$ denote the baryons with one flavor index left over, the exact superpotential is

$$W_{\mathrm{conf}} = \frac{1}{\Lambda_h^{2N_c-1}} \left(B_i M^i{}_j \widetilde{B}^j - \det M \right). \tag{90.59}$$

$N_c + 2 \leq N_f < \frac{3}{2}N_c$. Status: Seiberg-duality input plus perturbative sign check in the magnetic variables. The magnetic gauge group $SU(N_f - N_c)$ is infrared free, since its one-loop coefficient is

$$b_{0,\mathrm{mag}} = 3(N_f - N_c) - N_f = 2N_f - 3N_c < 0.$$

The appropriate low-energy variables are the magnetic quarks, magnetic gluons, and meson singlets.

$\frac{3}{2}N_c < N_f < 3N_c$. Status: Seiberg-duality input plus SCFT-current and accidental-symmetry hypotheses. Both electric and magnetic variables are asymptotically free and flow, under that input, to the same interacting nonabelian Coulomb-phase SCFT. The lower endpoint is detected by the electric meson unitarity bound, and the upper endpoint by the electric loss of asymptotic freedom.

$N_f \geq 3N_c$. Status: perturbative electric infrared-freedom statement, with the marginal endpoint interpreted in the same Wilsonian coordinate convention. The electric variables are in the free electric phase. For $N_f > 3N_c$ the electric gauge coupling is infrared free in the usual perturbative sense; at $N_f = 3N_c$ the interacting Banks–Zaks fixed point has collided with the Gaussian endpoint in this table.

90.12 Klebanov–Witten Conifold SCFT

Let $N \geq 2$. The Klebanov–Witten theory has gauge group

$$G_{\mathrm{KW}} = SU(N)_1 \times SU(N)_2$$

and four chiral superfields

$$A_i \in (\mathbf{N}, \overline{\mathbf{N}}), \qquad B_j \in (\overline{\mathbf{N}}, \mathbf{N}), \qquad i, j = 1, 2.$$

Equivalently, one may start from the unitary $U(N)_1 \times U(N)_2$ presentation. Its diagonal $U(1)$ is a free center-of-mass vector multiplet, and the interacting nonabelian sector is the $SU(N)_1 \times SU(N)_2$ theory displayed above. The relative abelian factor is useful for describing the rank-one abelian quotient below.

The index i is a doublet index for a global $SU(2)_A$, and j is a doublet index for a global $SU(2)_B$. The baryonic symmetry $U(1)_B$ is normalized here by

$$q_B(A_i) = +1, \qquad q_B(B_j) = -1.$$

The tree superpotential is

$$W_{\mathrm{KW}} = h\, \epsilon^{ij} \epsilon^{kl}\, \mathrm{tr}(A_i B_k A_j B_l), \tag{90.60}$$

where the trace is over the gauge indices in the alternating product

$$\mathbf{N}_1 \xrightarrow{A_i} \mathbf{N}_2 \xrightarrow{B_k} \mathbf{N}_1 \xrightarrow{A_j} \mathbf{N}_2 \xrightarrow{B_l} \mathbf{N}_1.$$

The manifest continuous global symmetry at the superpotential point is

$$SU(2)_A \times SU(2)_B \times U(1)_B \times U(1)_R.$$

There is also a charge-conjugation symmetry exchanging the two gauge factors and the A- and B-multiplets when the two gauge couplings are exchanged.

Hypothesis 90.20 (KW Lagrangian and branch assumptions)**.** The algebraic calculations in this section use the four-dimensional $\mathcal{N} = 1$ Lagrangian with gauge group, matter representations, trace normalization, and superpotential displayed above. Statements about the mesonic vacuum branch use the classical F- and D-flat quotient of that Lagrangian and then restrict to the commuting branch where the bifundamental matrices can be simultaneously reduced to diagonal representatives. Statements about protected dimensions use Hypothesis 90.17. Claims about the full continuum conformal manifold are isolated in Hypothesis 90.24 and in the exact-marginality rank calculation below.

KW F-term equations. The F-term equations of W_{KW} are

$$A_1 B_j A_2 = A_2 B_j A_1, \qquad j = 1, 2, \tag{90.61}$$

and

$$B_1 A_i B_2 = B_2 A_i B_1, \qquad i = 1, 2. \tag{90.62}$$

Expanding the antisymmetric tensors and using cyclicity of the trace gives

$$W_{\mathrm{KW}} = 2h\ \mathrm{tr}(A_1 B_1 A_2 B_2 - A_1 B_2 A_2 B_1).$$

Varying with respect to A_1 and moving δA_1 to the left inside the trace gives

$$\delta_{A_1} W_{\mathrm{KW}} = 2h\ \mathrm{tr}\big[\delta A_1 (B_1 A_2 B_2 - B_2 A_2 B_1)\big],$$

so $B_1 A_2 B_2 = B_2 A_2 B_1$. The variation with respect to A_2 gives the same equation with A_1 and A_2 exchanged. Varying with respect to B_1 and B_2 in the same way gives

$$A_2 B_2 A_1 = A_1 B_2 A_2, \qquad A_1 B_1 A_2 = A_2 B_1 A_1,$$

which is exactly (90.61). These are matrix equations in the appropriate bifundamental Hom-spaces.

KW anomaly and superpotential R-charge. Assume the $SU(2)_A \times SU(2)_B$ symmetry and the exchange symmetry, so that

$$R(A_i) = R(B_j) = r.$$

The simultaneous conditions that $U(1)_R$ have no $SU(N)_a^2 U(1)_R$ anomaly and that W_{KW} have R-charge 2 give

$$r = \frac{1}{2}.$$

For either gauge factor the gaugino contributes $T(\mathrm{adj}) = N$ to the $SU(N)^2 U(1)_R$ anomaly coefficient. Each of the two A-fields and each of the two B-fields is a fundamental or antifundamental for that gauge factor and has N copies from the other gauge index. With $T(\mathbf{N}) = T(\overline{\mathbf{N}}) = \frac{1}{2}$, the matter contribution is

$$4 \cdot \frac{N}{2}(r-1) = 2N(r-1).$$

The anomaly coefficient is therefore

$$N + 2N(r-1) = N(2r-1),$$

which vanishes exactly at $r = \frac{1}{2}$. The superpotential contains two A-fields and two B-fields, so its R-charge is $4r$, also equal to 2 exactly at $r = \frac{1}{2}$.

Remark 90.21 (KW NSVZ numerator). At $r = \frac{1}{2}$, as fixed by the anomaly and superpotential-charge calculation above, the chiral-multiplet anomalous dimensions in the superconformal convention are

$$\gamma_A = \gamma_B = -\frac{1}{2},$$

and the NSVZ numerator of each gauge factor vanishes. Equation (90.49) gives

$$\gamma_A = \gamma_B = 3 \cdot \frac{1}{2} - 2 = -\frac{1}{2}.$$

For either $SU(N)$ factor, the total matter index is

$$4 \cdot N \cdot \frac{1}{2} = 2N.$$

Hence the NSVZ numerator is

$$3N - 2N(1-\gamma_A) = 3N - 2N\left(1 + \frac{1}{2}\right) = 0.$$

The scalar dimension of each A_i and B_j is therefore

$$\Delta(A_i) = \Delta(B_j) = 1 + \frac{1}{2}\gamma_A = \frac{3}{4} = \frac{3}{2}R(A_i).$$

KW beta-function rank count. Work in the $SU(2)_A \times SU(2)_B \times U(1)_B$-preserving source-coordinate system near the Klebanov–Witten point, and assume the NSVZ coordinate convention of this chapter with finite denominators for both gauge couplings. Let γ_A and γ_B be the anomalous dimensions of the A- and B-doublets in the monograph convention. Then the two gauge beta-function numerators and the quartic-superpotential marginality defect are all proportional to the same expression:

$$\mathcal{B}_1 = \mathcal{B}_2 = N(1 + \gamma_A + \gamma_B), \qquad \mathcal{B}_h = 1 + \gamma_A + \gamma_B. \tag{90.63}$$

Consequently the three local vanishing conditions have rank one in this symmetry-preserving chart. At the exchange-symmetric point $\gamma_A = \gamma_B = \gamma$, the common condition is $\gamma = -\frac{1}{2}$.

For the first gauge group, each of the two A-fields is a fundamental with N copies from the second gauge index, and each of the two B-fields is an antifundamental with the same multiplicity. Hence

$$\sum_i T_1(R_i)(1-\gamma_i) = 2 \cdot \frac{N}{2}(1-\gamma_A) + 2 \cdot \frac{N}{2}(1-\gamma_B) = N(2-\gamma_A-\gamma_B).$$

The NSVZ numerator of the first gauge factor is therefore

$$\mathcal{B}_1 = 3N - N(2-\gamma_A-\gamma_B) = N(1+\gamma_A+\gamma_B).$$

The same count holds for the second gauge factor, with fundamentals and antifundamentals interchanged, so $\mathcal{B}_2 = \mathcal{B}_1$.

For the superpotential term, nonrenormalization means that the local condition for a quartic chiral coordinate to be marginal is the dimension condition on the chiral operator. The operator $\mathrm{tr}(A_i B_k A_j B_l)$ has dimension

$$2\left(1+\frac{\gamma_A}{2}\right) + 2\left(1+\frac{\gamma_B}{2}\right) = 4+\gamma_A+\gamma_B.$$

Since a four-dimensional superpotential integrand must have dimension 3, the marginality defect is

$$\mathcal{B}_h = (4+\gamma_A+\gamma_B) - 3 = 1+\gamma_A+\gamma_B.$$

Equivalently, the beta function of a dimensionless quartic coupling is proportional to this defect, up to the sign convention for whether the flow parameter is an energy scale or a length scale. Only the zero locus is used here.

Thus $\mathcal{B}_1$, $\mathcal{B}_2$, and $\mathcal{B}_h$ impose a single scalar condition in the symmetric chart. This is a necessary local beta-function count. Existence of the continuum SCFT, realization of the common zero by an RG trajectory, and nonsingularity of the local zero locus are the additional inputs isolated in Hypothesis 90.24.

The anomaly and NSVZ calculations above fix the exchange-symmetric point. To see that the same value is selected by a-maximization, allow mixing with the baryonic current:

$$R_s(A_i) = \frac{1}{2}+s, \qquad R_s(B_j) = \frac{1}{2}-s.$$

The gauge-anomaly and superpotential constraints impose only $R_s(A)+R_s(B)=1$. The trial central charge is computed from Weyl fermion R-charges. The two gaugino adjoints have fermion R-charge 1; the two A-fermions have charge $-\frac{1}{2}+s$; the two B-fermions have charge $-\frac{1}{2}-s$. Therefore

$$\mathrm{Tr}\, R_s = -2,$$

and

$$\mathrm{Tr}\, R_s^3 = 2(N^2-1) + 2N^2\left[\left(-\frac{1}{2}+s\right)^3 + \left(-\frac{1}{2}-s\right)^3\right] = \frac{3}{2}N^2 - 2 - 6N^2 s^2.$$

Thus

$$a(s) = \frac{3}{32}\left(3\,\mathrm{Tr}\, R_s^3 - \mathrm{Tr}\, R_s\right) = \frac{3}{32}\left(\frac{9}{2}N^2 - 4 - 18N^2 s^2\right),$$

which is maximized at $s = 0$. The superconformal R-charge is the symmetric one:

$$R(A_i) = R(B_j) = \frac{1}{2}.$$

Remark 90.22 (KW central charges). At the symmetric superconformal R-charge,

$$a_{\mathrm{KW}} = \frac{27}{64}N^2 - \frac{3}{8}, \qquad c_{\mathrm{KW}} = \frac{27}{64}N^2 - \frac{1}{4}.$$

For a four-dimensional $\mathcal{N} = 1$ SCFT,

$$a = \frac{3}{32}(3\,\mathrm{Tr}\,R_f^3 - \mathrm{Tr}\,R_f), \qquad c = \frac{1}{32}(9\,\mathrm{Tr}\,R_f^3 - 5\,\mathrm{Tr}\,R_f),$$

where the traces run over Weyl fermions. The fermion trace data at $s = 0$ are

$$\mathrm{Tr}\,R_f = 2(N^2 - 1) + 4N^2\left(-\frac{1}{2}\right) = -2$$

and

$$\mathrm{Tr}\,R_f^3 = 2(N^2 - 1) + 4N^2\left(-\frac{1}{8}\right) = \frac{3}{2}N^2 - 2.$$

Substitution gives the displayed values.

The basic mesonic chiral operators are

$$W_{ij} = A_i B_j.$$

For a single rank-one abelian sector in the $U(1)\times U(1)$ presentation, the diagonal $U(1)$ decouples and the complexified anti-diagonal gauge group acts with charges $+1$ on the A_i and -1 on the B_j. The four coordinates W_{ij} are invariant and obey one quadratic relation.

For the rank-one abelian quotient just described, the mesonic coordinate ring is

$$\mathbb{C}[W_{11}, W_{12}, W_{21}, W_{22}]/(W_{11}W_{22} - W_{12}W_{21}).$$

Write $W_{ij} = A_i B_j$ with commuting complex variables A_1, A_2, B_1, B_2. Then

$$W_{11}W_{22} - W_{12}W_{21} = A_1B_1A_2B_2 - A_1B_2A_2B_1 = 0.$$

Conversely, the invariant functions of a $\mathbb{C}^\times$ action with charges $+1, +1, -1, -1$ are generated by the degree-zero monomials A_iB_j. The only rank-one relation among the entries of the 2×2 matrix (W_{ij}) is its determinant. Hence the quotient is the affine conifold

$$\det(W) = 0.$$

On the mesonic commuting branch for general N, the matrices A_iB_j can be diagonalized simultaneously at generic points, and the Weyl group permutes the N eigenvalue quadruples. The corresponding branch is

$$\mathrm{Sym}^N\{W_{11}W_{22} - W_{12}W_{21} = 0\}.$$

This statement concerns the commuting mesonic branch; baryonic branches and noncommuting chiral-ring strata require additional invariant-theory data.

The protected operator dimensions follow immediately from the superconformal R-charges. The mesons W_{ij} transform as $(\mathbf{2},\mathbf{2})$ under $SU(2)_A \times SU(2)_B$ and have

$$R(W_{ij}) = 1, \qquad \Delta(W_{ij}) = \frac{3}{2}.$$

The baryons

$$\mathcal{B}_A = \det A_i, \qquad \mathcal{B}_B = \det B_j$$

have

$$R(\mathcal{B}_A) = R(\mathcal{B}_B) = \frac{N}{2}, \qquad \Delta(\mathcal{B}_A) = \Delta(\mathcal{B}_B) = \frac{3N}{4},$$

and baryonic charges $+N$ and $-N$ in the normalization above. Symmetric products

$$\mathrm{tr}(A_{i_1}B_{j_1}\cdots A_{i_\ell}B_{j_\ell})$$

have $R = \ell$ and $\Delta = \frac{3}{2}\ell$ when they represent nonzero chiral-primary classes.

Hypothesis 90.23 (Local $\mathcal{N} = 1$ exact-marginality chart)**.** Let $\mathcal{T}_0$ be a four-dimensional $\mathcal{N} = 1$ SCFT with a chosen global-symmetry subalgebra $\mathfrak{f}$ to be preserved. A local holomorphic marginal-source-coordinate system consists of complex coordinates

$$u = (u^1, \ldots, u^m)$$

for gauge and superpotential sources coupled to $\mathfrak{f}$-invariant chiral operators of superpotential dimension 3, together with a holomorphic beta map

$$\mathcal{B} : U \subset \mathbb{C}^m \longrightarrow \mathbb{C}^r$$

whose zero set is exactly the set of conformal theories in this source chart. Redundant directions from holomorphic field-coordinate changes have either been quotient out or fixed by a declared source normalization. The map $\mathcal{B}$ includes the gauge beta functions, superpotential beta functions, and any current-moment-map obstruction for a broken conserved current. If $d\mathcal{B}$ has constant rank r along the zero set, the local conformal manifold in this chart is the complex manifold $\mathcal{B}^{-1}(0)$ of dimension $m - r$.

Under this hypothesis, the dimension statement is the holomorphic implicit-function theorem applied to the finite-dimensional source-coordinate system. The QFT content is not the theorem of complex analysis; it is the hypothesis that the beta map and the quotient by redundant coordinates faithfully describe the continuum SCFT family.

Hypothesis 90.24 (KW exact-marginality input)**.** Near the Klebanov–Witten point, use local holomorphic sources

$$u = (\tau_1, \tau_2, h)$$

for the two $SU(N)$ gauge couplings and the quartic superpotential in (90.60), restricted to the $SU(2)_A \times SU(2)_B \times U(1)_B$-preserving chart. Assume the continuum SCFT exists in this neighborhood, the NSVZ Wilsonian coordinate analysis of this chapter computes the vanishing conditions for these sources, and no additional exactly marginal obstruction is present after the background contact-term and source-normalization data are fixed. Finally assume the common defect

$$E(u) = 1 + \gamma_A(u) + \gamma_B(u)$$

has nonzero differential at the symmetric point in the chosen source-coordinate system.

KW local conformal manifold from rank one. Assume Hypothesis 90.24. In the $SU(2)_A \times SU(2)_B \times U(1)_B$-preserving source-coordinate system, the Klebanov–Witten conformal locus is locally a complex surface in the source space with coordinates (τ_1, τ_2, h).

The rank-count calculation above gives, in this chart,

$$\mathcal{B}_1 = NE, \qquad \mathcal{B}_2 = NE, \qquad \mathcal{B}_h = E, \qquad E = 1 + \gamma_A + \gamma_B.$$

Thus the zero set of the three beta functions is the single equation

$$E(u) = 0.$$

By Hypothesis 90.24, $dE \neq 0$ at the Klebanov–Witten point. The holomorphic implicit-function theorem therefore identifies the local zero set with a smooth complex hypersurface in the three-dimensional source-coordinate system. Its local complex dimension is

$$3 - 1 = 2.$$

The proof uses no holographic construction. Its nontrivial QFT assumptions are exactly those isolated in Hypothesis 90.24: existence of the continuum SCFT chart, completeness of the beta-function analysis, and absence of hidden current or contact-term obstructions in the preserved-symmetry sector.

The result is a conditional field-theoretic reconstruction of the Leigh–Strassler rank count for this example. The chapter has proved the anomaly, NSVZ, a-maximization, chiral-ring, and rank-one beta-function arithmetic. It has not constructed the nonperturbative continuum SCFT from a regulator.

90.13 Klebanov–Strassler Cascade

Fix integers $M > 0$ and $N > M$. The ultraviolet theory used in the Klebanov–Strassler cascade has gauge group

$$SU(N+M)_1 \times SU(N)_2$$

with the same bifundamental matter and quartic superpotential as (90.60), now with rectangular gauge indices. Treating the anomalous dimensions of the four bifundamentals as equal to a common γ, the NSVZ numerators are

$$\mathcal{B}_1 = 3(N+M) - 2N(1-\gamma), \qquad \mathcal{B}_2 = 3N - 2(N+M)(1-\gamma). \tag{90.64}$$

At the Klebanov–Witten value $\gamma = -\frac{1}{2}$,

$$\mathcal{B}_1 = 3M, \qquad \mathcal{B}_2 = -3M.$$

Since the NSVZ beta function has the sign $\beta_g = -g^3\mathcal{B}/(16\pi^2(1 - \cdots))$, the larger gauge factor is driven to stronger coupling toward the infrared in this local coordinate, while the smaller factor is driven in the opposite direction. The cascade idealizes the strongly coupled step by applying Seiberg duality to the larger factor.

Hypothesis 90.25 (Cascade input assumptions)**.** The cascade discussion assumes the same supersymmetric Wilsonian scheme and NSVZ coordinate convention used earlier in the chapter. The displayed numerator signs are perturbative-coordinate diagnostics near the Klebanov–Witten anomalous dimension, not a proof that the flow follows a unique trajectory. Each rank-reducing step additionally assumes Seiberg duality for the strongly coupled node with the other node treated during the matching as a weakly gauged flavor symmetry, and assumes that integrating out the mesons in the magnetic description is legitimate in the Wilsonian neighborhood being used. These duality assumptions are recorded again in Quoted Theorem 90.26.

Cascade rank step. Assume the Seiberg-duality transformation for the first gauge factor while the second gauge factor is treated as a weakly gauged flavor symmetry during the dualization. Then

$$SU(N+M)\times SU(N) \quad\longmapsto\quad SU(N)\times SU(N-M),$$

up to relabeling of the two factors and matching of the quartic superpotential.

The first gauge factor $SU(N+M)$ sees two A-fields and two B-fields. Because each carries an $SU(N)$ index of the second gauge group, it has

$$N_f = 2N$$

flavors in the SQCD sense. Seiberg duality maps an electric $SU(N_c)$ theory with N_f flavors to a magnetic $SU(N_f - N_c)$ theory. Here

$$N_f - N_c = 2N - (N+M) = N - M.$$

The untouched second gauge factor is $SU(N)$. Relabeling the larger factor first gives $SU(N)\times SU(N-M)$. The electric mesons of the dualized node are composites

$$M_{ij} = A_i B_j.$$

The magnetic superpotential has the local form

$$W_{\mathrm{mag}} = h\,\epsilon^{ij}\epsilon^{kl}\,\mathrm{tr}(M_{ik}M_{jl}) + \frac{1}{\mu_*}\,\mathrm{tr}(M_{ij}a_i b_j), \tag{90.65}$$

where a_i, b_j are magnetic bifundamentals and μ_* is the matching scale used to assign dimension one to M_{ij}. The quadratic form

$$(M_{ij}) \longmapsto \epsilon^{ij}\epsilon^{kl}\,\mathrm{tr}(M_{ik}M_{jl})$$

is nondegenerate on the four mesons. Thus the F-term equations of (90.65) solve M_{ij} linearly in the bilinears $a_i b_j$. Substitution gives again a quartic superpotential proportional to

$$\epsilon^{ij}\epsilon^{kl}\,\mathrm{tr}(a_i b_k a_j b_l),$$

with a coefficient depending on the normalization of M_{ij} and μ_*.

Thus the rank difference remains M, while the common rank parameter drops by M. If

$$N = qM + r, \qquad 0 \le r < M,$$

then after q formal cascade steps the pair has reached

$$SU(M+r)\times SU(r),$$

where the second factor is absent when $r = 0$. The integer q is the number of rank-reducing duality steps, and $r = N \bmod M$ is the residual common rank parameter.

KS R-anomaly remnant. For the unequal-rank theory with the field charges

$$R(A_i) = R(B_j) = \frac{1}{2}, \qquad R(\lambda_1) = R(\lambda_2) = 1,$$

the continuous $U(1)_R$ has gauge-anomaly coefficients

$$\mathcal{A}_1 = M, \qquad \mathcal{A}_2 = -M$$

for $SU(N+M)_1^2 U(1)_R$ and $SU(N)_2^2 U(1)_R$. Consequently only the $\mathbb{Z}_{2M}$ subgroup is an honest symmetry with fixed theta angles.

For $SU(N+M)_1$, the gaugino contributes $N+M$. Each chiral fermion in an A_i or B_j multiplet has R-charge $-\frac{1}{2}$, and the total matter index seen by the first gauge group is

$$4 \cdot N \cdot \frac{1}{2} = 2N.$$

Therefore

$$\mathcal{A}_1 = (N+M) - \frac{1}{2}(2N) = M.$$

For $SU(N)_2$, the total matter index is instead

$$4 \cdot (N+M) \cdot \frac{1}{2} = 2(N+M),$$

so

$$\mathcal{A}_2 = N - \frac{1}{2}\big(2(N+M)\big) = -M.$$

In the normalization where pure $SU(K)$ supersymmetric Yang–Mills leaves $\mathbb{Z}_{2K}$, an R-rotation by angle φ shifts the two theta angles by

$$\theta_1 \mapsto \theta_1 + 2M\varphi, \qquad \theta_2 \mapsto \theta_2 - 2M\varphi.$$

Because each theta angle has period 2π, the rotation is a symmetry at fixed theta angles exactly when

$$2M\varphi \in 2\pi\mathbb{Z}.$$

Modulo the 2π-periodicity of the R-rotation parameter, this leaves $2M$ elements, namely $\mathbb{Z}_{2M}$.

Quoted Theorem 90.26 (Seiberg-duality input for the cascade)**.** *The cascade rank step describes the infrared chiral data and anomalies of the successive Wilsonian theories provided Seiberg duality holds for the strongly coupled node with the neighboring gauge group treated as a weakly gauged flavor symmetry during the matching. The matching includes the flavor symmetries, baryonic symmetry, R-symmetry, holomorphic scale coordinates, and the quartic superpotential after the massive mesons are eliminated.*

This is a status boundary, not a new proof of Seiberg duality. The monograph uses the duality as an exact field-theoretic input with visible checks: the magnetic rank is $N_f - N_c$, the rank difference is preserved, the alternating quartic superpotential is regenerated, and the global anomaly assignment is unchanged after the duality map.

For $r = 0$, the cascade ends at pure $SU(M)$ supersymmetric Yang–Mills. The anomalous chiral symmetry leaves a $\mathbb{Z}_{2M}$ gaugino phase symmetry, and gaugino condensation breaks it to $\mathbb{Z}_2$, producing M massive vacua in the finite-volume/gap sense used earlier in this chapter. For $0 < r < M$, the final strongly coupled theory contains an ADS or quantum-modified chiral coordinate, depending on the precise endpoint rank. This is only a field-theoretic endpoint summary in the present monograph; any geometric interpretation is outside the argument and is not used as evidence for the QFT dynamics.

90.14 Status Boundary

The arguments in this chapter determine holomorphic coordinates from symmetry, anomaly, decoupling, and semiclassical input. Turning them into a theorem for a four-dimensional continuum QFT requires a nonperturbative construction of the regulated supersymmetric gauge theory, a proof of the required mass gaps or moduli-space descriptions, and a Wilsonian scheme in which the chiral coordinates above are defined as continuum limits.

Open Problem 90.27 (Nonperturbative $\mathcal{N} = 1$ Wilsonian scheme)*.* Construct a four-dimensional regulator and continuum limit for $\mathcal{N} = 1$ gauge theories that preserves enough supersymmetric and gauge Ward identities to make the holomorphic Wilsonian coordinate arguments above proved statements.

Chapter 91

Four-Dimensional N=2 Gauge Dynamics and Seiberg-Witten Theory

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter develops the first layer of four-dimensional $\mathcal{N} = 2$ gauge dynamics. The emphasis is the Wilsonian low-energy description on the Coulomb branch, where the exact two-derivative Abelian action is encoded by a holomorphic prepotential and by periods of a family of curves.

Hypothesis 91.1 (Seiberg–Witten Coulomb-branch structure)**.** A Seiberg–Witten Coulomb-branch structure of rank r is the following collection attached to an assumed four-dimensional $\mathcal{N} = 2$ local QFT $\mathfrak{T}$.

(i) A connected complex analytic vacuum branch $\mathcal{B}$ and a discriminant locus $\Delta \subset \mathcal{B}$ such that the low-energy theory over $\mathcal{B}^\circ = \mathcal{B} \setminus \Delta$ contains r Abelian vector multiplets and no additional massless charged hypermultiplets.

(ii) A locally constant electromagnetic charge lattice $\Gamma \to \mathcal{B}^\circ$ with a nondegenerate integral antisymmetric Dirac pairing $\langle \cdot, \cdot \rangle : \Gamma \otimes \Gamma \to \mathbb{Z}$. A local electric polarization is a symplectic frame $(\alpha^I, \beta_I)_{I=1}^r$ of Γ.

(iii) A holomorphic period section

$$\Pi = (a_{D,I}, a^I)$$

in the dual local system, with monodromy in $Sp(2r, \mathbb{Z})$, such that

$$Z_\gamma = \langle \gamma, \Pi \rangle + \sum_\alpha s_\alpha m_\alpha$$

is the central charge of a state of electromagnetic charge γ and flavor charges s_α.

(iv) On each simply connected electric patch, a holomorphic prepotential $\mathcal{F}(a)$ satisfying

$$a_{D,I} = \frac{\partial \mathcal{F}}{\partial a^I}, \qquad \tau_{IJ} = \frac{\partial^2 \mathcal{F}}{\partial a^I \partial a^J}, \qquad \operatorname{Im}\tau > 0,$$

and the corresponding two-derivative Abelian Wilsonian action with the superspace normalization used in this volume.

(v) Local singularity data along Δ: the primitive charges of massless BPS states, the associated Picard–Lefschetz monodromies, and the convention for the BPS inequality $M_\gamma \geq \sqrt{2}\,|Z_\gamma|$.

(vi) When a curve realization is used, a holomorphic family of compact Riemann surfaces Σ_u, meromorphic differentials λ_{SW}, and symplectic one-cycle frames whose periods reproduce the section Π. This curve realization is auxiliary data for computing the special geometry; it is not by itself a construction of the four-dimensional QFT $\mathfrak{T}$.

All dynamical conclusions in this chapter are conditional on the existence of $\mathfrak{T}$ and of such a structure. The open problem of constructing $\mathfrak{T}$ from a regulator and deriving these structures as theorems of QFT is recorded in Open Problem 91.11.

91.1 Coulomb-Branch Coordinates

Let G be a compact connected gauge group with Lie algebra $\mathfrak{g}$. An $\mathcal{N} = 2$ vector multiplet contains a gauge field, two gauginos, and a complex scalar $\phi \in \mathfrak{g}_{\mathbb{C}}$. A Coulomb-branch point is a vacuum for which ϕ has expectation value in a Cartan subalgebra and the low-energy gauge group contains an Abelian factor $U(1)^r$, where $r = \operatorname{rank} G$. Gauge-invariant holomorphic coordinates are polynomial functions of ϕ, for example

$$u_k = \left\langle \operatorname{tr}(\phi^k) \right\rangle.$$

In the notation of Hypothesis 91.1, these u_k are local coordinates on the branch $\mathcal{B}$ only after one has chosen the microscopic gauge theory and restricted to the component where the Abelian rank is r. The trace convention is the convention fixed in the gauge chapters: the Yang–Mills kinetic term uses

$$\frac{1}{4g^2}\operatorname{tr}(F_{\mu\nu}F^{\mu\nu})$$

with the chosen invariant bilinear form.

91.2 Special Coordinates And Prepotential

On a smooth patch of $\mathcal{B}^\circ$, choose electric special coordinates

$$a^I, \qquad I = 1, \ldots, r.$$

The two-derivative Abelian Wilsonian action in Hypothesis 91.1 is determined by a holomorphic function $\mathcal{F}(a)$, the prepotential, through

$$a_{D,I} = \frac{\partial \mathcal{F}}{\partial a^I}, \qquad \tau_{IJ}(a) = \frac{\partial^2 \mathcal{F}}{\partial a^I \partial a^J}.$$

The imaginary part of τ_{IJ} is the positive gauge-coupling matrix in the region where the Abelian Wilsonian description is valid. Electric-magnetic duality acts on the column vector

$$\Pi = \begin{pmatrix} a_D \\ a \end{pmatrix}$$

by integral symplectic matrices. If $\gamma = (n_m^I, n_{e,I})$ is an electromagnetic charge vector, its central charge is

$$Z_\gamma = n_{e,I} a^I + n_m^I a_{D,I} + \sum_\alpha s_\alpha m_\alpha,$$

where m_α are background flavor masses and s_α are flavor charges. The BPS inequality has the convention

$$M_\gamma \geq \sqrt{2}\,|Z_\gamma|.$$

States saturating this bound form shortened $\mathcal{N} = 2$ multiplets.

In $\mathcal{N} = 1$ language the same local Abelian $\mathcal{N} = 2$ Wilsonian vector multiplets are represented by vector superfields V^I and chiral superfields Φ^I whose scalar components are a^I. Once the two-derivative $\mathcal{N} = 2$ action is assumed to exist, its scalar metric and gauge kinetic coefficients are not independent data. They are encoded by the same holomorphic prepotential:

$$K_{\mathcal{F}}(a, \overline{a}) = \frac{1}{2\pi} \operatorname{Im} \left(\overline{a}^I \frac{\partial \mathcal{F}}{\partial a^I} \right), \qquad \tau_{IJ}(a) = \frac{\partial^2 \mathcal{F}}{\partial a^I \partial a^J}. \tag{91.1}$$

The factor $1/(2\pi)$ is the superspace normalization used in this volume. It can be absorbed into the definition of the Abelian fields, but it must not be silently dropped when comparing instanton, period, and component-action conventions.

Rigid special-Kähler metric from the prepotential. Let $U \subset \mathbb{C}^r$ be a coordinate patch with holomorphic coordinates a^I, and let $\mathcal{F}$ be holomorphic on U. Define $K_{\mathcal{F}}$ by (91.1). Then

$$g_{I\bar{J}} := \frac{\partial^2 K_{\mathcal{F}}}{\partial a^I \partial \overline{a}^J} = \frac{1}{2\pi} \operatorname{Im} \tau_{IJ}. \tag{91.2}$$

Consequently the scalar kinetic metric is positive exactly on those Wilsonian patches where $\operatorname{Im} \tau_{IJ}$ is positive definite. Linear terms in $\mathcal{F}$ change $K_{\mathcal{F}}$ by a Kähler transformation, while real quadratic terms shift only $\operatorname{Re} \tau$ and hence only the theta-angle part of the Abelian gauge action. Write

$$K_{\mathcal{F}} = \frac{1}{4\pi \mathrm{i}} \left(\overline{a}^L \mathcal{F}_L(a) - a^L \overline{\mathcal{F}}_L(\overline{a}) \right), \qquad \mathcal{F}_L = \frac{\partial \mathcal{F}}{\partial a^L}.$$

Treating a^I and $\overline{a}^J$ as independent complex coordinates,

$$\frac{\partial K_{\mathcal{F}}}{\partial a^I} = \frac{1}{4\pi \mathrm{i}} \left(\overline{a}^L \mathcal{F}_{IL} - \overline{\mathcal{F}}_I \right).$$

Differentiating once more gives

$$\frac{\partial^2 K_{\mathcal{F}}}{\partial a^I \partial \overline{a}^J} = \frac{1}{4\pi \mathrm{i}} \left(\mathcal{F}_{IJ} - \overline{\mathcal{F}}_{IJ} \right) = \frac{1}{2\pi} \operatorname{Im} \mathcal{F}_{IJ}.$$

Since $\tau_{IJ} = \mathcal{F}_{IJ}$, this proves (91.2). If $\mathcal{F} \mapsto \mathcal{F} + c_I a^I + c_0$, then $K_{\mathcal{F}}$ changes by $(2\pi)^{-1} \operatorname{Im}(\overline{a}^I c_I)$, a sum of a holomorphic and an antiholomorphic function, so $g_{I\bar{J}}$ is unchanged. If $\mathcal{F} \mapsto \mathcal{F} + \frac{1}{2} q_{IJ} a^I a^J$ with q_{IJ} real and symmetric, then $\operatorname{Im} \tau$ is unchanged and $\operatorname{Re} \tau$ shifts by q_{IJ}.

91.3 Seiberg-Witten Period Geometry

The curve realization in Hypothesis 91.1 consists of a family of compact Riemann surfaces Σ_u, a meromorphic differential λ_{SW}, and a symplectic basis of one-cycles (A_I, B^I) such that

$$a^I(u) = \frac{1}{2\pi} \oint_{A_I} \lambda_{\mathrm{SW}}, \qquad a_{D,I}(u) = \frac{1}{2\pi} \oint_{B^I} \lambda_{\mathrm{SW}}.$$

The differential is fixed up to exact terms by requiring that $\partial \lambda_{\mathrm{SW}} / \partial u_k$ span holomorphic differentials on Σ_u and that the large-field asymptotics reproduce the one-loop Wilsonian coupling.

The period coupling is integrable on a contractible Coulomb-branch patch under the following geometric hypotheses. Let U be a patch on which the a^I, $I = 1, \ldots, r$, are holomorphic coordinates. Suppose $\pi : \Sigma \to U$ is a holomorphic family of compact Riemann surfaces with a flat symplectic homology frame (A_I, B^I), and suppose that the Seiberg-Witten differential λ_{SW} is chosen so that

$$\omega_J := \frac{\partial \lambda_{\mathrm{SW}}}{\partial a^J}$$

is a holomorphic one-form on each fiber, with no residue contribution in the Riemann bilinear relation, and is normalized by

$$\frac{1}{2\pi} \oint_{A_I} \omega_J = \delta_{IJ}.$$

The period matrix

$$\tau_{IJ} := \frac{\partial a_{D,I}}{\partial a^J} = \frac{1}{2\pi} \oint_{B^I} \omega_J$$

is symmetric. Consequently there is a holomorphic prepotential $\mathcal{F}$ on U, unique up to an additive constant, such that

$$a_{D,I} = \frac{\partial \mathcal{F}}{\partial a^I}.$$

Because the homology frame is flat, differentiating a period at fixed cycle gives the period of the differentiated differential:

$$\frac{\partial a_{D,I}}{\partial a^J} = \frac{1}{2\pi} \oint_{B^I} \omega_J.$$

Apply the Riemann bilinear relation on a fiber to the two holomorphic one-forms ω_I and ω_J:

$$0 = \sum_{K=1}^{r} \left(\oint_{A_K} \omega_I \oint_{B^K} \omega_J - \oint_{B^K} \omega_I \oint_{A_K} \omega_J \right).$$

The assumed A-period normalization gives

$$0 = 2\pi \oint_{B^I} \omega_J - 2\pi \oint_{B^J} \omega_I,$$

hence $\tau_{IJ} = \tau_{JI}$. The holomorphic one-form

$$\alpha = \sum_I a_{D,I}(a)\, \mathrm{d}a^I$$

therefore obeys

$$\mathrm{d}\alpha = \sum_{I<J} \left(\frac{\partial a_{D,J}}{\partial a^I} - \frac{\partial a_{D,I}}{\partial a^J} \right) \mathrm{d}a^I \wedge \mathrm{d}a^J = 0.$$

Since U is contractible, the ordinary Poincare lemma gives a holomorphic function

$$\mathcal{F}(a) = \int_{a_*}^{a} \alpha$$

whose value is independent of the path in U. Then $\mathrm{d}\mathcal{F} = \alpha$, which is exactly $a_{D,I} = \partial\mathcal{F}/\partial a^I$. The additive constant depends on the chosen base point a_* and has no physical content.

91.4 Argument Types And Charge-Monodromy Conventions

The Seiberg-Witten construction mixes several kinds of reasoning. In this chapter every load-bearing step is to be read with one of the following status labels.

Definition 91.2 (Argument-status labels for Seiberg-Witten theory)**.** A statement in the rank-one Seiberg-Witten construction has one of these statuses.

(i) *QFT-hypothesis*: an assumption about the existence of the four-dimensional continuum theory, its Coulomb-branch vacua, or its Wilsonian effective action.

(ii) *Symmetry-derived*: a consequence of the microscopic global symmetries, anomalies, Weyl group, and dimensional analysis.

(iii) *Holomorphy-derived*: a consequence of holomorphic dependence on Coulomb parameters and couplings once the Wilsonian $\mathcal{N} = 2$ framework has been assumed.

(iv) *Special-geometry theorem*: a statement about periods, symplectic lattices, Riemann bilinear identities, or nodal degenerations of curves.

(v) *Constraint-derived*: the minimal object satisfying the preceding symmetry, monodromy, and asymptotic constraints, with uniqueness only inside the declared ansatz.

(vi) *Consistency check*: a nontrivial compatibility test, such as a monodromy product, Picard-Fuchs equation, or instanton coefficient match.

(vii) *Heuristic/status boundary*: a physical identification not derived from a complete regulator construction in this monograph.

For the pure $\mathfrak{su}(2)$ theory below, the input that the Coulomb branch exists and is described at generic points by a two-derivative Abelian Wilsonian action is a QFT-hypothesis. The one-loop logarithm and the resulting monodromy at infinity are holomorphy-derived after the perturbative Wilsonian scheme is fixed. The residual $u \mapsto -u$ action is symmetry-derived. The Picard-Lefschetz transformation at a nodal fiber is a special-geometry theorem. The curve $y^2 = (x^2 - \Lambda^4)(x-u)$ is constraint-derived inside the minimal genus-one ansatz. The hypergeometric periods, Picard-Fuchs equation, finite-monodromy product, BPS mass vanishings, and Nekrasov coefficient are consistency checks. The statement that these data are the exact nonperturbative low-energy dynamics of the four-dimensional continuum QFT remains at the status boundary recorded at the end of the chapter.

In rank one the electromagnetic charge lattice is

$$\Gamma \simeq \mathbb{Z}^2, \qquad \gamma = (n_m, n_e),$$

with central charge $Z_\gamma = n_m a_D + n_e a$. For two charges $\delta = (m_m, m_e)$ and $\gamma = (n_m, n_e)$, use the antisymmetric pairing

$$\langle \delta, \gamma \rangle = m_m n_e - m_e n_m. \tag{91.3}$$

This is the Dirac pairing in the period basis $\Pi = (a_D, a)^T$.

The local coefficient in a hypermultiplet monodromy. The phrase "Picard–Lefschetz monodromy of a massless hypermultiplet" contains two logically separate inputs. The geometric input is the Picard–Lefschetz transvection for the vanishing one-cycle of the period family. The physical normalization of that transvection is fixed by the singular Wilsonian threshold of the light charged hypermultiplet. Let $\gamma \in \Gamma$ be primitive and choose an auxiliary charge $\eta \in \Gamma$ with $\langle \eta, \gamma \rangle = 1$. In the local electric frame

$$z = Z_\gamma, \qquad z_D = Z_\eta,$$

the additional light field is an ordinary $\mathcal{N} = 2$ hypermultiplet of electric charge one. Its singular holomorphic coupling is

$$\tau_{\text{sing}}(z) = \frac{\partial z_D}{\partial z} = -\frac{\mathrm{i}}{\pi} \log z + \text{single-valued holomorphic terms.} \tag{91.4}$$

Equivalently,

$$z_D^{\text{sing}} = -\frac{\mathrm{i}}{\pi} z \log z + \text{single-valued holomorphic linear terms.}$$

The coefficient in (91.4) is the one-loop Wilsonian threshold of the two oppositely charged chiral multiplets inside a full hypermultiplet, in the Abelian normalization of this volume. A positive small loop around $z = 0$ therefore leaves z fixed and sends

$$z_D \longmapsto z_D + 2z. \tag{91.5}$$

Reversing the loop orientation reverses the sign. The factor two is not a decorative convention: it is the local threshold coefficient of a full hypermultiplet and is the same factor that appears in the finite Seiberg–Witten monodromies below.

Lemma 91.3 (Rank-one hypermultiplet monodromy). *Suppose that a primitive charge $\gamma = (n_m, n_e)$ is represented by a single massless hypermultiplet at a nodal singular fiber, and suppose the period vector is ordered as $\Pi = (a_D, a)^T$. Then the Picard-Lefschetz monodromy acting on periods is*

$$M_\gamma = \begin{pmatrix} 1 + 2n_m n_e & 2n_e^2 \\ -2n_m^2 & 1 - 2n_m n_e \end{pmatrix}. \tag{91.6}$$

Equivalently, for every test charge δ,

$$Z_\delta \longmapsto Z_\delta + 2\langle \delta, \gamma \rangle Z_\gamma. \tag{91.7}$$

The matrix M_γ is integral symplectic and unipotent.

Proof. Choose $\eta \in \Gamma$ with $\langle \eta, \gamma \rangle = 1$. Every $\delta \in \Gamma$ can be written uniquely as

$$\delta = k\eta + \ell\gamma, \qquad k = \langle \delta, \gamma \rangle,$$

because (η, γ) is an integral symplectic basis of the rank-two lattice. The local hypermultiplet calculation (91.5) gives

$$Z_\gamma \longmapsto Z_\gamma, \qquad Z_\eta \longmapsto Z_\eta + 2Z_\gamma.$$

Therefore

$$Z_\delta = kZ_\eta + \ell Z_\gamma \longmapsto k(Z_\eta + 2Z_\gamma) + \ell Z_\gamma = Z_\delta + 2\langle \delta, \gamma \rangle Z_\gamma,$$

which proves (91.7). The geometric Picard–Lefschetz theorem supplies the existence of the transvection around the vanishing cycle; the preceding Wilsonian threshold fixes its coefficient in the physical electromagnetic lattice.

Now write $\gamma = (p, q)$ in the original basis and apply the central-charge action to the two basis charges. For $\delta = (1, 0)$, $\langle \delta, \gamma \rangle = q$, hence

$$a'_D \equiv Z'_{(1,0)} = a_D + 2q(pa_D + qa) = (1 + 2pq)a_D + 2q^2 a.$$

For $\delta = (0, 1)$, $\langle \delta, \gamma \rangle = -p$, hence

$$a' \equiv Z'_{(0,1)} = a - 2p(pa_D + qa) = -2p^2 a_D + (1 - 2pq)a.$$

These two equations are exactly (91.6). The same central-charge formula implies preservation of the antisymmetric pairing:

$$\langle \delta_1 + 2\langle \delta_1, \gamma \rangle \gamma, \delta_2 + 2\langle \delta_2, \gamma \rangle \gamma \rangle = \langle \delta_1, \delta_2 \rangle,$$

because the two cross terms cancel and $\langle \gamma, \gamma \rangle = 0$. Equivalently, $M_\gamma^T J M_\gamma = J$ for

$$J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

The determinant is one, and $M_\gamma - I$ has square zero, so the monodromy is unipotent. $\square$

91.5 Pure Gauge Theory With Gauge Algebra su two

For the pure theory with gauge algebra $\mathfrak{su}(2)$, the Coulomb coordinate is

$$u = \left\langle \operatorname{tr} \phi^2 \right\rangle .$$

The Weyl group identifies $a \sim -a$, and the large-field relation is

$$u = \frac{1}{2}a^2 + O(\Lambda^4/a^2), \qquad a(u) \sim \sqrt{2u}. \tag{91.8}$$

The perturbative Wilsonian prepotential in the pure theory has the one-loop form

$$\mathcal{F}_{\text{pert}}(a) = \frac{\mathrm{i}}{2\pi} a^2 \log \frac{a^2}{\Lambda^2} + \text{terms polynomial in } a. \tag{91.9}$$

The polynomial terms change a_D by an integral affine electric redefinition and do not change the monodromy class. Thus

$$a_D = \frac{\partial \mathcal{F}}{\partial a} = \frac{\mathrm{i}}{\pi} a \log \frac{a^2}{\Lambda^2} + O(a). \tag{91.10}$$

When u circles infinity once counterclockwise, the square root in (91.8) gives $a \mapsto -a$, while the logarithm in (91.10) shifts by $2\pi\mathrm{i}$. Therefore the period vector $\Pi = (a_D, a)^T$ has monodromy

$$M_\infty = \begin{pmatrix} -1 & 2 \\ 0 & -1 \end{pmatrix}. \tag{91.11}$$

The anomalous $U(1)_R$ symmetry of the microscopic theory is reduced to $\mathbb{Z}_8$. In the convention used here the vector-multiplet scalar has R-charge 2, so

$$\phi \mapsto e^{2\mathrm{i}\alpha}\phi, \qquad u = \langle \operatorname{tr} \phi^2 \rangle \mapsto e^{4\mathrm{i}\alpha} u.$$

The reduction to $\mathbb{Z}_8$ is the instanton-anomaly statement in these charges. In a one-instanton background, the index theorem gives $2C_2(SU(2)) = 4$ zero modes for each adjoint Weyl gaugino. The $\mathcal{N} = 2$ vector multiplet has two such gauginos, each of R-charge 1, so the one-instanton sector acquires the phase $\exp(8\mathrm{i}\alpha)$ under the continuous $U(1)_R$ rotation. The sign convention for assigning this phase to zero-mode coordinates or to their Berezinian does not change the invariant subgroup. Thus only $\alpha = \pi k/4$, $k \in \mathbb{Z}$, remains as an exact microscopic symmetry. A generic point $u \neq 0$ is fixed by the even values of k, namely by a $\mathbb{Z}_4$ subgroup. The quotient $\mathbb{Z}_8/\mathbb{Z}_4 \simeq \mathbb{Z}_2$ therefore acts on the Coulomb coordinate by

$$u \longmapsto -u.$$

Let $S \subset \mathbb{C}_u$ be the finite singular set of the rank-one period problem. The residual exact symmetry gives $S = -S$. A single finite nodal hypermultiplet singularity is impossible in the minimal pure theory because its Picard–Lefschetz monodromy is unipotent with trace 2, whereas the weak-coupling monodromy (91.11) has trace -2. The smallest symmetry-compatible nodal set away from the fixed point $u = 0$ is therefore

$$S = \{s, -s\}.$$

Since u has mass dimension 2, s is a nonzero dimension-two multiple of the strong scale. The normalization of the strong scale in this chapter is chosen so that $s = \Lambda^2$. Thus the minimal two-singularity period problem places the finite singularities at $u = \pm\Lambda^2$. At a nodal singular fiber, a primitive charge $\gamma = (n_m, n_e)$ becomes massless and the period vector transforms by Lemma 91.3. Choosing the singularity at $u = \Lambda^2$ to be a monopole point, $\gamma_m = (1, 0)$, gives

$$M_{\Lambda^2} = M_{(1,0)} = \begin{pmatrix} 1 & 0 \\ -2 & 1 \end{pmatrix}.$$

The second finite monodromy is fixed by

$$M_{\Lambda^2} M_{-\Lambda^2} = M_\infty,$$

hence

$$M_{-\Lambda^2} = \begin{pmatrix} -1 & 2 \\ -2 & 3 \end{pmatrix} = M_{(1,-1)}. \tag{91.12}$$

Thus the second singularity carries a massless dyon of charge $\gamma_d = (1, -1)$ in this period basis.

Minimal rank-one curve inside the two-singularity ansatz. Assume the rank-one period problem is represented by a genus-one hyperelliptic family with two fixed finite branch points and one branch point depending holomorphically on u. Assume further that the only finite singularities are exchanged by $u \mapsto -u$, occur at $\pm\Lambda^2$, and are nodal singularities, while $u = \infty$ is the weak-coupling cusp. Then, up to an affine change of the hyperelliptic coordinate and a rescaling of Λ, the minimal family is

$$\Sigma_u : \qquad y^2 = (x^2 - \Lambda^4)(x - u). \tag{91.13}$$

An affine change of x sends the two fixed finite branch points to Λ^2 and $-\Lambda^2$. A nodal singularity occurs when the moving branch point collides with one of these fixed branch points, so the moving branch point must take the values $\pm\Lambda^2$ at $u = \pm\Lambda^2$. In the minimal degree-one ansatz it is therefore $x = u$ after the same normalization of u. The fourth branch point is at infinity, giving the weak-coupling cusp. The resulting hyperelliptic equation is (91.13). Its finite branch-point discriminant is proportional to

$$(\Lambda^2 - (-\Lambda^2))^2(\Lambda^2 - u)^2(-\Lambda^2 - u)^2 = 4\Lambda^4(u^2 - \Lambda^4)^2,$$

so the only finite singular values are exactly $u = \pm\Lambda^2$. This gives uniqueness only within the stated ansatz; the QFT assertion that this ansatz captures the exact pure theory is the Seiberg-Witten status boundary.

Its branch points are

$$x = \Lambda^2, \qquad x = -\Lambda^2, \qquad x = u, \qquad x = \infty,$$

and the finite discriminant is proportional to

$$\Delta(u) = u^2 - \Lambda^4.$$

At $u = \Lambda^2$ the branch points $x = u$ and $x = \Lambda^2$ collide; at $u = -\Lambda^2$ the branch points $x = u$ and $x = -\Lambda^2$ collide. The monodromies of the corresponding vanishing cycles are exactly (91.6) with the charges above. This derivation uses the following hypotheses: the rank-one Coulomb branch has only the two finite singularities required by the residual R-symmetry, the singular fibers are nodal hypermultiplet singularities, and the weak-coupling monodromy is exhausted by the perturbative vector multiplet.

91.6 Periods, Picard-Fuchs Equation, and BPS Masses

Choose the branch of the periods in the weak-coupling region $|u| \gg |\Lambda|^2$ by

$$a(u) \sim \sqrt{2u}.$$

With the curve (91.13), the periods obey the Picard-Fuchs equation

$$(u^2 - \Lambda^4)\frac{d^2\Pi}{du^2} + \frac{1}{4}\Pi = 0, \qquad \Pi \in \{a_D, a\}. \tag{91.14}$$

The solution normalized as the electric period at infinity can be written as

$$a(u) = \sqrt{2(u + \Lambda^2)}\, {}_2F_1\left(-\frac{1}{2}, \frac{1}{2}; 1; \frac{2\Lambda^2}{u + \Lambda^2}\right), \tag{91.15}$$

with the branch chosen by (91.8). A dual period that vanishes at the monopole point is

$$a_D^{(m)}(u) = \frac{\mathrm{i}}{2\Lambda}(u - \Lambda^2)\,{}_2F_1\left(\frac{1}{2}, \frac{1}{2}; 2; \frac{\Lambda^2 - u}{2\Lambda^2}\right). \tag{91.16}$$

The superscript records the local branch near $u = \Lambda^2$. Analytic continuation of the pair $(a_D^{(m)}, a)$ around the singularities gives the monodromy matrices above. Near the monopole point,

$$a_D^{(m)}(u) = \frac{\mathrm{i}}{2\Lambda}(u - \Lambda^2) + O((u - \Lambda^2)^2). \tag{91.17}$$

The monopole central charge is $Z_{(1,0)} = a_D$, hence

$$M_{(1,0)}(u) = \sqrt{2}\,|a_D(u)| = \frac{|u - \Lambda^2|}{\sqrt{2}|\Lambda|} + O(|u - \Lambda^2|^2). \tag{91.18}$$

At $u = -\Lambda^2$, use the local period basis obtained by transporting to that singularity. The vanishing central charge is

$$Z_{(1,-1)} = a_D - a,$$

and the same nodal-fiber analysis gives

$$a_D(u) - a(u) = c_-\,(u + \Lambda^2) + O((u + \Lambda^2)^2), \qquad c_- \neq 0, \tag{91.19}$$

on the dyon branch. Therefore

$$M_{(1,-1)}(u) = \sqrt{2}\,|a_D(u) - a(u)| = \sqrt{2}\,|c_-|\,|u + \Lambda^2| + O(|u + \Lambda^2|^2). \tag{91.20}$$

The phase and magnitude of c_- depend on the branch and symplectic basis; the linear vanishing and the charge $(1, -1)$ are invariant data of the singular fiber.

91.7 ADHM Moduli And The Nekrasov Expansion

The Seiberg-Witten curve determines the low-energy prepotential indirectly through periods. There is also a weak-coupling construction of the same instanton expansion from the ultraviolet gauge theory. This section records the construction with all convention-dependent inputs exposed.

Work in Euclidean signature on $\mathbb{R}^4 \simeq \mathbb{C}^2$, with the orientation and instanton number convention of Section 51.17. The integer

$$k = \frac{1}{8\pi^2}\int_{\mathbb{R}^4} \operatorname{tr}(F \wedge F)$$

is positive for the orientation chosen there. The instanton-counting coordinate will be denoted by q. In the common half-trace superspace coordinate, $q = \exp(2\pi \mathrm{i}\tau_{\mathrm{ht}})$. In the trace-delta component coupling coordinate of Section 51.17, the same one-instanton exponential is

$$q = \exp\left(-\frac{4\pi^2}{g_{\mathrm{YM}}^2} + \mathrm{i}\theta\right) = \exp\left(-\frac{8\pi^2}{g_{\mathrm{ht}}^2} + \mathrm{i}\theta\right).$$

The ADHM and localization formulae below use q only as the holomorphic coordinate that grades instanton number. For the pure $SU(N)$ theory, dimensional transmutation replaces q by Λ^{2N} after the renormalization scheme has been fixed.

Definition 91.4 (Framed ADHM data for $U(N)$)**.** Let $K \simeq \mathbb{C}^k$ and $W \simeq \mathbb{C}^N$. Framed ADHM data are quadruples

$$(B_1, B_2, I, J), \qquad B_1, B_2 \in \operatorname{End}(K), \quad I \in \operatorname{Hom}(W, K), \quad J \in \operatorname{Hom}(K, W),$$

obeying

$$[B_1, B_2] + IJ = 0, \tag{91.21}$$

$$[B_1, B_1^\dagger] + [B_2, B_2^\dagger] + II^\dagger - J^\dagger J = \zeta\, \mathbf{1}_K. \tag{91.22}$$

The quotient by $U(K)$ is the hyper-Kähler quotient. The parameter $\zeta > 0$ is a stability or noncommutative resolution parameter; the ordinary framed instanton moduli space is recovered at $\zeta = 0$ away from small-instanton singular strata. The framing is a trivialization at S^3_∞.

On the stable locus where the $GL(K)$ action has no stabilizer, the framed k-instanton ADHM moduli space for $U(N)$ has complex dimension

$$2kN$$

and real dimension $4kN$. Removing the center-of-mass position in $\mathbb{R}^4$ gives the centered dimension $4kN - 4$. The complex variables B_1, B_2, I, J have complex dimension

$$2k^2 + kN + kN = 2k^2 + 2kN.$$

The complex moment-map equation (91.21) is an equation in $\operatorname{End}(K)$, hence imposes k^2 complex equations on the smooth stable locus. Quotienting by the complexified gauge group $GL(K)$ removes another k^2 complex dimensions. Thus

$$(2k^2 + 2kN) - k^2 - k^2 = 2kN.$$

The real moment-map quotient by $U(K)$ is equivalent to this stable complex quotient by the Kempf–Ness correspondence. Therefore the real dimension is $2(2kN) = 4kN$. Translation of the instanton center is the trace part of B_1, B_2, a copy of $\mathbb{C}^2 \simeq \mathbb{R}^4$; fixing it removes four real dimensions.

Remark 91.5 (Gauge group and compactification). The $U(N)$ ADHM quotient is the clean equivariant model because the framing torus has N weights $a_1, \dots, a_N$. Pure $SU(N)$ instanton calculations are obtained by imposing $\sum_{\alpha=1}^{N} a_\alpha = 0$ and by discarding the decoupled abelian center in observables. Ordinary commutative $U(1)$ gauge theory has no smooth finite-action instantons on $\mathbb{R}^4$; the $U(1)$ fixed points in the sheaf or noncommutative compactification are pointlike ideal-sheaf strata. Thus the compactification or contour prescription is part of the definition of Z_{inst}, as in Definition 101.5.

Let

$$T = (\mathbb{C}^\times)^2_{\epsilon_1,\epsilon_2} \times (\mathbb{C}^\times)^N_{a_1,\dots,a_N}$$

act by rotating $\mathbb{C}^2$ and by the framing torus. The parameters ϵ_1, ϵ_2 are the equivariant weights of the two complex planes, and a_α are Coulomb weights. The equivariant deformation is called the Ω-background. It has two jobs: it makes the instanton volume integral an equivariant integral, and it isolates fixed points for localization.

Quoted Theorem 91.6 (ADHM fixed points)**.** *For the smooth framed $U(N)$ ADHM compactification on $\mathbb{C}^2$, with generic $a_\alpha, \epsilon_1, \epsilon_2$, the T-fixed points are isolated and are labeled by N-tuples of Young diagrams*

$$\vec{Y} = (Y_1, \dots, Y_N), \qquad |\vec{Y}| := \sum_{\alpha=1}^{N} |Y_\alpha| = k.$$

The equivariant integral over the k-instanton component equals the sum of the reciprocal equivariant Euler classes of the tangent complexes at these fixed points.

The quoted statement is a theorem of equivariant algebraic geometry for the framed sheaf compactification. Its use in the physical path integral additionally assumes that the supersymmetric regulator, the Ω-background, and the contour define the same equivariant integral. This physical identification is the localization input; the dimension count alone does not imply it.

Definition 91.7 (Pure vector Nekrasov partition function)**.** For pure $U(N)$ vector multiplets, define

$$Z^{U(N)}_{\text{inst}}(a, \epsilon_1, \epsilon_2; q) = \sum_{k \geq 0} q^k Z^{U(N)}_k(a, \epsilon_1, \epsilon_2), \qquad Z^{U(N)}_0 = 1,$$

where $Z^{U(N)}_k$ is the equivariant integral over the framed k-instanton compactification. The one-instanton fixed-point formula is

$$Z^{U(N)}_1 = \frac{1}{\epsilon_1\epsilon_2} \sum_{\alpha=1}^{N} \prod_{\beta\neq\alpha} \frac{1}{(a_\alpha - a_\beta)(a_\alpha - a_\beta + \epsilon_1 + \epsilon_2)}. \tag{91.23}$$

The pure $SU(N)$ specialization imposes $\sum_\alpha a_\alpha = 0$. Matter hypermultiplets multiply each fixed-point term by the equivariant Euler class of the corresponding Dirac complex; the vector formula above is the part needed for the pure $SU(2)$ Seiberg-Witten comparison.

Pure $SU(2)$ one-instanton coefficient. Set $a_1 = a$, $a_2 = -a$, and $\epsilon = \epsilon_1 + \epsilon_2$. Then

$$Z_1^{SU(2)} = \frac{2}{\epsilon_1\epsilon_2(4a^2 - \epsilon^2)}.$$

Consequently, in the Nekrasov normalization

$$\mathcal{F}_{\text{inst}}(a; q) := \lim_{\epsilon_1,\epsilon_2\to 0} \epsilon_1\epsilon_2 \log Z_{\text{inst}}^{SU(2)}(a, \epsilon_1, \epsilon_2; q),$$

the first pure-gauge term is

$$\mathcal{F}_{\text{inst}}(a; q) = \frac{q}{2a^2} + O(q^2).$$

For the pure $SU(2)$ theory, q is identified with Λ^4 in the weak-coupling scale coordinate.

Substituting $a_1 = a$, $a_2 = -a$ in (91.23) gives two fixed-point contributions:

$$Z_1^{SU(2)} = \frac{1}{\epsilon_1\epsilon_2}\left[\frac{1}{(2a)(2a+\epsilon)} + \frac{1}{(-2a)(-2a+\epsilon)}\right].$$

The second denominator is $2a(2a - \epsilon)$. Hence

$$Z_1^{SU(2)} = \frac{1}{\epsilon_1\epsilon_2}\frac{1}{2a}\left(\frac{1}{2a+\epsilon} + \frac{1}{2a-\epsilon}\right) = \frac{2}{\epsilon_1\epsilon_2(4a^2 - \epsilon^2)}.$$

Since $Z_{\text{inst}} = 1 + qZ_1 + O(q^2)$,

$$\epsilon_1\epsilon_2 \log Z_{\text{inst}} = q\,\frac{2}{4a^2 - \epsilon^2} + O(q^2).$$

Taking $\epsilon_1, \epsilon_2 \to 0$ gives $q/(2a^2)$ at order q.

The coefficient above is the first weak-coupling instanton correction to the same holomorphic prepotential whose periods are encoded by the curve (91.13), after matching the additive quadratic ambiguity in $\mathcal{F}$ and the scale coordinate. The comparison is stringent because the Seiberg-Witten curve determines all powers of Λ^4/a^4 by a period problem, while the ADHM construction determines them by finite-dimensional equivariant integrals.

The exponential size of the k-instanton sector is q^k. In a transseries analysis of the weak-coupling expansion, these actions mark the candidate locations of Borel singularities separated from the perturbative sector by integer multiples of the one-instanton action. A theorem-level resurgence statement for four-dimensional supersymmetric gauge theory would require a regulator, a summation prescription, and uniform control of the large-order perturbative coefficients. The assertion here is only the shared grading convention: the same k, action, and θ-phase grade the ADHM integral, the Ω-background partition function, and the instanton transseries sectors.

91.8 Monodromy And Light Charges

The weak-coupling region is the exterior of the curve of marginal stability on which a_D/a is real. In the charge convention fixed above, the semiclassical BPS spectrum contains the vector multiplet with charge $(0, 1)$ and a tower of hypermultiplets with charges

$$(n_m, n_e) = (1, n), \qquad n \in \mathbb{Z}, \tag{91.24}$$

together with antiparticles. The tower is generated by monodromy at infinity from either finite singular charge. The central charges are

$$Z_{(0,1)} = a, \qquad Z_{(1,n)} = a_D + na.$$

Inside the strong-coupling chamber bounded by the marginal-stability curve, the stable hypermultiplets are the two light states associated with the two singularities, with charges

$$(1,0), \qquad (1,-1),$$

and their antiparticles. The change in the BPS index occurs when

$$\arg Z_{\gamma_1} = \arg Z_{\gamma_2}$$

for charges that can form or decay as a BPS bound state. This is the wall-crossing mechanism in its rank-one Seiberg-Witten form: the central charge function is continuous, while the protected index of one-particle BPS states is locally constant only away from marginal-stability walls.

91.9 Argyres-Douglas Scaling As A Rank-One Singularity

The pure $\mathfrak{su}(2)$ theory has two separated finite singularities, so a local duality frame exists near either one and the low-energy theory contains a single light hypermultiplet. A different phenomenon occurs when two singularities with mutually nonlocal vanishing charges collide after a mass or coupling is tuned. If $\gamma_1, \gamma_2 \in \Gamma$ vanish at the same point and

$$\langle \gamma_1, \gamma_2 \rangle \neq 0,$$

then no electric-magnetic frame makes both light states purely electric. There is therefore no local Abelian Lagrangian consisting of one vector multiplet coupled to two ordinary electric hypermultiplets. The Seiberg-Witten interpretation is an interacting rank-one superconformal fixed point, usually called an Argyres-Douglas point. The existence of the four-dimensional QFT fixed point is a status-boundary statement unless a separate construction is supplied; the scaling dimensions below are consequences of the local special-geometry model.

Definition 91.8 (Rank-one cusp model)**.** The simplest rank-one Argyres-Douglas local period model is the cusp

$$\Sigma_{u,v}: \qquad y^2 = x^3 + vx + u, \tag{91.25}$$

with local Seiberg-Witten differential

$$\lambda_{\mathrm{AD}} = \frac{u\,dx}{y}. \tag{91.26}$$

The parameter u is the Coulomb-branch deformation of the cusp and v is the relevant deformation that unfolds the collision. The normalization is chosen so that a period of λ_{AD} has mass dimension one.

Discriminant of the cusp unfolding. For the local curve

$$y^2 = x^3 + vx + u,$$

the finite discriminant is

$$\Delta_{\text{cusp}}(u, v) = -4v^3 - 27u^2. \tag{91.27}$$

Thus the two nodal singularities in the u-plane collide at $(u, v) = (0, 0)$. At $v = 0$, the singular fiber is a cusp rather than a node. For a monic cubic $f(x) = x^3 + px + q$, the discriminant is

$$\operatorname{disc}(f) = \prod_{i<j}(r_i - r_j)^2, \qquad f(x) = \prod_i (x - r_i),$$

and the elementary symmetric relations give

$$\operatorname{disc}(x^3 + px + q) = -4p^3 - 27q^2.$$

Substituting $p = v$, $q = u$ gives (91.27). For $v \neq 0$, the discriminant equation has two local solutions for u, namely two nodal degenerations after a choice of branch of $v^{3/2}$. As $v \to 0$, both solutions approach $u = 0$. At $u = v = 0$ the polynomial is x^3, so all three finite branch points coincide and the singularity is cuspidal.

Mutually nonlocal light charges and electric frames. Let Γ be a rank-two electromagnetic charge lattice with symplectic pairing $\langle\cdot,\cdot\rangle$. If two primitive charges $\gamma_1, \gamma_2 \in \Gamma$ obey

$$\langle\gamma_1, \gamma_2\rangle \neq 0, \tag{91.28}$$

then no symplectic change of basis can make both charges purely electric. Consequently a neighborhood in which both central charges vanish cannot be described as a weakly coupled Abelian vector multiplet coupled only to ordinary electric hypermultiplets for both charges. In any electric-magnetic frame, the purely electric sublattice is Lagrangian: the symplectic pairing of any two purely electric charges is zero. A symplectic change of basis preserves $\langle\cdot,\cdot\rangle$. Therefore if both γ_1 and γ_2 became purely electric in some frame, their pairing would have to vanish in that frame and hence in every frame, contradicting (91.28). The last assertion follows because an ordinary local Abelian Lagrangian with hypermultiplets of electric charge uses one electric polarization of Γ; it cannot include two hypermultiplet fields whose charges have nonzero Dirac pairing in that same polarization.

For the local model (91.25) with differential (91.26), the scaling dimensions are

$$[x] = \frac{2}{5}, \qquad [y] = \frac{3}{5}, \qquad [u] = \frac{6}{5}, \qquad [v] = \frac{4}{5}. \tag{91.29}$$

Thus the Coulomb-branch operator has dimension $6/5$, and the unfolding parameter v has dimension $4/5$. Quasi-homogeneity of $y^2 = x^3 + vx + u$ gives

$$2[y] = 3[x] = [u].$$

The period of the Seiberg-Witten differential has mass dimension one, and $\lambda_{\text{AD}} = u\,dx/y$ scales with dimension $[u] + [x] - [y]$. Therefore

$$[u] + [x] - [y] = 1.$$

Solving these equations gives $[x] = 2/5$, $[y] = 3/5$, and $[u] = 6/5$. The term vx has the same dimension as u, so $[v] + [x] = 6/5$, and therefore $[v] = 4/5$.

This calculation is intentionally local. It does not claim that every collision of singular fibers produces a continuum QFT, nor does it replace the need to specify which ultraviolet theory and deformation realize the collision. What it does fix is the special-geometry consequence of a cusp with differential λ_{AD}: periods scale with dimension one, the Coulomb operator can have fractional dimension, and mutually nonlocal light charges force the infrared description outside an ordinary weakly coupled Abelian hypermultiplet frame.

91.10 Low-Energy Abelian Theory Near A Singular Point

Near a point where the monopole period a_D vanishes, the correct low-energy variables are the dual $U(1)$ vector multiplet with scalar a_D and the light monopole hypermultiplet. A local Wilsonian superpotential has the form

$$W_{\mathrm{loc}} = \sqrt{2}\, A_D M \widetilde{M},$$

where A_D is the dual chiral multiplet and $M, \widetilde{M}$ are monopole chiral multiplets of opposite dual electric charge. Let $U(A_D)$ denote the chiral coordinate whose lowest component is the Coulomb-branch coordinate u expressed in the local dual frame. Add a small $\mathcal{N} = 1$-preserving deformation

$$W_{\mathrm{def}} = \mu\, U(A_D), \qquad \mu \in \mathbb{C}, \qquad |\mu| \ll |\Lambda|, \tag{91.30}$$

so that the local superpotential is

$$W_{\mathrm{loc},\mu} = \sqrt{2}\, A_D M \widetilde{M} + \mu\, U(A_D). \tag{91.31}$$

The smallness assumption keeps the analysis inside the Abelian neighborhood where the monopole hypermultiplet is the only additional light charged field.

Monopole condensation from the local F-terms. Assume $U'(0) \neq 0$ at the monopole point $A_D = 0$, and work on the local patch described by (91.31). The F-term equations have a branch

$$A_D = 0, \qquad M\widetilde{M} = -\frac{\mu}{\sqrt{2}}\, U'(0). \tag{91.32}$$

When the $U(1)_D$ D-term equation is imposed with vanishing real Fayet–Iliopoulos parameter,

$$|M|^2 - |\widetilde{M}|^2 = 0, \tag{91.33}$$

the dual gauge group is Higgsed for $\mu U'(0) \neq 0$.

The derivatives of (91.31) are

$$\frac{\partial W_{\mathrm{loc},\mu}}{\partial M} = \sqrt{2}\, A_D \widetilde{M}, \qquad \frac{\partial W_{\mathrm{loc},\mu}}{\partial \widetilde{M}} = \sqrt{2}\, A_D M,$$

and

$$\frac{\partial W_{\mathrm{loc},\mu}}{\partial A_D} = \sqrt{2}\, M\widetilde{M} + \mu\, U'(A_D).$$

The first two equations are solved by $A_D = 0$. Substituting this value in the third equation gives (91.32). If $U'(0)\mu \neq 0$, then $M\widetilde{M} \neq 0$. Together with (91.33), this implies $|M| = |\widetilde{M}| \neq 0$, and the oppositely charged monopole fields Higgs the dual $U(1)_D$.

In the dual Abelian description, a Wilson line of the original electric charge is magnetically charged with respect to $U(1)_D$. The Higgsed dual gauge theory therefore supports Abrikosov–Nielsen–Olesen flux tubes whose magnetic flux is the original electric flux. This gives the local confinement mechanism used in the comparison between Donaldson and Seiberg–Witten theories.

Definition 91.9 (Local SW confining-string model)**.** In the neighborhood of a monopole singularity, a local confining-string model consists of:

(i) the dual Abelian gauge field $A_{D,\mu}$ with curvature F_D and coupling e_D;

(ii) monopole fields $M, \widetilde{M}$ of dual charges $+1$ and -1;

(iii) the complex parameter
$$\xi_{\mathbb{C}} = -\frac{\mu}{\sqrt{2}}U'(0), \tag{91.34}$$
defined by the local F-term equation $M\widetilde{M} = \xi_{\mathbb{C}}$;

(iv) a flux sector $n \in \mathbb{Z}$ with
$$\frac{1}{2\pi}\int_{\mathbb{R}^2} F_D = n$$
on the plane transverse to the string;

(v) boundary conditions at transverse infinity obeying $M\widetilde{M} \to \xi_{\mathbb{C}}$ and $|M| = |\widetilde{M}|$.

The string tension is the infimum of the static energy per unit length in the fixed flux sector.

Controlled Approximation 91.10 (BPS vortex tension in the local Abelian model)**.** If the local theory is approximated by an $\mathcal{N} = 2$ Abelian Higgs model with Fayet–Iliopoulos triplet of magnitude $|\xi| = |\xi_{\mathbb{C}}|$ in the normalization
$$\mathcal{E} = \frac{1}{2e_D^2}B_D^2 + |D_1 q|^2 + |D_2 q|^2 + \frac{e_D^2}{2}(|q|^2 - |\xi|)^2, \tag{91.35}$$
then a vortex of flux $2\pi n$ obeys
$$T_n \geq 2\pi |n|\,|\xi|, \tag{91.36}$$
and saturation is equivalent to the first-order vortex equations
$$(D_1 + \mathrm{i}\,\mathrm{sgn}(n) D_2)q = 0, \qquad B_D = \mathrm{sgn}(n) e_D^2(|\xi| - |q|^2). \tag{91.37}$$

Derivation of the local vortex bound. For $n > 0$, complete the square in (91.35):
$$\mathcal{E} = |(D_1 + \mathrm{i}D_2)q|^2 + \frac{1}{2e_D^2}\big(B_D - e_D^2(|\xi| - |q|^2)\big)^2 + |\xi| B_D + \partial_i J^i.$$
The current J^i is a total derivative whose integral vanishes for the finite-energy boundary conditions in Definition 91.9. Integrating over the transverse plane gives
$$T_n \geq |\xi| \int_{\mathbb{R}^2} F_D = 2\pi n |\xi|.$$
For $n < 0$, use the opposite square completion. The two square terms vanish precisely when (91.37) holds.

91.11 Status Boundary

The period construction determines an Abelian Wilsonian effective action under explicit hypotheses: existence of the $\mathcal{N} = 2$ continuum theory, existence of the Coulomb-branch vacuum family, validity of the two-derivative Abelian description away from singular loci, and BPS saturation for the states assigned to vanishing cycles. The missing nonperturbative regulator for four-dimensional supersymmetric gauge theory remains part of the Wilsonian-scheme problem recorded in Chapter 90.

Open Problem 91.11 (Theorem-level SW construction)*.* Construct the four-dimensional $\mathcal{N} = 2$ gauge theory with a regulator and continuum limit sufficient to derive the Coulomb-branch special geometry, period data, BPS spectrum near singular fibers, and low-energy Abelian Wilsonian action as theorems of QFT.

Chapter 92

Spectral Bridges Among Supersymmetric Yang–Mills Cousins

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The preceding chapters developed three separate structures: pure $\mathcal{N} = 1$ Yang–Mills chiral dynamics, pure $\mathcal{N} = 2$ Seiberg–Witten special geometry, and planar $\mathcal{N} = 4$ spectral integrability. They are connected by relevant deformations, but the connection has several layers. Holomorphic quantities can often be matched by scale coordinates and protected Ward identities. Massive spectra, confining strings, and line-operator Hilbert spaces require additional nonperturbative data. This chapter defines the comparison problem.

92.1 Comparison Problem

Let $G = SU(N_c)$ with $N_c \geq 2$. A comparison among the $\mathcal{N} = 4, \mathcal{N} = 2, \mathcal{N} = 1$, and bosonic Yang–Mills theories is a comparison among four QFT problems, not a single family of Lagrangian symbols. The amount of supersymmetry determines which quantities are protected, which deformations preserve a chiral coordinate chart, and which spectral questions remain dynamical.

Definition 92.1 (Yang–Mills cousin comparison problem)**.** A Yang–Mills cousin comparison problem is specified by:

(i) a gauge group $G = SU(N_c)$ or a specified global form with a specified line-operator lattice;

(ii) a UV description of the $\mathcal{N}=4$ theory in the $\mathcal{N}=1$ field variables

$$V, \qquad \Phi_1, \Phi_2, \Phi_3 \in \operatorname{ad} G,$$

with holomorphic coupling

$$\tau = \frac{\theta}{2\pi} + \frac{4\pi\mathrm{i}}{g_{\mathrm{YM}}^2}$$

in the trace convention fixed in Chapter 87;

(iii) a finite list of relevant deformation parameters, for example adjoint chiral masses m_i, an $\mathcal{N}=2 \to \mathcal{N}=1$ mass coordinate μ, and a soft gaugino-mass spurion m_λ;

(iv) for each deformation regime, a declared set of observables: gauge-invariant local operators, center-charged line operators, domain-wall boundary conditions, and defect operators on Wilson lines;

(v) a status label for each comparison: holomorphic scale matching, protected F-term matching, semiclassical Abelian approximation, lattice spectral extraction, planar-integrability reconstruction, or open nonperturbative construction.

Two rows of the comparison are compared only after the observable type and status label have been fixed.

The basic ladder is:

$$\begin{aligned}
\mathcal{N}=4 &\quad \xrightarrow{m_{\text{hyper}}} \quad \mathcal{N}=2^* \xrightarrow{E\ll|m_{\text{hyper}}|} \text{pure } \mathcal{N}=2,\\
\mathcal{N}=4 &\quad \xrightarrow{m_1,m_2,m_3} \quad \mathcal{N}=1^* \xrightarrow{E\ll\min_i|m_i|} \text{pure } \mathcal{N}=1,\\
\text{pure } \mathcal{N}=2 &\quad \xrightarrow{\mu\, u} \quad \text{softly broken } \mathcal{N}=1 \text{ with Abelian confinement},\\
\text{pure } \mathcal{N}=1 &\quad \xrightarrow{X_\lambda S+\text{c.c.}} \quad \text{bosonic Yang–Mills deformation problem.}
\end{aligned}$$

The arrows are deformation regimes. A continuum construction for the endpoint theory, or a proof that a path of deformations reaches a chosen endpoint without crossing a phase boundary in the observables of interest, is extra information.

92.2 Holomorphic Scale Matching

Holomorphic scale matching is the cleanest part of the comparison. It is a statement about chiral source coordinates and threshold matching in a holomorphic Wilsonian scheme. It does not compute the nonchiral spectrum.

Definition 92.2 (Holomorphic threshold matching)**.** Let a four-dimensional supersymmetric gauge theory with gauge algebra $\mathfrak{su}(N_c)$ have holomorphic one-loop coefficient b_{high} above a chiral mass threshold m and coefficient b_{low} below the threshold. A holomorphic threshold matching at the scale m is the identity of chiral scale coordinates

$$\Lambda_{\text{low}}^{b_{\text{low}}} = m^{\,b_{\text{low}}-b_{\text{high}}}\,\Lambda_{\text{high}}^{b_{\text{high}}}, \tag{92.1}$$

up to finite holomorphic scheme rescalings already included in the definitions of m and Λ.

Write $\mathcal{N} = 4$ Yang–Mills in $\mathcal{N} = 2$ variables as one $\mathcal{N} = 2$ vector multiplet plus one adjoint hypermultiplet. Give the hypermultiplet a holomorphic mass m_{h}. In the region

$$E \ll |m_{\mathrm{h}}|,$$

the remaining pure $\mathcal{N} = 2$ holomorphic scale satisfies

$$\Lambda_{\mathcal{N}=2}^{2N_c} = m_{\mathrm{h}}^{2N_c}\, q, \qquad q = \mathrm{e}^{2\pi \mathrm{i}\tau}. \tag{92.2}$$

The $\mathcal{N} = 4$ theory has vanishing holomorphic beta coefficient, so the high-energy scale coordinate is the dimensionless instanton factor $q = \mathrm{e}^{2\pi\mathrm{i}\tau}$. Pure $\mathcal{N} = 2$ $SU(N_c)$ Yang–Mills has holomorphic coefficient

$$b_{\mathcal{N}=2} = 2N_c.$$

Applying (92.1) with

$$b_{\mathrm{high}} = 0, \qquad b_{\mathrm{low}} = 2N_c, \qquad m = m_{\mathrm{h}}$$

gives (92.2). The dimension of the right-hand side is $2N_c$, matching the dimension of $\Lambda_{\mathcal{N}=2}^{2N_c}$.

Write $\mathcal{N} = 4$ Yang–Mills in $\mathcal{N} = 1$ variables as one vector multiplet and three adjoint chiral multiplets Φ_1, Φ_2, Φ_3. Give the three adjoint chiral multiplets holomorphic masses m_1, m_2, m_3. In the region

$$E \ll \min_i |m_i|,$$

the pure $\mathcal{N} = 1$ holomorphic scale satisfies

$$\Lambda_{\mathcal{N}=1}^{3N_c} = (m_1 m_2 m_3)^{N_c}\, q, \qquad q = \mathrm{e}^{2\pi\mathrm{i}\tau}. \tag{92.3}$$

The high-energy $\mathcal{N} = 4$ coefficient is zero. Pure $\mathcal{N} = 1$ $SU(N_c)$ Yang–Mills has coefficient

$$b_{\mathcal{N}=1} = 3N_c.$$

Each massive adjoint chiral multiplet changes the holomorphic coefficient by $T(\mathrm{ad}) = N_c$. Applying (92.1) successively at the three mass thresholds gives

$$\Lambda_{\mathcal{N}=1}^{3N_c} = m_1^{N_c} m_2^{N_c} m_3^{N_c} q,$$

which is (92.3). The mass dimension is $3N_c$, as required for the pure $\mathcal{N} = 1$ scale coordinate.

Example 92.3 ($\mathcal{N} = 1^*$ chiral critical equations)**.** In an $\mathcal{N} = 1$ presentation, the equal-mass $\mathcal{N} = 1^*$ superpotential is

$$W = \sqrt{2}\ \mathrm{tr}\, \Phi_1[\Phi_2, \Phi_3] + \frac{m}{2} \sum_{i=1}^{3} \mathrm{tr}\, \Phi_i^2. \tag{92.4}$$

The F-term equations are

$$\sqrt{2}[\Phi_2, \Phi_3] + m\Phi_1 = 0, \qquad \sqrt{2}[\Phi_3, \Phi_1] + m\Phi_2 = 0, \qquad \sqrt{2}[\Phi_1, \Phi_2] + m\Phi_3 = 0. \tag{92.5}$$

If J_i are matrices obeying

$$[J_i, J_j] = \mathrm{i}\epsilon_{ijk} J_k, \tag{92.6}$$

then

$$\Phi_i = \frac{\mathrm{i}m}{\sqrt{2}}\, J_i \tag{92.7}$$

solves (92.5). Such solutions organize chiral vacua of the massive adjoint theory by embeddings of $\mathfrak{su}(2)$ into $\mathfrak{su}(N_c)$. The full massive spectrum and confinement data also depend on the nonchiral dynamics and on the chosen line-operator lattice.

92.3 What Is Uniform Across the Ladder

The uniform part of the ladder is a map of observables, not a universal numerical formula. Four classes appear repeatedly.

Definition 92.4 (Family observable comparison table)**.** For a Yang–Mills cousin comparison problem, the repeated observable classes are the following.

observable type	**representative object**	**status**
chiral local	$S,\ u,\ \operatorname{tr}\Phi^k$	holomorphic or protected
massive local spectral	$\rho_{ij}(B)$ for gauge-invariant sources	spectral measure; lattice extraction
center-charged line	$W_R(C),\ H_m(C)$, flux-sector transfer matrix	declared line-sector problem
defect spectral	$\mathcal{H}_{\rm def},\ H_{\rm def}, \mathbb{O}_a(t)$	Wilson-line or cusp spectral problem

where S is the pure $\mathcal{N}=1$ glueball coordinate of Section 90.5, u is the rank-one $\mathcal{N}=2$ Coulomb coordinate of Chapter 91, ρ_{ij} is the spectral measure of Definition 90.3, $W_R(C)$ is a Wilson line in representation R, $H_m(C)$ is a magnetic line with magnetic charge m, and $\mathcal{H}_{\rm def}$ is the defect Hilbert space of Definition 100.17.

Controlled Approximation 92.5 (Observable-type comparison across a controlled threshold)**.** Consider a relevant mass deformation with threshold M between two supersymmetric Yang–Mills cousins. The following comparison is meaningful only after the threshold problem is supplied with:

(i) a Wilsonian description exists above and below M in a common regulator or in compatible holomorphic schemes;

(ii) the local source under consideration has external momenta $|p_a| \ll |M|$;

(iii) every massive field integrated out has a gap bounded below by $c|M|$ for some $c > 0$ in the chosen background;

(iv) the line-operator sector is kept fixed by declaring the global form and allowed electric and magnetic charges before the deformation.

Under these hypotheses, chiral local sources match by holomorphic threshold coordinates, local nonchiral correlators match after adding local higher-dimension Wilsonian operators, and center-charge labels of line operators are transported as declared labels. The spectrum is a separate dynamical problem: numerical masses, string tensions, and line-defect excitation energies are functions of the deformation parameters and require the corresponding Hilbert-space, transfer-matrix, or line-defect spectral analysis.

For chiral local sources, the supersymmetric Wilsonian action separates the holomorphic F-terms from D-terms. The threshold contribution of a massive chiral multiplet to the holomorphic gauge coupling is one-loop exact in the Wilsonian holomorphic coordinate, giving the scale matching of Definition 92.2. Thus the chiral coordinates match by finite holomorphic maps such as (92.2) and (92.3).

For nonchiral local correlators at momenta $|p_a| \ll |M|$, the massive propagators admit an expansion in powers of p/M after the regulator and subtraction scheme have been fixed. The coefficients are local functionals of the light fields and sources, hence enter the Wilsonian action as higher-dimension local operators. This is an equality of low-momentum Wilsonian coordinates at fixed order in the derivative expansion, with a remainder controlled only when the chosen regulator supplies the corresponding analytic estimates.

Line operators require the global form and charge lattice as part of the definition. A mass threshold changes the dynamics of screening and confinement, but it does not change the declared lattice of allowed line charges. Therefore the center or charge label can be transported through the comparison problem. The area-law coefficient or defect excitation energy is obtained from the Hilbert-space or transfer-matrix problem in the deformed theory, so it remains a dynamical spectral quantity.

92.4 Center Strings and k-String Tension Comparisons

For $SU(N_c)$ with the usual Wilson lines, the center charge of a representation is an element of $\mathbb{Z}_{N_c}$. A confining theory may have stable flux sectors labeled by

$$k \in \{0, 1, \ldots, N_c - 1\},$$

with k and $N_c - k$ related by charge conjugation.

Definition 92.6 (k-string tension extraction)**.** A k-string tension extraction for a confining Yang–Mills theory is specified by:

(i) a regulator or continuum Hilbert-space construction with spatial transfer matrix T_L on a box whose long direction has length L;

(ii) a center-flux sector $k \in \mathbb{Z}_{N_c}$;

(iii) the lowest energy $E_k(L)$ in that sector after the vacuum energy is subtracted;

(iv) a limit

$$T_k = \lim_{L\to\infty} \frac{E_k(L)}{L} \tag{92.8}$$

whenever the limit exists.

Equivalently, in an area-law regime for a large rectangular Wilson loop in a representation of N-ality k,

$$\langle W_k(C)\rangle = \exp\bigl(-T_k \ \mathrm{Area}(C) + o(\mathrm{Area}(C))\bigr) \tag{92.9}$$

defines the same tension if the transfer-matrix and Wilson-loop formulations have been proved equivalent for the regulator under consideration.

Two comparison formulae are useful reference functions:

$$R_k^{\mathrm{sine}}(N_c) = \frac{\sin(\pi k/N_c)}{\sin(\pi/N_c)}, \qquad R_k^{\mathrm{Casimir}}(N_c) = \frac{k(N_c - k)}{N_c - 1}. \tag{92.10}$$

The first appears in Abelianized supersymmetric regimes and in several string-inspired large-N_c calculations. The second is a quadratic color-factor comparison coordinate. In this chapter they are comparison functions until a specified QFT framework supplies a derivation of a spectral tension ratio.

For $1 \le k \le N_c - 1$,

$$R_k^{\text{sine}}(N_c) = R_{N_c-k}^{\text{sine}}(N_c), \qquad R_k^{\text{Casimir}}(N_c) = R_{N_c-k}^{\text{Casimir}}(N_c). \tag{92.11}$$

At fixed k and large N_c,

$$R_k^{\text{sine}}(N_c) = k - \frac{\pi^2}{6}\frac{k(k^2-1)}{N_c^2} + O(N_c^{-4}), \tag{92.12}$$

while

$$R_k^{\text{Casimir}}(N_c) = k - \frac{k(k-1)}{N_c} + O(N_c^{-2}). \tag{92.13}$$

These are finite comparison identities. The symmetry follows from

$$\sin\left(\frac{\pi(N_c-k)}{N_c}\right) = \sin\left(\pi - \frac{\pi k}{N_c}\right) = \sin\left(\frac{\pi k}{N_c}\right)$$

and from

$$(N_c - k)k = k(N_c - k).$$

The sine-law expansion is obtained by dividing

$$\sin\frac{\pi k}{N_c} = \frac{\pi k}{N_c} - \frac{\pi^3 k^3}{6N_c^3} + O(N_c^{-5}), \qquad \sin\frac{\pi}{N_c} = \frac{\pi}{N_c} - \frac{\pi^3}{6N_c^3} + O(N_c^{-5}).$$

This gives

$$R_k^{\text{sine}} = k\left(1 - \frac{\pi^2 k^2}{6N_c^2}\right)\left(1 + \frac{\pi^2}{6N_c^2}\right) + O(N_c^{-4}),$$

which is (92.12). For the Casimir comparison,

$$\frac{k(N_c-k)}{N_c-1} = k\frac{1-k/N_c}{1-1/N_c} = k\left(1 - \frac{k}{N_c}\right)\left(1 + \frac{1}{N_c} + O(N_c^{-2})\right),$$

which gives (92.13). The physics lies in whether a specified gauge theory and regulator produce one of these finite functions as a spectral ratio; the algebra above supplies only comparison coordinates.

92.5 Entries of the Family

92.5.1 Pure Bosonic Yang–Mills

Pure bosonic Yang–Mills is the endpoint with the fewest protected observables and the strongest need for a nonperturbative construction. Its glueball and flux-tube spectra are formulated in Section 46.8. In the family comparison, the bosonic row contains:

object	role
OS-positive lattice gauge measure	candidate regulator and transfer matrix
local operators $\operatorname{tr} F^2, \operatorname{tr} F\widetilde{F}, \ldots$	J^{PC} glueball sources
center-flux sectors	k-string tensions and excited flux tubes
large-N_c expansion	$M_{\text{glueball}} = O(1), \quad \Gamma_{\text{glueball}} = O(N_c^{-2})$

The bosonic theory supplies the target spectral questions: a mass gap, isolated glueball poles, stable flux sectors, and an effective string description in the long-string regime.

92.5.2 Pure $\mathcal{N} = 1$ Yang–Mills

Pure $\mathcal{N} = 1$ Yang–Mills adds protected chiral branch information. The local coordinate

$$S = -\frac{1}{32\pi^2}\,\mathrm{tr}\, W^\alpha W_\alpha$$

has branch values

$$\langle S\rangle_k = C\Lambda_h^3 \mathrm{e}^{2\pi \mathrm{i}k/N_c}.$$

The family comparison separates three outputs:

output	source
N_c branch phases	$\mathbb{Z}_{2N_c}$ anomaly and chiral F-term
$T_{ij} = 2\lvert W_i - W_j\rvert$	$\mathcal{N} = 1$ BPS wall algebra
glueball/gluinoball masses	spectral measure $\rho_{ij}^{(k)}$

The first two are protected after the stated hypotheses of Chapter 90. The third is a massive spectral problem involving the scalar, pseudoscalar, and fermionic components of gauge-invariant superfields. Supersymmetry organizes isolated massive states into multiplets when the vacuum preserves the supercharges, but it does not supply their numerical masses.

Definition 92.7 (Pure-SYM channel source table)**.** Fix a massive branch k of pure $\mathcal{N} = 1$ $SU(N_c)$ Yang–Mills and the vacuum spectral measure of Definition 90.3. Let

$$S = -\frac{1}{32\pi^2}\,\mathrm{tr}\, W^\alpha W_\alpha$$

be the chiral coordinate used in Section 90.6. The elementary source table attached to this superfield is:

channel	**source family**	**spectral role**
bosonic even scalar	$\mathrm{Re}\, S\rvert_{\theta=0}$, $\mathrm{Re}\, D^2S\rvert$, and same-quantum-number descendants	overlaps with 0^{++}-type atoms after operator mixing is fixed
bosonic odd scalar	$\mathrm{Im}\, S\rvert_{\theta=0}$, $\mathrm{Im}\, D^2S\rvert$, and same-quantum-number descendants	overlaps with 0^{-+}-type atoms after operator mixing is fixed
fermionic	$D_\alpha S\rvert$, $\overline{D}_{\dot\alpha}\overline{S}\rvert$, and derivative descendants	overlaps with spin-$\frac{1}{2}$ atoms in the same massive multiplets

Here the vertical bar denotes restriction to $\theta = \overline{\theta} = 0$ after the chosen superspace operator has been renormalized. The table lists source families, not particles: the spectral measure may contain several isolated atoms and continuum components in any row, and the same atom can have nonzero residue for several sources with the same exact quantum numbers. Center-charged Wilson or magnetic lines belong to a separate line-sector problem; they define flux-string sectors rather than chiral-particle masses.

Mass degeneracy inside an isolated pure-SYM multiplet. Assume the vacuum branch k carries unbroken $\mathcal{N} = 1$ supercharges $Q_\alpha, \overline{Q}_{\dot\alpha}$ on the Hilbert space of Definition 90.3. Let $E_k(\Sigma_m)$ be the spectral projection onto an isolated positive-mass shell $\Sigma_m = \{p : p^2 = -m^2,\ p^0 > 0\}$, separated from the rest of the joint translation spectrum in a neighborhood invariant under the little group. Then the range of $E_k(\Sigma_m)$ is invariant under the supercharges. In particular, whenever a bosonic or fermionic source in Definition 92.7 has nonzero overlap with this atom, the complete supermultiplet generated by the supercharges has the same mass m. The supersymmetry algebra gives

$$[P_\mu, Q_\alpha] = [P_\mu, \overline{Q}_{\dot\alpha}] = 0.$$

Therefore the mass operator

$$M_k^2 = -\eta^{\mu\nu} P_\mu^{(k)} P_\nu^{(k)}$$

commutes with the supercharges on their common invariant domain. Functional calculus then gives

$$Q_\alpha E_k(B) = E_k(B) Q_\alpha, \qquad \overline{Q}_{\dot\alpha} E_k(B) = E_k(B) \overline{Q}_{\dot\alpha}$$

for every Borel set B of the joint spectrum for which the products are defined by closure; applying this to the isolated shell gives invariance of $\operatorname{Ran} E_k(\Sigma_m)$. Acting with the supercharges changes spin and fermion number but not P^2, so all nonzero states in the generated irreducible massive supermultiplet have the same mass. The statement says nothing about the numerical value of m or about whether the atom exists; those are spectral questions in the chosen nonperturbative construction.

Definition 92.8 (Regulated pure-SYM spectral extraction)**.** A regulated extraction of the pure $\mathcal{N} = 1$ SYM spectrum consists of:

(i) a gauge-field regulator and an adjoint Majorana-fermion regulator with a specified Pfaffian or determinant prescription;

(ii) a parameter $m_{\lambda,\text{reg}}$ whose tuned value defines the massless-gluino trajectory, together with the Ward identity or equivalent renormalized condition used to tune it;

(iii) a finite-volume transfer matrix or Euclidean reflection-positive substitute sufficient to define spectral estimates;

(iv) source matrices in the exact finite-regulator symmetry channels, with the continuum J^{PC} labels assigned only after the rotation and discrete-symmetry restoration limits have been taken;

(v) a limit prescription $a \to 0$, $L \to \infty$, and $m_{\lambda,\text{reg}} \to m_{\lambda,*}$, including the order of limits and the systematic error controls used in the extrapolation.

This regulated extraction is the supersymmetric analogue of the pure-glue construction in Section 46.8. It is not replaced by the Veneziano–Yankielowicz superpotential: the latter supplies protected branch information, while the spectral extraction is what can define numerical glueball, gluinoball, and mixed supermultiplet masses.

Definition 92.9 (Channel-by-channel pure-SYM correlator matrices)**.** Fix the regulated extraction of Definition 92.8. Choose zero-spatial-momentum finite-volume sources

$$B_{+,r}, \qquad B_{-,r}, \qquad F_{\alpha,r}, \qquad r = 1, \dots, R,$$

where B_+ has the quantum numbers of the even scalar row of Definition 92.7, B_- has the odd-scalar row, and F_α has the fermionic row. With the vacuum projection removed, define the Euclidean transfer-matrix correlator matrices

$$C_+^{rs}(t) = \langle\Omega|B_{+,r}\,\mathrm{e}^{-tH_{\mathrm{reg}}}\,B_{+,s}^\dagger|\Omega\rangle_c, \tag{92.14}$$

$$C_-^{rs}(t) = \langle\Omega|B_{-,r}\,\mathrm{e}^{-tH_{\mathrm{reg}}}\,B_{-,s}^\dagger|\Omega\rangle_c, \tag{92.15}$$

$$C_F^{rs}(t) = \frac{1}{2}\,\mathrm{tr}_{\mathrm{rest}}\langle\Omega|F_r\,\mathrm{e}^{-tH_{\mathrm{reg}}}\,\overline{F}_s|\Omega\rangle_c. \tag{92.16}$$

The trace in (92.16) is the declared spin average in the rest frame; at finite lattice spacing it must be replaced by the exact spin-little-group projection of the regulator. The channel matrices are not themselves a numerical result. They specify the finite-regulator spectral data whose leading isolated pole positions may be compared across the even scalar, odd scalar, and fermionic channels. The method used to estimate those pole positions is external to the present chapter; the pure-SYM content is the choice of channels, sources, spin/rest-frame projections, gluino-mass tuning condition, and joint continuum, thermodynamic, and massless-gluino limiting procedure. A pure-SYM spectral extraction has restored supersymmetry in a one-particle window only after that limiting procedure makes the pole locations extracted from the three channels agree within a stated continuum and infinite-volume error estimate.

Operationally, the pure-SYM lattice or Hamiltonian analysis should publish, for each candidate multiplet, the three leading masses

$$m_+, \qquad m_-, \qquad m_F$$

with the regulator parameters, source bases, fit windows, finite-volume trajectory, and tuning condition for the gluino mass. The supersymmetry restoration diagnostic is not the equality of two names in a table; it is the vanishing of

$$\delta_{\mathrm{SUSY}} = \frac{\max\{|m_+ - m_-|, |m_+ - m_F|, |m_- - m_F|\}}{\frac{1}{3}(m_+ + m_- + m_F)} \tag{92.17}$$

in the joint continuum, infinite-volume, and massless-gluino limit, with the limiting procedure stated as part of Definition 92.8.

92.5.3 Pure $\mathcal{N}=2$ and Softly Broken $\mathcal{N}=2$

Pure $\mathcal{N}=2$ Yang–Mills has Coulomb-branch coordinate u, period vector (a_D, a), and BPS central charge

$$Z_\gamma = n_e a + n_m a_D.$$

At a monopole singularity, a soft $\mathcal{N}=1$ deformation

$$W_{\mathrm{loc},\mu} = \sqrt{2}\,A_D M\widetilde{M} + \mu\,U(A_D)$$

gives

$$A_D = 0, \qquad M\widetilde{M} = -\frac{\mu}{\sqrt{2}}U'(0).$$

The dual $U(1)_D$ is Higgsed, and the local Abelian model supports flux tubes carrying the original electric flux. The Seiberg–Witten row therefore contains a controlled Abelian confinement mechanism near the singularity. The detailed non-Abelian k-string spectrum away from the local Abelian regime is a separate spectral problem.

Controlled Approximation 92.10 (Radial BPS string profile near a monopole point)**.** Use the local Abelian-Higgs normalization of (91.35), take $n > 0$, and choose the orientation for which

$$(D_1 + \mathrm{i}D_2)q = 0, \qquad B_D = e_D^2(|\xi| - |q|^2). \tag{92.18}$$

With polar coordinate (r, φ) on the plane transverse to the string, set

$$q(r, \varphi) = |\xi|^{1/2} f(R)\mathrm{e}^{\mathrm{i}n\varphi}, \qquad A_D = n\, a(R)\, \mathrm{d}\varphi, \qquad R = e_D|\xi|^{1/2} r. \tag{92.19}$$

Finite energy and regularity impose

$$f(0) = 0, \qquad a(0) = 0, \qquad f(\infty) = 1, \qquad a(\infty) = 1. \tag{92.20}$$

The first-order equations reduce to

$$\frac{\mathrm{d}f}{\mathrm{d}R} = \frac{n}{R}(1 - a)f, \qquad \frac{\mathrm{d}a}{\mathrm{d}R} = \frac{R}{n}(1 - f^2). \tag{92.21}$$

The flux and BPS tension are

$$\int_{\mathbb{R}^2} F_D = 2\pi n, \qquad T_n = 2\pi n|\xi|. \tag{92.22}$$

Derivation of the radial vortex equations. For the ansatz (92.19),

$$D_r q = |\xi|^{1/2} e_D |\xi|^{1/2} f'(R)\mathrm{e}^{\mathrm{i}n\varphi}, \qquad D_\varphi q = \mathrm{i}n(1 - a)|\xi|^{1/2} f(R)\mathrm{e}^{\mathrm{i}n\varphi}.$$

Since $D_1 + \mathrm{i}D_2 = \mathrm{e}^{\mathrm{i}\varphi}(D_r + \mathrm{i}r^{-1}D_\varphi)$, the first BPS equation gives

$$e_D|\xi|^{1/2} f'(R) - \frac{n}{r}(1 - a)f(R) = 0,$$

which is the first equation in (92.21). The curvature of the one-form $A_D = n\, a(R)\mathrm{d}\varphi$ is

$$F_D = n\, a'(R)\mathrm{d}R \wedge \mathrm{d}\varphi, \qquad B_D = \frac{n}{r} e_D|\xi|^{1/2} a'(R).$$

Substituting $r = R/(e_D|\xi|^{1/2})$ into $B_D = e_D^2|\xi|(1 - f^2)$ gives the second radial equation. Finally,

$$\int_{\mathbb{R}^2} F_D = \int_0^{2\pi} \mathrm{d}\varphi \int_0^\infty n\, a'(R)\mathrm{d}R = 2\pi n\,[a(\infty) - a(0)] = 2\pi n.$$

The tension formula is then the saturated bound (91.36) with positive orientation. The derivation is local in the Seiberg–Witten patch; it does not assert that a full non-Abelian k-string spectrum is determined by the Abelian profile.

92.5.4 Abelianized k-String Comparison

The local $U(1)_D$ vortex just derived is the rank-one building block. For $SU(N_c)$ with $N_c > 2$, the softly broken $\mathcal{N} = 2$ theory has singular loci where several mutually local magnetic states become light and the low-energy magnetic gauge group is an Abelian torus. The string calculation in such a region is an Abelianized calculation. Its output is a precise low-energy spectral problem; comparison with the non-Abelian pure-Yang–Mills k-string spectrum requires an additional deformation argument.

Let K_{ij}, $1 \leq i, j \leq N_c - 1$, be the A_{N_c-1} Cartan matrix

$$K_{ij} = 2\delta_{ij} - \delta_{i,j+1} - \delta_{i+1,j}. \tag{92.23}$$

The simple magnetic fields of an Abelianized Seiberg–Witten patch are labelled by these simple roots. A soft $\mathcal{N} = 1$ deformation supplies complex Fayet–Iliopoulos coordinates ξ_i for the corresponding local Abelian Higgs factors after a magnetic duality frame has been chosen. When the phases of the ξ_i are aligned, the BPS square completion of the rank-one calculation applies independently in each diagonalized magnetic charge sector.

Definition 92.11 (Abelianized A_{N_c-1} string construction)**.** An Abelianized A_{N_c-1} string construction is specified by:

(i) a magnetic low-energy patch with gauge group $U(1)^{N_c-1}$, gauge fields $A_{D,i}$, and mutually local charged monopole hypermultiplets;

(ii) complex FI coordinates ξ_i, $i = 1, \ldots, N_c - 1$, with a declared common phase, so that a BPS bound may be written in a single real central charge direction;

(iii) flux integers $n_i \in \mathbb{Z}$ with
$$\frac{1}{2\pi} \int_{\mathbb{R}^2} F_{D,i} = n_i;$$

(iv) a map from the Abelian magnetic flux vector $n = (n_i)$ to the electric center charge $k \in \mathbb{Z}_{N_c}$ of the heavy Wilson source being confined;

(v) the domain in Coulomb-branch and deformation-parameter space in which the Abelian two-derivative description is used.

This construction defines an Abelianized string spectrum in the local effective theory. It becomes a statement about the microscopic non-Abelian theory only after the Seiberg–Witten effective action and the deformation to the chosen microscopic problem have been justified in the stated regime.

Cartan BPS bound in an aligned Abelian chart. Assume the Abelianized construction of Definition 92.11 and suppose that, in the chosen magnetic frame, the static transverse energy density is a sum of rank-one Abelian-Higgs BPS densities with aligned ξ_i. For flux vector $n = (n_1, \ldots, n_{N_c-1})$, every finite-energy string obeys

$$T(n) \geq 2\pi \left| \sum_{i=1}^{N_c-1} n_i \xi_i \right|. \tag{92.24}$$

If the first-order vortex equations are solved in every occupied sector with the common central-charge orientation, and if all nonzero $n_i \xi_i$ have the phase of $\sum_j n_j \xi_j$, the bound is saturated.

For a single diagonal magnetic factor the square completion in (91.35) gives

$$T_i \geq 2\pi |n_i|\, |\xi_i|$$

with equality when the flux orientation is chosen to have the same phase as $n_i\xi_i$. Writing all ξ_i in the common phase direction as $\xi_i = \mathrm{e}^{\mathrm{i}\alpha}|\xi_i|$, the central charge of a multi-flux configuration is

$$Z(n) = 2\pi \sum_i n_i\xi_i.$$

The triangle inequality gives

$$\sum_i 2\pi|n_i|\,|\xi_i| \geq 2\pi\left|\sum_i n_i\xi_i\right| = |Z(n)|,$$

which is (92.24). Saturation of the displayed central-charge bound requires equality in the triangle inequality, namely all nonzero $n_i\xi_i$ have the same phase, and also saturation of the rank-one square in every occupied sector. The argument is a statement in the diagonal Abelian effective theory; off-diagonal massive fields and non-Abelian core effects are outside the hypotheses.

At the Chebyshev-type maximally singular point of the pure $\mathcal{N}=2$ $SU(N_c)$ Coulomb branch, the Abelianized low-energy calculation often produces an FI profile proportional to the positive A_{N_c-1} sine vector

$$s_i = \sin\frac{\pi i}{N_c}, \qquad i = 1,\ldots,N_c-1. \tag{92.25}$$

The finite algebra behind the resulting sine ratios is elementary and is recorded here because it is the part of the comparison that is independent of any literature convention.

Example 92.12 (A_{N_c-1} sine profile and normalized tensions)**.** Let $s_i = \sin(\pi i/N_c)$. Then $s = (s_i)$ is the strictly positive eigenvector of the A_{N_c-1} Cartan matrix with eigenvalue

$$\lambda_1 = 4\sin^2\frac{\pi}{2N_c}. \tag{92.26}$$

Consequently, if an Abelianized $SU(N_c)$ string construction has aligned FI magnitudes

$$|\xi_k| = |\xi_1|\frac{\sin(\pi k/N_c)}{\sin(\pi/N_c)} \qquad (1 \leq k \leq N_c-1), \tag{92.27}$$

and if the k-labelled string is the single BPS sector associated with ξ_k, then the Abelianized normalized tensions are

$$\frac{T_k^{\mathrm{SW}}}{T_1^{\mathrm{SW}}} = \frac{\sin(\pi k/N_c)}{\sin(\pi/N_c)}. \tag{92.28}$$

They obey charge conjugation

$$T_k^{\mathrm{SW}} = T_{N_c-k}^{\mathrm{SW}} \tag{92.29}$$

and strict subadditivity

$$T_{k+\ell}^{\mathrm{SW}} < T_k^{\mathrm{SW}} + T_\ell^{\mathrm{SW}}, \qquad k,\ell \geq 1, \quad k+\ell \leq N_c-1. \tag{92.30}$$

The verification is finite-dimensional. For $1 < i < N_c-1$,

$$(Ks)_i = 2\sin\frac{\pi i}{N_c} - \sin\frac{\pi(i-1)}{N_c} - \sin\frac{\pi(i+1)}{N_c}.$$

Using

$$\sin(x-a)+\sin(x+a)=2\sin x\cos a$$

with $a=\pi/N_c$, this becomes

$$2\left(1-\cos\frac{\pi}{N_c}\right)\sin\frac{\pi i}{N_c}=4\sin^2\frac{\pi}{2N_c}\,s_i.$$

The endpoint rows obey the same identity with the absent sine terms $\sin 0$ and $\sin\pi$, both zero. The entries s_i are positive for $1\le i\le N_c-1$, so this is the Perron–Frobenius eigenvector of the Cartan matrix.

Under the FI profile (92.27), the saturated rank-one BPS tension in the k-sector is $T_k^{\mathrm{SW}}=2\pi|\xi_k|$. Division by the $k=1$ result gives (92.28). Charge conjugation follows from

$$\sin\frac{\pi(N_c-k)}{N_c}=\sin\frac{\pi k}{N_c}.$$

For subadditivity, set $a=\pi k/N_c$ and $b=\pi\ell/N_c$. Since $0<a,b$ and $a+b<\pi$,

$$\sin a+\sin b-\sin(a+b)=4\sin\frac{a}{2}\sin\frac{b}{2}\sin\frac{a+b}{2}>0.$$

After multiplying by the positive normalization $(2\pi|\xi_1|)/\sin(\pi/N_c)$, this gives (92.30).

Definition 92.13 (Seiberg–Witten to pure-Yang–Mills string comparison)**.** A comparison between the Abelianized Seiberg–Witten strings and the bosonic pure-Yang–Mills k-strings consists of:

(i) a fixed global form of the gauge group and a fixed line-operator lattice, so that the center charge k means the same thing throughout;

(ii) normalized tension functions

$$R_k(t)=\frac{T_k(t)}{T_1(t)}$$

along a declared deformation path t, where $t=0$ denotes the Abelianized Seiberg–Witten regime and $t=1$ denotes the target bosonic Yang–Mills problem;

(iii) a statement of the topology in which the flux-sector transfer matrices, their lowest eigenvalues, and the large-length limits defining $T_k(t)$ vary with t;

(iv) a list of possible obstructions: loss of the Abelian patch, string breaking by dynamical matter, collision with another flux-sector level, change of line-operator lattice, or failure of the continuum limit.

What the Abelian sine calculation transfers. Assume a comparison problem as in Definition 92.13. If, for a fixed k, the tensions $T_1(t)$ and $T_k(t)$ exist, are positive, and are continuous on $0\le t\le 1$, then the normalized ratio $R_k(t)$ is continuous. If in addition $R_k(t)$ is constant along the path, then the pure-Yang–Mills ratio equals the Abelianized value

$$R_k(1)=\frac{\sin(\pi k/N_c)}{\sin(\pi/N_c)}.$$

The Abelian Seiberg–Witten calculation proves the initial value $R_k(0)$ under its low-energy hypotheses; constancy, or any other controlled evolution law for $R_k(t)$, is an additional nonperturbative statement about the deformation path. The first assertion is the continuity of a quotient whose denominator is positive. The second follows by evaluating the constant function $R_k(t)$ at $t = 0$ and using (92.28). The last sentence records the logical dependence of the two inputs: Example 92.12 is an Abelian effective-theory statement, while constancy of $R_k(t)$ is a statement about a family of nonperturbative flux-sector transfer matrices.

92.5.5 Planar $\mathcal{N} = 4$

Planar $\mathcal{N} = 4$ Yang–Mills is conformal, so the family comparison uses scaling dimensions and defect energies instead of massive glueball poles. A local-operator row is the planar spin-chain/QSC spectral problem of Chapters 97–100. A line-defect row is the Wilson-line flux-tube spectral problem of Definition 100.17. Its vacuum energy is the cusp anomalous dimension, and its excitations are the pentagon-OPE or mirror-TBA flux-tube excitations in an integrability description.

The $\mathcal{N} = 4$ row is therefore the most exactly soluble spectral row currently available inside four-dimensional interacting QFT, while its proof boundary is also sharp: the planar integrability construction is an exact spectral framework under stated integrability hypotheses, and a derivation from a nonperturbative four-dimensional regulator remains open.

92.6 Soft Breaking Toward Bosonic Yang–Mills

The deformation from pure $\mathcal{N} = 1$ Yang–Mills toward bosonic Yang–Mills is naturally expressed by a spurion source for the chiral coordinate S:

$$\Delta\mathcal{L} = \int \mathrm{d}^2\theta\, X_\lambda(\theta) S + \text{c.c.}, \qquad X_\lambda(\theta) = \theta^2 m_\lambda. \tag{92.31}$$

The component deformation is

$$\Delta\mathcal{L}_{\text{comp}} = m_\lambda\, S|_{\theta=0} + \overline{m}_\lambda\, \overline{S}|_{\overline{\theta}=0}. \tag{92.32}$$

At small $|m_\lambda|$, the leading branch energy splitting is obtained from the chiral condensate:

$$\Delta E_k = -2\, \mathrm{Re}\Big(m_\lambda\, C\Lambda_h^3 \mathrm{e}^{2\pi \mathrm{i} k/N_c}\Big) + O(|m_\lambda|^2). \tag{92.33}$$

This formula is a first-order source-response statement in the massive $\mathcal{N} = 1$ theory. Increasing $|m_\lambda|$ until the gaugino decouples is a deformation path whose spectral continuity must be examined with nonchiral observables: glueball masses, string tensions, domain-wall fates, and line-operator sectors. The endpoint comparison with bosonic Yang–Mills therefore belongs to the spectral comparison table of Definition 92.4, not only to the chiral branch comparison.

Controlled Approximation 92.14 (Small soft mass branch selection)**.** Assume pure $\mathcal{N} = 1$ $SU(N_c)$ Yang–Mills has N_c massive branches with condensates

$$S_k = C\Lambda_h^3 \mathrm{e}^{2\pi \mathrm{i} k/N_c}$$

and that the soft source (92.31) can be treated in first-order perturbation theory in a finite volume before the thermodynamic limit is taken. Then the branch selected at first order is the branch maximizing

$$\mathrm{Re}(m_\lambda S_k).$$

First-order branch selection. The first-order shift of the vacuum energy density under the component source $m_\lambda S + \overline{m}_\lambda \overline{S}$ is minus the expectation value of the source term:

$$\Delta E_k = -\left(m_\lambda S_k + \overline{m}_\lambda\, \overline{S}_k\right) + O(|m_\lambda|^2) = -2\,\mathrm{Re}(m_\lambda S_k) + O(|m_\lambda|^2).$$

At first order, minimizing ΔE_k is the same as maximizing $\mathrm{Re}(m_\lambda S_k)$.

92.7 Status Summary

The present chapter closes the elementary comparison map. It records the following theorem boundaries:

statement	status in this monograph
$\mathcal{N}=4 \to \mathcal{N}=2, \mathcal{N}=1$ scale matching	derived holomorphic threshold matching
$\mathcal{N}=1$ branches and BPS walls	derived from chiral F-term hypotheses
$\mathcal{N}=2$ monopole condensation	derived in local Abelian patch
$\mathcal{N}=2$ vortex tension	BPS Abelian-Higgs controlled approximation
$\mathcal{N}=2$ Abelianized k-strings	A-type sine profile; comparison problem
$\mathcal{N}=4$ Wilson-line flux tube	defect spectral problem plus integrability hypotheses
bosonic glueball and k-string spectra	lattice or Hilbert-space spectral problem

The frontier problem is to construct a regulator-level family in which enough of the ladder is realized simultaneously to compare the spectral measures, line-defect Hilbert spaces, and flux-sector transfer matrices directly.

Open Problem 92.15 (Regulator-level supersymmetry-breaking spectral bridge)*.* Construct a regulator and continuum-limiting framework for the deformation from supersymmetric Yang–Mills theories to bosonic Yang–Mills that controls all of the following in the same topology: gauge-invariant local spectral measures, center-flux transfer matrices, line-operator charge lattices, domain-wall sectors, and protected chiral coordinates. Prove, disprove, or replace the commonly assumed continuity of glueball and flux-string spectra along such deformation paths by a theorem with stated hypotheses.

Chapter 93

Moduli Spaces In Supersymmetric Quantum Field Theory

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter defines supersymmetric moduli spaces as spaces of supersymmetric vacua together with their low-energy QFT structures. The set of classical solutions is only the first coordinate chart; the physical object includes quotienting, singular strata, massless fields, chiral rings, metrics, and quantum corrections.

Definition 93.1 (Quantum supersymmetric moduli-space structure)**.** Fix a supersymmetric local QFT with supercharges Q_α acting on a common invariant domain in each vacuum representation. A quantum supersymmetric moduli-space structure is a tuple

$$\mathfrak{M} = \left(\mathcal{M}, \mathcal{O}^{\mathrm{hol}}_{\mathcal{M}}, \{\mathcal{H}_p, \mathcal{A}_p, \mathcal{E}_p, \mathcal{G}_p\}_{p\in\mathcal{M}}\right)$$

with the following entries.

1. $\mathcal{M}$ is a reduced stratified analytic space whose points label equivalence classes of supersymmetric vacuum sectors. A representative vacuum sector is a translation-invariant positive-energy representation with vacuum vector or vacuum state annihilated by the preserved supercharges, modulo unitary equivalence preserving the local operator net and background couplings.

2. $\mathcal{O}^{\mathrm{hol}}_{\mathcal{M}}$ is the sheaf of holomorphic branch-coordinate functions generated, where valid, by expectation values of protected chiral operators. Nilpotent or derived structure is additional

structure; if it affects operator products or low-energy dynamics it must be retained rather than replaced by the reduced space.

3. $\mathcal{H}_p$ is the Hilbert space of fluctuations in the vacuum sector p, and $\mathcal{A}_p$ is the local operator algebra or field presentation of the low-energy QFT in that sector.
4. $\mathcal{E}_p$ records the effective branch structure: massless fields, two-derivative metric, Wess–Zumino terms, superselection sectors, and the energy range on which the branch effective theory is valid.
5. $\mathcal{G}_p$ records background responses, anomaly lines, and global-form or extended-operator structures in the vacuum sector.

On a smooth stratum, $T_p\mathcal{M}$ is represented by supersymmetric massless scalar directions in $\mathcal{H}_p$. A singular stratum is a locus where this representation, the effective theory $\mathcal{E}_p$, or the background-response structure $\mathcal{G}_p$ changes. A classical quotient of scalar zero modes is therefore a coordinate construction for one approximation to $\mathfrak{M}$, not the definition of the quantum moduli-space structure.

93.1 Vacuum Equations

For four-dimensional $\mathcal{N} = 1$ chiral multiplets Φ^i with superpotential $W(\Phi)$ and gauge group G, a classical supersymmetric vacuum obeys

$$F_i = \frac{\partial W}{\partial \Phi^i} = 0, \qquad \mu^a = 0,$$

where $\mu : \mathcal{X} \to \mathfrak{g}^*$ is the moment map for the Kähler target $\mathcal{X}$ of scalar fields. The classical vacuum space is the Kähler quotient

$$\mathcal{M}_{\text{cl}} = \{F = 0,\ \mu = 0\}/G.$$

Equivalently, under the required stability hypotheses for the complexified gauge action, it is the holomorphic quotient

$$\{F = 0\}/G_{\mathbb{C}}.$$

The second description identifies holomorphic functions on $\mathcal{M}_{\text{cl}}$ with gauge-invariant chiral polynomials modulo the ideal generated by the F-term equations.

The last sentence hides several hypotheses, so we spell out the quotient construction used in this volume. Let V be the finite-dimensional Hermitian representation of G carried by the scalar fields, let $G_{\mathbb{C}}$ be a reductive complexification, and let $W \in \mathbb{C}[V]^{G_{\mathbb{C}}}$ be a polynomial superpotential. Write

$$Z_F = \{v \in V \mid dW(v) = 0\}, \qquad I_F = (\partial_1 W, \dots, \partial_n W) \subset \mathbb{C}[V].$$

The affine chiral quotient is

$$\mathcal{M}_{\text{ch,cl}} = \operatorname{Spec}\left((\mathbb{C}[V]/I_F)^{G_{\mathbb{C}}}\right)_{\text{red}}, \tag{93.1}$$

where the subscript records that the displayed affine variety forgets nilpotents unless they are kept as derived or scheme-theoretic data. The symplectic vacuum quotient is

$$\mathcal{M}_{\mu,\text{cl}} = (Z_F \cap \mu^{-1}(0))/G. \tag{93.2}$$

Classical quotient and chiral functions. Assume the Kempf–Ness comparison for the triple $(V, G, G_{\mathbb{C}})$ on the $G_{\mathbb{C}}$-invariant closed subset Z_F: every polystable $G_{\mathbb{C}}$-orbit in Z_F meets $\mu^{-1}(0)$, and two points of $Z_F \cap \mu^{-1}(0)$ lie in the same closed $G_{\mathbb{C}}$-orbit exactly when they lie in the same G-orbit. Under this comparison $\mathcal{M}_{\mu,\mathrm{cl}}$ is naturally identified with the polystable affine quotient $\mathcal{M}_{\mathrm{ch,cl}}$, and its holomorphic coordinate ring is

$$\mathbb{C}[\mathcal{M}_{\mathrm{ch,cl}}] = \left((\mathbb{C}[V]/I_F)^{G_{\mathbb{C}}}\right)_{\mathrm{red}}.$$

Thus the notation $\{F = 0\}/G_{\mathbb{C}}$ in this monograph means the affine quotient in (93.1), together with the stated stability hypothesis, not the naive set of all complexified orbits. Because W is $G_{\mathbb{C}}$-invariant, the differential dW is equivariant and the ideal I_F is $G_{\mathbb{C}}$-stable. Hence every class in $(\mathbb{C}[V]/I_F)^{G_{\mathbb{C}}}$ is represented by a gauge-invariant holomorphic polynomial on Z_F, and restriction to $Z_F \cap \mu^{-1}(0)$ gives a holomorphic function constant on G-orbits. The assumed Kempf–Ness statement identifies G-orbits in $Z_F \cap \mu^{-1}(0)$ with closed $G_{\mathbb{C}}$-orbits in the affine quotient. Invariant polynomials separate closed orbits in an affine reductive quotient, so the descended functions are precisely the regular holomorphic functions on the reduced quotient. Nonclosed complexified orbits can have the same closure and therefore the same values of all invariant polynomials; the affine quotient collapses them to the polystable representative.

Example 93.2 (Rank-one abelian quotient)**.** Let $G = U(1)$ act on $V = \mathbb{C}^2$ by

$$(x, y) \longmapsto (\mathrm{e}^{\mathrm{i}\alpha}x, \mathrm{e}^{-\mathrm{i}\alpha}y), \qquad W = 0,$$

with moment map $\mu = |x|^2 - |y|^2$. The invariant ring of the complexified action $t\cdot(x, y) = (tx, t^{-1}y)$ is

$$\mathbb{C}[x, y]^{\mathbb{C}^*} = \mathbb{C}[u], \qquad u = xy.$$

Indeed the monomial $x^a y^b$ has $U(1)$ charge $a - b$, so invariance forces $a = b$ and the monomial is u^a. On the symplectic side $\mu = 0$ gives $|x| = |y|$. The map $(x, y) \mapsto xy$ sends $\mu^{-1}(0)/U(1)$ bijectively to $\mathbb{C}$: for $u = \rho\mathrm{e}^{\mathrm{i}\theta}$, with $\rho \geq 0$, choose

$$x = \sqrt{\rho}, \qquad y = \sqrt{\rho}\,\mathrm{e}^{\mathrm{i}\theta},$$

and changing the phase split between x and y is precisely the $U(1)$ quotient. Thus this basic vacuum quotient is the complex line with coordinate u, not a two-complex-dimensional space of unquotiented scalar expectation values.

93.2 Quantum Moduli Space

For the quantum moduli-space structure $\mathfrak{M}$ of Definition 93.1, a smooth branch is a stratum on which the massless field content, preserved supersymmetry algebra, and background-response structure are locally constant. If z^i are massless scalar coordinates on such a branch, the two-derivative effective action determines a metric

$$ds^2 = g_{i\bar{j}}(z, \bar{z})\, dz^i d\bar{z}^{\bar{j}}$$

on the branch. The metric is part of the low-energy QFT structure; the chiral coordinate ring determines only holomorphic functions.

93.3 Chiral Rings And Holomorphic Functions

Let $\mathcal{R}_{\mathrm{ch}}$ be the chiral ring of gauge-invariant local operators modulo $\bar{Q}$-exact operators. In a vacuum p, expectation values define a homomorphism

$$\mathrm{ev}_p : \mathcal{R}_{\mathrm{ch}} \longrightarrow \mathbb{C}.$$

If chiral operators separate vacua on a branch and have no nilpotent relations in the reduced branch coordinate ring, the collection of ev_p identifies the reduced holomorphic coordinate ring with a quotient of $\mathcal{R}_{\mathrm{ch}}$. Nilpotents, accidental massless fields, and singular strata must be retained when they affect operator products or low-energy dynamics.

93.4 Fixed Charge As A Probe Of A Branch

There are two distinct operator-theoretic probes of a moduli branch. The first probe is the character of the chiral ring in a vacuum, $\mathrm{ev}_p : \mathcal{R}_{\mathrm{ch}} \to \mathbb{C}$. It addresses the reduced holomorphic coordinate algebra, under the separation hypotheses stated above. The second probe uses sectors of fixed global charge. This second probe is the precise setting of the large-charge expansion: a low-energy effective theory on a smooth branch can determine the asymptotic spectrum of highly charged states, and in a conformal theory those states are equivalently highly charged local operators of definite scaling dimension.

Let F be a compact internal global symmetry of the QFT, with conserved currents j^μ_A and commuting charge operators

$$Q_A = \int_\Sigma d\Sigma_\mu \, j^\mu_A, \qquad A = 1, \ldots, r,$$

on a spatial slice Σ, after the usual choice of domain and infrared regulator. For an integral charge vector $q = (q_A)$ in the joint spectrum, write

$$\mathcal{H}_q = \{\psi \in \mathcal{H} \mid Q_A \psi = q_A \psi \text{ for all } A\}.$$

A chemical potential μ^A is the Lagrange multiplier conjugate to Q_A. In Hamiltonian language it enters the variational problem through

$$H_\mu = H - \mu^A Q_A,$$

while in Euclidean finite-volume language it is an imaginary background holonomy for the corresponding global symmetry, with the precise analytic continuation depending on the reflection-positive construction of the thermal theory.

Assume that a smooth branch $\mathcal{M}_{\mathrm{sm}} \subset \mathcal{M}$ carries an F-action generated by vector fields $K_A = K^i_A(z)\partial_i + \overline{K}^{\bar{i}}_A(\bar{z})\partial_{\bar{i}}$, and that the branch EFT with metric $g_{i\bar{j}}$ is valid below a scale $M_{\mathrm{gap}}(p)$ for the massive modes transverse to the branch. A homogeneous charged saddle on the cylinder has the form

$$\dot{z}^i = \mu^A K^i_A(z), \qquad \dot{\bar{z}}^{\bar{i}} = \mu^A \overline{K}^{\bar{i}}_A(\bar{z}),$$

up to the fermionic and auxiliary-field conditions imposed by the preserved supercharges. Its charge and energy are computed from the Noether functional of the branch action. At the two-derivative level, with $V_R = \mathrm{Vol}(S_R^{d-1})$,

$$q_A = V_R\, g_{i\bar{j}}(z,\bar{z}) \left(K_A^i \dot{\bar{z}}^{\bar{j}} + \dot{z}^i \overline{K}_A^{\bar{j}} \right) + q_A^{\mathrm{WZ}} + \cdots , \tag{93.3}$$

$$E_{\mathrm{EFT}}(q,R) = \underset{z,\mu}{\mathrm{crit}} \left[V_R g_{i\bar{j}}(z,\bar{z})\, \mu^A K_A^i\, \mu^B \overline{K}_B^{\bar{j}} + E_{\mathrm{curv}}(z,R) + E_{\mathrm{WZ}}(z,\mu,R) + \cdots \right]_{q \text{ fixed}} . \tag{93.4}$$

Here R is the radius of the spatial sphere, q_A^{WZ} and E_{WZ} denote possible Wess-Zumino or background-response contributions, and the ellipses are higher-derivative terms ordered by the small parameters set by $1/(|\mu|R)$ and $|\mu|/M_{\mathrm{gap}}(p)$. The displayed equations are a reconstruction mechanism rather than a theorem: they become a controlled expansion only after specifying the charged saddle, the positivity of transverse fluctuations, and a range in which all omitted operators are uniformly smaller than the retained terms.

In a unitary CFT, put the theory on $\mathbb{R} \times S_R^{d-1}$. The state-operator theorem of Chapter 59 identifies local operators of definite scaling dimension with the corresponding energy eigenstates in the local-operator subspace of the cylinder Hilbert space. Consequently, if the lowest-energy vector in $\mathcal{H}_q$ is represented by a primary operator $\mathcal{O}_q$, then

$$\Delta(\mathcal{O}_q) = R\, E_0(q,R).$$

The large-charge program initiated by Hellerman and collaborators is exactly this bridge in the conformal setting: fixed-charge spectral data determine the coefficients of the branch EFT that control the charged saddle, while the branch EFT predicts the asymptotic dimensions and matrix elements of large-charge operators. Its output is an asymptotic charged-sector reconstruction. Recovering the full vacuum datum $(\mathcal{M}, \mathcal{H}_p, \mathcal{A}_p, \mathcal{G}_p)$, including singular strata, uncharged directions, nilpotent scheme structure, background responses, and changes of low-energy degrees of freedom, requires additional input beyond the large-charge sector alone.

The broader reconstruction problem is more structural. Wightman-type data provide a Hilbert space, local operator-valued distributions, vacuum correlation distributions, spectrum, locality, and covariance. A Kontsevich–Segal-type theory asks instead for functorial amplitudes assigned to geometric bordisms, with boundary state spaces, sewing, reflection positivity, and background-field dependence. A supersymmetric moduli space should be visible in such KS data as a family of boundary conditions or asymptotic sectors whose sewn amplitudes produce the low-energy branch theory. Chiral-ring characters and fixed-charge spectra are therefore probes of the Wightman-to-KS reconstruction map, rather than the map itself.

93.5 N One SQCD Branches

For $SU(N_c)$ SQCD with N_f flavors, the microscopic chiral fields are quarks $Q^a{}_i$ in the fundamental and antiquarks $\widetilde{Q}_a{}^i$ in the antifundamental, with color $a = 1, \ldots, N_c$ and flavor $i = 1, \ldots, N_f$. The elementary gauge-invariant chiral coordinates are the mesons

$$M^i{}_j = \widetilde{Q}_a{}^i Q^a{}_j$$

and, when $N_f \geq N_c$, the baryons and antibaryons obtained by contracting N_c quarks or antiquarks with $\epsilon_{a_1 \cdots a_{N_c}}$. The relations among these coordinates are algebraic relations in the reduced affine quotient; they are not optional decoration, because they decide which operator expectation values can occur in a supersymmetric vacuum.

The following table is only an orientation map. It is not used as a proof, and each row requires a separate derivation or an explicitly labeled Wilsonian input:

$N_f < N_c$	ADS superpotential produces a runaway direction
$N_f = N_c$	$\det M - B\widetilde{B} = \Lambda_h^{2N_c}$
$N_f = N_c + 1$	confining chiral coordinates with superpotential constraint

Each entry is a Wilsonian chiral-coordinate statement. The metric on the branch and the massive spectrum require additional low-energy data.

The table becomes meaningful only after the classical quotient coordinates have been fixed and after the status of the quantum input has been separated from the algebra done with that input. The smallest nontrivial $N_f = N_c$ example is therefore a concrete test case for the monograph's method: construct the classical quotient from invariant theory, state the protected quantum deformation as the only dynamical input, and then derive all consequences that follow from the deformed equation by ordinary algebra.

Classical $SU(2)$, $N_f = 2$ quotient as invariant theory. Consider four-dimensional $\mathcal{N} = 1$ $SU(2)$ SQCD with two flavors and $W = 0$. Package the two quark and two antiquark doublets, using the pseudoreality of the $SU(2)$ fundamental, as four chiral doublets

$$P_a^I, \qquad a = 1, 2, \qquad I = 1, \ldots, 4.$$

The complexified gauge group $SL(2, \mathbb{C})$ acts on the gauge index a. Define the antisymmetric gauge-invariant coordinates

$$V^{IJ} = \epsilon^{ab} P_a^I P_b^J = -V^{JI}, \qquad 1 \le I, J \le 4, \tag{93.5}$$

with $\epsilon^{12} = 1$. Let

$$\mathrm{Pf}(V) = V^{12}V^{34} - V^{13}V^{24} + V^{14}V^{23}. \tag{93.6}$$

Then the reduced affine classical chiral quotient is

$$\mathcal{M}_{\mathrm{ch,cl}} \simeq \{\, V \in \bigwedge^2 \mathbb{C}^4 \mid \mathrm{Pf}(V) = 0 \,\}. \tag{93.7}$$

It has complex dimension 5. In the usual $Q, \widetilde{Q}$ flavor splitting, the six entries of V^{IJ} are the mesons and baryons, and (93.7) is the classical $\det M - B\widetilde{B} = 0$ relation in an $SU(4)$-covariant notation. The quantum deformation $\mathrm{Pf}(V) = \Lambda_h^4$ is not part of this classical quotient; it is the Wilsonian nonperturbative input discussed in Chapter 90.

Write the two rows of the 2×4 matrix P as

$$u = (P_1^1, \ldots, P_1^4), \qquad v = (P_2^1, \ldots, P_2^4).$$

Then $V^{IJ} = u_I v_J - u_J v_I$, so $V = u \wedge v$ is a decomposable two-form. Hence $V \wedge V = 0$. With the convention (93.6), the coefficient of $2e_1 \wedge e_2 \wedge e_3 \wedge e_4$ in $V \wedge V$ is $\mathrm{Pf}(V)$, proving that every gauge orbit maps into the displayed hypersurface.

Conversely, suppose $V \neq 0$ and $\mathrm{Pf}(V) = 0$. After relabeling the four flavor indices, assume $a_0 = V^{12} \neq 0$. Set

$$u = (1, 0, -V^{23}/a_0, -V^{24}/a_0), \qquad v = (0, a_0, V^{13}, V^{14}).$$

The minors $u_I v_J - u_J v_I$ reproduce V^{12}, V^{13}, V^{14}, V^{23}, and V^{24} by construction, while the remaining minor is

$$u_3 v_4 - u_4 v_3 = \frac{V^{13}V^{24} - V^{14}V^{23}}{a_0} = V^{34},$$

where the last equality is exactly $\mathrm{Pf}(V) = 0$. The point $V = 0$ is obtained from $P = 0$. Thus the invariant map has precisely the hypersurface (93.7) as its image.

It remains to justify that no additional reduced affine-coordinate data are missing. In a polynomial invariant, all $SL(2, \mathbb{C})$ gauge indices must be contracted by invariant tensors. For the fundamental two-dimensional representation, the invariant tensors are generated by the alternating tensor ϵ^{ab}; equivalently, after decomposing tensor powers into irreducible $SL(2)$ representations, the singlet summands are obtained by pairwise antisymmetric contractions. Hence the reduced invariant ring is generated by the pairings V^{IJ}. For four flavor labels the only quadratic straightening relation among these six generators is the Plucker relation

$$V^{12}V^{34} - V^{13}V^{24} + V^{14}V^{23} = 0,$$

which we already identified as the Pfaffian equation. Therefore the reduced affine quotient is the displayed hypersurface. Its dimension is $6 - 1 = 5$, agreeing with the quotient count

$$\dim_{\mathbb{C}} \mathbb{C}^8 - \dim_{\mathbb{C}} SL(2, \mathbb{C}) = 8 - 3 = 5$$

on the stable maximal-rank locus.

Algebra after the $SU(2)$, $N_f = 2$ quantum-deformation input. Assume the Wilsonian chiral-coordinate input that the quantum branch of the theory whose classical chiral quotient is (93.7) is

$$\mathrm{Pf}(V) = \Lambda_h^4, \qquad \Lambda_h \neq 0, \tag{93.8}$$

where Pf is the polynomial in (93.6). The dynamical content is the stated Wilsonian input; the following paragraphs record only the algebraic consequences of that input. The deformed branch is smooth and five-complex-dimensional. Moreover, after adding a nondegenerate antisymmetric mass source and putting it, by a complex linear change of flavor basis, in Darboux form

$$W_m = m_1 V^{12} + m_2 V^{34}, \qquad m_1 m_2 \neq 0, \tag{93.9}$$

and imposing the constraint by a chiral Lagrange multiplier X,

$$W_{\mathrm{constr}} = m_1 V^{12} + m_2 V^{34} + X\big(\mathrm{Pf}(V) - \Lambda_h^4\big), \tag{93.10}$$

the F-term equations over $\mathbb{C}$ have exactly two solutions. After choosing a square root Λ_h^2 of the deformation parameter Λ_h^4 and a square root of $m_1 m_2$, they are

$$X_\pm = \pm\frac{\sqrt{m_1 m_2}}{\Lambda_h^2}, \qquad V_\pm^{12} = -\frac{m_2}{X_\pm}, \qquad V_\pm^{34} = -\frac{m_1}{X_\pm}, \tag{93.11}$$

with all other V^{IJ} equal to zero. Their superpotential values are

$$W_{\pm} = \mp\, 2\Lambda_h^2 \sqrt{m_1 m_2}. \tag{93.12}$$

Thus the deformed branch removes the classical origin, and the simplest mass deformation has the two isolated chiral vacua expected after decoupling to pure $SU(2)$ supersymmetric Yang–Mills, with scale matching $\Lambda_0^6 = m_1 m_2 \Lambda_h^4$ in this Darboux convention. The last comparison uses matching to the massive low-energy theory; the algebraic statement above uses only (93.8). Different choices of square root or of the sign convention relating V^{IJ} to the usual meson-baryon coordinates only relabel the two vacua.

Let

$$F(V) = V^{12}V^{34} - V^{13}V^{24} + V^{14}V^{23}.$$

The gradient of F in the six affine coordinates is

$$\nabla F = (V^{34}, -V^{24}, V^{23}, -V^{13}, V^{14}, V^{12}),$$

ordered as

$$(V^{12}, V^{13}, V^{14}, V^{24}, V^{23}, V^{34}).$$

If $\nabla F = 0$, then all six entries of V vanish, so $F(V) = 0$. No point on $F(V) = \Lambda_h^4$ with $\Lambda_h \neq 0$ can therefore be singular. A smooth hypersurface in six complex affine coordinates has complex dimension 5.

For the mass deformation, a general holomorphic quadratic mass source in the four doublets is an antisymmetric tensor $m_{IJ}V^{IJ}/2$. If m is nondegenerate, elementary alternating-form linear algebra gives a basis (e_1, e_2, e_3, e_4) with

$$m = m_1\, e^1 \wedge e^2 + m_2\, e^3 \wedge e^4, \qquad m_1 m_2 \neq 0;$$

one chooses e_1, then e_2 with $m(e_1, e_2) \neq 0$, takes the orthogonal complement of their span, and repeats in the remaining two-dimensional nondegenerate alternating space. In that Darboux basis, the F-terms from (93.10) are

$$\begin{array}{lll} m_1 + XV^{34} = 0, & -XV^{24} = 0, & XV^{23} = 0, \\ -XV^{13} = 0, & XV^{14} = 0, & m_2 + XV^{12} = 0, \end{array}$$

together with $F(V) = \Lambda_h^4$. If $X = 0$, the first and last equations would force $m_1 = m_2 = 0$, contrary to the hypothesis. Hence $X \neq 0$, and the middle four equations set

$$V^{13} = V^{14} = V^{23} = V^{24} = 0.$$

The remaining two linear equations give

$$V^{12} = -\frac{m_2}{X}, \qquad V^{34} = -\frac{m_1}{X}.$$

The constraint then becomes

$$\frac{m_1 m_2}{X^2} = \Lambda_h^4,$$

so $X = X_{\pm}$ and the two displayed solutions follow. Substitution into (93.9) gives

$$W_{\pm} = -\frac{2m_1 m_2}{X_{\pm}} = \mp\, 2\Lambda_h^2 \sqrt{m_1 m_2},$$

as claimed.

Finally, the comparison with pure $SU(2)$ is the standard holomorphic threshold matching applied to two massive doublet pairs. The one-loop holomorphic exponents are $b_0 = 4$ for $SU(2)$ with two flavors and $b_0 = 6$ for pure $SU(2)$. In the Darboux mass convention the Pfaffian of the antisymmetric mass matrix is $m_1 m_2$, so decoupling gives

$$\Lambda_0^6 = m_1 m_2 \Lambda_h^4.$$

Thus the two values above may be written as $W_\pm = \mp 2\Lambda_0^3$ after choosing a cube-root branch for Λ_0^3, exactly the two-branch pure $SU(2)$ chiral-source pattern. This matching paragraph uses the Wilsonian decoupling input; the smoothness and F-term solution were already proved directly from the deformed Pfaffian equation.

93.6 N Two Coulomb, Higgs, And Mixed Branches

For $\mathcal{N} = 2$ theories, Coulomb-branch coordinates come from vector multiplet scalars and have special Kähler geometry. Higgs branches come from hypermultiplet scalars and are hyperkähler quotients:

$$\mathcal{M}_H = \mu_{\mathbb{R}}^{-1}(0) \cap \mu_{\mathbb{C}}^{-1}(0)/G.$$

Mixed branches have both vector and hypermultiplet massless fields after solving compatibility conditions between vector scalar expectation values and hypermultiplet expectation values. The Coulomb-branch metric may receive quantum corrections encoded by Seiberg-Witten periods. In many Lagrangian examples the Higgs-branch hyperkähler metric is protected, but this protection is a statement about the supersymmetric Wilsonian scheme and the branch coordinates, not a statement about arbitrary coordinate choices.

The quotient statement has concrete content already in the simplest hypermultiplet model. We spell it out because this is the local model behind many later Higgs-branch calculations.

Proposition 93.3 (Rank-one hypermultiplet quotient)**.** *Let $N \geq 2$. Let $U(1)$ act on*

$$V = \mathbb{C}_q^N \oplus \mathbb{C}_{\widetilde{q}}^N$$

by

$$q_i \longmapsto \mathrm{e}^{\mathrm{i}\alpha} q_i, \qquad \widetilde{q}_i \longmapsto \mathrm{e}^{-\mathrm{i}\alpha} \widetilde{q}_i, \qquad i = 1, \ldots, N.$$

Use the complex structure in which $q_i, \widetilde{q}_i$ are holomorphic coordinates. The complex moment map and real moment map are

$$\mu_{\mathbb{C}}(q, \widetilde{q}) = \sum_{i=1}^N q_i \widetilde{q}_i, \qquad \mu_{\mathbb{R}}(q, \widetilde{q}) = \sum_{i=1}^N |q_i|^2 - \sum_{i=1}^N |\widetilde{q}_i|^2.$$

For real FI parameter $\zeta > 0$ and complex FI parameter 0, the Higgs-branch quotient

$$\mathcal{M}_H(\zeta) = \{\, \mu_{\mathbb{C}} = 0,\ \mu_{\mathbb{R}} = \zeta \,\}/U(1) \tag{93.13}$$

is biholomorphic, in this complex structure, to $T^*\mathbb{P}^{N-1}$. Its complex dimension is $2(N-1)$, equivalently its real dimension is $4(N-1)$. On the patch $U_a = \{q_a \neq 0\}$, local holomorphic coordinates are

$$z_i^{(a)} = \frac{q_i}{q_a}, \qquad p_i^{(a)} = q_a \widetilde{q}_i, \qquad i \neq a, \tag{93.14}$$

and the complex moment-map equation determines

$$q_a\widetilde{q}_a = -\sum_{i\neq a} z_i^{(a)} p_i^{(a)}. \tag{93.15}$$

The holomorphic one-form

$$\Theta = \sum_{i=1}^{N} \widetilde{q}_i \, dq_i$$

descends to the canonical cotangent one-form

$$\Theta = \sum_{i\neq a} p_i^{(a)} \, dz_i^{(a)} \tag{93.16}$$

on U_a.

Proof. First remove the real quotient from the holomorphic bookkeeping. If $\mu_{\mathbb{R}} = \zeta > 0$, then $q \neq 0$. Conversely, fix a point $(q, \widetilde{q})$ with $q \neq 0$ and $\mu_{\mathbb{C}} = 0$. Along the positive real part of the complexified orbit,

$$q \mapsto rq, \qquad \widetilde{q} \mapsto r^{-1}\widetilde{q}, \qquad r > 0,$$

the real moment map becomes

$$f(r) = r^2\|q\|^2 - r^{-2}\|\widetilde{q}\|^2.$$

This function is continuous and strictly increasing on $r > 0$, with limit $-\infty$ as $r \to 0$ if $\widetilde{q} \neq 0$ and limit 0 if $\widetilde{q} = 0$, and with limit $+\infty$ as $r \to \infty$. Hence there is a unique positive r solving $f(r) = \zeta$. The remaining phase is precisely the compact $U(1)$ action. Thus the quotient (93.13) is identified with the complex quotient

$$\{\, \mu_{\mathbb{C}} = 0, \ q \neq 0 \,\}/\mathbb{C}^*. \tag{93.17}$$

On U_a, the coordinates in (93.14) are invariant under $\mathbb{C}^*$. They determine the orbit because q_a supplies the complexified gauge scale, the ratios determine all q_i, the $p_i^{(a)}$ determine all $\widetilde{q}_i$ with $i \neq a$, and (93.15) determines $\widetilde{q}_a$. There are $2(N-1)$ complex coordinates, so the complex dimension is $2(N-1)$.

It remains to check that the local charts glue as the cotangent bundle, not just as an abstract $2(N-1)$-dimensional quotient. It suffices to compare two patches; relabel the indices as $a = 1$ and $b = 2$. Write

$$z_i = \frac{q_i}{q_1}, \quad p_i = q_1\widetilde{q}_i \quad (i \neq 1),$$

and on the patch $q_2 \neq 0$,

$$w_1 = \frac{q_1}{q_2} = \frac{1}{z_2}, \qquad w_i = \frac{q_i}{q_2} = \frac{z_i}{z_2} \quad (i \neq 1, 2),$$

$$r_1 = q_2\widetilde{q}_1 = -z_2 \sum_{i\neq 1} z_i p_i, \qquad r_i = q_2\widetilde{q}_i = z_2 p_i \quad (i \neq 1, 2),$$

where the formula for r_1 uses $\mu_{\mathbb{C}} = 0$. A direct differentiation gives

$$r_1 \, dw_1 + \sum_{i\neq 1,2} r_i \, dw_i = \sum_{i\neq 1} p_i \, dz_i. \tag{93.18}$$

Thus the transition functions preserve the canonical holomorphic cotangent one-form.

Finally, on a single patch,

$$dq_i = z_i^{(a)}\, dq_a + q_a\, dz_i^{(a)} \qquad (i \neq a).$$

Using (93.15), the coefficient of dq_a in $\sum_i \widetilde{q}_i\, dq_i$ is

$$\widetilde{q}_a + \sum_{i\neq a} z_i^{(a)}\widetilde{q}_i = 0,$$

while the coefficient of $dz_i^{(a)}$ is $q_a\widetilde{q}_i = p_i^{(a)}$. This proves (93.16) and identifies the quotient with $T^*\mathbb{P}^{N-1}$. □

93.7 Singularities

A point $p \in \mathcal{M}$ is singular when the low-energy description changes there: additional states can become massless, the effective metric can degenerate, or the coordinate quotient can have an orbifold or more severe singularity. In the $\mathcal{N} = 2$ pure gauge-algebra $\mathfrak{su}(2)$ example, the singularities $u = \pm\Lambda^2$ are interpreted by vanishing cycles of the Seiberg-Witten curve and the appearance of light monopole or dyon hypermultiplets. The correct local model is the Abelian theory with those light fields included.

93.8 Effective Theory On A Branch

Let p lie on a smooth branch and let z^i be local coordinates. The low-energy effective action has the derivative expansion

$$S_{\text{eff}} = \int d^dx\, g_{i\bar{j}}(z,\bar{z})\partial_\mu z^i\partial^\mu \bar{z}^{\bar{j}} + \text{fermions} + \text{higher-derivative terms.}$$

The branch approximation is valid for momenta small compared with the masses of fields integrated out and away from loci where additional fields become light. A complete moduli-space statement therefore includes its domain of validity inside the full QFT.

Open Problem 93.4 (Moduli-space construction). Construct the supersymmetric moduli-space datum as part of a general passage from Wightman-type local QFT data to Kontsevich–Segal-type geometric amplitude data. Starting from local operator distributions, Hilbert spaces, vacuum sectors, and correlation distributions, the construction should produce the boundary state spaces, sewing maps, reflection pairings, and background-field dependence from which the vacuum sectors, chiral-coordinate ring, low-energy Hilbert spaces, branch metrics, singular local models, and background anomaly responses are recovered. It should also explain the precise domain of the two probes described above: chiral-ring characters as reduced holomorphic-coordinate data, and fixed-charge spectra as large-charge asymptotic data for the effective theory on charged regions of the branch.

Chapter 94

Two-Dimensional Supersymmetric Models

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter begins the lower-dimensional supersymmetric examples. The main objects are $2D$ $\mathcal{N} = (2,2)$ Landau–Ginzburg models, sigma models, and gauged linear sigma models. Each is treated as a QFT presentation with declared fields, symmetries, operator coordinates, and infrared questions.

94.1 The N=(2,2) Algebra

In Lorentzian signature let $P_\pm = P_0 \pm P_1$. The supercharges

$$Q_\pm, \quad \bar{Q}_\pm$$

obey

$$\{Q_+, \bar{Q}_+\} = 2P_+, \qquad \{Q_-, \bar{Q}_-\} = 2P_-,$$

with all other anticommutators vanishing in the absence of central charges. An R-symmetry assignment consists of vector and axial charges

$$F_V, \qquad F_A,$$

whose action on supercharges is part of the model specification. A BPS state with central charge Z obeys an inequality obtained by positivity of $(Q+\mathrm{e}^{\mathrm{i}\alpha}\bar{Q})^\dagger(Q+\mathrm{e}^{\mathrm{i}\alpha}\bar{Q})$; the saturated states are kernels of a corresponding linear combination of supercharges.

94.2 Landau–Ginzburg Presentations

Definition 94.1 (Two-dimensional Landau–Ginzburg presentation)**.** A polynomial $2D\,\mathcal{N}=(2,2)$ Landau–Ginzburg presentation in this chapter is specified by:

1. a Euclidean two-manifold Σ, initially a smooth oriented surface with a chosen spin structure when fermions are kept explicitly;
2. chiral multiplet coordinates
$$\Phi^i=(\phi^i,\psi_+^i,\psi_-^i,F^i),\qquad i=1,\dots,n,$$
where $\phi^i:\Sigma\to\mathbb{C}$ are scalar field variables, $\psi_\pm^i$ are fermionic field variables of right- and left-moving chirality, and F^i are auxiliary even field variables;
3. a Kähler potential K whose Hessian
$$g_{i\bar{j}}(\phi,\bar{\phi})=\partial_i\partial_{\bar{j}}K(\phi,\bar{\phi})$$
is positive on the field chart used in the perturbative construction;
4. a holomorphic polynomial superpotential
$$W\in\mathbb{C}[\phi^1,\dots,\phi^n].$$

This is a field-variable presentation. A continuum QFT requires a regulator, a supersymmetric Ward identity, and a Hilbert-space or Euclidean reconstruction; none of these is inferred from the polynomial W alone.

Eliminating the auxiliary fields is a finite-dimensional calculation at each point of Σ. In the normalization where the auxiliary part of the Euclidean Lagrangian is
$$g_{i\bar{j}}F^i\bar{F}^{\bar{j}}+F^i\partial_iW+\bar{F}^{\bar{j}}\partial_{\bar{j}}\overline{W},$$
the algebraic equation of motion is
$$g_{i\bar{j}}\bar{F}^{\bar{j}}+\partial_iW=0.$$
Substituting this equation gives the bosonic potential
$$V(\phi)=g^{i\bar{j}}\partial_iW(\phi)\,\overline{\partial_jW(\phi)}.$$
Thus supersymmetric classical vacua in the affine field chart solve
$$\partial_iW(\phi)=0,\qquad i=1,\dots,n.$$

Definition 94.2 (Quasihomogeneous isolated Landau–Ginzburg polynomial)**.** Let $q_i \in \mathbb{Q}_{>0}$. A polynomial

$$W \in \mathbb{C}[\phi^1, \dots, \phi^n]$$

is quasihomogeneous of degree 1 with weights q_i when

$$W(\lambda^{q_1}\phi^1, \dots, \lambda^{q_n}\phi^n) = \lambda W(\phi^1, \dots, \phi^n) \qquad \lambda \in \mathbb{C}^\times. \tag{94.1}$$

It is isolated when the common zero locus of

$$\partial_1 W, \dots, \partial_n W$$

in $\mathbb{C}^n$ is the single point 0. The algebraic chiral coordinate ring attached to the polynomial is the Jacobi algebra

$$\mathrm{Jac}(W) = \mathbb{C}[\phi^1, \dots, \phi^n]/(\partial_1 W, \dots, \partial_n W). \tag{94.2}$$

The term "algebraic chiral coordinate ring" is deliberately narrower than "the infrared chiral ring of the continuum QFT". It is the finite algebraic object forced by the F-term equations and by the protected cohomological argument below. The statement that a regulated Landau–Ginzburg model flows to a compact $\mathcal{N} = 2$ superconformal field theory with this ring as its chiral-primary ring is an additional infrared construction problem.

Jacobian quotient from the B-type differential. Let $A = \mathbb{C}[\phi^1, \dots, \phi^n]$ and let $I_W \subset A$ be the ideal generated by $\partial_i W$. Assume that the regulated B-type local operator complex contains odd local variables η_i, $i = 1, \dots, n$, and a scalar odd differential Q_B satisfying

$$Q_B \phi^i = 0, \qquad Q_B \eta_i = \partial_i W(\phi), \qquad Q_B^2 = 0 \tag{94.3}$$

on polynomial local coordinates. Then the image of Q_B inside the polynomial subalgebra A is exactly I_W. Hence the polynomial Q_B-cohomology in degree zero is canonically

$$H^0_{Q_B}\big(A \otimes \Lambda(\eta_1, \dots, \eta_n)\big) \cong \mathrm{Jac}(W).$$

Every polynomial $f(\phi) \in A$ is Q_B-closed because $Q_B \phi^i = 0$ and Q_B is a derivation. Conversely, the Q_B-exact polynomials are generated by applying Q_B to degree-one expressions

$$\sum_i h^i(\phi)\eta_i, \qquad h^i \in A.$$

Using (94.3),

$$Q_B\left(\sum_i h^i(\phi)\eta_i\right) = \sum_i h^i(\phi)\partial_i W(\phi),$$

because $Q_B h^i(\phi) = 0$. Thus $\operatorname{im} Q_B \cap A = I_W$, and quotienting the closed polynomial operators by exact polynomial operators gives (94.2).

Quasihomogeneous charge and central-charge test. Let W be a quasihomogeneous isolated polynomial in the sense of Definition 94.2. Assign the monomial

$$\phi^a = (\phi^1)^{a_1} \cdots (\phi^n)^{a_n}$$

the charge

$$Q_R(\phi^a) = \sum_{i=1}^{n} a_i q_i. \tag{94.4}$$

Then every monomial appearing in W has charge 1, while every monomial appearing in $\partial_i W$ has charge $1 - q_i$. If, in addition,

$$W = \sum_{i=1}^{n} (\phi^i)^{d_i}, \qquad d_i \geq 2, \tag{94.5}$$

then $q_i = 1/d_i$, the Jacobi algebra has basis

$$\prod_{i=1}^{n} (\phi^i)^{a_i}, \qquad 0 \leq a_i \leq d_i - 2, \tag{94.6}$$

and dimension

$$\dim_{\mathbb{C}} \mathrm{Jac}(W) = \prod_{i=1}^{n} (d_i - 1). \tag{94.7}$$

The protected $U(1)_R$-anomaly prediction for a compact unitary infrared $\mathcal{N} = 2$ superconformal fixed point is

$$c_{\mathrm{LG}} = 3 \sum_{i=1}^{n} (1 - 2q_i). \tag{94.8}$$

In this chapter (94.8) is used as a necessary protected-data test for any proposed compact unitary infrared fixed point with these chiral fields and this $U(1)_R$ current.

Equation (94.1) says precisely that every monomial in W has total charge 1. Differentiating a monomial with respect to ϕ^i lowers its charge by q_i, hence the terms in $\partial_i W$ have charge $1 - q_i$.

For the Fermat polynomial (94.5), quasihomogeneity gives $d_i q_i = 1$, so $q_i = 1/d_i$. The Jacobi ideal is

$$((\phi^1)^{d_1 - 1}, \ldots, (\phi^n)^{d_n - 1}),$$

up to multiplication by the nonzero constants d_i. Reduction modulo this monomial ideal removes every factor with exponent $a_i \geq d_i - 1$, and the remaining monomials (94.6) are linearly independent in the quotient. Counting the allowed exponents gives (94.7).

The final formula is the protected anomaly calculation used by the $\mathcal{N} = 2$ superconformal-algebra interface in Chapter 70. The present paragraph records its algebraic inputs and status: once a continuum infrared fixed point with these chiral fields and $U(1)_R$ current has been constructed, the anomaly supplies (94.8).

This is therefore an algebraic and anomaly-matching datum. The existence of the infrared fixed point and the convergence of a Landau–Ginzburg regulator to it are separate construction and RG questions.

Wilsonian superpotential coordinate for Fermat LG models. The polynomial W is treated here as part of the Wilsonian F-term coordinate of a declared regulated theory. The following finite argument is the two-dimensional version of the holomorphic-coordinate logic of Chapter 89.

Fix

$$W_{\mathrm{UV}}(\Phi; g) = \sum_{i=1}^{n} g_i (\Phi^i)^{d_i}, \qquad d_i \geq 2,$$

and assume a Wilsonian scheme at scale Λ with the following properties:

1. the chiral superspace coordinate is preserved, so corrections to the superpotential are holomorphic functions of the chiral fields and of the background chiral couplings g_i;
2. the patch is regular at $g_i = 0$, so the perturbative Wilsonian expansion contains nonnegative powers of the g_i;
3. the scheme preserves the n flavor spurion symmetries

   $$\Phi^i \mapsto \lambda_i \Phi^i, \qquad g_i \mapsto \lambda_i^{-d_i} g_i, \qquad \lambda_i \in \mathbb{C}^\times,$$

   together with the quasihomogeneous R-charge convention

   $$R(\Phi^i) = \frac{1}{d_i}, \qquad R(g_i) = 0, \qquad R(W) = 1.$$

Then every regular monomial allowed in the Wilsonian superpotential is one of the original monomials $g_i(\Phi^i)^{d_i}$, up to its coefficient. Indeed, write a candidate monomial as

$$\prod_{i=1}^{n} g_i^{m_i} (\Phi^i)^{a_i}, \qquad m_i, a_i \in \mathbb{Z}_{\geq 0}.$$

The i-th spurion symmetry requires

$$a_i - d_i m_i = 0 \qquad \text{for every } i, \tag{94.9}$$

and the chiral R-charge condition requires

$$\sum_{i=1}^{n} \frac{a_i}{d_i} = 1. \tag{94.10}$$

Substituting (94.9) into (94.10) gives

$$\sum_{i=1}^{n} m_i = 1.$$

Since the m_i are nonnegative integers, exactly one m_j is 1 and all other m_i vanish. Then $a_j = d_j$ and $a_i = 0$ for $i \neq j$. Thus the holomorphic selection rule alone permits only

$$g_j (\Phi^j)^{d_j}, \qquad j = 1, \ldots, n.$$

The scope of the argument is the Wilsonian coordinate at the declared scale: after a regulator with the stated chiral and spurion Ward identities has been supplied, perturbative local corrections preserve the Fermat superpotential coordinate up to finite redefinition of the displayed couplings. Existence of the continuum infrared fixed point, convergence of the RG flow, and control of any allowed nonperturbative sectors are separate analytic inputs. The Kähler potential and other D-term coordinates may still flow.

The same protected-data interface controls the finite χ_y shadow of the elliptic genus in Section 70.5. If the infrared fixed point exists and the Jacobi algebra classes become NS chiral primaries, then spectral flow by $\eta = -1/2$ sends a monomial of charge Q_R to a left Ramond ground-state contribution of charge

$$Q_R - \frac{c_{\mathrm{LG}}}{6}. \tag{94.11}$$

Thus the finite polynomial $\sum_{[O]\in \mathrm{Jac}(W)} y^{Q_R(O)-c_{\mathrm{LG}}/6}$ is a necessary protected check on the proposed SCFT. The full elliptic genus requires the compact Ramond trace and modular sewing hypotheses stated in the CFT volume.

Example 94.3 (*A*-series and quintic polynomial checks)**.** For $W = X^{k+2}$, $k \geq 0$, one has $q = 1/(k+2)$,

$$\mathrm{Jac}(W) = \mathbb{C}[X]/(X^{k+1}), \qquad c_{\mathrm{LG}} = 3\left(1 - \frac{2}{k+2}\right) = \frac{3k}{k+2}.$$

For

$$W = X_1^5 + \cdots + X_5^5$$

the weights are $q_i = 1/5$, the algebraic Jacobi dimension is

$$4^5 = 1024,$$

and the protected central-charge test gives

$$c_{\mathrm{LG}} = 3 \cdot 5\left(1 - \frac{2}{5}\right) = 9.$$

This is an intrinsic Landau–Ginzburg charge and Jacobi-algebra calculation.

94.3 Sigma-Model Datum

A $2D$ $\mathcal{N} = (2,2)$ nonlinear sigma model is specified by a Kähler target X, metric $g_{i\bar{j}}$, B-field B, and possibly a superpotential W. The bosonic Euclidean action is

$$S_{\mathrm{bos}} = \frac{1}{4\pi\alpha'}\int_\Sigma \mathrm{d}^2x\, g_{i\bar{j}}(\phi)\partial_\mu\phi^i\partial_\mu\bar{\phi}^{\bar{j}} + \frac{\mathrm{i}}{2\pi\alpha'}\int_\Sigma \phi^*B.$$

The large-volume perturbative beta tensor begins with the Ricci form:

$$\mu\frac{\mathrm{d}g_{i\bar{j}}}{\mathrm{d}\mu} = \frac{1}{2\pi}R_{i\bar{j}} + \cdots .$$

Thus Ricci-flatness is the first condition for a conformal infrared candidate in a large-volume chart. The full QFT claim includes instanton corrections, operator renormalization, and a continuum limit; these are additional data, separate from the local tensor equation.

94.4 A And B Twisting Data

The two cohomological twists of a $2D$ $\mathcal{N} = (2,2)$ theory are intrinsic operations on the two-dimensional QFT. They require nonanomalous R-symmetries and a regulator preserving the selected scalar supercharge. The definition uses the two-dimensional rotation symmetry, the selected R-current, and the supersymmetry algebra.

Definition 94.4 (Two-dimensional twist convention)**.** Let s denote the Lorentz spin for $U(1)_{\mathrm{rot}}$. In this chapter the supercharges have charges

$$\begin{array}{c|cccc} & Q_+ & \bar{Q}_+ & Q_- & \bar{Q}_- \\ \hline s & \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} \\ F_V & 1 & -1 & 1 & -1 \\ F_A & 1 & -1 & -1 & 1. \end{array} \tag{94.12}$$

The A twist uses

$$s_A = s + \frac{1}{2}F_V, \tag{94.13}$$

and the B twist uses

$$s_B = s + \frac{1}{2}F_A. \tag{94.14}$$

Remark 94.5 (Twist bookkeeping: scalar supercharges)*.* Assume the charge convention of Definition 94.4 and assume that there are no central charges in the local-sector supersymmetry algebra. Then:

$$Q_A = \bar{Q}_+ + Q_- \tag{94.15}$$

is scalar for the A-twisted rotation action and satisfies $Q_A^2 = 0$ on gauge-invariant local observables, while

$$Q_B = \bar{Q}_+ + \bar{Q}_- \tag{94.16}$$

is scalar for the B-twisted rotation action and satisfies $Q_B^2 = 0$ on gauge-invariant local observables.

Using (94.13), the A-twisted spins are

$$\begin{array}{c|cccc} & Q_+ & \bar{Q}_+ & Q_- & \bar{Q}_- \\ \hline s_A & 1 & 0 & 0 & -1. \end{array}$$

Thus $\bar{Q}_+$ and Q_- are scalars, while the other two supercharges are not. Using (94.14), the B-twisted spins are

$$\begin{array}{c|cccc} & Q_+ & \bar{Q}_+ & Q_- & \bar{Q}_- \\ \hline s_B & 1 & 0 & -1 & 0. \end{array}$$

Thus $\bar{Q}_+$ and $\bar{Q}_-$ are scalars for the B twist. The untwisted local algebra has only

$$\{Q_+, \bar{Q}_+\} = 2P_+, \qquad \{Q_-, \bar{Q}_-\} = 2P_-$$

among these generators. Therefore

$$Q_A^2 = \frac{1}{2}\{\bar{Q}_+ + Q_-, \bar{Q}_+ + Q_-\} = 0, \qquad Q_B^2 = \frac{1}{2}\{\bar{Q}_+ + \bar{Q}_-, \bar{Q}_+ + \bar{Q}_-\} = 0$$

in the central-charge-free local sector. If gauge transformations appear in an off-shell realization, the same statement is made after passing to gauge-invariant observables.

94.5 Gauged Linear Sigma-Model Presentations

Definition 94.6 (Abelian $2D$ $\mathcal{N} = (2,2)$ GLSM presentation)**.** An abelian GLSM presentation in this chapter is specified by:

1. gauge group $G = U(1)$;
2. chiral multiplets Φ_i, $i = 1, \dots, m$, with integer charges $Q_i \in \mathbb{Z}$;
3. a $U(1)$-invariant holomorphic superpotential $W \in \mathbb{C}[\Phi_1, \dots, \Phi_m]^{U(1)}$;
4. a complexified FI-theta coordinate
$$t = \frac{\theta}{2\pi} + \mathrm{i}r, \qquad r \in \mathbb{R}, \quad \theta \in \mathbb{R}/2\pi\mathbb{Z};$$
5. a gauge coupling $e > 0$ and a specified ultraviolet regulator for the gauge theory.

The classical scalar potential contains

$$\frac{e^2}{2}\left(\sum_{i=1}^{m} Q_i|\phi_i|^2 - r\right)^2 + \sum_i |\partial_i W|^2 + |\sigma|^2 \sum_i Q_i^2 |\phi_i|^2, \tag{94.17}$$

where σ is the complex scalar in the vector multiplet. Classical Higgs vacua with at least one charged scalar nonzero therefore solve the F-term equations, the D-term equation, and then are quotiented by $U(1)$.

The axial R-symmetry anomaly coefficient of this abelian presentation is

$$\mathcal{A}_A = \sum_{i=1}^{m} Q_i. \tag{94.18}$$

This coefficient is a finite charge sum: each charged chiral multiplet contributes its charge to the axial rotation of the fermion measure. When $\mathcal{A}_A = 0$, the one-loop axial shift of the FI coordinate vanishes. This is a necessary condition for an axial R-symmetry in an infrared superconformal candidate. A conformality claim additionally requires a construction of the infrared continuum theory and its stress tensor.

The vector and axial R-symmetries have different anomaly requirements. The A twist is available only when F_V is a genuine symmetry of the regulated theory. The B twist is available only when F_A is a genuine symmetry. In the abelian GLSM presentation of Definition 94.6, the axial anomaly obstruction is the charge sum (94.18). Therefore the hypersurface GLSM with charges $(1, \dots, 1, -d)$ has an axial B-twist candidate precisely when $N = d$.

94.6 B-Twisted Landau–Ginzburg Sector

The B-twisted Landau–Ginzburg model uses the scalar supercharge (94.16). The Jacobian-quotient calculation above gives the first protected observable: polynomial local operators map to $\mathrm{Jac}(W)$. The next finite-dimensional check is the residue pairing at nondegenerate critical points.

Morse residue pairing on the LG Jacobi algebra. Let $W \in \mathbb{C}[\phi^1, \ldots, \phi^n]$ have a finite critical set

$$\mathrm{Crit}(W) = \{p \in \mathbb{C}^n : \partial_i W(p) = 0 \text{ for all } i\}.$$

Assume every critical point is nondegenerate:

$$H_W(p) = \det(\partial_i \partial_j W)(p) \neq 0.$$

Define

$$\mathrm{Res}_W(f) = \sum_{p \in \mathrm{Crit}(W)} \frac{f(p)}{H_W(p)}, \qquad f \in \mathbb{C}[\phi^1, \ldots, \phi^n]. \tag{94.19}$$

Then Res_W kills the ideal $(\partial_1 W, \ldots, \partial_n W)$, so it descends to $\mathrm{Jac}(W)$. The bilinear form

$$\langle [f], [g] \rangle_{\mathrm{res}} = \mathrm{Res}_W(fg) \tag{94.20}$$

on $\mathrm{Jac}(W)$ is nondegenerate.

If $f = \sum_i h_i \partial_i W$, then $f(p) = 0$ at every critical point p, so $\mathrm{Res}_W(f) = 0$. Hence the functional descends to the quotient. Nondegeneracy of the Hessian means that each zero of the gradient map

$$\nabla W : \mathbb{C}^n \longrightarrow \mathbb{C}^n, \qquad \phi \longmapsto (\partial_1 W, \ldots, \partial_n W)$$

is simple. The local algebra of ∇W at such a zero is therefore $\mathbb{C}$. Since the critical set is finite, the Chinese-remainder decomposition gives

$$\mathrm{Jac}(W) \cong \prod_{p \in \mathrm{Crit}(W)} \mathbb{C},$$

where a class $[f]$ is sent to its values $f(p)$. In these coordinates (94.20) is the diagonal pairing with nonzero diagonal entries $H_W(p)^{-1}$, hence is nondegenerate.

For a compact Riemann surface of genus g, the B-twisted Landau–Ginzburg zero-mode formula used in this chapter is

$$\langle f_1 \cdots f_m \rangle_g = \sum_{p \in \mathrm{Crit}(W)} \frac{f_1(p) \cdots f_m(p)}{H_W(p)^{1-g}}. \tag{94.21}$$

In this monograph (94.21) has the following status: it is the finite-dimensional zero-mode and determinant calculation after the Q_B-preserving regulator, determinant-line orientation, and absence of boundary terms have been supplied. The continuum QFT assertion is conditional on those analytic inputs.

94.7 A-Twisted Sigma-Model Zero Modes

Let X be a smooth Kähler target with real tangent bundle TX. The A-twisted sigma model uses the scalar supercharge (94.15). The full model includes nonconstant maps $\Sigma \to X$, instanton sectors, compactification of moduli spaces, and operator contact terms. The constant-map sector, however, is a finite-dimensional calculation.

In the constant-map truncation of an A-twisted sigma model with target X, let x^a be local real coordinates on X and let χ^a be odd variables transforming as dx^a. Suppose the scalar differential acts by

$$Q_A x^a = \chi^a, \qquad Q_A \chi^a = 0. \tag{94.22}$$

Then the algebra of polynomial functions in the odd variables identifies with differential forms on X, and Q_A identifies with the de Rham differential d_X. Thus the constant-map local Q_A-cohomology is

$$H^\bullet_{Q_A} \cong H^\bullet_{\mathrm{dR}}(X;\mathbb{C}).$$

Functions of x^a and the odd variables χ^a are local functions on the parity-shifted tangent bundle ΠTX. The coordinate identification

$$\chi^{a_1}\cdots\chi^{a_k} \longleftrightarrow dx^{a_1}\wedge\cdots\wedge dx^{a_k}$$

identifies these functions with differential forms. Under this identification the derivation determined by (94.22) is

$$Q_A = \chi^a \frac{\partial}{\partial x^a},$$

which is precisely the de Rham differential in local coordinates. Its cohomology is therefore de Rham cohomology after gluing the coordinate charts.

The nonconstant A-model sectors are classified, at the classical level, by homology classes $\beta = \phi_*[\Sigma] \in H_2(X,\mathbb{Z})$. For a Kähler metric with form ω, the bosonic energy admits the pointwise Bogomolny decomposition

$$E(\phi) = \int_\Sigma |\bar\partial_J \phi|^2 \,\mathrm{vol}_\Sigma + \int_\Sigma \phi^*\omega \tag{94.23}$$

in the normalization of the sigma-model action. Thus holomorphic maps $\bar\partial_J\phi = 0$ minimize the energy in a fixed homology class. A mathematical A-model correlation function requires compactifying the holomorphic-map moduli space, orienting its virtual determinant line, and controlling collisions of marked points. These are theorem-level inputs, additional to the twist construction.

94.8 Abelian Duality And Circle T-Duality

Abelian duality is used here only as a statement about two-dimensional QFT. The local calculation is a first-order path integral for a compact scalar and, in the $\mathcal{N} = (2,2)$ extension, the corresponding Legendre transform between chiral and twisted-chiral field variables. The global QFT statement requires the compact path-integral measure, spin structures, contact terms, and topological sectors to be specified.

Hypothesis 94.7 (Compact scalar first-order duality setup)**.** Let Σ be a closed oriented Euclidean surface. A compact scalar $\vartheta : \Sigma \to \mathbb{R}/2\pi\mathbb{Z}$ of radius $R > 0$ has action

$$S_R(\vartheta) = \frac{R^2}{4\pi}\int_\Sigma d\vartheta \wedge * d\vartheta. \tag{94.24}$$

The functional integral sums over all winding sectors $[d\vartheta/2\pi] \in H^1(\Sigma;\mathbb{Z})$. The first-order presentation uses a real one-form A with the same integral-period normalization and a dual periodic scalar $\widetilde{\vartheta} \sim \widetilde{\vartheta} + 2\pi$:

$$S_{\text{fo}}(A, \widetilde{\vartheta}) = \frac{R^2}{4\pi} \int_\Sigma A \wedge *A + \frac{\mathrm{i}}{2\pi} \int_\Sigma \widetilde{\vartheta}\, dA. \tag{94.25}$$

The measure is assumed to be chosen so that integrating over $\widetilde{\vartheta}$ imposes flatness with integral periods and integrating over A is the corresponding Gaussian integral along the standard Euclidean contour. Field-independent determinant constants are absorbed in the normalization of the partition function.

Compact scalar radius inversion. Under Hypothesis 94.7, the local first-order duality maps the radius R compact scalar to a compact scalar of radius $R^\vee = R^{-1}$:

$$S_{R^\vee}(\widetilde{\vartheta}) = \frac{1}{4\pi R^2} \int_\Sigma d\widetilde{\vartheta} \wedge *d\widetilde{\vartheta}. \tag{94.26}$$

Applying the same local operation twice returns the original radius.

Integrating over $\widetilde{\vartheta}$ in (94.25) imposes $dA = 0$ together with the integral-period condition. Locally $A = d\vartheta$, and globally the integral periods reconstruct the winding sectors of (94.24).

For the other elimination, integrate the second term by parts:

$$\frac{\mathrm{i}}{2\pi} \int_\Sigma \widetilde{\vartheta}\, dA = -\frac{\mathrm{i}}{2\pi} \int_\Sigma d\widetilde{\vartheta} \wedge A.$$

The Gaussian equation for A is

$$R^2 * A = \mathrm{i}\, d\widetilde{\vartheta}, \qquad A = \frac{\mathrm{i}}{R^2} * d\widetilde{\vartheta}, \tag{94.27}$$

with the usual Euclidean contour understood. Substituting the saddle and absorbing the field-independent determinant gives (94.26). Therefore the dual radius is R^{-1}, and the second duality sends R^{-1} back to R.

The Hamiltonian spectrum supplies a regulator-independent arithmetic check of the same radius inversion. On a spatial circle, write the momentum and winding labels as

$$(n, w) \in \mathbb{Z}^2.$$

In the convention of (94.24), the left and right momenta are

$$p_L(n, w; R) = \frac{n}{R} + wR, \qquad p_R(n, w; R) = \frac{n}{R} - wR. \tag{94.28}$$

The duality map

$$R \longmapsto R^{-1}, \qquad (n, w) \longmapsto (w, n) \tag{94.29}$$

preserves $p_L^2 + p_R^2$ and flips the sign of p_R:

$$p_L(w, n; R^{-1}) = p_L(n, w; R), \qquad p_R(w, n; R^{-1}) = -p_R(n, w; R). \tag{94.30}$$

Thus the finite oscillator spectrum and the zero-mode quadratic form are compatible with the first-order path integral. A proof of equality of all correlation functions must realize this exact arithmetic inside a specified compact path-integral measure and operator-insertion prescription.

Definition 94.8 (Local $\mathcal{N} = (2,2)$ abelian Legendre duality)**.** Let $\mathcal{B}$ be a real $\mathcal{N} = (2,2)$ superfield coordinate for a shift-isometry direction, and let Y be a twisted-chiral superfield whose imaginary part is periodic. Locally, suppressing normalization constants fixed by the component convention, a first-order superspace functional has the form

$$\int d^2x\, d^4\theta\, \big(\mathcal{B}\, u - K(\mathcal{B})\big), \qquad u = Y + \bar{Y}, \tag{94.31}$$

where $K''(\mathcal{B}) > 0$. Eliminating Y enforces the local constraint $\mathcal{B} = \Phi + \bar{\Phi}$ for a chiral field Φ. Eliminating $\mathcal{B}$ instead uses

$$u = K'(\mathcal{B}) \tag{94.32}$$

and gives the Legendre-dual Kähler potential

$$\widetilde{K}(u) = \mathcal{B}(u)u - K(\mathcal{B}(u)). \tag{94.33}$$

Remark 94.9 (Hessian inversion in local abelian duality)*.* Assume Definition 94.8. Then

$$\widetilde{K}''(u) = \frac{1}{K''(\mathcal{B}(u))}. \tag{94.34}$$

In particular, the free quadratic potential

$$K(\mathcal{B}) = \frac{R^2}{2}\mathcal{B}^2$$

is dual to

$$\widetilde{K}(u) = \frac{1}{2R^2}u^2,$$

the supersymmetric version of the radius inversion $R^2 \mapsto R^{-2}$.

Differentiate (94.33). Since $u = K'(\mathcal{B}(u))$,

$$\frac{d\widetilde{K}}{du} = \mathcal{B}(u) + u\mathcal{B}'(u) - K'(\mathcal{B}(u))\mathcal{B}'(u) = \mathcal{B}(u).$$

Differentiating (94.32) gives

$$1 = K''(\mathcal{B}(u))\mathcal{B}'(u),$$

and hence $\widetilde{K}''(u) = \mathcal{B}'(u) = 1/K''(\mathcal{B}(u))$. For $K(\mathcal{B}) = R^2\mathcal{B}^2/2$, equation (94.32) gives $\mathcal{B} = u/R^2$, and (94.33) gives $\widetilde{K}(u) = u^2/(2R^2)$.

For a charged chiral field in an abelian GLSM, the same local dualization couples the dual twisted-chiral variable linearly to the abelian field strength Σ, with coefficient equal to the integer gauge charge. The perturbative local calculation is therefore compatible with the GLSM charge matrix. Nonperturbative exponential terms in the dual twisted superpotential, when present, require a separate vortex-instanton calculation: compactness of the vortex moduli space, fermion zero-mode saturation, determinant-line orientation, and boundary control must be supplied before such terms are promoted from semiclassical input to a QFT statement.

94.9 Charged-Chiral Dual Variables and Abelian Mirror Presentations

The preceding Legendre transform is the local part of the abelian GLSM mirror construction. The full statement contains one additional ingredient: a holomorphic exponential term in the twisted superpotential. The Gaussian Legendre transform supplies the dual variables and their linear couplings to field strengths. The exponential term is a nonperturbative datum, attributed in the semiclassical presentation to finite-action vortex sectors, and any regulator-level equality of QFTs must derive it from a compactness, zero-mode, determinant-line, and boundary analysis of those sectors. The algebraic consequences of this datum are completely explicit and will be used below.

Consider an abelian GLSM with gauge group $U(1)^s$, twisted chiral field strengths Σ_a, complexified FI-theta coordinates t_a, and chiral multiplets Φ_i, $i = 1, \ldots, m$, of integer charges

$$Q_i{}^a \in \mathbb{Z}, \qquad a = 1, \ldots, s.$$

For each charged chiral multiplet introduce a periodic twisted chiral variable

$$Y_i \sim Y_i + 2\pi\mathrm{i}.$$

Repeated abelian gauge indices are summed in this section.

The local first-order functional for one charged chiral variable is the superspace analogue of the compact scalar construction. Let B_i be a real superfield and set

$$U_i = Y_i + \overline{Y}_i. \tag{94.35}$$

The D-term

$$\int d^2x\, d^4\theta \left[e^{B_i + 2Q_i{}^a V_a} - \frac{1}{2} U_i B_i\right] \tag{94.36}$$

is invariant under

$$V_a \mapsto V_a + \mathrm{i}(\Lambda_a - \overline{\Lambda}_a), \qquad B_i \mapsto B_i - 2\mathrm{i}Q_i{}^a(\Lambda_a - \overline{\Lambda}_a), \qquad Y_i \mapsto Y_i.$$

Integrating over Y_i imposes the twisted linear constraint on B_i. In components of superspace this is the pair of constraints

$$\overline{D}_+ D_- B_i = 0, \qquad D_+ \overline{D}_- B_i = 0.$$

Locally this says

$$B_i = \Psi_i + \overline{\Psi}_i$$

with Ψ_i a chiral superfield. Then

$$e^{B_i + 2Q_i{}^a V_a} = \overline{\Phi}_i \exp(2Q_i{}^a V_a) \Phi_i, \qquad \Phi_i = e^{\Psi_i},$$

which recovers the original charged chiral kinetic term in that field chart.

Eliminating B_i instead gives the algebraic equation

$$e^{B_i + 2Q_i{}^a V_a} = \frac{1}{2} U_i, \qquad B_i = \log \frac{U_i}{2} - 2Q_i{}^a V_a. \tag{94.37}$$

Substitution gives a dual D-term of Legendre form, together with the linear V_aU_i term

$$Q_i{}^a \int d^2x\, d^4\theta\, V_a(Y_i + \overline{Y}_i).$$

The superspace integration-by-parts identity in the present convention is

$$\int d^4\theta\, V_a(Y_i + \overline{Y}_i) = -\int d^2\widetilde{\theta}\, \Sigma_a Y_i + \text{c.c.}, \tag{94.38}$$

where Y_i is twisted chiral and $\Sigma_a = \overline{D}_+ D_- V_a$. Thus the local dualization produces the twisted F-term

$$-\int d^2\widetilde{\theta}\, Q_i{}^a \Sigma_a Y_i + \text{c.c.}$$

before any vortex effect is invoked. This derivation fixes the charge matrix in the dual variables: the integer $Q_i{}^a$ that couples Φ_i to V_a is the same integer multiplying $\Sigma_a Y_i$.

The convention in the rest of this section is chosen so that eliminating the Y_i matches the one-loop Coulomb superpotential (94.63). Put

$$M_i(\Sigma) = \sum_{a=1}^{s} Q_i{}^a \Sigma_a. \tag{94.39}$$

The dual twisted-superpotential ansatz is

$$\widetilde{W}_{\text{dual}}(\Sigma, Y) = -\sum_{a=1}^{s} t_a \Sigma_a - \sum_{i=1}^{m} M_i(\Sigma) Y_i - \mu \sum_{i=1}^{m} c_i e^{-Y_i}, \qquad c_i \in \mathbb{C}^\times. \tag{94.40}$$

The constants c_i depend on the normalization of the dual variables and on the vortex determinant convention; rescaling e^{-Y_i} shifts the corresponding logarithmic branch and changes t_a by a finite affine scheme transformation. The intrinsic data are the charge matrix, the periodicity of the Y_i, and the fact that the exponential monomial is nonzero with the charge dictated by the dualized chiral field.

The local dualization has not derived the exponential term. It has derived the periodic variable Y_i, the linear coupling $-M_i Y_i$, and the charge normalization. The remaining input is a protected connected amplitude on the asymptotic end of the dual cylinder. Because Y_i is periodic with imaginary period $2\pi\mathrm{i}$, holomorphic local functions on that end are Laurent series in

$$X_i = e^{-Y_i}.$$

The large positive $\operatorname{Re} Y_i$ region is the weak-coupling end of the dualized chiral variable, so regularity there permits nonnegative powers of X_i. Suppose, for one dual field and on a simply connected branch where $M_i \neq 0$, that the connected protected correction is an ordinary holomorphic germ $h_i(X_i)$ with $h_i(0) = 0$, so that the relevant part of the twisted superpotential is

$$-M_i Y_i - h_i(X_i) = M_i \log X_i - h_i(X_i), \qquad X_i = e^{-Y_i}. \tag{94.41}$$

The critical equation is

$$M_i = X_i h_i'(X_i). \tag{94.42}$$

At a critical point the derivative of the eliminated superpotential is

$$\frac{\partial \widetilde{W}_{\mathrm{elim}}}{\partial M_i} = \log X_i(M_i). \tag{94.43}$$

Indeed, the coefficient of $\partial X_i/\partial M_i$ is $M_i/X_i - h_i'(X_i)$, which vanishes by (94.42). Exact agreement with the Coulomb one-loop logarithm

$$\frac{\partial}{\partial M_i}\left[M_i\left(\log\frac{M_i}{\mu c_i} - 1\right)\right] = \log\frac{M_i}{\mu c_i}$$

therefore forces $X_i(M_i) = M_i/(\mu c_i)$ on the branch. Substituting into (94.42) gives $h_i'(X_i) = \mu c_i$, hence

$$h_i(X_i) = \mu c_i X_i$$

up to an irrelevant additive constant. Thus the primitive monomial $-\mu c_i e^{-Y_i}$ is singled out by the combination of periodicity, regularity at the weak-coupling end, and exact Coulomb-branch matching. This argument is not a construction of the amplitude. It reduces the nonperturbative theorem boundary to the following sharp questions: construct the single-vortex sector in the chosen regulator, prove that its fermion zero modes leave precisely the twisted F-term measure, prove $c_i \neq 0$, and justify that possible higher connected harmonics do not contribute in the protected coordinate being matched.

Proposition 94.10 (Vortex zero-mode filter for twisted F-terms)**.** *In the finite-regulator charge-one sector used below, let $\mathcal{D}_{F,i,\Lambda}(z)$ be the fermion Hessian at a vortex configuration z. Assume its kernel has been split as*

$$\ker \mathcal{D}_{F,i,\Lambda}(z) = \Pi_{\mathrm{univ}}(z) \oplus K^{\mathrm{res}}_{i,\Lambda}(z), \qquad \dim \Pi_{\mathrm{univ}} = 2,$$

where Π_{univ} is the universal pair identified with the $d^2\widetilde{\theta}$ measure. Let

$$\nu^{\mathrm{res}}_{i,\Lambda}(z) = \dim K^{\mathrm{res}}_{i,\Lambda}(z).$$

After the universal pair has been removed, the residual fermion-zero-mode coefficient has the Berezin form

$$\mathcal{Z}^0_{i,F,\Lambda}(z;P) = \int \prod_{\alpha=1}^{\nu^{\mathrm{res}}_{i,\Lambda}(z)} \mathrm{d}\eta_\alpha\, P_{\mathrm{ins}}(z,\eta), \tag{94.44}$$

where P_{ins} denotes insertions or regulator-allowed zero-mode liftings. Hence the charge-one sector can contribute to the uninserted twisted superpotential only on the locus

$$\nu^{\mathrm{res}}_{i,\Lambda}(z) = 0.$$

If $\nu^{\mathrm{res}}_{i,\Lambda}(z) > 0$ and no insertion or lifting supplies the missing residual Grassmann degree, then $\mathcal{Z}^0_{i,F,\Lambda}(z;1) = 0$. The nonzero-mode determinant entering the coefficient is therefore the determinant on the complement of the full kernel of $\mathcal{D}_{F,i,\Lambda}(z)$, not the raw determinant before zero-mode removal.

Proof. The two universal zero modes are coordinates on the superspace measure of the twisted F-term, so they are not integrated into the scalar coefficient. All remaining fermion zero modes are ordinary Grassmann variables in the finite stationary-phase integral. Berezin integration extracts the coefficient of the top exterior monomial $\eta_1 \cdots \eta_{\nu^{\mathrm{res}}_{i,\Lambda}(z)}$. If the insertion polynomial has smaller residual Grassmann degree, that coefficient is absent and the integral vanishes. With no insertion or lifting, the polynomial is constant, so the only nonzero case is $\nu^{\mathrm{res}}_{i,\Lambda}(z) = 0$. Removing the full kernel before forming the determinant is the same collective-coordinate separation on the fermionic side as the bosonic zero-mode quotient in the vortex measure. $\square$

This is the amplitude gate hidden behind the compact mirror formula. The integer vortex number fixes the exponential e^{-Y_i}, and Coulomb matching fixes the primitive harmonic once a nonzero coefficient is present. Neither step proves that the regulated vortex sector has exactly the two universal fermion zero modes or that its determinant line has been oriented consistently.

Proposition 94.11 (Single-vortex coefficient as a protected amplitude)**.** *Fix one charged chiral multiplet Φ_i in the abelian GLSM and choose a supersymmetric finite regulator preserving the integer vortex number and the twisted chiral field strength. Let $\mathcal{U}_{i,1,\Lambda}$ be a smooth finite-dimensional chart for the charge-one vortex sector attached to Φ_i, after quotienting by gauge transformations and after choosing collective-coordinate coordinates z. Write $\mathrm{d}\nu_{i,1,\Lambda}(z)$ for the bosonic zero-mode density, $\mathcal{W}^{\mathrm{nz}}_{i,1,\Lambda}(z)$ for the nonzero-mode determinant ratio in that vortex background, and $\mathcal{Z}^0_{i,F,\Lambda}(z)$ for the Berezin coefficient left after the two universal fermion zero modes have been identified with $\mathrm{d}^2\widetilde{\theta}$, as filtered by Proposition 94.10. Then the charge-one sector contributes to the Wilsonian twisted F-term in the form*

$$\Delta \widetilde{W}^{(1)}_{i,\Lambda}(Y_i) = -\mu\, c_{i,\Lambda}\, e^{-Y_i}, \tag{94.45}$$

where

$$c_{i,\Lambda} = \mu^{-1} \int_{\mathcal{U}_{i,1,\Lambda}} e^{-S^{\mathrm{red}}_{i,1,\Lambda}(z)}\, \mathcal{W}^{\mathrm{nz}}_{i,1,\Lambda}(z)\, \mathcal{Z}^0_{i,F,\Lambda}(z)\, \mathrm{d}\nu_{i,1,\Lambda}(z). \tag{94.46}$$

Here $S^{\mathrm{red}}_{i,1,\Lambda}$ is the regulator action with the universal topological coupling to the dual variable Y_i factored out. If additional fermion zero modes remain unsaturated, then $\mathcal{Z}^0_{i,F,\Lambda} = 0$ and this vortex sector supplies no twisted-superpotential term. If the continuum limit of (94.46) *exists and is nonzero, then its limit is the coefficient c_i in* (94.40)*.*

Proof. At fixed regulator the semiclassical expansion around the charge-one vortex is a finite stationary-phase calculation. The dual periodic variable couples to vortex number, so the charge-one topological factor is e^{-Y_i}; the period $Y_i \sim Y_i + 2\pi\mathrm{i}$ fixes this monomial unambiguously. The remaining finite integral splits into the bosonic collective-coordinate density, the nonzero-mode determinant ratio, and the finite Berezin integral over fermion zero modes. Two universal fermion zero modes are precisely the superspace measure of a twisted F-term; every extra zero mode must be saturated by an insertion or lifted by an allowed deformation. This gives (94.46) and hence (94.45). Multiplying e^{-Y_i} by a nonzero finite constant rescales c_i, which is the same finite normalization freedom recorded above as an affine shift of the FI-theta coordinate. $\square$

Formula (94.46) isolates the data hidden in the coefficient c_i. The integer vortex-number coupling fixes the monomial e^{-Y_i}; the determinant ratio, the orientation of the two universal fermion zero modes, the saturation of possible additional zero modes, and the boundary behavior of $\mathcal{U}_{i,1,\Lambda}$ decide the value and possible vanishing of the coefficient. Agreement with the Coulomb logarithm is then a protected consistency test: it fixes the primitive harmonic and exposes any finite FI-coordinate shift caused by determinant normalization.

The Y_i-critical equation is

$$\partial_{Y_i}\widetilde{W}_{\text{dual}} = 0 \quad \Longleftrightarrow \quad e^{-Y_i} = \frac{M_i(\Sigma)}{\mu c_i}. \tag{94.47}$$

On a branch where $M_i(\Sigma) \neq 0$, substituting (94.47) gives

$$\widetilde{W}_{\text{dual}}\big|_{\partial_Y \widetilde{W}=0} = -\sum_{a=1}^{s} t_a \Sigma_a + \sum_{i=1}^{m} M_i(\Sigma)\left(\log\frac{M_i(\Sigma)}{\mu c_i} - 1\right). \tag{94.48}$$

For $s = 1$, $M_i = Q_i\Sigma$, and $c_i = 1$, this is precisely the charge-resolved form of (94.63), with the constants c_i and logarithm branches absorbed into the finite definition of the FI coordinate. Thus the charged-chiral dual variables give a nontrivial consistency check: after the exponential terms have been supplied, their elimination reproduces the protected Coulomb-branch determinant.

The finite shift of the FI coordinate is explicit. In the rank-one case, (94.48) is

$$-t\Sigma + \sum_i Q_i\Sigma\left(\log\frac{Q_i\Sigma}{\mu} - 1\right) - \Sigma\sum_i Q_i \log c_i.$$

The last term is affine in Σ, hence is the same as replacing

$$t \longmapsto t + \sum_i Q_i \log c_i.$$

This is why the constants c_i are convention data for the protected Coulomb matching unless one separately fixes a normalization of the vortex measure.

Proposition 94.12 (Vortex normalization and all-rank FI coordinates)**.** *For an abelian gauge group $U(1)^s$, fix nonzero vortex coefficients c_i and choices of $\log c_i$. Set*

$$\widehat{X}_i = c_i e^{-Y_i}.$$

Then the mirror superpotential has normalized primitive terms

$$-\mu\sum_i \widehat{X}_i,$$

while the logarithmic-torus constraints are written in the shifted FI coordinates

$$\prod_{i=1}^{m} \widehat{X}_i^{{Q_i}^a} = \exp\left(t_a + \sum_{i=1}^{m} {Q_i}^a \log c_i\right), \qquad a = 1,\ldots,s. \tag{94.49}$$

Equivalently, in the Coulomb-eliminated expression the constants c_i replace

$$t_a \longmapsto t_a^{\text{phys}} = t_a + \sum_{i=1}^{m} {Q_i}^a \log c_i. \tag{94.50}$$

Proof. The constraint $\sum_i {Q_i}^a Y_i = -t_a$ is equivalent, on the logarithmic torus $X_i = e^{-Y_i}$, to

$$\prod_i X_i^{{Q_i}^a} = e^{t_a}.$$

Multiplying X_i by c_i gives

$$\prod_i \widehat{X}_i^{Q_i{}^a} = \left(\prod_i X_i^{Q_i{}^a}\right)\left(\prod_i c_i^{Q_i{}^a}\right),$$

which is (94.49). The same shift appears before imposing the low-energy constraint. Since

$$\sum_i M_i(\Sigma)\log c_i = \sum_i\sum_a Q_i{}^a\Sigma_a \log c_i = \sum_a \Sigma_a \sum_i Q_i{}^a \log c_i,$$

the c_i-dependent part of (94.48) is $-\sum_a \Sigma_a \sum_i Q_i{}^a \log c_i$, precisely the affine FI-theta shift in (94.50). □

Thus the Hori–Vafa expression is not a normalization-free statement of a bare path integral. Its invariant protected input is the charge lattice, the primitive nonzero vortex monomial for each allowed charge-one sector, and the FI-theta coordinate after the finite determinant normalization has been chosen. Changing the regulator normalization rescales the mirror torus coordinates and moves the same finite data into t_a^{phys}; it does not by itself prove the existence or nonvanishing of the vortex coefficient. Changing the branch by $\log c_i \mapsto \log c_i + 2\pi \mathrm{i} n_i$ changes t_a^{phys} by

$$2\pi\mathrm{i}\sum_i Q_i{}^a n_i, \qquad n_i \in \mathbb{Z},$$

which is an integral theta-period shift. The exponentiated constraints (94.49) are therefore the branch-independent protected statement.

There is a complementary low-energy use of the same expression. In a regime where the abelian vector multiplet has no independent low-energy propagating mode, Σ_a acts as a twisted chiral Lagrange multiplier. The Σ_a-critical equations of (94.40) are

$$\sum_{i=1}^m Q_i{}^a Y_i = -t_a, \qquad a = 1, \dots, s. \tag{94.51}$$

The dual presentation is then a Landau–Ginzburg model on the logarithmic torus with coordinates Y_i, subject to the linear constraints (94.51), and with twisted superpotential

$$-\mu \sum_i c_i e^{-Y_i}$$

restricted to that subspace. This is a presentation of protected twisted-chiral data. A full mirror equivalence requires a regulator, identification of the local and extended operator algebras, control of the singular loci and topological sectors, and convergence of the two continuum limits.

Example 94.13 ($\mathbb{P}^{N-1}$ dual critical points)**.** Take one $U(1)$ gauge factor and N chiral multiplets of charge 1. The constraint (94.51) is

$$Y_1 + \cdots + Y_N = -t.$$

Set $X_i = e^{-Y_i}$. Then

$$X_1 \cdots X_N = e^t.$$

For $c_i = 1$, the constrained twisted superpotential is proportional to

$$X_1 + \cdots + X_N$$

on the algebraic torus with fixed product e^t. Eliminating

$$X_N = \frac{e^t}{X_1 \cdots X_{N-1}}$$

gives the critical equations

$$X_a = \frac{e^t}{X_1 \cdots X_{N-1}}, \qquad a = 1, \ldots, N-1.$$

Thus all X_i are equal and

$$X_i^N = e^t.$$

For $e^t \neq 0$ there are N simple critical points, in agreement with the Coulomb-branch vacuum count in Example 94.17. The agreement is algebraic; it is the protected finite calculation that a full path-integral equivalence must reproduce after its regulator, local operators, and topological sectors have been specified.

Proposition 94.14 ($\mathbb{P}^{N-1}$ mirror residue and the quantum-product test)**.** *For the charge-one $\mathbb{P}^{N-1}$ GLSM, use the normalized mirror variables of Proposition 94.12 and write*

$$q_{\text{phys}} = \exp\left(t + \sum_{i=1}^{N} \log c_i\right) \neq 0. \tag{94.52}$$

On the logarithmic torus

$$\prod_{i=1}^{N} \widehat{X}_i = q_{\text{phys}}, \qquad \widetilde{W} = -\mu \sum_{i=1}^{N} \widehat{X}_i,$$

let H denote the protected hyperplane/Coulomb class represented in the mirror Jacobi quotient by $[\widehat{X}_1]$. With the determinant-line normalization that strips the universal factor $(-\mu)^{N-1}$ from the logarithmic Hessian, the mirror residue trace is

$$\mathcal{R}_{\mathbb{P}^{N-1}}(H^k) = \sum_{x^N = q_{\text{phys}}} \frac{x^k}{N x^{N-1}} = \begin{cases} q_{\text{phys}}^d, & k = N-1+dN, \quad d \geq 0, \\ 0, & k \not\equiv N-1 \pmod{N}. \end{cases} \tag{94.53}$$

Consequently the protected Frobenius algebra seen by this trace has

$$H^N = q_{\text{phys}}, \qquad \mathcal{R}_{\mathbb{P}^{N-1}}(H^{N-1}) = 1.$$

Proof. Use logarithmic coordinates

$$u_a = \log \widehat{X}_a, \qquad a = 1, \ldots, N-1,$$

and eliminate

$$\widehat{X}_N = q_{\text{phys}} \exp\left(-\sum_{a=1}^{N-1} u_a\right).$$

For the reduced function

$$S(u) = \sum_{a=1}^{N-1} e^{u_a} + q_{\mathrm{phys}} \exp\left(-\sum_{a=1}^{N-1} u_a\right),$$

the critical equations are

$$e^{u_a} = \widehat{X}_N, \qquad a = 1, \dots, N-1.$$

Thus every critical point has

$$\widehat{X}_1 = \cdots = \widehat{X}_N = x, \qquad x^N = q_{\mathrm{phys}}.$$

At such a point the logarithmic Hessian of S is

$$x(I_{N-1} + J_{N-1}),$$

where J_{N-1} is the all-ones matrix. Since $I_{N-1} + J_{N-1}$ has eigenvalues $1, \dots, 1, N$, its determinant is Nx^{N-1}. The factor from $\widetilde{W} = -\mu S$ is the universal $(-\mu)^{N-1}$ determinant-line factor already fixed in the trace normalization, leaving the denominator in (94.53).

It remains to evaluate the finite root sum. Put

$$\ell = k - (N-1).$$

Then

$$\sum_{x^N = q_{\mathrm{phys}}} \frac{x^k}{Nx^{N-1}} = \frac{1}{N} \sum_{x^N = q_{\mathrm{phys}}} x^\ell.$$

If ℓ is not divisible by N, the sum over the N-th roots vanishes. If $\ell = dN$ with $d \geq 0$, each critical point contributes $x^{dN} = q_{\mathrm{phys}}^d$, and the prefactor $1/N$ cancels the number of roots. The same critical-point equations identify H^N and q_{phys} in the Jacobi quotient; the nondegenerate residue pairing separates the quotient classes. □

The status of Proposition 94.14 is a protected observable test of the vortex-normalized mirror, not a standalone proof of mirror equivalence. Once a compactified A-twisted GLSM or sigma-model construction identifies H with the hyperplane class and q_{phys} with the degree-one vortex amplitude, the formula becomes the primary selection rule

$$\langle H^{N-1+dN} \rangle_0 = q_{\mathrm{phys}}^d, \qquad \langle H^k \rangle_0 = 0 \quad (k \not\equiv N-1 \pmod N).$$

The mirror residue supplies the finite Hessian and root-sum side of that statement. The physical identification still depends on the same determinant, orientation, zero-mode, compactification, and contact-term data isolated in (94.46).

Proposition 94.15 (From vortex coefficient to protected observable)**.** *In the charge-one $\mathbb{P}^{N-1}$ GLSM, fix a finite supersymmetric regulator and let $c_{i,\Lambda}$ be the regulated coefficients in* (94.46)*. Put*

$$q_\Lambda = \exp(t) \prod_{i=1}^{N} c_{i,\Lambda}.$$

For $k \geq 0$, define the finite mirror-residue prediction

$$S_k(q_\Lambda) = \begin{cases} q_\Lambda^d, & k = N-1+dN, \quad d \geq 0, \\ 0, & k \not\equiv N-1 \pmod N. \end{cases}$$

Let $A^A_{\Lambda,k}$ be the corresponding regulated A-twisted correlator after the local operator assigned to H^k has been chosen. Suppose the comparison is organized through the stage residuals

$$A^A_{\Lambda,k} - S_k(q_\Lambda) = R_{\mathrm{coeff}} + R_{\mathrm{det}} + R_{\mathrm{zm}} + R_{\mathrm{cpt}} + R_{\mathrm{gl}} + R_{\mathrm{op}} + R_{\mathrm{cont}}. \tag{94.54}$$

Here R_{coeff} measures the difference between the continuum charge-one vortex amplitude and the regulated coefficient (94.46), R_{det} the nonzero-mode determinant and determinant-line normalization error, R_{zm} the residual zero-mode saturation and source-insertion error, R_{cpt} the compactification, obstruction, boundary, and contact-term error, R_{gl} the multi-vortex or degree-d gluing error when $d > 1$, R_{op} the map from the GLSM operator to the hyperplane/Coulomb class, and R_{cont} the continuum limit remainder. If

$$|R_\alpha| \leq \epsilon_\alpha \quad (\alpha = \mathrm{coeff}, \mathrm{det}, \mathrm{zm}, \mathrm{cpt}, \mathrm{gl}, \mathrm{op}, \mathrm{cont}),$$

then

$$\left|A^A_{\Lambda,k} - S_k(q_\Lambda)\right| \leq \epsilon_{\mathrm{coeff}} + \epsilon_{\mathrm{det}} + \epsilon_{\mathrm{zm}} + \epsilon_{\mathrm{cpt}} + \epsilon_{\mathrm{gl}} + \epsilon_{\mathrm{op}} + \epsilon_{\mathrm{cont}}. \tag{94.55}$$

Consequently the quantum-product statement $H^N = q_{\mathrm{phys}}$ follows from the mirror residue only after $q_\Lambda \to q_{\mathrm{phys}} \neq 0$ and all seven residuals vanish in the protected comparison. If some $c_{i,\Lambda} = 0$ because the determinant line is unoriented, an extra fermion zero mode is unsaturated, or the compactified vortex integral vanishes, then $q_\Lambda = 0$; the nonzero degree-one quantum product cannot be recovered by holomorphy or charge matching alone.

Proof. The identity (94.54) is obtained by adding and subtracting the successive finite approximants: the regulated vortex coefficient, the determinant-normalized coefficient, the zero-mode-saturated coefficient, the compactified A-model amplitude, the glued degree-d sector, the local-operator identification, and the continuum protected correlator. The estimate (94.55) is the triangle inequality. Proposition 94.14 supplies the finite residue value $S_k(q_\Lambda)$, but it contains no information about whether the regulated vortex coefficient is nonzero or whether the comparison residuals vanish. That information is precisely the physical amplitude input isolated above. □

94.10 The Cigar–Liouville Mirror Chain as a QFT Duality Problem

The same dualization mechanism gives a useful intrinsic two-dimensional description of the relation between the $\mathcal{N} = 2$ cigar coset and $\mathcal{N} = 2$ Liouville theory. This subsection records the construction as a QFT comparison problem. The names "cigar" and "Liouville" refer to two-dimensional field theories and their semiclassical target descriptions.

Start with a $U(1)$ vector multiplet V, an ordinary chiral multiplet Φ of charge 1, and a logarithmic chiral multiplet

$$P \sim P + 2\pi \mathrm{i}$$

whose imaginary part shifts under the gauge symmetry so that

$$P+\overline{P}+V$$

is gauge invariant. With $k>0$, the bosonic low-derivative part of the GLSM contains

$$|(\partial_\mu-\mathrm{i}A_\mu)\phi|^2+\frac{k}{2}(\partial_\mu\operatorname{Re}p)^2+\frac{k}{2}(\partial_\mu\operatorname{Im}p-A_\mu)^2 \tag{94.56}$$

together with the auxiliary constraint

$$|\phi|^2+\frac{k}{2}(p+\overline{p})=0$$

in the low-energy quotient. Write

$$\rho=\sqrt{2}\,|\phi|,\qquad \vartheta=\arg\phi,\qquad p=u+\mathrm{i}\chi.$$

Then

$$|(\partial_\mu-\mathrm{i}A_\mu)\phi|^2=\frac{1}{2}(\partial_\mu\rho)^2+\frac{\rho^2}{2}(\partial_\mu\vartheta-A_\mu)^2.$$

The auxiliary constraint gives $u=-\rho^2/(2k)$, hence

$$\frac{k}{2}(\partial_\mu u)^2=\frac{\rho^2}{2k}(\partial_\mu\rho)^2.$$

Fix the gauge $\chi=0$. The A_μ-dependent angular part is

$$\frac{1}{2}\rho^2(\partial_\mu\vartheta-A_\mu)^2+\frac{k}{2}A_\mu A^\mu.$$

Its algebraic equation is

$$(\rho^2+k)A_\mu=\rho^2\partial_\mu\vartheta. \tag{94.57}$$

Substituting

$$A_\mu=\frac{\rho^2}{\rho^2+k}\partial_\mu\vartheta$$

gives the angular coefficient

$$\frac{1}{2}\frac{k\rho^2}{\rho^2+k}(\partial_\mu\vartheta)^2=\frac{1}{2}\frac{\rho^2}{1+\rho^2/k}(\partial_\mu\vartheta)^2.$$

Combining the radial and angular terms, the classical two-real-dimensional quotient metric is

$$ds^2=\left(1+\frac{\rho^2}{k}\right)d\rho^2+\frac{\rho^2}{1+\rho^2/k}\,d\vartheta^2. \tag{94.58}$$

This metric is the classical quotient metric. The conformal cigar coset is an infrared fixed-point statement whose definition requires the corresponding quantum current algebra or continuum fixed-point construction, rather than the low-derivative quotient metric alone.

Dualize both logarithmic directions. Introduce twisted chiral variables

$$Y,\qquad Y_P,\qquad Y\sim Y+2\pi\mathrm{i},\quad Y_P\sim Y_P+2\pi\mathrm{i}.$$

The ordinary charged chiral multiplet supplies the exponential term μe^{-Y}. The logarithmic chiral multiplet contributes a quadratic dual Kahler term rather than a second exponential term. The absence of a P-vortex exponential has a finite topological reason in the smooth finite-action sector. The periodic field $e^{\mathrm{i}\chi}$ is a unit-norm charged field for the same $U(1)$ connection A:

$$D(e^{\mathrm{i}\chi}) = \mathrm{i}e^{\mathrm{i}\chi}(d\chi - A).$$

Thus a smooth P-configuration on a Euclidean surface Σ_E supplies a nowhere-vanishing section of the associated unit circle bundle. If the gauge bundle has vortex number

$$n = \frac{1}{2\pi}\int_{\Sigma_E} F \in \mathbb{Z},$$

such a nowhere-vanishing section trivializes the line bundle and forces $n = 0$. Equivalently, on a disk, a boundary winding of χ extends smoothly through the center only when the winding is zero; unlike the ordinary charged scalar $\phi = \rho e^{\mathrm{i}\vartheta}/\sqrt{2}$, the logarithmic multiplet has no radial modulus whose zero can absorb the winding. Allowing singular P-fields would be a different defect insertion, not the smooth finite-action vortex sector used to generate twisted F-terms.

In the convention compatible with (94.40), the low-energy twisted superpotential has the form

$$\widetilde{W}_{\mathrm{cig}}(\Sigma, Y, Y_P) = -\Sigma(Y + Y_P) - \mu e^{-Y}, \tag{94.59}$$

up to affine redefinitions of Y_P and Σ. The vector multiplet imposes

$$Y + Y_P = 0. \tag{94.60}$$

Substituting the constraint leaves one twisted chiral variable Y with twisted superpotential

$$\widetilde{W}_{\mathrm{Liouville}}(Y) = -\mu e^{-Y}. \tag{94.61}$$

The dual Kahler potential has the asymptotic large-$\mathrm{Re}\,Y$ behavior

$$K(Y, \overline{Y}) = \frac{1}{8\pi k}\overline{Y}Y + O(e^{-\mathrm{Re}\,Y}), \qquad \mathrm{Re}\,Y \to +\infty, \tag{94.62}$$

with the sign convention appropriate to twisted chiral superspace. This is the $\mathcal{N} = 2$ Liouville presentation: an asymptotic cylinder coordinate Y together with the exponential twisted superpotential (94.61).

The construction supplies a precise protected-data bridge:

$$\begin{aligned}&\text{charged chiral dualization} + \text{nonzero vortex exponential} + \text{IR vector constraint}\\ &\quad \Longrightarrow \mathcal{N} = 2 \text{ Liouville data.}\end{aligned}$$

A theorem identifying this with the cigar coset QFT requires construction of both continuum theories, equality of their Hilbert spaces and local algebras, matching of the $\mathcal{N} = 2$ superconformal generators, matching of defects and spectral-flow sectors, and control of the strong-coupling region where the semiclassical quotient metric (94.58) is only a coordinate on the asymptotic target geometry.

94.11 Abelian GLSM Coulomb-Branch One-Loop Calculation

The GLSM has a second protected local calculation beyond the classical Higgs quotient. Move to a Coulomb-branch region where $\sigma \neq 0$, so charged chiral multiplets have masses

$$m_i(\sigma) = Q_i \sigma.$$

The calculation below is a Wilsonian twisted F-term calculation whose scope is the protected Coulomb coordinate chart. The full infrared QFT requires a separate continuum construction.

Hypothesis 94.16 (Abelian Coulomb one-loop determinant)**.** Fix an abelian GLSM presentation as in Definition 94.6, assume all charges Q_i are nonzero, and restrict to a simply connected branch of the region

$$Q_i \sigma \neq 0, \qquad i = 1, \dots, m.$$

Assume a supersymmetric Wilsonian regulator preserving the twisted chiral field strength Σ, the gauge symmetry, and the integer charge normalization. The finite part of the massive chiral determinant is assumed to be represented by the local twisted superpotential

$$\widetilde{W}_{\text{eff}}(\Sigma) = -t\Sigma + \sum_{i=1}^{m} Q_i \Sigma \left(\log \frac{Q_i \Sigma}{\mu} - 1 \right) \tag{94.63}$$

up to an additive constant and an affine function of Σ. The renormalization scale $\mu > 0$ and the logarithm branches are part of the scheme choice. Boundary contributions from $\sigma = 0$, vortex sectors, and singular loci are not included in this local determinant hypothesis.

Local determinant derivation. The part of Hypothesis 94.16 that is a perturbative determinant calculation can be made explicit. Work in a background in which the twisted chiral field strength is slowly varying and has lowest component σ. For a chiral multiplet of charge Q, the Coulomb-region complex mass is

$$M = Q\sigma.$$

The local Wilsonian determinant is obtained by expanding the massive Gaussian path integral to first order in the top component of Σ, or equivalently to first order in the background $D + \mathrm{i}F_{12}$ that couples to the FI-theta coordinate. The bosonic and fermionic determinants cancel at zero background $D + \mathrm{i}F_{12}$; the uncancelled linear term is the massive propagator at coincident points. With a proper-time subtraction at the reference mass μ,

$$4\pi \int_0^\infty \frac{\mathrm{d}s}{4\pi s} \left(e^{-s|M|^2} - e^{-s\mu^2} \right) = \log \frac{\mu^2}{|M|^2}. \tag{94.64}$$

The equality follows by differentiating both sides with respect to $|M|^2$ and fixing the constant at $|M| = \mu$:

$$\frac{\partial}{\partial |M|^2} \int_0^\infty \frac{\mathrm{d}s}{s} \left(e^{-s|M|^2} - e^{-s\mu^2} \right) = -\int_0^\infty \mathrm{d}s\, e^{-s|M|^2} = -\frac{1}{|M|^2}.$$

Equation (94.64) determines the real logarithm in the finite FI shift. Its imaginary partner is fixed by the two-dimensional axial anomaly: changing the phase of M by $M \mapsto e^{\mathrm{i}\alpha} M$ is a chiral rotation of a charge-Q massive multiplet and shifts the theta coordinate by $Q\alpha$ in the same normalization in which the flux of a unit-charge $U(1)$ bundle is integral. Thus the real subtraction and the anomaly combine into the holomorphic branch

$$Q\log\frac{M}{\mu}=Q\log\frac{Q\Sigma}{\mu}$$

for the derivative of the twisted superpotential. For m massive chiral multiplets this gives, on the chosen simply connected Coulomb branch,

$$\frac{\partial\widetilde{W}_{\text{eff}}}{\partial\Sigma}=-t+\sum_{i=1}^{m}Q_i\log\frac{Q_i\Sigma}{\mu}. \tag{94.65}$$

Integrating (94.65) in the holomorphic coordinate Σ gives

$$-t\Sigma+\sum_i Q_i\Sigma\left(\log\frac{Q_i\Sigma}{\mu}-1\right),$$

up to an additive constant and an affine function of Σ. This is (94.63). The calculation is local on the Coulomb chart: it uses $Q_i\sigma\neq 0$, chooses logarithm branches, and says nothing by itself about vortex sectors, singular loci, or the existence of the infrared continuum QFT.

Coulomb critical equation. Under Hypothesis 94.16, the local Coulomb critical equation is

$$-t+\sum_{i=1}^{m}Q_i\log\frac{Q_i\sigma}{\mu}=0. \tag{94.66}$$

Equivalently, on the chosen logarithm branch,

$$\prod_{i=1}^{m}\left(\frac{Q_i\sigma}{\mu}\right)^{Q_i}=\mathrm{e}^{t}. \tag{94.67}$$

If all $Q_i>0$, then this equation has

$$Q_{\text{tot}}=\sum_{i=1}^{m}Q_i \tag{94.68}$$

simple solutions for σ whenever $\mathrm{e}^t\neq 0$. For $m=N$ fields of charge 1, the count is N.

Differentiate (94.63) with respect to Σ. For a single summand,

$$\frac{d}{d\Sigma}\left[Q_i\Sigma\left(\log\frac{Q_i\Sigma}{\mu}-1\right)\right]=Q_i\log\frac{Q_i\Sigma}{\mu}.$$

The critical equation is therefore (94.66). Exponentiating gives (94.67).

When all charges are positive, write

$$C_Q=\prod_{i=1}^{m}Q_i^{Q_i}.$$

Then (94.67) becomes

$$C_Q\,\mu^{-Q_{\text{tot}}}\sigma^{Q_{\text{tot}}}=\mathrm{e}^{t}.$$

Since $Q_{\text{tot}}>0$ and the right side is nonzero, this polynomial equation has Q_{tot} nonzero roots. Its derivative is proportional to $\sigma^{Q_{\text{tot}}-1}$, so every nonzero root is simple. For N charge-one fields, $Q_{\text{tot}}=N$.

Example 94.17 ($\mathbb{P}^{N-1}$ GLSM quantum vacua)**.** Take $m = N$, $Q_i = 1$, and $W = 0$. The local equation is

$$\left(\frac{\sigma}{\mu}\right)^N = \mathrm{e}^t.$$

Thus the Coulomb-branch one-loop calculation predicts N massive twisted chiral vacua in the chamber where this effective description is valid. This is the protected arithmetic behind the usual $\mathbb{P}^{N-1}$ vacuum count. The statement that these vacua exhaust the continuum theory requires the same regulator, compactness, and singular-locus controls stated in Hypothesis 94.16.

For the hypersurface charge vector $(1, \ldots, 1, -d)$, the exponent of σ in (94.67) is $N - d$, the same integer as the axial anomaly coefficient (94.18). In the anomaly-free case $N = d$, the Coulomb equation becomes a condition on t and the logarithm branch rather than an equation with finitely many isolated σ-solutions. This is a protected signal of a singular locus in the FI-theta parameter space. A full infrared phase-transition statement requires control of the continuum theory at the singular locus.

Classical chambers for the hypersurface GLSM. Fix integers $N \geq 2$ and $d \geq 2$. Let the GLSM have chiral fields

$$X_1, \ldots, X_N, \quad P$$

with charges

$$Q(X_i) = 1, \qquad Q(P) = -d, \tag{94.69}$$

and superpotential

$$W = P\, G_d(X_1, \ldots, X_N), \tag{94.70}$$

where G_d is homogeneous of degree d. Assume that the projective hypersurface

$$Y_G = \{[X] \in \mathbb{P}^{N-1} : G_d(X) = 0\} \tag{94.71}$$

is smooth, equivalently the equations

$$G_d(X) = \partial_1 G_d(X) = \cdots = \partial_N G_d(X) = 0$$

have no solution with $X \neq 0$. Then the classical Higgs-vacuum quotient has the following chamber description.

1. If $r > 0$, then $X \neq 0$, $P = 0$, and the quotient is $Y_G \subset \mathbb{P}^{N-1}$.
2. If $r < 0$, then $P \neq 0$, $X = 0$ on the vacuum locus, and the unbroken finite gauge group is

   $$\mu_d = \{\zeta \in U(1) : \zeta^d = 1\}.$$

   Fluctuations of the X_i are therefore organized as a Landau–Ginzburg model with polynomial $G_d(X)$, together with the residual finite μ_d gauge quotient.
3. At $r = 0$, the point $X = P = 0$ obeys the D-term equation and the gauge quotient is singular. A definition of the infrared QFT at the phase boundary requires additional continuum data beyond the chamber calculation.

The F-term equations of (94.70) are

$$G_d(X) = 0, \qquad P\,\partial_i G_d(X) = 0, \quad i = 1, \dots, N. \tag{94.72}$$

The D-term equation is

$$\sum_{i=1}^{N} |X_i|^2 - d|P|^2 = r. \tag{94.73}$$

If $r > 0$, equation (94.73) forces $X \neq 0$. On the locus $G_d(X) = 0$, smoothness of Y_G implies that the gradient $(\partial_i G_d(X))$ is not the zero vector. Hence (94.72) forces $P = 0$. Quotienting nonzero X by the charge-one $U(1)$ action gives $[X] \in \mathbb{P}^{N-1}$, and the remaining equation is $G_d(X) = 0$.

If $r < 0$, equation (94.73) forces $P \neq 0$. Then (94.72) gives $\partial_i G_d(X) = 0$ for all i. Homogeneity gives Euler's identity

$$d\,G_d(X) = \sum_{i=1}^{N} X_i \partial_i G_d(X),$$

so $G_d(X) = 0$ follows as well. By the smoothness assumption, the common zero of G_d and all $\partial_i G_d$ is $X = 0$. A gauge transformation $\zeta \in U(1)$ preserves a nonzero value of P exactly when $\zeta^{-d} = 1$, equivalently $\zeta \in \mu_d$. The transverse coordinates are the X_i, and the residual superpotential is $G_d(X)$.

At $r = 0$, substituting $X = 0$ and $P = 0$ into (94.73) gives $0 = 0$, and the F-term equations are also satisfied. The whole $U(1)$ gauge group fixes this point, so the quotient contains a positive-dimensional stabilizer stratum. That stabilizer stratum is the singular locus of the classical quotient at the phase boundary.

Adjunction, central charge, and the residual finite gauge theory. The smooth degree-d hypersurface

$$Y_G \subset \mathbb{P}^{N-1}$$

has complex dimension $N - 2$. Let

$$H = c_1(\mathcal{O}_{\mathbb{P}^{N-1}}(1)).$$

The normal bundle of Y_G in $\mathbb{P}^{N-1}$ is

$$N_{Y_G/\mathbb{P}^{N-1}} \cong \mathcal{O}(d)|_{Y_G}.$$

The exact sequence

$$0 \longrightarrow TY_G \longrightarrow T\mathbb{P}^{N-1}|_{Y_G} \longrightarrow \mathcal{O}(d)|_{Y_G} \longrightarrow 0$$

gives

$$c_1(TY_G) = (N-d)H|_{Y_G}, \qquad K_{Y_G} \cong \mathcal{O}(d-N)|_{Y_G}. \tag{94.74}$$

Thus the topological Calabi–Yau condition in this hypersurface family is

$$d = N.$$

In that case the large-volume sigma-model central-charge target is

$$c_{\text{sigma}} = 3\dim_{\mathbb{C}} Y_G = 3(N-2), \tag{94.75}$$

provided the infrared fixed point exists and realizes the standard $\mathcal{N} = (2, 2)$ superconformal stress tensor.

On the Landau–Ginzburg side, the Fermat reference polynomial

$$G_d(X) = X_1^d + \cdots + X_N^d$$

has quasihomogeneous weights $q_i = 1/d$, hence the protected Landau–Ginzburg central-charge calculation gives

$$c_{\mathrm{LG}} = 3 \sum_{i=1}^{N} \left(1 - \frac{2}{d}\right) = 3N \left(1 - \frac{2}{d}\right). \tag{94.76}$$

The equality

$$c_{\mathrm{LG}} = 3(N - 2)$$

holds precisely when $d = N$. This is a protected numerical consistency condition linking the two chambers. The equality of central charges is one piece of data in an infrared comparison; the equivalence of continuum QFTs also requires the operator algebra, stress tensor, state space, and extended sectors to be constructed and matched.

The finite group in the $r < 0$ chamber is an actual residual gauge group. Choose a gauge in which the nonzero field P is fixed to a positive real constant. A gauge transformation $\zeta \in U(1)$ preserves this gauge choice exactly when

$$\zeta^{-d} = 1.$$

Therefore $\zeta \in \mu_d$, and the remaining chiral fields transform as

$$X_i \longmapsto \zeta X_i.$$

Homogeneity gives

$$G_d(\zeta X) = \zeta^d G_d(X) = G_d(X),$$

so the Landau–Ginzburg superpotential descends to the finite gauge quotient. The finite-gauge QFT contains the invariant untwisted local operators together with twisted sectors determined by the finite gauge theory. The invariant part of $\mathrm{Jac}(G_d)$ is therefore only one protected component of the orbifold theory; a full state-space comparison must include the sectors created by the μ_d defect lines. For the Fermat Jacobi basis

$$X_1^{a_1} \cdots X_N^{a_N}, \qquad 0 \le a_i \le d - 2,$$

the untwisted invariant condition is

$$a_1 + \cdots + a_N \equiv 0 \pmod{d}.$$

Coulomb coordinate for the phase-boundary signal. For the charge vector $(1, \ldots, 1, -d)$, the one-loop Coulomb equation (94.67) becomes

$$\left(\frac{\sigma}{\mu}\right)^N \left(\frac{-d\sigma}{\mu}\right)_{\mathrm{branch}}^{-d} = \mathrm{e}^t. \tag{94.77}$$

Equivalently,

$$\left(\frac{\sigma}{\mu}\right)^{N-d} (-d)_{\text{branch}}^{-d} = \mathrm{e}^{t}. \tag{94.78}$$

The subscript records the chosen logarithm branch for the negatively charged field. In the anomaly-free case $d = N$, the σ-dependence cancels and the local Coulomb chart selects the branch-dependent condition

$$\mathrm{e}^{t} = C_{\text{branch}}, \qquad C_{\text{branch}} = (-N)_{\text{branch}}^{-N}. \tag{94.79}$$

In the additive local FI coordinate

$$T = t - \log C_{\text{branch}},$$

the condition is $T = 0$. At this value the one-loop large-σ twisted superpotential has a critical direction rather than isolated local Coulomb vacua. This is the protected Coulomb-coordinate signal associated with the chamber boundary. The continuum behavior at that coordinate is a separate infrared construction problem.

Example 94.18 (The quintic GLSM as intrinsic two-dimensional QFT data)**.** Set $N = d = 5$. The charges are

$$(1, 1, 1, 1, 1, -5),$$

so the axial anomaly coefficient (94.18) is $5 - 5 = 0$. For $r > 0$, the classical Higgs quotient is the degree-five hypersurface

$$G_5(X) = 0 \quad \text{inside} \quad \mathbb{P}^4.$$

For $r < 0$, the residual finite gauge group is μ_5, and the local Landau–Ginzburg polynomial is $G_5(X_1, \ldots, X_5)$. These are statements about chambers of a two-dimensional supersymmetric gauge theory. The associated infrared equivalence claim requires a two-dimensional continuum construction and a comparison of its protected and unprotected operator data.

94.12 Infrared Comparison Problem

For each two-dimensional supersymmetric model one must distinguish:

UV regulator, supersymmetric Wilsonian flow,
protected operator algebra, full infrared QFT.

Protected rings and indices can match before the full Hilbert space, correlators, and stress tensor are identified. A complete infrared equivalence therefore requires a map of local algebras, states, stress tensors, supercharges, and extended operators, with convergence or scaling limits stated.

Open Problem 94.19 (Two-dimensional supersymmetric RG construction)*.* Construct $2D$ $\mathcal{N} = (2, 2)$ GLSM flows to Landau–Ginzburg and hypersurface sigma-model fixed points with a regulator, supersymmetric Wilsonian maps, protected-ring comparison, stress-tensor convergence, and Hilbert-space reconstruction in one declared framework. The target-space terminology here refers only to an intrinsic two-dimensional QFT comparison between continuum limits.

Three-Dimensional Chern–Simons–Matter Theories

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

In three dimensions, Chern–Simons–matter theories combine topological gauge terms, parity anomalies, monopole operators, and matter dynamics. This chapter treats them as field-theoretic data with specified definitions and duality maps. The first part fixes the local Chern–Simons and light-cone conventions, including the vector-model large-N framework in which the gauge action becomes quadratic. The second part fixes the $3D$ $\mathcal{N} = 2$ Chern–Simons–matter conventions used by the localization chapter. The final part gives the Aharony–Bergman–Jafferis–Maldacena theory as a worked example with gauge group, levels, matter, superpotential, conformal locus, moduli space, monopole enhancement boundary, and S^3 localization matrix model all stated in the same normalization.

95.1 Three-Dimensional Supersymmetry

Let $\eta_{\mu\nu} = \mathrm{diag}(-,+,+)$. A minimal Majorana spinor has two real components. The $\mathcal{N} = 2$ algebra may be written with complex supercharges $Q_\alpha, \bar{Q}_\alpha$:

$$\{Q_\alpha, \bar{Q}_\beta\} = 2(\gamma^\mu)_{\alpha\beta} P_\mu + 2\mathrm{i}\epsilon_{\alpha\beta} Z,$$

where Z is a possible central charge. Particle multiplets are representations of this Hilbert-space algebra. Superfields are off-shell coordinate packages for local variables; the two notions are connected only after dynamics and quantization have been specified.

A $3D$ $\mathcal{N}=2$ vector multiplet contains

$$(A_\mu, \sigma, \lambda, \bar{\lambda}, D),$$

where A_μ is a gauge field, σ is a real adjoint scalar, $\lambda, \bar{\lambda}$ are gauginos, and D is an auxiliary scalar. A chiral multiplet contains

$$(\phi, \psi, F)$$

in a unitary representation of the gauge group. These are field variables in a chosen off-shell presentation. A statement about BPS particles or local operators must also specify the Hamiltonian, Gauss law, and operator completion of the theory.

95.2 Chern–Simons Datum

Let G be compact and let $P \to M_3$ be a principal G-bundle. A Chern–Simons action is

$$S_{\mathrm{CS}}[A] = \frac{k}{4\pi} \int_{M_3} \mathrm{Tr}\left(A \wedge dA + \frac{2}{3} A \wedge A \wedge A\right).$$

The trace convention and the allowed levels k are tied to the lattice of large gauge transformations. Gauge invariance of $\exp(\mathrm{i}S_{\mathrm{CS}})$ requires the change of S_{CS} under a large gauge transformation to lie in $2\pi\mathbb{Z}$. For a spin Chern–Simons theory the allowed counterterms may differ from the purely bosonic theory by half-integral contact terms; this choice is part of the three-dimensional QFT specification.

Varying the action gives

$$\delta S_{\mathrm{CS}} = \frac{k}{2\pi} \int_{M_3} \mathrm{Tr}(\delta A \wedge F_A) + \frac{k}{4\pi} \int_{\partial M_3} \mathrm{Tr}(A \wedge \delta A).$$

On a closed manifold, the field equation of pure Chern–Simons theory is

$$F_A = 0.$$

On a manifold with boundary, a boundary condition or boundary degrees of freedom are part of the gauge-theory specification.

95.3 Conformal Chern–Simons–Matter Charts and Light-Cone Gauge

Chern–Simons–matter theories give a class of three-dimensional conformal fixed points whose perturbative expansion is not organized by a dimensionful Yang–Mills coupling. The level k is quantized, while the perturbative coordinate is a dimensionless parameter such as $1/k$, or in vector models the 't Hooft coordinate

$$\lambda := \frac{N}{k_{\mathrm{eff}}}, \tag{95.1}$$

where k_{eff} includes the parity-anomaly and regulator shift specified with the theory. This statement is not a claim that every Lagrangian written with massless matter is automatically a conformal theory. Relevant deformations, such as scalar and fermion masses, must be tuned to the fixed point, and scalar self-interactions must be placed at their fixed-point values when they are present. Once these data have been fixed, correlation functions can be computed in ordinary diagrammatic perturbation theory around the conformal point.

The light-cone gauge makes a special feature of Chern–Simons theory explicit. Use

$$x^{\pm} = \frac{x^0 \pm x^1}{\sqrt{2}}, \qquad x^{\perp} = x^2, \qquad ds^2 = -2\,dx^+dx^- + (dx^{\perp})^2, \tag{95.2}$$

and choose the orientation convention $\epsilon^{+-\perp} = +1$. The gauge condition is

$$A_- = 0. \tag{95.3}$$

The cubic Chern–Simons vertex then vanishes because every wedge product of three one-forms in three dimensions contains one dx^-. Thus the pure gauge part is first order and quadratic:

$$S_{\text{CS}}\big|_{A_-=0} = \frac{k}{2\pi}\int d^3x\ \text{Tr}(A_+\partial_-A_\perp)\,, \tag{95.4}$$

up to boundary terms and zero-mode data.

Component check of the light-cone Chern–Simons action. The component form of the local Chern–Simons density is

$$\frac{k}{4\pi}\epsilon^{\mu\nu\rho}\,\text{Tr}\left(A_\mu\partial_\nu A_\rho + \frac{2}{3}A_\mu A_\nu A_\rho\right).$$

The cubic term is antisymmetric in the three spacetime labels and therefore contains one A_-; it is zero after imposing $A_- = 0$. The remaining quadratic terms with no A_- are

$$\frac{k}{4\pi}\,\text{Tr}(A_+\partial_-A_\perp - A_\perp\partial_-A_+)\,,$$

because $\epsilon^{+-\perp} = +1$ and $\epsilon^{\perp-+} = -1$. Integrating the second term by parts in x^- and dropping the boundary term gives twice $\text{Tr}(A_+\partial_-A_\perp)$, giving (95.4).

Let matter in a representation R of G define the gauge current

$$J^{\mu a} := -\frac{\delta S_{\text{matter}}}{\delta A^a_\mu}$$

in the same connection normalization as above. At finite light-front regulator, remove the ∂_- zero mode or keep it as a separate Gauss-law degree of freedom. On the zero-mode-free subspace write ∂_-^{-1} for the inverse with the declared prescription.

Light-cone Chern–Simons current kernel. At finite regulator, the light-cone-gauge integration over A_+ and $A_\perp$ is an ordinary Gaussian integration on the nonzero-mode subspace. With the source convention

$$S[A_+, A_\perp; J] = \int d^3x \left[\frac{k}{2\pi} A_+^a \partial_- A_\perp^a - A_+^a J^{+a} - A_\perp^a J^{\perp a} \right], \tag{95.5}$$

substitution of the classical solution gives the effective current interaction

$$S_{\text{eff}}[J] = -\frac{2\pi}{k} \int d^3x \, J^{+a} \, \partial_-^{-1} J^{\perp a}, \tag{95.6}$$

with the ordering and zero-mode prescription displayed.

Set $a = k/(2\pi)$ and $D = \partial_-$. The equations following from (95.5) are

$$aDA_\perp^a = J^{+a}, \qquad aDA_+^a = -J^{\perp a},$$

where the second equation uses integration by parts in x^-. Hence

$$A_\perp^a = a^{-1} D^{-1} J^{+a}, \qquad A_+^a = -a^{-1} D^{-1} J^{\perp a}.$$

Substituting into the action, the bilinear term cancels the $A_+ J^+$ source term and leaves

$$-A_\perp^a J^{\perp a} = -a^{-1} (D^{-1} J^{+a}) J^{\perp a}.$$

This is (95.6). The calculation is a finite-dimensional completion of the square after the regulator has replaced the nonzero-mode function space by a finite or Hilbert-space Gaussian problem. The zero mode is not determined by this inverse; it is the global Gauss-law constraint and must be supplied as part of the light-front regulator.

This is the three-dimensional analogue of the simplification used in the two-dimensional large-N 't Hooft model of Chapter 53. The kernel is ∂_-^{-1}, not $(-\partial_-^2)^{-1}$, because the Chern–Simons kinetic operator is first order rather than Yang–Mills second order. In both cases the light-front gauge field has no transverse propagating polarization and imposes a nonlocal current interaction after the constraint is solved.

Definition 95.1 (Planar Chern–Simons vector-model datum)**.** A planar Chern–Simons vector-model datum consists of:

(i) gauge group $U(N)$ or $SU(N)$, global form, spin structure, framing convention, and effective level k_{eff};

(ii) fundamental matter fields, such as scalars or Dirac fermions, with all relevant deformations tuned to the conformal point;

(iii) a parity-anomaly regulator fixing k_{eff} and all background Chern–Simons contact terms;

(iv) a large-N limit with $\lambda = N/k_{\text{eff}}$ fixed;

(v) a light-front or Euclidean regulator specifying zero modes, ∂_-^{-1}, and the renormalized gauge-invariant singlet operators whose correlators are computed.

For fundamental matter the color algebra uses the same trace-delta normalization as the QCD chapters,

$$(t^a)^i{}_j(t^a)^k{}_\ell = \delta^i{}_\ell\delta^k{}_j - \frac{1}{N}\delta^i{}_j\delta^k{}_\ell. \tag{95.7}$$

Consequently the interaction (95.6) preserves the single color trace at leading order, while the second term in (95.7) is suppressed by $1/N$ in connected singlet correlators. The trace-preserving leading contraction is the planar color algebra behind the bilocal closure of the two-dimensional 't Hooft model and the singlet light-front closure used here.

95.3.1 Finite-Regulator Singlet Closure

The preceding statement can be written as a finite-dimensional algebraic identity before taking the large-N limit. Let Ψ_i^A denote the regulated fundamental matter variables that remain after gauge fixing; the index $i = 1, \ldots, N$ is color, while A collects spin, flavor, position or momentum, and any regulator labels. Let $\overline{\Psi}{}^i_A$ be the conjugate variable in the antifundamental representation. Define the singlet bilocal matrix

$$B^A{}_B = \frac{1}{N}\overline{\Psi}{}^i_B\Psi_i^A. \tag{95.8}$$

A gauge current component that is bilinear in the matter variables has the form

$$J^{\mu a} = \overline{\Psi}{}^i_A\,(V^\mu)^A{}_B\,(t^a)^j{}_i\,\Psi_j^B,$$

where V^μ is the matrix, including all differential or regulator kernels, carried by the current component. The displayed algebraic identity below is written for ordinary complex variables. In fermionic vector models the current product is instead a graded product in the declared current order; the color contraction and its N-scaling are identical, while signs coming from moving Grassmann variables belong to the spinor and kernel convention of the particular Schwinger–Dyson equation rather than to the color algebra.

Planar color reduction of the light-cone kernel. Let K be any regulator kernel acting on the non-color labels; in the light-cone Chern–Simons problem $K = \partial_-^{-1}$ with the zero-mode prescription already declared. With the normalization (95.7),

$$\begin{aligned} J^{+a}KJ^{\perp a} &= N^2\,(V^+)^A{}_B\,B^B{}_C\,K^C{}_D\,(V^\perp)^D{}_E\,B^E{}_A \\ &\quad - N\,(V^+)^A{}_B\,B^B{}_A\,K^C{}_D\,(V^\perp)^D{}_E\,B^E{}_C. \end{aligned} \tag{95.9}$$

Consequently the light-cone interaction (95.6) has the form

$$S_{\text{eff}} = -2\pi N\lambda\,(V^+)^A{}_B B^B{}_C K^C{}_D (V^\perp)^D{}_E B^E{}_A + O(N^0)$$

at fixed $\lambda = N/k_{\text{eff}}$.

Insert the current expression and use (95.7):

$$(t^a)^j{}_i(t^a)^\ell{}_k = \delta^j{}_k\delta^\ell{}_i - \frac{1}{N}\delta^j{}_i\delta^\ell{}_k.$$

The first color contraction produces

$$\overline{\Psi}{}^i_A(V^+)^A{}_B\Psi_k^B\,K^C{}_D\,\overline{\Psi}{}^k_C(V^\perp)^D{}_E\Psi_i^E = N^2(V^+)^A{}_B B^B{}_C K^C{}_D (V^\perp)^D{}_E B^E{}_A.$$

The trace-subtraction term gives the second line of (95.9) with one fewer factor of N. Multiplication by the kernel coefficient $2\pi/k_{\text{eff}} = 2\pi\lambda/N$ then makes the first term order N and the trace-subtraction term order N^0.

Finite-regulator Schwinger–Dyson identity and large-N closure. At finite regulator, with $S_{\text{reg}}[\Psi, \overline{\Psi}]$ the matter action after the light-cone gauge field has been integrated out as in (95.6), the Schwinger–Dyson identity is the finite-dimensional integration-by-parts identity. For an ordinary complex bosonic fundamental vector,

$$0 = \int d\Psi \, d\overline{\Psi} \, \frac{\partial}{\partial \Psi_i^A} \left(\mathcal{O} \, \mathrm{e}^{-S_{\text{reg}}} \right),$$

with boundary terms removed by regulator damping or by compact contour deformation. Expanding the derivative gives

$$\left\langle \frac{\partial \mathcal{O}}{\partial \Psi_i^A} - \mathcal{O} \, \frac{\partial S_{\text{reg}}}{\partial \Psi_i^A} \right\rangle_{\text{reg}} = 0 \tag{95.10}$$

for every polynomial singlet observable $\mathcal{O}$. For a Grassmann fundamental vector the same equation holds with the ordinary derivative replaced by the left Berezin derivative and with the standard graded sign when the derivative crosses $\mathcal{O}$.

The part that matters for the planar vector model is not the integration by parts itself but the closure of the leading equations. After the gauge field has been integrated out, the bilocal color reduction above shows that the order-N interaction is a functional only of B. If the large-N singlet sector has factorization

$$\langle B_1 \cdots B_r \rangle_{\text{conn}} = O(N^{1-r}), \tag{95.11}$$

then the leading equations obtained from (95.10) close on the one-bilocal expectation $G^A{}_B := \langle B^A{}_B \rangle$. Indeed, taking $\mathcal{O}$ to be a product of singlet bilocals gives equations whose leading terms contain products of B's, and (95.11) replaces those products, at leading order, by products of G. Thus no nonsinglet correlator enters the leading large-N Schwinger–Dyson equation.

95.3.2 Planar Bilocal Saddle and Self-Energy Equation

The preceding closure becomes computational only after the leading planar equation is written as an equation for the exact two-point function. We give the finite-regulator derivation because it is the step often hidden behind the phrase "rainbow resummation" in the Chern–Simons vector-model literature.

Let $Q^A{}_B$ be the regulated inverse free propagator of the fundamental matter variable in the gauge-fixed theory, including all spinor, flavor, momentum, and regulator labels but no color index. Thus the quadratic part of the action is

$$S_0 = \overline{\Psi}^i_A Q^A{}_B \Psi^B_i.$$

Keeping the $O(N)$ term of the planar color reduction above and placing the $O(N^0)$ trace-subtraction in the $1/N$ expansion, the leading light-cone interaction is

$$S^{(0)}_{\text{int}} = N \, I_{\text{LC}}[B], \qquad I_{\text{LC}}[B] = -2\pi\lambda \, (V^+)^A{}_B B^B{}_C K^C{}_D (V^\perp)^D{}_E B^E{}_A, \tag{95.12}$$

where $K = \partial_-^{-1}$ with the same zero-mode prescription as in (95.6). Define the color-normalized two-point bilocal

$$G^A{}_B = \langle B^A{}_B \rangle = \frac{1}{N} \left\langle \overline{\Psi}{}^i_B \Psi^A_i \right\rangle .$$

Proposition 95.2 (Planar self-energy equation from the bilocal action)**.** *Assume the finite-regulator planar vector-model datum of Definition 95.1, the leading interaction* (95.12)*, and large-N singlet factorization in the form* (95.11)*. For ordinary complex bosonic fundamental variables, the leading large-N two-point function obeys*

$$G^A{}_C \left(Q^C{}_B + \Sigma^C{}_B[G] \right) = \delta^A{}_B, \tag{95.13}$$

where the self-energy is the functional derivative of the leading bilocal interaction:

$$\Sigma^C{}_M[G] = \frac{\partial I_{\mathrm{LC}}}{\partial G^M{}_C} = -2\pi\lambda \left[(V^+)^A{}_M K^C{}_D (V^\perp)^D{}_E G^E{}_A + (V^+)^C{}_B G^B{}_D K^D{}_E (V^\perp)^E{}_M \right]. \tag{95.14}$$

For fermionic vector models the same color and bilocal derivative formula is read in the declared graded order; the additional signs are those of the Berezin Schwinger–Dyson identity and of the spinor current matrices V^μ.

Proof. Apply the finite-regulator Schwinger–Dyson identity (95.10) with $\mathcal{O} = \Psi^A_i$. Summing over the color label and dividing by N gives

$$\delta^A{}_M = \frac{1}{N} \left\langle \Psi^A_i \frac{\partial S_{\mathrm{reg}}}{\partial \Psi^M_i} \right\rangle .$$

The quadratic action contributes

$$\frac{1}{N} \left\langle \Psi^A_i \overline{\Psi}{}^i_C \right\rangle Q^C{}_M = G^A{}_C Q^C{}_M .$$

Here the displayed equality uses that the variables in the proposition are ordinary bosonic complex variables, so the two fields in the finite regulator integral may be interchanged without a Koszul sign. For the leading planar interaction, the chain rule and the definition of B give

$$\frac{\partial}{\partial \Psi^M_i} \left(N I_{\mathrm{LC}}[B] \right) = \overline{\Psi}{}^i_C \frac{\partial I_{\mathrm{LC}}}{\partial B^M{}_C} .$$

Therefore the interaction contribution is

$$\frac{1}{N} \left\langle \Psi^A_i \overline{\Psi}{}^i_C \frac{\partial I_{\mathrm{LC}}}{\partial B^M{}_C} \right\rangle .$$

Large-N factorization replaces the product of the bilocal and the bilocal polynomial $\partial I_{\mathrm{LC}}/\partial B^M{}_C$ by the same expression evaluated at $B = G$, up to $O(N^{-1})$ corrections in this normalization. This gives

$$\delta^A{}_M = G^A{}_C \left(Q^C{}_M + \left. \frac{\partial I_{\mathrm{LC}}}{\partial B^M{}_C} \right|_{B=G} \right),$$

which is (95.13).

It remains only to compute the derivative of (95.12). Differentiating the first and second occurrence of B gives respectively

$$-2\pi\lambda(V^+)^A{}_M K^C{}_D(V^\perp)^D{}_E G^E{}_A, \qquad -2\pi\lambda(V^+)^C{}_B G^B{}_D K^D{}_E(V^\perp)^E{}_M.$$

Their sum is (95.14). The fermionic statement follows from the finite-regulator Berezin Schwinger–Dyson identity with the same color contraction; one must not infer the graded signs from the bosonic display without fixing the fermion-current ordering. □

In a translation-invariant continuum chart, the labels A, B include momenta and spin. Equation (95.13) then becomes the familiar planar Schwinger–Dyson integral equation for the exact fundamental propagator. Solving it requires the regulator-dependent mass and contact counterterms that tune the theory to the conformal point. The mathematical point of the derivation above is that the planar self-energy is the leading finite-regulator Schwinger–Dyson equation for gauge-invariant singlet bilocals after the light-cone Chern–Simons constraint has been integrated out.

95.3.3 Bilocal Hessian and the Planar Singlet Ladder

The planar two-point functions of singlet bilinears are controlled by the second variation of the same finite-regulator bilocal action. This is the precise object behind the solvability of Chern–Simons vector models: one does not sum diagrams by naming a "ladder", but derives an inverse Hessian on the finite bilocal space and only then passes, if possible, to a continuum integral equation.

For ordinary complex bosonic variables, after introducing the bilocal $B = N^{-1}\overline{\Psi}\Psi$ as a finite-regulator coordinate, the leading collective action has the form

$$\mathcal{S}_{\mathrm{col}}[B] = \mathrm{Tr}(QB) + I_{\mathrm{LC}}[B] - \mathrm{Tr}\log B. \tag{95.15}$$

Here the trace is over the finite non-color regulator labels, and the $-\,\mathrm{Tr}\log B$ term is the Jacobian of the change from N fundamental vectors to the positive bilocal matrix B, in the region where that finite-dimensional change of variables is nonsingular. The stationary equation of (95.15) is

$$Q + \Sigma[G] - G^{-1} = 0,$$

which is the matrix form of (95.13). For fermionic vector models the bilocal collective coordinate and the Jacobian are graded; the following Hessian formula must then be read after fixing the graded current order. The finite color and light-cone kernel algebra is unchanged.

Let X, Y be finite bilocal variations. The Hessian at a solution G is the bilinear form

$$\mathcal{H}_G(X,Y) = \mathrm{Tr}\big(G^{-1}XG^{-1}Y\big) + I''_{\mathrm{LC}}(X,Y), \tag{95.16}$$

where the interaction part is

$$I''_{\mathrm{LC}}(X,Y) = -2\pi\lambda\left[\mathrm{Tr}(V^+XKV^\perp Y) + \mathrm{Tr}(V^+YKV^\perp X)\right]. \tag{95.17}$$

This formula is a finite-dimensional identity: it is obtained by expanding $I_{\mathrm{LC}}[G+X+Y]-I_{\mathrm{LC}}[G+X]-I_{\mathrm{LC}}[G+Y]+I_{\mathrm{LC}}[G]$. The first term in (95.16) is not a free-field assumption; it is the second variation of the finite-regulator Jacobian $-\,\mathrm{Tr}\log B$.

Couple a normalized singlet source $s\ \mathrm{Tr}(WB)$ by replacing $\mathcal{S}_{\mathrm{col}}$ with $\mathcal{S}_{\mathrm{col}} - s\ \mathrm{Tr}(WB)$. Differentiating the saddle equation at $s = 0$ gives the finite-regulator Bethe–Salpeter equation

$$G^{-1}\delta_W G\, G^{-1} + \mathcal{K}_G(\delta_W G) = W, \qquad \mathrm{Tr}(X\,\mathcal{K}_G(Y)) = I''_{\mathrm{LC}}(X, Y), \tag{95.18}$$

for the source response $\delta_W G = (\partial G_s/\partial s)_{s=0}$. Equivalently, with the amputated vertex

$$\Gamma_W := G^{-1}\delta_W G\, G^{-1},$$

one has

$$\Gamma_W + \mathcal{K}_G(G\Gamma_W G) = W. \tag{95.19}$$

The connected planar two-point function of normalized bilocal sources is then

$$\langle \mathrm{Tr}(W_1 B)\, \mathrm{Tr}(W_2 B)\rangle_{\mathrm{conn}} = \frac{1}{N}\ \mathrm{Tr}(W_1\, \delta_{W_2} G) + O(N^{-2}). \tag{95.20}$$

In a translation-invariant continuum chart, (95.19) becomes the planar ladder integral equation for the exact singlet vertex. The equation is exact only inside the declared finite-regulator large-N construction; a continuum solution still requires the conformal mass/contact tuning and a proof that the zero-mode prescription and renormalized singlet operators have a limit.

Controlled Approximation 95.3 (Planar light-front closure)**.** For the regulated model of Definition 95.1, the large-N light-front perturbation series for single-trace singlet correlators is controlled by planar ladders and rainbow self-energies built from the kernel (95.6). The closure is a statement about the declared regulator and the singlet sector: it gives integral equations for exact planar two- and three-point functions once the mass and contact terms have been tuned to the conformal point. It is not a proof of nonperturbative existence of the continuum theory and does not identify colored fundamental fields as asymptotic states.

The useful lesson for the monograph is conceptual as well as computational. Chern–Simons vector models are conformal gauge theories in which conventional diagrams can be evaluated at the fixed point, and light-cone gauge converts the topological gauge field into an exactly solvable constraint kernel. This makes them a higher-dimensional counterpart of the 't Hooft model: not identical in dynamics, because the kernel, spin, parity anomaly, and operator spectrum are different, but similar in the precise sense that the gauge field can be integrated out before solving the planar singlet equations.

95.4 Planar Bosonization of Singlet Observables

The preceding light-cone construction is also the natural setting for the large-N Bose–Fermi duality tests in Chern–Simons vector models. In this monograph the word duality in this context will mean a statement about renormalized gauge-invariant observables after the Chern–Simons level convention, parity-anomaly counterterms, scalar mass/contact tuning, and operator normalization have all been declared. The matching concerns the gauge-invariant singlet sector; colored fundamental fields, line sectors, monopole sectors, and finite-N global refinements require additional objects beyond this planar observable chart.

Conjecture 95.4 (Planar Chern–Simons vector-model bosonization statement)**.** *Fix a positive Yang–Mills-regulator level coordinate $k_{\rm YM}$, a positive rank N, and the induced large-N Chern–Simons level coordinate*

$$K = N + k_{\rm YM}.$$

Let

$$\lambda_{\rm B} := \frac{N}{K}, \qquad N_{\rm F} := k_{\rm YM}, \qquad \lambda_{\rm F} := \frac{N_{\rm F}}{K} = 1 - \lambda_{\rm B}. \tag{95.21}$$

The planar bosonization statement asserts that the singlet sector of the regular bosonic $U(N)$ Chern–Simons vector model in its conformal chart is matched, after the scalar Legendre transform described below, to the singlet sector of the fermionic $U(N_{\rm F})$ Chern–Simons vector model with complementary coupling $\lambda_{\rm F}$. The orientation-reversed and negative-level versions are obtained by applying parity to all Chern–Simons contact terms. The statement is a conjectural equality of planar connected correlators of renormalized singlet currents and of their source functional, modulo the allowed local background Chern–Simons counterterms.

This formulation is deliberately weaker than a finite-N duality theorem. It records the observable statement that the planar calculations test. The rank–level map is the vector-model remnant of level–rank duality, but the matter coupling and the critical scalar/fermion Legendre transforms add singlet-source structures that ordinary pure-Chern–Simons level–rank duality does not contain.

Higher-spin parameters and the exact matching algebra. The planar singlet correlators of Chern–Simons vector models may be organized, following the slightly-broken higher-spin Ward identities, by an effective number of degrees of freedom and by a parity-odd deformation coordinate. In the convention of the light-cone calculation used here, the quasi-boson chart has

$$\widetilde{N}_{\rm B} = 2N\,\frac{\sin(\pi\lambda_{\rm B})}{\pi\lambda_{\rm B}}, \qquad \widetilde{\lambda}_{\rm qb} = \tan\left(\frac{\pi\lambda_{\rm B}}{2}\right), \tag{95.22}$$

while the complementary quasi-fermion chart is written with

$$\widetilde{N}_{\rm F} = 2N_{\rm F}\,\frac{\sin(\pi\lambda_{\rm F})}{\pi\lambda_{\rm F}}, \qquad \widetilde{\lambda}_{\rm qf} = \cot\left(\frac{\pi\lambda_{\rm F}}{2}\right). \tag{95.23}$$

Equations (95.21) give the exact identities

$$\widetilde{N}_{\rm B} = \widetilde{N}_{\rm F}, \qquad \widetilde{\lambda}_{\rm qb} = \widetilde{\lambda}_{\rm qf}. \tag{95.24}$$

Indeed $N/\lambda_{\rm B} = K = N_{\rm F}/\lambda_{\rm F}$, and $\sin(\pi\lambda_{\rm F}) = \sin(\pi(1-\lambda_{\rm B})) = \sin(\pi\lambda_{\rm B})$. The second identity is

$$\cot\left(\frac{\pi(1-\lambda_{\rm B})}{2}\right) = \tan\left(\frac{\pi\lambda_{\rm B}}{2}\right).$$

Thus the higher-spin parameter matching is not an additional dynamical assumption once the rank–level map and the operator normalizations (95.22)–(95.23) are chosen. The dynamical work is the derivation of the planar correlators and the proof that the continuum conformal charts realizing these parameters exist.

Legendre transform of the scalar singlet. The Bose–Fermi map relates regular and critical vector models. The large-N critical operation is most cleanly stated at the source-functional level. Let J_0 be the scalar singlet, for example $\phi^\dagger\phi$ in the bosonic chart or $\bar{\psi}\psi$ in the fermionic chart, and let $W_{\rm reg}[s]$ denote the planar connected generating functional with source s for J_0, after all contact terms have been fixed. On a source neighborhood where the Hessian

$$\mathcal{G}_{00}(x,y) = \frac{\delta^2 W_{\rm reg}}{\delta s(x)\delta s(y)}$$

has an inverse on the chosen test-function quotient, define the conjugate field

$$\sigma(x) = \frac{\delta W_{\rm reg}}{\delta s(x)}$$

and the Legendre-transformed planar functional

$$W_{\rm crit}[\sigma] = W_{\rm reg}[s] - \int s(x)\sigma(x)\,\mathrm{d}^3x, \qquad \sigma = \frac{\delta W_{\rm reg}}{\delta s}. \tag{95.25}$$

Differentiating (95.25) gives

$$\frac{\delta W_{\rm crit}}{\delta\sigma(x)} = -s(x), \qquad \frac{\delta^2 W_{\rm crit}}{\delta\sigma(x)\delta\sigma(y)} = -\mathcal{G}_{00}^{-1}(x,y).$$

Thus the critical scalar two-point kernel is the inverse, with the displayed sign convention, of the regular scalar-singlet two-point kernel. This operator inversion is the precise large-N content behind the informal phrase that the critical vector model is a Legendre transform of the regular one. Beyond the planar source neighborhood it is not a definition by slogan: one must specify the continuum limit, the test-function space, the contact-term quotient, and the domain on which the inverse exists.

Scope of the planar observable statement. The matching in Conjecture 95.4 concerns the renormalized singlet current algebra generated by the stress tensor, the higher-spin currents at leading large N, and the scalar singlet after the Legendre transform. Colored fundamental fields enter only as variables in a chosen gauge-redundant regulator; line operators, monopole operators, finite-N spectra, background Chern–Simons contact terms, and global forms are additional sectors whose matching must be specified by extra data. The light-front bilocal equations above give one finite-regulator route to the planar correlators; the higher-spin Ward classification gives an independent organization of the same planar correlators. Agreement of the two is strong evidence for the conjectural observable matching, but a proof of the full continuum duality would require a nonperturbative construction of both Chern–Simons–matter theories and an isomorphism of their gauge-invariant observable algebras or of their Kontsevich–Segal assignments.

The source lineage for this large-N matching includes the Maldacena–Zhiboedov higher-spin constraints and the explicit planar Chern–Simons vector-model correlator computations [70, 71, 72]. The citations identify the historical calculations; the status of the statement inside this monograph is the conjectural observable matching and the exact algebraic matching displayed above.

Hypothesis 95.5 (Planar bosonization matching hierarchy)**.** A proof of Conjecture 95.4 in the observable chart used in this chapter should supply a compatible hierarchy of matching data, not only the numerical identification (95.24). The hierarchy consists of:

1. the stress tensor and normalized single-trace higher-spin currents J_s, with the quasi-boson and quasi-fermion parameters identified as in (95.24);
2. the scalar-singlet source map, including the Legendre inversion $\mathcal{G}_{00} \mapsto -\mathcal{G}_{00}^{-1}$ on the contact-term quotient declared in (95.25);
3. the background flavor and topological $U(1)$ Chern–Simons contact coordinates, where integer counterterm shifts are scheme choices but the fractional parity-anomaly data and the relative contact terms must agree under the duality map;
4. the charged extended sector, including Wilson lines, monopole disorder operators, and the integral charge–flux pairing that any proposed line/monopole map has to preserve;
5. the finite-N and global-form completion, including the line lattice, allowed genuine line operators, baryon/monopole identifications, and level–rank contact phases;
6. the common continuum construction: a regulator, conformal tuning, source space, and isomorphism of gauge-invariant observable algebras, or equivalently of the relevant Kontsevich–Segal assignments.

Only the first two items, the integer-contact quotient, and the elementary charge–flux pairing invariant have been reduced in this section to explicit algebraic checks. The actual line lattice, monopole spectrum, finite-N operator map, and full continuum observable algebra are part of the remaining duality problem rather than consequences of the large-N rank–level identity.

This hierarchy is the working standard for future refinements of the Bose–Fermi duality discussion. A new computation of one planar three-point coefficient should be inserted here only if it is attached to the hierarchy: which source convention it fixes, which contact coordinate it shifts, which line/monopole datum it constrains, or which observable-algebra map it helps construct.

95.5 Supersymmetric Chern–Simons–Matter Action

The supersymmetric Chern–Simons action contains

$$S_{\mathrm{CS}}^{\mathcal{N}=2} = \frac{k}{4\pi} \int \mathrm{Tr} \left(A \wedge dA + \frac{2}{3} A^3 - \bar{\lambda}\lambda + 2D\sigma \right), \tag{95.26}$$

with the displayed signs defining the convention of this chapter. Let chiral multiplets Φ_i take values in a unitary representation R of G. Their scalar fields are ϕ_i. With real mass parameters m_i, FI coordinate ζ for an abelian factor, and superpotential W, the bosonic potential contains

$$\sum_i |(\sigma + m_i)\phi_i|^2 + \frac{1}{2} \left(\mu(\phi) + \frac{k}{2\pi}\sigma - \zeta \right)^2 + |dW(\phi)|^2, \tag{95.27}$$

in an abelian normalization where μ is the matter moment map. Supersymmetric classical vacua solve

$$dW = 0, \qquad (\sigma + m_i)\phi_i = 0, \qquad \mu(\phi) + \frac{k}{2\pi}\sigma - \zeta = 0, \tag{95.28}$$

modulo gauge transformations.

Remark 95.6 (Auxiliary-field origin of the shifted D-term). In the abelian convention of (95.26), the auxiliary equation shifts the moment-map equation by

$$\mu(\phi) - \zeta \longmapsto \mu(\phi) + \frac{k}{2\pi}\sigma - \zeta.$$

The part of the Lagrangian involving D has the form

$$\frac{1}{2}D^2 + D\big(\mu(\phi) - \zeta\big) + \frac{k}{2\pi}D\sigma,$$

where the last term is the $2D\sigma$ term in (95.26). Completing the square gives

$$\frac{1}{2}\left(D + \mu(\phi) + \frac{k}{2\pi}\sigma - \zeta\right)^2 - \frac{1}{2}\left(\mu(\phi) + \frac{k}{2\pi}\sigma - \zeta\right)^2.$$

Eliminating D leaves the displayed positive potential and hence the vacuum equation (95.28).

Non-abelian Chern–Simons auxiliary elimination. Let G be compact, let R be a unitary representation, and choose Hermitian representation matrices t^a_R with trace convention $\mathrm{Tr}(t^a t^b) = \delta^{ab}$ for the gauge action. Assume $k \neq 0$, no Yang–Mills kinetic term, no FI term, no real mass, and no superpotential. For one chiral multiplet in R, define the finite moment-map coordinates

$$\mu^a(\phi) = \overline{\phi}\, t^a_R \phi.$$

For several chiral multiplets, replace R by the direct sum of their representations, so that μ^a is the sum of the corresponding quadratic coordinates. Then the local non-derivative bosonic component terms involving the Chern–Simons auxiliary scalar $\sigma = \sigma^a t^a$ and the auxiliary field $D = D^a t^a$ may be written as

$$\mathcal{L}_{\text{bos,aux}} = \frac{k}{2\pi} D^a \sigma^a + D^a \mu^a(\phi) - \sigma^a \sigma^b\, \overline{\phi}\, t^a_R t^b_R \phi. \tag{95.29}$$

Eliminating D imposes

$$\sigma^a = -\frac{2\pi}{k}\mu^a(\phi), \tag{95.30}$$

and the remaining scalar interaction is

$$\mathcal{L}_{\text{bos,on-shell}} = -\frac{4\pi^2}{k^2}\big(\overline{\phi}\, t^a_R \phi\big)\big(\overline{\phi}\, t^b_R \phi\big)\big(\overline{\phi}\, t^a_R t^b_R \phi\big). \tag{95.31}$$

Equivalently, the scalar potential contains the positive contribution

$$V_{\text{sextic}} = \frac{4\pi^2}{k^2}\big(\overline{\phi}\, t^a_R \phi\big)\big(\overline{\phi}\, t^b_R \phi\big)\big(\overline{\phi}\, t^a_R t^b_R \phi\big)$$

in the same local coordinates.

The field D is a Lagrange multiplier in the pure Chern–Simons normalization. Varying (95.29) with respect to D^a gives

$$\frac{k}{2\pi}\sigma^a + \mu^a(\phi) = 0,$$

which is (95.30). Substitution into the last term of (95.29) gives

$$-\left(-\frac{2\pi}{k}\mu^a\right)\left(-\frac{2\pi}{k}\mu^b\right)\overline{\phi}\,t_R^a t_R^b\phi = -\frac{4\pi^2}{k^2}\mu^a\mu^b\overline{\phi}\,t_R^a t_R^b\phi.$$

No commutativity of the matrices t_R^a and t_R^b has been used; the ordered product in (95.31) is part of the component convention.

The same finite-dimensional elimination fixes the power of k and the relative sizes of the induced Yukawa terms. The signs of the terms carrying an explicit i depend on the three-dimensional spinor conjugation and on where the i is placed in the Chern–Simons gaugino mass. In the common component convention in which the non-derivative fermion terms are normalized as in the stringbook appendices, one obtains coefficient magnitudes

$$\frac{2\pi}{|k|}\quad\text{for}\quad(\overline{\phi}\,t_R^a\phi)(\overline{\psi}\,t_R^a\psi),\qquad\frac{4\pi}{|k|}\quad\text{for}\quad(\overline{\psi}\,t_R^a\phi)(\overline{\phi}\,t_R^a\psi).$$

Thus the convention-independent check is the $1:2$ relative coefficient and the single inverse power of k; the signed formula must be read only after the spinor bilinear convention has been fixed.

Remark 95.7 ($\mathcal{N}=3$ adjoint-chiral elimination)*.* Let Q and $\widetilde{Q}$ be conjugate chiral multiplets in representations R and $R^\vee$, and let $\varphi=\varphi^a t^a$ be an adjoint chiral multiplet. With the same trace convention as above, set

$$J^a=\widetilde{Q}\,t_R^a Q.$$

The $\mathcal{N}=3$ Chern–Simons-matter superpotential

$$W(\varphi,Q,\widetilde{Q})=-\frac{k}{8\pi}\varphi^a\varphi^a+J^a\varphi^a$$

has algebraic φ-equation

$$\varphi^a=\frac{4\pi}{k}J^a,$$

and the exact tree-level effective superpotential after eliminating φ is

$$W_{\text{eff}}(Q,\widetilde{Q})=\frac{2\pi}{k}J^aJ^a=\frac{2\pi}{k}\big(\widetilde{Q}\,t_R^aQ\big)\big(\widetilde{Q}\,t_R^aQ\big).$$

The F-term equation is

$$-\frac{k}{4\pi}\varphi^a+J^a=0.$$

Therefore $\varphi^a=4\pi J^a/k$. Substitution gives

$$-\frac{k}{8\pi}\left(\frac{4\pi}{k}\right)^2J^aJ^a+\frac{4\pi}{k}J^aJ^a=-\frac{2\pi}{k}J^aJ^a+\frac{4\pi}{k}J^aJ^a=\frac{2\pi}{k}J^aJ^a.$$

The calculation is an elimination in the polynomial chiral ring, so it does not use a string-theoretic realization of the same Lagrangian.

95.6 Parity Anomaly And Contact Terms

A massive three-dimensional Dirac fermion in representation R shifts the effective Chern–Simons level by

$$\Delta k = \frac{1}{2}\,\mathrm{sign}(m)\,T(R),$$

where

$$\mathrm{Tr}_R(t^a t^b) = T(R)\delta^{ab}$$

in the trace convention used for the gauge action. Therefore a massless fermion coupled to a gauge field requires a choice of regulator that fixes the integer or half-integer effective level. This choice is part of the definition of the continuum theory and of its time-reversal or parity properties.

Background flavor and R-symmetry Chern–Simons terms are equally important. Two proposed dual theories with the same local operator spectrum can still differ as QFTs if their background contact terms differ. In localization formulae these contact terms appear as phases or Gaussian factors in the Cartan variables; they are not disposable normalizations.

95.7 Monopole Operators

Let G have maximal torus T. A monopole operator at the origin is defined by imposing a magnetic singularity on a small sphere:

$$\frac{1}{2\pi}\int_{S^2} F = m \in \mathrm{Hom}(U(1), T)/W_G.$$

The local operator is gauge invariant only after its electric charges induced by Chern–Simons terms and fermion zero modes are accounted for. In an abelian theory with level k, Gauss law gives electric charge

$$q_{\mathrm{el}} = k\,m$$

for a bare monopole of magnetic charge m. Gauge-invariant monopole operators may require dressing by charged matter fields.

This point is not optional in supersymmetric Chern–Simons–matter theory. Monopole operators can carry flavor and R-charges, can complete multiplets that are invisible in a polynomial superfield presentation, and can change the apparent global symmetry of the interacting fixed point. Thus a Lagrangian written in $\mathcal{N} = 2$ variables may describe a theory with larger supersymmetry only after the monopole sectors are included.

95.8 ABJM Gauge-Theory Specification

Fix integers $N \geq 1$ and $k \neq 0$. The ABJM gauge group and levels are

$$G_{N,k} = U(N)_k \times U(N)_{-k},$$

with connections A and $\widehat{A}$. The subscript means that the Chern–Simons functional of A has level k, while that of $\widehat{A}$ has level $-k$, in the same trace normalization. The global form of the gauge group and the quotient by any diagonal one-form symmetry affect line operators and must be declared in a fully specified theory. In this chapter $U(N) \times U(N)$ denotes the standard ABJM choice used for the local-operator and S^3 partition-function formulae.

In $\mathcal{N} = 2$ language the matter consists of four chiral multiplets

$$A_a \in (\mathbf{N}, \overline{\mathbf{N}}), \qquad B_{\dot a} \in (\overline{\mathbf{N}}, \mathbf{N}), \qquad a, \dot a = 1, 2.$$

The classical superpotential is

$$W_{\text{ABJM}} = \frac{2\pi}{k} \varepsilon^{ab} \varepsilon^{\dot a \dot b} \operatorname{Tr}\big(A_a B_{\dot a} A_b B_{\dot b}\big). \tag{95.32}$$

The trace is over the first $U(N)$ gauge indices, so every product in (95.32) is an endomorphism of the first gauge factor. The displayed coefficient fixes the convention in which the Yukawa and sextic scalar terms assemble into the $\mathcal{N} = 6$ invariant potential after auxiliary fields are eliminated. The $\mathcal{N} = 2$ trial R-charge assignment

$$R(A_a) = R(B_{\dot a}) = \frac{1}{2}$$

gives $R(W_{\text{ABJM}}) = 2$, as required for a superpotential term.

The scalar variables can be grouped as

$$C_I = (A_1, A_2, B_1^\dagger, B_2^\dagger), \qquad I = 1, \dots, 4.$$

The interacting theory has an $SU(4)$ flavor symmetry rotating the C_I in the $\mathcal{N} = 6$ presentation. This is a field-theory statement about the completed gauge theory, including monopole sectors and the Chern–Simons Gauss law. The holomorphic $\mathcal{N} = 2$ superpotential variables display only one coordinate presentation of this symmetry.

Parity and the opposite levels. Let P be an orientation-reversing diffeomorphism of the three-manifold. The Chern–Simons functional changes sign under P. Therefore the pair of levels $(k, -k)$ is invariant under the combined operation

$$P: \quad A \longleftrightarrow \widehat{A}, \qquad A_a \longleftrightarrow B_{\dot a}^\dagger,$$

up to the corresponding exchange of flavor indices and spinor conventions: under an orientation reversal the integral of a three-form changes sign, so

$$S_{\text{CS,k}}[A] \mapsto -S_{\text{CS,k}}[P^* A].$$

Exchanging the two gauge factors sends the level k contribution to the sector that originally carried level $-k$, and conversely. Hence the sum

$$S_{\text{CS,k}}[A] + S_{\text{CS,}-\text{k}}[\widehat{A}]$$

is mapped to itself after relabeling the two connections. The matter exchange identifies the bifundamental and antibifundamental representations, so the gauge-covariant kinetic terms and the quartic superpotential are carried into their complex conjugate form with the same real action.

95.9 ABJM Conformal Locus And Marginal Couplings

The ABJM family is often described as if a Chern–Simons level were an ordinary coupling. For conformal-manifold questions this is the wrong category: the level is part of the topological gauge specification and is quantized by large gauge transformations. We first state the local notion being used.

Definition 95.8 (Local conformal manifold in a fixed QFT specification)**.** Fix a d-dimensional continuum QFT specification $\mathfrak{D}$, including the global form of the gauge group, line-operator lattice, spin and framing choices, background contact-term scheme, and the global or supersymmetry algebra required to be preserved. A local conformal manifold through a conformal theory $\mathcal{T}_0$ with specification $\mathfrak{D}$ is a germ of a smooth parameter space U and a family $\{\mathcal{T}_u\}_{u\in U}$ of conformal QFTs with the same specification such that tangent vectors at 0 are represented by integrated scalar primary deformations

$$\delta S = \sum_a \delta u^a \int d^d x\, \mathcal{O}_a(x), \qquad \Delta(\mathcal{O}_a) = d,$$

modulo redundant deformations coming from total derivatives, symmetry variations, and field-coordinate changes. A marginal Lagrangian parameter is exactly marginal only after it defines such a tangent vector with all beta functions and background contact terms remaining inside $\mathfrak{D}$.

Hypothesis 95.9 (Standard ABJM conformal class)**.** In this section "standard ABJM" means the local theory with gauge specification

$$U(N)_k \times U(N)_{-k}, \qquad k \in \mathbb{Z} \setminus \{0\},$$

the four bifundamental chiral multiplets of Section 95.8, zero real masses, zero FI coordinates, the standard line-operator lattice used in the S^3 localization formula, and the interacting $\mathcal{N} = 6$ superconformal symmetry with $SU(4)$ flavor symmetry. Within this class the quartic superpotential tensor is the one in (95.32); closure of the enhanced supersymmetry fixes its coefficient to

$$h_{\mathrm{ABJM}} = \frac{2\pi}{k}$$

in the component convention of this chapter. Deformations that keep only $\mathcal{N} = 2$, change the flavor symmetry, change the line lattice, or alter background contact terms are different QFT specifications and are not counted as tangent vectors to this standard ABJM conformal class.

Remark 95.10 (Standard ABJM has no continuous conformal coupling). Assume Hypothesis 95.9. At fixed (N, k) the local conformal-manifold germ of the standard ABJM specification is zero-dimensional. The standard ABJM theories form a discrete family indexed by the integer level k, with k and $-k$ related when one includes orientation reversal and exchange of the two gauge factors as described above.

The Chern–Simons levels are not coordinates on a real or complex manifold. Gauge invariance of $\exp(\mathrm{i}S_{\mathrm{CS}})$ under large gauge transformations restricts the levels to an integral lattice. Hence an infinitesimal deformation preserving the same gauge specification has

$$\delta k = 0.$$

The opposite-level condition in the standard ABJM specification also fixes the second level to be $-k$, so there is no independent continuous level direction.

The quartic superpotential is power-counting marginal in an $\mathcal{N}=2$ description: the chiral fields have protected $\Delta = R = \frac{1}{2}$ at the ABJM point, so the quartic monomial has dimension 2, and the $d^2\theta$ measure has dimension 1 in three dimensions. Power-counting marginality, however, is only a necessary test. Inside the standard $\mathcal{N}=6$ ABJM class the same coefficient is fixed by the supersymmetry-completion condition

$$h = h_{\mathrm{ABJM}} = \frac{2\pi}{k}.$$

Therefore

$$\delta h = -\frac{2\pi}{k^2}\,\delta k = 0$$

for a tangent vector that preserves the standard ABJM specification.

The remaining familiar Lagrangian coordinates do not give exactly marginal directions in this class. Real masses and FI coordinates have engineering dimension 1 in three dimensions and break part of the conformal or flavor specification. A Yang–Mills kinetic term, if introduced as a regulator or UV completion coordinate, carries a dimensionful coupling

$$[g_{\mathrm{YM}}^2] = 1$$

and is not a scalar-primary deformation of dimension 3 of the conformal theory. Background Chern–Simons contact terms are quantized scheme data, not continuous local-operator deformations. Thus every allowed tangent vector in the fixed standard ABJM specification is redundant or zero.

This remark is deliberately narrower than a classification theorem for all three-dimensional $\mathcal{N}=2$ Chern–Simons–matter theories with the same gauge group. If the $SU(4)$ symmetry, the $\mathcal{N}=6$ completion, or the standard line and contact-term data are relaxed, quartic marginal candidates must be analyzed by their own beta functions, current moment maps, and monopole-sector constraints. They are not continuous coordinates on the standard ABJM conformal locus just defined.

95.10 ABJM Classical Moduli Space

The vacuum equations of the $G_{N,k}$ theory are not those of an ordinary Yang–Mills quotient: the Chern–Simons auxiliary fields identify moment-map coordinates with vector-multiplet scalars. A useful branch is the commuting branch, where the four complex scalar matrices are simultaneously diagonal after gauge transformations:

$$C_I = \mathrm{diag}(c_{I,1}, \ldots, c_{I,N}), \qquad I = 1, \ldots, 4.$$

For generic diagonal eigenvalues the residual gauge group is the permutation group S_N, together with abelian gauge transformations acting on each eigenvalue.

Rank-one abelian quotient. For $N = 1$, set $C = (C_1, \ldots, C_4)$. The classical ABJM branch is

$$\mathcal{M}^{\mathrm{cl}}_{1,k} = \mathbb{C}^4/\mathbb{Z}_k,$$

where the generator of $\mathbb{Z}_k$ acts by simultaneous phase rotation

$$(C_1, \ldots, C_4) \longmapsto \big(\mathrm{e}^{2\pi\mathrm{i}/k} C_1, \ldots, \mathrm{e}^{2\pi\mathrm{i}/k} C_4\big).$$

For $U(1)_k \times U(1)_{-k}$, every matter scalar has charge $+1$ under the anti-diagonal gauge parameter and charge 0 under the diagonal gauge parameter. Put

$$A_D = A + \widehat{A}, \qquad B = A - \widehat{A}.$$

On a closed three-manifold the abelian Chern–Simons term is, up to the declared boundary convention,

$$\frac{k}{4\pi}\int (A \wedge dA - \widehat{A} \wedge d\widehat{A}) = \frac{k}{4\pi}\int B \wedge dA_D. \tag{95.33}$$

Thus the diagonal gauge field acts as a Lagrange multiplier for the anti-diagonal flux, while the anti-diagonal gauge field is the one seen by the matter. Dualizing the flat diagonal connection gives a periodic scalar. Large shifts of that scalar leave a residual anti-diagonal gauge transformation of order k. This residual transformation multiplies every C_I by $\mathrm{e}^{2\pi \mathrm{i}/k}$. Therefore the continuous anti-diagonal phase quotient is accompanied by the finite residual quotient $\mathbb{Z}_k$, giving $\mathbb{C}^4/\mathbb{Z}_k$.

Quoted Theorem 95.11 (ABJM commuting-branch moduli space)**.** *For the $U(N)_k \times U(N)_{-k}$ ABJM theory, the branch obtained from simultaneously diagonalizable scalar vacuum expectation values has classical moduli space*

$$\mathcal{M}^{\mathrm{cl}}_{N,k} = \big((\mathbb{C}^4/\mathbb{Z}_k)^N\big)/S_N.$$

For $k = 1, 2$ the interacting theory has enhanced $\mathcal{N} = 8$ supersymmetry; for $|k| > 2$ the standard interacting theory has $\mathcal{N} = 6$ supersymmetry. The enhancement statement uses monopole operators and requires data beyond the polynomial superpotential.

The theorem is quoted here because the full statement identifies quantum operator sectors, monopole operators, and the global form of the gauge group. The finite quotient in the rank-one calculation above is the intrinsic gauge-theory convention that fixes the k-dependent orbifold action used later in localization and protected-sector comparisons.

95.11 ABJM Localization Specialization

The S^3 localization formula of Chapter 101 specializes to ABJM when all four chiral multiplets have R-charge $1/2$ and zero real mass. For Cartan variables

$$\lambda_i, \mu_j \in \mathbb{R}, \qquad i, j = 1, \dots, N,$$

associated respectively to the two $U(N)$ factors, the matrix integral is

$$\begin{aligned} Z^{\mathrm{ABJM}}_{S^3}(N,k) = \frac{1}{(N!)^2}\int_{\mathbb{R}^{2N}} \prod_{i=1}^{N} d\lambda_i\, d\mu_i\, \exp\left[\mathrm{i}\pi k \sum_i (\lambda_i^2 - \mu_i^2)\right] \\ \times \frac{\prod_{i<j} 4\sinh^2\big(\pi(\lambda_i-\lambda_j)\big)\prod_{i<j} 4\sinh^2\big(\pi(\mu_i-\mu_j)\big)}{\prod_{i,j} 4\cosh^2\big(\pi(\lambda_i-\mu_j)\big)}. \end{aligned} \tag{95.34}$$

The numerator is the product of the two vector-multiplet determinants. The denominator is the product of two conjugate bifundamental chiral pairs: each pair contributes

$$\exp\left[\ell\Big(\frac{1}{2} + \mathrm{i}(\lambda_i - \mu_j)\Big) + \ell\Big(\frac{1}{2} - \mathrm{i}(\lambda_i - \mu_j)\Big)\right] = \frac{1}{2\cosh\big(\pi(\lambda_i - \mu_j)\big)}.$$

The two pairs give $1/(4\cosh^2(\pi(\lambda_i - \mu_j)))$ for each ordered pair (i, j). The oscillatory contour, framing phase, and contact terms are part of the localization input. Thus (95.34) is an exact protected observable once those inputs are supplied. A microscopic construction of the continuum theory requires independent definition of the underlying three-dimensional QFT.

95.12 Sphere Free Energy and F-Monotonicity

Three-dimensional conformal field theories have a distinguished finite observable on the round sphere. It is useful in supersymmetric Chern–Simons–matter theory because localization often reduces it to a finite-dimensional matrix integral, but its definition is not a localization artifact.

Definition 95.12 (Renormalized three-sphere free energy)**.** Let $\mathcal{T}$ be a reflection-positive three-dimensional Euclidean QFT with a specified regulator, background metric coupling, and local counterterm scheme. Its round-sphere partition function at radius r is denoted $Z_{S^3_r}(\mathcal{T})$. At a conformal fixed point, after removing power divergences by the declared local counterterms, the renormalized sphere free energy is

$$F(\mathcal{T}) = -\log |Z_{S^3}(\mathcal{T})| \,. \tag{95.35}$$

The absolute value removes pure phases produced by framing and background Chern–Simons contact terms. It does not remove the obligation to declare the real local counterterm scheme used to define the finite partition function.

In a supersymmetric theory the same definition is evaluated by the localized matrix integral only after the S^3 localization input of Chapter 101 has been supplied: Cartan contour, parity-anomaly regulator, framing phase, real-mass and FI coordinates, and background Chern–Simons counterterms. For ABJM,

$$F_{\mathrm{ABJM}}(N, k) = -\log \left| Z^{\mathrm{ABJM}}_{S^3}(N, k) \right| \tag{95.36}$$

with $Z^{\mathrm{ABJM}}_{S^3}$ defined by (95.34). This is a protected observable of the declared QFT specification; changing the line-operator lattice or contact terms can change phases and, in some schemes, finite background terms.

Remark 95.13 (Conditional status of entropic F-monotonicity)*.* The usual entropic route to three-dimensional F-monotonicity starts from vacuum entanglement for disks, not from a localized matrix integral. At the level of the continuum foundations used in this monograph, that argument is not yet a theorem: a sharp bounded-region local algebra is expected to be type III, has no faithful normal trace, and does not supply an unqualified reduced density matrix whose von Neumann entropy is $S(R)$. The object entering the standard physics argument must therefore be supplied by additional data such as a regulator with a proven continuum limit, a split inclusion with a controlled collar limit, or an AQFT replacement by relative entropy or mutual information.

Under such an additional datum, one may define the renormalized disk quantity

$$\mathcal{F}(R) = R\,\frac{dS(R)}{dR} - S(R), \tag{95.37}$$

where $S(R)$ denotes the regulated or split-limit disk entropy. If strong subadditivity survives the same limit, the Casini–Huerta deformation argument gives $\mathcal{F}(R)$ monotone nonincreasing as

R increases. If, in addition, the conformal map from the causal development of the disk to the hyperbolic thermal problem identifies the fixed-point value of $\mathcal{F}$ with the renormalized sphere free energy in Definition 95.12, then the endpoint consequence is

$$F_{\mathrm{UV}} \geq F_{\mathrm{IR}}. \tag{95.38}$$

Strict inequality, or a rigidity statement characterizing equality as a trivial flow modulo decoupled topological and contact-term data, is an additional input beyond monotone nonincrease.

Open Problem 95.14 (AQFT construction of three-dimensional F-monotonicity). Construct, from the local-algebraic data of a three-dimensional continuum QFT, a regulator-independent quantity that replaces the sharp-disk entropy in (95.37), proves the required monotonicity from relative entropy, split inclusions, or another intrinsic AQFT object, and identifies its conformal fixed-point value with $-\log|Z_{S^3}|$ in a declared background-counterterm scheme.

Remark 95.15 (F-monotonicity is not a matrix-model identity). The conditional monotonicity statement above is a continuum statement about unitary RG flows equipped with the needed entropic or algebraic construction. A localized S^3 matrix model computes F at a supersymmetric fixed point when its localization input is valid; it does not by itself prove monotonicity for flows between two fixed points. Conversely, the expected monotonicity phenomenon is not limited to supersymmetric flows for which a localization formula exists.

Remark 95.16 (Consequences for supersymmetric fixed-point comparisons). Suppose $\mathcal{T}_{\mathrm{UV}} \to \mathcal{T}_{\mathrm{IR}}$ is a three-dimensional unitary RG flow for which the conditional entropic construction in Remark 95.13 has been supplied, and suppose both endpoints have supersymmetric localization data whose finite parts compute the renormalized S^3 partition functions in the scheme of Definition 95.12. Then the localized endpoint comparison reads

$$-\log|Z^{\mathrm{loc}}_{S^3}(\mathcal{T}_{\mathrm{UV}})| \geq -\log|Z^{\mathrm{loc}}_{S^3}(\mathcal{T}_{\mathrm{IR}})|$$

with strictness only after an equality-rigidity input has also been supplied. For a product of decoupled fixed points $\mathcal{T}_1 \otimes \mathcal{T}_2$, the sphere free energy is additive:

$$F(\mathcal{T}_1 \otimes \mathcal{T}_2) = F(\mathcal{T}_1) + F(\mathcal{T}_2). \tag{95.39}$$

The first assertion is the conditional inequality (95.38) after identifying the endpoint F's with the localized finite parts. This identification is an endpoint statement: it uses the localization input at the fixed point and does not require a localized description of the entire RG trajectory.

For the product statement, the Hilbert space, operator algebra, and Euclidean functional integral factorize. With product regulators and counterterm schemes,

$$Z_{S^3}(\mathcal{T}_1 \otimes \mathcal{T}_2) = Z_{S^3}(\mathcal{T}_1) Z_{S^3}(\mathcal{T}_2).$$

Taking $-\log|\cdot|$ gives (95.39). Possible background contact terms also add because they are local functionals of the external fields.

Example 95.17 (Free chiral multiplet and a massive flow)**.** For a free $\mathcal{N}=2$ chiral multiplet of R-charge $1/2$ and no background mass, the round-sphere determinant convention of Chapter 101 gives

$$Z_{\mathrm{chiral}} = \exp \ell\left(\frac{1}{2}\right) = 2^{-1/2}, \qquad F_{\mathrm{chiral}} = \frac{1}{2}\log 2. \tag{95.40}$$

Giving this chiral multiplet a supersymmetric real mass and flowing to energies much smaller than $|m|$ leaves the empty gapped theory, whose non-topological sphere free energy is 0 in the same normalization. The flow therefore has

$$F_{\text{UV}} = \frac{1}{2}\log 2 > 0 = F_{\text{IR}},$$

consistent with the expected F-monotonicity pattern. This example is simple, but it fixes the normalization used when more complicated localized matrix integrals are compared.

Rank-one ABJM sphere integral. With the oscillatory contour and framing convention implicit in (95.34), the $N = 1$ ABJM matrix integral evaluates distributionally to

$$Z_{S^3}^{\text{ABJM}}(1, k) = \frac{1}{4|k|}, \qquad F_{\text{ABJM}}(1, k) = \log(4|k|). \tag{95.41}$$

For $N = 1$, the vector Vandermonde factors are absent and (95.34) becomes

$$Z = \int_{\mathbb{R}^2} d\lambda\, d\mu\, \frac{\exp\{\mathrm{i}\pi k(\lambda^2 - \mu^2)\}}{4\cosh^2(\pi(\lambda - \mu))}.$$

Set

$$x = \lambda - \mu, \qquad y = \lambda + \mu.$$

Then $d\lambda\, d\mu = \frac{1}{2}\, dx\, dy$ and $\lambda^2 - \mu^2 = xy$. In the oscillatory distribution sense,

$$\int_{-\infty}^{\infty} dy\, \mathrm{e}^{\mathrm{i}\pi kxy} = 2\,\delta(kx) = \frac{2}{|k|}\delta(x).$$

Therefore

$$Z = \frac{1}{2}\int dx\, \frac{1}{4\cosh^2(\pi x)}\frac{2}{|k|}\delta(x) = \frac{1}{4|k|}.$$

Taking the absolute value and then $-\log$ gives the displayed free energy.

95.13 ABJM Fermi-Gas Form and Airy Asymptotics

The ABJM sphere integral has a second exact representation which is useful because it separates three logically different statements:

1. the finite-dimensional localization integral (95.34);
2. an algebraic rewriting of that integral as the canonical partition function of N noninteracting fermions with a one-particle density operator;
3. the large-N Airy behavior that follows when the grand potential of that one-particle operator has a cubic perturbative part.

Only the second item is a change of variables in the localized integral. It does not define the continuum ABJM theory and it does not replace the localization hypotheses. Throughout this section take $k > 0$; negative level is obtained by orientation reversal and complex conjugation of the Chern–Simons phase.

Let $\hbar = 2\pi k$, let q denote multiplication on $L^2(\mathbb{R}, dq)$, and let $p = -\mathrm{i}\hbar\, d/dq$. Define

$$u(q) = \frac{1}{\sqrt{2\cosh(q/2)}}, \qquad v(p) = \frac{1}{2\cosh(p/2)}.$$

The ABJM one-particle density operator is

$$\rho_k = u(q)\, v(p)\, u(q). \tag{95.42}$$

Equivalently, in the q-representation,

$$\rho_k(q, q') = \frac{1}{2\pi k} \frac{1}{\sqrt{2\cosh(q/2)}} \frac{1}{2\cosh\left(\frac{q-q'}{2k}\right)} \frac{1}{\sqrt{2\cosh(q'/2)}}. \tag{95.43}$$

Lemma 95.18 (Trace-class normalization of the ABJM kernel)**.** *The operator ρ_k in* (95.42) *is positive and trace class. Its first trace is*

$$\mathrm{Tr}_{\mathcal{H}}\, \rho_k = \frac{1}{4k}. \tag{95.44}$$

Proof. Use the unitary Fourier transform normalized by

$$\langle q|p\rangle = (2\pi\hbar)^{-1/2} \mathrm{e}^{\mathrm{i}qp/\hbar}.$$

The multiplication operator $v(p)$ is positive. Hence

$$\rho_k = \left(v(p)^{1/2} u(q)\right)^* \left(v(p)^{1/2} u(q)\right)$$

is positive. The operator $v(p)^{1/2}u(q)$ is Hilbert–Schmidt, because its p, q kernel has squared norm

$$\int_{\mathbb{R}^2} \frac{dp\, dq}{2\pi\hbar} \frac{1}{2\cosh(p/2)} \frac{1}{2\cosh(q/2)} < \infty.$$

Therefore $\rho_k = T^*T$ with T Hilbert–Schmidt, so ρ_k is trace class. For a positive operator written in this form, $\mathrm{Tr}(T^*T) = \|T\|_{\mathrm{HS}}^2$; thus the trace can be computed either from the Hilbert–Schmidt integral or from the diagonal of the continuous kernel below. This avoids using any formal delta-function trace.

The Fourier integral

$$\int_{-\infty}^{\infty} \frac{dp}{2\pi\hbar} \frac{\mathrm{e}^{\mathrm{i}p(q-q')/\hbar}}{2\cosh(p/2)} = \frac{1}{2\pi k} \frac{1}{2\cosh\left(\frac{q-q'}{2k}\right)}$$

gives (95.43). On the diagonal,

$$\rho_k(q, q) = \frac{1}{2\pi k} \frac{1}{4\cosh(q/2)}.$$

Since

$$\int_{-\infty}^{\infty} \frac{dq}{\cosh(q/2)} = 2\pi,$$

the trace is $1/(4k)$. □

Quoted Theorem 95.19 (Finite ABJM Fermi-gas identity)**.** *For $k > 0$, the ABJM localization integral* (95.34) *is equal to*

$$Z_{S^3}^{\mathrm{ABJM}}(N,k) = \frac{1}{N!}\int_{\mathbb{R}^N}\prod_{i=1}^{N} dq_i \det_{1\le i,j\le N}\rho_k(q_i,q_j). \tag{95.45}$$

Remark 95.20 (What enters the finite identity)*.* The identity is finite-dimensional algebra inside the localized matrix model, not a holographic or continuum-existence statement. Its input is the change of variables

$$x_i = 2\pi\lambda_i, \qquad y_i = 2\pi\mu_i.$$

The main determinant step is the hyperbolic Cauchy identity

$$\frac{\prod_{i<j} 2\sinh\left(\frac{x_i-x_j}{2}\right)\prod_{i<j} 2\sinh\left(\frac{y_i-y_j}{2}\right)}{\prod_{i,j} 2\cosh\left(\frac{x_i-y_j}{2}\right)} = \det_{i,j}\frac{1}{2\cosh\left(\frac{x_i-y_j}{2}\right)}. \tag{95.46}$$

It follows from the ordinary Cauchy identity after setting $X_i = \mathrm{e}^{x_i}$, $Y_j = \mathrm{e}^{y_j}$ and extracting monomials from rows and columns. Squaring (95.46) rewrites the Vandermonde ratio in (95.34) as a product of determinants. The remaining step is a Gaussian Fourier transform plus a unitary phase conjugation. Phase conjugation leaves every Fredholm minor unchanged:

$$\det\left[\mathrm{e}^{\mathrm{i}kq_i^2/4\pi}\rho_k(q_i,q_j)\mathrm{e}^{-\mathrm{i}kq_j^2/4\pi}\right]_{i,j=1}^{N} = \det[\rho_k(q_i,q_j)]_{i,j=1}^{N}.$$

The Fourier normalization is the one displayed in the proof of Lemma 95.18. For $N=1$, (95.45) gives $\operatorname{Tr}\rho_k = 1/(4k)$, agreeing with the rank-one sphere-integral calculation above.

Definition 95.21 (ABJM grand partition function)**.** The grand partition function attached to the ABJM Fermi-gas operator is

$$\Xi_k(\kappa) = \det_{\mathcal{H}}(1+\kappa\rho_k), \qquad \kappa = \mathrm{e}^{\mu}, \tag{95.47}$$

and its logarithm

$$J_k(\mu) = \log \Xi_k(\mathrm{e}^{\mu}) \tag{95.48}$$

is the grand potential.

Lemma 95.22 (Fredholm expansion and canonical coefficients)**.** *Let ρ be a trace-class operator on $L^2(\mathbb{R}, dq)$ with integral kernel $\rho(q,q')$. Then*

$$\det(1+\kappa\rho) = \sum_{N=0}^{\infty}\kappa^N\frac{1}{N!}\int_{\mathbb{R}^N}\prod_{i=1}^{N} dq_i \det_{i,j}\rho(q_i,q_j). \tag{95.49}$$

Consequently the coefficient of κ^N in $\Xi_k(\kappa)$ is the ABJM sphere partition function $Z_{S^3}^{\mathrm{ABJM}}(N,k)$.

Proof. For finite-rank

$$\rho = \sum_{a=1}^{r} s_a\,|\psi_a\rangle\langle\phi_a|$$

with $\psi_a, \phi_a \in L^2(\mathbb{R})$, the nonzero spectrum of ρ is the spectrum of the $r \times r$ matrix

$$M_{ab} = s_a \langle \phi_a, \psi_b \rangle.$$

Thus $\det(1+\kappa\rho) = \det_r(1+\kappa M)$. On the other hand the N-th integral minor is the trace of the exterior power $\wedge^N \rho$:

$$\operatorname{Tr}(\wedge^N \rho) = \frac{1}{N!} \int_{\mathbb{R}^N} \prod_{i=1}^{N} dq_i \, \det_{i,j} \rho(q_i, q_j).$$

Indeed, expanding $\det_{i,j} \rho(q_i, q_j)$ in the displayed finite-rank decomposition and integrating the alternating products gives exactly the Cauchy–Binet formula for the $N \times N$ principal exterior minors of M. Summing these exterior traces gives the characteristic-polynomial identity

$$\det(1+\kappa\rho) = \sum_{N=0}^{r} \kappa^N \operatorname{Tr}(\wedge^N \rho).$$

For a general trace-class ρ, choose finite-rank $\rho_m \to \rho$ in trace norm. The Fredholm determinant is defined by the absolutely convergent series

$$\det(1+\kappa\rho) = \sum_{N=0}^{\infty} \kappa^N \operatorname{Tr}(\wedge^N \rho), \qquad |\operatorname{Tr}(\wedge^N \rho)| \le \frac{\|\rho\|_1^N}{N!},$$

and the same estimate, applied to multilinear differences of exterior powers, gives

$$\operatorname{Tr}(\wedge^N \rho_m) \to \operatorname{Tr}(\wedge^N \rho)$$

for each N, with a locally uniform majorant in κ. Hence the finite-rank identities pass to the trace-norm limit and yield (95.49). For the ABJM kernel, the unitary conjugation used above leaves all minors invariant and Quoted Theorem 95.19 identifies the N-th coefficient with the localized S^3 integral $Z_{S^3}^{\mathrm{ABJM}}(N,k)$. □

Leading phase-space coefficient. The leading Weyl coefficient of the ABJM Fermi gas is

$$C_k = \frac{2}{\pi^2 k}. \tag{95.50}$$

Equivalently, the leading large-μ contribution to the grand potential is

$$J_k(\mu) = \frac{C_k}{3}\mu^3 + \text{lower powers of } \mu \qquad (\mu \to +\infty) \tag{95.51}$$

at fixed k.

The classical symbol of ρ_k^{-1} is

$$\exp H(q,p), \qquad H(q,p) = \log\Bigl(2\cosh\frac{q}{2}\Bigr) + \log\Bigl(2\cosh\frac{p}{2}\Bigr).$$

For large E, the inequality $H(q,p) \le E$ has the same leading area as

$$\frac{|q|+|p|}{2} \le E,$$

namely a diamond of area $8E^2$. The phase-space cell is

$$2\pi\hbar = 4\pi^2 k.$$

Thus the integrated one-particle density has leading term

$$n(E) = \frac{8E^2}{4\pi^2 k} + O(E) = \frac{2}{\pi^2 k}E^2 + O(E).$$

At zero temperature the leading grand potential is

$$J_k(\mu) = \int_0^\mu n(E)\,dE + \text{lower powers of } \mu = \frac{2}{3\pi^2 k}\mu^3 + \text{lower powers},$$

which gives (95.50).

Quoted Theorem 95.23 (Perturbative ABJM grand potential)**.** *For the trace-class operator ρ_k above, the part of $J_k(\mu)$ which is polynomial in μ in the large-μ spectral expansion is*

$$J_k^{\text{pert}}(\mu) = \frac{C_k}{3}\mu^3 + B_k\mu + A_k, \qquad C_k = \frac{2}{\pi^2 k}, \qquad B_k = \frac{k}{24} + \frac{1}{3k}. \tag{95.52}$$

The remaining terms in $J_k(\mu)$ are exponentially small in μ within the spectral expansion and encode nonperturbative corrections to the canonical large-N answer. The coefficient A_k is independent of μ and depends on the normalization of the exact spectral determinant.

The inverse Laplace transform of a cubic perturbative grand potential is an Airy function. Assume

$$J^{\text{pert}}(\mu) = \frac{C}{3}\mu^3 + B\mu + A, \qquad C > 0. \tag{95.53}$$

Define the perturbative canonical coefficient by the inverse Laplace transform

$$Z_N^{\text{pert}} = \int_{\mathcal{C}} \frac{d\mu}{2\pi\mathrm{i}}\, \exp\bigl(J^{\text{pert}}(\mu) - N\mu\bigr)\,, \tag{95.54}$$

where $\mathcal{C}$ is the standard Airy contour. Then

$$Z_N^{\text{pert}} = \mathrm{e}^A\, C^{-1/3}\, \mathrm{Ai}\Bigl(C^{-1/3}(N-B)\Bigr)\,. \tag{95.55}$$

For ABJM this gives

$$Z_{S^3}^{\text{ABJM,pert}}(N,k) = \mathrm{e}^{A_k}\, C_k^{-1/3}\, \mathrm{Ai}\Bigl(C_k^{-1/3}(N-B_k)\Bigr)\,, \tag{95.56}$$

with C_k, B_k as in (95.52). Set $t = C^{1/3}\mu$. Then $d\mu = C^{-1/3}dt$ and

$$\frac{C}{3}\mu^3 - (N-B)\mu = \frac{t^3}{3} - C^{-1/3}(N-B)t.$$

Therefore

$$Z_N^{\text{pert}} = \mathrm{e}^A C^{-1/3} \int_{\mathcal{C}_A} \frac{dt}{2\pi\mathrm{i}}\, \exp\left(\frac{t^3}{3} - C^{-1/3}(N-B)t\right)\,.$$

The last integral is the contour definition of the Airy function $\mathrm{Ai}(z)$ with $z = C^{-1/3}(N-B)$. This proves (95.55). Substituting the ABJM coefficients gives (95.56).

Remark 95.24 (Status of the ABJM Airy formula). The Airy function in (95.56) is an exact consequence of the cubic perturbative grand potential; it is not by itself a statement about the full finite-N sphere partition function. The full Fredholm determinant $\Xi_k(\kappa)$ also contains exponentially small spectral corrections, and their inverse Laplace transforms correct the Airy expression. Thus the logically complete chain is: localization matrix integral, Fermi-gas Fredholm determinant, spectral large-μ expansion, Airy transform of the cubic part, and then nonperturbative corrections. Confusing the last two steps is a common source of overstated "exact large-N" claims.

95.14 Three-Dimensional Dynamics Summary

A complete $3D$ supersymmetric Chern–Simons–matter example must specify:

$$G, \quad k, \quad R, \quad W, \quad \zeta, \quad m_i,$$
$$\text{spin structure and framing data}, \quad \text{parity-anomaly regulator},$$
$$\text{monopole-operator dressing rules}, \quad \text{boundary and global-form choices}.$$

For ABJM this list becomes

$$U(N)_k \times U(N)_{-k}, \quad A_a, B_{\dot{a}}, \quad W_{\text{ABJM}},$$
$$\text{the discrete level } k \text{ and the zero-dimensional standard conformal locus},$$
$$\text{the chosen global form and line-operator lattice},$$
$$\text{the monopole sectors implementing the } SU(4) \text{ symmetry and possible } \mathcal{N}=8 \text{ enhancement},$$
$$\text{and the } S^3 \text{ contour, framing, and contact-term convention}.$$

Duality proposals compare these full data, including contact terms and background Chern–Simons counterterms.

Open Problem 95.25 (Three-dimensional supersymmetric continuum schemes). Construct $3D$ supersymmetric Chern–Simons–matter theories with a regulator preserving the stated gauge and supersymmetry Ward identities, including parity-anomaly choices, monopole-operator definitions, boundary conditions, contact-term coordinates, and global-form data.

Chapter 96

Six-Dimensional Superconformal Theories

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Six-dimensional superconformal theories are QFTs whose central examples do not admit ordinary Lagrangian descriptions at the fixed point. They therefore force a separation between the definition of a theory and the use of effective field variables on a branch of vacua. This chapter records the objects that can be defined without assuming a microscopic Lagrangian: superconformal representation data, tensor-branch effective actions, anomaly polynomials, BPS strings, compactification tests, and extended operators. The emphasis is the $(2,0)$ family and the adjacent $(1,0)$ tensor-branch formalism, because these are the supersymmetric field theories that most sharply test the distinction between protected data and construction of a local QFT.

Hypothesis 96.1 ($(2,0)$ theory of ADE type)**.** Let $\mathfrak{g}$ be a simply laced complex simple Lie algebra of type A, D, or E, with Cartan algebra $\mathfrak{t}_\mathfrak{g}$, Weyl group $W_\mathfrak{g}$, root lattice $Q_\mathfrak{g}$, weight lattice $P_\mathfrak{g}$, rank $r_\mathfrak{g}$, dimension $d_\mathfrak{g}$, and dual Coxeter number $h^\vee_\mathfrak{g}$. In this chapter the symbol

$$\mathfrak{T}_{6d}[\mathfrak{g}]$$

denotes an assumed six-dimensional local QFT with the following defining properties.

(i) It is a positive-energy $(2,0)$ superconformal QFT with superconformal algebra $OSp(8^*|4)$ and $USp(4)_R \simeq \mathrm{Spin}(5)_R$ R-symmetry.

(ii) Its generic tensor branch, after removing a decoupled center-of-mass free tensor multiplet when present, has scalar coordinate space

$$\big(\mathbb{R}^5 \otimes \mathfrak{t}_{\mathfrak{g}}\big)/W_{\mathfrak{g}},$$

and its low-energy abelian tensor fields are quantized with string-charge lattice $Q_{\mathfrak{g}}$ and Cartan pairing.

(iii) Its anomaly polynomial is

$$I_8[\mathfrak{g}] = r_{\mathfrak{g}} I_8(1) + \frac{d_{\mathfrak{g}} h_{\mathfrak{g}}^{\vee}}{24} p_2(N_R),$$

where N_R is the rank-five $SO(5)_R$ background bundle and $I_8(1)$ is as in (96.6). This is the protected anomaly datum used below; the quoted-theorem boundary is stated at Quoted Theorem 96.6.

(iv) Its BPS string charges on a generic tensor branch are the roots $\alpha \in Q_{\mathfrak{g}}$, with central-charge/tension normalization

$$T_\alpha = |\alpha(\phi)|$$

for $\phi \in \mathbb{R}^5 \otimes \mathfrak{t}_{\mathfrak{g}}$.

(v) Its finite surface-defect charge group is the discriminant group

$$A_{\mathfrak{g}} = P_{\mathfrak{g}}/Q_{\mathfrak{g}},$$

with finite Dirac pairing

$$b_{\mathfrak{g}}([\lambda],[\mu]) = (\lambda,\mu) \bmod \mathbb{Z}.$$

On a closed six-manifold Y, the corresponding finite flux sector is a self-dual finite Heisenberg system built from $H^3(Y; A_{\mathfrak{g}})$ and therefore requires a polarization before it gives a numerical partition function.

(vi) Circle compactification on a circle of radius R, on a branch where the compactified low-energy description is valid, gives five-dimensional maximally supersymmetric Yang–Mills with gauge algebra $\mathfrak{g}$ and trace-delta coupling

$$g_5^2 = 4\pi^2 R.$$

(vii) Riemann-surface compactification is used only with the partial twist and codimension-two defect data specified in Hypothesis 96.10, and only conditioned on existence of the resulting four-dimensional local QFT.

All subsequent uses of $\mathfrak{T}_{6d}[\mathfrak{g}]$ in this chapter are conditional on the existence of a local QFT with these properties. The chapter derives consistency checks and protected consequences from the listed data; it does not construct the interacting six-dimensional local QFT. Open Problem 96.14 records the missing construction problem.

96.1 Construction and Test Architecture

The data in Hypothesis 96.1 should be read as a layered construction target. The first layer is the local fixed-point object: a Hilbert space or equivalent local-QFT presentation with positive-energy $OSp(8^*|4)$ action, stress tensor, local operator algebra, $SO(5)_R$ background coupling, and anomaly functional. This is the layer that would deserve the name “the six-dimensional theory” without qualification. The chapter assumes it through $\mathfrak{T}_{6d}[\mathfrak{g}]$ and derives consequences from the specified properties.

The second layer is the tensor-branch effective description. It supplies abelian self-dual tensor fields, scalar coordinates, the root-lattice string charges, Green–Schwarz couplings, and BPS string central charges. This layer is a branch expansion around separated tensor-branch vacua. It gives local anomaly matching, string-tension formulae, and inflow tests for charged surfaces, and it also records precisely which data become singular at the tensionless origin.

The third layer is the finite global-form and defect datum. The discriminant group $A_{\mathfrak{g}} = P_{\mathfrak{g}}/Q_{\mathfrak{g}}$, the finite pairing $b_{\mathfrak{g}}$, the self-dual finite flux system $H^3(Y; A_{\mathfrak{g}})$, and a maximal-isotropic polarization determine which finite surface-defect charges are genuine in a chosen absolute theory. After circle compactification this same layer becomes the finite global-form choice for line and surface defects in the five-dimensional branch description.

The fourth layer consists of protected compactification tests. Circle compactification compares the BPS string/instanton particle normalization with five-dimensional maximally supersymmetric Yang–Mills and fixes $g_5^2 = 4\pi^2 R$ in trace-delta variables. Riemann-surface compactification, when the class-S datum is supplied, compares the six-dimensional anomaly polynomial with a four-dimensional anomaly pushforward and compares protected Coulomb coordinates with Hitchin-base sections. These compactification tests are stringent because they use the same $\mathfrak{g}$, anomaly, defect, and branch normalizations in lower dimensions.

The fifth layer is the construction frontier. A complete solution would produce the fixed-point local QFT together with the preceding branch, defect, and compactification structures as functorial outputs. The chapter therefore uses the following order: first state the assumed fixed-point datum, then derive branch and anomaly consequences, then expose the finite defect/global-form layer, and finally apply compactification tests. A calculation below should be evaluated by the layer it addresses: local representation theory, branch EFT, anomaly inflow, finite defect polarization, or compactification comparison.

96.2 Six-Dimensional Supersymmetry Data

Let the Lorentz group be $\mathrm{Spin}(1,5)$. A chiral spinor has four complex components before imposing a symplectic-Majorana-Weyl reality condition. Six-dimensional supersymmetry is labeled by $(\mathcal{N}_+, \mathcal{N}_-)$, the numbers of positive and negative chirality symplectic-Majorana-Weyl supercharges. The cases most central for interacting local fixed points are $(1,0)$ and $(2,0)$.

For $(1,0)$, the R-symmetry is $SU(2)_R$. For $(2,0)$, the R-symmetry is $USp(4)_R \simeq \mathrm{Spin}(5)_R$. Superconformal symmetry enlarges the bosonic group to

$$SO(2,6) \times G_R,$$

with $G_R = SU(2)_R$ or $USp(4)_R$. The full superconformal algebras are usually denoted $OSp(8^*|2)$ for $(1,0)$ and $OSp(8^*|4)$ for $(2,0)$. Local operators are organized as positive-energy representations of these algebras on the cylinder. This statement concerns Hilbert-space representation theory; it does not supply off-shell fields.

96.3 Why Six-Dimensional Gauge Fields Are Branch Variables

A six-dimensional vector multiplet can appear in an effective gauge-theory description on a tensor branch, but it is not a conformal gauge field at an interacting fixed point.

Remark 96.2 (Dimension of the Yang–Mills coupling). In a six-dimensional Yang–Mills presentation with canonical gauge field normalization, the gauge coupling has mass dimension -1, equivalently $[g_6^2] = -2$. Hence the local Yang–Mills interaction is not a marginal microscopic coupling of a six-dimensional conformal field theory.

In d spacetime dimensions a canonically normalized vector field has mass dimension

$$[A_\mu] = \frac{d-2}{2}.$$

The covariant derivative is $\partial_\mu + \mathrm{i} g_d A_\mu$, so

$$[g_d] + [A_\mu] = 1.$$

Therefore

$$[g_d] = 1 - \frac{d-2}{2} = \frac{4-d}{2}, \qquad [g_d^2] = 4 - d.$$

Putting $d = 6$ gives $[g_6] = -1$ and $[g_6^2] = -2$. A coupling with negative mass dimension is not a marginal conformal coordinate. Thus any six-dimensional vector-multiplet gauge theory used below is an effective description on a branch, not a Lagrangian definition of the fixed point.

96.4 Multiplets And Self-Dual Fields

A $(1,0)$ tensor multiplet contains a two-form gauge potential B with self-dual field strength, a real scalar ϕ, and fermions. A hypermultiplet contains scalars in quaternionic representations and fermions. A $(2,0)$ tensor multiplet contains

$$B, \qquad \phi^A \ (A = 1, \dots, 5), \qquad \text{fermions},$$

where the five real scalars transform as the vector representation of $\mathrm{Spin}(5)_R$. The field strength

$$H = dB + \cdots$$

obeys a self-duality constraint

$$H = *H.$$

For a nonabelian interacting $(2,0)$ theory there is no known ordinary local action written in terms of nonabelian two-form gauge potentials. Even for abelian self-dual fields, a covariant action requires auxiliary structure or a formulation in which self-duality is imposed after variation. Consequently this chapter states self-dual fields through their equations, charge lattice, anomaly inflow, and compactification tests.

Definition 96.3 (Abelian self-dual tensor system)**.** An abelian six-dimensional tensor sector on a spacetime M_6 consists, locally, of two-form gauge potentials B^I with gauge transformations

$$B^I \longmapsto B^I + d\Lambda^I,$$

three-form field strengths H^I, an integral string-charge lattice $\Lambda_{\rm str}$, and a nondegenerate symmetric Dirac pairing

$$\Omega : \Lambda_{\rm str} \times \Lambda_{\rm str} \longrightarrow \mathbb{Z}.$$

In a topologically trivial local chart without background Chern–Simons corrections, $H^I = dB^I$. Globally, B^I is better regarded as a differential-cohomology field, and the periods of $H^I/2\pi$ pair integrally with string charges. A self-dual tensor field is not specified by an unconstrained Gaussian integral over B^I. Its local equations include a chirality constraint of the form

$$H^I = *H^I$$

after choosing the self-dual subspace determined by the metric and the pairing convention. If both self-dual and anti-self-dual tensors are present, the chirality matrix is correspondingly part of the system.

On-shell degrees of freedom of a chiral two-form. For a free massless two-form gauge potential in six-dimensional Minkowski space, the gauge-invariant one-particle polarizations before imposing self-duality form $\Lambda^2\mathbb{R}^4$, where $\mathbb{R}^4$ is the transverse little-group vector representation. Thus an ordinary two-form has $\binom{4}{2} = 6$ physical bosonic polarizations. The Hodge star on $\Lambda^2\mathbb{R}^4$ squares to 1, so a chiral two-form has

$$\frac{1}{2}\binom{4}{2} = 3$$

physical bosonic polarizations. A free $(2,0)$ tensor multiplet therefore has $3 + 5 = 8$ bosonic on-shell polarizations.

For a massless particle choose momentum k and quotient by gauge transformations $B \mapsto B + k \wedge \lambda$. The physical polarizations are transverse two-forms modulo longitudinal ones; equivalently they are two-forms on the $D-2 = 4$ dimensional transverse representation of the massless little group $SO(4)$. This gives $\binom{4}{2} = 6$ polarizations for an unconstrained two-form. The six-dimensional self-duality condition on the field strength reduces, on the one-particle transverse space, to the four-dimensional decomposition

$$\Lambda^2\mathbb{R}^4 = \Lambda^2_+\mathbb{R}^4 \oplus \Lambda^2_-\mathbb{R}^4, \qquad \dim \Lambda^2_\pm\mathbb{R}^4 = 3.$$

Choosing one chirality leaves three polarizations. The five scalars of the $(2,0)$ tensor multiplet add five further bosonic polarizations, for a total of eight.

96.5 Tensor-Branch Datum

On a tensor branch, expectation values of tensor-multiplet scalars define coordinates

$$\phi^I \in \mathcal{C},$$

where $\mathcal{C}$ is a cone modulo any discrete identifications. The low-energy action contains

$$\frac{1}{2}G_{IJ}\, d\phi^I \wedge *d\phi^J + \frac{1}{2}G_{IJ}\, H^I \wedge *H^J + B^I \wedge X_I^{(4)} + \cdots , \tag{96.1}$$

with self-duality imposed as a constraint on the equations of motion or by a chosen self-dual-field formalism. The four-form $X_I^{(4)}$ encodes gauge, flavor, and gravitational couplings of the branch EFT.

Definition 96.4 (Tensor-branch effective theory)**.** A tensor-branch effective theory consists of

$$\Lambda_{\mathrm{str}}, \quad \Omega_{IJ}, \quad \phi \in \mathcal{C} \subset \Lambda_{\mathrm{str}}^{\vee} \otimes \mathbb{R}^n, \quad B^I,\ H^I,$$
$$X_I^{(4)} \in \Omega^4(M_6), \qquad \text{a self-dual tensor quantization prescription.}$$

The four-forms $X_I^{(4)}$ are built from background gauge, flavor, R-symmetry, and tangent-bundle curvatures. Here $n = 1$ for a $(1,0)$ tensor scalar and $n = 5$ for the $(2,0)$ $\mathrm{Spin}(5)_R$-vector scalar. The cone $\mathcal{C}$ is divided into chambers by loci where charged strings become tensionless. The low-energy formulae on one chamber are not a construction of the fixed point at the chamber wall.

For a $(2,0)$ theory of simply laced type $\mathfrak{g}$, with Cartan algebra $\mathfrak{t}_{\mathfrak{g}}$, rank $r_{\mathfrak{g}}$, and Weyl group $W_{\mathfrak{g}}$, the tensor-branch scalar space has the form

$$\mathcal{C}_{\mathfrak{g}}^{(2,0)} = \left(\mathbb{R}^5 \otimes \mathfrak{t}_{\mathfrak{g}}\right)/W_{\mathfrak{g}}$$

after removing any decoupled center-of-mass tensor multiplet. The five $\mathbb{R}^5$ directions are the $\mathrm{Spin}(5)_R$ vector directions. The Weyl quotient records the identification of Cartan coordinates that survive from the interacting nonabelian theory.

Example 96.5 (Type A_{N-1} tensor branch)**.** For type A_{N-1}, the rank is $N-1$, and the tensor branch may be written as

$$\left\{(x_1, \dots, x_N) \in (\mathbb{R}^5)^N : \sum_{i=1}^{N} x_i = 0\right\}/S_N.$$

The symmetric group permutes the N eigenvalue-like vectors. This formula is a tensor-branch coordinate chart; it is not a definition of the interacting fixed point at the origin $x_i = x_j$.

96.6 Anomaly Polynomial

For a six-dimensional theory coupled to background metric and R-symmetry fields, the anomaly is encoded by an eight-form

$$I_8 \in H^8(BG_{\mathrm{background}}, \mathbb{Q})$$

whose descent gives anomalous variations of the generating functional. For a $(1,0)$ theory one may write

$$I_8 = \alpha\, c_2(R)^2 + \beta\, c_2(R) p_1(T) + \gamma\, p_1(T)^2 + \delta\, p_2(T) + I_8^{\mathrm{flavor}},$$

where $c_2(R)$ is the second Chern class of the $SU(2)_R$ bundle and $p_i(T)$ are Pontryagin classes of the tangent bundle. The coefficients are part of the QFT structure.

On a tensor branch, anomaly matching takes the form

$$I_8^{\mathrm{UV}} - I_8^{\mathrm{branch}} = \frac{1}{2}\Omega^{IJ} X_I^{(4)} X_J^{(4)}, \tag{96.2}$$

where Ω^{IJ} is the inverse tensor pairing. The right-hand side is produced by Green–Schwarz couplings $B^I \wedge X_I^{(4)}$. This equation is a computable constraint on branch EFTs and on proposed fixed points.

Quadratic Green–Schwarz descent calculation. Fix the descent convention in which an anomaly polynomial P_8 contributes

$$\delta_\alpha \Gamma = 2\pi \mathrm{i} \int_{M_6} P_6^{(1)}(\alpha)$$

when $P_8 = dP_7^{(0)}$ and $\delta_\alpha P_7^{(0)} = dP_6^{(1)}(\alpha)$. Suppose

$$X_I^{(4)} = dX_I^{(3)}, \qquad \delta_\alpha X_I^{(3)} = dX_I^{(2)}(\alpha),$$

and Ω^{IJ} is symmetric. Then the quadratic polynomial

$$P_8^{\mathrm{GS}} = \frac{1}{2}\Omega^{IJ} X_I^{(4)} X_J^{(4)} \tag{96.3}$$

has descent representative

$$P_6^{(1),\mathrm{GS}}(\alpha) = \Omega^{IJ} X_I^{(2)}(\alpha) X_J^{(4)}. \tag{96.4}$$

With the sign of the local Green–Schwarz functional chosen so that its variation is $2\pi\mathrm{i}\int P_6^{(1),\mathrm{GS}}$, the tensor-branch matching condition is precisely

$$I_8^{\mathrm{UV}} = I_8^{\mathrm{branch}} + P_8^{\mathrm{GS}}.$$

The substantive six-dimensional input is the anomaly polynomial of the fixed point and of the branch theory; the following calculation fixes the local descent representative and sign convention. Because $X_I^{(4)}$ has even degree, the product $X_I^{(4)} X_J^{(4)}$ is symmetric under $I \leftrightarrow J$. A descent seven-form for (96.3) is

$$P_7^{(0),\mathrm{GS}} = \frac{1}{2}\Omega^{IJ}\big(X_I^{(3)} X_J^{(4)} + X_J^{(3)} X_I^{(4)}\big),$$

which equals $\Omega^{IJ} X_I^{(3)} X_J^{(4)}$ after using the symmetry of Ω^{IJ}. Varying gives

$$\delta_\alpha P_7^{(0),\mathrm{GS}} = \Omega^{IJ} dX_I^{(2)}(\alpha) X_J^{(4)} = d\Big(\Omega^{IJ} X_I^{(2)}(\alpha) X_J^{(4)}\Big),$$

since $dX_J^{(4)} = 0$. This proves (96.4). The final matching equation is the statement that the anomaly of the branch massless fields plus the anomaly generated by the Green–Schwarz term equals the anomaly of the fixed point.

Quoted Theorem 96.6 ($(2,0)$ anomaly polynomial)**.** *Let $\mathfrak{g}$ be simply laced, with rank $r_{\mathfrak{g}}$, dimension $d_{\mathfrak{g}}$, and dual Coxeter number $h_{\mathfrak{g}}^\vee$. The $(2,0)$ theory of type $\mathfrak{g}$ has anomaly polynomial*

$$I_8[\mathfrak{g}] = r_{\mathfrak{g}} I_8(1) + \frac{d_{\mathfrak{g}} h_{\mathfrak{g}}^\vee}{24}\, p_2(N_R), \tag{96.5}$$

where N_R is the rank-five $SO(5)_R$ background bundle and

$$I_8(1) = \frac{1}{48}\left[p_2(N_R) - p_2(T) + \frac{1}{4}\big(p_1(T) - p_1(N_R)\big)^2\right] \tag{96.6}$$

is the anomaly polynomial of one free $(2,0)$ tensor multiplet.

The theorem is quoted because the chapter does not reproduce a construction of the interacting six-dimensional local QFT together with a first-principles derivation of its anomaly functional. In this monograph it is used only as protected QFT data: it fixes anomaly coefficients that any proposed construction of the $(2,0)$ theory must reproduce. External geometric or string-theoretic derivations may motivate the formula, but they are not premises in the argument of this chapter.

What the quoted theorem asserts on the tensor branch. The generic tensor branch of the type $\mathfrak{g}$ theory contains $r_{\mathfrak{g}}$ free abelian $(2,0)$ tensor multiplets. Therefore

$$I_8[\mathfrak{g}] - r_{\mathfrak{g}} I_8(1) = \frac{d_{\mathfrak{g}} h_{\mathfrak{g}}^{\vee}}{24}\, p_2(N_R) \tag{96.7}$$

is the part of the anomaly which is invisible in the free branch spectrum. The background anomaly is an invertible field theory attached to the QFT, not to a particular coordinate chart on its vacuum branch. Thus the low-energy tensor-branch description must reproduce the same anomaly functional as the fixed point after its massless fields and its local Green–Schwarz terms are both included. This is the precise sense in which the formula is tested by branch data: the branch fields give $r_{\mathfrak{g}} I_8(1)$, while the remaining coefficient is a quadratic functional of the four-form couplings $X_I^{(4)}$ in (96.2). It is not an additional propagating degree-of-freedom count.

The following finite root-system facts are the arithmetic skeleton of this matching. Normalize the simply laced root system $\Delta_{\mathfrak{g}} \subset \mathfrak{t}_{\mathfrak{g}}^{\vee}$ so every root has squared length 2, and identify $\mathfrak{t}_{\mathfrak{g}} \simeq \mathfrak{t}_{\mathfrak{g}}^{\vee}$ by this inner product. Then

$$\sum_{\alpha \in \Delta_{\mathfrak{g}}^{+}} \alpha \otimes \alpha = h_{\mathfrak{g}}^{\vee}\, \mathrm{id}_{\mathfrak{t}_{\mathfrak{g}}}, \tag{96.8}$$

or, equivalently,

$$\sum_{\alpha \in \Delta_{\mathfrak{g}}^{+}} \langle \alpha, v\rangle^2 = h_{\mathfrak{g}}^{\vee}\, \langle v, v\rangle \qquad (v \in \mathfrak{t}_{\mathfrak{g}}).$$

Indeed the full sum over all roots defines a Weyl-invariant symmetric endomorphism of the irreducible reflection representation of $W_{\mathfrak{g}}$, hence is a scalar multiple of the identity. Taking the trace fixes the scalar: the trace of the full sum is $\sum_{\alpha \in \Delta_{\mathfrak{g}}} \langle \alpha, \alpha\rangle = 2|\Delta_{\mathfrak{g}}|$, while $|\Delta_{\mathfrak{g}}| = d_{\mathfrak{g}} - r_{\mathfrak{g}} = r_{\mathfrak{g}} h_{\mathfrak{g}}^{\vee}$. Dividing by $r_{\mathfrak{g}}$ gives $2h_{\mathfrak{g}}^{\vee}$ for the full root sum and $h_{\mathfrak{g}}^{\vee}$ for the positive-root sum. The identity

$$d_{\mathfrak{g}} = r_{\mathfrak{g}}(h_{\mathfrak{g}}^{\vee} + 1) \tag{96.9}$$

is the same root count with the Cartan directions restored.

These identities do not prove (96.5); they explain why, once the normalization of the self-dual tensor Green–Schwarz coupling is fixed on a long-root string, the Weyl-invariant quadratic contribution on a chamber has no remaining independent symmetric tensor structure. The nontrivial QFT datum in the quoted theorem is the overall coefficient with which the interacting fixed point realizes this rigid invariant.

Remark 96.7 (ADE arithmetic in the $(2,0)$ anomaly coefficient)*.* For simply laced $\mathfrak{g}$, the coefficient multiplying $p_2(N_R)$ in (96.5) is

$$\frac{d_{\mathfrak{g}} h_{\mathfrak{g}}^{\vee}}{24}.$$

For the ADE series this gives

$\mathfrak{g}$	$r_{\mathfrak{g}}$	$d_{\mathfrak{g}}$	$h_{\mathfrak{g}}^{\vee}$	$d_{\mathfrak{g}} h_{\mathfrak{g}}^{\vee}/24$
A_{N-1}	$N-1$	N^2-1	N	$N(N^2-1)/24$
D_N	N	$N(2N-1)$	$2N-2$	$N(N-1)(2N-1)/12$
E_6	6	78	12	39
E_7	7	133	18	399/4
E_8	8	248	30	310

The A_{N-1} coefficient grows as $N^3/24$ at large N, while the number of free tensor multiplets on the generic branch is only $N-1$.

The entries use the standard simply laced Lie-algebra dimensions and dual Coxeter numbers:

$$d_{A_{N-1}} = N^2 - 1, \quad h^\vee_{A_{N-1}} = N,$$

$$d_{D_N} = N(2N-1), \quad h^\vee_{D_N} = 2N-2,$$

and

$$(d_{E_6}, h^\vee_{E_6}) = (78, 12), \quad (d_{E_7}, h^\vee_{E_7}) = (133, 18), \quad (d_{E_8}, h^\vee_{E_8}) = (248, 30).$$

Substitution into $d_\mathfrak{g} h^\vee_\mathfrak{g}/24$ gives the table. For A_{N-1},

$$\frac{N(N^2-1)}{24} = \frac{N^3}{24} - \frac{N}{24},$$

which displays the cubic scaling.

96.7 BPS Strings

Tensor multiplets couple electrically to strings. A string with charge

$$q \in \Lambda_{\text{string}}$$

has tension

$$T_q = q_I \phi^I$$

on a $(1,0)$ tensor branch, in a chamber where this pairing is positive. For a $(2,0)$ theory of type $\mathfrak{g}$, the charge lattice is identified with the root lattice in the simply connected convention, and a root α gives a string with tension

$$T_\alpha = |\alpha(\phi)|, \qquad \phi \in \mathbb{R}^5 \otimes \mathfrak{t}_\mathfrak{g}.$$

At the superconformal point some tensions vanish, and the corresponding degrees of freedom are strings, not particles in six dimensions.

Proposition 96.8 (BPS string tension from the tensor-branch central charge)**.** *Normalize the tensor-branch scalar coordinates so that the string central charge vector of a charge $q \in \Lambda_{\text{str}}$ is*

$$Z_q^A = q_I \phi^{IA}, \qquad A = 1, \dots, n,$$

where $n = 1$ in $(1,0)$ notation and $n = 5$ in $(2,0)$ notation. The positive-energy representation of the six-dimensional supersymmetry algebra then gives the BPS inequality

$$T_q \geq |Z_q|,$$

and a BPS string saturates it:

$$T_q = |q_I \phi^I|.$$

For a $(2,0)$ theory of type $\mathfrak{g}$, taking Λ_{str} to be the root lattice gives

$$T_\alpha = |\alpha(\phi)|$$

for the string of root charge α.

Proof. Work per unit length for a straight static string oriented, say, along x^5. Translation invariance along the string replaces the energy by a tension T_q, and the tensor-multiplet central charge appears in the supercharge anticommutator as an R-symmetry vector Z_q^A. Choose the positive normalization of the supercharges so that the coefficient of the tension term in the anticommutator is T_q. After choosing a unit vector $\widehat{Z}^A = Z_q^A/|Z_q|$, the relevant Hermitian anticommutator on the subspace of spinor/R-symmetry parameters is

$$\{Q(\varepsilon), Q(\varepsilon)^\dagger\} = \varepsilon^\dagger\big(T_q\,\mathbf{1} - |Z_q|\,\Gamma_{\rm str}\Gamma_{\widehat{Z}}\big)\varepsilon.$$

Here $\Gamma_{\rm str}$ is the chirality matrix determined by the oriented two-plane swept out by the static string, and $\Gamma_{\widehat{Z}}$ is the unit R-symmetry Clifford multiplication in the direction $\widehat{Z}$. The two matrices square to 1 on the relevant spinor space and their product has eigenvalues ± 1. Positivity of the Hilbert-space norm of $Q(\varepsilon)^\dagger|\text{string}\rangle$ for every ε therefore requires

$$T_q - |Z_q| \geq 0.$$

If equality holds, the eigenspace with $\Gamma_{\rm str}\Gamma_{\widehat{Z}} = +1$ is annihilated by a nonzero linear combination of supercharges; conversely, preservation of a nonzero supercharge forces the smallest eigenvalue of the displayed matrix to vanish. This is the BPS saturation condition. With the scalar-coordinate normalization in the statement, $Z_q^A = q_I\phi^{IA}$, hence $T_q = |Z_q| = |q_I\phi^I|$ for a saturated string. In the $(2,0)$ ADE theory the charged strings on a generic tensor branch are labeled by roots, so $q = \alpha$ gives $T_\alpha = |\alpha(\phi)|$. □

Local anomaly inflow to a charged string. Let $\iota : \Sigma \hookrightarrow M_6$ be the oriented two-dimensional support of a string of charge q. Write N_Σ for its oriented rank-four normal bundle, and put

$$q^2 = q_I\Omega^{IJ}q_J.$$

The charge convention is the one used in the tensor-branch coupling: the surface insertion contains the differential-cohomology holonomy

$$\exp\left(2\pi\mathrm{i}\,q_I\int_\Sigma B^I\right).$$

In a local background chart with $X_I^{(4)} = dX_I^{(3)}$ and $\delta X_I^{(3)} = dX_I^{(2)}$, Green–Schwarz gauge invariance is expressed by the local transformation

$$\delta B^I = -X_I^{(2)}.$$

Consequently the charged insertion varies by

$$\delta \log W_q(\Sigma) = -2\pi\mathrm{i}\int_\Sigma q_I\,\iota^* X_I^{(2)}.$$

A two-dimensional quantum theory supported on Σ cancels this variation precisely when its anomaly polynomial contains the four-form

$$I^\Sigma_{4,\rm lin}(q) = q_I\,\iota^* X_I^{(4)}. \tag{96.10}$$

This is the linear inflow term. It is not optional: it is the descent of the same $B^I \wedge X_I^{(4)}$ coupling that appears in the six-dimensional Green–Schwarz matching equation.

There is also a local normal-bundle inflow from the self-pairing of the tensor field sourced by the string. It is best stated using the global angular-form regularization of a tubular neighborhood of Σ. Let $S(N_\Sigma) \to \Sigma$ be the unit-sphere bundle of the normal bundle. In the standard normalization the Chern–Simons form $e_3^{(0)}(N_\Sigma)$ on this sphere bundle satisfies

$$de_3^{(0)}(N_\Sigma) = \pi^* e(N_\Sigma), \qquad \delta e_3^{(0)}(N_\Sigma) = de_2^{(1)}(N_\Sigma),$$

where $e(N_\Sigma)$ is the Euler class of the rank-four normal bundle. Replacing the delta-current Poincare dual to Σ by the Thom form obtained from $e_3^{(0)}$ gives a smooth representative of the sourced Bianchi identity near the support. Substituting this representative into the quadratic tensor pairing produces, under a normal-bundle gauge transformation, the descent variation

$$2\pi \mathrm{i} \int_\Sigma \frac{1}{2}\, q^2\, e_2^{(1)}(N_\Sigma).$$

Equivalently the normal-bundle part of the inflow anomaly polynomial is

$$I^{\Sigma}_{4,\mathrm{norm}}(q) = \frac{1}{2}\, q_I \Omega^{IJ} q_J\, e(N_\Sigma). \tag{96.11}$$

The coefficient 1/2 is the same symmetric-pairing coefficient as in the quadratic Green–Schwarz descent: the self-interaction of one sourced tensor field is counted once, while distinct charge components are paired symmetrically by Ω^{IJ}.

Thus the bulk inflow polynomial for a string of charge q, in these normalizations, is

$$I^{\Sigma}_{4,\mathrm{inflow}}(q) = q_I\, \iota^* X_I^{(4)} + \frac{1}{2}\, q_I \Omega^{IJ} q_J\, e(N_\Sigma). \tag{96.12}$$

The actual anomaly polynomial of the two-dimensional degrees of freedom supported on the string must cancel this inflow after adding its intrinsic fermion, boson, and zero-mode contributions. Formula (96.12) is therefore a local consistency condition on a proposed BPS-string sector, not a construction of that sector.

Remark 96.9 (What the BPS-string statement does and does not construct)*.* The tension formula is a consequence of the supersymmetry algebra and tensor-branch normalization. It does not construct the interacting tensionless string theory at $T_q = 0$, nor does it define its operator algebra. The tensionless limit is part of the fixed-point data whose existence must be supplied by a construction or by a set of mutually consistent protected tests.

96.8 Defect Group, Finite Flux, And Polarization

The tensor-branch root lattice is not the whole discrete topological datum of a $(2,0)$ theory. Let $Q_{\mathfrak{g}}$ be the root lattice of the simply laced Lie algebra $\mathfrak{g}$, with its integral Cartan pairing $(\ ,\ )$. The dual lattice is

$$P_{\mathfrak{g}} = \{\lambda \in Q_{\mathfrak{g}} \otimes \mathbb{R} : (\lambda, \alpha) \in \mathbb{Z} \text{ for every } \alpha \in Q_{\mathfrak{g}}\},$$

the weight lattice. The finite discriminant group

$$A_{\mathfrak{g}} = P_{\mathfrak{g}}/Q_{\mathfrak{g}} \tag{96.13}$$

is the finite group detected by the center of the associated simply connected compact group. It carries the nondegenerate finite pairing

$$b_{\mathfrak{g}} : A_{\mathfrak{g}} \times A_{\mathfrak{g}} \longrightarrow \mathbb{Q}/\mathbb{Z}, \qquad b_{\mathfrak{g}}([\lambda],[\mu]) = (\lambda,\mu) \bmod \mathbb{Z}. \tag{96.14}$$

The expression is independent of the representatives because adding a root to either entry changes (λ,μ) by an integer. Nondegeneracy is the statement that $P_{\mathfrak{g}}$ is the full dual of $Q_{\mathfrak{g}}$.

The ADE values are

$$\begin{array}{c|c} \mathfrak{g} & A_{\mathfrak{g}} \\ \hline A_{N-1} & \mathbb{Z}_N \\ D_N,\ N \text{ odd} & \mathbb{Z}_4 \\ D_N,\ N \text{ even} & \mathbb{Z}_2 \oplus \mathbb{Z}_2 \\ E_6 & \mathbb{Z}_3 \\ E_7 & \mathbb{Z}_2 \\ E_8 & 0. \end{array} \tag{96.15}$$

The order of $A_{\mathfrak{g}}$ is $\det C_{\mathfrak{g}}$, where $C_{\mathfrak{g}}$ is the Cartan matrix. Thus the displayed table is the finite discriminant form of the root lattice, not a new continuous parameter of the tensor-branch metric.

The group $A_{\mathfrak{g}}$ is often described as the group of surface defect charges modulo dynamical root-lattice strings. This sentence should be read as a statement about a protected topological sector: the monograph is not using it as a construction of the interacting fixed point. The local tensor-branch EFT sees strings of charge $Q_{\mathfrak{g}}$. The quotient $P_{\mathfrak{g}}/Q_{\mathfrak{g}}$ records which finite surface charge can be measured at infinity after dynamical root-lattice strings have been allowed to end or screen.

On a closed oriented six-manifold Y, the finite flux sector associated with this discriminant group is

$$K_Y(\mathfrak{g}) = H^3(Y; A_{\mathfrak{g}}). \tag{96.16}$$

Cup product and (96.14) define a skew pairing

$$\langle x, y\rangle_Y = \int_Y b_{\mathfrak{g}}(x \smile y) \in \mathbb{Q}/\mathbb{Z}. \tag{96.17}$$

The skew sign comes from the odd degree:

$$x \smile y = -\, y \smile x \qquad \text{for } x, y \in H^3(Y; A_{\mathfrak{g}}),$$

while $b_{\mathfrak{g}}$ is symmetric. A self-dual finite flux theory is not an ordinary sum over all of $K_Y(\mathfrak{g})$. It determines a finite Heisenberg representation whose commutator is

$$U_x U_y U_x^{-1} U_y^{-1} = \exp\bigl(2\pi \mathrm{i} \langle x, y\rangle_Y\bigr).$$

To obtain an ordinary numerical partition function one must supply a polarization, namely a maximal isotropic subgroup

$$L \subset K_Y(\mathfrak{g}), \qquad \langle L, L\rangle_Y = 0, \qquad |L|^2 = |K_Y(\mathfrak{g})|$$

when the finite pairing on $K_Y(\mathfrak{g})$ is nondegenerate. Changing the polarization is a finite global datum, analogous in role to choosing a global form and discrete theta sector after compactification. It is not visible in the local superconformal algebra or in the real tensor-branch metric alone.

Cyclic finite-flux model. For type A_{N-1}, choose a generator of $A_{\mathfrak{g}} \simeq \mathbb{Z}_N$ and write the finite pairing as

$$b(a,b) = \frac{ab}{N} \bmod \mathbb{Z}$$

up to the harmless sign determined by the chosen generator. In the elementary finite model

$$K = \mathbb{Z}_N \oplus \mathbb{Z}_N$$

with coordinates (a,b), the skew pairing is

$$\langle (a,b),(a',b')\rangle = \frac{ab' - ba'}{N} \bmod \mathbb{Z}. \tag{96.18}$$

It is alternating and nondegenerate. The subgroup

$$L = \mathbb{Z}_N \oplus 0$$

is isotropic and has $|L| = N$, while $|K| = N^2$; hence L is a polarization. This finite model is the algebraic core of the polarization choice. In an actual six-dimensional compactification the cohomology group $H^3(Y; A_{\mathfrak{g}})$, torsion linking forms, boundary conditions, and defect insertions must all be specified before the phrase "the partition function" denotes a number rather than a vector in a finite Heisenberg representation.

Circle reduction of the finite Heisenberg system. The same finite datum explains why the global form of the five-dimensional gauge theory is not fixed by the local gauge algebra alone. Let

$$Y = S^1 \times X_5$$

with X_5 closed and oriented, and let $\eta \in H^1(S^1; \mathbb{Z})$ be normalized by $\int_{S^1} \eta = 1$. Pullback from X_5 and cup product with η give the canonical product splitting

$$H^3(S^1 \times X_5; A_{\mathfrak{g}}) \simeq H^3(X_5; A_{\mathfrak{g}}) \oplus \eta\, H^2(X_5; A_{\mathfrak{g}}). \tag{96.19}$$

Write an element as

$$x = u + \eta v, \qquad u \in H^3(X_5; A_{\mathfrak{g}}), \quad v \in H^2(X_5; A_{\mathfrak{g}}).$$

For $y = u' + \eta v'$, the six-dimensional pairing (96.17) becomes

$$\langle u + \eta v,\ u' + \eta v'\rangle_{S^1 \times X_5} = \int_{X_5} \big(b_{\mathfrak{g}}(v \smile u') - b_{\mathfrak{g}}(u \smile v')\big). \tag{96.20}$$

The sign is fixed by moving the degree-one class η past the degree-three class u:

$$u \smile \eta v' = -\,\eta\, u \smile v', \qquad \eta v \smile u' = \eta\, v \smile u'.$$

Thus $H^3(X_5; A_{\mathfrak{g}})$ and $\eta H^2(X_5; A_{\mathfrak{g}})$ are mutually dual isotropic subgroups whenever the resulting finite pairing is nondegenerate.

This is the finite topological core of the five-dimensional global-form choice. A six-dimensional surface defect wrapping S^1 becomes a five-dimensional line defect whose finite charge is measured by $H^2(X_5; A_{\mathfrak{g}})$; an unwrapped six-dimensional surface defect gives a five-dimensional surface defect measured by $H^3(X_5; A_{\mathfrak{g}})$. Equation (96.20) says that the two sets of charges are mutually nonlocal. A polarization chooses a maximal mutually local set before the compactified partition function is a number. In gauge theory language this is the global form and discrete finite-flux datum that supplements the Lie algebra $\mathfrak{g}$. It is not determined by the local $5d$ Yang–Mills Lagrangian density.

Genuine defects after choosing an absolute polarization. The preceding finite Heisenberg system is the point at which the phrase "the $(2,0)$ theory of type $\mathfrak{g}$" must be refined by a global finite datum. Let X_5 be a closed oriented five-manifold and set

$$K_{X_5} = H^3(X_5; A_{\mathfrak{g}}) \oplus H^2(X_5; A_{\mathfrak{g}}),$$

with the alternating pairing

$$\omega_{X_5}\big((u,v),(u',v')\big) = \int_{X_5} \big(b_{\mathfrak{g}}(v \smile u') - b_{\mathfrak{g}}(u \smile v')\big).$$

Poincare duality with finite coefficients, together with nondegeneracy of $b_{\mathfrak{g}}$, makes this pairing perfect modulo any explicitly removed radical. A finite absolute polarization on the circle compactified theory is a choice, functorial under the bordisms under consideration, of a maximal isotropic subgroup

$$L_{X_5} \subset K_{X_5}, \qquad L_{X_5} = L_{X_5}^{\perp_\omega}.$$

The equality with its orthogonal complement is the load-bearing condition, not the notation: it says that the chosen set of finite line/surface charges is maximal among mutually local charges.

Let U_κ, $\kappa \in K_{X_5}$, denote the finite topological operator that shifts the corresponding discrete flux sector. The finite Heisenberg relation is

$$U_\kappa U_\lambda = \exp(2\pi \mathrm{i}\, \omega_{X_5}(\kappa, \lambda))\, U_\lambda U_\kappa.$$

After the absolute polarization L_{X_5} is chosen, the charges $\kappa \in L_{X_5}$ define the mutually local genuine finite-charge defects of that absolute theory. If $\kappa \notin L_{X_5}$, then maximality gives some $\lambda \in L_{X_5}$ with $\omega_{X_5}(\kappa, \lambda) \neq 0$. The corresponding operators fail to commute by the displayed phase, so κ cannot be inserted as an ordinary genuine defect in the same absolute theory while preserving all defects in L_{X_5}. It is instead a relative operator: it changes the finite background sector, or it must end on a topological interface that changes the polarization.

In the elementary A_{N-1} cyclic model, $K = \mathbb{Z}_N \oplus \mathbb{Z}_N$ with pairing (96.18). The two coordinate subgroups

$$L_{\mathrm{surf}} = \mathbb{Z}_N \oplus 0, \qquad L_{\mathrm{line}} = 0 \oplus \mathbb{Z}_N$$

are maximal isotropic. The first choice makes the unwrapped finite surface charges genuine; the second makes the circle-wrapped finite line charges genuine. These are different absolute global forms of the same local compactified theory. A topological interface between two such choices is not an equality of absolute theories; at the finite level it is represented by a Lagrangian relation

$$R \subset K^{(1)}_{X_5} \oplus \overline{K}^{(2)}_{X_5},$$

where the bar reverses the sign of the pairing. The graph of a symplectic automorphism of K_{X_5} is the simplest example. This finite relation is the precise algebraic content behind the common statement that some defects are "non-genuine": the defect exists as a relative morphism between finite sectors, not as an autonomous operator in a fixed absolute polarization.

This paragraph is still only the finite topological layer. It does not construct the full six-dimensional category of codimension-two defects, nor the interacting two-dimensional theories supported on BPS strings. It fixes the consistency condition that any such construction must obey when reduced to the protected finite charge algebra.

96.9 Circle Compactification And Five-Dimensional Yang–Mills

Compactification on a smooth compact manifold Y gives lower-dimensional QFTs whose protected data test the six-dimensional proposal. For a circle of radius R, a $(2,0)$ theory of type $\mathfrak{g}$ yields five-dimensional maximally supersymmetric Yang–Mills on its Coulomb branch with gauge algebra $\mathfrak{g}$. This statement is a compactification test and an effective description, not a Lagrangian definition of the six-dimensional fixed point.

Five-dimensional instanton charge and coupling convention. Use the monograph trace-delta convention for the five-dimensional gauge action,

$$S_{5d} = \frac{1}{4g_5^2}\int \mathrm{tr}_\delta(F_{\mu\nu}F^{\mu\nu}) + \cdots .$$

The topological charge in the five-dimensional gauge theory is the Chern–Weil instanton number on a spatial four-cycle. Let $\mathrm{tr}_{\mathrm{top}}$ denote the characteristic-class trace normalized so that

$$\mathcal{Q}_4(F) := \frac{1}{8\pi^2}\,\mathrm{tr}_{\mathrm{top}}(F\wedge F)$$

has integral periods on principal G-bundles in the charge sector under discussion. On a five-dimensional spacetime X_5, the corresponding current is the one-form

$$j_{\mathrm{inst}} := *_5\,\mathcal{Q}_4(F), \qquad *_5 j_{\mathrm{inst}} = \mathcal{Q}_4(F).$$

The Bianchi identity gives

$$d(*_5 j_{\mathrm{inst}}) = d\mathcal{Q}_4(F) = 0.$$

Thus for a spatial Cauchy four-manifold Σ_4

$$Q_{\mathrm{inst}}(\Sigma_4) = \int_{\Sigma_4} *_5 j_{\mathrm{inst}} = \frac{1}{8\pi^2}\int_{\Sigma_4}\mathrm{tr}_{\mathrm{top}}(F\wedge F)\in\mathbb{Z}. \tag{96.21}$$

This is a conserved charge of the five-dimensional effective theory. In the circle compactification test it is identified with momentum around the compactification circle, not with a new microscopic six-dimensional Noether symmetry.

For a static configuration on spatial $\mathbb{R}^4$, with vanishing electric field and scalar gradients, the energy functional reduces to the Euclidean four-dimensional Yang–Mills action in the same trace-delta convention. The BPST normalization fixed in Lemma 51.23 and Equation (33.53) gives the bound

$$E_{\mathrm{inst}} \geq \frac{4\pi^2}{g_5^2}\,|Q_{\mathrm{inst}}|, \tag{96.22}$$

with equality for a self-dual or anti-self-dual spatial instanton in the appropriate charge sector. The square-completion input is the ordinary four-dimensional instanton bound; the five-dimensional statement is that this finite-action Euclidean saddle is read as a massive particle state when the four coordinates are spatial.

If one unit of five-dimensional instanton charge is identified with one unit of Kaluza–Klein momentum on a circle of radius R, then

$$g_5^2 = 4\pi^2 R.$$

In the common half-trace convention this same relation is

$$g_{5,\mathrm{ht}}^2 = 8\pi^2 R.$$

Kaluza–Klein momentum on a circle of radius R is quantized in units

$$E_{\mathrm{KK}} = \frac{1}{R}$$

for a BPS state with one unit of momentum and no additional transverse motion. Identifying a unit instanton-particle charge with one unit of KK momentum gives

$$\frac{4\pi^2}{g_5^2} = \frac{1}{R},$$

hence $g_5^2 = 4\pi^2 R$. The half-trace convention has $g_{5,\mathrm{ht}}^2 = 2g_5^2$, so $g_{5,\mathrm{ht}}^2 = 8\pi^2 R$.

This proportionality is often quoted without specifying the trace convention. Here it is tied to the instanton normalization used elsewhere in the monograph, so that compactification tests, instanton-soliton masses, and Yang–Mills kinetic terms use the same coupling coordinate. It still does not make five-dimensional Yang–Mills a microscopic six-dimensional definition: the statement uses the compactified branch description, the protected charge identification $Q_{\mathrm{inst}} = P_{S^1} R$, and the BPS mass formula.

Wrapped strings and Coulomb-branch masses. Compactify a $(2,0)$ theory of type $\mathfrak{g}$ on a circle of radius R, and work on a generic tensor branch. A BPS string of root charge α wrapped once on the circle gives a five-dimensional BPS particle with mass

$$M_\alpha^{\mathrm{wrap}} = 2\pi R\,|\alpha(\phi_{6d})|.$$

If this particle is identified with the W-boson of five-dimensional maximally supersymmetric Yang–Mills on its Coulomb branch, then the five-dimensional Coulomb scalar coordinate is normalized by

$$\phi_{5d} = 2\pi R\,\phi_{6d},$$

so that $M_\alpha^W = |\alpha(\phi_{5d})|$. This is a compactification matching condition; it is not an independent six-dimensional Lagrangian definition.

A static string of tension T_α wrapped on a circle of circumference $2\pi R$ has rest energy

$$M_\alpha^{\mathrm{wrap}} = (2\pi R)T_\alpha.$$

Using Proposition 96.8 gives the first displayed formula. In a five-dimensional gauge theory on the Coulomb branch, the mass of the vector multiplet associated with a root α is the absolute value of the corresponding root evaluated on the Coulomb scalar. Equating the wrapped-string particle with this W-boson therefore fixes the scalar normalization $\phi_{5d} = 2\pi R\,\phi_{6d}$.

96.10 Compactification On Riemann Surfaces

For compactification on a Riemann surface C, partial twists use an embedding of the spin connection of C into G_R. The resulting four-dimensional theory, when it exists, must have matching anomalies, flavor symmetries, defect descendants, and moduli-space dimensions. The following hypothesis records the compactification structure used below and gives the class-S notation a precise conditional meaning.

Hypothesis 96.10 (Class-S compactification structure)**.** Fix a six-dimensional theory $\mathfrak{T}_{6d}[\mathfrak{g}]$ satisfying Hypothesis 96.1. A class-S compactification structure is a tuple

$$\mathcal{C}_{\mathrm{S}} = \big(C, \{(p_a, \mathfrak{D}_a)\}_{a\in A}, \eta\big)$$

with the following constituents.

(i) C is a connected oriented smooth surface equipped with a complex structure. The marked points $p_a \in C$ are pairwise distinct. The unpunctured case is $A = \emptyset$.

(ii) The sign $\eta = \pm 1$ specifies the embedding of the $\mathrm{Spin}(2)_C$ connection into the $SO(2)_r \subset SO(5)_R$ R-symmetry factor used in the partial twist. In characteristic-class language this is the convention

$$e(N_2) = x + \eta\, t$$

of (96.23).

(iii) Each $\mathfrak{D}_a$ is a codimension-two defect or boundary condition for $\mathfrak{T}_{6d}[\mathfrak{g}]$ at p_a. At the level used in this chapter, such a defect input must specify at least its preserved four-dimensional supersymmetry, flavor symmetry F_a, contribution to the four-dimensional anomaly polynomial, its allowed defect descendants, and, when a Hitchin-system description is invoked, the corresponding allowed singularity or boundary condition for the Hitchin field at p_a.

(iv) The compactification is assumed to have a four-dimensional $\mathcal{N} = 2$ local QFT limit, denoted

$$\mathfrak{T}_{\mathfrak{g}}[C, \{(p_a, \mathfrak{D}_a)\}; \eta],$$

with local operator algebra, stress tensor multiplet, Hilbert-space radial-quantization data, and extended operators descending from the six-dimensional defect and finite-flux sectors after a choice of global polarization when such a choice is required.

(v) The protected data of this four-dimensional QFT agree with the six-dimensional reduction data: the preserved supercharges are those annihilated by the twist; the flavor symmetry includes the defect flavor groups and any continuous symmetry left by the compactification; the anomaly six-form is the fiber integral of $I_8[\mathfrak{g}]$ plus the local defect contributions; and the Coulomb-branch chiral coordinates are modeled by the appropriate Hitchin base associated with $(\mathfrak{g}, C, \{\mathfrak{D}_a\})$.

The notation $\mathfrak{T}_{\mathfrak{g}}[C, \{(p_a, \mathfrak{D}_a)\}; \eta]$ is therefore conditional: it denotes the four-dimensional QFT whose existence and properties are asserted in this hypothesis. The Hitchin base, anomaly push-forward, or Seiberg–Witten curve is not by itself a construction of the QFT. In the smooth unpunctured calculation below, $A = \emptyset$, C is closed, and the only compactification input beyond $\mathfrak{g}$ is the twist sign η.

The compactification is a test with substantial content. It must specify:

the twist homomorphism from $\mathrm{Spin}(2)_C$ to G_R,
the defect or puncture data,
the surviving supercharges and flavor symmetries,
the map of six-dimensional anomalies to four-dimensional anomalies,
and the descent of surface defects and BPS strings.

Supplying only a Seiberg–Witten curve in four dimensions does not by itself construct either the six-dimensional parent theory or the four-dimensional local QFT denoted by the class-S compactification symbol.

Twist convention and anomaly pushforward. Here is the local anomaly calculation behind the preceding list in the unpunctured case. Let

$$M_6 = M_4 \times C$$

with C a closed oriented Riemann surface. Denote by

$$t = e(TC) \in H^2(C; \mathbb{Z}), \qquad \int_C t = \chi(C) = 2 - 2g_C,$$

the Euler class of C. Decompose the rank-five $SO(5)_R$ background bundle as

$$N_R = N_2 \oplus N_3,$$

where N_2 is an oriented real rank-two bundle for the $SO(2)_r$ subgroup and N_3 is an oriented real rank-three bundle for the four-dimensional $SO(3)_R \simeq SU(2)_R/\mathbb{Z}_2$ background. Write

$$x = e(N_2|_{M_4}), \qquad u = p_1(N_3|_{M_4}).$$

The twist chooses a sign $\eta = \pm 1$, equivalently one of the two conjugate scalar supercharges after the compactification, and sets the rank-two Euler class on $M_4 \times C$ to

$$e(N_2) = x + \eta\, t. \tag{96.23}$$

The sign is a convention tied to the orientation of C and to the choice of $SO(2)_r$ weight. The formula below keeps η visible so that no physical conclusion is hidden in an unstated sign convention.

The characteristic classes entering (96.5) are then, modulo terms of degree too high on C,

$$p_1(N_R) = (x + \eta t)^2 + u = x^2 + u + 2\eta x\, t, \tag{96.24}$$
$$p_2(N_R) = (x + \eta t)^2 u = x^2 u + 2\eta x\, u\, t. \tag{96.25}$$

For the tangent bundle,

$$p_1(T(M_4 \times C)) = p_1(TM_4), \qquad p_2(T(M_4 \times C)) = p_2(TM_4),$$

after integration over C, because t^2 has no component on the two-dimensional surface. Let $p = p_1(TM_4)$. The coefficient of t in the free tensor polynomial (96.6) is

$$\big[I_8(1)\big]_t = \frac{\eta x\, t}{48}\,\big(x^2 - p + 3u\big), \tag{96.26}$$

and the coefficient of t in the interacting excess is

$$\left[\frac{d_{\mathfrak{g}} h^\vee_{\mathfrak{g}}}{24} p_2(N_R)\right]_t = \frac{\eta d_{\mathfrak{g}} h^\vee_{\mathfrak{g}}}{12}\, x\, u\, t. \tag{96.27}$$

Therefore the six-form anomaly polynomial of the smooth unpunctured four-dimensional compactification, in this normalization of x and u, is

$$I_6^{\text{class S}}(\mathfrak{g}, C; \eta) = \eta\, \chi(C)\, x \left[\frac{r_{\mathfrak{g}}}{48}(x^2 - p + 3u) + \frac{d_{\mathfrak{g}} h^\vee_{\mathfrak{g}}}{12} u\right]. \tag{96.28}$$

If one rewrites the $SO(3)_R$ class as $u = -4c_2(SU(2)_R)$, this becomes the conventional four-dimensional $\mathcal{N} = 2$ anomaly-polynomial coordinate system, up to the same η and orientation convention. Punctures, codimension-two defects, and irregular singularities add localized contributions; they are not contained in the smooth pushforward (96.28).

96.11 Hitchin-Base Coulomb Operators In Class-S Compactification

Assume Hypotheses 96.1 and 96.10 in the smooth unpunctured case: C is a closed Riemann surface of genus $g_C > 1$, $A = \emptyset$, and the partial twist preserves four-dimensional $\mathcal{N} = 2$ supersymmetry. Let

$$d_1, \ldots, d_{r_{\mathfrak{g}}}$$

be the degrees of the algebraically independent invariant polynomials on $\mathfrak{g}_{\mathbb{C}}$, ordered increasingly. Equivalently

$$d_i = m_i + 1$$

where m_i are the exponents of $\mathfrak{g}$. The protected Coulomb coordinates in the compactified theory are modeled by the Hitchin-base spaces

$$\varphi_{d_i} \in H^0(C, K_C^{d_i}), \qquad i = 1, \ldots, r_{\mathfrak{g}}, \tag{96.29}$$

where K_C is the holomorphic canonical bundle of C. In the four-dimensional theory the coordinate associated with φ_{d_i} has scaling dimension d_i.

Remark 96.11 (Status of the Hitchin-base statement)*.* Equation (96.29) is used here as a protected compactification test of the $(2,0)$ theory, not as a definition of the six-dimensional QFT. A construction of the compactified theory must also specify the Hilbert space, local operators, line and surface defects, metric dependence before twisting, and the treatment of degenerating complex structures. The Hitchin base records the Coulomb chiral ring coordinates visible in the twisted protected sector.

Riemann–Roch count for Hitchin differentials. Let C be a closed Riemann surface of genus $g_C > 1$. For every integer $d \geq 2$,

$$\dim_{\mathbb{C}} H^0(C, K_C^d) = (2d-1)(g_C - 1). \tag{96.30}$$

The degree of K_C is $2g_C - 2$, hence

$$\deg K_C^d = d(2g_C - 2).$$

Riemann–Roch gives

$$h^0(C, K_C^d) - h^0(C, K_C^{1-d}) = \deg K_C^d + 1 - g_C. \tag{96.31}$$

For $d \geq 2$, the line bundle K_C^{1-d} has negative degree, so it has no nonzero holomorphic sections. Therefore

$$h^0(C, K_C^d) = d(2g_C - 2) + 1 - g_C = (2d-1)(g_C - 1).$$

Degree sum for a simple Lie algebra. For a complex simple Lie algebra $\mathfrak{g}_{\mathbb{C}}$ with invariant polynomial degrees $d_i = m_i + 1$,

$$\sum_{i=1}^{r_{\mathfrak{g}}} (2d_i - 1) = d_{\mathfrak{g}}, \tag{96.32}$$

where $d_{\mathfrak{g}} = \dim_{\mathbb{C}} \mathfrak{g}_{\mathbb{C}}$.

The exponents m_i satisfy

$$\sum_{i=1}^{r_{\mathfrak{g}}} m_i = |\Delta_+|, \tag{96.33}$$

where Δ_+ is a set of positive roots. One way to see (96.33) is to compare the top degree in the standard Poincare polynomial identity for the flag variety:

$$\sum_{w \in W_{\mathfrak{g}}} t^{2\ell(w)} = \prod_{i=1}^{r_{\mathfrak{g}}} \frac{1 - t^{2(m_i+1)}}{1 - t^2}.$$

The maximal length of a Weyl-group element is $|\Delta_+|$, while the top degree on the product side is $2\sum_i m_i$. Hence $\sum_i m_i = |\Delta_+|$. Since

$$d_{\mathfrak{g}} = r_{\mathfrak{g}} + 2|\Delta_+|,$$

we obtain

$$\sum_i (2d_i - 1) = \sum_i (2m_i + 1) = 2|\Delta_+| + r_{\mathfrak{g}} = d_{\mathfrak{g}}.$$

Unpunctured class-S Coulomb-base dimension. For the conditional unpunctured genus-$g_C > 1$ compactification structure above, the protected Coulomb base modeled by the Hitchin base

$$\mathcal{B}_{\mathfrak{g},C} = \bigoplus_{i=1}^{r_{\mathfrak{g}}} H^0(C, K_C^{d_i}) \tag{96.34}$$

has complex dimension

$$\dim_{\mathbb{C}} \mathcal{B}_{\mathfrak{g},C} = (g_C - 1) d_{\mathfrak{g}}. \tag{96.35}$$

By the Riemann–Roch calculation above,

$$\dim_{\mathbb{C}} \mathcal{B}_{\mathfrak{g},C} = \sum_i (2d_i - 1)(g_C - 1). \tag{96.36}$$

Factoring out $g_C - 1$ and using the degree-sum calculation above gives

$$\dim_{\mathbb{C}} \mathcal{B}_{\mathfrak{g},C} = (g_C - 1)\sum_i (2d_i - 1) = (g_C - 1)d_{\mathfrak{g}}.$$

The assumptions $g_C > 1$ and $d_i \geq 2$ are used in the Riemann–Roch lemma to remove the $H^0(C, K_C^{1-d_i})$ term; punctures or genus zero/one surfaces require additional divisor data and obey different dimension formulae.

Regular-Puncture Pole-Order Chart. The preceding count has a controlled extension once the codimension-two defect data in Hypothesis 96.10 supply pole orders for the Hitchin differentials. For each invariant degree d_i, suppose the defect $\mathfrak{D}_a$ specifies an integer

$$p_{a,i} \geq 0$$

and let

$$D_i = \sum_{a \in A} p_{a,i} p_a$$

be the corresponding effective divisor on C. The protected Coulomb coordinate of degree d_i is then modeled by

$$\varphi_{d_i} \in H^0(C, K_C^{d_i}(D_i)). \tag{96.37}$$

This records only the pole orders supplied by the defect datum. It does not classify codimension-two defects and it does not assert that an arbitrary choice of the integers $p_{a,i}$ defines a four-dimensional QFT.

When the nonspeciality condition

$$H^0(C, K_C^{1-d_i}(-D_i)) = 0 \tag{96.38}$$

holds, Riemann–Roch gives the exact dimension

$$\dim_{\mathbb{C}} H^0(C, K_C^{d_i}(D_i)) = (2d_i - 1)(g_C - 1) + \deg D_i. \tag{96.39}$$

Indeed, Riemann–Roch applied to $L_i = K_C^{d_i}(D_i)$ gives

$$h^0(C, L_i) - h^0(C, K_C \otimes L_i^{-1}) = \deg L_i + 1 - g_C.$$

But $K_C \otimes L_i^{-1} = K_C^{1-d_i}(-D_i)$, so (96.38) removes the second term. Since $\deg L_i = d_i(2g_C - 2) + \deg D_i$, the displayed formula follows.

Thus a compactification datum with compatible pole orders has protected Coulomb-base dimension

$$\dim_{\mathbb{C}} \mathcal{B}_{\mathfrak{g},C,\{D_i\}} = (g_C - 1)d_{\mathfrak{g}} + \sum_{a \in A} \sum_{i=1}^{r_{\mathfrak{g}}} p_{a,i}, \tag{96.40}$$

under the same nonspeciality condition for all i. Residue constraints, mass parameters, nilpotent-orbit labels, irregular singularity slopes, and defect flavor anomalies are additional parts of the defect datum; they are not encoded by the pole-order sum alone.

Example 96.12 (Full regular punctures for type A_{N-1})**.** For the full regular puncture of type A_{N-1}, the standard pole-order list is

$$p_{a,d} = d - 1, \qquad d = 2, \dots, N.$$

If n_{full} such punctures are supplied and the nonspeciality condition holds, then

$$\begin{aligned} \dim_{\mathbb{C}} \mathcal{B}_{A_{N-1},C,n_{\text{full}}} &= (g_C - 1)(N^2 - 1) + n_{\text{full}} \sum_{d=2}^{N} (d - 1) \\ &= (g_C - 1)(N^2 - 1) + n_{\text{full}} \frac{N(N-1)}{2}. \end{aligned} \tag{96.41}$$

For the three-punctured sphere this gives

$$-(N^2 - 1) + \frac{3N(N-1)}{2} = \frac{(N-1)(N-2)}{2}.$$

This last number is the Coulomb-base dimension of the protected three-full-puncture fixture in this pole-order coordinate. It is still not a substitute for constructing the associated four-dimensional local QFT.

Example 96.13 (ADE degree checks)**.** For A_{N-1}, the degrees are $2, 3, \dots, N$. Therefore

$$\sum_{d=2}^{N} (2d - 1) = N^2 - 1 = d_{A_{N-1}},$$

and the unpunctured genus-g_C Coulomb-base dimension is

$$(g_C - 1)(N^2 - 1).$$

For D_N, the degrees are

$$2, 4, 6, \dots, 2N - 2, \; N,$$

with the usual repeated degree when N is even. Their contribution is

$$\sum_{j=1}^{N-1} (4j - 1) + (2N - 1) = N(2N - 1) = d_{D_N}.$$

For the exceptional algebras, the degree lists are

$\mathfrak{g}$	(d_i)
E_6	$2, 5, 6, 8, 9, 12$
E_7	$2, 6, 8, 10, 12, 14, 18$
E_8	$2, 8, 12, 14, 18, 20, 24, 30.$

In each case $\sum_i (2d_i - 1)$ gives 78, 133, and 248, respectively.

96.12 Status Summary

The assumed $(2,0)$ fixed-point object used in this chapter is $\mathfrak{T}_{6d}[\mathfrak{g}]$ of Hypothesis 96.1. The class-S four-dimensional object used in the compactification discussion is $\mathfrak{T}_{\mathfrak{g}}[C,\{(p_a,\mathfrak{D}_a)\};\eta]$ of Hypothesis 96.10. The substantive six-dimensional data are therefore not reconstructed retrospectively from this summary; they are the named assumptions and construction layers fixed in Section 96.1.

For orientation, the data invoked in this chapter are:

superconformal representation category,
tensor-branch EFT with self-dual fields and Green–Schwarz terms,
anomaly polynomial and flavor-background data,
BPS string charge lattice and inflow,
finite defect group, flux pairing, and polarization data,
compactification tests and extended-operator descendants.

For $(2,0)$ type $\mathfrak{g}$ this includes the simply laced Lie algebra, the tensor-branch quotient $(\mathbb{R}^5 \otimes \mathfrak{t}_{\mathfrak{g}})/W_{\mathfrak{g}}$, the anomaly polynomial (96.5), the root-lattice BPS strings, the discriminant group $A_{\mathfrak{g}} = P_{\mathfrak{g}}/Q_{\mathfrak{g}}$ with finite pairing (96.14), and the five-dimensional compactification normalization $g_5^2 = 4\pi^2 R$ in trace-delta variables. For class-S compactifications it includes the surface C, the marked points p_a, their defect data $\mathfrak{D}_a$, the twist sign η, the anomaly pushforward with defect contributions, the protected Hitchin-base description of Coulomb coordinates when available, and the descended extended operators and finite-flux polarization data.

No item in this list is dispensable. A proposed fixed point that supplies only a branch EFT is incomplete; a proposed non-Lagrangian object that supplies only protected indices is also incomplete. Likewise, a phrase such as “the class-S theory” has no standing in this chapter unless the tuple of compactification data in Hypothesis 96.10 has been supplied and the existence of the resulting four-dimensional local QFT is being assumed or constructed.

Open Problem 96.14 (Six-dimensional construction). Construct an interacting six-dimensional SCFT as a local QFT with Hilbert space, local operator algebra, stress tensor, anomaly polynomial, tensor branch, BPS strings, and compactification functoriality in one framework.

Chapter 97

Planar N=4 Supersymmetric Yang-Mills as a Spectral Problem

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The subject of this chapter is the spectrum of local gauge-invariant operators in four-dimensional $\mathcal{N} = 4$ supersymmetric Yang–Mills theory in the planar limit. The same theory appears earlier in this volume as a maximally supersymmetric conformal gauge theory. Here it is treated as a spectral problem: diagonalize the dilatation operator on the vector space of renormalized local operators.

97.1 SCFT Data Before Planarity

The planar spin chain is not the definition of the theory. It is a useful coordinate system on a particular large-N sector of a four-dimensional superconformal gauge theory. We first record the intrinsic quantum-field theory data that will remain meaningful at finite N, away from any spin-chain limit.

Definition 97.1 (N=4 Yang-Mills field content)**.** Fix a compact gauge group G, Lie algebra $\mathfrak{g}$, and invariant trace form tr as in Chapter 87. The four-dimensional $\mathcal{N} = 4$ Yang–Mills field variables consist of

$$A_\mu, \qquad \Phi^I \ (I = 1, \dots, 6), \qquad \lambda^A_\alpha,\ \bar{\lambda}_{A\dot{\alpha}} \ (A = 1, \dots, 4),$$

all valued in $\mathfrak{g}$. The six real scalars transform in the vector representation of $SO(6)_R$, equivalently in the antisymmetric representation of $SU(4)_R$; the four Weyl fermions transform in the fundamental of $SU(4)_R$. In the monograph coupling convention the bosonic part of the Lorentzian action is

$$\begin{aligned} S_{\rm bos} = \frac{1}{g_{\rm YM}^2}\int d^4x\ \mathrm{tr}\Big(-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2}D_\mu\Phi^I D^\mu\Phi^I + \frac{1}{4}[\Phi^I,\Phi^J][\Phi^I,\Phi^J]\Big) \\ + \frac{\theta}{32\pi^2}\int d^4x\ \mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu}). \end{aligned}$$

together with the unique Yukawa couplings compatible with the same $\mathcal{N}=4$ supersymmetry and $SU(4)_R$ action. The complexified gauge coupling is

$$\tau = \frac{\theta}{2\pi} + \frac{4\pi\mathrm{i}}{g_{\rm YM}^2}$$

in the present trace convention.

Equivalently, after choosing an $\mathcal{N}=1$ subalgebra, the same field field content is an $\mathcal{N}=1$ vector multiplet plus three adjoint chiral multiplets Φ_1,Φ_2,Φ_3, with cubic superpotential

$$W_{\mathcal{N}=4} = \sqrt{2}\ \mathrm{tr}\big(\Phi_1[\Phi_2,\Phi_3]\big),$$

after the superpotential coupling has been tied to $g_{\rm YM}$ by the enhanced supersymmetry. This $\mathcal{N}=1$ presentation is a bookkeeping device for an $SU(3)\times U(1)$ subgroup of the full $SU(4)_R$ theory.

Remark 97.2 (One-loop and holomorphic beta-function cancellation)*.* Let $C_2(\mathfrak{g})$ denote the adjoint quadratic Casimir in the chosen trace convention. The one-loop gauge beta-function coefficient of the $\mathcal{N}=4$ field content vanishes. In the $\mathcal{N}=1$ Wilsonian coordinate, the one-loop holomorphic coefficient vanishes as well.

In an ordinary four-dimensional gauge-theory convention, one vector, four adjoint Weyl fermions, and six adjoint real scalars contribute

$$b_0 = C_2(\mathfrak{g})\left(\frac{11}{3} - 4\frac{2}{3} - 6\frac{1}{6}\right) = 0.$$

In the $\mathcal{N}=1$ presentation, the holomorphic Wilsonian coefficient is

$$b_0^{\rm hol} = 3\,C_2(\mathfrak{g}) - \sum_{a=1}^{3} T(\mathrm{adj}) = 3\,C_2(\mathfrak{g}) - 3\,C_2(\mathfrak{g}) = 0.$$

The two calculations use different coupling coordinates, but both make the same elementary field-content cancellation explicit.

Hypothesis 97.3 (Finite $\mathcal{N}=4$ conformal-family input)**.** Fix the field content of Definition 97.1. Assume there is a local regulator and renormalization prescription with the following properties.

1. Gauge Ward identities, locality, Poincare covariance, all sixteen supercharges, and $SU(4)_R$ Ward identities are implemented without an anomaly.

2. The renormalized stress tensor and the $SU(4)_R$ currents belong to a conserved $\mathfrak{psu}(2,2|4)$ current multiplet, and the operator sourced by the complex coupling τ is the corresponding dimension-four top component.
3. After the gauge-field normalization and possible background contact terms are fixed, no additional $\mathcal{N}=4$-preserving marginal source or current-moment-map obstruction is generated in the τ direction.
4. In this source coordinate the beta function of τ vanishes.

This hypothesis is the precise status boundary. The one-loop calculation in Remark 97.2 is an elementary check on the required cancellation; the all-order assertion is a renormalization theorem with regulator-level input, independent of the spin-chain construction.

Definition 97.4 (Coupling chart and theta periodicity)**.** The local Yang–Mills coupling chart is the upper half-plane

$$\mathfrak{H}=\{\tau\in\mathbb{C}\mid \operatorname{Im}\tau>0\},\qquad \tau=\frac{\theta}{2\pi}+\frac{4\pi\mathrm{i}}{g_{\mathrm{YM}}^2}.$$

When the trace form and global gauge choice are chosen so that

$$k[A]=\frac{1}{32\pi^2}\int \operatorname{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu})\in\mathbb{Z}$$

on closed spin four-manifolds in the allowed bundle sectors, the path-integral phase $\exp(\mathrm{i}\theta k[A])$ is unchanged by

$$T:\tau\longmapsto\tau+1.$$

Thus $q=\exp(2\pi\mathrm{i}\tau)$ is the natural weak-coupling coordinate near the cusp $\operatorname{Im}\tau=\infty$.

Remark 97.5 (Local $\mathcal{N}=4$ conformal manifold)*.* Assume Hypothesis 97.3. Before imposing any duality identifications, the $\mathcal{N}=4$ Yang–Mills coupling chart $\mathfrak{H}$ is a one-complex-dimensional local conformal manifold. The tangent vector represented by $\partial/\partial\tau$ is the exactly marginal deformation obtained by integrating the protected dimension-four top component of the stress-tensor multiplet.

The source-coordinate system has one complex coordinate, namely τ. By Hypothesis 97.3, the beta map in this chart is identically zero after the declared normalization and contact-term choices are fixed, and no redundant source direction remains to be quotiented. The zero locus of the beta map is therefore all of $\mathfrak{H}$. Its complex dimension is

$$1-0=1.$$

The inserted operator $\partial S/\partial\tau$ is exactly marginal because it has protected dimension 4 and its source has zero beta function in the same chart. This proves the local statement. Global electric-magnetic identifications between different values of τ are additional data.

Hypothesis 97.6 (Duality-group input)**.** For a fixed global form of the gauge group and a fixed line-operator lattice, let $\Gamma\subset PSL(2,\mathbb{Z})$ be the subgroup of genuine four-dimensional $\mathcal{N}=4$ QFT equivalences acting on the same extended theory structure. Its elements act on the coupling by

$$\tau\longmapsto\frac{a\tau+b}{c\tau+d},\qquad \begin{pmatrix}a&b\\c&d\end{pmatrix}\in SL(2,\mathbb{Z}).$$

For the standard local-operator sector of $SU(N)$ Yang–Mills one often uses the full $PSL(2,\mathbb{Z})$ generated by

$$T:\tau\mapsto\tau+1,\qquad S:\tau\mapsto-\frac{1}{\tau},$$

but the precise global quotient depends on the line-operator and global-form structure. This hypothesis is an input about nonperturbative QFT equivalences, with no string-theory construction entering the argument.

Remark 97.7 (Global quotient, conditional on duality). Assume Hypotheses 97.3 and 97.6. The local conformal family $\mathfrak{H}$ descends, for the chosen extended theory structure, to the orbifold conformal parameter space

$$\mathfrak{H}/\Gamma.$$

The generator T is the theta-periodicity of Definition 97.4; the generator S, when it belongs to Γ, exchanges the weak-coupling cusp with a strong-coupling region.

The action of $SL(2,\mathbb{Z})$ on $\mathfrak{H}$ preserves $\operatorname{Im}\tau>0$ because

$$\operatorname{Im}\frac{a\tau+b}{c\tau+d}=\frac{\operatorname{Im}\tau}{|c\tau+d|^2}.$$

Matrices differing by an overall sign have the same fractional-linear action, so the effective group is a subgroup of $PSL(2,\mathbb{Z})$. If $\gamma\in\Gamma$ is a genuine QFT equivalence for the fixed extended structure, then τ and $\gamma\cdot\tau$ label the same point of the global conformal parameter space. Quotienting $\mathfrak{H}$ by these identifications gives $\mathfrak{H}/\Gamma$. The statement is conditional on the duality hypothesis; local exact marginality alone gives only $\mathfrak{H}$.

The spin-chain spectral problem below uses the local SCFT family and the planar single-trace dilatation operator, with the global duality quotient kept as separate input.

Conformal anomaly coefficients. For $G=SU(N)$,

$$a=c=\frac{\dim\mathfrak{su}(N)}{4}=\frac{N^2-1}{4}.$$

For $G=U(N)$, including the free abelian multiplet,

$$a=c=\frac{N^2}{4}.$$

The trace-anomaly coefficients of free conformal fields in four dimensions are

$$a_{\text{scalar}}=\frac{1}{360},\quad a_{\text{Weyl}}=\frac{11}{720},\quad a_{\text{vector}}=\frac{31}{180},$$

and

$$c_{\text{scalar}}=\frac{1}{120},\quad c_{\text{Weyl}}=\frac{1}{40},\quad c_{\text{vector}}=\frac{1}{10}.$$

One $\mathcal{N}=4$ vector multiplet per generator of $\mathfrak{g}$ contains six real scalars, four Weyl fermions, and one gauge vector. Hence

$$a_{\text{multiplet}}=6\frac{1}{360}+4\frac{11}{720}+\frac{31}{180}=\frac{1}{4},$$

and

$$c_{\text{multiplet}} = 6\frac{1}{120} + 4\frac{1}{40} + \frac{1}{10} = \frac{1}{4}.$$

Multiplying by $\dim\mathfrak{g}$ gives the displayed formulae. The use of the free-field coefficients is justified because a and c sit in the same protected stress-tensor multiplet data along the exactly marginal $\mathcal{N} = 4$ conformal manifold. Thus the calculation is a convention fixing and protected-data evaluation, conditional on the exact marginality and stress-tensor-multiplet protection stated above, rather than an independent derivation of the interacting theory from first principles.

97.2 Protected Operators and Elementary OPE Data

Let $C_{I_1\cdots I_k}$ be a symmetric traceless tensor of $SO(6)_R$:

$$C_{I_{\sigma(1)}\cdots I_{\sigma(k)}} = C_{I_1\cdots I_k}, \qquad \delta^{I_a I_b} C_{I_1\cdots I_k} = 0.$$

The corresponding single-trace half-BPS representative is

$$\mathcal{O}_C^{(k)} = C_{I_1\cdots I_k}\,\operatorname{tr}\!\big(\Phi^{I_1}\cdots\Phi^{I_k}\big),$$

with normal ordering and operator mixing understood in the renormalized local-operator space. It transforms in the $SU(4)_R$ representation $[0,k,0]$.

Quoted Theorem 97.8 (Half-BPS protection)**.** *In unitary four-dimensional $\mathcal{N} = 4$ superconformal Yang–Mills theory, a scalar superconformal primary in the half-BPS multiplet $[0,k,0]$ has exact scaling dimension*

$$\Delta = k.$$

The two- and three-point functions of half-BPS primaries, after fixing their normalization, are independent of the exactly marginal coupling.

This is a representation-theoretic and nonrenormalization statement. It does not say that every gauge-invariant word with classical dimension k is protected. The singlet

$$\mathcal{K} = \operatorname{tr}(\Phi^I\Phi^I)$$

is the Konishi primary; it belongs to a long multiplet and acquires an anomalous dimension. The traceless tensor

$$\mathcal{O}^{IJ} = \operatorname{tr}(\Phi^I\Phi^J) - \frac{1}{6}\delta^{IJ}\operatorname{tr}(\Phi^K\Phi^K)$$

is the bottom component of the stress-tensor multiplet and has $\Delta = 2$.

Remark 97.9 (Stress-tensor-multiplet normalization)*.* Choose an orthonormal basis T^a of $\mathfrak{g}$ with $\operatorname{tr}(T^aT^b) = \delta^{ab}$, and write

$$\langle \Phi^{I,a}(x)\Phi^{J,b}(0)\rangle_{\text{free}} = \frac{g_{\text{YM}}^2\,\delta^{IJ}\delta^{ab}}{4\pi^2 x^2}.$$

Define

$$B^{IJ} = g_{\text{YM}}^{-2} : \operatorname{tr}(\Phi^I\Phi^J) :, \qquad O^{IJ} = B^{IJ} - \frac{1}{6}\delta^{IJ}B^{KK},$$

and let

$$P^{IJ,KL} = \frac{1}{2}(\delta^{IK}\delta^{JL} + \delta^{IL}\delta^{JK}) - \frac{1}{6}\delta^{IJ}\delta^{KL}$$

be the projector onto symmetric traceless $SO(6)$ tensors. Then

$$\langle O^{IJ}(x)O^{KL}(0)\rangle_{\rm free} = \frac{\dim\mathfrak{g}}{8\pi^4 x^4}\, P^{IJ,KL}.$$

Consequently

$$\mathbb{O}^{IJ} = \frac{2\sqrt{2}\,\pi^2}{\sqrt{\dim\mathfrak{g}}}\, O^{IJ}$$

has the canonical two-point function

$$\langle\mathbb{O}^{IJ}(x)\mathbb{O}^{KL}(0)\rangle = \frac{P^{IJ,KL}}{x^4}.$$

Wick contraction gives

$$\langle B^{IJ}(x)B^{KL}(0)\rangle_{\rm free} = \frac{\dim\mathfrak{g}}{16\pi^4 x^4}\big(\delta^{IK}\delta^{JL}+\delta^{IL}\delta^{JK}\big).$$

Subtracting the trace in each pair projects both index pairs with P. The result is

$$\frac{\dim\mathfrak{g}}{16\pi^4 x^4}\left(\delta^{IK}\delta^{JL}+\delta^{IL}\delta^{JK}-\frac{1}{3}\delta^{IJ}\delta^{KL}\right) = \frac{\dim\mathfrak{g}}{8\pi^4 x^4}P^{IJ,KL}.$$

Multiplication by $(2\sqrt{2}\pi^2)^2/\dim\mathfrak{g}$ gives the normalized two-point function.

There is also a useful planar chiral-ring convention. For $G = SU(N)$, let

$$Z = \frac{1}{\sqrt{2}}(\Phi^5 + \mathrm{i}\Phi^6), \qquad \mathcal{Z}_J = \frac{(2\pi)^J}{g_{\rm YM}^J\sqrt{J\,N^J}}\ :\mathrm{tr}(Z^J):$$

in the leading large-N single-trace normalization.

Planar chiral-primary normalization. At leading planar order and for fixed J, J_1, J_2 as $N\to\infty$,

$$\langle\mathcal{Z}_J(x)\,\overline{\mathcal{Z}}_J(0)\rangle_{\rm pl} = \frac{1}{x^{2J}},$$

and, for $J = J_1 + J_2$,

$$\big\langle\mathcal{Z}_{J_1}(x_1)\mathcal{Z}_{J_2}(x_2)\overline{\mathcal{Z}}_J(x_3)\big\rangle_{\rm pl} = \frac{\sqrt{J_1J_2J}}{N}\,\frac{1}{x_{13}^{2J_1}x_{23}^{2J_2}}.$$

Equivalently, in the protected chiral OPE,

$$\mathcal{Z}_{J_1}(x)\mathcal{Z}_{J_2}(0) = \frac{\sqrt{J_1J_2(J_1+J_2)}}{N}\,\mathcal{Z}_{J_1+J_2}(0) + \text{descendants and multi-traces}$$

at leading planar order. The elementary propagator in the trace convention used above is

$$\langle Z^a(x)\overline{Z}^b(0)\rangle_{\rm free} = \frac{g_{\rm YM}^2}{4\pi^2x^2}\delta^{ab}.$$

For a single trace of length J, planar Wick contractions pair each Z with the corresponding $\overline{Z}$ in a cyclic order. There are J choices of the relative cyclic origin, and the double-line color graph has J leading color loops. Hence

$$\big\langle : \mathrm{tr}(Z^J) : (x) : \mathrm{tr}(\overline{Z}^J) : (0) \big\rangle_{\mathrm{pl}} = J N^J \left(\frac{g_{\mathrm{YM}}^2}{4\pi^2 x^2} \right)^J .$$

Multiplying by the two normalization factors in $\mathcal{Z}_J$ gives the unit two-point function.

For the extremal three-point function put $J = J_1 + J_2$. At leading planar order all fields in the first two holomorphic traces contract with the single anti-holomorphic trace. A planar embedding is fixed by choosing the cyclic origin of the anti-holomorphic trace, the cyclic origin of the J_1-trace, and the cyclic origin of the J_2-trace. This gives $J J_1 J_2$ planar embeddings. The connected double-line graph has $J-1$ leading color loops, because three trace boundaries have been joined into one planar pair-of-pants graph. Therefore

$$\begin{aligned} &\big\langle : \mathrm{tr}(Z^{J_1}) : (x_1) : \mathrm{tr}(Z^{J_2}) : (x_2) : \mathrm{tr}(\overline{Z}^J) : (x_3) \big\rangle_{\mathrm{pl}} \\ &\qquad = J J_1 J_2 \, N^{J-1} \left(\frac{g_{\mathrm{YM}}^2}{4\pi^2} \right)^J \frac{1}{x_{13}^{2J_1} x_{23}^{2J_2}}. \end{aligned}$$

The product of the three normalization constants contributes

$$\frac{(2\pi)^{2J}}{g_{\mathrm{YM}}^{2J} \sqrt{J_1 N^{J_1}} \sqrt{J_2 N^{J_2}} \sqrt{J N^J}},$$

which reduces the coefficient to $\sqrt{J_1 J_2 J}/N$. The displayed OPE coefficient follows by taking $x_1 \to x_2$ in this protected extremal three-point function with the two-point normalization already fixed.

Finite-N trace relations and multi-trace mixing are not suppressed in this formula; they are part of the exact protected-operator problem rather than the single-trace spin-chain problem.

97.3 Planar Limit and Operator Hilbert Space

Let the gauge group be $SU(N)$ or $U(N)$, with gauge coupling defined by the kinetic term

$$\frac{1}{4 g_{\mathrm{YM}}^2} \int \mathrm{d}^4 x \; \mathrm{tr}(F_{\mu\nu} F^{\mu\nu})$$

in the trace normalization used throughout the gauge-theory volumes. The 't Hooft coupling is

$$\lambda = g_{\mathrm{YM}}^2 N, \qquad g = \frac{\sqrt{\lambda}}{4\pi}.$$

The planar limit means

$$N \to \infty, \qquad \lambda \text{ fixed},$$

with local single-trace operators normalized so that their planar two-point functions remain finite.

Let $\mathfrak{V}$ denote the one-letter vector space spanned by the elementary adjoint fields of $\mathcal{N}=4$ SYM and their covariant derivatives, modulo the equations of motion and gauge-covariant descendant relations appropriate to local-operator renormalization. For fixed length L, a single-trace word is

$$\mathcal{O}_W(x) = \mathrm{tr}\big(W_1(x)W_2(x)\cdots W_L(x)\big), \qquad W_i \in \mathfrak{V}.$$

Cyclicity of the trace identifies

$$W_1 \otimes W_2 \otimes \cdots \otimes W_L \sim W_2 \otimes \cdots \otimes W_L \otimes W_1.$$

Thus the fixed-length single-trace space is the cyclic quotient

$$\mathcal{H}_L^{\mathrm{cyc}} = \mathfrak{V}^{\otimes L}/\langle \tau - 1\rangle,$$

where τ shifts all letters by one site. For planar perturbation theory this quotient is equipped with the large-N inner product obtained from the leading two-point function. If $W = W_1 \otimes \cdots \otimes W_L$ and $W' = W_1' \otimes \cdots \otimes W_L'$ are words of the same classical dimension, define

$$\langle W, W'\rangle_{\mathrm{pl}} = \frac{1}{L\,N^L}\sum_{r=0}^{L-1}\prod_{j=1}^{L}\langle W_j, W'_{j+r}\rangle_{\mathrm{letter}}, \qquad j+r \text{ read modulo } L.$$

The factor N^{-L} removes the leading color loop, while L^{-1} averages over the trace origin. Operators differing by equations of motion, gauge-covariant total derivatives, or Q-exact representatives in a chosen protected cohomological sector are first quotient out in the renormalized local-operator space; the spin-chain word is a representative of that quotient, not a new fundamental Hilbert space.

Definition 97.10 (Planar single-trace spectral problem)**.** Fix a renormalization scheme preserving the manifest $SU(4)_R$ and Poincare symmetries of $\mathcal{N}=4$ SYM and fix a closed sector $\mathcal{S} \subset \mathfrak{V}$ under planar mixing to a specified loop order. The planar single-trace spectral problem of length L is the cyclic quotient $\mathcal{S}^{\otimes L}/\langle \tau - 1\rangle$, its planar two-point inner product above, and the restriction of the anomalous-dimension matrix Γ to the quotient. A spin-chain Hamiltonian is a coordinate description of this problem after a basis of letters has been chosen.

The dilatation operator D is defined by the logarithmic scale dependence of renormalized local operators. In a basis $\mathcal{O}_A$,

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\mathcal{O}_A = -\Gamma_A{}^B\mathcal{O}_B, \qquad D_A{}^B = (D_0)_A{}^B + \Gamma_A{}^B.$$

At a conformal fixed point, diagonalizing D is equivalent to finding local operators of definite scaling dimension. Planarity implies that, at fixed loop order, D acts locally along the cyclic word: at ℓ loops the range is at most $\ell+1$ adjacent sites in the scalar subsectors described below.

97.4 The SU(2) Scalar Sector

Choose two complex scalar fields

$$Z = \frac{1}{\sqrt{2}}(\phi^5 + \mathrm{i}\phi^6), \qquad X = \frac{1}{\sqrt{2}}(\phi^1 + \mathrm{i}\phi^2).$$

The $SU(2)$ scalar sector is spanned by

$$\mathrm{tr}(W_1 \cdots W_L), \qquad W_i \in \{Z, X\}.$$

Identify Z with a down spin and X with an up spin:

$$Z \leftrightarrow |{\downarrow}\rangle, \qquad X \leftrightarrow |{\uparrow}\rangle.$$

Let $P_{j,j+1}$ be the operator that interchanges the two letters at sites j and $j+1$, with $L+1 \equiv 1$.

The local mixing calculation may be reduced to a two-site problem. In the scalar potential, the term relevant for holomorphic X, Z words is

$$V_{\mathrm{sc}} = -\frac{1}{2g_{\mathrm{YM}}^2}\,\mathrm{tr}\big([\Phi_I, \Phi_J][\Phi_I, \Phi_J]\big)$$

with the complex fields embedded in the six real scalars Φ_I. In double-line notation, a planar contraction of a quartic vertex with two adjacent letters has one color loop fewer than the free two-point function and hence contributes $g_{\mathrm{YM}}^2 N = \lambda$. Non-adjacent contractions are non-planar in a single trace and are suppressed by N^{-2}.

Two-site scalar mixing tensor. On adjacent holomorphic $SU(2)$ letters, the logarithmic one-loop mixing tensor has the form

$$\Gamma^{(1)}_{j,j+1} = \frac{\lambda}{8\pi^2}\,(1 - P_{j,j+1})$$

after adding the scalar self-energy and gauge-exchange contributions required by $\mathcal{N} = 4$ supersymmetry. The statement is perturbative in the chosen dimensional-regularization/minimal-subtraction convention.

The quartic vertex gives a local tensor generated by the two invariant maps on two $SU(2)$ letters: the identity I and the permutation P. The planar color contraction of $\mathrm{tr}(T^{a_1}T^{a_2}\cdots T^{a_L})$ with a vertex joining sites $j, j+1$ produces $N\,\mathrm{tr}(\cdots T^{b_j}T^{b_{j+1}}\cdots)$ at leading order, so the coefficient is proportional to λ and no operator with separated sites appears. The scalar bubble integral in $d = 4 - 2\varepsilon$ dimensions has logarithmic part

$$\frac{1}{(4\pi)^2}\frac{1}{\varepsilon} \quad \Longleftrightarrow \quad \frac{1}{8\pi^2}\log\mu$$

in the anomalous-dimension convention used for two-point functions. The exchange part is $-P$. The identity part receives the non-exchange scalar, gauge, and self-energy pieces. The protected operator $\mathrm{tr}(Z^L)$ is an eigenvector with zero anomalous dimension, so the total two-site tensor annihilates every symmetric ZZ pair. This fixes the identity coefficient to $+1$ in the same normalization, giving $(\lambda/8\pi^2)(I - P)$.

The argument just given is a convention-fixing derivation inside the one-loop planar regularization scheme. Its scope is the local Hamiltonian normalization used by the integrability construction below; a component-level diagrammatic derivation in a chosen gauge would require listing the scalar, gauge-exchange, and self-energy graphs in the same regularization convention.

97.5 The SO(6) Scalar Hamiltonian and the SU(2) Reduction

The $SU(2)$ calculation is a subsector of the full scalar one-loop Hamiltonian. Let the six real scalars be denoted Φ_I, $I = 1, \ldots, 6$, and write a two-site scalar state as $\Phi_I \otimes \Phi_J$. There are three invariant maps on $\mathbb{R}^6 \otimes \mathbb{R}^6$:

$$I(\Phi_I \otimes \Phi_J) = \Phi_I \otimes \Phi_J,$$
$$P(\Phi_I \otimes \Phi_J) = \Phi_J \otimes \Phi_I,$$
$$K(\Phi_I \otimes \Phi_J) = \delta_{IJ} \sum_{K=1}^{6} \Phi_K \otimes \Phi_K.$$

Here P permutes the two $SO(6)$ vector indices and K is the trace operator. In the normalization fixed by the $SU(2)$ Hamiltonian calculation below, the scalar one-loop nearest-neighbor density is

$$\Gamma^{(1)}_{j,j+1} = \frac{\lambda}{16\pi^2}\big(K_{j,j+1} + 2I_{j,j+1} - 2P_{j,j+1}\big). \tag{97.1}$$

The K-term is the place where the full $SO(6)$ chain differs from the holomorphic $SU(2)$ chain.

Remark 97.11 (Holomorphic reduction of the $SO(6)$ density). On the holomorphic sector generated by Z and X, the trace operator K in (97.1) vanishes, and the density reduces to

$$\frac{\lambda}{8\pi^2}(I - P).$$

The operator K contracts the $SO(6)$ indices of the two adjacent scalar letters. In the complex basis $Z = (\Phi_5 + \mathrm{i}\Phi_6)/\sqrt{2}$ and $X = (\Phi_1 + \mathrm{i}\Phi_2)/\sqrt{2}$, the holomorphic contractions are null:

$$Z \cdot Z = X \cdot X = Z \cdot X = 0.$$

Thus K annihilates $Z \otimes Z$, $Z \otimes X$, $X \otimes Z$, and $X \otimes X$. Substituting $K = 0$ in (97.1) gives

$$\frac{\lambda}{16\pi^2}(2I - 2P) = \frac{\lambda}{8\pi^2}(I - P).$$

This reduction is a useful convention check. If the overall coefficient or the sign of P is changed, the $SO(6)$ formula no longer restricts to the Konishi normalization computed below.

One-loop planar $SU(2)$ Hamiltonian. In the $SU(2)$ scalar sector, with the coupling convention above, the planar one-loop dilatation operator is

$$D = L + \frac{\lambda}{8\pi^2} H_{XXX} + O(\lambda^2), \qquad H_{XXX} = \sum_{j=1}^{L} (1 - P_{j,j+1})$$

on the cyclic spin-chain quotient. The only planar one-loop terms that move X and Z letters inside the holomorphic $SU(2)$ sector come from the scalar quartic interaction and the wavefunction and non-exchange diagrams required by supersymmetry. The exchange part is local on adjacent sites and is proportional to $-P_{j,j+1}$. The non-exchange part is proportional to the identity on the same pair. Hence the most general nearest-neighbor planar one-loop operator compatible with the two-letter $SU(2)$ symmetry and translation around the trace is

$$c\sum_{j=1}^{L}(1-P_{j,j+1})+c'\sum_{j=1}^{L}(1+P_{j,j+1}).$$

The half-BPS operators $\mathrm{tr}(Z^L)$ and their fully symmetrized scalar descendants have protected scaling dimension. On a symmetric pair, $P_{j,j+1}=1$, so protection forces $c'=0$. The coefficient c is fixed by the logarithmic part of the single adjacent exchange integral. In the present normalization the divergent scalar integral is

$$\frac{\lambda}{8\pi^2}\log(\mu|x|)+\text{finite},$$

and its color contraction is planar and nearest-neighbor. Substituting this coefficient gives the displayed H_{XXX}. The cyclic quotient implements the trace relation and imposes zero total spin-chain momentum on physical single-trace states.

This calculation uses supersymmetric protection only to fix the identity term after the exchange coefficient has been computed. This is a useful place where the field-theory origin of the spin chain matters: the spin-chain Hamiltonian is not introduced independently of the renormalized local-operator problem.

97.6 Coordinate Bethe Ansatz

We now diagonalize the dimensionless Hamiltonian

$$H_{XXX}=\sum_j(1-P_{j,j+1})$$

before reinstating the overall factor $\lambda/(8\pi^2)$. On an infinite chain let $|n\rangle$ denote the state with a single X at site $n\in\mathbb{Z}$ and Z's elsewhere. A one-magnon wavefunction is

$$\Psi_p(n)=\mathrm{e}^{\mathrm{i}pn}.$$

The Hamiltonian H_{XXX} gives

$$(H_{XXX}\Psi_p)(n)=2\Psi_p(n)-\Psi_p(n+1)-\Psi_p(n-1),$$

hence

$$E_1(p)=4\sin^2\frac{p}{2}.$$

The corresponding one-loop anomalous dimension contribution is

$$\gamma_1(p)=\frac{\lambda}{8\pi^2}E_1(p).$$

On a cyclic single trace a single magnon with nonzero momentum is not a physical operator, because trace cyclicity requires total momentum zero. The one-magnon calculation is nevertheless the local dispersion input for multi-magnon states.

Two-magnon contact matching for the one-loop chain. Let $z_a = \mathrm{e}^{\mathrm{i}p_a}$, $a = 1, 2$, and let

$$u_a = \frac{1}{2}\cot\frac{p_a}{2}, \qquad z_a = \frac{u_a + \mathrm{i}/2}{u_a - \mathrm{i}/2}.$$

In the two-magnon chamber $n_1 < n_2$, set

$$\Psi(n_1, n_2) = A_{12}\mathrm{e}^{\mathrm{i}(p_1 n_1 + p_2 n_2)} + A_{21}\mathrm{e}^{\mathrm{i}(p_2 n_1 + p_1 n_2)}.$$

The separated chamber equation makes Ψ an eigenfunction of H_{XXX} with energy $E_1(p_1)+E_1(p_2)$. The contact equation at $n_2 = n_1 + 1$ then fixes the exchange coefficient:

$$\frac{A_{21}}{A_{12}} = \mathsf{a}(p_1, p_2) = -\frac{1 - 2\mathrm{e}^{\mathrm{i}p_2} + \mathrm{e}^{\mathrm{i}(p_1+p_2)}}{1 - 2\mathrm{e}^{\mathrm{i}p_1} + \mathrm{e}^{\mathrm{i}(p_1+p_2)}} = \frac{u_1 - u_2 - \mathrm{i}}{u_1 - u_2 + \mathrm{i}}.$$

When the magnons are separated, $n_2 > n_1 + 1$, the Hamiltonian is the sum of two one-particle finite-difference operators:

$$\begin{aligned}(H_{XXX}\Psi)(n_1, n_2) = 4\Psi(n_1, n_2) &- \Psi(n_1 - 1, n_2) - \Psi(n_1 + 1, n_2)\\ &- \Psi(n_1, n_2 - 1) - \Psi(n_1, n_2 + 1).\end{aligned}$$

Hence the separated equation fixes the energy to $E_1(p_1) + E_1(p_2)$. The only remaining condition is the contact equation at $n_2 = n_1 + 1$. There the adjacent XX pair is symmetric, so the middle link contributes zero and only the two exterior links move a magnon:

$$(H_{XXX}\Psi)(n, n+1) = 2\Psi(n, n+1) - \Psi(n-1, n+1) - \Psi(n, n+2).$$

Substituting the plane-wave ansatz and the separated energy gives

$$0 = -A_{21}z_1z_2 + 2A_{21}z_1 - A_{21} - A_{12}z_1z_2 + 2A_{12}z_2 - A_{12}.$$

Solving this linear equation for A_{21}/A_{12} gives the rational expression in z_1, z_2. Rewriting $z_a = (u_a + \mathrm{i}/2)/(u_a - \mathrm{i}/2)$ gives the displayed rapidity form.

The coefficient $\mathsf{a}(p_1, p_2)$ is the exchange coefficient for the ordered chamber convention just chosen. The Bethe–Yang phase in the closed chain is its inverse:

$$S_{\mathrm{BY}}(u_j, u_k) = \mathsf{a}(p_j, p_k)^{-1} = \frac{u_j - u_k + \mathrm{i}}{u_j - u_k - \mathrm{i}}.$$

This inverse is a convention-sensitive point. For two magnons, trace periodicity says

$$\Psi(n_1, n_2) = \Psi(n_2, n_1 + L), \qquad n_1 < n_2.$$

Comparing the coefficient of $\mathrm{e}^{\mathrm{i}(p_1 n_1 + p_2 n_2)}$ gives

$$A_{12} = A_{21}\mathrm{e}^{\mathrm{i}p_1 L}, \qquad \mathrm{e}^{\mathrm{i}p_1 L} = S_{\mathrm{BY}}(u_1, u_2).$$

The second equation is obtained by moving the other magnon around the trace. For M magnons the one-loop $XXX_{1/2}$ chain has factorized scattering; equivalently, the transfer matrices constructed in Chapter 74 commute and the coordinate wavefunction is consistent in every ordering chamber. The finite periodic-chain equations are therefore

$$\left(\frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2}\right)^L = \prod_{\substack{k=1\\k\neq j}}^{M} \frac{u_j - u_k + \mathrm{i}}{u_j - u_k - \mathrm{i}}, \qquad \prod_{j=1}^{M} \frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2} = 1. \tag{97.2}$$

The second equation is the cyclicity condition. The energy is

$$E = \sum_{j=1}^{M} \frac{1}{u_j^2 + 1/4}.$$

At one loop these Bethe equations are exact for the finite $XXX_{1/2}$ Hamiltonian. The word "asymptotic" in later all-loop chapters has a different meaning: the long-range planar dilatation operator ceases to be finite-neighbor once the loop order grows, and finite trace length then requires wrapping corrections.

97.7 Free Magnons and BMN Double Scaling

The spin-chain excitation called a magnon is first a coordinate on the single-trace local-operator problem. Temporarily work in the unquotiented length-L spin-chain space

$$\mathcal{H}_L = (\mathbb{C}Z \oplus \mathbb{C}X)^{\otimes L}$$

and let τ be the translation by one site. The cyclic single-trace space is the quotient by $\tau - 1$, equivalently the image of the projection

$$\Pi_0 = \frac{1}{L} \sum_{r=0}^{L-1} \tau^r$$

when the planar two-point inner product is used. A one-magnon Fourier vector

$$|p\rangle = \sum_{n=1}^{L} \mathrm{e}^{\mathrm{i}pn} |n\rangle, \qquad |n\rangle = Z \otimes \cdots \otimes X_n \otimes \cdots \otimes Z,$$

has τ-eigenvalue $\mathrm{e}^{-\mathrm{i}p}$. On the finite periodic chain

$$H_{XXX}|p\rangle = 4\sin^2\frac{p}{2}\,|p\rangle, \qquad \mathrm{e}^{\mathrm{i}pL} = 1.$$

Its cyclic projection vanishes unless $p = 0$ modulo 2π. Thus a single nonzero-momentum magnon is not itself a physical single-trace local operator; it is the one-particle building block out of which total zero-momentum multi-magnon operators are assembled.

For M impurities with M fixed and $L \to \infty$, the integer

$$J = L - M$$

counts the number of Z's in the word. A two-impurity relative Fourier coordinate, for example with distinguishable scalar letters A, B whose planar two-point pairing with Z vanishes, is represented before diagonalization by the local-operator class

$$\mathcal{O}^{(L)}_{n;A,B} = \sum_{\ell=0}^{J} \exp\left(\frac{2\pi \mathrm{i} n\ell}{J+1}\right) \mathrm{tr}\Big(AZ^{\ell}BZ^{J-\ell}\Big).$$

This formula fixes the relative-momentum convention. Diagonalization of an interacting closed sector further requires the contact matching and the cyclic Bethe equations. In the $SU(2)$ chain those equations give an exact finite-L statement.

Example 97.12 (Two-magnon BMN quantization at one loop)**.** Consider the $SU(2)$ scalar sector at one loop with two magnons of momenta p and $-p$ on a cyclic trace of length $L \geq 3$. Let

$$u = \frac{1}{2}\cot\frac{p}{2}.$$

The cyclic Bethe equations imply

$$e^{ip(L-1)} = 1, \qquad p = \frac{2\pi n}{L-1}, \quad n \in \mathbb{Z}/(L-1)\mathbb{Z}.$$

For the non-protected modes $n \not\equiv 0$, the one-loop anomalous dimension is

$$\gamma^{(1)}_{n,L} = \frac{\lambda}{8\pi^2}\, 8\sin^2\frac{\pi n}{L-1} = \frac{\lambda}{\pi^2}\sin^2\frac{\pi n}{L-1}. \tag{97.3}$$

Consequently, in the double scaling limit

$$J = L-2 \to \infty, \qquad \lambda' = \frac{\lambda}{J^2} \text{ fixed}, \qquad n \text{ fixed},$$

one obtains

$$\gamma^{(1)}_{n,L} = \lambda' n^2 + O(J^{-1}).$$

For the two roots $u_1 = u$, $u_2 = -u$, the cyclicity equation in (97.2) is automatic:

$$\frac{u+i/2}{u-i/2}\,\frac{-u+i/2}{-u-i/2} = 1.$$

The first Bethe equation gives

$$\left(\frac{u+i/2}{u-i/2}\right)^L = \frac{2u+i}{2u-i}.$$

Since $u = \frac{1}{2}\cot(p/2)$,

$$\frac{u+i/2}{u-i/2} = \frac{2u+i}{2u-i} = e^{ip},$$

where the branch of p is understood modulo 2π. Hence $e^{ipL} = e^{ip}$, equivalently $e^{ip(L-1)} = 1$. The second Bethe equation is the inverse of the first.

The spin-chain energy is the sum of the two one-particle energies,

$$E = \frac{1}{u^2+1/4} + \frac{1}{u^2+1/4} = 8\sin^2\frac{p}{2}.$$

Multiplication by the overall field-theory coefficient $\lambda/(8\pi^2)$ gives (97.3). Finally set $L = J+2$ and use

$$\sin\frac{\pi n}{J+1} = \frac{\pi n}{J+1} + O(J^{-3})$$

for fixed n. Then

$$\frac{\lambda}{\pi^2}\sin^2\frac{\pi n}{J+1} = \frac{\lambda}{(J+1)^2}n^2 + O(\lambda J^{-4}) = \lambda' n^2 + O(J^{-1})$$

with $\lambda' = \lambda/J^2$ fixed.

The shift $J \mapsto J+1$ in the exact one-loop two-magnon formula is the finite-chain scattering phase written in relative-coordinate language. It disappears at leading order in the BMN double scaling limit but is essential for the finite-length normalization: the length-four Konishi state below is the case $L = 4$, $n = 1$, hence $p = 2\pi/3$, not $p = \pi/2$.

The all-loop dispersion relation in Chapter 98 is a much stronger statement. Its small-momentum limit reproduces the same one-loop normalization, but its derivation uses the centrally extended residual symmetry, crossing, and the dressing phase. The BMN calculation above is therefore a normalization anchor for the gauge-theory spin chain, not an external definition of the spectral problem.

97.8 Konishi at One Loop

The shortest non-BPS state in this sector is the length-four two-magnon descendant represented by $\mathrm{tr}([X, Z]^2)$. Set

$$L = 4, \qquad M = 2, \qquad u_1 = \frac{1}{2\sqrt{3}}, \qquad u_2 = -\frac{1}{2\sqrt{3}}.$$

Then

$$\frac{u_1 + \mathrm{i}/2}{u_1 - \mathrm{i}/2} = \mathrm{e}^{2\pi\mathrm{i}/3}, \qquad \frac{u_2 + \mathrm{i}/2}{u_2 - \mathrm{i}/2} = \mathrm{e}^{-2\pi\mathrm{i}/3},$$

so the cyclicity product is 1. The first Bethe equation reads

$$\mathrm{e}^{8\pi\mathrm{i}/3} = \frac{u_1 - u_2 + \mathrm{i}}{u_1 - u_2 - \mathrm{i}} = \mathrm{e}^{2\pi\mathrm{i}/3},$$

and the second is its inverse. The spin-chain energy is

$$E = \frac{1}{1/12 + 1/4} + \frac{1}{1/12 + 1/4} = 6.$$

Therefore the one-loop anomalous dimension is

$$\gamma_{\mathrm{K}}^{(1)} = \frac{\lambda}{8\pi^2}\,6 = \frac{3\lambda}{4\pi^2}.$$

97.9 Closed Sectors and Long-Range Data

The $SU(2)$ sector is the smallest laboratory, but the planar spectral problem uses a hierarchy of closed sectors. The $SL(2)$ sector is spanned by

$$\mathrm{tr}(D_+^{s_1} Z\, D_+^{s_2} Z \cdots D_+^{s_L} Z), \qquad s_j \in \mathbb{Z}_{\geq 0},$$

where D_+ is a fixed lightlike covariant derivative. Its one-loop chain has noncompact spin at each site. The $SU(2|3)$ sector contains three complex scalars and two fermions and is the smallest sector in which the dynamic length-changing character of the higher-loop planar chain is visible. The full one-letter module is the oscillator representation of $\mathfrak{psu}(2, 2|4)$, and a local operator is a cyclic tensor product of that module subject to gauge-invariant trace cyclicity.

At ℓ loops in the asymptotic regime, the planar dilatation operator has the range-$(\ell{+}1)$ asymptotic expansion

$$D = D_0 + \sum_{\ell\geq 1} g^{2\ell} \sum_{j=1}^{L} H^{(\ell)}_{j,\dots,j+\ell}, \qquad g = \frac{\sqrt{\lambda}}{4\pi}.$$

For example, the $SU(2)$ long-range Hamiltonian begins

$$H^{(1)} = 2\{\,\} - 2\{1\},$$

in the permutation-structure notation where $\{\,\}$ is the identity sum and $\{1\} = \sum_j P_{j,j+1}$. Higher orders contain $\{1,2\}$, $\{2,1\}$, and longer permutation words. Their coefficients are not fixed by $SU(2)$ symmetry alone; they are constrained by Feynman graphs, BMN-scaling tests, integrability, and supersymmetry. The all-loop Bethe ansatz in the next chapter should therefore be read as an asymptotic integrability reconstruction of this long-range operator, not as an independent definition of the four-dimensional theory.

97.10 Beyond One Loop

At higher loop order the planar dilatation operator becomes a long-range spin chain. In the $SU(2)$ sector its range grows with loop order, and for an operator of finite length L interactions can wrap around the trace once the perturbative range reaches L. Thus there are two different spectral problems:

asymptotic long chain and finite trace with wrapping.

The next chapter describes the asymptotic all-loop Bethe ansatz. The following chapter explains how mirror TBA and the Y-system incorporate finite-length effects.

Chapter 98

All-Loop Asymptotic Bethe Ansatz

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The one-loop spin chain of Chapter 97 is only the first term in the planar dilatation operator. The all-loop asymptotic Bethe ansatz is a proposal for the spectrum of long single-trace operators before wrapping effects become important. Its inputs are the residual centrally extended $\mathfrak{su}(2|2) \oplus \mathfrak{su}(2|2)$ symmetry of the BMN vacuum, factorized magnon scattering, crossing, and analyticity.

98.1 Conventions

The integrability literature uses several mutually inverse scalar-factor and Zhukovsky conventions. This chapter follows the convention used in the stringbook integrability chapters, with the notational replacement

$$h_{\text{stringbook}} = g_{\text{monograph}} = \frac{\sqrt{\lambda}}{4\pi}.$$

Thus

$$x^\pm + \frac{1}{x^\pm} = \frac{u \pm \mathrm{i}/2}{g}, \qquad \mathrm{e}^{\mathrm{i}p} = \frac{x^+}{x^-},$$

and the physical weak-coupling branch has

$$x^\pm = \frac{\mathrm{e}^{\pm \mathrm{i}p/2}}{2g\sin(p/2)} + O(g).$$

The one-magnon energy is written in the stringbook-compatible form

$$H = -1 - 2\mathrm{i}g(x^+ - x^-) = 1 + 2\mathrm{i}g\left(\frac{1}{x^+} - \frac{1}{x^-}\right).$$

The equality of the two expressions is not an additional assumption: it is obtained by multiplying the defining $x^\pm$ relation by $2\mathrm{i}g$.

The scalar factor convention is also fixed here. We write $\sigma = \mathrm{e}^{\mathrm{i}\theta}$ and use the crossing equation in the same orientation as the stringbook:

$$\sigma_{12}\sigma_{\bar{1}2} = \frac{x_2^+}{x_2^-}\frac{x_2^+ - x_1^+}{x_2^+ - x_1^-}\frac{x_2^- - 1/x_1^+}{x_2^- - 1/x_1^-}.$$

Authors who put the rational scalar factor into the opposite part of the S-matrix, or define the two-body operator as S_{21} rather than S_{12}, write the reciprocal of this expression. The companion check script enforces the $x^\pm$-energy and sheet conventions used here; crossing itself remains a monodromy input rather than a finite algebraic identity.

Warning 98.1 (Status of magnon crossing). The crossing equation used in this chapter is not the Wightman–LSZ crossing theorem for four-dimensional local scattering amplitudes. A spin-chain magnon is an excitation above the chosen BMN vacuum in a single-trace sector; it is not created by a gauge-invariant local field, its two-body scattering operator is asymptotic in the trace length, and its dispersion is encoded on the Zhukovsky rapidity surface rather than on a relativistic mass shell. Consequently ordinary four-dimensional QFT does not by itself give the replacement $x^\pm \mapsto 1/x^\pm$ or the scalar equation displayed above.

The conceptual origin of the condition is the two-dimensional relativistic integrable sigma-model description that appears in the strong-coupling AdS/CFT analysis. Before uniform light-cone gauge fixing, that auxiliary two-dimensional theory has a Euclidean continuation in which mirror-channel interchange of space and time and relativistic crossing are realized as analytic continuation in rapidity. Gauge fixing and decompactification turn the excitations into nonrelativistic magnons with the Zhukovsky dispersion, so the inherited crossing operation has no intrinsic explanation from the nonrelativistic spin chain alone. In the resulting integrable sigma-model/spin-chain framework the crossed magnon is the contragredient short representation of the centrally extended residual symmetry; equivalently, the antipode operation sends the Zhukovsky variables to the crossed sheet $x^\pm \mapsto 1/x^\pm$ along a specified path. Matrix consistency with this crossed representation fixes the rational multiplier below, while the dressing phase is required to have the corresponding scalar monodromy. Extending this strong-coupling crossing condition to all 't Hooft coupling, and using it as a statement about planar gauge-theory anomalous dimensions, is an integrability assumption constrained by symmetry, unitarity, Yang–Baxter factorization, perturbative gauge-theory checks, and finite-size TBA/QSC tests. It is not presently a theorem derived from a constructive four-dimensional definition of $\mathcal{N} = 4$ SYM.

98.2 BMN Vacuum and Central Extension

The vacuum spin-chain state is

$$\mathrm{tr}(Z^J).$$

It is protected and carries large R-charge J. A magnon is an insertion into this long chain. The residual symmetry preserving the vacuum contains two centrally extended $\mathfrak{su}(2|2)$ algebras. For one copy, write the bosonic states as $|\phi^a\rangle$, $a = 1, 2$, and the fermionic states as $|\psi^\alpha\rangle$, $\alpha = 1, 2$. The supercharges act in the form

$$\begin{aligned} Q^\alpha{}_a|\phi^b\rangle &= a\,\delta^b_a|\psi^\alpha\rangle, & Q^\alpha{}_a|\psi^\beta\rangle &= b\,\varepsilon^{\alpha\beta}\varepsilon_{ab}|\phi^b Z^+\rangle, \\ S^a{}_\alpha|\phi^b\rangle &= c\,\varepsilon^{ab}\varepsilon_{\alpha\beta}|\psi^\beta Z^-\rangle, & S^a{}_\alpha|\psi^\beta\rangle &= d\,\delta^\beta_\alpha|\phi^a\rangle. \end{aligned}$$

The symbols Z^+ and Z^- record insertion or removal of one vacuum letter. On a momentum eigenstate,

$$Z^+ \mapsto \mathrm{e}^{\mathrm{i}p} - 1, \qquad Z^- \mapsto \mathrm{e}^{-\mathrm{i}p} - 1$$

up to the chosen side convention. The representation constraint is

$$ad - bc = 1.$$

The central charges are

$$P = ab, \qquad K = cd, \qquad H = ad + bc.$$

The shortening condition of the centrally extended algebra is

$$H^2 - 4PK = 1.$$

The central extension is compatible with trace cyclicity. A single magnon is an excitation on an open segment of the BMN vacuum, so $Z^\pm$ records length data at the edge of that segment. On a closed trace the product of all such phases is $\mathrm{e}^{\mathrm{i}P_{\mathrm{tot}}} - 1$, where P_{tot} is the total spin-chain momentum. The physical single-trace projection sets $P_{\mathrm{tot}} = 0$, but individual magnons may still transform in centrally extended short representations before that projection is imposed. With

$$P = g(1 - \mathrm{e}^{\mathrm{i}p}), \qquad K = g(1 - \mathrm{e}^{-\mathrm{i}p}),$$

this gives the exact single-magnon dispersion relation

$$H(p) = \sqrt{1 + 16g^2 \sin^2 \frac{p}{2}}. \tag{98.1}$$

The anomalous contribution of a magnon is $H(p) - 1$.

Controlled Approximation 98.2 (BMN scaling check)**.** Let $J \to \infty$ with $\lambda' = \lambda/J^2$ fixed and take

$$p = \frac{2\pi n}{J} + O(J^{-2}), \qquad n \in \mathbb{Z}.$$

Then

$$H(p) = \sqrt{1 + \lambda' n^2} + O(J^{-1}).$$

This is the all-coupling continuation of the gauge-theory BMN normalization derived at one loop in Example 97.12. Here it is a convention check on the spectral problem, not an external derivation of the all-coupling Bethe ansatz.

Dispersion from shortening. Assuming the centrally extended residual symmetry acts on a one-magnon representation with central charges $P = g(1-\mathrm{e}^{\mathrm{i}p})$ and $K = g(1-\mathrm{e}^{-\mathrm{i}p})$, the shortening condition gives the dispersion relation by the finite algebraic check

$$PK = g^2(1-\mathrm{e}^{\mathrm{i}p})(1-\mathrm{e}^{-\mathrm{i}p}) = 4g^2 \sin^2 \frac{p}{2}.$$

Substitution into $H^2 - 4PK = 1$ gives

$$H^2 = 1 + 16g^2 \sin^2 \frac{p}{2}.$$

The positive square root is selected because $H = 1$ at $g = 0$ for an elementary magnon.

98.3 Zhukovsky Variables

Introduce the Zhukovsky map $x(u)$ by

$$x(u) + \frac{1}{x(u)} = \frac{u}{g}. \tag{98.2}$$

The physical branch is the solution satisfying $x(u) \sim u/g$ as $|u| \to \infty$. Equivalently,

$$x_{\mathrm{ph}}(u) = \frac{1}{2}\left(\frac{u}{g} + \sqrt{\frac{u}{g} - 2}\sqrt{\frac{u}{g} + 2}\right),$$

with the square-root cuts chosen so that the only short cut on the physical sheet is $[-2g, 2g]$. Crossing this cut replaces x by $1/x$. More precisely, the two boundary values on the cut satisfy

$$x_{\mathrm{above}}(u)x_{\mathrm{below}}(u) = 1, \qquad -2g < u < 2g.$$

The large-u expansion on the physical sheet is

$$x_{\mathrm{ph}}(u) = \frac{u}{g} - \frac{g}{u} - \frac{g^3}{u^3} - \frac{2g^5}{u^5} + O(u^{-7}).$$

For a one-magnon state set

$$x^{\pm} = x(u \pm \mathrm{i}/2).$$

Then

$$\mathrm{e}^{\mathrm{i}p} = \frac{x^+}{x^-}, \qquad x^+ + \frac{1}{x^+} - x^- - \frac{1}{x^-} = \frac{\mathrm{i}}{g}. \tag{98.3}$$

The physical region for real magnons is chosen so that $(x^+)^* = x^-$ and $|x^{\pm}| > 1$ at weak coupling. The magnon energy is the sheet-dependent but single-valued physical-branch expression

$$H = -1 - 2\mathrm{i}g(x^+ - x^-) = 1 + 2\mathrm{i}g\left(\frac{1}{x^+} - \frac{1}{x^-}\right), \tag{98.4}$$

with the same branch as (98.1). Conserved charges used in the dressing phase are

$$q_r(x^{\pm}) = \frac{\mathrm{i}}{r-1}\left[\frac{1}{(x^+)^{r-1}} - \frac{1}{(x^-)^{r-1}}\right], \qquad r \geq 2.$$

Zhukovsky form of the dispersion. Let $x^{\pm}$ obey (98.3) on the physical sheet. Then (98.4) is equal to

$$\sqrt{1+16g^2\sin^2\frac{p}{2}}.$$

For a physical real magnon write

$$x^{\pm}=\mathrm{e}^{\pm\mathrm{i}p/2}\frac{1+\sqrt{1+16g^2\sin^2(p/2)}}{4g\sin(p/2)}.$$

This parametrization gives $x^+/x^-=\mathrm{e}^{\mathrm{i}p}$. Substituting it into the difference $x^++1/x^+-x^--1/x^-$ gives i/g, so it is the physical solution of (98.3). The inverse difference is

$$\frac{1}{x^+}-\frac{1}{x^-}=\frac{\sqrt{1+16g^2\sin^2(p/2)}-1}{2\mathrm{i}g}.$$

Equation (98.4) therefore reproduces (98.1). The equality extends to the physical sheet by analytic continuation away from the branch points.

Warning 98.3 (Sheet data in crossing). The formal replacement $x^{\pm}\mapsto 1/x^{\pm}$ is not a harmless algebraic substitution. It records a path on the Zhukovsky surface. Poles crossed by that path alter the scalar factor through the crossing equation, and the answer depends on whether the continuation crosses the short cut of x^+, the short cut of x^-, or the composed path used in the mirror theory. In the u-plane, the cuts of $x^{\pm}=x(u\pm\mathrm{i}/2)$ have endpoints

$$u=\pm 2g-\mathrm{i}/2,\qquad u=\pm 2g+\mathrm{i}/2.$$

The physical crossing path for one magnon winds around the appropriate pair of these branch points so that both x^+ and x^- reach the crossed sheet. Applying the path twice generally lands on a different sheet of the scalar factor even though the projected $x^{\pm}$-values have returned.

Definition 98.4 (Crossing path for the Zhukovsky variables)**.** Let $x(u)$ be the physical Zhukovsky branch, $x(u)\sim u/g$ at infinity, and set $x^{\pm}(u)=x(u\pm\mathrm{i}/2)$. A crossing path for the first magnon is a path γ_{cr} on the u-surface, starting at a physical point and ending above the same projected u-value on a crossed sheet, with the following topological data:

$$w_{\gamma_{\mathrm{cr}}}\left(2g-\frac{\mathrm{i}}{2}\right)=1,\qquad w_{\gamma_{\mathrm{cr}}}\left(2g+\frac{\mathrm{i}}{2}\right)=1 \pmod 2,$$

and with even winding around the other two shifted endpoints in this right-endpoint convention. Equivalently, the lower shifted cut of x^+ and the upper shifted cut of x^- are each crossed once. When this path is used in the DHM contour formula below, it is also required to avoid the Cauchy and Gamma-function singularities except for the controlled residue crossings described in Proposition 98.5.

Zhukovsky monodromy along the crossing path. Analytic continuation of $x^{\pm}(u)$ along a path with the winding data of Definition 98.4 gives

$$\bar{x}^{\pm}(u)=\frac{1}{x^{\pm}(u)}.$$

Consequently,

$$\frac{\bar{x}^+}{\bar{x}^-} = \left(\frac{x^+}{x^-}\right)^{-1}, \qquad H(\bar{x}^\pm) = -H(x^\pm),$$

where $H(x^\pm) = 1 + 2\mathrm{i}g(1/x^+ - 1/x^-)$ is the physical-sheet energy continued as a meromorphic function of $x^\pm$.

Write

$$x(u) = \frac{1}{2}\left(\frac{u}{g} + \sqrt{\left(\frac{u}{g}\right)^2 - 4}\right)$$

on the physical branch. Encircling either endpoint of the short cut $[-2g, 2g]$ changes the sign of the square root and therefore sends

$$x(u) \longmapsto \frac{1}{2}\left(\frac{u}{g} - \sqrt{\left(\frac{u}{g}\right)^2 - 4}\right) = \frac{1}{x(u)}.$$

For $x^+(u) = x(u + \mathrm{i}/2)$, the relevant shifted cut has endpoint $2g - \mathrm{i}/2$; for $x^-(u) = x(u - \mathrm{i}/2)$, it has endpoint $2g + \mathrm{i}/2$. The mod-two winding data in Definition 98.4 therefore inverts both x^+ and x^-. The momentum ratio is then inverted immediately. Finally, using the stringbook energy identity

$$H(x^\pm) = -1 - 2\mathrm{i}g(x^+ - x^-) = 1 + 2\mathrm{i}g(1/x^+ - 1/x^-)$$

on the physical sheet, the crossed value is

$$H(\bar{x}^\pm) = 1 + 2\mathrm{i}g(x^+ - x^-) = -H(x^\pm).$$

98.4 Two-Body S-Matrix

The magnon two-body S-matrix is fixed by symmetry up to a scalar factor, after one has fixed the dynamic spin-chain frame. Let S_{12}^{mat} denote the matrix part determined by the two centrally extended $\mathfrak{su}(2|2)$ copies. The full two-magnon operator is

$$S_{12} = S_0(x_1^\pm, x_2^\pm)\, S_{12}^{\mathrm{mat}}.$$

For one $\mathfrak{su}(2|2)$ copy, write $S_{12}^{(1)}$ for the intertwiner before tensoring the left and right copies. It is defined by

$$S_{12}^{(1)}\Delta_{12}(J) = \Delta_{21}(J)S_{12}^{(1)}, \qquad J \in \mathfrak{su}(2|2)_{\mathrm{c}},$$

where the coproduct includes the braiding phase carried by the magnon momentum. The labels $1, 2$ on one-particle states record the momenta p_1, p_2, not extra internal indices. We use unnormalized symmetrization and antisymmetrization:

$$v^{\{a}w^{b\}} = v^a w^b + v^b w^a, \qquad v^{[a}w^{b]} = v^a w^b - v^b w^a.$$

With this convention the most general $\mathfrak{su}(2)\oplus\mathfrak{su}(2)$-covariant two-particle operator has ten amplitudes:

$$
\begin{aligned}
S^{(1)}_{12}|\phi^a_1\phi^b_2\rangle &= A_{12}|\phi^{\{a}_2\phi^{b\}}_1\rangle + B_{12}|\phi^{[a}_2\phi^{b]}_1\rangle + \frac{1}{2}C_{12}\varepsilon^{ab}\varepsilon_{\alpha\beta}|\psi^\alpha_2\psi^\beta_1\rangle,\\
S^{(1)}_{12}|\psi^\alpha_1\psi^\beta_2\rangle &= D_{12}|\psi^{\{\alpha}_2\psi^{\beta\}}_1\rangle + E_{12}|\psi^{[\alpha}_2\psi^{\beta]}_1\rangle + \frac{1}{2}F_{12}\varepsilon^{\alpha\beta}\varepsilon_{ab}|\phi^a_2\phi^b_1\rangle,\\
S^{(1)}_{12}|\phi^a_1\psi^\beta_2\rangle &= G_{12}|\psi^\beta_2\phi^a_1\rangle + H_{12}|\phi^a_2\psi^\beta_1\rangle,\\
S^{(1)}_{12}|\psi^\alpha_1\phi^b_2\rangle &= K_{12}|\psi^\alpha_2\phi^b_1\rangle + L_{12}|\phi^b_2\psi^\alpha_1\rangle.
\end{aligned}
$$

The length-changing markers are suppressed in this display but not forgotten: the C_{12} channel carries the Z^- marker and the F_{12} channel carries the Z^+ marker in the stringbook dynamic spin-chain frame. The markers are precisely the source of the braided coproduct.

For a magnon i write its representation coefficients as a_i, b_i, c_i, d_i. The stringbook frame relates them to $x^\pm_i$ by

$$
x^+_i = \mathrm{i}\frac{d_i}{b_i},\qquad x^-_i = -\mathrm{i}\frac{a_i}{c_i},\qquad a_id_i - b_ic_i = 1.
$$

The same $x^\pm_i$ obey the Zhukovsky relations already fixed in (98.3). At generic non-pole kinematics the tensor product of two fundamental short representations is long and the intertwiner is unique up to one scalar. Let this one-copy scalar be denoted $\mathcal{S}_{12}$. Solving the finite intertwining equations gives

$$
\begin{aligned}
A_{12} &= \mathcal{S}_{12}\frac{x^+_2 - x^-_1}{x^-_2 - x^+_1},\\
B_{12} &= A_{12}\left[1 - 2\frac{x^+_2 - x^+_1}{x^+_2 - x^-_1}\frac{x^-_2 - 1/x^+_1}{x^-_2 - 1/x^-_1}\right],\\
C_{12} &= \mathcal{S}_{12}\frac{2g^{-1}a_1a_2}{x^-_1x^-_2 - 1}\frac{x^+_2 - x^+_1}{x^-_2 - x^+_1},\\
D_{12} &= -\mathcal{S}_{12},\\
E_{12} &= -\mathcal{S}_{12}\left[1 - 2\frac{x^-_2 - x^-_1}{x^-_2 - x^+_1}\frac{x^+_2 - 1/x^-_1}{x^+_2 - 1/x^+_1}\right],\\
F_{12} &= -\mathcal{S}_{12}\frac{2g(x^+_1 - x^-_1)(x^+_2 - x^-_2)}{a_1a_2(x^+_1x^+_2 - 1)}\frac{x^-_2 - x^-_1}{x^-_2 - x^+_1},\\
G_{12} &= \mathcal{S}_{12}\frac{x^+_2 - x^+_1}{x^-_2 - x^+_1},\qquad H_{12} = \mathcal{S}_{12}\frac{a_1}{a_2}\frac{x^+_2 - x^-_2}{x^-_2 - x^+_1},\\
K_{12} &= \mathcal{S}_{12}\frac{a_2}{a_1}\frac{x^+_1 - x^-_1}{x^-_2 - x^+_1},\qquad L_{12} = \mathcal{S}_{12}\frac{x^-_2 - x^-_1}{x^-_2 - x^+_1}.
\end{aligned}
\tag{98.5}
$$

Generic row-rank computation for the one-copy intertwiner. Let

$$
d_{12} = x^-_2 - x^+_1,\qquad n_{12} = x^+_2 - x^-_1,
$$

and work on the generic open set where

$$
x^\pm_1x^\pm_2d_{12}n_{12}a_1a_2(x^-_1x^-_2 - 1)(x^+_1x^+_2 - 1) \neq 0.
$$

After the dynamic-frame Q- and S-intertwining equations are written on the ten $\mathfrak{su}(2)\oplus\mathfrak{su}(2)$-covariant amplitudes and the representation ratios

$$x_i^+ = \mathrm{i}d_i/b_i, \qquad x_i^- = -\mathrm{i}a_i/c_i, \qquad a_id_i - b_ic_i = 1$$

are used, the finite linear system has the following row-echelon chart:

$$\begin{gathered} B_{12} = \beta_{12}A_{12}, \qquad C_{12} = \gamma_{12}A_{12}, \qquad D_{12} = \delta_{12}A_{12}, \qquad E_{12} = \varepsilon_{12}A_{12}, \\ F_{12} = \varphi_{12}A_{12}, \qquad G_{12} = g_{12}A_{12}, \qquad H_{12} = h_{12}A_{12}, \qquad K_{12} = k_{12}A_{12}, \qquad L_{12} = \ell_{12}A_{12}, \end{gathered} \tag{98.6}$$

where

$$\begin{aligned} \beta_{12} &= 1 - 2\frac{x_2^+ - x_1^+}{n_{12}}\frac{x_2^- - 1/x_1^+}{x_2^- - 1/x_1^-}, & \gamma_{12} &= \frac{2a_1a_2}{g}\frac{x_2^+ - x_1^+}{(x_1^-x_2^- - 1)n_{12}}, \\ \delta_{12} &= -\frac{d_{12}}{n_{12}}, & \varepsilon_{12} &= -\frac{d_{12}}{n_{12}}\left[1 - 2\frac{x_2^- - x_1^-}{d_{12}}\frac{x_2^+ - 1/x_1^-}{x_2^+ - 1/x_1^+}\right], \\ \varphi_{12} &= -\frac{2g}{a_1a_2}\frac{(x_1^+ - x_1^-)(x_2^+ - x_2^-)(x_2^- - x_1^-)}{(x_1^+x_2^+ - 1)n_{12}}, & g_{12} &= \frac{x_2^+ - x_1^+}{n_{12}}, \\ h_{12} &= \frac{a_1}{a_2}\frac{x_2^+ - x_2^-}{n_{12}}, & k_{12} &= \frac{a_2}{a_1}\frac{x_1^+ - x_1^-}{n_{12}}, \\ \ell_{12} &= \frac{x_2^- - x_1^-}{n_{12}}. \end{aligned} \tag{98.7}$$

Consequently the solution space of the finite intertwining equations is one-dimensional on this open set. Choosing

$$A_{12} = \mathcal{S}_{12}\frac{n_{12}}{d_{12}}$$

recovers the ten amplitudes in (98.5).

This row chart is a finite row-reduction attached to the chosen dynamic frame; the theorem-level inputs are the representation and analytic construction of the planar magnon S-matrix. The unknown vector is

$$(A, B, C, D, E, F, G, H, K, L).$$

Each equation in (98.6) has the form

$$X - r_XA = 0, \qquad X \in \{B, C, D, E, F, G, H, K, L\},$$

with r_X one of the nine coefficients in (98.7). Ordered by $(B, C, D, E, F, G, H, K, L)$, these nine equations have pivot coefficient 1 in nine distinct columns. Their coefficient matrix therefore has rank nine, so its kernel in the ten-dimensional amplitude space is one dimensional and is parametrized by A.

It remains only to identify the parametrization with the convention used in (98.5). Substituting $A_{12} = \mathcal{S}_{12}n_{12}/d_{12}$ into (98.6) gives, term by term, the formulas for $B, C, D, E, F, G, H, K, L$ in (98.5). The genericity assumptions are exactly the denominators that appear in this chart and in the two channels where the $Z^{\pm}$ markers enter. At their zero loci the tensor product can become reducible or the chosen dynamic-frame chart can degenerate; those special loci are the bound-state and pole analyses, not the generic two-magnon scattering case.

Local intertwining and block-unitarity checks. Assume the denominators in (98.5) are non-zero. The amplitudes above satisfy the highest-weight Q-intertwining relation

$$A_{12} = \frac{a_1}{a_2} K_{12} + G_{12} = L_{12} + \frac{a_2}{a_1} H_{12}. \tag{98.8}$$

After factoring out $\mathcal{S}_{12}$, the same amplitudes also obey the local analytic unitarity identities

$$R_{12}^{\mathrm{BB}} R_{21}^{\mathrm{BB}} = 1, \qquad R_{12}^{\mathrm{BF}} R_{21}^{\mathrm{BF}} = 1,$$

on the boson-boson/fermion-fermion block R^{BB} and the mixed boson-fermion block R^{BF} written, for fixed distinct doublet indices, in the ordered bases

$$(\psi_1^1 \psi_2^2, \psi_1^2 \psi_2^1, \phi_1^1 \phi_2^2, \phi_1^2 \phi_2^1), \qquad (\phi_1^1 \psi_2^1, \psi_1^1 \phi_2^1).$$

The blocks are explicitly

$$R_{12}^{\mathrm{BB}} = \frac{1}{\mathcal{S}_{12}} \begin{pmatrix} (D-E)/2 & (D+E)/2 & -F/2 & F/2 \\ (D+E)/2 & (D-E)/2 & F/2 & -F/2 \\ -C/2 & C/2 & (A-B)/2 & (A+B)/2 \\ C/2 & -C/2 & (A+B)/2 & (A-B)/2 \end{pmatrix}_{12}, \qquad R_{12}^{\mathrm{BF}} = \frac{1}{\mathcal{S}_{12}} \begin{pmatrix} H & G \\ L & K \end{pmatrix}_{12}.$$

Equivalently, the matrix part has the correct inverse when the two magnons are exchanged; the scalar unitarity condition is the separate condition $\mathcal{S}_{12}\mathcal{S}_{21} = 1$, or, for the full two-copy scalar split, $S_{0,12} S_{0,21} = 1$.

The finite check is local in the chosen dynamic frame. The first identity is the result of applying ${Q^\alpha}_a$ to the symmetric boson state and comparing the independent $|\psi_2 \phi_1\rangle$ and $|\phi_2 \psi_1\rangle$ components. Substituting (98.5) gives

$$\begin{aligned} \frac{a_1}{a_2} K_{12} + G_{12} &= \mathcal{S}_{12} \frac{x_1^+ - x_1^- + x_2^+ - x_1^+}{x_2^- - x_1^+} = \mathcal{S}_{12} \frac{x_2^+ - x_1^-}{x_2^- - x_1^+} = A_{12}, \\ L_{12} + \frac{a_2}{a_1} H_{12} &= \mathcal{S}_{12} \frac{x_2^- - x_1^- + x_2^+ - x_2^-}{x_2^- - x_1^+} = A_{12}. \end{aligned}$$

The remaining Q- and S-intertwining equations are obtained in the same finite way from the other highest-weight components. Clearing denominators reduces them to polynomial identities in $x_i^\pm$ and the representation ratios a_1/a_2, together with the defining relations for b_i, c_i, d_i above. The companion calculation check constructs the two nontrivial finite blocks explicitly from (98.5) and verifies $R_{12}R_{21} = 1$ on nonsingular physical-branch samples. This check is not a substitute for crossing or Yang–Baxter factorization; it verifies the local frame and amplitude algebra used by the nested Bethe derivation below.

The convenient scalar split used in the stringbook is

$$\mathcal{S}_{12} = \left[\frac{x_2^- - x_1^+}{x_2^+ - x_1^-} \frac{1 - 1/(x_2^+ x_1^-)}{1 - 1/(x_2^- x_1^+)} \right]^{1/2} \sigma_{12}.$$

Consequently the compact $SU(2)$-sector two-copy amplitude $(A_{12})^2$ contains the rational factor

$$\frac{x_2^+ - x_1^-}{x_2^- - x_1^+} \frac{1 - 1/(x_2^+ x_1^-)}{1 - 1/(x_2^- x_1^+)}$$

times σ_{12}^2, in the orientation fixed by the conventions above. Equivalently, the full scalar factor may be written as

$$S_0(x_1^\pm, x_2^\pm) = S_{\rm rat}(x_1^\pm, x_2^\pm)\,\sigma(x_1^\pm, x_2^\pm)^2, \qquad \sigma = \mathrm{e}^{\mathrm{i}\theta}.$$

The rational part is fixed by the same representation data that determine the matrix part. The dressing phase has the antisymmetric charge expansion

$$\theta(x_1^\pm, x_2^\pm) = -\sum_{r=2}^{\infty} \sum_{\substack{s>r\\ r+s \text{ odd}}} c_{r,s}(g)\,\big(q_r(x_1^\pm)q_s(x_2^\pm) - q_s(x_1^\pm)q_r(x_2^\pm)\big).$$

Dressing unitarity from charge antisymmetry. Work in a domain of the physical sheet where the charge expansion for $\theta_{12} = \theta(x_1^\pm, x_2^\pm)$ is either finite after truncation or absolutely convergent, and use the same branch of the phase for the exchanged pair $\theta_{21} = \theta(x_2^\pm, x_1^\pm)$. Then

$$\theta_{21} = -\theta_{12}, \qquad \sigma_{12}\sigma_{21} = 1.$$

Consequently the squared dressing factor appearing in the $SU(2)$ asymptotic Bethe equation also satisfies

$$\sigma_{12}^2\sigma_{21}^2 = 1.$$

For each pair $r < s$ with $r+s$ odd, define

$$A_{r,s}(1,2) = q_r(x_1^\pm)q_s(x_2^\pm) - q_s(x_1^\pm)q_r(x_2^\pm).$$

Exchanging the two magnons gives

$$A_{r,s}(2,1) = q_r(x_2^\pm)q_s(x_1^\pm) - q_s(x_2^\pm)q_r(x_1^\pm) = -A_{r,s}(1,2).$$

The coefficients $c_{r,s}(g)$ are scalar functions of the coupling and the integer pair (r,s), not of the ordering of the two magnons. Therefore the whole series changes sign under $1 \leftrightarrow 2$, proving $\theta_{21} = -\theta_{12}$. Since $\sigma = \mathrm{e}^{\mathrm{i}\theta}$,

$$\sigma_{12}\sigma_{21} = \mathrm{e}^{\mathrm{i}(\theta_{12}+\theta_{21})} = 1.$$

Squaring gives the last statement.

This is only the scalar dressing part of physical two-body unitarity. The rational scalar factor and the matrix part must obey their own unitarity relations in the same frame. The computation also does not replace crossing: after analytic continuation around Zhukovsky cuts the charge expansion must be continued with its prescribed monodromy, and that monodromy is precisely the additional crossing datum discussed below.

Equivalently, the BES phase may be packaged as

$$\begin{aligned} \theta(x_1^\pm, x_2^\pm) &= \chi(x_1^+, x_2^+) - \chi(x_1^+, x_2^-) - \chi(x_1^-, x_2^+) + \chi(x_1^-, x_2^-), \\ \chi(x,y) &= -\mathrm{i}\oint \frac{\mathrm{d}z}{2\pi\mathrm{i}} \oint \frac{\mathrm{d}w}{2\pi\mathrm{i}} \frac{1}{x-z}\frac{1}{y-w} \log\frac{\Gamma\big(1+\mathrm{i}g(z+z^{-1}-w-w^{-1})\big)}{\Gamma\big(1-\mathrm{i}g(z+z^{-1}-w-w^{-1})\big)}. \end{aligned} \tag{98.9}$$

The contours encircle the unit circle singularities of z and w in the domain where $|x| > 1$, $|y| > 1$. Formula (98.9) is therefore not a global formula on all sheets by itself; outside that domain it is continued with the crossing prescription.

Proposition 98.5 (Local DHM residue continuation)**.** *Let*

$$\mathcal{L}_g(z,w) = \log \frac{\Gamma\big(1 + \mathrm{i}g(z + z^{-1} - w - w^{-1})\big)}{\Gamma(1 - \mathrm{i}g(z + z^{-1} - w - w^{-1}))}.$$

Fix x, y away from the unit circle and away from the Gamma-function poles. Denote by $\chi_{\mathrm{raw}}^{\epsilon_x,\epsilon_y}(x,y)$ the same unit-circle double contour integral as in (98.9), with the x-Cauchy kernel expanded radially outside the contour when $\epsilon_x = +$ and inside the contour when $\epsilon_x = -$, and similarly for y. Thus $\chi_{\mathrm{raw}}^{+,+}$ is the original DHM branch. With the stringbook orientation for crossing inward through $|x| = 1$ and $|y| = 1$, define the one-residue corrections by

$$\Psi_x^{\epsilon_y}(x,y) = \chi_{\mathrm{raw}}^{-,\epsilon_y}(x,y) - \chi_{\mathrm{raw}}^{+,\epsilon_y}(x,y), \qquad \Psi_y^{\epsilon_x}(x,y) = \chi_{\mathrm{raw}}^{\epsilon_x,+}(x,y) - \chi_{\mathrm{raw}}^{\epsilon_x,-}(x,y). \tag{98.10}$$

Equivalently, Ψ_x is the residue picked up by the pole $z = x$, with the sign fixed by the kernel $1/(x - z)$, while Ψ_y is written with the opposite sign because the stringbook formula adds the y-crossing correction. The analytic continuation of the original outside branch into the three neighboring radial chambers is

$$\chi_{\mathrm{cont}}^{-,+}(x,y) = \chi_{\mathrm{raw}}^{-,+}(x,y) - \Psi_x^{+}(x,y), \tag{98.11}$$

$$\chi_{\mathrm{cont}}^{+,-}(x,y) = \chi_{\mathrm{raw}}^{+,-}(x,y) + \Psi_y^{+}(x,y), \tag{98.12}$$

$$\chi_{\mathrm{cont}}^{-,-}(x,y) = \chi_{\mathrm{raw}}^{-,-}(x,y) - \Psi_x^{-}(x,y) + \Psi_y^{-}(x,y) - \mathcal{C}_g(x,y), \tag{98.13}$$

where the contact term is the double residue

$$\mathcal{C}_g(x,y) = \mathrm{i}\,\mathcal{L}_g(x,y). \tag{98.14}$$

These formulas are local sheet-transition rules for the DHM contour. The global Janik crossing equation additionally specifies a path on the u-surface, hence which of $x^{\pm}(u)$ winds around which shifted Zhukovsky branch point.

Proof. The only singularities that move when x crosses the unit circle are the Cauchy poles $z = x$; the Gamma-function poles are excluded by hypothesis. For fixed y-chamber, deforming the z-contour back to the unit circle therefore changes the raw integral exactly by the residue at $z = x$. This gives the first definition in (98.10) and hence the first continuation formula. The y-crossing computation is the same, except that the sign is recorded in Ψ_y so that the stringbook notebook convention reads as addition in the second formula.

If both variables cross, the two single residues count the intersection where $z = x$ and $w = y$ once too many. The product of the residue signs from $1/(x - z)$ and $1/(y - w)$, together with the overall factor $-\mathrm{i}$ in χ, gives the contact term $\mathrm{i}\mathcal{L}_g(x,y)$. Subtracting this double residue gives the final $-\mathrm{i}\mathcal{L}_g(x,y)$ contribution in (98.13). The planar $N = 4$ companion calculation check verifies these signs on finite Laurent models of the DHM kernel, including the failure that occurs if the contact term is omitted. ∎

DHM pole lattice and admissible local continuations. Let

$$\Delta(z,w) = z + z^{-1} - w - w^{-1}.$$

For fixed $g > 0$, the Gamma-kernel logarithm $\mathcal{L}_g(z, w)$ can develop singularities only on the divisors

$$\Delta(z,w) = \frac{\mathrm{i}n}{g} \quad \text{or} \quad \Delta(z,w) = -\frac{\mathrm{i}n}{g}, \qquad n \in \mathbb{Z}_{\geq 1}. \tag{98.15}$$

Consequently the one-residue correction $\Psi_x^{\epsilon_y}(x, y)$ is a single-valued holomorphic function on any connected region in which

$$x + x^{-1} - w - w^{-1} \notin \frac{\mathrm{i}}{g}\big(\mathbb{Z} \setminus \{0\}\big)$$

for every w on the chosen y-contour, and similarly for $\Psi_y^{\epsilon_x}$. The contact term $\mathcal{C}_g(x, y) = \mathrm{i}\mathcal{L}_g(x, y)$ is holomorphic precisely away from the endpoint divisors

$$x + x^{-1} - y - y^{-1} \in \frac{\mathrm{i}}{g}\big(\mathbb{Z} \setminus \{0\}\big).$$

If a crossing path for $x_1^\pm$ satisfies these avoidance conditions for each of the four pairs (x_1^α, x_2^β), $\alpha, \beta \in \{+, -\}$, except for the Cauchy-pole crossings already accounted for in Proposition 98.5, then the local BES-continuation formula below applies with no additional Gamma-pole residue terms.

The Gamma function has poles at $0, -1, -2, \ldots$. The numerator in $\mathcal{L}_g$ is singular only when

$$1 + \mathrm{i}g\Delta(z, w) = 1 - n, \qquad n \in \mathbb{Z}_{\geq 1},$$

which is equivalent to $\Delta(z, w) = \mathrm{i}n/g$. The denominator is singular only when

$$1 - \mathrm{i}g\Delta(z, w) = 1 - n, \qquad n \in \mathbb{Z}_{\geq 1},$$

which is equivalent to $\Delta(z, w) = -\mathrm{i}n/g$. This proves (98.15). The displayed conditions for Ψ_x, Ψ_y, and $\mathcal{C}_g$ are the same divisors evaluated after setting $z = x$, $w = y$, or one variable on the remaining contour. Away from those divisors the integrands are holomorphic in the external variables and the contour deformations are ordinary Cauchy deformations. Thus a path that crosses only the specified Cauchy poles has exactly the residue contributions listed above, with no further Gamma-kernel terms.

Local crossing of the BES phase. Assume $x_1^\pm$ and $x_2^\pm$ lie in the physical DHM chamber $|x_1^\pm| > 1$, $|x_2^\pm| > 1$, and continue the first magnon along the crossing path of Definition 98.4, so that $\bar{x}_1^\pm = 1/x_1^\pm$ lie in the inside radial chamber. Suppose the path avoids the Gamma-function poles of the DHM kernel. Define

$$\begin{aligned} \theta_{\mathrm{raw}}^{-,+}(\bar{x}_1^\pm, x_2^\pm) &= \chi_{\mathrm{raw}}^{-,+}(\bar{x}_1^+, x_2^+) - \chi_{\mathrm{raw}}^{-,+}(\bar{x}_1^+, x_2^-) - \chi_{\mathrm{raw}}^{-,+}(\bar{x}_1^-, x_2^+) + \chi_{\mathrm{raw}}^{-,+}(\bar{x}_1^-, x_2^-), \\ \Delta_{\bar{1}}\theta &= -\Psi_x^+(\bar{x}_1^+, x_2^+) + \Psi_x^+(\bar{x}_1^+, x_2^-) + \Psi_x^+(\bar{x}_1^-, x_2^+) - \Psi_x^+(\bar{x}_1^-, x_2^-). \end{aligned} \tag{98.16}$$

Then the local DHM continuation of the BES phase for the crossed first particle is

$$\theta_{\bar{1}2}^{\mathrm{loc}} = \theta_{\mathrm{raw}}^{-,+}(\bar{x}_1^\pm, x_2^\pm) + \Delta_{\bar{1}}\theta. \tag{98.17}$$

The BES phase is the alternating four-kernel combination

$$\chi(x_1^+, x_2^+) - \chi(x_1^+, x_2^-) - \chi(x_1^-, x_2^+) + \chi(x_1^-, x_2^-).$$

Along the stated crossing path, only the first argument of each kernel crosses from the outside chamber to the inside chamber; the second argument stays outside. The local DHM continuation formula for one kernel therefore adds the correction $-\Psi_x^+$ to each crossed kernel. Multiplying these four single-kernel corrections by the signs $+, -, -, +$ in the BES combination gives exactly the four terms defining $\Delta_{\bar{1}}\theta$. The raw continued kernels give $\theta_{\mathrm{raw}}^{-,+}$, so their sum is (98.17).

This local contour computation fixes how the DHM residue terms enter the four-kernel BES phase in the stringbook convention, but it does not by itself prove the scalar crossing equation (98.27). That equation also requires the global branch of the scalar factor, the homotopy class of the crossing path, and the absence or prescribed treatment of additional crossed singularities.

Inside this domain the weak-coupling coefficients can be extracted without any sheet continuation. Expand

$$\chi(x,y) = \sum_{r=2}^{\infty} \sum_{\substack{s>r \\ r+s \text{ odd}}} \frac{c_{r,s}(g)}{(r-1)(s-1)} \left(\frac{1}{x^{r-1}y^{s-1}} - \frac{1}{x^{s-1}y^{r-1}} \right). \tag{98.18}$$

The charge-expansion convention above uses the same $c_{r,s}$; the two forms agree because $q_r = \mathrm{i}A_r/(r-1)$, where $A_r = (x^+)^{1-r} - (x^-)^{1-r}$.

Proposition 98.6 (Weak coefficients from the DHM contour)**.** *For $N = 2m+1 \geq 3$, let $R_{r,s}^{(N)}$ be the Laurent coefficient*

$$R_{r,s}^{(N)} = [z^{-(r-1)}w^{-(s-1)}]\big(z + z^{-1} - w - w^{-1}\big)^N.$$

Then the contribution of order g^N to the coefficient $c_{r,s}(g)$ in (98.18) is

$$c_{r,s}(g)\big|_{g^N} = \frac{2(-1)^{m+1}}{N}(r-1)(s-1)R_{r,s}^{(N)}\,\zeta(N)g^N. \tag{98.19}$$

Equivalently, writing

$$c_{r,s}(g)\big|_{g^N} = C_{r,s}^{(N)}\zeta(N)g^N,$$

one has the closed coefficient

$$C_{r,s}^{(N)} = \frac{2(-1)^{(N-1)/2+s}(r-1)(s-1)N!(N-1)!}{\Gamma\big(\frac{N-r-s+4}{2}\big)\,\Gamma\big(\frac{N+r-s+2}{2}\big)\,\Gamma\big(\frac{N-r+s+2}{2}\big)\,\Gamma\big(\frac{N+r+s}{2}\big)}, \tag{98.20}$$

when the four Gamma-function arguments are positive integers; otherwise this order gives zero. In particular, the coefficient vanishes unless the Laurent powers can be supplied by the N factors in $(z+z^{-1}-w-w^{-1})^N$. In particular,

$$c_{2,3}(g) = 4\zeta(3)g^3 - 40\zeta(5)g^5 + O(g^7).$$

The first dressing contribution to a weak-coupling anomalous dimension is nevertheless order g^6, since $q_2 = O(g)$ and $q_3 = O(g^2)$ on the physical weak-coupling branch.

Proof. For $|x|, |y| > 1$,

$$\frac{1}{x-z}\frac{1}{y-w} = \sum_{a,b\geq 0} \frac{z^a w^b}{x^{a+1}y^{b+1}}.$$

The logarithm in (98.9) has the Taylor expansion at small g

$$\log \frac{\Gamma(1+\eta)}{\Gamma(1-\eta)} = -2\gamma\eta - 2\sum_{m=1}^{\infty} \frac{\zeta(2m+1)}{2m+1}\eta^{2m+1}, \qquad \eta = \mathrm{i}g(z+z^{-1}-w-w^{-1}).$$

The linear Euler-constant term is symmetric data that drops out of the antisymmetric coefficient family $s>r$. For $N=2m+1\geq 3$, multiplying by the outside factor $-\mathrm{i}$ gives

$$\frac{2(-1)^{m+1}\zeta(N)}{N} g^N \left(z+z^{-1}-w-w^{-1}\right)^N.$$

The two contour integrals pick the coefficient of $z^{-1}w^{-1}$. Thus the coefficient of $x^{1-r}y^{1-s}$ is the displayed constant times $R^{(N)}_{r,s}$. Comparing with (98.18) proves (98.19).

It remains to evaluate the Laurent coefficient. Put $a=r-1$ and $b=s-1$. Expanding first in the number ℓ of $(-w-w^{-1})$ factors gives the finite convolution

$$R^{(N)}_{r,s} = \sum_{\ell=0}^{N} (-1)^{\ell} \binom{N}{\ell} \binom{N-\ell}{(N-\ell+a)/2} \binom{\ell}{(\ell+b)/2}, \tag{98.21}$$

where a binomial coefficient is declared zero unless its lower entry is an integer between 0 and the upper entry. This convention records the parity and support restrictions.

For the closed evaluation, compare Fourier coefficients by writing $z=\mathrm{e}^{\mathrm{i}\theta}$, $w=\mathrm{e}^{\mathrm{i}\varphi}$, $A=(\theta+\varphi)/2$, and $B=(\theta-\varphi)/2$. Then

$$z+z^{-1}-w-w^{-1} = -4\sin A\,\sin B, \qquad z^{-a}w^{-b} = \mathrm{e}^{-\mathrm{i}(a+b)A}\mathrm{e}^{-\mathrm{i}(a-b)B}.$$

The elementary expansion

$$\sin^N t = (2\mathrm{i})^{-N}\sum_{j=0}^{N}(-1)^j\binom{N}{j}\mathrm{e}^{\mathrm{i}(N-2j)t}$$

therefore gives

$$R^{(N)}_{r,s} = (-1)^{N+a}\binom{N}{(N+a+b)/2}\binom{N}{(N+a-b)/2},$$

with the same convention that the binomial coefficient is zero unless its lower entry is an integer between 0 and N. Since N is odd and the nonzero cases have $a+b$ odd, the sign is $(-1)^{N+a} = (-1)^b = (-1)^{s-1}$. Rewriting the two binomial coefficients as Gamma functions gives

$$R^{(N)}_{r,s} = (-1)^{s-1}\frac{(N!)^2}{\Gamma\left(\frac{N-r-s+4}{2}\right)\Gamma\left(\frac{N+r-s+2}{2}\right)\Gamma\left(\frac{N-r+s+2}{2}\right)\Gamma\left(\frac{N+r+s}{2}\right)}.$$

The lower-entry bounds in the binomial formula are exactly the positivity conditions on the four Gamma-function arguments; outside those bounds the coefficient is zero. Substitution into (98.19) gives (98.20). For $r=2, s=3$,

$$R^{(3)}_{2,3} = 3, \qquad R^{(5)}_{2,3} = 50,$$

which gives $4\zeta(3)g^3 - 40\zeta(5)g^5$. □

A saddle expansion of the same contour representation gives the AFS and Hernandez–Lopez strong-coupling terms.

Crossing scalar convention algebra. Assume $x_1^\pm, x_2^\pm$ are non-zero and avoid the displayed denominators. In the stringbook scalar-factor orientation used in this chapter set

$$\Xi_{12} = \frac{x_2^+}{x_2^-}\frac{x_2^+ - x_1^+}{x_2^+ - x_1^-}\frac{x_2^- - 1/x_1^+}{x_2^- - 1/x_1^-}.$$

The common reciprocal orientation is

$$\Xi_{12}^{\mathrm{rec}} = \frac{x_2^-}{x_2^+}\frac{x_2^+ - x_1^-}{x_2^+ - x_1^+}\frac{x_2^- - 1/x_1^-}{x_2^- - 1/x_1^+},$$

and satisfies

$$\Xi_{12}^{\mathrm{rec}} = \Xi_{12}^{-1}.$$

This is the product of the three displayed inverse factors:

$$\Xi_{12}\Xi_{12}^{\mathrm{rec}} = \frac{x_2^+}{x_2^-}\frac{x_2^-}{x_2^+}\frac{x_2^+ - x_1^+}{x_2^+ - x_1^-}\frac{x_2^+ - x_1^-}{x_2^+ - x_1^+}\frac{x_2^- - 1/x_1^+}{x_2^- - 1/x_1^-}\frac{x_2^- - 1/x_1^-}{x_2^- - 1/x_1^+} = 1.$$

Moreover the algebraic substitution $x_1^\pm \mapsto 1/x_1^\pm$ does not leave this multiplier invariant as a rational function. At

$$x_1^+ = 2, \qquad x_1^- = 3, \qquad x_2^+ = 5, \qquad x_2^- = 7$$

one obtains $\Xi_{12} = 117/112$, whereas the same formula with $x_1^\pm$ replaced by $1/x_1^\pm$ gives 675/784. Hence equality can hold only on a proper algebraic sublocus, not as a convention-independent identity.

Matrix-channel origin of the scalar crossing multiplier. Let $\bar{x}_1^\pm = 1/x_1^\pm$ denote the crossed-sheet continuation of the first magnon and assume all displayed denominators are non-zero. Form the crossed amplitude $L_{\bar{1}2}$ from (98.5) by replacing (x_1^+, x_1^-) with $(\bar{x}_1^+, \bar{x}_1^-)$, and form G_{21} by exchanging the two magnons and using the analytic-unitarity convention $\mathcal{S}_{21} = \mathcal{S}_{12}^{-1}$. Then

$$\mathcal{R}_{\mathrm{cr}} := \frac{L_{\bar{1}2}}{G_{21}} = \mathcal{S}_{\bar{1}2}\mathcal{S}_{12}\frac{(x_2^- - 1/x_1^-)\,x_1^+(x_1^- - x_2^+)}{(x_2^- x_1^+ - 1)(x_1^+ - x_2^+)}. \tag{98.22}$$

Substitute the stringbook scalar split for $\mathcal{S}_{12}$ and $\mathcal{S}_{\bar{1}2}$. In the chamber

$$x_2^- > x_1^+ > 1, \qquad x_2^+ > x_1^- > 1,$$

where the square roots in the scalar split are taken continuously from positive real values, the finite channel condition $\mathcal{R}_{\mathrm{cr}} = 1$ is equivalent to

$$\sigma(\bar{x}_1^\pm, x_2^\pm)\sigma(x_1^\pm, x_2^\pm) = \Xi_{12}. \tag{98.23}$$

The formula for $L_{\bar{1}2}$ is

$$L_{\bar{1}2} = \mathcal{S}_{\bar{1}2}\frac{x_2^- - 1/x_1^-}{x_2^- - 1/x_1^+},$$

whereas the exchanged G-amplitude is

$$G_{21} = \mathcal{S}_{21}\frac{x_1^+ - x_2^+}{x_1^- - x_2^+}.$$

Using $\mathcal{S}_{21} = \mathcal{S}_{12}^{-1}$ and rewriting $(x_2^- - 1/x_1^+) = (x_2^- x_1^+ - 1)/x_1^+$ gives (98.22).

Now write

$$\mathcal{S}_{12} = R_{12}^{1/2}\sigma_{12}, \qquad \mathcal{S}_{\bar{1}2} = R_{\bar{1}2}^{1/2}\sigma_{\bar{1}2},$$

with R the rational factor displayed in the scalar split. Squaring the condition $\mathcal{R}_{\rm cr} = 1$ removes the square-root branch and gives a rational identity:

$$R_{12}R_{\bar{1}2}\Xi_{12}^2 \left[\frac{(x_2^- - 1/x_1^-)\, x_1^+ (x_1^- - x_2^+)}{(x_2^- x_1^+ - 1)(x_1^+ - x_2^+)}\right]^2 = 1.$$

After cancellation this identity is exactly the product of the factors in Ξ_{12}. The stated real chamber fixes the sign of the square root, so the unsquared channel equation is (98.23). This is the finite matrix-amplitude calculation behind the scalar multiplier; it does not construct the analytic crossed scalar branch.

Scalar crossing monodromy cocycle. Let C_1 denote a chosen crossing continuation of the first magnon along $\gamma_{\rm cr}$ from Definition 98.4. Fix a scalar branch $\sigma_{12}^{[\gamma]}$ on a sheet reached by a path γ from the physical chamber, and write

$$\sigma_{12}^{[\gamma\mathsf{C}_1]} := \sigma^{[\gamma\mathsf{C}_1]}(x_1^\pm, x_2^\pm)$$

for the same external coordinates evaluated after analytic continuation along the concatenated path. Assume that the crossed path avoids all poles and zeros in the denominators below and that Janik crossing holds on each crossed segment in the stringbook orientation,

$$\sigma_{12}^{[\gamma\mathsf{C}_1]}\,\sigma_{12}^{[\gamma]} = \Xi_{12}(x_1^\pm, x_2^\pm).$$

Then the second crossing is not an involution on the scalar branch. It acts by

$$\frac{\sigma_{12}^{[\gamma\mathsf{C}_1\mathsf{C}_1]}}{\sigma_{12}^{[\gamma]}} = \frac{\Xi_{12}(1/x_1^\pm, x_2^\pm)}{\Xi_{12}(x_1^\pm, x_2^\pm)} =: \mathcal{M}_{12}^{(2)}, \tag{98.24}$$

where explicitly

$$\mathcal{M}_{12}^{(2)} = \frac{x_2^+ - 1/x_1^+}{x_2^+ - 1/x_1^-}\,\frac{x_2^+ - x_1^-}{x_2^+ - x_1^+}\,\frac{x_2^- - x_1^+}{x_2^- - x_1^-}\,\frac{x_2^- - 1/x_1^-}{x_2^- - 1/x_1^+}. \tag{98.25}$$

In the reciprocal scalar convention $\sigma_{12}^{\rm rec} := \sigma_{12}^{-1}$, the one-crossing multiplier and the double-crossing multiplier are inverted. The first crossing gives

$$\sigma_{12}^{[\gamma\mathsf{C}_1]} = \frac{\Xi_{12}(x_1^\pm, x_2^\pm)}{\sigma_{12}^{[\gamma]}}.$$

After that continuation the projected Zhukovsky variables of the first magnon are $1/x_1^\pm$. Applying the same crossing equation once more therefore gives

$$\sigma_{12}^{[\gamma\mathsf{C}_1\mathsf{C}_1]} = \frac{\Xi_{12}(1/x_1^\pm, x_2^\pm)}{\sigma_{12}^{[\gamma\mathsf{C}_1]}} = \frac{\Xi_{12}(1/x_1^\pm, x_2^\pm)}{\Xi_{12}(x_1^\pm, x_2^\pm)}\sigma_{12}^{[\gamma]}.$$

Substituting the definition of Ξ_{12} cancels the common x_2^+/x_2^- factor and yields (98.25). If the reciprocal scalar factor is used, every displayed crossing equation is inverted because $\sigma_{12}^{\rm rec} = 1/\sigma_{12}$; the same two-line calculation then gives $(\mathcal{M}_{12}^{(2)})^{-1}$. The argument proves the rational branch displacement forced by the chosen crossing law. It does not classify all possible homotopy classes of scalar branches or prove that the BES branch is the unique minimal solution.

Proposition 98.7 (CDD ambiguity of the scalar crossing problem)**.** *Let $\mathcal{U}$ be a regular domain of scalar branches closed under particle exchange and under the chosen first-particle crossing segments C_1, with no zero or pole of the functions below on the crossed segments. Suppose σ_{12} and σ'_{12} are two non-zero meromorphic scalar branches on $\mathcal{U}$ satisfying the same Janik crossing equation*

$$\sigma_{12}^{[\gamma \mathsf{C}_1]}\,\sigma_{12}^{[\gamma]} = \sigma_{12}'^{[\gamma \mathsf{C}_1]}\,\sigma_{12}'^{[\gamma]} = \Xi_{12}$$

and the same scalar unitarity equation

$$\sigma_{21}^{[\gamma P]}\sigma_{12}^{[\gamma]} = \sigma_{21}'^{[\gamma P]}\sigma_{12}'^{[\gamma]} = 1,$$

where P exchanges the two particles. Set

$$\mathcal{F}_{12}^{[\gamma]} := \frac{\sigma_{12}'^{[\gamma]}}{\sigma_{12}^{[\gamma]}}.$$

Then $\mathcal{F}$ is a CDD factor in this convention:

$$\mathcal{F}_{12}^{[\gamma \mathsf{C}_1]}\mathcal{F}_{12}^{[\gamma]} = 1, \qquad \mathcal{F}_{21}^{[\gamma P]}\mathcal{F}_{12}^{[\gamma]} = 1, \qquad \mathcal{F}_{12}^{[\gamma \mathsf{C}_1 \mathsf{C}_1]} = \mathcal{F}_{12}^{[\gamma]}. \tag{98.26}$$

Conversely, multiplying any scalar solution by a non-zero meromorphic $\mathcal{F}$ satisfying the first two equations in (98.26) gives another scalar solution with the same crossing multiplier and scalar unitarity. If $\mathcal{F}$ has a zero of order m at a regular point of a branch, then it has a pole of order m at the corresponding crossed point and at the exchanged point. Thus a CDD-free BES branch is a minimality and analyticity choice, not a formal consequence of the finite matrix crossing multiplier.

Proof. Dividing the crossing equation for σ' by the crossing equation for σ gives

$$\mathcal{F}_{12}^{[\gamma \mathsf{C}_1]}\mathcal{F}_{12}^{[\gamma]} = 1.$$

Dividing scalar unitarity for σ' by scalar unitarity for σ gives

$$\mathcal{F}_{21}^{[\gamma P]}\mathcal{F}_{12}^{[\gamma]} = 1.$$

Applying the first identity on the already crossed branch gives

$$\mathcal{F}_{12}^{[\gamma \mathsf{C}_1 \mathsf{C}_1]}\mathcal{F}_{12}^{[\gamma \mathsf{C}_1]} = 1.$$

Together with $\mathcal{F}_{12}^{[\gamma \mathsf{C}_1]} = (\mathcal{F}_{12}^{[\gamma]})^{-1}$, this proves the double-crossing identity for the CDD factor. Conversely, if $\sigma'_{12} := \mathcal{F}_{12}\sigma_{12}$, then the first CDD equation cancels the extra factor in crossing and the second cancels the extra factor in scalar unitarity.

For the divisor statement, work in a coordinate chart where crossing and exchange are biholomorphic. The identity $\mathcal{F}^{[\gamma \mathsf{C}_1]} = 1/\mathcal{F}^{[\gamma]}$ changes an order-m zero into an order-m pole on the crossed branch, and the exchange identity does the same on the exchanged branch. In a simply connected pole-free subdomain one may write $\mathcal{F} = \exp \ell$, and the equations become

$$\ell_{12}^{[\gamma \mathsf{C}_1]} = -\ell_{12}^{[\gamma]}, \qquad \ell_{21}^{[\gamma P]} = -\ell_{12}^{[\gamma]}.$$

Hence setting $\ell = 0$, or equivalently $\mathcal{F} = 1$, is an additional minimal-branch normalization. $\square$

Crossing relates $\sigma(x_1^\pm, x_2^\pm)$ to the phase obtained by analytically continuing the first magnon through the crossed sheet $x_1^\pm \mapsto 1/x_1^\pm$. It supplies an additional analyticity condition on the scalar factor beyond factorized Yang–Baxter compatibility. The preceding propositions fix the rational convention carried by the chosen scalar split, its finite crossed-amplitude origin, and the double-crossing sheet displacement forced by that convention, while (98.26) identifies the remaining CDD freedom. They do not derive the global monodromy condition from finite algebra. Homotopic crossing paths inside a singularity-free chamber give the same rational cocycle, but paths separated by poles, zeros, or extra CDD singularities can land on different scalar branches. In the normalization where the rational matrix part is separated as above, Janik crossing has the convention-fixed form

$$\sigma(\bar{x}_1^\pm, x_2^\pm)\sigma(x_1^\pm, x_2^\pm) = \frac{x_2^+}{x_2^-}\frac{x_2^+ - x_1^+}{x_2^+ - x_1^-}\frac{x_2^- - 1/x_1^+}{x_2^- - 1/x_1^-}, \tag{98.27}$$

where $\bar{x}_1^\pm$ denotes the crossed-sheet continuation of the first magnon on the same rapidity surface. The equation is best read as a monodromy statement for the scalar factor on the Zhukovsky rapidity surface. The BES solution selects the minimal solution compatible with (98.27), unitarity $\sigma_{12}\sigma_{21} = 1$, and the prescribed weak/strong asymptotics.

Definition 98.8 (Dressing-phase data and status)**.** The scalar dressing phase used in the asymptotic equations is specified by the antisymmetric charge expansion above, the AFS leading strong-coupling term $c_{r,r+1}(g) = g + O(g^0)$, the Hernandez–Lopez semiclassical correction, Janik crossing on the Zhukovsky surface, and the BES integral representation selecting the minimal crossing-symmetric solution. Its weak series begins with

$$c_{2,3}(g) = 4\zeta(3)g^3 + O(g^5),$$

and, because the weak charges contribute $q_2q_3 - q_3q_2 = O(g^3)$, the first dressing contribution to Konishi enters at four loops. This is an exact datum of the planar-integrability framework and a highly tested claim about gauge theory, not a theorem here derived from a constructive definition of four-dimensional $\mathcal{N} = 4$ SYM.

Quoted Theorem 98.9 (Asymptotic planar magnon S-matrix)**.** *Assume planar integrability of the long $\mathcal{N} = 4$ SYM spin chain, the centrally extended residual symmetry, physical unitarity, Yang–Baxter factorization, crossing, and the minimal analyticity condition used in the BES construction. Then the asymptotic two-body magnon S-matrix is the $\mathfrak{su}(2|2)^2$-invariant matrix part multiplied by the scalar dressing factor whose phase has the charge expansion above with the BES coefficients $c_{r,s}(g)$.*

This is stated as a quoted theorem because the full claim is not a theorem of four-dimensional QFT derived from a nonperturbative definition of the gauge theory. It is an integrability theorem inside a framework whose physical identification with the planar gauge-theory dilatation operator has extensive checks and strong structural constraints.

98.5 Asymptotic Bethe Equations

Assumption 98.10 (Asymptotic Bethe–Yang regime)**.** The all-loop asymptotic Bethe ansatz is used as a long-chain Bethe–Yang quantization rule for planar single traces. More precisely, for a sequence of operators of length L, with either fixed magnon number or a controlled large-L distribution of Bethe roots, one assumes:

$$L \to \infty, \qquad \text{virtual propagation around the trace is suppressed,}$$

and the many-magnon quantization is obtained by factorizing scattering into the two-body S-matrix of the preceding section. This intended domain includes high-density configurations of roots in the $L \to \infty$ limit. The additional assumption is not thermodynamic Bethe ansatz; it is the asymptotic finite-volume quantization of the physical spin-chain problem. At finite L, or at a loop order where the long-range dilatation operator can wrap around the trace, the omitted mirror-winding effects are no longer parametrically absent.

The word "asymptotic" in this assumption refers to the spatial length of the spin chain, not to a sparse-gas approximation. The following elementary counting calculation is the precise large-L bridge used whenever an ABA solution is replaced by a macroscopic root distribution.

Finite-density ABA counting equation. Consider a diagonal component of a long-chain Bethe–Yang problem with rapidity variables u_j, $j = 1, \dots, M_L$, and logarithmic equations

$$Lp(u_j) + \sum_{\substack{k=1\\k\neq j}}^{M_L} \Theta(u_j, u_k) = 2\pi I_j, \qquad I_j \in \mathbb{Z}. \tag{98.28}$$

Assume a branch of the two-body phase Θ has been chosen on the rapidity interval under consideration; possible diagonal jumps have either been removed by this branch choice or are treated as explicit source terms. Assume also that M_L/L has a finite limit and that the empirical measures

$$\nu_L = \frac{1}{L}\sum_{j=1}^{M_L} \delta_{u_j}$$

converge weakly to $\rho(v)\mathrm{d}v$ on compact subintervals where p and Θ are C^1. Define

$$Z_L(u) = p(u) + \frac{1}{L}\sum_{j=1}^{M_L} \Theta(u, u_j), \qquad Z(u) = p(u) + \int \Theta(u, v)\rho(v)\,\mathrm{d}v.$$

Then $Z_L \to Z$ locally uniformly after differentiating under the stated regularity hypotheses, and the density of available Bethe levels is

$$\rho(u) + \rho_\mathrm{h}(u) = \frac{1}{2\pi}Z'(u) = \frac{p'(u)}{2\pi} + \int K(u, v)\rho(v)\,\mathrm{d}v, \qquad K(u, v) = \frac{1}{2\pi}\partial_u\Theta(u, v). \tag{98.29}$$

Here ρ_h is the macroscopic density of unoccupied integer levels in the chosen branch. In a completely filled interval $\rho_\mathrm{h} = 0$.

Weak convergence gives

$$\frac{1}{L}\sum_{j=1}^{M_L} \Theta(u, u_j) \longrightarrow \int \Theta(u, v)\rho(v)\,\mathrm{d}v$$

uniformly on compact subsets on which the phase is continuous and the root cloud stays away from unaccounted singularities. The same statement applied to $\partial_u\Theta$ gives the derivative formula for $Z'(u)$. Equation (98.28) says that the integer level attached to rapidity u is, to leading order, $LZ(u)/(2\pi)$. Hence the number of available integer levels in a small interval $[u, u + \mathrm{d}u]$ is

$$\frac{L}{2\pi} Z'(u)\,\mathrm{d}u + o(L\,\mathrm{d}u).$$

Dividing by $L\,\mathrm{d}u$ gives the density of occupied plus unoccupied available levels, namely $\rho + \rho_{\mathrm{h}}$. This proves (98.29).

This is a large-L continuum limit of the same physical ABA equations. It is not mirror TBA: no mirror energy, entropy functional, pseudoenergy, or thermal variational problem has been introduced. The additional dynamical assumption is exactly the one stated above, namely that the long-chain two-body magnon S-matrix continues to quantize the physical chain when $M_L/L = O(1)$, as long as mirror winding remains asymptotically suppressed.

For the rank-one equation in the stringbook $SL(2)$-vacuum orientation, the all-loop asymptotic Bethe equations can be written

$$\left(\frac{x_j^+}{x_j^-}\right)^L = \prod_{\substack{k=1\\k\neq j}}^{M} \frac{x_j^- - x_k^+}{x_j^+ - x_k^-}\,\frac{1 - 1/(x_j^+ x_k^-)}{1 - 1/(x_j^- x_k^+)}\,\sigma(x_j^\pm, x_k^\pm)^2, \tag{98.30}$$

with cyclicity

$$\prod_{j=1}^{M} \frac{x_j^+}{x_j^-} = 1.$$

The scaling dimension is

$$\Delta = L + \sum_{j=1}^{M} \left(\sqrt{1 + 16g^2 \sin^2 \frac{p_j}{2}} - 1\right),$$

up to wrapping corrections. The full $\mathfrak{psu}(2,2|4)$ asymptotic Bethe equations require nested roots for the residual symmetry algebra. Their algebraic role is the same as in Chapter 75; their physical meaning is different because these auxiliary roots organize polarizations of magnons on a gauge-theory trace.

The first nesting step can be derived without the full $\mathfrak{psu}(2,2|4)$ bookkeeping. Start with M level-I magnons $\phi_1(p_k)$. A single level-II fermionic excitation with spectral parameter y is a wave packet

$$|\Psi_{\mathrm{II}}(y)\rangle = \sum_{k=1}^{M} C_k(y;\{p_j\})\,|\phi_1(p_1)\cdots\psi(p_k)\cdots\phi_1(p_M)\rangle,$$

where the omitted flavour index of ψ is a spectator. Write $x_i^\pm = x^\pm(p_i)$ and let $\mathsf{a}_i = \mathsf{a}(p_i)$ be the nonzero representation coefficient which converts a bosonic vacuum magnon to the chosen fermionic excitation in the spin-chain basis. Normalize the two-body matrix part by the boson-boson amplitude A_{12}. In the stringbook orientation of the $\mathfrak{su}(2|2)_{\mathrm{c}}$ intertwiner, the four mixed amplitudes needed for one fermionic defect obey

$$\begin{aligned}\frac{G_{12}}{A_{12}} &= \frac{x_2^+ - x_1^+}{x_2^+ - x_1^-}, \quad \frac{K_{12}}{A_{12}} = \frac{\mathsf{a}_2}{\mathsf{a}_1}\frac{x_1^+ - x_1^-}{x_2^+ - x_1^-},\\ \frac{L_{12}}{A_{12}} &= \frac{x_2^- - x_1^-}{x_2^+ - x_1^-}, \quad \frac{H_{12}}{A_{12}} = \frac{\mathsf{a}_1}{\mathsf{a}_2}\frac{x_2^+ - x_2^-}{x_2^+ - x_1^-}.\end{aligned} \tag{98.31}$$

These are ratios of matrix amplitudes, so the scalar dressing factor and reciprocal scalar-factor conventions cancel.

Lemma 98.11 (Single level-II nesting step)**.** *Assume $x_i^\pm$, a_i, and the denominators in (98.31) are nonzero. The one-defect ansatz*

$$C_k(y;\{p_j\}) = f(y,p_k)\prod_{\ell<k} S^{\mathrm{II,I}}(y,p_\ell)$$

is compatible with every adjacent transposition of level-I magnons if

$$f(y,p) = \frac{\mathsf{a}(p)}{y - x^+(p)}, \qquad S^{\mathrm{II,I}}(y,p) = \frac{y - x^-(p)}{y - x^+(p)}. \tag{98.32}$$

The normalization of f may be multiplied by a function of y alone; this rescales the one-defect state and has no Bethe-equation content.

Proof. It is enough to check a two-site exchange, because the many-site statement is then obtained by multiplying the same local move along the chain. Let

$$f_i = f(y,p_i), \qquad S_i = S^{\mathrm{II,I}}(y,p_i).$$

Before exchanging magnons 1 and 2, the defect can sit on the first or second site with coefficients f_1 and f_2S_1. After applying the matrix S-matrix to this two-site block, equality with the ansatz in the exchanged order gives the two coefficient equations

$$\begin{aligned}f_1L_{12} + f_2S_1H_{12} &= S_2f_1A_{12},\\ f_1K_{12} + f_2S_1G_{12} &= f_2A_{12}.\end{aligned} \tag{98.33}$$

These equations are the algebraic content of moving a single auxiliary fermion through two neighbouring physical magnons.

Substitute (98.31) and (98.32). The second equation in (98.33) reduces, after clearing the common factor $A_{12}\mathsf{a}_2/((y - x_1^+)(x_2^+ - x_1^-))$, to

$$(x_1^+ - x_1^-)(y - x_2^+) + (x_2^+ - x_1^+)(y - x_1^-) = (x_2^+ - x_1^-)(y - x_1^+).$$

The first equation reduces in the same way to

$$(x_2^- - x_1^-)(y - x_2^+) + (x_2^+ - x_2^-)(y - x_1^-) = (x_2^+ - x_1^-)(y - x_2^-).$$

Both are polynomial identities in y. Therefore the local exchange is consistent, and repeated adjacent exchanges give the displayed coefficient formula for an arbitrary ordering of the level-I magnons. □

The square-root braiding factors of the string basis multiply (98.32) by convention-dependent one-body factors; they cancel from the local identities above after the corresponding basis change is applied to the mixed amplitudes.

With two level-II fermions there is a genuine contact term: when the two auxiliary fermions occupy the same level-I site, the local state can turn into the boson ϕ_2 accompanied by the length-changing marker Z^+. Let

$$v(y) = y + y^{-1}.$$

In the spin-chain basis, the local two-defect calculation fixes the $SU(2)$-invariant level-II matrix

$$(S^{\mathrm{II}})^{\delta\gamma}_{\alpha\beta}(y_1, y_2) = \delta^\delta_\alpha \delta^\gamma_\beta \, M(y_1, y_2) + \delta^\gamma_\alpha \delta^\delta_\beta \, N(y_1, y_2), \tag{98.34}$$

with

$$M + N = -1, \qquad M - N = \frac{v(y_1) - v(y_2) - \mathrm{i}/g}{v(y_1) - v(y_2) + \mathrm{i}/g}. \tag{98.35}$$

Equivalently,

$$M(y_1, y_2) = -\frac{\mathrm{i}/g}{v(y_1) - v(y_2) + \mathrm{i}/g}, \qquad N(y_1, y_2) = -\frac{v(y_1) - v(y_2)}{v(y_1) - v(y_2) + \mathrm{i}/g}.$$

The accompanying same-site coefficient is

$$\mathsf{f}^{(2)}(y_1, y_2; p) = \frac{g}{\mathsf{a}(p)^2} \left(\frac{x^-(p)}{x^+(p)} - 1 \right) \frac{y_1 y_2 - x^+(p) x^-(p)}{y_1 y_2} \frac{y_1 - y_2}{v(y_1) - v(y_2) + \mathrm{i}/g}. \tag{98.36}$$

The sign $M + N = -1$ is not a scalar scattering phase to be inserted into the level-III vacuum Bethe equation. It is the ungraded matrix eigenvalue on the state with two identical level-II fermions; after the fermionic exchange sign is accounted for, the level-III vacuum scattering is trivial. This is the local sign convention behind the sentence that the ψ_1-vacuum has $S^{\mathrm{II,II}} = 1$.

Single level-III nesting step. Assume $g \neq 0$, $v(y_1) - v(y_2) + \mathrm{i}/g \neq 0$, and the denominators below are nonzero. In the graded convention just described, a single level-III excitation with spectral parameter w has one-body coefficient

$$\gamma(w, y) = \frac{w + \mathrm{i}/(2g)}{w - v(y) + \mathrm{i}/(2g)}$$

and level-III/level-II scattering factor

$$S^{\mathrm{III,II}}(w, y) = \frac{w - v(y) - \mathrm{i}/(2g)}{w - v(y) + \mathrm{i}/(2g)}. \tag{98.37}$$

This is a two-site compatibility calculation after the level-II matrix, contact-term convention, and graded exchange sign have been fixed. Put $\eta = \mathrm{i}/(2g)$, $v_i = v(y_i)$, $D = v_1 - v_2$, and $a_i = w - v_i$. Then $a_2 = a_1 + D$, and (98.35) is equivalent to

$$M = -\frac{2\eta}{D + 2\eta}, \qquad N = -\frac{D}{D + 2\eta}.$$

For an adjacent exchange of two level-II sites, the two independent coefficients must obey

$$\begin{aligned}\gamma(w,y_1)M+\gamma(w,y_2)S^{\mathrm{III,II}}(w,y_1)N&=-\gamma(w,y_2),\\ \gamma(w,y_1)N+\gamma(w,y_2)S^{\mathrm{III,II}}(w,y_1)M&=-\gamma(w,y_1)S^{\mathrm{III,II}}(w,y_2).\end{aligned}\tag{98.38}$$

The minus signs are precisely the fermionic exchange signs which convert the ungraded $M+N=-1$ vacuum eigenvalue into trivial graded vacuum scattering.

Substituting $\gamma(w,y_i)=(w+\eta)/(a_i+\eta)$ and $S^{\mathrm{III,II}}(w,y_i)=(a_i-\eta)/(a_i+\eta)$, the first equation in (98.38) reduces to

$$-2\eta(a_2+\eta)-D(a_1-\eta)=-(D+2\eta)(a_1+\eta).$$

The second reduces to

$$-D(a_2+\eta)-2\eta(a_1-\eta)=-(D+2\eta)(a_2-\eta).$$

Both identities follow immediately from $a_2=a_1+D$. Therefore the one-level-III ansatz is compatible with every adjacent level-II exchange.

A pair of level-III roots scatters by

$$S^{\mathrm{III,III}}(w_1,w_2)=\frac{w_1-w_2+\mathrm{i}/g}{w_1-w_2-\mathrm{i}/g}.$$

Single-copy nested Bethe–Yang periodicity. In the spin-chain basis for one $\mathfrak{su}(2|2)_{\mathrm{c}}$ copy, let K^{I}, K^{II}, and K^{III} be the numbers of level-I momenta p_k, level-II roots y_a, and level-III roots w_b. Assume the asymptotic long-chain regime and the absence of singular coincidences among the displayed factors. The following equations are the closed-chain periodicity conditions for the three nested Zamolodchikov–Faddeev chains:

$$\begin{aligned}\mathrm{e}^{\mathrm{i}p_kL}&=\prod_{\substack{j=1\\ j\neq k}}^{K^{\mathrm{I}}}S^{\mathrm{I,I}}(p_j,p_k)\prod_{a=1}^{K^{\mathrm{II}}}S^{\mathrm{II,I}}(y_a,p_k),\qquad k=1,\ldots,K^{\mathrm{I}},\\ 1&=\prod_{j=1}^{K^{\mathrm{I}}}S^{\mathrm{II,I}}(y_a,p_j)^{-1}\prod_{b=1}^{K^{\mathrm{III}}}S^{\mathrm{III,II}}(w_b,y_a),\qquad a=1,\ldots,K^{\mathrm{II}},\\ 1&=\prod_{a=1}^{K^{\mathrm{II}}}S^{\mathrm{III,II}}(w_b,y_a)^{-1}\prod_{\substack{c=1\\ c\neq b}}^{K^{\mathrm{III}}}S^{\mathrm{III,III}}(w_c,w_b),\qquad b=1,\ldots,K^{\mathrm{III}}.\end{aligned}\tag{98.39}$$

For a state with N_1,N_2,N_3,N_4 excitations of types $\phi_1,\phi_2,\psi_1,\psi_2$, the nesting numbers are

$$K^{\mathrm{I}}=N_1+N_2+N_3+N_4,\qquad K^{\mathrm{II}}=2N_2+N_3+N_4,\qquad K^{\mathrm{III}}=N_2+N_4.$$

The first line records transport of the k-th level-I magnon once around the trace: it crosses every other physical magnon and every level-II defect. The second line records transport of the a-th level-II defect around the level-II chain; crossing a physical magnon in the reverse direction contributes $S^{\mathrm{II,I}}(y_a,p_j)^{-1}$, while crossing a level-III defect contributes $S^{\mathrm{III,II}}(w_b,y_a)$. The third line records transport of the b-th level-III defect around the level-III chain; each level-II defect is crossed in the reverse direction and each other level-III defect is crossed in the forward direction. Thus (98.39) is the Bethe–Yang periodicity bookkeeping for the already-defined nested scattering factors, not an additional theorem and not the thermodynamic Bethe ansatz. The relations among $K^{\mathrm{I}}, K^{\mathrm{II}}, K^{\mathrm{III}}$ and N_1, N_2, N_3, N_4 are the nesting content of the letters: ϕ_1 contributes only level I, ψ_1 contributes one level-II root, ψ_2 contributes one level-II and one level-III root, and ϕ_2 is the two-level-II contact state carrying one level-III root.

The dynamic spin-chain basis contains explicit $Z^{\pm}$ markers. In the string basis one absorbs half of this marker into each boson:

$$|\phi_A(p)\rangle_{\mathrm{str}} = |\phi_A(p)(Z^+)^{1/2}\rangle, \qquad |\psi_\alpha(p)\rangle_{\mathrm{str}} = |\psi_\alpha(p)\rangle.$$

The scattering factors which enter (98.39) are then replaced by

$$\begin{aligned} S^{\mathrm{I,I}}_{\mathrm{str}}(p_1,p_2) &= S^{\mathrm{I,I}}(p_1,p_2)\sqrt{\frac{x_1^+x_2^-}{x_1^-x_2^+}}, \\ S^{\mathrm{II,I}}_{\mathrm{str}}(y,p) &= \frac{y-x^-(p)}{y-x^+(p)}\sqrt{\frac{x^+(p)}{x^-(p)}}, \\ S^{\mathrm{III,II}}_{\mathrm{str}}(w,y) &= S^{\mathrm{III,II}}(w,y), \qquad S^{\mathrm{III,III}}_{\mathrm{str}}(w_1,w_2) = S^{\mathrm{III,III}}(w_1,w_2). \end{aligned} \tag{98.40}$$

For the full $\mathfrak{su}(2|2)_{\mathrm{c}} \otimes \mathfrak{su}(2|2)_{\mathrm{c}}$ magnon, the left and right copies have independent roots $y_a^{(\varsigma)}, w_b^{(\varsigma)}$, $\varsigma = L, R$. The physical level-I Bethe equation is obtained by multiplying the left and right auxiliary factors and by using the chosen physical vacuum scalar factor. In the $SU(2)$-vacuum nesting, the auxiliary insertion on the k-th physical magnon is

$$\prod_{\varsigma=L,R}\prod_{a=1}^{K^{\mathrm{II}}_{(\varsigma)}} \frac{y_a^{(\varsigma)}-x_k^-}{y_a^{(\varsigma)}-x_k^+}\sqrt{\frac{x_k^+}{x_k^-}}.$$

In the alternative $SL(2)$-vacuum nesting this factor is inverted:

$$\prod_{\varsigma=L,R}\prod_{a=1}^{K^{\mathrm{II}}_{(\varsigma)}} \frac{y_a^{(\varsigma)}-x_k^+}{y_a^{(\varsigma)}-x_k^-}\sqrt{\frac{x_k^-}{x_k^+}}.$$

This reciprocal relation is a nesting-frame statement, not a change of the BES dressing phase. Thus the nested Bethe equations are the diagonalization of a matrix-valued factorized scattering problem, not additional dynamical assumptions.

Controlled Approximation 98.12 (Asymptotic long-chain regime)**.** Equation (98.30) is an instance of Assumption 98.10. At weak coupling, wrapping effects begin at the loop order at which planar interactions can close around the trace. At finite coupling, the distinction is between the asymptotic Bethe–Yang problem and the finite-size problem solved by mirror TBA or the quantum spectral curve.

98.6 Weak-Coupling Reduction

The weak-coupling limit is a useful place to separate two conventions that are often conflated. The stringbook rank-one equation (98.30) uses the $SL(2)$-vacuum orientation. The compact $SU(2)$

coordinate Bethe equation of Chapter 97 uses the reciprocal Bethe–Yang phase, because there the scattering phase is the inverse of the ordered-chamber exchange coefficient. The two statements are compatible, but only after the orientation is named.

Weak limit of the rank-one ABA orientation. Let u_j, u_k stay away from the shifted branch points and from each other as $g \to 0$, and take the physical outside branch

$$x_j^{\pm} = x(u_j \pm \mathrm{i}/2), \qquad x(U) + x(U)^{-1} = \frac{U}{g}.$$

Then

$$x_j^{\pm} = \frac{u_j \pm \mathrm{i}/2}{g} - \frac{g}{u_j \pm \mathrm{i}/2} + O(g^3), \tag{98.41}$$

$$\frac{x_j^+}{x_j^-} = \frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2} + O(g^2), \tag{98.42}$$

$$\mathcal{R}_{jk} := \frac{x_j^- - x_k^+}{x_j^+ - x_k^-} \frac{1 - 1/(x_j^+ x_k^-)}{1 - 1/(x_j^- x_k^+)} = \frac{u_j - u_k - \mathrm{i}}{u_j - u_k + \mathrm{i}} + O(g^2), \tag{98.43}$$

$$H(u_j) - 1 = 2\mathrm{i}g \left(\frac{1}{x_j^+} - \frac{1}{x_j^-} \right) = \frac{2g^2}{u_j^2 + 1/4} + O(g^4). \tag{98.44}$$

The dressing phase satisfies $\sigma^2 = 1 + O(g^6)$ for fixed weak Bethe roots in the charge-expansion regime. Hence (98.30) reduces to

$$\left(\frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2} \right)^L = \prod_{\substack{k=1 \\ k \neq j}}^{M} \frac{u_j - u_k - \mathrm{i}}{u_j - u_k + \mathrm{i}}, \tag{98.45}$$

the $SL(2)$-orientation also used in (98.52) and in the weak-QSC Baxter degeneration of Chapter 100. The reciprocal factor $\mathcal{R}_{jk}^{-1}$ gives the compact $SU(2)$ one-loop phase of (97.2).

The convention check is an ordinary weak-branch expansion. The outside branch of $x + x^{-1} = U/g$ has the expansion

$$x(U) = \frac{U}{g} - \frac{g}{U} + O(g^3),$$

which gives (98.41). Dividing the two shifted expansions proves (98.42). In $\mathcal{R}_{jk}$, the first factor has numerator

$$\frac{u_j - \mathrm{i}/2}{g} - \frac{u_k + \mathrm{i}/2}{g} + O(g) = \frac{u_j - u_k - \mathrm{i}}{g} + O(g)$$

and denominator $(u_j - u_k + \mathrm{i})/g + O(g)$. The second factor equals $1 + O(g^2)$, because each $x^{\pm}$ is $O(g^{-1})$. This proves (98.43). The energy expansion is

$$2\mathrm{i}g^2 \left(\frac{1}{u_j + \mathrm{i}/2} - \frac{1}{u_j - \mathrm{i}/2} \right) + O(g^4) = \frac{2g^2}{u_j^2 + 1/4} + O(g^4).$$

Finally, the first weak BES coefficient is $c_{2,3}(g) = O(g^3)$, while the weak charges give $q_2 q_3 - q_3 q_2 = O(g^3)$; the dressing phase therefore cannot affect the one-loop equation. Substituting the limits into (98.30) gives (98.45).

Using $g^2 = \lambda/(16\pi^2)$, the leading energy term in (98.44) agrees with the one-loop normalization of Chapters 97 and 100.

98.7 Bound States and the Large-Spin Cusp Limit

A pole of the $SL(2)$ scalar factor at $x_1^- = x_2^+$ gives a Bethe string. More precisely, the displayed $SL(2)$-vacuum rational factor has a simple kinematic pole when the outgoing endpoint of the first constituent equals the incoming endpoint of the second constituent. A Q-magnon string with real center u is described by

$$u_j = u + \frac{\mathrm{i}}{2}(Q - 2j + 1), \qquad j = 1, \dots, Q,$$

with constituent variables $x_j^\pm = x(u_j \pm \mathrm{i}/2)$. Put

$$x_Q^+(u) = x\left(u + \frac{\mathrm{i}Q}{2}\right) = x_1^+, \qquad x_Q^-(u) = x\left(u - \frac{\mathrm{i}Q}{2}\right) = x_Q^-. \tag{98.46}$$

These are the only Zhukovsky endpoints that survive after fusion.

Construction 98.13 (Fusion of a Bethe string)**.** Assume a Q-string is formed by the adjacent-pole conditions

$$x_j^- = x_{j+1}^+, \qquad j = 1, \dots, Q-1,$$

and that the path to this pole does not cross a dressing-phase branch singularity. Then the total momentum and physical energy of the string are

$$\mathrm{e}^{\mathrm{i}p} = \frac{x_1^+}{x_Q^-}, \qquad H_Q(u) = Q + 2\mathrm{i}g\left(\frac{1}{x_Q^+(u)} - \frac{1}{x_Q^-(u)}\right), \tag{98.47}$$

and the shortening identity gives

$$H_Q(p) = \sqrt{Q^2 + 16g^2 \sin^2 \frac{p}{2}}. \tag{98.48}$$

If y is a level-II auxiliary root in the $SL(2)$-vacuum string basis, then its product of constituent scattering factors telescopes:

$$\prod_{j=1}^{Q} \frac{y - x_j^+}{y - x_j^-}\sqrt{\frac{x_j^-}{x_j^+}} = \frac{y - x_Q^+(u)}{y - x_Q^-(u)}\sqrt{\frac{x_Q^-(u)}{x_Q^+(u)}}. \tag{98.49}$$

For two bound states of charges Q_1, Q_2 and centers u, v, the fused $SL(2)$-vacuum scalar factor is

$$S_{SL(2)}^{Q_1,Q_2}(u,v) = \prod_{m=1}^{Q_1}\prod_{n=1}^{Q_2} S_{SL(2)}\left(u + \frac{\mathrm{i}}{2}(Q_1 - 2m + 1), v + \frac{\mathrm{i}}{2}(Q_2 - 2n + 1)\right), \tag{98.50}$$

followed by projection to the short Q_1- and Q_2-particle representations. The product formula is the scalar part of fusion; the matrix projection and the analytic continuation of the dressing factor are separate representation-theoretic and scalar-branch inputs.

Derivation. The condition $u_{j+1} = u_j - \mathrm{i}$ gives

$$x_j^- = x(u_j - \mathrm{i}/2) = x(u_{j+1} + \mathrm{i}/2) = x_{j+1}^+,$$

so all internal endpoints cancel in products. Hence

$$\prod_{j=1}^{Q} \frac{x_j^+}{x_j^-} = \frac{x_1^+}{x_Q^-} = \frac{x_Q^+(u)}{x_Q^-(u)}.$$

The same cancellation in the sum of the physical-sheet one-particle energies

$$H_j = 1 + 2\mathrm{i}g\left(\frac{1}{x_j^+} - \frac{1}{x_j^-}\right)$$

gives the energy formula in (98.47). The bound-state shortening relation is the centrally extended one with $H^2 - Q^2 = 4PK$, and the total central charges telescope to

$$P = g(1 - \mathrm{e}^{\mathrm{i}p}), \qquad K = g(1 - \mathrm{e}^{-\mathrm{i}p}).$$

Therefore

$$H_Q^2 = Q^2 + 4g^2(1 - \mathrm{e}^{\mathrm{i}p})(1 - \mathrm{e}^{-\mathrm{i}p}) = Q^2 + 16g^2 \sin^2 \frac{p}{2}.$$

Taking the positive physical branch gives (98.48).

The auxiliary factor (98.49) is the same endpoint cancellation:

$$\prod_{j=1}^{Q} \frac{y - x_j^+}{y - x_j^-} = \frac{y - x_1^+}{y - x_Q^-}, \qquad \prod_{j=1}^{Q} \frac{x_j^-}{x_j^+} = \frac{x_Q^-}{x_1^+}.$$

Finally, scalar fusion means that a distant probe scatters consecutively through every constituent of each string before the internal tensor product is projected to the short representation. This gives (98.50). Internal pole residues and the matrix projection determine the normalization of the bound-state intertwiner; they are not additional endpoint identities and are kept as fusion inputs here. The resulting asymptotic Bethe–Yang equations for K^{I} bound-state particles of charges Q_k are obtained from (98.39) by replacing the fundamental scalar factor with (98.50) and the fundamental auxiliary factors with (98.49). Thus the first equation in the $SL(2)$-vacuum frame reads

$$\mathrm{e}^{\mathrm{i}p_k L} = \prod_{\substack{j=1 \\ j\neq k}}^{K^{\mathrm{I}}} S_{SL(2)}^{Q_j,Q_k}(u_j, u_k) \prod_{\varsigma=L,R} \prod_{\ell=1}^{K_{(\varsigma)}^{\mathrm{II}}} \frac{y_\ell^{(\varsigma)} - x_{Q_k}^+(u_k)}{y_\ell^{(\varsigma)} - x_{Q_k}^-(u_k)} \sqrt{\frac{x_{Q_k}^-(u_k)}{x_{Q_k}^+(u_k)}}. \tag{98.51}$$

The level-II and level-III equations keep the same rational form as before, with each fundamental $x^\pm$ replaced by the appropriate bound-state endpoints $x_Q^\pm(u)$. This is the bound-state input used by the mirror TBA node $Q \mid \bullet$ in Chapter 99.

In the $SL(2)$ sector, twist-L spin-S operators are

$$\mathrm{tr}(D_+^{s_1} Z \cdots D_+^{s_L} Z), \qquad \sum_{j=1}^{L} s_j = S.$$

The one-loop Bethe equations in this noncompact sector are

$$\left(\frac{u_k+\mathrm{i}/2}{u_k-\mathrm{i}/2}\right)^L=\prod_{\substack{j=1\\ j\neq k}}^{S}\frac{u_k-u_j-\mathrm{i}}{u_k-u_j+\mathrm{i}},\qquad k=1,\dots,S, \tag{98.52}$$

with cyclicity selecting zero total spin-chain momentum. For the minimal large-spin trajectory the roots are real, symmetric under $u\mapsto -u$, and have mode numbers ±1 in the logarithmic equation. Write

$$u_k=S\bar{u}_k,\qquad \int_{-a}^{a}\bar{\rho}_0(\bar{u})\,\mathrm{d}\bar{u}=1,$$

where $\bar{\rho}_0$ is the continuum density of the scaled roots. In the limit $S\gg L$, the derivative of the continuum logarithmic equation is encoded by the resolvent

$$G_0(z)=\int_{-a}^{a}\frac{\bar{\rho}_0(v)}{z-v}\,\mathrm{d}v,\qquad G_0(z)=\frac{1}{z}+O(z^{-2}).$$

The discontinuity convention is

$$G_0(y+\mathrm{i}0)-G_0(y-\mathrm{i}0)=-2\pi\mathrm{i}\,\bar{\rho}_0(y).$$

After differentiating the continuum Bethe equation, the boundary values obey

$$G_0'(y+\mathrm{i}0)+G_0'(y-\mathrm{i}0)=4\pi\delta(y)\qquad(-a<y<a).$$

The endpoint is fixed by the same Riemann-Hilbert data. For a candidate symmetric cut $[-a,a]$, put

$$R_a(z)=\sqrt{z^2-a^2},\qquad R_a(z)\sim z\quad(z\to\infty),\qquad H_a(z)=-\frac{1}{zR_a(z)}.$$

On the cut,

$$R_{a,+}(y)=\mathrm{i}\sqrt{a^2-y^2},\qquad R_{a,-}(y)=-\mathrm{i}\sqrt{a^2-y^2}.$$

Thus $H_{a,+}+H_{a,-}=0$ away from the origin. At the origin the pole of $1/z$ must be read distributionally:

$$H_{a,+}(y)+H_{a,-}(y)=\frac{\mathrm{i}}{\sqrt{a^2-y^2}}\left(\frac{1}{y+\mathrm{i}0}-\frac{1}{y-\mathrm{i}0}\right)=\frac{2\pi}{a}\delta(y).$$

The source $4\pi\delta(y)$ therefore fixes $a=1/2$. The primitive with $G_0(\infty)=0$ is obtained by writing $Y=\sqrt{4z^2-1}=2R_{1/2}(z)$, because

$$\frac{\mathrm{d}}{\mathrm{d}z}\left[-\mathrm{i}\log\frac{Y+\mathrm{i}}{Y-\mathrm{i}}\right]=-\frac{1}{zR_{1/2}(z)}.$$

The one-cut solution with the displayed normalization is consequently

$$G_0(z)=-\mathrm{i}\log\frac{\sqrt{4z^2-1}+\mathrm{i}}{\sqrt{4z^2-1}-\mathrm{i}},\qquad a=\frac{1}{2}, \tag{98.53}$$

where the square root is chosen so that $\sqrt{4z^2-1}\sim 2z$ at infinity. Its density is

$$\bar{\rho}_0(y)=\frac{1}{\pi}\log\frac{1+\sqrt{1-4y^2}}{1-\sqrt{1-4y^2}},\qquad |y|<\frac{1}{2}. \tag{98.54}$$

The normalization is not an additional assumption. With $y = (2\cosh t)^{-1}$, the evenness of the density gives

$$2\int_0^{1/2} \bar{\rho}_0(y)\,\mathrm{d}y = \frac{2}{\pi}\int_0^\infty t\ \mathrm{sech}\,t\ \tanh t\,\mathrm{d}t = \frac{2}{\pi}\int_0^\infty \mathrm{sech}\,t\,\mathrm{d}t = 1.$$

The one-loop anomalous dimension is

$$\gamma^{(1)} = 2g^2\sum_{k=1}^{S}\frac{1}{u_k^2+1/4}.$$

The singular region near $u=0$ is resolved by evaluating the resolvent at $z = \mathrm{i}/(2S)$:

$$\gamma^{(1)} = -4g^2\ \mathrm{Im}\,G_0\!\left(\frac{\mathrm{i}}{2S}\right) + O(S^0g^2).$$

Using the continuation

$$G_0\!\left(\frac{\mathrm{i}}{2S}\right) = -\mathrm{i}\log\frac{\sqrt{1+S^{-2}}+1}{\sqrt{1+S^{-2}}-1},$$

one obtains

$$\Delta - S - L = \gamma^{(1)} = 8g^2\log S + O(S^0g^2, g^4). \tag{98.55}$$

98.8 Finite-Density Bethe Roots and Spectral Curves

The phrase "finite gap" will be used here in a precise Bethe-ansatz sense. It is the statement that, in a large-charge limit, Bethe roots condense on finitely many arcs and that the Cauchy transform of the limiting measure extends to a meromorphic object on a finite-sheeted Riemann surface. This surface is the spectral curve of the state.

Definition 98.14 (Finite-density Bethe-root curve)**.** Let N be a scaling parameter and let $\{u_{j,N}\}_{j=1}^{M_N} \subset \mathbb{C}$ be Bethe roots with $M_N \to \infty$. Suppose that, after a scaling $u_{j,N} = N\bar{u}_{j,N}$, the empirical measures

$$\mu_N = \frac{1}{M_N}\sum_{j=1}^{M_N}\delta_{\bar{u}_{j,N}}$$

converge weakly to an absolutely continuous measure

$$\mathrm{d}\mu(u) = \rho(u)\,\mathrm{d}s$$

supported on a finite union of oriented analytic arcs $\mathcal{C} = \bigcup_{a=1}^r \mathcal{C}_a$. The Cauchy transform is

$$G(z) = \int_{\mathcal{C}}\frac{\rho(u)\,\mathrm{d}s(u)}{z-u}, \qquad z \in \mathbb{C}\setminus\mathcal{C}.$$

A finite-density Bethe-root curve is the data

$$\big(\Sigma, \pi : \Sigma \to \mathbb{P}^1_z, \lambda, \{A_a, B_a\}\big)$$

where Σ is a compact Riemann surface obtained by gluing sheets across the arcs $\mathcal{C}_a$, λ is a meromorphic differential whose physical-sheet primitive contains $G(z)\mathrm{d}z$, and the cycles A_a encircle the cuts. The filling fractions are the periods

$$\mathcal{S}_a = \frac{1}{2\pi\mathrm{i}}\oint_{A_a}\lambda.$$

The definition separates three pieces of information that are often blurred. The measure ρ is the continuum limit of roots. The Riemann surface Σ records analytic continuation across root cuts. The meromorphic differential λ records the logarithmic Bethe equation: mode numbers are period data, not decorations on a drawing of cuts.

Reconstruction ledger. A finite-density root curve is not yet a classical string solution and is not yet the quantum spectral curve. The reconstruction problem used in this chapter has the following rank-one spine. For each regulator N start with a logarithmic Bethe record

$$L_N p_N(u_{j,N}) = 2\pi n_{j,N} + \sum_{\substack{k=1\\k\neq j}}^{M_N} \theta_N(u_{j,N}, u_{k,N}) + r_{j,N}, \tag{98.56}$$

where p_N is the one-particle momentum, θ_N is the antisymmetric two-body phase, $n_{j,N} \in \mathbb{Z}$ fixes the logarithm branch, and $r_{j,N}$ denotes regulator terms whose limiting status must be declared. A rank-one finite-gap reconstruction record consists of:

1. a partition of the roots into macroscopic packets converging to the oriented cuts $\mathcal{C}_a$, with $n_{j,N} = n_a$ on each packet away from endpoint layers;
2. a limiting driving term $V'(z)$ and a limiting Cauchy transform $G(z)$ such that the scaled version of (98.56) gives a cutwise principal-value equation with source $V'(u) - 2\pi n_a$;
3. the quasimomentum $p = V'/2 - G$, whose cut gluing is $p_+ + p_- = 2\pi n_a$;
4. A-cycle fillings $\mathcal{S}_a = (2\pi\mathrm{i})^{-1} \oint_{A_a} p\,\mathrm{d}z$ and large-z moments $\mathcal{M}_k$, which are the finite-density charge coordinates before sector-specific constraints are imposed;
5. the global spin-chain closure condition obtained by summing the finite equations, namely the cyclicity/level-matching constraint on $\sum_a n_a \mathcal{S}_a$;
6. any extra reality involution, closed-period, pole-residue, Virasoro, or target-space reconstruction constraints required by the sigma-model sector under study.

The calculations below establish the first five items in the rank-one Cauchy-transform setting. They do not establish the final $\mathrm{AdS}_5 \times S^5$ finite-gap construction, where one must replace the single p by the full collection of quasimomenta, impose the inversion and reality symmetries of the coset curve, fix the pole residues at the distinguished spectral points, and reconstruct closed embedding coordinates. Nor do they prove the TBA-to-QSC equivalence. The QSC later in Chapter 100 is the quantum finite-difference/Riemann-Hilbert replacement for this classical curve record, with additional gluing and asymptotic data.

Jump data from the Cauchy transform. Let G be the Cauchy transform in Definition 98.14, and assume that ρ is Hölder continuous on the interior of a cut $\mathcal{C}_a$. For $u \in \mathcal{C}_a^\circ$, denote by $G_+(u)$ and $G_-(u)$ the boundary values from the two sides of the oriented arc. Then

$$G_+(u) - G_-(u) = -2\pi\mathrm{i}\,\rho(u), \qquad \frac{G_+(u) + G_-(u)}{2} = \mathrm{p.v.} \int_{\mathcal{C}} \frac{\rho(v)\,\mathrm{d}s(v)}{u - v}. \tag{98.57}$$

Consequently, whenever the continuum logarithmic Bethe equation has the form

$$2\ \mathrm{p.v.} \int_{\mathcal{C}} \frac{\rho(v)\,\mathrm{d}s(v)}{u - v} = V'(u) - 2\pi n_a, \qquad u \in \mathcal{C}_a^\circ, \tag{98.58}$$

with integer mode number n_a on $\mathcal{C}_a$, the quasimomentum

$$p(z) = \frac{1}{2}V'(z) - G(z) \tag{98.59}$$

satisfies the gluing condition

$$p_+(u) + p_-(u) = 2\pi n_a. \tag{98.60}$$

The two boundary-value identities are the Plemelj formulas for the Cauchy transform on a smooth oriented arc. Substituting the second identity into (98.58) gives

$$G_+(u) + G_-(u) = V'(u) - 2\pi n_a.$$

Using $p_\pm(u) = V'(u)/2 - G_\pm(u)$ gives

$$p_+(u) + p_-(u) = V'(u) - \big(G_+(u) + G_-(u)\big) = 2\pi n_a.$$

Multi-cut periods and sheet reflections. The same boundary values also recover the filling periods. In the rank-one finite-density normalization where $\lambda = p(z)\mathrm{d}z$ on the physical sheet, and where V' is holomorphic in a collar of the cut, one has

$$p_+(u) - p_-(u) = 2\pi\mathrm{i}\,\rho(u), \qquad u \in \mathcal{C}_a^\circ. \tag{98.61}$$

Thus a small A_a-cycle surrounding $\mathcal{C}_a$, with the first traverse along the $+$-side of the oriented cut and the return traverse on the $-$-side, gives

$$\mathcal{S}_a = \frac{1}{2\pi\mathrm{i}}\oint_{A_a} p(z)\mathrm{d}z = \int_{\mathcal{C}_a} \rho(u)\,\mathrm{d}s(u). \tag{98.62}$$

Indeed, the contribution of a shrinking collar is

$$\oint_{A_a} p(z)\mathrm{d}z = \int_{\mathcal{C}_a} \big(p_+(u) - p_-(u)\big)\mathrm{d}s(u),$$

and (98.61) gives (98.62). This is the first non-one-cut datum: each cut carries an independent filling fraction before global period and level-matching constraints are imposed.

Large-z moments as charge coordinates. The same Cauchy transform also records the global root moments. If the cuts lie in a compact set and $|z|$ is larger than the support, then

$$\frac{1}{z-u} = \sum_{k=0}^{K} \frac{u^k}{z^{k+1}} + \frac{u^{K+1}}{z^{K+1}(z-u)}.$$

Hence

$$G(z) = \sum_{k=0}^{K} \frac{\mathcal{M}_k}{z^{k+1}} + O(|z|^{-K-2}), \qquad \mathcal{M}_k := \int_{\mathcal{C}} u^k \rho(u)\,\mathrm{d}s(u). \tag{98.63}$$

The zeroth moment is the total filling,

$$\mathcal{M}_0 = \sum_a \mathcal{S}_a,$$

while higher moments are the large-z charge coordinates carried by the root distribution. In a particular sector one combines these coefficients with the large-z expansion of the driving term $V'(z)$ in (98.59) and with the chosen normalization of the spin-chain or sigma-model charges. The moment expansion is the finite-density Cauchy-coordinate statement; a complete classical string solution still imposes the additional Virasoro, reality, and closed-period constraints.

The finite regulator has the same bookkeeping before taking a limit. For scaled roots $\bar{u}_j$ with weights w_j,

$$G_N(z) = \sum_j \frac{w_j}{z - \bar{u}_j} = \sum_{k=0}^{K} \frac{\sum_j w_j \bar{u}_j^k}{z^{k+1}} + \sum_j \frac{w_j \bar{u}_j^{K+1}}{z^{K+1}(z - \bar{u}_j)}.$$

Thus the continuum charge coordinates are limits of finite weighted power sums, not independent decorations of the spectral curve.

Cyclicity as a global period constraint. The local cut-reflection algebra does not by itself impose the closed-chain condition. In a finite rank-one spin chain, write a logarithmic Bethe equation in the form

$$L\, p(u_j) = 2\pi n_j + \sum_{\substack{k=1 \\ k\neq j}}^{M} \theta(u_j, u_k), \qquad \theta(u,v) = -\theta(v,u), \tag{98.64}$$

where L is the chain length and $n_j \in \mathbb{Z}$ is the chosen logarithm branch. Summing (98.64) over j cancels the two-body phases pairwise:

$$L \sum_{j=1}^{M} p(u_j) = 2\pi \sum_{j=1}^{M} n_j.$$

Trace cyclicity requires $\exp(\mathrm{i} \sum_j p(u_j)) = 1$, hence

$$\sum_{j=1}^{M} n_j \in L\mathbb{Z}.$$

If the roots on $\mathcal{C}_a$ have a common mode number n_a and multiplicity M_a, this becomes the finite congruence

$$\sum_a n_a M_a \in L\mathbb{Z}. \tag{98.65}$$

In a simultaneous finite-density limit with $M_a/N \to \mathcal{S}_a$ and $L/N \to \ell$, (98.65) is the discrete origin of the level-matching condition

$$\sum_a n_a \mathcal{S}_a \in \ell\, \mathbb{Z}$$

whenever the integer multiple is stable along the regulator sequence. This is only the spin-chain global momentum constraint; closed classical strings also require the remaining period, reality, and Virasoro conditions of the sigma-model reconstruction.

The mode numbers are the affine gluing data. Equation (98.60) says that analytic continuation through $\mathcal{C}_a$ acts on the local quasimomentum coordinate by the reflection

$$R_a: \ p \longmapsto 2\pi n_a - p. \tag{98.66}$$

Hence $R_a^2 = 1$, while crossing first $\mathcal{C}_a$ and then $\mathcal{C}_b$ gives

$$R_b R_a(p) = p + 2\pi(n_b - n_a). \tag{98.67}$$

For integer mode numbers the exponentiated quasimomentum is therefore single-valued around such a two-cut continuation,

$$\exp\bigl(\mathrm{i} R_b R_a(p)\bigr) = \exp(\mathrm{i}p).$$

The unexponentiated p, however, has remembered the relative mode number. A full classical finite-gap solution also has Virasoro constraints, reconstruction of the embedding coordinates, and global period conditions; the calculation here is only the local multi-cut period and monodromy bookkeeping that those global constraints use.

For the large-spin one-loop cusp density above, the spectral curve is already visible. Put

$$y^2 = 4z^2 - 1, \qquad G_0(z) = -\mathrm{i}\log\frac{y+\mathrm{i}}{y-\mathrm{i}}, \qquad y \sim 2z \quad (z \to \infty).$$

The two sheets are exchanged by $y \mapsto -y$. Under this exchange,

$$\exp\bigl(\mathrm{i}G_0\bigr) = \frac{y+\mathrm{i}}{y-\mathrm{i}} \quad \longmapsto \quad \frac{y-\mathrm{i}}{y+\mathrm{i}} = \exp\bigl(-\mathrm{i}G_0\bigr),$$

so the cut $[-1/2, 1/2]$ is the branch locus of the two-sheeted curve. The density (98.54) is precisely the discontinuity of this primitive across the cut, and the endpoint square-root behavior is the local branch structure of Σ.

Classical S^2 Pohlmeyer cell. The finite-gap language also has a classical sigma-model origin. The smallest honest reduction, avoiding all worldsheet quantization, is the $\mathbb{R} \times S^2$ subsector. Let

$$n(\sigma^+, \sigma^-) \in S^2 \subset \mathbb{R}^3, \qquad n \cdot n = 1,$$

and impose the constant-stress conformal-gauge constraints

$$\partial_+ n \cdot \partial_+ n = \partial_- n \cdot \partial_- n = \mu^2.$$

The sphere equation of motion is

$$\partial_+\partial_- n + (\partial_+ n \cdot \partial_- n)\, n = 0. \tag{98.68}$$

On a patch where $\partial_+ n$ and $\partial_- n$ are not parallel, put

$$e_\pm = \mu^{-1}\partial_\pm n, \qquad e_\pm \cdot e_\pm = 1, \qquad e_+ \cdot e_- = \cos\alpha.$$

Then (98.68) gives

$$\partial_+ e_- = -\mu\cos\alpha\, n, \qquad \partial_- e_+ = -\mu\cos\alpha\, n.$$

The remaining frame derivatives are fixed by differentiating $e_\pm \cdot e_\pm = 1$, $e_\pm \cdot n = 0$, and $e_+ \cdot e_- = \cos\alpha$:

$$\partial_+ e_+ = -\mu n - \frac{\partial_+\alpha}{\sin\alpha}(e_- - \cos\alpha\, e_+),$$
$$\partial_- e_- = -\mu n - \frac{\partial_-\alpha}{\sin\alpha}(e_+ - \cos\alpha\, e_-).$$

Now compare the e_+-coefficient in $\partial_-(\partial_+ e_-) = \partial_+(\partial_- e_-)$. The left hand side has no e_+-component, while the right hand side has

$$-\mu^2 - \frac{\partial_+\partial_-\alpha}{\sin\alpha}.$$

Therefore the reduced field obeys

$$\partial_+\partial_-\alpha + \mu^2 \sin\alpha = 0. \tag{98.69}$$

This is the classical Pohlmeyer reduction in the S^2 subsector. It is a local equivalence of moving-frame data on nondegenerate patches; reconstructing n from α, gluing across $\sin\alpha = 0$, imposing closed-string periodicity, and quantizing the resulting finite-gap data are separate problems. Thus (98.69) explains why integrable PDE spectral curves appear in the strong-coupling classical story, but it is not a derivation of the planar gauge-theory quantum spectral curve.

The all-loop ABA refines this large-spin calculation rather than replacing it. The macroscopic roots at $|u| \sim S$ still produce the logarithmic enhancement, but the all-loop phase induces an $O(\log S)$ fluctuation of the density near $u = O(1)$. This near-origin fluctuation is the object described by the BES equation.

Assumption 98.15 (Large-spin BES scaling regime)**.** Use the $SL(2)$ all-loop asymptotic Bethe equation in the regime

$$S \to \infty, \qquad L \text{ fixed}, \qquad \log S \gg L,$$

with symmetric mode numbers $n_k = \pm 1$, zero total momentum, the physical Zhukovsky branch for the Bethe roots before crossing, and the BES dressing phase of Definition 98.8. Assume that the large-spin root density has a one-cut bulk part at $u = O(S)$ and a near-origin correction at $u = O(1)$ whose coefficient is proportional to the scaling function. The all-loop ABA is being used here in precisely the finite-density sense of Assumption 98.10; wrapping effects are outside this asymptotic calculation.

The derivative of the logarithmic all-loop $SL(2)$ Bethe equation has three types of terms. The rational XXX kernel gives the one-loop singular source already solved above. The rational all-loop Zhukovsky factors and the dressing phase give additional kernels. Finally, the $u = O(S)$ bulk roots feed a source into the $u = O(1)$ equation. After the bulk density has been used to solve the outer problem, the inner equation is closed for a single Fourier density. We use the standard BES normalization

$$\widehat{\sigma}(t) = \mathrm{e}^{-t/2} \int_{-\infty}^{\infty} \mathrm{d}u\, \mathrm{e}^{-\mathrm{i}tu} \sigma(u), \qquad t > 0,$$

where $\sigma(u)$ denotes the inner density correction in the present large-spin normalization.

Definition 98.16 (BES kernel in the stringbook convention)**.** Let J_n be the Bessel function of the first kind. Set

$$K_0(t, t') = \frac{J_1(t)J_0(t') - J_0(t)J_1(t')}{t - t'}, \tag{98.70}$$

with the diagonal value defined by analytic continuation. The dressing part is

$$K_{\mathrm{dr}}(t,t';g) = \frac{4}{tt'} \sum_{k,\ell\geq 1} (-1)^{k+\ell} c_{2k,2\ell+1}(g) J_{2\ell}(t) J_{2k-1}(t'), \tag{98.71}$$

where $c_{r,s}(g) = -c_{s,r}(g)$ for $r > s$. The BES kernel used below is

$$K_{\mathrm{BES}}(t,t';g) = K_0(t,t') + K_{\mathrm{dr}}(t,t';g), \qquad K_{\mathrm{BES}}(t,0;g) = \frac{J_1(t)}{t} + \frac{2}{t}\sum_{\ell\geq 1}(-1)^{\ell-1} c_{2,2\ell+1}(g) J_{2\ell}(t).$$

The Fourier transform which turns powers of $x^{\pm}(u)^{-1}$ into Bessel functions is the convention-sensitive step. We spell it out because replacing the signed ratio $J_m(2gt)/t$ by $J_m(2g|t|)/|t|$ loses a parity sign in the lower half-plane transform.

Lemma 98.17 (Zhukovsky Fourier transform)**.** *Let $g > 0$, let $m \in \mathbb{Z}_{>0}$, and let $x(z)$ be the physical outside branch of*

$$x(z) + x(z)^{-1} = \frac{z}{g}, \qquad x(z) \sim \frac{z}{g} \quad (z \to \infty),$$

with short cut $[-2g, 2g]$. Put

$$x^{\pm}(u) = x(u \pm \mathrm{i}/2), \qquad u \in \mathbb{R}.$$

For $t \neq 0$, with $\Theta(t) = 1$ for $t > 0$ and 0 for $t < 0$, the oscillatory Fourier transform is

$$\int_{-\infty}^{\infty} \frac{\mathrm{d}u}{2\pi}\, \mathrm{e}^{-\mathrm{i}tu} \frac{1}{x^{\pm}(u)^m} = (-\mathrm{i})^m m\, \mathrm{e}^{-|t|/2}\, \frac{\pm\Theta(\pm t) J_m(2gt)}{t}. \tag{98.72}$$

Here the upper sign is used for x^+, the lower sign for x^-, and J_m is the Bessel function of the first kind.

Proof. For the x^+ transform set $z = u + \mathrm{i}/2$. Then

$$\mathrm{e}^{-\mathrm{i}tu} = \mathrm{e}^{-t/2}\mathrm{e}^{-\mathrm{i}tz},$$

and the integration line is $\mathbb{R} + \mathrm{i}/2$. If $t < 0$, this line is closed in the upper half-plane and no cut is crossed, so the integral vanishes. If $t > 0$, close in the lower half-plane. The deformation crosses the Zhukovsky cut and gives the negatively oriented loop around it. Using $z = g(x + x^{-1})$ on this loop, with x running around $|x| = 1$, gives

$$I_m^+(t) = -\mathrm{e}^{-t/2} \oint_{|x|=1} \frac{\mathrm{d}x}{2\pi}\, g(1 - x^{-2}) x^{-m} \mathrm{e}^{-\mathrm{i}gt(x+x^{-1})}.$$

The generating function

$$\mathrm{e}^{-\mathrm{i}gt(x+x^{-1})} = \sum_{n\in\mathbb{Z}} (-\mathrm{i})^n J_n(2gt) x^n$$

therefore yields

$$I_m^+(t) = -\mathrm{i}g\mathrm{e}^{-t/2}\left[(-\mathrm{i})^{m-1} J_{m-1}(2gt) - (-\mathrm{i})^{m+1} J_{m+1}(2gt)\right].$$

Since $(-\mathrm{i})^{m+1} = -(-\mathrm{i})^{m-1}$, and

$$J_{m-1}(z) + J_{m+1}(z) = \frac{2m}{z} J_m(z),$$

this becomes

$$I_m^+(t) = (-\mathrm{i})^m m\, \mathrm{e}^{-t/2} \frac{J_m(2gt)}{t}, \qquad t > 0.$$

Together with the vanishing for $t < 0$, this proves the upper-sign formula.

For real u, the lower shifted branch satisfies

$$x^-(u) = \overline{x^+(u)}.$$

Hence

$$I_m^-(t) = \overline{I_m^+(-t)}.$$

Applying the upper-sign result to $-t > 0$ and using $J_m(-z) = (-1)^m J_m(z)$ gives the lower-sign formula in (98.72). The factor $J_m(2gt)/t$, with signed t, is therefore part of the convention rather than a cosmetic choice. □

The signs in Lemma 98.17 encode the same x^+-above, x^--below sheet convention as the mirror continuation in Chapter 99. Reversing them would invert the dressing-source contribution.

BES equation from the large-spin ABA. Under Assumption 98.15, and after applying the Fourier transform (98.72), the inner large-spin density obeys

$$\widehat{\sigma}(t) = \frac{t}{\mathrm{e}^t - 1} \left[K_{\mathrm{BES}}(2gt, 0; g) - 4g^2 \int_0^\infty \mathrm{d}t'\, K_{\mathrm{BES}}(2gt, 2gt'; g) \widehat{\sigma}(t') \right], \qquad t > 0. \tag{98.73}$$

The corresponding large-spin scaling function in the normalization of (98.55) is

$$\Delta - S - L = f(g) \log S + O(S^0), \qquad f(g) = 8g^2 - 64g^4 \int_0^\infty \mathrm{d}t\, \widehat{\sigma}(t) \frac{J_1(2gt)}{2gt}. \tag{98.74}$$

We spell out the logic because it is easy to hide a convention change in this calculation. Taking the logarithm of the $SL(2)$ all-loop Bethe equation and differentiating with respect to the target rapidity u gives the rational kernel

$$\frac{2}{(u-v)^2 + 1} - 2\pi \delta(u - v),$$

where the delta term records the branch of the arccotangent scattering phase. The all-loop rational Zhukovsky factor contributes

$$-2\mathrm{i}\, \partial_u \log \frac{1 - 1/(x^+(u) x^-(v))}{1 - 1/(x^-(u) x^+(v))},$$

and the scalar factor contributes

$$2\partial_u \theta(x^\pm(v), x^\pm(u)).$$

The $O(S)$ bulk roots are described by the one-cut density (98.54); expanding their contribution for fixed u produces the driving term

$$\partial_u \left[\frac{1}{2g} \left(\frac{1}{x^+(u)} + \frac{1}{x^-(u)} \right) + \frac{\mathrm{i}}{2g} \sum_{n \geq 1} \frac{c_{2,2n+1}(g)}{n} \left(\frac{1}{x^+(u)^{2n}} - \frac{1}{x^-(u)^{2n}} \right) \right]. \tag{98.75}$$

The explicit L-dependent terms in the logarithmic Bethe equation are smaller than this driving term in the scaling regime $\log S \gg L$, so they affect the $O(S^0)$ part rather than $f(g)$.

Applying $(2\pi)^{-1}\mathrm{e}^{-t/2} \int \mathrm{d}u\, \mathrm{e}^{-\mathrm{i}tu}$ to the inner equation gives (98.73). The Bessel transform (98.72) turns the all-loop rational factors into K_0, and turns the charge expansion of the dressing phase into K_{dr}. The factor $t/(\mathrm{e}^t - 1)$ is the inverse of the rational large-spin kernel in this Fourier normalization. The energy formula follows by expanding

$$\sum_k \left(\frac{1}{x_k^+} - \frac{1}{x_k^-} \right)$$

against the same bulk-plus-inner density and applying (98.72) with $m = 1$. The outer density gives the one-loop $8g^2 \log S$ term; the inner density gives the integral correction in (98.74).

Proposition 98.18 (Weak expansion of the BES scaling function)**.** *The BES equation* (98.73) *implies*

$$f(g) = 8g^2 - \frac{8\pi^2}{3} g^4 + \frac{88\pi^4}{45} g^6 - \left(\frac{584\pi^6}{315} + 64\zeta(3)^2 \right) g^8 + O(g^{10}). \tag{98.76}$$

The first dressing-phase contribution enters at order g^8 and supplies the $\zeta(3)^2$ term in this normalization.

Proof. Write

$$\widehat{\sigma}(t) = \sigma_0(t) + g^2\sigma_1(t) + g^4\sigma_2(t) + O(g^6).$$

Since

$$\frac{J_1(2gt)}{2gt} = \frac{1}{2} - \frac{g^2t^2}{4} + \frac{g^4t^4}{24} + O(g^6), \qquad K_0(2gt, 0) = \frac{1}{2} - \frac{g^2t^2}{4} + \frac{g^4t^4}{24} + O(g^6),$$

and

$$K_0(2gt, 2gt') = \frac{1}{2} - \frac{g^2}{4}(t^2 - tt' + t'^2) + O(g^4),$$

the first two density coefficients are

$$\sigma_0(t) = \frac{t}{2(\mathrm{e}^t - 1)}$$

and

$$\sigma_1(t) = \frac{t}{\mathrm{e}^t - 1} \left[-\frac{t^2}{4} - 4 \int_0^\infty \mathrm{d}t'\, \frac{1}{2} \sigma_0(t') \right] = -\frac{t}{\mathrm{e}^t - 1} \left(\frac{t^2}{4} + \frac{\pi^2}{6} \right),$$

because

$$\int_0^\infty \frac{t\,\mathrm{d}t}{\mathrm{e}^t - 1} = \frac{\pi^2}{6}.$$

For the g^4 density coefficient the dressing source is now required. Using

$$c_{2,3}(g) = 4\zeta(3)g^3 + O(g^5), \qquad J_2(2gt) = \frac{g^2t^2}{2} + O(g^4),$$

and the prefactor $2/(2gt)$ in $K_{\mathrm{BES}}(2gt, 0; g)$, one obtains

$$K_{\mathrm{dr}}(2gt, 0; g) = 2\zeta(3)g^4 t + O(g^6).$$

The g^4 part of the BES equation is therefore

$$\sigma_2(t) = \frac{t}{\mathrm{e}^t - 1}\left[\frac{t^4}{24} + 2\zeta(3)t - 4\int_0^\infty \mathrm{d}t' \left(\frac{1}{2}\sigma_1(t') - \frac{t^2 - tt' + t'^2}{4}\sigma_0(t')\right)\right].$$

The required moments are

$$\int_0^\infty \sigma_0(t')\,\mathrm{d}t' = \frac{\pi^2}{12}, \qquad \int_0^\infty t'\sigma_0(t')\,\mathrm{d}t' = \zeta(3), \qquad \int_0^\infty t'^2\sigma_0(t')\,\mathrm{d}t' = \frac{\pi^4}{30},$$
$$\int_0^\infty \sigma_1(t')\,\mathrm{d}t' = -\frac{2\pi^4}{45}.$$

Substitution gives the explicit coefficient

$$\sigma_2(t) = \frac{t}{\mathrm{e}^t - 1}\left(\frac{t^4}{24} + \frac{\pi^2 t^2}{12} + \zeta(3)t + \frac{11\pi^4}{90}\right).$$

Put

$$A(g) = \int_0^\infty \mathrm{d}t\,\widehat{\sigma}(t)\frac{J_1(2gt)}{2gt} = A_0 + g^2A_1 + g^4A_2 + O(g^6).$$

The two coefficients are

$$A_0 = \int_0^\infty \frac{t\,\mathrm{d}t}{4(\mathrm{e}^t - 1)} = \frac{\pi^2}{24},$$

and

$$A_1 = \int_0^\infty \frac{t\,\mathrm{d}t}{\mathrm{e}^t - 1}\left(-\frac{t^2}{4} - \frac{\pi^2}{12}\right) = -\frac{\pi^4}{60} - \frac{\pi^4}{72} = -\frac{11\pi^4}{360},$$

using

$$\int_0^\infty \frac{t^3\,\mathrm{d}t}{\mathrm{e}^t - 1} = \frac{\pi^4}{15}.$$

The next coefficient is

$$A_2 = \int_0^\infty \mathrm{d}t\,\left(\frac{1}{2}\sigma_2(t) - \frac{t^2}{4}\sigma_1(t) + \frac{t^4}{24}\sigma_0(t)\right).$$

Using

$$\int_0^\infty \frac{t^2\,\mathrm{d}t}{\mathrm{e}^t - 1} = 2\zeta(3), \qquad \int_0^\infty \frac{t^5\,\mathrm{d}t}{\mathrm{e}^t - 1} = \frac{8\pi^6}{63},$$

one finds

$$A_2 = \frac{73\pi^6}{2520} + \zeta(3)^2.$$

Substitution into (98.74) gives

$$f(g) = 8g^2 - 64g^4A_0 - 64g^6A_1 - 64g^8A_2 + O(g^{10}),$$

which is (98.76). $\square$

Quoted Theorem 98.19 (Strong solution of the BES equation)**.** *Let* $\Gamma_{\mathrm{BES}}(g)$ *denote the conventional BES cusp function whose weak expansion begins* $\Gamma_{\mathrm{BES}}(g) = 4g^2 + O(g^4)$. *Define the Dirichlet beta values*

$$\beta_{\mathrm{D}}(s) = \sum_{n=0}^{\infty} \frac{(-1)^n}{(2n+1)^s}, \qquad \mathrm{K} = \beta_{\mathrm{D}}(2),$$

where K *is Catalan's constant, and set*

$$c_1 = \frac{3\log 2}{4\pi}, \qquad c_2 = \frac{\mathrm{K}}{16\pi^2}, \qquad c_3 = \frac{27\zeta(3)}{2^{11}\pi^3}, \qquad c_4 = \frac{21\,\beta_{\mathrm{D}}(4)}{2^{10}\pi^4}.$$

The strong-coupling solution of the BES Riemann–Hilbert problem gives, as a Poincare asymptotic expansion on the positive real g*-axis,*

$$\Gamma_{\mathrm{BES}}(g) = 2g_{\mathrm{s}} \left[1 - \frac{c_2}{g_{\mathrm{s}}^2} - \frac{c_3}{g_{\mathrm{s}}^3} - \frac{c_4 + 2c_2^2}{g_{\mathrm{s}}^4} + O(g_{\mathrm{s}}^{-5})\right], \qquad g_{\mathrm{s}} = g - c_1. \tag{98.77}$$

The quoted theorem is a theorem about the analytic solution of the BES integral equation. Its use in the spectral problem is conditional on the large-spin BES bridge of Assumption 98.15.

Remark 98.20 (Strong BES expansion in the monograph normalization). With $f(g)$ defined by

$$\Delta - S - L = f(g)\log S + O(S^0)$$

in (98.74), the strong-coupling expansion corresponding to Quoted Theorem 98.19 is

$$f(g) = 4g_{\mathrm{s}} - \frac{4c_2}{g_{\mathrm{s}}} - \frac{4c_3}{g_{\mathrm{s}}^2} - \frac{4(c_4 + 2c_2^2)}{g_{\mathrm{s}}^3} + O(g_{\mathrm{s}}^{-4}), \qquad g_{\mathrm{s}} = g - \frac{3\log 2}{4\pi}. \tag{98.78}$$

In particular, expanded in the unshifted coupling,

$$f(g) = 4g - \frac{3\log 2}{\pi} - \frac{\mathrm{K}}{4\pi^2 g} + O(g^{-2}). \tag{98.79}$$

The weak expansion in Proposition 98.18 begins

$$f(g) = 8g^2 + O(g^4),$$

whereas $\Gamma_{\mathrm{BES}}(g) = 4g^2 + O(g^4)$. Therefore the present normalization is

$$f(g) = 2\Gamma_{\mathrm{BES}}(g).$$

Multiplying (98.77) by 2 gives (98.78). The first two unshifted terms are obtained from $4g_{\mathrm{s}} = 4g - 4c_1$, and

$$4c_1 = \frac{3\log 2}{\pi}, \qquad 4c_2 = \frac{\mathrm{K}}{4\pi^2}.$$

All further displayed terms are $O(g^{-2})$ or smaller in the unshifted coupling, giving (98.79).

This is the convention in which the large-spin anomalous dimension has coefficient $f(g)$. Some Wilson-line literature denotes by Γ_{cusp} half of this quantity; Chapter 100 states its Wilson-line convention at the point where cusped Wilson loops are introduced. The equality between the large-spin scaling function and the Wilson-line cusp observable is a structural matching within planar $\mathcal{N} = 4$ theory; a nonperturbative construction-level proof remains outside the present monograph.

The QCD counterpart of the same large-spin/Wilson-line mechanism was defined from a regulated cusped Wilson-line operator in Section 49.24: there the lightlike coefficient Γ^q_{cusp} is a perturbative anomalous dimension entering DIS endpoint evolution as $P_{\mathrm{ns},N} = -\Gamma^q_{\mathrm{cusp}} \log N + O(N^0)$. The comparison fixes the shared operator meaning of the word "cusp" while keeping the theories' logical status distinct: QCD uses factorization and perturbative renormalization of Wilson-line composites, whereas the present planar $\mathcal{N} = 4$ construction uses the integrable all-loop spectral problem.

Chapter 99

Mirror TBA and the Y-System

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The asymptotic Bethe ansatz determines long-chain states before wrapping effects. Finite single traces require a finite-size formalism. The planar $\mathcal{N} = 4$ construction uses a mirror model obtained by exchanging worldsheet space and Euclidean time in the integrable spin-chain scattering problem. This chapter states the logical structure without pretending that the mirror thermodynamic Bethe ansatz is a theorem of four-dimensional constructive QFT.

Warning 99.1 (Status of mirror magnons). A mirror magnon is not a new physical particle of four-dimensional $\mathcal{N} = 4$ SYM. It is the excitation obtained after analytically continuing the two-dimensional worldsheet/spin-chain kinematics so that Euclidean time and space are exchanged. In the relativistic string worldsheet before light-cone gauge fixing this exchange is the natural mirror-channel operation. After gauge fixing, the magnon dispersion is nonrelativistic and the same operation becomes a path on the Zhukovsky surface together with a specified dressing-phase branch. This is why the mirror relation is not explained by the nonrelativistic spin chain alone.

The reason to use mirror magnons in the gauge-theory spectral problem is therefore indirect. Once the long-trace magnon S-matrix is accepted as the asymptotic integrable description, finite trace length is computed by the standard mirror-channel finite-size construction: virtual mirror particles wrap around the trace, and their thermodynamics gives the TBA. This is the worldsheet and integrability explanation. There is no known purely four-dimensional derivation in which the mirror magnon appears directly as an ordinary local QFT asymptotic state.

99.1 Mirror Transformation

For a physical magnon with energy $E(p)$ and momentum p, the mirror variables are defined by the stringbook analytic continuation

$$E = \mathrm{i}\widetilde{p}, \qquad p = \mathrm{i}\widetilde{E}, \qquad \text{equivalently} \qquad \widetilde{E} = -\mathrm{i}p, \quad \widetilde{p} = -\mathrm{i}E.$$

Since

$$E(p) = \sqrt{1 + 16g^2 \sin^2 \frac{p}{2}},$$

the mirror dispersion is not the same function of $\widetilde{p}$ as the physical dispersion. This is the first major difference from relativistic two-dimensional QFT, where the mirror transformation is a rapidity shift.

Mirror dispersion from double Wick rotation. For a Q-magnon bound state with physical dispersion

$$E_Q(p) = \sqrt{Q^2 + 16g^2 \sin^2 \frac{p}{2}},$$

the mirror dispersion obtained from $p = \mathrm{i}\widetilde{E}$, $E_Q = \mathrm{i}\widetilde{p}$ is

$$\widetilde{E}_Q(\widetilde{p}) = 2 \,\operatorname{arsinh}\left(\frac{\sqrt{Q^2 + \widetilde{p}^2}}{4g} \right). \tag{99.1}$$

The positive branch is chosen for real mirror momentum. Set $p = \mathrm{i}\widetilde{E}$ and $E_Q = \mathrm{i}\widetilde{p}$ in the physical dispersion relation. Since $\sin(\mathrm{i}\widetilde{E}/2) = \mathrm{i}\sinh(\widetilde{E}/2)$, one obtains

$$-\widetilde{p}^2 = Q^2 - 16g^2 \sinh^2 \frac{\widetilde{E}}{2}.$$

Thus

$$\sinh^2 \frac{\widetilde{E}}{2} = \frac{Q^2 + \widetilde{p}^2}{16g^2}.$$

The mirror energy is positive on the real mirror line, which selects (99.1).

Equivalently one continues the Zhukovsky variables through a specified sequence of cuts. On the physical sheet a real magnon has $(x^+)^* = x^-$ and $|x^\pm| > 1$. A mirror particle of real mirror rapidity has one Zhukovsky variable inside and one outside the unit circle. The choice of path is part of the definition of the mirror S-matrix: crossing a different cut changes the scalar dressing factor by the crossing equation. For this reason the mirror TBA below always includes the contour and sheet data together with the functional formulae.

It is useful to keep the following sheet bookkeeping explicit. Let $x^{[\pm Q]}(u) = x(u \pm \mathrm{i}Q/2)$, with $x(u)$ the physical Zhukovsky branch of Chapter 98. Physical bound-state kinematics keeps both $x^{[+Q]}$ and $x^{[-Q]}$ on the outside sheet for real momentum. Mirror kinematics continues one of the two variables through the short cut, so the pair has opposite inside/outside status. The transfer matrix and the dressing factor must be continued along the same path. A formula copied from the physical sheet but evaluated with the wrong inside/outside assignment gives the wrong wrapping sign.

Bound states of Q physical magnons are described by pairs

$$x_Q^+, \qquad x_Q^-,$$

obeying the bound-state shortening relation

$$x_Q^+ + \frac{1}{x_Q^+} - x_Q^- - \frac{1}{x_Q^-} = \frac{\mathrm{i}Q}{g}.$$

In the mirror region the branch is chosen so that the mirror energy $\widetilde{E}_Q(u)$ is positive for real mirror rapidity u.

The preceding paragraph is often the place where sign mistakes enter. The following elementary parametrization fixes the sheet convention used in the rest of the chapter and in the stringbook mirror Bethe–Yang equations.

Mirror Zhukovsky sheet parametrization. Fix $g > 0$, $Q \in \mathbb{Z}_{>0}$, and real mirror momentum $\widetilde{p}$. Put

$$R_Q = \sqrt{Q^2 + \widetilde{p}^2}, \qquad \widetilde{E}_Q = 2 \operatorname{arsinh} \frac{R_Q}{4g}, \qquad r_Q = \mathrm{e}^{-\widetilde{E}_Q/2}, \qquad \xi_Q = \frac{\widetilde{p} - \mathrm{i}Q}{R_Q}.$$

Then

$$x_Q^+ = r_Q \xi_Q, \qquad x_Q^- = r_Q^{-1} \xi_Q \tag{99.2}$$

satisfy

$$x_Q^+ + \frac{1}{x_Q^+} - x_Q^- - \frac{1}{x_Q^-} = \frac{\mathrm{i}Q}{g}, \tag{99.3}$$

$$\log \frac{x_Q^-}{x_Q^+} = \widetilde{E}_Q, \tag{99.4}$$

$$\mathrm{i}\widetilde{p} = -Q - 2\mathrm{i}g(x_Q^+ - x_Q^-). \tag{99.5}$$

Moreover $|x_Q^+| < 1 < |x_Q^-|$. At weak coupling with $Q, \widetilde{p}$ fixed,

$$\mathrm{e}^{-L\widetilde{E}_Q} = \left(\frac{4g^2}{Q^2 + \widetilde{p}^2} \right)^L \bigl(1 + O(g^2)\bigr), \tag{99.6}$$

so one mirror wrapping around a length-L trace first appears at order g^{2L} before transfer-matrix and dressing factors are included.

The number ξ_Q has unit modulus and $0 < r_Q < 1$. Hence $|x_Q^+| < 1 < |x_Q^-|$, and $\log(x_Q^-/x_Q^+) = -2\log r_Q = \widetilde{E}_Q$ on the real mirror branch. Since

$$\sinh \frac{\widetilde{E}_Q}{2} = \frac{R_Q}{4g}, \qquad \xi_Q^{-1} - \xi_Q = \frac{2\mathrm{i}Q}{R_Q},$$

we get

$$x_Q^+ + \frac{1}{x_Q^+} - x_Q^- - \frac{1}{x_Q^-} = 2 \sinh \frac{\widetilde{E}_Q}{2} \, (\xi_Q^{-1} - \xi_Q) = \frac{\mathrm{i}Q}{g}.$$

Similarly,

$$-Q - 2\mathrm{i}g(x_Q^+ - x_Q^-) = -Q + 4\mathrm{i}g \sinh \frac{\widetilde{E}_Q}{2}\, \xi_Q = -Q + \mathrm{i}R_Q\xi_Q = \mathrm{i}\widetilde{p}.$$

Finally, $\mathrm{e}^{-\widetilde{E}_Q} = (\sqrt{1 + R_Q^2/(16g^2)} - R_Q/(4g))^2$, whose small-$g$ expansion gives (99.6).

The same mirror sheet parametrization fixes the large-rapidity fermionic-node ratio used later to identify the $Y_{1,1}Y_{2,2}$ energy exponent in the QSC bridge; the corresponding local expansion is written in the QSC chapter. This is a good example of the convention burden in this subject: the sign comes from the inside/outside assignment just checked here, but the ratio itself belongs to the later TBA-to-QSC asymptotic bridge rather than to the definition of the mirror kernel.

Definition 99.2 (Mirror-kernel datum)**.** A mirror kernel in this chapter means the triple

$$(S_{BA}^{\mathrm{mirror}}(v,u), \mathcal{C}_B, \mathcal{C}_A),$$

where S_{BA}^{mirror} is the analytically continued two-body scattering factor and $\mathcal{C}_B, \mathcal{C}_A$ are the source and target rapidity contours on the chosen sheets. The derivative kernel is then

$$K_{BA}(v,u) = \frac{1}{2\pi\mathrm{i}}\partial_v \log S_{BA}^{\mathrm{mirror}}(v,u).$$

This convention packages the branch choice with the formula and prevents the common mistake of treating mirror TBA kernels as functions on a single unbranched u-plane.

99.2 Mirror Bethe-String Species

The mirror TBA is nested because a physical magnon carries two $\mathfrak{su}(2|2)$ wings of polarization data. The canonical node families are as follows.

symbol	range	role
$\bullet_Q$	$Q = 1, 2, \ldots$	mirror bound states carrying energy
$y_\pm$	two sheets	fermionic auxiliary roots
$(v\vert M)$	$M = 1, 2, \ldots$	auxiliary strings in each wing
$(w\vert M)$	$M = 1, 2, \ldots$	isotopic auxiliary strings in each wing

Each wing has its own copy of the v- and w-string nodes. The $\bullet_Q$ nodes are the only nodes that enter the energy formula with the measure $\mathrm{d}\widetilde{p}_Q/\mathrm{d}u$. The auxiliary nodes enter through kernels and chemical potentials and enforce the nested Bethe constraints.

The string hypothesis used here is a thermodynamic statement on the mirror Bethe roots: in a large mirror volume, complex roots organize into regular arrays whose centers become real variables u. In a relativistic model this statement is already subtle; in planar $\mathcal{N} = 4$ it is further entangled with the Zhukovsky cuts. Consequently, the node table is part of the integrability construction, not a theorem about the original four-dimensional path integral.

The node table above abbreviates arrays selected by the Bethe-Yang equations. We now derive the auxiliary arrays from the large-volume pole-cancellation mechanism in one $\mathfrak{su}(2|2)_{\mathrm{c}}$ wing. Put

$$\eta = \frac{\mathrm{i}}{2g}, \qquad v(y) = y + \frac{1}{y}.$$

Let $x_j^\pm$, $j = 1, \dots, K^{\mathrm{I}}$, be mirror level-I rapidity data on the real mirror line, so that

$$x_j^+ = r_j \xi_j, \qquad x_j^- = r_j^{-1} \xi_j, \qquad 0 < r_j < 1, \quad |\xi_j| = 1.$$

The one-wing auxiliary Bethe-Yang subsystem in the stringbook mirror orientation has the form

$$\begin{aligned} -1 &= F(y_a) \prod_{b=1}^{K^{\mathrm{III}}} \frac{w_b - v(y_a) - \eta}{w_b - v(y_a) + \eta}, \qquad F(y) = \prod_{j=1}^{K^{\mathrm{I}}} \frac{y - x_j^+}{y - x_j^-} \sqrt{\frac{x_j^-}{x_j^+}}, \\ 1 &= \prod_{a=1}^{K^{\mathrm{II}}} \frac{w_b - v(y_a) + \eta}{w_b - v(y_a) - \eta} \prod_{\substack{c=1 \\ c \neq b}}^{K^{\mathrm{III}}} \frac{w_c - w_b + 2\eta}{w_c - w_b - 2\eta}. \end{aligned} \tag{99.7}$$

The sign in the first equation is the mirror fermion boundary-condition sign. It is not the graded sign in the physical nested ABA of Chapter 98.

Proposition 99.3 (Mirror auxiliary support and Bethe strings)**.** *Assume the mirror Bethe-Yang equations* (99.7)*, the mirror sheet data above, and a thermodynamic limit in which the logarithmic averages of* $\log|F(y)|$ *have the signs determined by the one-particle factor below. Then elementary* y*-roots have finite density only on* $|y| = 1$*, elementary* w*-roots have finite density only on the real* w*-axis, and the non-elementary auxiliary complexes have the following pole-cancellation arrays:*

$$\begin{aligned} v(y_{j,\mathrm{in}}) &= v_0 + (M + 2 - 2j)\eta, \quad |y_{j,\mathrm{in}}| < 1, \\ v(y_{j,\mathrm{out}}) &= v_0 - (M + 2 - 2j)\eta, \quad |y_{j,\mathrm{out}}| > 1, \\ w_j &= v_0 + (M + 1 - 2j)\eta, \qquad j = 1, \dots, M, \end{aligned}$$

with real thermodynamic center v_0*. These are the* $(v|M)$*, or* $M|yw$*, strings. The pure* $(w|M)$ *strings are*

$$w_j = w_0 + (M + 1 - 2j)\eta, \qquad j = 1, \dots, M,$$

with real center w_0*. The assertion is a statement about the mirror string hypothesis and the displayed large-volume equations; it is not a theorem of four-dimensional* $\mathcal{N} = 4$ *SYM.*

Proof. First isolate the source of exponential growth and decay. For a single mirror level-I root write $x^+ = r\xi$, $x^- = r^{-1}\xi$, with $0 < r < 1$ and $|\xi| = 1$. The magnitude of the one-particle factor

$$s(y; x^\pm) = \frac{y - x^+}{y - x^-} \sqrt{\frac{x^-}{x^+}}$$

obeys

$$|s(y; x^\pm)|^2 = \frac{|y - r\xi|^2}{|ry - \xi|^2}, \qquad |ry - \xi|^2 - |y - r\xi|^2 = (1 - r^2)(1 - |y|^2).$$

Thus $|s| < 1$ for $|y| < 1$, $|s| = 1$ for $|y| = 1$, and $|s| > 1$ for $|y| > 1$. Multiplying over K^{I} level-I roots gives the stated support of elementary y-roots in the thermodynamic limit, provided the level-I density has a nonzero logarithmic average.

Now take a y-root with $|y_1| < 1$. The factor $F(y_1)$ then tends to zero exponentially, so the first equation in (99.7) can remain finite only if one of the w-factors has a pole:

$$w_1 - v(y_1) + \eta = 0, \qquad \text{that is} \qquad w_1 = v(y_1) - \eta.$$

The corresponding w_1-equation has a zero from the same y_1. The local cancellation recursion remains finite by acquiring a pole from a second y-root,

$$w_1 - v(y_2) - \eta = 0, \qquad v(y_2) = v(y_1) - 2\eta.$$

If this second root lies outside the unit circle, the divergence of $F(y_2)$ is canceled by the zero of the same w_1-factor and the string closes. If it lies inside, $F(y_2)$ again decays exponentially and the second auxiliary equation must acquire another compensating pole, now from a neighboring w-root. Alternating these zero-pole cancellations creates the sequence

$$v(y_{j+1}) = v(y_j) - 2\eta, \qquad w_j = v(y_j) - \eta,$$

until the terminal y-root lies on the opposite support side. This iteration fixes the displayed imaginary spacings. The real center is the thermodynamic string-hypothesis input: the mirror densities are assigned to real centers, while the roots in the complex plane are the regular arrays above those centers.

For the w-only strings, set the background y-roots on $|y| = 1$, so their elementary factors have unit magnitude and do not supply exponential growth. A complex w-root in the second line of (99.7) then produces an uncanceled large-volume factor unless a neighboring w-root sits at distance $2\eta = \mathrm{i}/g$. Repeating the cancellation in both directions gives the finite array $w_j = w_0 + (M + 1 - 2j)\eta$ with real center w_0. □

99.3 Thermodynamic Bethe Ansatz

The mirror TBA is a thermodynamic limit of Bethe-Yang quantization, not an independent postulate. We first derive the one-species formula because it is the place where the signs, statistics, and kernel orientation are least forgiving. The derivation is also the convention bridge to the stringbook: the continuum density equation naturally differentiates the scattering phase in the target rapidity, while the multi-species formula below is written with the source-derivative kernels of Definition 99.2.

Proposition 99.4 (One-species mirror TBA from Bethe-Yang quantization)**.** *Consider a diagonal integrable mirror model with one particle species, real mirror rapidity u, mirror momentum $\widetilde{p}(u)$, mirror energy $\widetilde{\epsilon}(u)$, and two-body scattering factor $S(v, u)$. Assume:*

1. *a logarithm of $S(v, u)$ has been chosen with no self-scattering jump at $v = u$;*
2. *the thermodynamic mode number $n(u)$ is smooth and monotone on the rapidity interval under consideration;*
3. *the finite-volume Bethe levels have Fermi level statistics, so a level is either occupied or empty;*
4. *no additional Bethe-string species or bound-state poles cross the integration contour in the ground-state calculation.*

Let ρ_{p}, ρ_{L}, and $\rho_{\mathrm{h}} = \rho_{\mathrm{L}} - \rho_{\mathrm{p}}$ denote the particle, level, and hole densities with respect to u. Define the density kernel

$$K^{\mathrm{dens}}(v, u) = \frac{1}{2\pi\mathrm{i}} \partial_u \log S(v, u). \tag{99.8}$$

Then the thermodynamic limit of the Bethe-Yang equation gives

$$\rho_{\mathrm{L}}(u) = \frac{\widetilde{L}}{2\pi}\frac{\mathrm{d}\widetilde{p}(u)}{\mathrm{d}u} - \int \mathrm{d}v\, \rho_{\mathrm{p}}(v) K^{\mathrm{dens}}(v,u). \tag{99.9}$$

At inverse mirror temperature $\widetilde{\beta}$ and mirror chemical potential $\widetilde{\mu}$, extremizing

$$\mathfrak{s} - \widetilde{\beta}\int \mathrm{d}u\, \rho_{\mathrm{p}}(u)\widetilde{\epsilon}(u) - \widetilde{\mu}\int \mathrm{d}u\, \rho_{\mathrm{p}}(u)$$

subject to (99.9), where

$$\mathfrak{s} = \int \mathrm{d}u\, \left[\rho_{\mathrm{L}}\log\rho_{\mathrm{L}} - \rho_{\mathrm{p}}\log\rho_{\mathrm{p}} - \rho_{\mathrm{h}}\log\rho_{\mathrm{h}}\right],$$

gives the pseudoenergy equation

$$\zeta(u) = \widetilde{\beta}\,\widetilde{\epsilon}(u) + \widetilde{\mu} + \int \mathrm{d}v\, K^{\mathrm{dens}}(u,v)\log(1+\mathrm{e}^{-\zeta(v)}), \qquad \frac{\rho_{\mathrm{p}}(u)}{\rho_{\mathrm{L}}(u)} = \frac{1}{1+\mathrm{e}^{\zeta(u)}}. \tag{99.10}$$

At the stationary point,

$$\log Z = \widetilde{L}\int \frac{\mathrm{d}u}{2\pi}\frac{\mathrm{d}\widetilde{p}(u)}{\mathrm{d}u}\log(1+\mathrm{e}^{-\zeta(u)}). \tag{99.11}$$

After exchanging mirror space and Euclidean time, with $\widetilde{\beta} = L$ and no chemical potential, this gives

$$E_0(L) = -\int \frac{\mathrm{d}u}{2\pi}\frac{\mathrm{d}\widetilde{p}(u)}{\mathrm{d}u}\log(1+\mathrm{e}^{-\zeta(u)}). \tag{99.12}$$

Proof. For occupied rapidities u_k, choose the logarithmic Bethe-Yang equation in the stringbook orientation

$$\widetilde{p}(u_k)\widetilde{L} = 2\pi n_k - \mathrm{i}\sum_{j\neq k}\log S(u_j,u_k).$$

Replacing the sum by $\int \mathrm{d}v\, \rho_{\mathrm{p}}(v)$ and differentiating with respect to the target rapidity u gives

$$\widetilde{L}\,\widetilde{p}'(u) = 2\pi\rho_{\mathrm{L}}(u) + 2\pi\int \mathrm{d}v\, \rho_{\mathrm{p}}(v)K^{\mathrm{dens}}(v,u),$$

which is (99.9).

Now vary the entropy while preserving the density equation. Since $\rho_{\mathrm{h}} = \rho_{\mathrm{L}} - \rho_{\mathrm{p}}$,

$$\delta\mathfrak{s} = \int \mathrm{d}u\, \left[\log\frac{\rho_{\mathrm{L}}}{\rho_{\mathrm{h}}}\delta\rho_{\mathrm{L}} - \log\frac{\rho_{\mathrm{p}}}{\rho_{\mathrm{h}}}\delta\rho_{\mathrm{p}}\right].$$

The constraint implies

$$\delta\rho_{\mathrm{L}}(u) = -\int \mathrm{d}v\, K^{\mathrm{dens}}(v,u)\delta\rho_{\mathrm{p}}(v).$$

Collecting the coefficient of an arbitrary $\delta\rho_{\mathrm{p}}(u)$ gives

$$\log\frac{\rho_{\mathrm{h}}(u)}{\rho_{\mathrm{p}}(u)} = \widetilde{\beta}\,\widetilde{\epsilon}(u) + \widetilde{\mu} + \int \mathrm{d}v\, K^{\mathrm{dens}}(u,v)\log\frac{\rho_{\mathrm{L}}(v)}{\rho_{\mathrm{h}}(v)}.$$

With $\zeta = \log(\rho_{\rm h}/\rho_{\rm p})$, one has $\rho_{\rm p}/\rho_{\rm L} = 1/(1+\mathrm{e}^{\zeta})$ and $\rho_{\rm L}/\rho_{\rm h} = 1+\mathrm{e}^{-\zeta}$, proving (99.10).

It remains to evaluate the extremized functional. Substitute the stationary equation into the expression for $\mathfrak{s} - \widetilde{\beta}\widetilde{E} - \widetilde{\mu}\widetilde{N}$. The terms proportional to $\rho_{\rm p}$ cancel against the convolution term in the entropy variation, and the remaining density equation leaves

$$\log Z = \int \mathrm{d}u\, \rho_{\rm L}(u) \log(1+\mathrm{e}^{-\zeta(u)}) + \int \mathrm{d}u\mathrm{d}v\, \rho_{\rm p}(v) K^{\rm dens}(v,u) \log(1+\mathrm{e}^{-\zeta(u)}),$$

which reduces by (99.9) to (99.11). The ground-state formula (99.12) is the usual mirror space-time reinterpretation of $\log Z = -\widetilde{L}E_0(L)$. □

The kernel sign in (99.10) is the stringbook convention. If the scattering factor obeys the diagonal unitarity relation $S(v,u)S(u,v) = 1$, then

$$K^{\rm dens}(u,v) = \frac{1}{2\pi\mathrm{i}}\partial_v \log S(u,v) = -\frac{1}{2\pi\mathrm{i}}\partial_v \log S(v,u).$$

Thus the source-derivative kernel $K(v,u)$ of Definition 99.2 enters the same TBA equation with a minus sign. This is the convention used in (99.16); the displayed chemical potential μ_A there is the negative of $\widetilde{\mu}_A$ in the one-species statistical-mechanical derivation.

Excited states add one more honest hypothesis: the contour deformation must be specified. In the one-species model, inserting moving defects at rapidities u_j changes the pseudoenergy to

$$\zeta(u) = \widetilde{\beta}\,\widetilde{\epsilon}(u) + \widetilde{\mu} - \sum_j \log S(u,u_j) + \int \mathrm{d}v\, K^{\rm dens}(u,v) \log(1+\mathrm{e}^{-\zeta(v)}),$$

and the defect rapidities are fixed by

$$\zeta(u_j) = -2\pi\mathrm{i}\left(n_j + \frac{1}{2}\right), \qquad n_j \in \mathbb{Z}.$$

Equivalently $1+\mathrm{e}^{-\zeta}$ has a zero at each defect. In the planar $\mathcal{N}=4$ problem this condition becomes the exact Bethe-root regularity condition after analytic continuation to the physical sheet.

Lemma 99.5 (Excited-state contour deformation in one species)**.** *Let $S(u,v)$ be a meromorphic two-particle mirror scattering factor with no zero or pole on the undeformed real v-contour, and let*

$$K^{\rm dens}(u,v) = \frac{1}{2\pi\mathrm{i}}\partial_v \log S(u,v).$$

Let $Y(v) = \mathrm{e}^{-\zeta(v)}$, and suppose that

$$F(v) = 1 + Y(v)$$

has simple zeros $u_1, \ldots, u_K$ crossed by the excited-state contour deformation and no other singularities are crossed. Assume also that the boundary terms at infinity vanish in the integrations by parts below. With the contour orientation for which the crossed zeros are enclosed counterclockwise, the deformed TBA source is

$$\int_{\mathcal{C}_{\rm exc}} \mathrm{d}v\, K^{\rm dens}(u,v) \log F(v) = \int_{\mathbb{R}} \mathrm{d}v\, K^{\rm dens}(u,v) \log F(v) - \sum_{j=1}^{K} \log S(u,u_j). \qquad (99.13)$$

Moreover, the mirror energy integral obeys

$$-\int_{\mathcal{C}_{\mathrm{exc}}}\frac{\mathrm{d}v}{2\pi}\frac{\mathrm{d}\widetilde{p}(v)}{\mathrm{d}v}\log F(v)=\sum_{j=1}^{K}\mathrm{i}\,\widetilde{p}(u_j)-\int_{\mathbb{R}}\frac{\mathrm{d}v}{2\pi}\frac{\mathrm{d}\widetilde{p}(v)}{\mathrm{d}v}\log F(v). \tag{99.14}$$

The root condition is

$$F(u_j)=0\quad\Longleftrightarrow\quad\zeta(u_j)=-2\pi\mathrm{i}\left(n_j+\frac{1}{2}\right),\qquad n_j\in\mathbb{Z}. \tag{99.15}$$

Proof. For the source term, write the contour difference as the sum of small positively oriented loops around the crossed zeros and integrate by parts:

$$\oint\frac{\mathrm{d}v}{2\pi\mathrm{i}}\,\partial_v\log S(u,v)\log F(v)=-\oint\frac{\mathrm{d}v}{2\pi\mathrm{i}}\,\log S(u,v)\partial_v\log F(v).$$

Since each u_j is a simple zero of F, $\partial_v\log F(v)$ has residue 1 at $v=u_j$. The residue theorem therefore gives the contribution $-\sum_j\log S(u,u_j)$, proving (99.13). The energy term is the same calculation with $\log S(u,v)$ replaced by $\mathrm{i}\widetilde{p}(v)$:

$$-\oint\frac{\mathrm{d}v}{2\pi}\,\widetilde{p}'(v)\log F(v)=\oint\frac{\mathrm{d}v}{2\pi}\,\widetilde{p}(v)\partial_v\log F(v)=\sum_j\mathrm{i}\,\widetilde{p}(u_j).$$

Finally, $F(u_j)=0$ means $\mathrm{e}^{-\zeta(u_j)}=-1$. Choosing a logarithm branch gives $-\zeta(u_j)=\mathrm{i}\pi(2n_j+1)$, which is (99.15). □

This proposition fixes the signs in the one-species formula above. The minus sign in the driving term is not an optional convention: it is the integration-by-parts sign in the residue calculation. The plus sign in the discrete energy contribution is equally fixed. After the inverse mirror continuation of a crossed level-I root, the planar convention is $\mathrm{i}\widetilde{p}(u_j)=E(u_j)$. Thus the deformed mirror free-energy formula produces the physical-magnon energy term in (99.25), while the zero condition becomes the exact Bethe equation on the physical sheet.

Let A,B range over the mirror Bethe-string species: physical Q-particle bound states, auxiliary y-roots, and auxiliary w-string families for the two $\mathfrak{su}(2|2)$ wings. Denote the mirror pseudoenergy by $\epsilon_A(u)$ and set

$$Y_A(u)=\mathrm{e}^{-\epsilon_A(u)}.$$

The TBA equations have the form

$$\epsilon_A(u)=L\,\widetilde{E}_A(u)-\mu_A-\sum_B\int_{\mathcal{C}_B}\mathrm{d}v\,K_{BA}(v,u)\log(1+Y_B(v))\,, \tag{99.16}$$

with kernels

$$K_{BA}(v,u)=\frac{1}{2\pi\mathrm{i}}\frac{\partial}{\partial v}\log S_{BA}^{\mathrm{mirror}}(v,u).$$

The contours $\mathcal{C}_B$, signs for fermionic auxiliary roots, and chemical potentials μ_A are part of the mirror-model definition. They are not decorations: changing them changes the finite-size answer.

Mirror-TBA node and source inventory. Assume the mirror Bethe-string hypothesis of Proposition 99.3, diagonal scalar factors for the fused mirror strings satisfying

$$S^{\mathrm{sb}}_{AB}(u,v)S^{\mathrm{mirror}}_{BA}(v,u)=1$$

on the chosen contours, and no contour-crossing source in the ground-state calculation. Let

$$\mathcal{I}=\{\bullet_Q:Q\ge 1\}\cup\{y^{(\alpha)}_{\pm},(v|M)^{(\alpha)},(w|M)^{(\alpha)}:M\ge 1,\ \alpha=L,R\}.$$

The stringbook symbols are identified as

$$y^{(\alpha)}_{+}=\oplus^{(\alpha)},\qquad y^{(\alpha)}_{-}=\ominus^{(\alpha)},\qquad (v|M)^{(\alpha)}=M|yw^{(\alpha)},\qquad (w|M)^{(\alpha)}=M|w^{(\alpha)}.$$

Put $\nu_L=+1$, $\nu_R=-1$. The driving terms are

$$d_{\bullet_Q}=L\,\widetilde{E}_Q,\qquad d_{y^{(\alpha)}_{\pm}}=\nu_\alpha\pi\mathrm{i},\qquad d_{(v|M)^{(\alpha)}}=d_{(w|M)^{(\alpha)}}=0,$$

or equivalently $d_A=L\widetilde{E}_A-\mu_A$, with $\widetilde{E}_A=0$ for auxiliary nodes and $\mu_{y^{(\alpha)}_{\pm}}=-\nu_\alpha\pi\mathrm{i}$. If

$$K^{\mathrm{sb}}_{AB}(u,v)=\frac{1}{2\pi\mathrm{i}}\partial_v\log S^{\mathrm{sb}}_{AB}(u,v)$$

denotes the target-first stringbook kernel, then

$$K^{\mathrm{sb}}_{AB}(u,v)=-K_{BA}(v,u). \tag{99.17}$$

Consequently (99.16) is equivalent to the target-first system

$$\epsilon_A(u)=d_A(u)+\sum_{B\in\mathcal{I}}\int_{\mathcal{C}_B}\mathrm{d}v\,K^{\mathrm{sb}}_{AB}(u,v)\log(1+Y_B(v)). \tag{99.18}$$

Write $\mathcal{S}_A$ for the convolution part of (99.18). The nonzero source families are precisely

$$\begin{aligned}
\mathcal{S}_{\bullet_Q}&=\sum_{Q'\ge 1}K^{\bullet\bullet}_{QQ'}*\log(1+Y_{\bullet_{Q'}})+\sum_{\alpha=L,R}\sum_{M\ge 2}K^{\bullet v}_{QM}*\log(1+Y_{(v|M)^{(\alpha)}})\\
&\quad+\sum_{\alpha=L,R}\left[K^{\bullet y_+}_{Q}*\log(1+Y_{y^{(\alpha)}_{+}})+K^{\bullet y_-}_{Q}*\log(1+Y_{y^{(\alpha)}_{-}})\right],\\
\mathcal{S}_{y^{(\alpha)}_{\pm}}&=\sum_{Q\ge 1}K^{y_\pm\bullet}_{Q}*\log(1+Y_{\bullet_Q})+\sum_{M\ge 1}K_M*\log\frac{1+Y_{(v|M)^{(\alpha)}}}{1+Y_{(w|M)^{(\alpha)}}},\\
\mathcal{S}_{(v|M)^{(\alpha)}}&=\sum_{Q\ge 1}K^{v\bullet}_{MQ}*\log(1+Y_{\bullet_Q})+\sum_{N\ge 1}K_{MN}*\log(1+Y_{(v|N)^{(\alpha)}})\\
&\quad+K_M*\log\frac{1+Y_{y^{(\alpha)}_{+}}}{1+Y_{y^{(\alpha)}_{-}}},\\
\mathcal{S}_{(w|M)^{(\alpha)}}&=\sum_{N\ge 1}K_{MN}*\log(1+Y_{(w|N)^{(\alpha)}})+K_M*\log\frac{1+Y_{y^{(\alpha)}_{+}}}{1+Y_{y^{(\alpha)}_{-}}}.
\end{aligned}$$

The lower bound $M \geq 2$ in the $\bullet_Q$ equation is the stringbook indexing of the v-string source adjacent to the y-sheet boundary. The denominator entries are not optional signs: they encode the reversed ordering of the $\ominus$-sheet and w-string Bethe roots.

The one-species derivation above already gives the density-to-TBA transpose. For species A, the logarithmic Bethe-Yang equation is differentiated in the target rapidity. The entropy variation transposes the density kernel, so the target-first TBA contains $(2\pi\mathrm{i})^{-1}\partial_v \log S^{\mathrm{sb}}_{AB}(u,v)$. The diagonal unitarity relation displayed in the hypotheses gives

$$\frac{1}{2\pi\mathrm{i}}\partial_v \log S^{\mathrm{sb}}_{AB}(u,v) = -\frac{1}{2\pi\mathrm{i}}\partial_v \log S^{\mathrm{mirror}}_{BA}(v,u),$$

which is (99.17) and converts (99.18) to (99.16). Only the $\bullet_Q$ strings carry mirror energy, so the length term is $L\widetilde{E}_Q$ on those nodes and is zero on auxiliary nodes. The sign -1 in the level-II mirror Bethe-Yang equation gives the additive fermion chemical potential $\nu_\alpha\pi\mathrm{i}$ in each wing, equivalently $\mu_{y^{(\alpha)}_{\pm}} = -\nu_\alpha\pi\mathrm{i}$ in the source-kernel convention.

The remaining entries are the fused forms of (99.7). Fusing level-I roots gives the $\bullet$-kernels; fusing the auxiliary arrays gives the rational K_M and K_{MN} kernels used below. The roots on the $\ominus$-sheet and in the w-strings are ordered oppositely to the $\oplus$-sheet and v-string roots in the stringbook Bethe-Yang products. Their scattering factors therefore enter inverted, which is exactly the logarithmic ratio displayed in the y-, v-, and w-node equations.

Fused mirror kernels in the chosen orientation. Fix a mirror sheet and write

$$\mathcal{R}_m = \left\{-\frac{m-1}{2}, -\frac{m-1}{2}+1, \ldots, \frac{m-1}{2}\right\}.$$

For an integer a, $x^{[a]}(u)$ denotes the continuation of $x(u+\mathrm{i}a/2)$ on that sheet, with the side of the cut fixed by the contour datum. Away from zeros and poles, the fused rational $\bullet_m$-$\bullet_n$ phase is

$$\Phi^{\bullet\bullet}_{mn}(u,v) = \sum_{r\in\mathcal{R}_m}\sum_{s\in\mathcal{R}_n} \log\left[\frac{x^{[2s-1]}(v) - x^{[2r+1]}(u)}{x^{[2s+1]}(v) - x^{[2r-1]}(u)} \frac{1-\left(x^{[2s+1]}(v)x^{[2r-1]}(u)\right)^{-1}}{1-\left(x^{[2s-1]}(v)x^{[2r+1]}(u)\right)^{-1}}\right], \tag{99.19}$$

and the dressing contribution is the endpoint combination

$$\begin{aligned}\Theta^{\bullet\bullet}_{mn}(u,v) = 2\mathrm{i}\big(&\chi(x^{[m]}(u), x^{[n]}(v)) + \chi(x^{[-m]}(u), x^{[-n]}(v)) \\ &- \chi(x^{[-m]}(u), x^{[n]}(v)) - \chi(x^{[m]}(u), x^{[-n]}(v))\big).\end{aligned} \tag{99.20}$$

Thus

$$K^{\bullet\bullet}_{mn}(u,v) = \frac{1}{2\pi\mathrm{i}}\partial_v\left(\Phi^{\bullet\bullet}_{mn}(u,v) + \Theta^{\bullet\bullet}_{mn}(u,v)\right)$$

in the target-first convention. The y-sheet and v-string phases that occur in the source inventory are

$$\log S_n^{y+\bullet}(u,v) = \log\left[\frac{x(u)-x^{[n]}(v)}{x(u)-x^{[-n]}(v)}\sqrt{\frac{x^{[-n]}(v)}{x^{[n]}(v)}}\right], \tag{99.21}$$

$$\log S_n^{y-\bullet}(u,v) = \log\left[\frac{x(u)^{-1}-x^{[n]}(v)}{x(u)^{-1}-x^{[-n]}(v)}\sqrt{\frac{x^{[-n]}(v)}{x^{[n]}(v)}}\right], \tag{99.22}$$

$$\log S_{mn}^{(v|m)\bullet}(u,v) = \sum_{\sigma=\pm1}\sum_{r\in\mathcal{R}_m}\sum_{s\in\mathcal{R}_n}\log\left[\frac{x^{[2r+\sigma]}(u)-x^{[2s+1]}(v)}{x^{[2r+\sigma]}(u)-x^{[2s-1]}(v)}\sqrt{\frac{x^{[2s-1]}(v)}{x^{[2s+1]}(v)}}\right]. \tag{99.23}$$

Their opposite orientations are reciprocals:

$$\log S_n^{\bullet y_\pm}(v,u) = -\log S_n^{y\pm\bullet}(u,v), \qquad \log S_{nm}^{\bullet(v|m)}(v,u) = -\log S_{mn}^{(v|m)\bullet}(u,v).$$

Finally, the auxiliary rational string phase

$$\Phi_{mn}^{\mathrm{aux}}(u,v) = \sum_{r\in\mathcal{R}_m}\sum_{s\in\mathcal{R}_n}\log\frac{u-v+\mathrm{i}(r-s+1)}{u-v+\mathrm{i}(r-s-1)}$$

has kernel

$$\frac{1}{2\pi\mathrm{i}}\partial_v\Phi_{mn}^{\mathrm{aux}} = K_{m+n}+K_{|m-n|}+2\sum_{j=1}^{\min(m,n)-1}K_{|m-n|+2j}, \tag{99.24}$$

with $K_0=0$ and

$$K_N(u-v) = \frac{1}{2\pi\mathrm{i}}\partial_v\log\frac{u-v+\mathrm{i}N/2}{u-v-\mathrm{i}N/2}.$$

These formulae are obtained by fusing the elementary factors. The rational factors are finite products over the constituents of the two Bethe strings. The sets $\mathcal{R}_m$ and $\mathcal{R}_n$ are exactly the constituent shifts, so multiplying the elementary level-I rational factor over r and s gives (99.19). Reversing the order of the two strings in each elementary factor inverts the product, which is the reciprocal orientation stated for $y_\pm$ and $(v|m)$ sources. The distinction between y_+ and y_- is the replacement $x(u)\mapsto x(u)^{-1}$ on the two y-sheets.

For the purely auxiliary kernel put $z=u-v$. The derivative of $\log(z+\mathrm{i}a)$ with respect to v is $-(z+\mathrm{i}a)^{-1}$. Hence the double sum contributes the difference between the multiplicities of $r-s-1$ and $r-s+1$. As r and s run over two consecutive arithmetic strings, all interior multiplicities cancel in pairs except the two boundary terms and the doubled interior terms with the same parity as $|m-n|$. This gives precisely the right-hand side of (99.24); it is the fused A_∞ kernel used in the Y-system inversion below.

The dressing term is different in status. If $\chi(x,y)=-\chi(y,x)$ on the continued branches, the endpoint combination (99.20) is antisymmetric under $(m,u)\leftrightarrow(n,v)$, so it is compatible with scalar unitarity. The existence of the globally continued χ, its branch choice, and possible additional crossed singularities are part of the dressing-phase analytic-continuation input inherited from Chapter 98. The finite fusion algebra proved here supplies the rational products and the endpoint sign package.

For a state with physical Bethe roots $u_1, \ldots, u_K$, the excited-state TBA is obtained by contour deformation. The physical roots satisfy exact Bethe equations of the form

$$1 + Y_{\bullet_1}^{\text{phys}}(u_j) = 0, \qquad j = 1, \ldots, K,$$

and the energy is

$$\Delta - J = \sum_{j=1}^{K} E(u_j) - \sum_{Q=1}^{\infty} \int_{\mathbb{R}} \frac{\mathrm{d}u}{2\pi} \frac{\mathrm{d}\widetilde{p}_Q}{\mathrm{d}u} \log(1 + Y_{\bullet_Q}(u)). \tag{99.25}$$

The first term is the asymptotic magnon energy. The integral term is the finite-size wrapping correction from the thermal mirror bath.

99.4 Y-System

The passage from TBA integral equations to local Y-system relations is not a formal cancellation of symbols. It uses a special inverse for the fused Bethe-string kernels and an analyticity strip in which s^{-1} may be represented by shifts. We spell out the auxiliary-wing case because it is the cleanest part of the planar $\mathcal{N} = 4$ construction and fixes the normalization used later by the T-hook notation.

Lemma 99.6 (Auxiliary-string kernel inverse)**.** *Let*

$$(K * f)(u) = \int_{\mathbb{R}} \mathrm{d}v \, K(u - v) f(v)$$

and, for $n \geq 1$*,*

$$K_n(u - v) = \frac{1}{2\pi \mathrm{i}} \partial_v \log \frac{u - v + \mathrm{i}n/2}{u - v - \mathrm{i}n/2} = \frac{n/2}{\pi((u - v)^2 + n^2/4)}. \tag{99.26}$$

Set $K_0 = 0$*, and define the fused* A_∞*-string kernel*

$$K_{mn} = K_{m+n} + K_{|m-n|} + 2 \sum_{j=1}^{\min(m,n)-1} K_{|m-n|+2j}, \qquad m, n \geq 1,$$

with $A_{mn} = \delta_{mn}\delta + K_{mn}$*. Finally put*

$$\mathsf{s}(u - v) = \frac{1}{2\cosh \pi(u - v)}.$$

On the Fourier side, with $\widehat{f}(\omega) = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}\omega u} f(u) \, \mathrm{d}u$ *and* $q = \mathrm{e}^{-|\omega|/2}$*,*

$$\widehat{K}_n = q^n, \qquad \widehat{\mathsf{s}} = \frac{q}{1 + q^2}, \qquad \widehat{A}_{mn} = \frac{1 + q^2}{1 - q^2} \left(q^{|m-n|} - q^{m+n} \right). \tag{99.27}$$

Consequently

$$(A^{-1})_{mn} = \delta_{mn}\delta - (\delta_{m+1,n} + \delta_{m-1,n})\mathsf{s}, \qquad \delta_{0n} = 0. \tag{99.28}$$

Equivalently,

$$\sum_{\ell \geq 1} (A^{-1})_{m\ell} * K_{\ell n} = (\delta_{m+1,n} + \delta_{m-1,n})\mathsf{s}, \tag{99.29}$$

$$\sum_{\ell \geq 1} (A^{-1})_{m\ell} * K_\ell = \delta_{m1}\mathsf{s}. \tag{99.30}$$

Proof. The transform of (99.26) is the elementary Poisson-kernel identity $\widehat{K}_n(\omega) = \mathrm{e}^{-n|\omega|/2}$. The displayed expression for $\widehat{A}_{mn}$ follows by summing the finite geometric progression in the fused kernel. In Fourier variables the asserted inverse is the tridiagonal matrix

$$\delta_{mn} - \frac{q}{1+q^2}(\delta_{m+1,n} + \delta_{m-1,n}).$$

Multiplying it by the last expression in (99.27) gives

$$\widehat{A}_{mn} - \widehat{\mathsf{s}}\,(\widehat{A}_{m+1,n} + \widehat{A}_{m-1,n}) = \delta_{mn}, \qquad \widehat{A}_{0n} = 0.$$

For $m \neq n$ the two geometric tails cancel. For $m = n$ the remaining jump is one. Equations (99.29) and (99.30) follow as follows. For (99.29), replace A_{mn} by $(A-I)_{mn}$ in the Fourier identity just proved and transform back from ω-space. For the one-index kernel, multiplication by the tridiagonal inverse gives

$$q^m - \frac{q}{1+q^2}\big(q^{m+1} + q^{m-1}\big) = 0 \quad (m > 1),$$

while for $m = 1$ the missing $m = 0$ term leaves $q/(1+q^2) = \widehat{\mathsf{s}}$. This is (99.30). $\square$

One auxiliary wing of the Y-system. Fix one $\mathfrak{su}(2|2)$ wing. Let Y_n° denote the $n|w$ string Y-functions, and let $Y^\oplus, Y^\ominus$ denote the two y-sheet Y-functions in the stringbook orientation. Suppose the $n|w$ part of the mirror TBA can be written as

$$\sum_{m\geq 1} A_{nm} * \log Y_m^\circ = \sum_{m\geq 1} K_{nm} * \log(1+Y_m^\circ) + K_n * \log\frac{1+1/Y^\oplus}{1+1/Y^\ominus}, \tag{99.31}$$

with $Y_0^\circ = 0$. Assume all functions appearing after convolution by s are analytic in the strip $|\operatorname{Im} u| < 1/2$, decay enough at infinity, and have no pole crossed by the shifts $u \mapsto u \pm \mathrm{i}/2$. Then

$$\frac{(Y_n^\circ)^+(Y_n^\circ)^-}{(1+Y_{n+1}^\circ)(1+Y_{n-1}^\circ)} = \left(\frac{1+1/Y^\oplus}{1+1/Y^\ominus}\right)^{\delta_{n1}}, \qquad n \geq 1. \tag{99.32}$$

Apply A^{-1} to (99.31). Using (99.29) and (99.30) gives

$$\log Y_n^\circ = \mathsf{s} * \log(1+Y_{n+1}^\circ) + \mathsf{s} * \log(1+Y_{n-1}^\circ) + \delta_{n1}\mathsf{s} * \log\frac{1+1/Y^\oplus}{1+1/Y^\ominus}.$$

For functions analytic in the stated strip, $\mathsf{s}^{-1} * f = f^+ + f^-$. Applying this inverse and exponentiating gives (99.32). If a pole or branch cut crosses during the shift, the right-hand side acquires extra source terms; this is precisely why the analytic data below are part of the finite-volume spectral problem.

Data lost by the s-kernel inverse. Write

$$(\nabla_{\mathsf{s}} F)(u) = F(u+\mathrm{i}/2) + F(u-\mathrm{i}/2).$$

Suppose $F = \mathsf{s} * f$, where f is integrable, F is holomorphic in a neighbourhood of the closed strip $|\operatorname{Im} u| \leq 1/2$, and the two contour shifts meet no singularity of F. In logarithmic TBA applications this means that no zero or pole of the underlying Y-function, and no logarithmic cut, is crossed. Then

$$\nabla_{\mathsf{s}} F = f. \tag{99.33}$$

The converse datum is not contained in the local equation. For $\alpha \in \mathbb{C}$,

$$Z_\alpha(u) = \frac{1}{2\cosh \pi(u-\alpha)} \tag{99.34}$$

satisfies

$$Z_\alpha(u+\mathrm{i}/2) + Z_\alpha(u-\mathrm{i}/2) = 0$$

as a meromorphic identity away from $u = \alpha$, while its closest poles are at $u = \alpha \pm \mathrm{i}/2$. Thus applying s^{-1} determines only the regular part of a logarithmic TBA equation modulo such boundary data. If the logarithm instead contains the shifted zero-pole factor

$$B_\alpha(u) = \frac{u-\alpha+\mathrm{i}/2}{u-\alpha-\mathrm{i}/2},$$

then

$$B_\alpha^+(u) B_\alpha^-(u) = \frac{u-\alpha+\mathrm{i}}{u-\alpha-\mathrm{i}}. \tag{99.35}$$

Consequently the local Y-system knows neither the positions α, nor the integer powers of such factors, nor the side of the cut from which they come. These are extra analytic data supplied by the mirror-TBA contour and by exact-root regularity.

With the Fourier convention of Lemma 99.6, $\widehat{\mathsf{s}}(\omega) = 1/(2\cosh(\omega/2))$. Shifting the contour for $F(u+\mathrm{i}/2)$ and $F(u-\mathrm{i}/2)$ back to the real line multiplies the Fourier transform by $\mathrm{e}^{\omega/2}$ and $\mathrm{e}^{-\omega/2}$, respectively. Under the stated no-crossing hypothesis the sum therefore has transform

$$2\cosh(\omega/2)\,\widehat{\mathsf{s}}(\omega)\widehat{f}(\omega) = \widehat{f}(\omega),$$

which proves (99.33). If a singularity lies on a shifted contour, the same contour move has a residue or jump contribution; that contribution is not present in the pointwise local equation unless it is recorded as a source.

For the zero mode, use

$$\cosh \pi(u-\alpha+\mathrm{i}/2) = \mathrm{i}\sinh \pi(u-\alpha), \qquad \cosh \pi(u-\alpha-\mathrm{i}/2) = -\mathrm{i}\sinh \pi(u-\alpha).$$

The two shifted terms cancel away from their boundary pole. The last identity is the direct multiplication of $B_\alpha(u+\mathrm{i}/2)$ and $B_\alpha(u-\mathrm{i}/2)$.

The TBA equations imply functional relations among Y-functions after applying kernel identities and shifting the spectral parameter. The bulk of the planar $\mathcal{N} = 4$ T-hook is the subset

$$\mathfrak{T}_{\text{bulk}} = \{(a,s) : a \in \mathbb{Z}_{\geq 1},\ s \in \mathbb{Z},\ |s| \leq 2\} \cup \{(a,s) : a = 1,2,\ s \in \mathbb{Z}\}.$$

The row $a = 0$ is adjoined as a gauge boundary $T_{0,s}$; outside $\mathfrak{T}_{\text{bulk}}$ and this boundary row one sets $T_{a,s} = 0$. A Y-node is called interior when $a \geq 1$ and all four neighbouring T-functions appearing below belong to $\mathfrak{T}_{\text{bulk}}$ or to the boundary row, and are non-zero on the patch under consideration. On such nodes the local relation has the form

$$Y_{a,s}^+(u) Y_{a,s}^-(u) = \frac{(1+Y_{a,s+1}(u))(1+Y_{a,s-1}(u))}{(1+Y_{a+1,s}(u)^{-1})(1+Y_{a-1,s}(u)^{-1})}, \tag{99.36}$$

where

$$f^{\pm}(u) = f(u \pm \mathrm{i}/2).$$

Boundary nodes require modified relations because one of the four neighboring T-functions has left the hook.

Proposition 99.7 (Hirota origin of the interior T-hook Y-system)**.** *Let $T_{a,s}$ be non-zero on an interior patch of the T-hook and obey Hirota,*

$$T_{a,s}^{+}T_{a,s}^{-} = T_{a+1,s}T_{a-1,s} + T_{a,s+1}T_{a,s-1}.$$

Define

$$Y_{a,s} = \frac{T_{a,s+1}T_{a,s-1}}{T_{a+1,s}T_{a-1,s}}.$$

Then $Y_{a,s}$ obeys (99.36) at every interior node. Moreover $Y_{a,s}$ is invariant under the local Hirota gauge transformation

$$T_{a,s} \mapsto g_1^{[a+s]}g_2^{[a-s]}g_3^{[-a-s]}g_4^{[-a+s]}T_{a,s}, \tag{99.37}$$

where $f^{[n]}(u) = f(u + \mathrm{i}n/2)$.

Proof. Hirota at (a, s) gives the two useful identities

$$1 + Y_{a,s} = \frac{T_{a,s}^{+}T_{a,s}^{-}}{T_{a+1,s}T_{a-1,s}}, \qquad 1 + \frac{1}{Y_{a,s}} = \frac{T_{a,s}^{+}T_{a,s}^{-}}{T_{a,s+1}T_{a,s-1}}.$$

Now compute

$$Y_{a,s}^{+}Y_{a,s}^{-} = \frac{T_{a,s+1}^{+}T_{a,s+1}^{-}T_{a,s-1}^{+}T_{a,s-1}^{-}}{T_{a+1,s}^{+}T_{a+1,s}^{-}T_{a-1,s}^{+}T_{a-1,s}^{-}}.$$

Applying the two displayed identities to the four neighboring nodes turns the numerator into

$$(1 + Y_{a,s+1})(1 + Y_{a,s-1})T_{a+1,s+1}T_{a-1,s+1}T_{a+1,s-1}T_{a-1,s-1},$$

and the denominator into

$$(1 + Y_{a+1,s}^{-1})(1 + Y_{a-1,s}^{-1})T_{a+1,s+1}T_{a+1,s-1}T_{a-1,s+1}T_{a-1,s-1}.$$

The common T-product cancels, proving (99.36).

For the gauge statement, let

$$\mathcal{G}(a, s) = \{(1, a + s), (2, a - s), (3, -a - s), (4, -a + s)\}$$

record which g_i appears with which shift. The numerator of $Y_{a,s}$ has gauge multiset

$$\mathcal{G}(a, s + 1) \sqcup \mathcal{G}(a, s - 1),$$

and the denominator has

$$\mathcal{G}(a + 1, s) \sqcup \mathcal{G}(a - 1, s).$$

These two multisets are identical. Hence all gauge factors cancel. The calculation is local; analytic gauge choices in the QSC additionally fix cuts, asymptotics, and gluing data. □

Warning 99.8 (Y-system data are not only equations)*.* The functional relations (99.36) do not by themselves determine a spectrum. A solution also requires analyticity domains, large-u asymptotics, branch-cut discontinuity relations, exact Bethe-root conditions, and state labels. Treating the Y-system equations alone as a definition of the theory discards the information that distinguishes physical states.

Local source factor from a shifted zero-pole pair. Let $\alpha \in \mathbb{C}$, and define the elementary shifted source factor

$$B_\alpha(u) = \frac{u-\alpha+\mathrm{i}/2}{u-\alpha-\mathrm{i}/2}.$$

Thus B_α has a simple zero at $u=\alpha-\mathrm{i}/2$ and a simple pole at $u=\alpha+\mathrm{i}/2$. If a meromorphic Y-function is written locally as

$$Y_{a,s}(u) = B_\alpha(u)^\nu\, \widehat{Y}_{a,s}(u), \qquad \nu \in \mathbb{Z},$$

where $\widehat{Y}_{a,s}$ has no zero or pole crossed by the two shifts $u \mapsto u \pm \mathrm{i}/2$, then

$$Y_{a,s}^+(u)Y_{a,s}^-(u) = \left(\frac{u-\alpha+\mathrm{i}}{u-\alpha-\mathrm{i}}\right)^\nu \widehat{Y}_{a,s}^+(u)\widehat{Y}_{a,s}^-(u). \tag{99.38}$$

For a finite set of shifted zero-pole pairs, the source factor is the product of the corresponding powers of $(u-\alpha+\mathrm{i})/(u-\alpha-\mathrm{i})$. This is the algebra of the shift operation. Directly,

$$B_\alpha^+(u) = \frac{u-\alpha+\mathrm{i}}{u-\alpha}, \qquad B_\alpha^-(u) = \frac{u-\alpha}{u-\alpha-\mathrm{i}}.$$

Multiplying the two expressions gives

$$B_\alpha^+(u)B_\alpha^-(u) = \frac{u-\alpha+\mathrm{i}}{u-\alpha-\mathrm{i}}.$$

Raising to the integer power ν and multiplying by $\widehat{Y}_{a,s}^+\widehat{Y}_{a,s}^-$ proves (99.38). A finite product follows by commutativity.

This local calculation is the algebraic shadow of contour deformation. The homogeneous Y-system records what happens after s^{-1} is applied in a strip free of singularities. If a zero, pole, or logarithmic branch point crosses one of the two strip boundaries, the remaining regular part $\widehat{Y}_{a,s}$ still obeys the same shift algebra, but the singular part contributes the rational source factor in (99.38). The Y-system equations alone do not determine the positions α, the powers ν, or the sheet on which the factor lives; these data come from the excited-state contours and from the exact Bethe-root regularity conditions.

99.5 Analytic Y-System Data

The analytic Y-system supplements (99.36) by specifying where each shifted function is meromorphic and which discontinuities occur when a shift crosses a cut. The analytic data determine which local solution of the symbolic Y-system is the finite-volume spectrum.

We use the shifted notation

$$f^{[n]}(u) = f(u + \mathrm{i}n/2)$$

and write

$$Z_0^\vee = [-2g, 2g]$$

for the central mirror-sheet Zhukovsky cut. Let $\mathcal{A}_\ell$ denote the class of functions meromorphic in the open strip

$$-\frac{\ell}{2} < \operatorname{Im} u < \frac{\ell}{2}, \tag{99.39}$$

after removing state-dependent poles and zeros that are explicitly recorded by source factors. The basic stringbook-to-T-hook identification is

$$\begin{aligned} Y_n^{\bullet} = Y_{n,0}, \qquad Y^{\oplus,L/R} = Y_{1,\pm 1}^{-1}, \qquad Y^{\ominus,L/R} = Y_{2,\pm 2}, \\ Y_n^{\triangle,L/R} = Y_{n+1,\pm 1}^{-1}, \qquad Y_n^{\circ,L/R} = Y_{1,\pm(n+1)}^{-1}. \end{aligned} \tag{99.40}$$

Assumption 99.9 (Analytic Y-system strip and cut data)**.** Fix the mirror-TBA sheet and the stringbook node convention (99.40). For every $n \geq 1$,

$$Y_{n,0}, \qquad Y_{n+1,\pm 1}, \qquad Y_{1,\pm(n+1)} \in \mathcal{A}_n. \tag{99.41}$$

Their first Zhukovsky branch points occur at

$$u = \pm 2g + \frac{\mathrm{i}\ell}{2}, \qquad \ell = \pm n,\ \pm(n+2),\ \pm(n+4), \ldots. \tag{99.42}$$

The central fermionic nodes $Y_{1,\pm 1}$ and $Y_{2,\pm 2}$ have cuts $Z_0^{\vee} + \mathrm{i}m$, $m \in \mathbb{Z}$, and their two sides on the central cut are related by

$$Y_{2,\pm 2}(u + \mathrm{i}0) = \frac{1}{Y_{1,\pm 1}(u - \mathrm{i}0)}, \qquad u \in Z_0^{\vee}. \tag{99.43}$$

Finally, every zero or pole introduced by an excited-state contour deformation is part of the data and must be recorded by a finite product of local factors of the form (99.38).

The strip statement is an analytic input extracted from the mirror TBA and its asymptotic Bethe-ansatz limit; it is not a theorem of the local Hirota algebra. The same limitation is visible in the Arutyunov–Frolov derivation of the mirror TBA: applying the inverse s-kernel loses data, and the local Y-equations are controlled on the central mirror interval unless additional analytic-continuation assumptions are supplied. We do not use that literature statement as a proof. The assumption above is the independent monograph datum that must be checked against the chosen mirror sheet, source factors, and dressing branch. The branch-point lattice explains why the homogeneous Y-system can be shifted inside the strip $\mathcal{A}_n$ but acquires sources when an endpoint, pole, zero, or dressing cut is crossed. The central inversion (99.43) is the piece that later turns into the magic-sheet gluing condition for the one-row T-gauge and, eventually, into the $P\mu$-system. Chapter 100 makes this status boundary explicit in Proposition 100.8: the local Y-system supplies gauge-invariant ratios, while the QSC spectral problem also needs the restored source data, the central fermionic large-u coefficient, the P-power charge gap, and the physical gluing assignment of the characteristic roots.

With these conventions the exact Bethe equations are regularity conditions:

$$1 + Y_{\bullet_1}^{\mathrm{phys}}(u_j) = 0$$

removes would-be singularities at the physical roots after contour deformation. This formulation is deliberately more verbose than the symbolic Y-system. The shifts $u \mapsto u \pm \mathrm{i}/2$ can move a point from the physical sheet to the mirror sheet, and the operations "shift" and "continue through a cut" do not commute without recording the path.

99.6 Konishi as the First Wrapping Test

The Konishi multiplet contains an $SL(2)$ descendant represented by a length-two state with two derivative magnons. In the asymptotic Bethe ansatz, the two physical roots are opposite,

$$u_1 = -u_2.$$

At weak coupling the one-loop solution is

$$u_1 = \frac{1}{2\sqrt{3}}, \qquad u_2 = -\frac{1}{2\sqrt{3}},$$

in the normalization of the rational Bethe equations. The asymptotic dimension matches direct perturbative gauge theory through the orders before wrapping appears. The first wrapping correction is supplied by the mirror integral term in (99.25). Conceptually, this is the finite-length correction to the trace, not a correction to the two-magnon dispersion relation.

The exact finite-coupling Konishi dimension is obtained by solving the excited-state TBA or, more efficiently, the quantum spectral curve of the next chapter. In this monograph the TBA formula is used as a logically explicit construction of the finite-size correction: every input is an S-matrix kernel, a contour, a chemical potential, or a Bethe-root condition.

At weak coupling the leading finite-size effect is the Luescher or first wrapping correction. The $SL(2)$ Konishi descendant has $K = 2$ physical roots $u_1 = -u_2$ with

$$u_1 = \frac{1}{2\sqrt{3}}\big(1 + 8g^2 - 20g^4 + (112 + 48\zeta(3))g^6 + O(g^8)\big)$$

in the asymptotic equation. The asymptotic energy gives

$$\Delta_{\mathrm{K}}^{\mathrm{ABA}} = 4 + 12g^2 - 48g^4 + 336g^6 - (2820 + 288\zeta(3))g^8 + O(g^{10}).$$

Assumption 99.10 (Leading Konishi mirror input)**.** The leading weak-coupling wrapping computation uses the following mirror-TBA data. First, the physical roots in all factors contributing at order g^8 are the one-loop values

$$u_* = \frac{1}{2\sqrt{3}}, \qquad u_1 = u_*, \qquad u_2 = -u_*.$$

Second, the virtual particles are the mirror Q-particle bound states, $Q \in \mathbb{Z}_{>0}$, in the antisymmetric $SL(2)$-type mirror sector. Third, for real mirror rapidity u the weak mirror branch is

$$x^{[Q]}(u) = \frac{g}{u + \mathrm{i}Q/2} + O(g^3), \qquad x^{[\ell]}(u) = \frac{u + \mathrm{i}\ell/2}{g} + O(g), \qquad -Q \le \ell \le Q - 1.$$

Fourth, the leading contribution of the dressing phase to the asymptotic mirror Y_Q-function starts beyond the displayed g^8 coefficient. Finally, the excited-state contour deformation is the one for which (99.25) has no additional weak-coupling μ-term for Konishi.

Under this assumption the asymptotic mirror density has the stringbook form

$$Y_{\bullet_Q}(u) = g^8\, Y_Q^{(0)}(u) + O(g^{10}), \tag{99.44}$$

where

$$Y_Q^{(0)}(u) = \frac{4Q^2\left(u^2 - u_*^2 + (Q^2-1)/4\right)^2}{(u^2+Q^2/4)^4} \times \prod_{\varepsilon=\pm1} \frac{1}{((u-\varepsilon u_*)^2 + (Q+1)^2/4)\,((u-\varepsilon u_*)^2+(Q-1)^2/4)}. \tag{99.45}$$

All symbols in (99.45) are now fixed: Q is the positive integer mirror bound-state charge, $u \in \mathbb{R}$ is the mirror rapidity, and $g = \sqrt{\lambda}/(4\pi)$ is the coupling of Chapter 98.

The mirror momentum measure is also a branch-sensitive datum. In the same convention as the stringbook, the mirror Q-particle satisfies

$$\mathrm{i}\widetilde{p}_Q(u) = -Q - 2\mathrm{i}g\big(x^{[Q]}(u) - x^{[-Q]}(u)\big).$$

Substituting the weak mirror branch of Assumption 99.10 gives

$$\mathrm{i}\widetilde{p}_Q(u) = -Q - 2\mathrm{i}g\left(\frac{g}{u+\mathrm{i}Q/2} - \frac{u-\mathrm{i}Q/2}{g}\right) + O(g^2) = 2\mathrm{i}u + O(g^2),$$

and therefore

$$\frac{\mathrm{d}\widetilde{p}_Q}{\mathrm{d}u} = 2 + O(g^2). \tag{99.46}$$

This is the sign check that fixes the convention in the energy correction.

Konishi weak-density rationalization. Let $u_* = 1/(2\sqrt{3})$ and put $q = 2u$. For $Q \geq 1$, define

$$B_Q^-(q) = 9q^4 + 6(3(Q-2)Q+2)q^2 + (3(Q-2)Q+4)^2,$$
$$B_Q^+(q) = 9q^4 + 6(3Q(Q+2)+2)q^2 + (3Q(Q+2)+4)^2.$$

Then the weak mirror density (99.45) is equivalently

$$Y_Q^{(0)}(q/2) = \frac{147456Q^2(3q^2+3Q^2-4)^2}{(q^2+Q^2)^4 B_Q^-(q)B_Q^+(q)}. \tag{99.47}$$

The first denominator factor and the numerator become

$$u^2 + \frac{Q^2}{4} = \frac{q^2+Q^2}{4}, \qquad u^2 - u_*^2 + \frac{Q^2-1}{4} = \frac{3q^2+3Q^2-4}{12}.$$

It remains only to rationalize the two factors involving u_*. For any real a,

$$\prod_{\varepsilon=\pm1}\left(\left(\frac{q}{2} - \frac{\varepsilon}{2\sqrt{3}}\right)^2 + \frac{a^2}{4}\right) = \frac{1}{16}\left[q^4 + 2\left(a^2 - \frac{1}{3}\right)q^2 + \left(a^2+\frac{1}{3}\right)^2\right].$$

Multiplying the bracket by 9, and setting $a = Q-1$ and $a = Q+1$, gives respectively $B_Q^-(q)$ and $B_Q^+(q)$. Hence each such product is $B_Q^{\pm}(q)/144$. Substituting these three elementary identities in (99.45) gives

$$\frac{4Q^2\left((3q^2+3Q^2-4)/12\right)^2}{((q^2+Q^2)/4)^4\,B_Q^-(q)B_Q^+(q)/144^2},$$

which simplifies to (99.47).

Pole structure of the Konishi weak density. Let $Q \geq 1$, and let $Y_Q^{(0)}(q/2)$ be the rational function in (99.47). Then

$$B_Q^-(q) = 9 \prod_{\sigma=\pm 1} \left(\left(q - \frac{\sigma}{\sqrt{3}} \right)^2 + (Q-1)^2 \right),$$
$$B_Q^+(q) = 9 \prod_{\sigma=\pm 1} \left(\left(q - \frac{\sigma}{\sqrt{3}} \right)^2 + (Q+1)^2 \right).$$

After the removable $Q = 1$ cancellation described below, the function has no pole on the real q-axis and obeys $Y_Q^{(0)}(q/2) = O(q^{-12})$ as $|q| \to \infty$. Its upper-half-plane poles are the fourth-order pole $q = \mathrm{i}Q$, the simple poles

$$q = \pm \frac{1}{\sqrt{3}} + \mathrm{i}(Q+1),$$

and, for $Q > 1$, the simple poles

$$q = \pm \frac{1}{\sqrt{3}} + \mathrm{i}(Q-1).$$

For $Q = 1$ the latter two points are real removable points, not contour poles.

For any real a,

$$\prod_{\sigma=\pm 1} \left(\left(q - \frac{\sigma}{\sqrt{3}} \right)^2 + a^2 \right) = q^4 + 2\left(a^2 - \frac{1}{3} \right) q^2 + \left(a^2 + \frac{1}{3} \right)^2.$$

Multiplication by 9, followed by $a = Q - 1$ and $a = Q + 1$, gives the two displayed factorizations and therefore the zero locations. The factor $(q^2+Q^2)^4$ gives a fourth-order zero of the denominator at $q = \mathrm{i}Q$ and at $q = -\mathrm{i}Q$. For real q, the factors with $a > 0$ are strictly positive. The only exceptional case is $Q = 1$ in B_1^-, where

$$B_1^-(q) = (3q^2 - 1)^2.$$

The numerator of (99.47) contains the identical factor $(3q^2-1)^2$, so the singularities at $q = \pm 1/\sqrt{3}$ are removable. Finally, before this cancellation the numerator has degree 4 and the denominator has degree 16. For $Q = 1$, after cancellation the numerator has degree 0 and the denominator has degree 12. In both cases the decay is q^{-12}.

Lemma 99.11 (Residue reduction for the Konishi summand)**.** *For $Q \geq 1$, put*

$$\mathcal{Y}_Q(q) = \frac{147456 Q^2 (3q^2 + 3Q^2 - 4)^2}{(q^2 + Q^2)^4 B_Q^-(q) B_Q^+(q)}$$

and

$$I_Q = -\int_{\mathbb{R}} \frac{\mathrm{d}q}{2\pi} \, \mathcal{Y}_Q(q),$$

with the $Q = 1$ removable real points understood as in the pole-structure calculation above. Then

$$I_Q = R_Q + \frac{864}{Q^3} - \frac{1440}{Q^5}, \tag{99.48}$$

where

$$R_Q = -\frac{7776Q\,N(Q)}{(9Q^4 - 3Q^2 + 1)^4(27Q^6 - 27Q^4 + 36Q^2 + 16)}$$

and

$$N(Q) = 19683Q^{18} - 78732Q^{16} + 150903Q^{14} - 134865Q^{12} + 1458Q^{10} \\ + 48357Q^8 - 13311Q^6 - 1053Q^4 + 369Q^2 - 10.$$

Proof. Write

$$\mathcal{N}_Q(q) = 147456Q^2(3q^2 + 3Q^2 - 4)^2.$$

By the pole-structure calculation above, the upper contour encloses the fourth-order pole at $q = \mathrm{i}Q$, the two simple poles with $a = Q + 1$, and, when $Q > 1$, the two simple poles with $a = Q - 1$. Hence

$$I_Q = -\mathrm{i}\left(\rho_Q^{(4)} + \rho_Q^{(+)} + \mathbf{1}_{Q>1}\rho_Q^{(-)}\right),$$

where

$$\rho_Q^{(4)} = \frac{1}{3!}\,\frac{\mathrm{d}^3}{\mathrm{d}q^3}\frac{\mathcal{N}_Q(q)}{(q+\mathrm{i}Q)^4 B_Q^-(q)B_Q^+(q)}\bigg|_{q=\mathrm{i}Q}.$$

For the simple poles, set $a_\eta = Q + \eta$ for $\eta = \pm 1$, $q_{\sigma,\eta} = \sigma/\sqrt{3} + \mathrm{i}a_\eta$, and use the convention $B_Q^{+1} = B_Q^+$, $B_Q^{-1} = B_Q^-$. When $a_\eta > 0$,

$$\rho_Q^{(\eta)} = \sum_{\sigma=\pm 1} \frac{\mathcal{N}_Q(q_{\sigma,\eta})}{(q_{\sigma,\eta}^2 + Q^2)^4 B_Q^{-\eta}(q_{\sigma,\eta})\partial_q B_Q^{\eta}(q_{\sigma,\eta})}.$$

The derivative in the denominator is not an implicit convention. The factorization in the pole-structure calculation above gives

$$\partial_q B_Q^{\eta}(q_{\sigma,\eta}) = 24\mathrm{i}a_\eta(1 + \sigma\mathrm{i}\sqrt{3}\,a_\eta).$$

These displayed formulas reduce the contour calculation to arithmetic in the field $\mathbb{Q}(\sqrt{3}, \mathrm{i})$. Adding the $\sigma = +1$ and $\sigma = -1$ residues cancels the $\sqrt{3}$-odd part. Combining the two simple-pole pairs with the fourth-order Laurent coefficient over a common denominator then gives exactly (99.48). The companion calculation check performs this Laurent extraction literally, including the $Q = 1$ omission of the removable $a_- = 0$ pair. □

Leading Konishi wrapping integral. Assume the mirror input of Assumption 99.10. Then the order g^8 finite-size correction to the Konishi dimension is

$$\Delta_{\mathrm{K}}^{\mathrm{wrap}} = (324 + 864\zeta(3) - 1440\zeta(5))g^8 + O(g^{10}).$$

Since $Y_{\bullet_Q} = O(g^8)$,

$$\log(1 + Y_{\bullet_Q}) = Y_{\bullet_Q} + O(g^{16}).$$

The $O(g^{10})$ uncertainty in (99.44), rather than the logarithm square, controls the next uncomputed term. Combining (99.25), (99.44), and (99.46) gives

$$\Delta_{\mathrm{K}}^{\mathrm{wrap}} = -g^8 \sum_{Q=1}^{\infty} \int_{\mathbb{R}} \frac{\mathrm{d}u}{\pi}\, Y_Q^{(0)}(u) + O(g^{10}).$$

Set $q = 2u$ and use the weak-density rationalization above. The coefficient of g^8 becomes

$$\sum_{Q=1}^{\infty} I_Q,$$

with

$$I_Q = -\int_{-\infty}^{\infty} \frac{\mathrm{d}q}{2\pi} \frac{147456Q^2(3q^2 + 3Q^2 - 4)^2}{(q^2 + Q^2)^4 B_Q^-(q) B_Q^+(q)}, \tag{99.49}$$

where $B_Q^{\pm}$ are the polynomials in the weak-density rationalization above. By Lemma 99.11, this integral satisfies (99.48). The non-zeta part is not left as a numerical experiment: it telescopes. Define

$$F_Q = -\frac{648P(Q)}{(3Q^2+1)(3Q^2-6Q+4)(3Q^2-3Q+1)^4},$$

with

$$\begin{aligned} P(Q) = 486Q^{10} &- 2430Q^9 + 5184Q^8 - 6156Q^7 + 4752Q^6 - 2916Q^5 \\ &+ 1521Q^4 - 504Q^3 + 51Q^2 + 12Q - 2. \end{aligned}$$

A direct common-denominator calculation verifies

$$R_Q = F_Q - F_{Q+1}.$$

Moreover $F_1 = 324$ and $F_Q \to 0$ as $Q \to \infty$. Hence

$$\sum_{Q=1}^{\infty} R_Q = 324.$$

The remaining two sums in (99.48) are absolutely convergent and give $864\zeta(3) - 1440\zeta(5)$. This proves the displayed coefficient.

Combining the asymptotic and wrapping pieces gives the physical four-loop coefficient

$$-2496 + 576\zeta(3) - 1440\zeta(5).$$

The companion script `calculation-checks/planar_n4_integrability_checks.py` now checks the stringbook u-integrand against the $q = 2u$ rational form, numerically integrates the first four real-line rational integrals, and verifies the exact telescoping identity for the rational tail. The conceptual assumptions remain those isolated in Assumption 99.10; the finite residue and summation algebra is not conjectural.

99.7 Relation to Relativistic Integrable QFT

The nested TBA of Chapter 78 supplies the finite-density variational logic. The present system differs in three ways. First, the dispersion is not relativistic. Second, the mirror theory has an infinite family of bound-state and auxiliary nodes. Third, the spectral problem is a gauge-theory local-operator problem, so the circle length is the trace length L or a charge shifted from it by sector-dependent conventions. These differences are why the planar $\mathcal{N} = 4$ TBA is placed in the supersymmetric gauge-theory volume rather than in the relativistic integrable-QFT volume.

Chapter 100

Quantum Spectral Curve and Hexagon Form Factors

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The mirror TBA is exact but highly redundant. The quantum spectral curve compresses the same spectral information into a finite system of analytic functions. This chapter states the $P\mu$-system, explains its weak-coupling reduction to Baxter equations, and records the separate hexagon framework for three-point functions.

100.1 Analytic T-Hook Gauge

Before introducing the $P\mu$-system it is useful to isolate the analytic T-hook step that makes the later two-row Wronskians plausible. The input is not the full QSC; it is the analytic Y-system data of Chapter 99 together with a gauge choice for Hirota T-functions.

Assumption 100.1 (One-row analytic T-gauge)**.** Use the Hirota equation

$$T_{a,s}^{+}T_{a,s}^{-} = T_{a+1,s}T_{a-1,s} + T_{a,s+1}T_{a,s-1}, \qquad f^{\pm}(u) = f(u \pm \mathrm{i}/2).$$

In a horizontal wing of the planar $\mathcal{N}=4$ T-hook, choose a gauge with

$$\mathcal{T}_{0,m} = 1, \qquad \mathcal{T}_{1,m} \in \mathcal{A}_m, \qquad \mathcal{T}_{1,m}(u) \to m \quad (u \to \infty), \qquad m \geq 1,$$

where $\mathcal{A}_m = \{|\operatorname{Im} u| < m/2\}$ with the prescribed Zhukovsky cuts removed. Assume that the discontinuity data of the two fermionic nodes can be represented by a real density ρ through Cauchy transforms

$$G(u) = -\int \frac{\mathrm{d}v}{2\pi\mathrm{i}} \frac{\rho(v)}{u-v}, \qquad \operatorname{Im} u > 0, \qquad \overline{G}(u) = +\int \frac{\mathrm{d}v}{2\pi\mathrm{i}} \frac{\rho(v)}{u-v}, \qquad \operatorname{Im} u < 0.$$

The gauge is normalized so that

$$\mathcal{T}_{1,m} = m + G^{[m]} + \overline{G}^{[-m]}, \qquad m \geq 1. \tag{100.1}$$

This assumption is deliberately stated as an analytic reconstruction datum. It summarizes the information normally hidden in the phrase "choose the $\mathcal{T}$-gauge": asymptotics, analyticity strips, and the branch on which the Cauchy transforms are evaluated.

Under Assumption 100.1, the Hirota equation at $(1, m)$, $m \geq 2$, gives

$$\mathcal{T}_{2,m} = \left(1 + G^{[m+1]} - G^{[m-1]}\right)\left(1 + \overline{G}^{[-m-1]} - \overline{G}^{[-m+1]}\right). \tag{100.2}$$

Since $\mathcal{T}_{0,m} = 1$, Hirota gives

$$\mathcal{T}_{2,m} = \mathcal{T}_{1,m}^{+}\mathcal{T}_{1,m}^{-} - \mathcal{T}_{1,m+1}\mathcal{T}_{1,m-1}.$$

Put

$$a = G^{[m+1]}, \quad b = G^{[m-1]}, \quad c = \overline{G}^{[-m-1]}, \quad d = \overline{G}^{[-m+1]}.$$

Then the right-hand side is

$$(m + a + d)(m + b + c) - (m + 1 + a + c)(m - 1 + b + d).$$

Expanding and collecting terms gives

$$1 + a - b + c - d + (a - b)(c - d) = (1 + a - b)(1 + c - d),$$

which is (100.2).

Magic-sheet continuation algebra. Assume the one-row gauge of Assumption 100.1. Suppose that, across the mirror cut in the strip under consideration, the analytic Y-system gluing condition

$$Y_{2,\pm 2}(u + \mathrm{i}0) = \frac{1}{Y_{1,\pm 1}(u - \mathrm{i}0)}$$

imposes the Cauchy-transform boundary relation

$$G(u + \mathrm{i}0) = -\overline{G}(u - \mathrm{i}0).$$

Define the magic-sheet continuation by

$$\widehat{G} = \begin{cases} G, & \text{on the branch reached from the upper half-plane,} \\ -\overline{G}, & \text{on the branch reached from the lower half-plane.} \end{cases}$$

Then, on the continued sheet,

$$\widehat{\mathcal{T}}_{1,m} = m + \widehat{G}^{[m]} - \widehat{G}^{[-m]}, \qquad \widehat{\mathcal{T}}_{2,m} = \widehat{\mathcal{T}}_{1,1}^{[m]} \widehat{\mathcal{T}}_{1,1}^{[-m]}, \qquad m \geq 2. \tag{100.3}$$

The boundary relation says precisely that the upper branch G and the negative of the lower branch $-\overline{G}$ glue with the same boundary value across the mirror cut. Thus $\widehat{G}$ is a single continued Cauchy transform on the magic sheet; the remaining discontinuity data are carried by the Zhukovsky short cut rather than by two independent upper/lower transforms.

In the original strip,

$$\mathcal{T}_{1,m} = m + G^{[m]} + \overline{G}^{[-m]}.$$

After continuation through the mirror cut, the upper shifted term remains $\widehat{G}^{[m]}$, while the lower shifted term satisfies $\overline{G}^{[-m]} = -\widehat{G}^{[-m]}$. This gives the first formula in (100.3).

For the two-row function use the factorization (100.2). Its first factor becomes

$$1 + \widehat{G}^{[m+1]} - \widehat{G}^{[m-1]} = \widehat{\mathcal{T}}_{1,1}^{[m]},$$

and its second factor becomes

$$1 + \widehat{G}^{[-m+1]} - \widehat{G}^{[-m-1]} = \widehat{\mathcal{T}}_{1,1}^{[-m]}.$$

Multiplying the two factors gives the second formula. This calculation is local in the strip: if a pole or endpoint is crossed, the missing information is an extra source term rather than a failure of the algebra.

The hats emphasize that these are not new functions on the same sheet but analytic continuations through the Zhukovsky cut. In the strip $|\operatorname{Im} u| < m/2$, $\widehat{\mathcal{T}}_{1,m}$ agrees with the original $\mathcal{T}_{1,m}$. Outside that strip, the equality is a statement about a chosen continuation path. The $P\mu$-system below is a finite Riemann–Hilbert compression of this analytically continued T-hook data.

100.1.1 Gauge Chain and Fermionic Discontinuities

The stringbook derivation passes through two further analytic gauges before introducing P-functions. We spell out the finite algebra because the same formulae fix the signs in the $Y_{1,1}Y_{2,2}$ product and in the large-u energy exponent.

Assumption 100.2 (Fermionic $\mathbf{T}$-gauge and $\mathbb{T}$-gauge)**.** Choose a Hirota gauge $\mathbf{T}_{a,s}$ with the same Y-functions as Chapter 99. For $n \geq 1$, its central analyticity strips satisfy

$$\mathbf{T}_{n-1,0}, \quad \mathbf{T}_{n,\pm 1}, \quad \mathbf{T}_{n+1,\pm 2} \in \mathcal{A}_n.$$

The boundary and left-right identifications are

$$\mathbf{T}_{n,\pm 2} = \mathbf{T}_{2,\pm n} \quad (n \geq 3), \qquad \mathbf{T}_{0,0}^{[+1]} = \mathbf{T}_{0,0}^{[-1]}, \qquad \mathbf{T}_{0,s} = \mathbf{T}_{0,0}^{[s]}.$$

On a patch where the indicated square roots are fixed, define

$$\mathbb{T}_{a,s} = (-1)^{as} \mathbf{T}_{a,s} \left(\mathbf{T}_{0,0}^{[a+s]} \right)^{(a-2)/2}. \tag{100.4}$$

Then $\mathbb{T}_{0,s} = 1$, and the magic-sheet continuations obey

$$\widehat{\mathbb{T}}_{1,m} = \widehat{h}^{[m]}\widehat{h}^{[-m]}\widehat{\mathcal{T}}_{1,m}, \tag{100.5}$$
$$\widehat{\mathbb{T}}_{2,m} = \widehat{h}^{[m+1]}\widehat{h}^{[m-1]}\widehat{h}^{[-m+1]}\widehat{h}^{[-m-1]}\widehat{\mathcal{T}}_{2,m}, \qquad m \geq 2, \tag{100.6}$$

for a function $\widehat{h}$ with only the central short cut in this gauge.

The assumption records an analytic gauge choice, not a new dynamical equation. The gauge transformation leaves the local Y-functions unchanged; its role is to put the central row and the two horizontal wings in a form adapted to single-short-cut Wronskians.

Fermionic product and central-row telescope. In the $\mathbf{T}$-gauge of Assumption 100.2,

$$Y_{1,1}Y_{2,2} = \frac{\mathbf{T}_{1,0}}{\mathbf{T}_{0,0}^{[+1]}}. \tag{100.7}$$

Moreover, for every $n \geq 1$,

$$\prod_{a=1}^{n}\left(1 + Y_{a,0}^{[2n-a]}\right) = \frac{\mathbf{T}_{1,0}^{[2n]}\mathbf{T}_{n,0}^{[n-1]}}{\mathbf{T}_{0,0}^{[2n-1]}\mathbf{T}_{n+1,0}^{[n]}}. \tag{100.8}$$

Consequently the analytic-Y-system discontinuity input

$$\mathrm{Disc}\,(\log Y_{1,1}Y_{2,2})^{[2n]} = \sum_{a=1}^{n}\mathrm{Disc}\log\left(1 + Y_{a,0}^{[2n-a]}\right)$$

is equivalently written as

$$\mathrm{Disc}\,(\log Y_{1,1}Y_{2,2})^{[2n]} = \mathrm{Disc}\log\frac{\mathbf{T}_{1,0}^{[2n]}\mathbf{T}_{n,0}^{[n-1]}}{\mathbf{T}_{0,0}^{[2n-1]}\mathbf{T}_{n+1,0}^{[n]}}. \tag{100.9}$$

Use the local T-system definition

$$Y_{a,s} = \frac{\mathbf{T}_{a,s+1}\mathbf{T}_{a,s-1}}{\mathbf{T}_{a+1,s}\mathbf{T}_{a-1,s}}.$$

Then

$$Y_{1,1}Y_{2,2} = \frac{\mathbf{T}_{1,2}\mathbf{T}_{1,0}}{\mathbf{T}_{2,1}\mathbf{T}_{0,1}}\frac{\mathbf{T}_{2,3}\mathbf{T}_{2,1}}{\mathbf{T}_{3,2}\mathbf{T}_{1,2}} = \frac{\mathbf{T}_{1,0}\mathbf{T}_{2,3}}{\mathbf{T}_{0,1}\mathbf{T}_{3,2}}.$$

The $\mathbf{T}$-gauge identifications give $\mathbf{T}_{3,2} = \mathbf{T}_{2,3}$ and $\mathbf{T}_{0,1} = \mathbf{T}_{0,0}^{[+1]}$, proving (100.7).

For the telescope, Hirota gives

$$1 + Y_{a,0} = \frac{\mathbf{T}_{a,0}^{+}\mathbf{T}_{a,0}^{-}}{\mathbf{T}_{a+1,0}\mathbf{T}_{a-1,0}}.$$

After the shift by $[2n-a]$, the a-th factor is

$$\frac{\mathbf{T}_{a,0}^{[2n-a+1]}\mathbf{T}_{a,0}^{[2n-a-1]}}{\mathbf{T}_{a+1,0}^{[2n-a]}\mathbf{T}_{a-1,0}^{[2n-a]}}.$$

Multiplying from $a = 1$ to $a = n$, every interior $\mathbf{T}_{b,0}^{[2n-b+1]}$ and $\mathbf{T}_{b,0}^{[2n-b-1]}$ with $2 \le b \le n-1$ appears once in the numerator and once in the denominator. The surviving boundary terms are $\mathbf{T}_{1,0}^{[2n]}$, $\mathbf{T}_{n,0}^{[n-1]}$, $\mathbf{T}_{0,0}^{[2n-1]}$, and $\mathbf{T}_{n+1,0}^{[n]}$, which is (100.8). Taking logarithmic discontinuities along the central cut gives (100.9). The first displayed discontinuity relation is the analytic-Y-system input from the mirror TBA; the telescope above supplies its T-gauge form.

$\mathbb{T}$-gauge compatibility. Under Assumption 100.2 and the magic-sheet continuation algebra above,

$$\widehat{\mathbb{T}}_{2,m} = \widehat{\mathbb{T}}_{1,1}^{[m]}\widehat{\mathbb{T}}_{1,1}^{[-m]}, \qquad m \ge 2.$$

Thus the two-row Wronskian reconstruction used below may be normalized in the $\mathbb{T}$-gauge without changing the one-row magic-sheet algebra.

Substitute $\widehat{\mathcal{T}}_{2,m} = \widehat{\mathcal{T}}_{1,1}^{[m]}\widehat{\mathcal{T}}_{1,1}^{[-m]}$ from (100.3) into (100.6). The four $\widehat{h}$-factors become

$$\widehat{h}^{[m+1]}\widehat{h}^{[m-1]}\widehat{h}^{[-m+1]}\widehat{h}^{[-m-1]}.$$

Using (100.5) at arguments $u + \mathrm{i}m/2$ and $u - \mathrm{i}m/2$ gives

$$\widehat{\mathbb{T}}_{1,1}^{[m]} = \widehat{h}^{[m+1]}\widehat{h}^{[m-1]}\widehat{\mathcal{T}}_{1,1}^{[m]}, \qquad \widehat{\mathbb{T}}_{1,1}^{[-m]} = \widehat{h}^{[-m+1]}\widehat{h}^{[-m-1]}\widehat{\mathcal{T}}_{1,1}^{[-m]}.$$

Multiplication gives the claim. The statement is local in the chosen analytic gauge; zeros of $\widehat{h}$ or Wronskian degeneracies are handled by analytic continuation on the neighboring patch.

100.2 Pmu System

Let $u \in \mathbb{C}$ be the spectral parameter. The quantum spectral curve uses four functions $P_a(u)$, $a = 1, \ldots, 4$, and an antisymmetric matrix $\mu_{ab}(u) = -\mu_{ba}(u)$. The functions P_a have one short branch cut, conventionally on $[-2g, 2g]$, on their principal sheet. Analytic continuation through this cut is denoted by a tilde. Introduce

$$P^a = \chi^{ab} P_b,$$

where χ^{ab} is the fixed antisymmetric tensor with nonzero entries chosen so that $P_a P^a = 0$.

The $P\mu$-system is

$$\widetilde{P}_a(u) = \mu_{ab}(u) P^b(u), \tag{100.10}$$

$$\widetilde{\mu}_{ab}(u) - \mu_{ab}(u) = P_a(u)\widetilde{P}_b(u) - P_b(u)\widetilde{P}_a(u), \tag{100.11}$$

$$\mu_{ab}(u + \mathrm{i}) = \widetilde{\mu}_{ab}(u). \tag{100.12}$$

The normalization is completed by the Pfaffian condition

$$\operatorname{Pf}\mu = \mu_{12}\mu_{34} - \mu_{13}\mu_{24} + \mu_{14}\mu_{23} = 1, \tag{100.13}$$

up to the standard P-basis gauge transformations. The tilde operation is analytic continuation through the short cut of the corresponding function; it is not complex conjugation. On real states one imposes an additional reality or gluing condition relating the two sheets.

Definition 100.3 (QSC Riemann–Hilbert datum)**.** Within the planar integrability framework, a $P\mu$ Riemann–Hilbert datum consists of the spectral plane with parameter $u \in \mathbb{C}$, four single-short-cut functions P_a, an antisymmetric matrix μ_{ab}, the fixed antisymmetric tensor χ^{ab}, and the continuation operation $\widetilde{\ }$ through the short cut $[-2g, 2g]$. The datum is required to satisfy (100.10)–(100.12), (100.13), regularity on the defining sheet, and large-u asymptotics specifying the global charges. A physical solution adds state-dependent gluing conditions and cyclic single-trace constraints.

This is a Riemann–Hilbert problem, not a finite collection of ordinary functions on one copy of the plane. The data above tell the reader both what is evaluated on the defining sheet and how the functions are continued to the neighboring sheets.

Assumption 100.4 (Two-row T-hook reconstruction datum)**.** Use the shift notation

$$f^{[n]}(u) = f(u + n\mathrm{i}/2).$$

In the physical or magic T-hook gauge, assume that the two horizontal rows adjacent to the central node are reconstructed from two single-short-cut functions P_1, P_2 by

$$\mathbb{T}_{1,m} = P_1^{[m]} P_2^{[-m]} - P_2^{[m]} P_1^{[-m]}, \qquad m \geq 1, \tag{100.14}$$

and that Hirota continuation extends this expression to the central nodes. Let

$$\mathbb{T}_{0,1} = \mu_{12}^2, \qquad \mathbb{T}_{3,2} = \mathbb{T}_{2,3}\mu_{12}.$$

The functions $\mathbb{T}_{2,1}$ and $\mathbb{T}_{1,0}$ are assumed to be regular across the central short cut in the strip where the following calculation is made. Finally, the Wronskian

$$D = P_1^{[+2]} P_2^{[-2]} - P_2^{[+2]} P_1^{[-2]}$$

is not identically zero; any isolated zeros are handled by analytic continuation of the resulting identities.

Local T-hook algebra behind the $P\mu$ bridge. Under Assumption 100.4, regularity of the T-hook functions across the central short cut forces

$$\widetilde{\mu}_{12} - \mu_{12} = P_1 \widetilde{P}_2 - P_2 \widetilde{P}_1. \tag{100.15}$$

Moreover

$$\mathbb{T}_{1,0} = \mu_{12}\widetilde{\mu}_{12}, \qquad Y_{1,1}Y_{2,2} = \frac{\widetilde{\mu}_{12}}{\mu_{12}} = 1 + \frac{P_1\widetilde{P}_2 - P_2\widetilde{P}_1}{\mu_{12}}. \tag{100.16}$$

The preceding assumption is the nontrivial analytic input: it asserts that a two-row Wronskian reconstruction by single-short-cut P-functions exists in the strip, and that the relevant central T-hook nodes are regular there. The displayed formulae below are the local Pluecker calculation extracted from that input.

Write $P_a^+ = P_a^{[+2]}$, $P_a^- = P_a^{[-2]}$, and

$$D = P_1^+ P_2^- - P_2^+ P_1^-.$$

The Hirota equation at the $(2,2)$ square, expressed through the Wronskians in (100.14), gives in the upper half-plane sector

$$\mathbb{T}_{2,1} = (\widetilde{P}_1 P_2^- - \widetilde{P}_2 P_1^-)(P_1^+ P_2 - P_2^+ P_1) - \mu_{12} D.$$

Continuing across the central cut replaces P_1, P_2, μ_{12} in the unshifted slot by their tilded values, so the same node is

$$\widetilde{\mathbb{T}}_{2,1} = (P_1 P_2^- - P_2 P_1^-)(P_1^+ \widetilde{P}_2 - P_2^+ \widetilde{P}_1) - \widetilde{\mu}_{12} D.$$

Since $\mathbb{T}_{2,1}$ is regular in this strip, these two expressions are equal. Moving the μ-terms to one side gives

$$(\mu_{12} - \widetilde{\mu}_{12}) D = A - B,$$

where

$$A = (\widetilde{P}_1 P_2^- - \widetilde{P}_2 P_1^-)(P_1^+ P_2 - P_2^+ P_1),$$
$$B = (P_1 P_2^- - P_2 P_1^-)(P_1^+ \widetilde{P}_2 - P_2^+ \widetilde{P}_1).$$

Expanding both products and canceling pairwise gives the Pluecker identity

$$A - B = (\widetilde{P}_1 P_2 - \widetilde{P}_2 P_1) D.$$

Because D is not identically zero, division by D on the open set where it is nonzero gives

$$\mu_{12} - \widetilde{\mu}_{12} = \widetilde{P}_1 P_2 - \widetilde{P}_2 P_1,$$

and analyticity extends the identity through isolated zeros of D. This is (100.15).

The $(1,1)$ Hirota square gives the central-node relation

$$\frac{\mathbb{T}_{1,0}}{\mu_{12}} = \mu_{12} + \widetilde{P}_2 P_1 - \widetilde{P}_1 P_2.$$

Using the discontinuity identity just proved, the right side is $\widetilde{\mu}_{12}$, hence $\mathbb{T}_{1,0} = \mu_{12}\widetilde{\mu}_{12}$. In this gauge

$$Y_{1,1} Y_{2,2} = \frac{\mathbb{T}_{1,0}}{\mathbb{T}_{0,1}} = \frac{\mu_{12}\widetilde{\mu}_{12}}{\mu_{12}^2},$$

which proves the first equality in (100.16). The second equality is the same statement after substituting (100.15).

Fermionic-node asymptotics. Let $x_{\mathrm{f}}(u)$ be the fermionic-node Zhukovsky sheet used in the large-u expansion of $Y_{1,1}Y_{2,2}$, normalized by

$$x_{\mathrm{f}}(u) = \frac{g}{u} + O(u^{-3}), \qquad u \to \infty.$$

For a mirror Q-particle at rapidity v, write

$$a = x_Q^+(v), \qquad b = x_Q^-(v), \qquad |a| < 1 < |b|, \qquad \widetilde{E}_Q(v) = \log \frac{b}{a},$$

with the logarithm on the real mirror branch, and use the mirror momentum normalization of Chapter 99,

$$\mathrm{i}\widetilde{p}_Q(v) = -Q - 2\mathrm{i}g(a - b). \tag{100.17}$$

Define the fermionic-node scattering-ratio factor

$$R_Q(u,v) = \frac{x_{\mathrm{f}}(u) - a}{x_{\mathrm{f}}(u) - b}\,\frac{x_{\mathrm{f}}(u)^{-1} - b}{x_{\mathrm{f}}(u)^{-1} - a}.$$

On the branch of $\log R_Q$ which tends to $\log(a/b)$ at $u = \infty$,

$$\log R_Q(u,v) = -\widetilde{E}_Q(v) - \frac{\widetilde{p}_Q(v)}{u} + O(u^{-2}). \tag{100.18}$$

After the inverse mirror continuation of the second particle, $\widetilde{E} = -\mathrm{i}p$, $\widetilde{p} = -\mathrm{i}E$, the same local expansion becomes

$$\log R_1^{\mathrm{phys}}(u,u_j) = \mathrm{i}p(u_j) + \frac{\mathrm{i}E(u_j)}{u} + O(u^{-2}).$$

Indeed, set $x = x_{\mathrm{f}}(u)$. Since $x = g/u + O(u^{-3})$,

$$\frac{x-a}{x-b} = \frac{a}{b}\left(1 + x\left(\frac{1}{b} - \frac{1}{a}\right) + O(x^2)\right), \qquad \frac{x^{-1}-b}{x^{-1}-a} = 1 + x(a-b) + O(x^2).$$

Multiplying,

$$R_Q(u,v) = \frac{a}{b}\left[1 + \frac{g}{u}\left(a - b + \frac{1}{b} - \frac{1}{a}\right) + O(u^{-2})\right].$$

The constant term gives $\log(a/b) = -\widetilde{E}_Q$. For the coefficient of u^{-1}, use the bound-state shortening condition

$$a + \frac{1}{a} - b - \frac{1}{b} = \frac{\mathrm{i}Q}{g}.$$

It implies

$$g\left(a - b + \frac{1}{b} - \frac{1}{a}\right) = 2g(a-b) - \mathrm{i}Q = -\widetilde{p}_Q,$$

where the last equality is (100.17). Taking the logarithm gives (100.18). The physical expansion is the same identity written with the stringbook double-Wick convention $\widetilde{E} = -\mathrm{i}p$, $\widetilde{p} = -\mathrm{i}E$.

Assumption 100.5 (Fermionic-product energy normalization)**.** Work in the analytic T-hook gauge of Chapter 99, and consider an $SL(2)$ single-trace state of twist J, Lorentz spin S, and total physical momentum zero. Let $Y_{1,1}$ and $Y_{2,2}$ denote the two fermionic T-hook nodes adjacent to the central strip in this gauge. The local reconstruction algebra in the local T-hook algebra above supplies the $P\mu$ expression for $Y_{1,1}Y_{2,2}$. The remaining framework input is the energy normalization inherited from the excited-state mirror TBA:

$$\log\bigl(Y_{1,1}(u)Y_{2,2}(u)\bigr) = \frac{\mathrm{i}(\Delta - J)}{u} + O(u^{-2}), \qquad u \to \infty$$

in the upper-half-plane sector used for the $SL(2)$ large-u asymptotics. The fermionic-node asymptotics calculation above is the local sheet calculation behind this normalization: in the standard excited-state mirror-TBA formula, the fermionic product is assembled from the ratio R_Q, and its u^{-1} coefficient is the same mirror-momentum functional that appears in the energy formula (99.25). The assumption that remains is the global TBA contour formula for $Y_{1,1}Y_{2,2}$, not an independent sign choice in the QSC.

Dimension exponent of μ_{12}. Under Assumption 100.5 and the $P\mu$ equations,

$$Y_{1,1}(u)Y_{2,2}(u) = \frac{\mu_{12}(u+\mathrm{i})}{\mu_{12}(u)}. \tag{100.19}$$

If μ_{12} has power-law large-u behavior on this sheet, then

$$\mu_{12}(u) \sim u^{\Delta-J}.$$

The $(1,2)$ component of the $P\mu$ discontinuity equation gives

$$\widetilde{\mu}_{12}(u) - \mu_{12}(u) = P_1(u)\widetilde{P}_2(u) - P_2(u)\widetilde{P}_1(u).$$

Dividing by $\mu_{12}(u)$ and using the bridge formula (100.16) gives

$$Y_{1,1}(u)Y_{2,2}(u) = \frac{\widetilde{\mu}_{12}(u)}{\mu_{12}(u)}.$$

Pseudo-periodicity (100.12) then gives (100.19). Now suppose $\mu_{12}(u) = Cu^{\alpha}(1+O(u^{-1}))$ with $C \neq 0$. Then

$$\log\frac{\mu_{12}(u+\mathrm{i})}{\mu_{12}(u)} = \alpha\log\left(1+\frac{\mathrm{i}}{u}\right) + O(u^{-2}) = \frac{\mathrm{i}\alpha}{u} + O(u^{-2}).$$

Comparison with the large-u energy normalization in Assumption 100.5 gives $\alpha = \Delta - J$.

State quantum numbers also enter through large-u asymptotics of P_a and the remaining μ_{ab}. In the $SL(2)$ sector with twist J, spin S, and dimension Δ, these asymptotics encode the charges

$$(J, S, \Delta)$$

through powers and leading coefficients constrained by the algebraic relations of the QSC. With the $SL(2)$ conventions used in the previous chapter, the large-u powers of the P-functions are

$$(P_1, P_2, P_3, P_4) \sim (A_1u^{-J/2}, A_2u^{-J/2-1}, A_3u^{J/2}, A_4u^{J/2-1}).$$

Together with the dimension-exponent calculation above, the leading terms in

$$\widetilde{P}_a = \mu_{ab}P^b, \qquad (P^1, P^2, P^3, P^4) = (-P_4, P_3, -P_2, P_1)$$

then force the remaining μ-powers. For the characteristic calculation one should not insert the physical value of the exponent too early: keep a trial exponent α and write

$$(\mu_{12}, \mu_{13}, \mu_{14}, \mu_{23}, \mu_{24}, \mu_{34}) \sim (u^{\alpha-J}, u^{\alpha+1}, u^{\alpha}, u^{\alpha}, u^{\alpha-1}, u^{\alpha+J}), \tag{100.20}$$

provided the leading terms do not undergo accidental cancellations. The physical branch later has $\alpha = \Delta$.

Large-u power balance for the $P\mu$ sheet equation. Fix the $SL(2)$ P-powers displayed above and use $(P^1,P^2,P^3,P^4)=(-P_4,P_3,-P_2,P_1)$. Suppose that in the trial large-u sector $\widetilde{P}_a$ has the common sheet exponent shift

$$\widetilde{P}_a=O(u^{\alpha+p_a}),\qquad (p_1,p_2,p_3,p_4)=\left(-\frac{J}{2},-\frac{J}{2}-1,\frac{J}{2},\frac{J}{2}-1\right),$$

and that the μ_{12} exponent is $\alpha-J$. If no leading row of $\widetilde{P}_a=\mu_{ab}P^b$ is cancelled identically, then the six μ-exponents are exactly those in (100.20). With these exponents, every term kept in the leading monodromy system (100.22) has the same power as $\mu_{ab}(u+\mathrm{i})-\mu_{ab}(u)$ in its component.

Let $e_{ab}=e_{ba}$ be the large-u exponent of μ_{ab}, and let

$$(q_1,q_2,q_3,q_4)=\left(\frac{J}{2}-1,\frac{J}{2},-\frac{J}{2}-1,-\frac{J}{2}\right)$$

be the powers of (P^1,P^2,P^3,P^4). The row $a=1$ in $\widetilde{P}_a=\mu_{ab}P^b$ has target exponent $\alpha-J/2$. Since $e_{12}=\alpha-J$,

$$e_{12}+q_2=\alpha-\frac{J}{2},\qquad e_{13}+q_3=\alpha-\frac{J}{2},\qquad e_{14}+q_4=\alpha-\frac{J}{2},$$

and hence $e_{13}=\alpha+1$, $e_{14}=\alpha$. Applying the same balance to the second row, whose target exponent is $\alpha-J/2-1$, gives

$$e_{23}+q_3=\alpha-\frac{J}{2}-1,\qquad e_{24}+q_4=\alpha-\frac{J}{2}-1,$$

so $e_{23}=\alpha$ and $e_{24}=\alpha-1$. The third row has target $\alpha+J/2$, and therefore

$$e_{34}+q_4=\alpha+\frac{J}{2},$$

which gives $e_{34}=\alpha+J$. The fourth row gives the same value and is a consistency check. These are precisely the powers in (100.20).

For the monodromy recursion, the left side of the (a,b) component has power $e_{ab}-1$, since

$$\mu_{ab}(u+\mathrm{i})-\mu_{ab}(u)=\mathrm{i}e_{ab}m_{ab}u^{e_{ab}-1}+\cdots.$$

Each retained term on the right is of the form $P_a\mu_{bc}P^c$ or $P_b\mu_{ac}P^c$. The row balance just proved says

$$e_{bc}+q_c=\alpha+p_b,\qquad e_{ac}+q_c=\alpha+p_a.$$

Thus these terms have powers $p_a+\alpha+p_b$ and $p_b+\alpha+p_a$. A direct substitution of the exponents above gives

$$p_a+p_b+\alpha=e_{ab}-1$$

for the six pairs $(12),(13),(14),(23),(24),(34)$. Hence the leading linear system is homogeneous in powers of u, as required.

Large-u characteristic determinant. Let

$$X = A_1 A_4, \qquad Y = A_2 A_3.$$

Insert the $SL(2)$ P-powers and the trial μ-powers (100.20) into the one-step monodromy recursion (100.23). For a nonzero leading vector with $\alpha \neq 0$, the characteristic equation is

$$\Phi(\alpha) = (J+1)^2\alpha^2 - 4\mathrm{i}J(J+1)Y - \Big(\alpha^2 + J - \mathrm{i}(J+1)Y + \mathrm{i}(J-1)X\Big)^2 = 0. \tag{100.21}$$

Write

$$P_1 = A_1 u^{-J/2}, \quad P_2 = A_2 u^{-J/2-1}, \quad P_3 = A_3 u^{J/2}, \quad P_4 = A_4 u^{J/2-1}$$

at leading order, and use $(P^1, P^2, P^3, P^4) = (-P_4, P_3, -P_2, P_1)$. If $\mu_{ab} = m_{ab} u^{e_{ab}} + \cdots$, then $\mu_{ab}(u+\mathrm{i}) - \mu_{ab}(u) = \mathrm{i}e_{ab}m_{ab}u^{e_{ab}-1} + \cdots$. Keeping the leading power in each component gives the finite linear system

$$\begin{aligned}
\mathrm{i}(\alpha - J)m_{12} &= (X-Y)m_{12} + A_2^2 m_{13} - A_1A_2 m_{14} - A_1A_2 m_{23} + A_1^2 m_{24},\\
\mathrm{i}(\alpha+1)m_{13} &= -A_3^2 m_{12} + (X+Y)m_{13} - A_1A_3 m_{14} - A_1A_3 m_{23} + A_1^2 m_{34},\\
\mathrm{i}\alpha m_{14} &= -A_3A_4 m_{12} + A_2A_4 m_{13} - A_1A_3 m_{24} + A_1A_2 m_{34},\\
\mathrm{i}\alpha m_{23} &= -A_3A_4 m_{12} + A_2A_4 m_{13} - A_1A_3 m_{24} + A_1A_2 m_{34},\\
\mathrm{i}(\alpha-1)m_{24} &= -A_4^2 m_{12} + A_2A_4 m_{14} + A_2A_4 m_{23} - (X+Y)m_{24} + A_2^2 m_{34},\\
\mathrm{i}(\alpha+J)m_{34} &= -A_4^2 m_{13} + A_3A_4 m_{14} + A_3A_4 m_{23} - A_3^2 m_{24} + (-X+Y)m_{34}.
\end{aligned} \tag{100.22}$$

Let $\mathcal{M}_\alpha$ be the coefficient matrix obtained by moving the right-hand side to the left. Expanding the determinant and collecting only the invariant products $X = A_1A_4$ and $Y = A_2A_3$ gives

$$\det \mathcal{M}_\alpha = \alpha^2 \Phi(\alpha).$$

The factor α^2 records a degenerate zero-exponent subspace of this redundant six-coordinate leading system before imposing the Pfaffian and gauge reductions. The nonzero characteristic exponents used below therefore obey $\Phi(\alpha) = 0$.

Assumption 100.6 (Physical QSC characteristic roots)**.** For an $SL(2)$ single-trace state of twist J, Lorentz spin S, and dimension Δ, the physical large-u gluing/asymptotic data select, after quotienting the redundant α^2 factor above, the roots

$$\alpha = \Delta, \qquad \alpha = S - 1$$

of the characteristic polynomial (100.21); cases in which the spin-shadow root coincides with the zero sector are understood by continuity.

This root assignment is not a path-integral theorem. It is the large-u representation-theory and QSC-gluing input in this gauge. The local algebra above is included because it is a common source of sign errors: the products A_1A_4 and A_2A_3 carry the sign convention for χ, for $f^{[\pm 1]}(u) = f(u \pm \mathrm{i}/2)$, and for the short-cut sheet.

Large-u coefficient products. Under Assumption 100.6, the leading coefficient products are

$$A_1A_4 = \mathrm{i}\,\frac{((J+S-2)^2-\Delta^2)((J-S)^2-\Delta^2)}{16J(J-1)},$$
$$A_2A_3 = \mathrm{i}\,\frac{((J-S+2)^2-\Delta^2)((J+S)^2-\Delta^2)}{16J(J+1)}.$$

Put $\beta = S-1$. Since $\Phi(\Delta) = \Phi(\beta) = 0$, subtracting the two equations cancels the term proportional to Y and gives

$$\Delta^2+\beta^2+2J+2U = (J+1)^2, \qquad U = -\mathrm{i}(J+1)Y+\mathrm{i}(J-1)X,$$

as long as $\Delta^2 \neq \beta^2$; the degenerate cases are obtained by continuity. Thus

$$U = \frac{J^2+1-\Delta^2-\beta^2}{2}.$$

Substituting this value in $\Phi(\Delta)=0$ gives

$$4\mathrm{i}J(J+1)Y = (J+1)^2\Delta^2 - \frac{1}{4}\left(\Delta^2+(J+1)^2-\beta^2\right)^2.$$

Now

$$(J+1)^2-\beta^2 = (J-S+2)(J+S),$$

and the elementary factorization

$$4(J+1)^2\Delta^2 - \left(\Delta^2+(J-S+2)(J+S)\right)^2 = -\left(\Delta^2-(J-S+2)^2\right)\left(\Delta^2-(J+S)^2\right)$$

gives the displayed formula for $A_2A_3 = Y$. The formula for $A_1A_4 = X$ follows from

$$\mathrm{i}(J-1)X = U + \mathrm{i}(J+1)Y$$

and the same factorization with $(J-S+2, J+S)$ replaced by $(J-S, J+S-2)$.

Consistency of the $P\mu$ discontinuity. The discontinuity equation (100.11) preserves the Pfaffian normalization (100.13) if the P-functions satisfy

$$P_aP^a = 0.$$

Use the rank-two Pfaffian identity

$$\mathrm{Pf}(M+v\wedge w) = \mathrm{Pf}(M)\left(1+w^TM^{-1}v\right)$$

for an invertible antisymmetric 4×4 matrix M. Here $M=\mu$, $v=P$, and $w=\widetilde{P}=\mu P^\sharp$, where $(P^\sharp)^a = P^a = \chi^{ab}P_b$. Hence

$$w^T\mu^{-1}v = (\mu P^\sharp)^T\mu^{-1}P = -(P^\sharp)^TP = -P^aP_a = 0,$$

because χ^{ab} is antisymmetric. Therefore crossing the cut does not change $\mathrm{Pf}\,\mu$, so the normalization can be imposed on one sheet and transported consistently.

Monodromy recursion for μ. The $P\mu$ equations imply the one-step continuation formula

$$\mu_{ab}(u+\mathrm{i}) = \mu_{ab}(u) + P_a(u)\mu_{bc}(u)P^c(u) - P_b(u)\mu_{ac}(u)P^c(u). \tag{100.23}$$

Consequently, once the functions in one strip and the continued P-sheet are known, the shifted μ-sheets are generated recursively by algebraic substitution.

Use the pseudo-periodicity equation (100.12) and the discontinuity equation (100.11):

$$\mu_{ab}(u+\mathrm{i}) - \mu_{ab}(u) = P_a(u)\widetilde{P}_b(u) - P_b(u)\widetilde{P}_a(u).$$

Substituting $\widetilde{P}_b = \mu_{bc}P^c$ from (100.10) gives (100.23). Applying the same identity at successively shifted arguments gives the recursion through the tower of short cuts. The recursion is algebraic; it does not by itself prove that the regularity, gluing, and large-u conditions select a unique physical solution.

Quoted Theorem 100.7 (Quantum spectral curve spectral problem)**.** *Within the planar $\mathcal{N} = 4$ integrability framework, a physical single-trace state is specified by QSC analyticity, gluing, asymptotic, and regularity data. Solving the resulting $P\mu$-system determines the exact planar scaling dimension of the state as a function of λ.*

The theorem is quoted with its framework stated. The QSC is a powerful exact solution of the planar integrability system; it is not presently a constructive definition of four-dimensional $\mathcal{N} = 4$ SYM. In this chapter, the algebraic consequences of the $P\mu$ equations are derived when feasible: Pfaffian preservation, monodromy recursion, the weak-coupling Baxter degeneration, and the one-loop dimension extraction below. The existence of the single-short-cut P-functions, the normalization of the discontinuity coefficient in (100.11), the physical gluing conditions, and the equivalence to the exact planar gauge-theory spectrum remain QSC framework inputs.

100.2.1 TBA-to-QSC Compression Record

The mirror TBA, the analytic Y-system, the T-hook gauges, and the QSC are not four independent spectral claims. They are successive ways of packaging the same planar-integrability data after extra analytic information has been attached. The local Y-system by itself remembers Hirota-gauge invariant ratios, but it does not remember the source factors lost by the inverse s-kernel, the sheet on which the central fermionic discontinuity is read, or the large-u charge normalization. The $P\mu$-system is the finite Riemann–Hilbert package obtained only after those pieces have been restored.

Proposition 100.8 (TBA-to-QSC charge record)**.** *Fix an $SL(2)$ single-trace state in the analytic framework used above. Assume that the mirror-TBA analytic Y-system data of Assumption 99.9, the T-gauge chain of Assumption 100.2, and the local two-row $P\mu$ bridge of Assumption 100.4 have all been fixed. Suppose further that*

$$\log\bigl(Y_{1,1}(u)Y_{2,2}(u)\bigr) = \frac{\mathrm{i}r}{u} + O(u^{-2}), \qquad u \to \infty,$$

and that the P-function powers are

$$(p_1, p_2, p_3, p_4) = \left(-\frac{J}{2}, -\frac{J}{2} - 1, \frac{J}{2}, \frac{J}{2} - 1\right), \qquad P_a(u) = O(u^{p_a}).$$

If the physical gluing/asymptotic data select the nonzero characteristic roots $\alpha = \Delta$ and $\beta = S-1$ in Assumption 100.6, then the bridge recovers the charge triple by the finite record

$$J = p_3 - p_1 = p_4 - p_2, \qquad \Delta = J + r, \qquad S = \beta + 1. \tag{100.24}$$

Consequently the symbolic Y-system plus Hirota algebra is not, by itself, the QSC spectral problem: the fermionic large-u coefficient, the P-power gap, and the physical characteristic-root assignment are all separate inputs.

Proof. The local T-hook calculation above gives

$$Y_{1,1}Y_{2,2} = \frac{\widetilde{\mu}_{12}}{\mu_{12}} = \frac{\mu_{12}(u+\mathrm{i})}{\mu_{12}(u)}.$$

If $\mu_{12}(u) = Cu^{\gamma}(1 + O(u^{-1}))$, then

$$\log \frac{\mu_{12}(u+\mathrm{i})}{\mu_{12}(u)} = \frac{\mathrm{i}\gamma}{u} + O(u^{-2}).$$

Comparison with the assumed fermionic-product expansion gives $\gamma = r$. In the physical branch the dimension-exponent calculation above identifies $\gamma = \Delta - J$, hence $\Delta = J + r$.

The P-powers independently recover the twist:

$$p_3 - p_1 = \frac{J}{2} - \left(-\frac{J}{2}\right) = J, \qquad p_4 - p_2 = \frac{J}{2} - 1 - \left(-\frac{J}{2} - 1\right) = J.$$

Finally the physical characteristic-root input identifies the spin-shadow root $\beta = S - 1$, so $S = \beta + 1$. These three finite readings give (100.24). Omitting any of them leaves visible ambiguity: r is unchanged under the simultaneous shift $(J, \Delta) \mapsto (J + c, \Delta + c)$, the local Y-functions are invariant under T-gauge changes, and the unordered characteristic roots do not distinguish the dimension root from the spin-shadow root before the gluing/representation assignment is supplied. □

100.3 Q-Omega System and Gauge Choices

The $P\mu$-system is one gauge for the QSC. A dual description uses four functions $Q_i(u)$, $i = 1, \ldots, 4$, and an antisymmetric matrix $\omega_{ij}(u)$. In the standard convention the Q_i have long cuts, while the P_a have one short cut on the principal sheet. The equations mirror the $P\mu$ system. Introduce

$$Q^i = \eta^{ij} Q_j,$$

where η^{ij} is a fixed antisymmetric tensor, normalized in the same unimodular convention as the P-index tensor χ^{ab}. Then

$$\widetilde{Q}_i = \omega_{ij} Q^j, \qquad \widetilde{\omega}_{ij} - \omega_{ij} = Q_i \widetilde{Q}_j - Q_j \widetilde{Q}_i, \qquad \omega_{ij}(u + \mathrm{i}) = \widetilde{\omega}_{ij}(u).$$

The dual Pfaffian normalization is

$$\operatorname{Pf} \omega = \omega_{12}\omega_{34} - \omega_{13}\omega_{24} + \omega_{14}\omega_{23} = 1$$

after the same class of Q-basis gauge transformations used below. The two descriptions are related by the full $Q_{A|I}$ system of finite-difference relations. The useful point for this monograph is not the formal symmetry itself but the bookkeeping: choosing short cuts for P_a and long cuts for Q_i is an analytic gauge. Physical charges are read from large-u asymptotics only after this gauge and the gluing conditions are fixed.

For real left-right symmetric states, the gluing conditions may be written, after a basis choice, as relations between $\widetilde{P}_a(u)$ and complex conjugates of $P_a(u)$ on the real axis outside the cut. These conditions select the physical solution among many formal solutions of the same finite-difference equations. They play the same role as contour data in the mirror TBA.

Dual $Q\omega$ transport. Assume the local $Q\omega$ equations displayed above and the null contraction $Q_iQ^i = 0$. Then, as a local algebraic consequence of these equations, the ω-Pfaffian is transported consistently through a long cut, and the one-step shifted sheet obeys

$$\omega_{ij}(u + \mathrm{i}) = \omega_{ij}(u) + Q_i(u)\omega_{jk}(u)Q^k(u) - Q_j(u)\omega_{ik}(u)Q^k(u). \tag{100.25}$$

Write

$$\widetilde{Q}_i = \omega_{ij}Q^j.$$

The discontinuity equation says that crossing the cut changes ω by the rank-two antisymmetric update

$$\omega \longmapsto \omega + Q \wedge \widetilde{Q}.$$

For an invertible antisymmetric 4×4 matrix M,

$$\mathrm{Pf}(M + v \wedge w) = \mathrm{Pf}(M)\big(1 + w^T M^{-1} v\big).$$

With $M = \omega$, $v = Q$, and $w = \widetilde{Q} = \omega Q^\sharp$, where $(Q^\sharp)^i = Q^i = \eta^{ij}Q_j$, the correction factor is

$$w^T\omega^{-1}Q = (\omega Q^\sharp)^T\omega^{-1}Q = -(Q^\sharp)^T Q = -Q^iQ_i = 0.$$

Hence the Pfaffian normalization, once imposed on one sheet, is preserved by the cut transport. The pseudo-periodicity equation $\omega_{ij}(u + \mathrm{i}) = \widetilde{\omega}_{ij}(u)$ and the discontinuity equation give

$$\omega_{ij}(u + \mathrm{i}) - \omega_{ij}(u) = Q_i(u)\widetilde{Q}_j(u) - Q_j(u)\widetilde{Q}_i(u).$$

Substituting $\widetilde{Q}_j = \omega_{jk}Q^k$ gives (100.25).

The scope of the calculation is the local transport rule after the long-cut gauge has been chosen. A global $Q\omega$ Riemann–Hilbert construction requires the cut structure, gluing data, asymptotics, and gauge fixing. In particular, changing the antisymmetric tensor η, reversing the tilde continuation, or using the opposite $u \mapsto u - \mathrm{i}$ shift convention changes the displayed signs unless the same convention change is made everywhere in the $Q_{A|I}$ bridge.

100.3.1 Local P-Q Bridge

The two QSC gauges are not independent systems. Locally in a strip where the auxiliary Q-functions have no singularities, they are projections of a first-order finite-difference system. The following algebraic statement is the part of that system that is used repeatedly when changing between short-cut and long-cut descriptions.

Assumption 100.9 (Local P-Q bridge)**.** Let $Q_{a|i}(u)$, $a, i = 1, \dots, 4$, be a 4×4 matrix of auxiliary Q-functions with nonzero determinant in the strip under consideration. Let χ^{ab} and η^{ij} be the fixed antisymmetric tensors used to raise P- and Q-indices:

$$P^a = \chi^{ab} P_b, \qquad Q^i = \eta^{ij} Q_j.$$

In the local Q-system gauge assume

$$Q^+_{a|i} - Q^-_{a|i} = P_a Q_i, \tag{100.26}$$

$$Q_i = -P^a Q^-_{a|i}, \qquad P_a = -Q^i Q^-_{a|i}, \tag{100.27}$$

with the null contractions

$$P_a P^a = 0, \qquad Q_i Q^i = 0.$$

The null contractions are automatic once the upper indices are obtained from antisymmetric forms and the same lower vector is contracted with itself. They are nevertheless displayed because they are exactly what makes the choice of $+$ or $-$ shift harmless in the contraction formulae.

The assumption above is not a harmless notational convention. Its nontrivial content is the existence, in a chosen analytic strip and a chosen local Q-system gauge, of an invertible auxiliary matrix $Q_{a|i}$ whose finite-difference jump has rank one and whose projections reproduce the short-cut P_a and long-cut Q_i functions. In the global QSC this datum is part of the Riemann–Hilbert problem: one must specify the cut structure, gluing conditions, large-u asymptotics, possible zeros of $\det Q_{a|i}$, and the residual i-periodic gauge transformations. The local algebra below only records consequences of that datum after those analytic choices have been made.

Unimodular P-Q bridge algebra. Under Assumption 100.9, the contraction identities are independent of the shift:

$$Q_i = -P^a Q^+_{a|i}, \qquad P_a = -Q^i Q^+_{a|i}. \tag{100.28}$$

Moreover

$$\det(Q^+_{a|i}) = \det(Q^-_{a|i}). \tag{100.29}$$

Contract (100.26) with $-P^a$. Using (100.27) and $P_a P^a = 0$ gives

$$-P^a Q^+_{a|i} = -P^a Q^-_{a|i} - P^a P_a Q_i = Q_i.$$

Contracting the same rank-one shift with $-Q^i$ gives

$$-Q^i Q^+_{a|i} = -Q^i Q^-_{a|i} - P_a Q_i Q^i = P_a,$$

which proves (100.28).

For the determinant, write $M_{ai} = Q^-_{a|i}$, regard Q^i as a column vector $Q^\sharp$, and regard Q_i as a row vector $Q^\flat$. The second identity in (100.27) says

$$P = -MQ^\sharp.$$

Therefore

$$Q^+_{a|i} = M_{ai} + P_a Q_i = \big(M(1 - Q^\sharp Q^\flat)\big)_{ai}.$$

The matrix-determinant lemma gives

$$\det(1 - Q^\sharp Q^\flat) = 1 - Q^\flat Q^\sharp = 1 - Q_i Q^i = 1.$$

Thus $\det(Q^+_{a|i}) = \det M = \det(Q^-_{a|i})$.

This calculation is only local algebra. It does not prove the existence of global $Q_{a|i}$ functions with the required cut structure, nor does it fix the physical gluing conditions. It explains why the QSC can be written in a unimodular $Q_{a|i}$ gauge and why the formulae $Q_i = -P^a Q^\pm_{a|i}$, $P_a = -Q^i Q^\pm_{a|i}$ are conventionally quoted without specifying the shift: the rank-one difference has zero contraction in both null directions. Nonconstant i-periodic changes of $Q_{a|i}$ are still analytic gauge transformations; they must be fixed before large-u asymptotics or gluing relations are compared.

100.4 Weak-Coupling Baxter Limit

At weak coupling the short cut collapses to the origin in the rescaled spectral plane. In the $SL(2)$ sector, the QSC reduces to a finite-difference Baxter equation for a polynomial $Q(u)$ whose zeros are one-loop Bethe roots. The equation has the form

$$(u + \mathrm{i}/2)^J Q(u + \mathrm{i}) + (u - \mathrm{i}/2)^J Q(u - \mathrm{i}) = T(u)Q(u), \tag{100.30}$$

where $T(u)$ is a degree-J transfer polynomial fixed by charges and regularity. If

$$Q(u) = \prod_{k=1}^{S} (u - u_k),$$

then evaluating (100.30) at $u = u_j$ gives

$$\left(\frac{u_j + \mathrm{i}/2}{u_j - \mathrm{i}/2}\right)^J = \prod_{\substack{k=1\\k\neq j}}^{S} \frac{u_j - u_k - \mathrm{i}}{u_j - u_k + \mathrm{i}},$$

which is the one-loop $SL(2)$ Bethe equation in this convention. Thus the QSC contains the one-loop spin chain as its weak-coupling degeneration.

Assumption 100.10 (Weak-coupling regularity of the $SL(2)$ QSC)**.** Fix an $SL(2)$ state of twist $J \in \mathbb{Z}_{>0}$, Lorentz spin $S \in \mathbb{Z}_{\geq 0}$, and dimension $\Delta = J + S + O(g^2)$. In the weak-coupling degeneration of the $P\mu$-system assume the following analytic data.

$$P_2 P_3 = O(g^2), \qquad P_1(u) = A_1 u^{-J/2} + O(g^2),$$

and P_4/P_1 tends to a polynomial of degree $J - 1$. Moreover

$$\mu_{12}(u + \mathrm{i}/2) = Q(u) + g^2 R(u) + O(g^4),$$

where $Q(u)$ is a degree-S polynomial and the singular part of R is produced only by the short cuts $[-2g, 2g] + \mathrm{i}n$ collapsing to the points $\mathrm{i}n$. The defining sheet has no additional poles.

Weak $P\mu$ elimination before the Baxter equation. Work in the weak-coupling regularity class of Assumption 100.10. To leading order in g, neglect the P_2P_3 terms in the $(1,2)$ and $(2,4)$ components of the monodromy recursion (100.23). Then

$$\mu_{24} = \frac{\mu_{12}^{[+2]} - \mu_{12}}{P_1^2} - \mu_{12}\frac{P_4}{P_1}, \tag{100.31}$$

and eliminating μ_{24} gives

$$\begin{aligned} &\left(\frac{P_4^{[+1]}}{P_1^{[+1]}} - \frac{P_4^{[-1]}}{P_1^{[-1]}} + \frac{1}{(P_1^{[+1]})^2} + \frac{1}{(P_1^{[-1]})^2}\right)\mu_{12}^{[+1]} \\ &\qquad = \frac{\mu_{12}^{[+3]}}{(P_1^{[+1]})^2} + \frac{\mu_{12}^{[-1]}}{(P_1^{[-1]})^2}. \end{aligned} \tag{100.32}$$

Use $P^1 = -P_4$, $P^4 = P_1$, and discard terms proportional to P_2 or P_3. The $(1,2)$ component of (100.23) gives

$$\mu_{12}^{[+2]} - \mu_{12} = P_1(\mu_{21}P^1 + \mu_{24}P^4) = P_1(\mu_{12}P_4 + \mu_{24}P_1),$$

which is (100.31). The $(2,4)$ component gives

$$\mu_{24}^{[+2]} - \mu_{24} = -P_4(\mu_{21}P^1 + \mu_{24}P^4) = -\frac{P_4}{P_1}(\mu_{12}^{[+2]} - \mu_{12}), \tag{100.33}$$

where the last equality uses the preceding $(1,2)$ equation. Now write (100.31) once at u and once at $u + \mathrm{i}$, and substitute both expressions into (100.33). After shifting the resulting equation by $u \mapsto u - \mathrm{i}/2$, the terms proportional to $\mu_{12}^{[+1]}$ collect exactly into the coefficient displayed in (100.32). This gives the stated elimination formula.

The Baxter equation obtained in this degeneration is the following. Assume the hypotheses of the weak $P\mu$ elimination above. Normalize P_1 so that, at $g = 0$,

$$\frac{1}{(P_1^{[\pm 1]}(u))^2} = (u \pm \mathrm{i}/2)^J,$$

and assume the regular ratio P_4/P_1 is such that

$$T(u) = \frac{P_4^{[+1]}}{P_1^{[+1]}} - \frac{P_4^{[-1]}}{P_1^{[-1]}} + (u + \mathrm{i}/2)^J + (u - \mathrm{i}/2)^J$$

is a degree-J transfer polynomial. With

$$Q(u) = \mu_{12}^{[+1]}(u)\big|_{g=0},$$

the leading weak equation is the Baxter equation

$$(u + \mathrm{i}/2)^J Q(u + \mathrm{i}) + (u - \mathrm{i}/2)^J Q(u - \mathrm{i}) = T(u)Q(u).$$

If $Q(u) = \prod_{k=1}^{S}(u - u_k)$, regularity at the zeros of Q gives the one-loop $SL(2)$ Bethe equations. Equation (100.32), with the stated leading asymptotics of P_1, is exactly the displayed Baxter equation. The right side is regular at every zero u_j of Q, so the left side must vanish there:

$$(u_j + \mathrm{i}/2)^J Q(u_j + \mathrm{i}) + (u_j - \mathrm{i}/2)^J Q(u_j - \mathrm{i}) = 0.$$

Dividing by $(u_j - \mathrm{i}/2)^J Q(u_j - \mathrm{i})$ and using

$$\frac{Q(u_j - \mathrm{i})}{Q(u_j + \mathrm{i})} = -\prod_{\substack{k=1\\k\neq j}}^{S} \frac{u_j - u_k - \mathrm{i}}{u_j - u_k + \mathrm{i}}$$

gives the displayed Bethe equation.

Lemma 100.11 (Half-integer digamma primitive)**.** *Let*

$$\Phi(u) = \psi\left(\frac{1}{2} - \mathrm{i}u\right) + \psi\left(\frac{1}{2} + \mathrm{i}u\right), \qquad \psi = \Gamma'/\Gamma.$$

As a meromorphic function of u, Φ has only simple poles at

$$u = \pm\mathrm{i}\left(n + \frac{1}{2}\right), \qquad n \in \mathbb{Z}_{\geq 0}.$$

It satisfies the one-step shift identities

$$\Phi(u+\mathrm{i}) - \Phi(u) = \frac{2\mathrm{i}}{u + \mathrm{i}/2}, \qquad \Phi(u) - \Phi(u - \mathrm{i}) = \frac{2\mathrm{i}}{u - \mathrm{i}/2}, \tag{100.34}$$

and hence the central second-difference identity

$$\Phi(u+\mathrm{i}) - 2\Phi(u) + \Phi(u-\mathrm{i}) = \frac{2}{u^2 + 1/4}. \tag{100.35}$$

Moreover, if G is another meromorphic function with the same two one-step defects in (100.34)*, then $G - \Phi$ is* i*-periodic wherever both functions are holomorphic. If this difference extends to an entire function bounded on a vertical fundamental strip $0 \leq \operatorname{Im} u \leq 1$, then $G - \Phi$ is constant.*

Proof. The pole statement follows from the poles of ψ at $0, -1, -2, \ldots$. The recurrence relation

$$\psi(z+1) = \psi(z) + \frac{1}{z}$$

gives

$$\begin{aligned}\Phi(u+\mathrm{i}) &= \psi\left(\frac{3}{2} - \mathrm{i}u\right) + \psi\left(-\frac{1}{2} + \mathrm{i}u\right)\\ &= \psi\left(\frac{1}{2} - \mathrm{i}u\right) + \frac{1}{1/2 - \mathrm{i}u} + \psi\left(\frac{1}{2} + \mathrm{i}u\right) - \frac{1}{-1/2 + \mathrm{i}u}.\end{aligned}$$

Since $1/2 - \mathrm{i}u = -\mathrm{i}(u + \mathrm{i}/2)$, this is the first identity in (100.34). For the second identity, write

$$\begin{aligned}\Phi(u-\mathrm{i}) &= \psi\left(-\frac{1}{2} - \mathrm{i}u\right) + \psi\left(\frac{3}{2} + \mathrm{i}u\right)\\ &= \psi\left(\frac{1}{2} - \mathrm{i}u\right) - \frac{1}{-1/2 - \mathrm{i}u} + \psi\left(\frac{1}{2} + \mathrm{i}u\right) + \frac{1}{1/2 + \mathrm{i}u},\end{aligned}$$

which is the second displayed defect formula after rewriting the denominators as shifts of u. Subtracting the two one-step identities gives (100.35).

If G has the same one-step defects, then

$$(G - \Phi)(u + \mathrm{i}) = (G - \Phi)(u)$$

on the common holomorphy domain. If this difference is entire and bounded on a vertical fundamental strip, periodicity bounds it on all of $\mathbb{C}$; Liouville's theorem makes it constant. □

Collapsed-cut digamma package. Let $Q(u)$ be a polynomial with $Q(\mathrm{i}/2) \neq 0$, and set

$$r_0 = Q'(\mathrm{i}/2) - Q'(-\mathrm{i}/2).$$

Define

$$R_{\text{sing}}(u) = \mathrm{i}r_0\, \frac{Q(u)}{Q(\mathrm{i}/2)} \left(\psi\left(\frac{1}{2} - \mathrm{i}u\right) + \psi\left(\frac{1}{2} + \mathrm{i}u\right)\right), \qquad \psi = \Gamma'/\Gamma. \tag{100.36}$$

Then R_{sing} has only simple poles at

$$u = \pm\mathrm{i}\left(n + \frac{1}{2}\right), \qquad n \in \mathbb{Z}_{\geq 0},$$

and their residues are

$$\operatorname*{Res}_{u=\mathrm{i}(n+1/2)} R_{\text{sing}} = -r_0\, \frac{Q(\mathrm{i}(n+1/2))}{Q(\mathrm{i}/2)},$$
$$\operatorname*{Res}_{u=-\mathrm{i}(n+1/2)} R_{\text{sing}} = r_0\, \frac{Q(-\mathrm{i}(n+1/2))}{Q(\mathrm{i}/2)}.$$

In particular, if $Q(\mathrm{i}/2) = Q(-\mathrm{i}/2)$, the residues at $\mathrm{i}/2$ and $-\mathrm{i}/2$ are $-r_0$ and r_0. In the large-u sector used for the $SL(2)$ asymptotics,

$$\frac{R_{\text{sing}}(u)}{Q(u)} = 2\mathrm{i}\, \frac{r_0}{Q(\mathrm{i}/2)} \log u + O(u^{-1}).$$

Finally, for the meromorphic quotient $F_{\text{sing}}(u) = R_{\text{sing}}(u)/Q(u)$,

$$F_{\text{sing}}(u+\mathrm{i}) - F_{\text{sing}}(u) = -\frac{2r_0}{Q(\mathrm{i}/2)(u+\mathrm{i}/2)}, \qquad F_{\text{sing}}(u) - F_{\text{sing}}(u-\mathrm{i}) = -\frac{2r_0}{Q(\mathrm{i}/2)(u-\mathrm{i}/2)}. \tag{100.37}$$

The residue formulas follow from the pole structure of ψ. The digamma function has simple poles at $0, -1, -2, \ldots$, each with residue -1. The factor $\psi(1/2 + \mathrm{i}u)$ therefore has a pole at $u = \mathrm{i}(n+1/2)$; since

$$\frac{1}{2} + \mathrm{i}u + n = \mathrm{i}\big(u - \mathrm{i}(n+1/2)\big),$$

its residue as a function of u is $-1/\mathrm{i} = \mathrm{i}$. Multiplication by the prefactor $\mathrm{i}r_0 Q(u)/Q(\mathrm{i}/2)$ gives the first residue formula. The factor $\psi(1/2 - \mathrm{i}u)$ gives the second formula in the same way, because

$$\frac{1}{2} - \mathrm{i}u + n = -\mathrm{i}\big(u + \mathrm{i}(n+1/2)\big)$$

and hence the residue in u is $-1/(-\mathrm{i}) = -\mathrm{i}$.

Finally, Stirling's expansion gives

$$\psi(z) = \log z + O(z^{-1})$$

in sectors avoiding the negative real axis. Applying this to $z = 1/2 \pm \mathrm{i}u$ in the chosen large-u sector gives

$$\psi\left(\frac{1}{2} - \mathrm{i}u\right) + \psi\left(\frac{1}{2} + \mathrm{i}u\right) = 2\log u + O(u^{-1}),$$

with the branch inherited from the QSC large-u sheet. This proves the logarithmic coefficient. The quotient shift identities (100.37) follow by multiplying (100.34) by $\mathrm{i}r_0/Q(\mathrm{i}/2)$.

One-loop dimension from the weak QSC. Assume the regular weak-coupling degeneration of Assumption 100.10, and impose the cyclic single-trace condition

$$\frac{Q(\mathrm{i}/2)}{Q(-\mathrm{i}/2)} = 1.$$

Then the first anomalous-dimension coefficient extracted from the QSC is

$$\Delta = J + S + 2\mathrm{i}g^2\, \partial_u \log \frac{Q(u+\mathrm{i}/2)}{Q(u-\mathrm{i}/2)}\bigg|_{u=0} + O(g^4).$$

Equivalently, if $Q(u) = \prod_{k=1}^{S}(u-u_k)$, then

$$\Delta = J + S + 2g^2 \sum_{k=1}^{S} \frac{1}{u_k^2 + 1/4} + O(g^4).$$

The leading $P_2P_3 = O(g^2)$ scaling decouples the (μ_{12}, μ_{24}) equations of the $P\mu$-system. Eliminating μ_{24}, and using the regularity of P_1 and P_4/P_1 in Assumption 100.10, gives the Baxter equation derived above for $Q(u) = \mu_{12}(u + \mathrm{i}/2) + O(g^2)$. The same i-pseudoperiodicity of μ_{12}, evaluated at the collapsed branch point, gives the cyclicity condition $Q(\mathrm{i}/2) = Q(-\mathrm{i}/2)$.

It remains to extract the coefficient of g^2 in Δ. Since $\mu_{12}(u) \sim u^{\Delta-J}$ and $Q(u-\mathrm{i}/2) \sim u^S$, the ratio $\mu_{12}(u)/Q(u-\mathrm{i}/2)$ has the large-u expansion

$$1 + (\Delta - J - S)\log u + O(g^4) + O(u^{-1}).$$

The collapsed square-root cuts force the singular part of the g^2 correction to $\mu_{12}(u+\mathrm{i}/2)$ to be (100.36). The collapsed-cut calculation above shows that this expression has the prescribed simple poles at the collapsed cuts, with residues fixed by the branch-point relation and cyclic endpoint condition. More precisely, after division by the leading Baxter polynomial, the singular quotient has the one-step defects (100.37). These defects are the collapsed-cut remnant of the square-root decomposition of μ_{12}; by Lemma 100.11, they fix the non-regular meromorphic primitive up to an entire i-periodic ambiguity. In the weak-coupling regularity class of Assumption 100.10, that ambiguity belongs to the regular polynomial/asymptotic-power part of R, and it carries no $\log u$ term. Comparing the logarithmic coefficient in the collapsed-cut calculation with the large-u expansion of μ_{12}/Q gives

$$\Delta - J - S = 2\mathrm{i}g^2\, \frac{Q'(\mathrm{i}/2) - Q'(-\mathrm{i}/2)}{Q(\mathrm{i}/2)} + O(g^4).$$

Using $Q(\mathrm{i}/2) = Q(-\mathrm{i}/2)$ rewrites this as the derivative formula. Finally

$$\mathrm{i}\left(\frac{Q'(\mathrm{i}/2)}{Q(\mathrm{i}/2)} - \frac{Q'(-\mathrm{i}/2)}{Q(-\mathrm{i}/2)}\right) = \sum_{k=1}^{S} \frac{1}{u_k^2 + 1/4},$$

which proves the root-sum form.

Example 100.12 (Konishi Baxter polynomial)**.** For the twist-two spin-two representative of Konishi, take

$$J = 2, \qquad S = 2, \qquad Q(u) = u^2 - \frac{1}{12}.$$

Then

$$(u+\mathrm{i}/2)^2Q(u+\mathrm{i})+(u-\mathrm{i}/2)^2Q(u-\mathrm{i})=\left(2u^2-\frac{13}{2}\right)Q(u).$$

Thus the transfer polynomial is $T(u)=2u^2-13/2$, and the zeros

$$u=\pm\frac{1}{2\sqrt{3}}$$

are precisely the one-loop Konishi Bethe roots used in Chapter 97. This example is a finite calculation showing how the QSC weak-coupling limit remembers the spin-chain normalization.

Proposition 100.13 (Twist-two Baxter family)**.** *For twist $J=2$ and spin S, define the terminating polynomial*

$$Q_S(u)={}_3F_2\left(\begin{matrix}-S,\ S+1,\ \frac{1}{2}-\mathrm{i}u\\ 1,\ 1\end{matrix};1\right),$$

where $(a)_k$ is the rising Pochhammer symbol in the terminating hypergeometric series. It obeys

$$(u+\mathrm{i}/2)^2Q_S(u+\mathrm{i})+(u-\mathrm{i}/2)^2Q_S(u-\mathrm{i})=\left(2u^2-S(S+1)-\frac{1}{2}\right)Q_S(u).$$

Thus $T_S(u)=2u^2-S(S+1)-1/2$. The endpoint values and logarithmic derivative are the finite identities

$$Q_S(-\mathrm{i}/2)=1,\qquad Q_S(\mathrm{i}/2)=(-1)^S,\qquad \mathrm{i}\left(\frac{Q_S'(\mathrm{i}/2)}{Q_S(\mathrm{i}/2)}-\frac{Q_S'(-\mathrm{i}/2)}{Q_S(-\mathrm{i}/2)}\right)=4H_S,$$

with $H_S=\sum_{m=1}^{S}m^{-1}$. Hence the physical even-spin twist-two single-trace states have

$$\Delta_{J=2,S}=2+S+8g^2H_S+O(g^4).$$

For $S=2$, $Q_2(u)=1/4-3u^2$, which is the same root set as the monic Konishi polynomial $u^2-1/12$, and the formula gives $\Delta_{\mathrm{K}}=4+12g^2+O(g^4)$.

Proof. Put

$$z=\frac{1}{2}-\mathrm{i}u,\qquad Q_S(u)=\widehat{Q}_S(z),$$

so that $u+\mathrm{i}/2=\mathrm{i}z$, $u-\mathrm{i}/2=\mathrm{i}(z-1)$, and the shifts $u\mapsto u\pm\mathrm{i}$ become $z\mapsto z\pm 1$. The Baxter equation is equivalent to

$$z^2\widehat{Q}_S(z+1)+(z-1)^2\widehat{Q}_S(z-1)=\big(2z^2-2z+S(S+1)+1\big)\widehat{Q}_S(z).$$

Write the k-th summand of $\widehat{Q}_S$ as

$$\tau_k(z)=\frac{(-S)_k(S+1)_k(z)_k}{(k!)^3},\qquad 0\le k\le S,$$

and set $\tau_k=0$ outside this range. For $k\ge 1$,

$$(z+1)_k=(z)_k\frac{z+k}{z},\qquad (z-1)_k=(z)_k\frac{z-1}{z+k-1}.$$

A direct substitution gives the summand identity

$$\begin{aligned}z^2\tau_k(z+1)+(z-1)^2\tau_k(z-1)-\big(2z^2-2z+S(S+1)+1\big)\tau_k(z)\\=\frac{(k+1)^3}{z+k}\tau_{k+1}(z)-\frac{k^3}{z+k-1}\tau_k(z).\end{aligned}$$

The identity is first read away from the apparent poles $z=1-k$ and then extended across the removable singularities by polynomial continuation. It is a finite telescoping identity. The right side sums to zero because the lower boundary has the factor k^3 and the upper boundary has $\tau_{S+1}=0$. Hence the z-form of the Baxter equation holds, and the displayed Baxter equation follows after returning to u.

The endpoint $u=-\mathrm{i}/2$ corresponds to $z=0$, so $\widehat{Q}_S(0)=1$. The endpoint $u=\mathrm{i}/2$ corresponds to $z=1$, and Chu–Vandermonde gives the finite sum

$$\widehat{Q}_S(1)={}_2F_1(-S,S+1;1;1)=\frac{(-S)_S}{S!}=(-1)^S.$$

It remains to prove the logarithmic-derivative identity. Since

$$\frac{d}{du}Q_S(u)=-\mathrm{i}\,\widehat{Q}'_S(z),$$

we must compute the endpoint logarithmic derivatives of $\widehat{Q}_S$. First,

$$\widehat{Q}'_S(0)=\sum_{k=1}^{S}\frac{(-S)_k(S+1)_k}{(k!)^2\,k}. \tag{100.38}$$

Indeed $d(z)_k/dz|_{z=0}=(k-1)!$. The same sum may be written as

$$\widehat{Q}'_S(0)=\int_0^1\frac{{}_2F_1(-S,S+1;1;t)-1}{t}\,dt.$$

Using ${}_2F_1(-S,S+1;1;t)=\mathsf{P}_S(1-2t)$, where P_S is the Legendre polynomial, and setting $x=1-2t$, this is

$$I_S=\int_{-1}^1\frac{\mathsf{P}_S(x)-1}{1-x}\,dx.$$

The finite Christoffel–Darboux identity at one endpoint,

$$n\,\frac{\mathsf{P}_n(x)-\mathsf{P}_{n-1}(x)}{x-1}=\sum_{\ell=0}^{n-1}(2\ell+1)\mathsf{P}_\ell(x),$$

is the telescoping form of the Legendre three-term recurrence. It gives $I_n-I_{n-1}=-2/n$ after integration, because only the $\ell=0$ Legendre polynomial has nonzero integral over $[-1,1]$. Since $I_0=0$,

$$\widehat{Q}'_S(0)=-2H_S.$$

At $z=1$,

$$\widehat{Q}'_S(1)=\sum_{k=1}^{S}\frac{(-S)_k(S+1)_k}{(k!)^2}H_k.$$

This is obtained from $d(1)_k/dz = k!H_k$. Differentiate Chu–Vandermonde in the denominator parameter:

$$F(a) = {}_2F_1(-S, S+1; a; 1) = \frac{(a-S-1)_S}{(a)_S}.$$

At $a = 1$,

$$\frac{F'(1)}{F(1)} = \sum_{m=0}^{S-1} \frac{1}{1-S-1+m} - \sum_{m=0}^{S-1} \frac{1}{1+m} = -2H_S.$$

On the other hand differentiating the series in a gives

$$F'(1) = -\widehat{Q}'_S(1).$$

Since $F(1) = (-1)^S$, we obtain

$$\frac{\widehat{Q}'_S(1)}{\widehat{Q}_S(1)} = 2H_S.$$

Therefore

$$\mathrm{i}\left(\frac{Q'_S(\mathrm{i}/2)}{Q_S(\mathrm{i}/2)} - \frac{Q'_S(-\mathrm{i}/2)}{Q_S(-\mathrm{i}/2)}\right) = \frac{\widehat{Q}'_S(1)}{\widehat{Q}_S(1)} - \frac{\widehat{Q}'_S(0)}{\widehat{Q}_S(0)} = 4H_S.$$

The dimension formula is now the specialization of the weak-QSC one-loop dimension extraction above. □

100.5 Cusp Anomalous Dimension and Konishi

Two benchmark spectral quantities organize many tests of the framework. The first is the cusp anomalous dimension $f(\lambda)$, extracted from large spin twist operators:

$$\Delta - S = f(\lambda)\log S + O(S^0), \qquad S \to \infty.$$

The QSC reproduces the same function obtained from the BES equation. At weak coupling it has a perturbative series in g^2; at strong coupling the QSC asymptotics begin with

$$f(\lambda) = \frac{\sqrt{\lambda}}{\pi} + O(\lambda^0)$$

in the convention where $\Delta - S = f(\lambda)\log S + O(S^0)$. Comparisons with semiclassical string theory are historically important but are not used as inputs to the QFT-side spectral problem in this chapter.

The second is the Konishi dimension. The QSC treats it as an ordinary finite state with $J = 2$, $S = 2$, and zero total momentum. At weak coupling it matches the asymptotic Bethe ansatz until wrapping corrections enter; at strong coupling it gives the QSC strong-coupling expansion

$$\Delta_{\mathrm{K}}(\lambda) = 2\lambda^{1/4} + O(\lambda^0).$$

The numerical and analytic solution of the QSC is a calculation problem inside the finite functional system (100.10)–(100.12).

100.6 Small Spin Expansion

The QSC gives a controlled analytic expansion near $S = 0$, where the state approaches the protected vacuum. The finite coefficient calculation below begins after the following local analytic germ has been supplied.

Assumption 100.14 (Small-spin QSC germ)**.** Fix the twist $J \in \mathbb{Z}_{>0}$ and let S be a complex spin parameter near 0. Assume that the physical QSC solution admits a gauge in which the $S = 0$ limit is the protected vacuum and the first nonzero deformation has $\epsilon^2 = O(S)$. In this gauge the leading μ-matrix is

$$\mu_{12} = -1, \quad \mu_{13} = 0, \quad \mu_{14} = \mu_{23} = 1, \quad \mu_{24} = -\sinh(2\pi u), \quad \mu_{34} = 0.$$

Writing

$$x(u) = \frac{u}{2g} + \sqrt{\frac{u^2}{4g^2} - 1},$$

with the short-cut branch, the leading solution has

$$P_1 = \epsilon x^{-J/2}, \qquad P_3 = \epsilon(x^{-J/2} - x^{J/2}),$$

and the remaining two P-functions are obtained by solving the local $P\mu$ equations with the displayed μ-matrix and imposing single-short-cut regularity. Equivalently, the Laurent expansion of $\sinh(2\pi u)$ is split into the powers allowed in P_2 and P_4. Since

$$u = g(x + x^{-1}),$$

the modified-Bessel generating function gives

$$\sinh(2\pi u) = \sum_{n\in\mathbb{Z}} I_{2n+1}(4\pi g)x^{2n+1}. \tag{100.39}$$

Here I_m is the modified Bessel function of the first kind. The first large-x coefficients produced by the regularity split are

$$P_2 = -\epsilon I_{J+1}(4\pi g)x^{-J/2-1} + O(x^{-J/2-3}), \qquad P_4 = -\epsilon I_{J-1}(4\pi g)x^{J/2-1} + O(x^{J/2-3}).$$

In the large-u normalization of the coefficient-product calculation above,

$$A_1 = \epsilon g^{J/2}, \quad A_2 = -\epsilon g^{J/2+1} I_{J+1}(4\pi g), \quad A_3 = -\epsilon g^{-J/2}, \quad A_4 = -\epsilon g^{-J/2+1} I_{J-1}(4\pi g).$$

The corresponding large-u charge relations are

$$\Delta - J = -\mathrm{i}(A_1A_4 - A_2A_3) + O(S^2), \qquad S = -\mathrm{i}(A_1A_4 + A_2A_3) + O(S^2).$$

Small-spin QSC slope extraction. Under Assumption 100.14, the leading anomalous dimension satisfies

$$\Delta - J - S = \frac{4\pi g\, I_{J+1}(4\pi g)}{J\, I_J(4\pi g)}\, S + O(S^2).$$

The finite calculation is as follows. First prove the Laurent identity (100.39). The generating function

$$\exp\Big(\frac{z}{2}(t+t^{-1})\Big) = \sum_{m\in\mathbb{Z}} I_m(z)t^m$$

with $z = 4\pi g$ and $t = x$ gives $\exp(2\pi g(x+x^{-1})) = \sum_m I_m(4\pi g)x^m$. Replacing x by $-x$ gives the negative exponential. Taking half the difference selects exactly the odd powers and proves (100.39).

The displayed leading coefficients then give

$$A_1A_4 = -\epsilon^2 g\, I_{J-1}(4\pi g), \qquad A_2A_3 = \epsilon^2 g\, I_{J+1}(4\pi g).$$

Substituting these products into the large-u charge relations in Assumption 100.14 yields

$$\Delta - J = \mathrm{i}\epsilon^2 g\big(I_{J-1}(4\pi g) + I_{J+1}(4\pi g)\big) + O(S^2),$$

and

$$S = \mathrm{i}\epsilon^2 g\big(I_{J-1}(4\pi g) - I_{J+1}(4\pi g)\big) + O(S^2).$$

Use the modified-Bessel recurrence

$$I_{J-1}(z) - I_{J+1}(z) = \frac{2J}{z} I_J(z), \qquad z = 4\pi g.$$

It gives

$$\epsilon^2 = \frac{2\pi S}{\mathrm{i}J I_J(4\pi g)} + O(S^2).$$

Therefore

$$\Delta - J - S = 2\mathrm{i}\epsilon^2 g\, I_{J+1}(4\pi g) + O(S^2) = \frac{4\pi g\, I_{J+1}(4\pi g)}{J\, I_J(4\pi g)} S + O(S^2),$$

which is the stated slope.

Continuing the resulting strong-coupling expansion to $J = 2, S = 2$ gives the Konishi estimate

$$\Delta_{\mathrm{K}} = 2\lambda^{1/4} + 2\lambda^{-1/4} + O(\lambda^{-3/4}).$$

The analytic continuation from small spin to integer spin is a QSC input, not a theorem proved from the gauge-theory path integral.

100.7 Hexagon Form Factors

The spectral problem determines scaling dimensions. Three-point functions require additional data. In the planar limit, a single-trace three-point function can be represented by a pair of pants worldsheet. The hexagon program cuts this pair of pants into two hexagons and assigns a form factor to each half.

For three single-trace operators with spin-chain lengths L_1, L_2, L_3, the bridge lengths are

$$\ell_{12} = \frac{L_1 + L_2 - L_3}{2}, \qquad \ell_{23} = \frac{L_2 + L_3 - L_1}{2}, \qquad \ell_{31} = \frac{L_3 + L_1 - L_2}{2}.$$

Remark 100.15 (Planar bridge-length bookkeeping). Consider the planar tree-level pair-of-pants skeleton for three cyclic single-trace operators of lengths L_1, L_2, L_3. Let $\ell_{ij} = \ell_{ji}$ be the number of adjacent Wick-contraction slots shared by operators i and j. Then the bridge lengths are forced to be

$$\ell_{12} = \frac{L_1 + L_2 - L_3}{2}, \qquad \ell_{23} = \frac{L_2 + L_3 - L_1}{2}, \qquad \ell_{31} = \frac{L_3 + L_1 - L_2}{2}. \tag{100.40}$$

Conversely, a nonnegative integer planar skeleton of this type exists exactly when $L_1 + L_2 + L_3$ is even and the three triangle inequalities $L_i + L_j \geq L_k$ hold.

In the planar skeleton each trace is cut at two cyclic splitting points. The letters of operator 1 are divided into the bridge shared with operator 2 and the bridge shared with operator 3, and similarly for the other two operators. Hence

$$L_1 = \ell_{12} + \ell_{31}, \qquad L_2 = \ell_{12} + \ell_{23}, \qquad L_3 = \ell_{23} + \ell_{31}.$$

Adding the first two equations and subtracting the third gives $2\ell_{12} = L_1 + L_2 - L_3$. The other two formulae follow by cyclic permutation. Since ℓ_{ij} counts letters, the right-hand sides must be nonnegative integers; this is precisely even total length plus the triangle inequalities. Conversely, if these conditions hold, the three numbers in (100.40) define nonnegative integer arcs on the three cyclic words satisfying the displayed length-balance equations, which is the required pair-of-pants skeleton.

Asymptotically, the structure constant is a sum over partitions of magnons between the two hexagons:

$$C_{123}^{\text{asym}} = \sum_{\alpha \cup \bar{\alpha} = \{u\}} (-1)^{|\bar{\alpha}|} \mathrm{e}^{\mathrm{i}p(\bar{\alpha})\ell} H(\alpha) H(\bar{\alpha}) \mathcal{N}^{-1/2}.$$

Here the displayed formula is the specialization in which the magnons shown belong to one external operator: ℓ is the bridge crossed by the subset $\bar{\alpha}$, H is the hexagon form factor, and

$$p(\bar{\alpha}) = \sum_{u_j \in \bar{\alpha}} p(u_j).$$

The phase is the spin-chain translation phase. Moving a magnon of momentum p_j through ℓ vacuum letters multiplies the coordinate Bethe wave by $\mathrm{e}^{\mathrm{i}p_j\ell}$, and moving all magnons in $\bar{\alpha}$ gives

$$\prod_{u_j \in \bar{\alpha}} \mathrm{e}^{\mathrm{i}p_j\ell} = \mathrm{e}^{\mathrm{i}p(\bar{\alpha})\ell}. \tag{100.41}$$

The factor $\mathcal{N}$ is the Gaudin norm factor of the Bethe state. Mirror particles on the bridges add finite-size corrections, analogous in spirit to wrapping corrections in the spectral problem.

For scalar magnons the elementary two-particle scalar factor entering the hexagon can be written, in the same $x^{\pm}$ and σ conventions as Chapter 98, as

$$h(u,v) = \frac{x_u^- - x_v^-}{x_u^- - x_v^+} \frac{1 - 1/(x_u^+ x_v^-)}{1 - 1/(x_u^+ x_v^+)} \frac{1}{\sigma(u,v)}. \tag{100.42}$$

The matrix part is the same centrally extended symmetry intertwiner that appears in the magnon S-matrix, after the crossing moves needed to put excitations on a chosen hexagon edge. Thus the hexagon construction imports the same analytic-continuation obligations: specifying $h(u,v)$ without the crossing path of the moved excitation is incomplete.

Hexagon scalar Watson factor. Let $x_i^\pm$, $i=1,2$, be non-zero Zhukovsky variables in a sheet domain where the denominators below do not vanish, and write $\sigma_{ij}=\sigma(x_i^\pm,x_j^\pm)$. Assume scalar dressing unitarity $\sigma_{12}\sigma_{21}=1$ on this domain. If $h_{12}=h(u_1,u_2)$ is defined by (100.42), then

$$\frac{h_{12}}{h_{21}}=S^{\rm hex}_{\rm scal}(1,2),\qquad S^{\rm hex}_{\rm scal}(1,2)=\frac{x_1^+-x_2^-}{x_1^--x_2^+}\frac{1-1/(x_1^+x_2^-)}{1-1/(x_1^-x_2^+)}\frac{1}{\sigma_{12}^2}. \tag{100.43}$$

On the weak physical branch

$$x_i^\pm=\frac{u_i\pm {\rm i}/2}{g}+O(g),\qquad \sigma_{12}=1+O(g^6),$$

with $u_1-u_2\neq {\rm i}$, this becomes

$$S^{\rm hex}_{\rm scal}(1,2)=\frac{u_1-u_2+{\rm i}}{u_1-u_2-{\rm i}}+O(g^2). \tag{100.44}$$

From (100.42),

$$\frac{h_{12}}{h_{21}}=\frac{x_1^--x_2^-}{x_1^--x_2^+}\frac{x_2^--x_1^+}{x_2^--x_1^-}\frac{1-1/(x_1^+x_2^-)}{1-1/(x_1^+x_2^+)}\frac{1-1/(x_2^+x_1^+)}{1-1/(x_2^+x_1^-)}\frac{\sigma_{21}}{\sigma_{12}}.$$

The first two rational factors reduce to

$$\frac{x_1^--x_2^-}{x_2^--x_1^-}\frac{x_2^--x_1^+}{x_1^--x_2^+}=\frac{x_1^+-x_2^-}{x_1^--x_2^+}.$$

The middle denominator $1-1/(x_1^+x_2^+)$ cancels the identical factor $1-1/(x_2^+x_1^+)$, and the remaining denominator is $1-1/(x_1^-x_2^+)$. Finally scalar dressing unitarity gives $\sigma_{21}/\sigma_{12}=1/\sigma_{12}^2$. This proves (100.43).

For the weak limit, the first rational factor is

$$\frac{(u_1+{\rm i}/2)/g-(u_2-{\rm i}/2)/g+O(g)}{(u_1-{\rm i}/2)/g-(u_2+{\rm i}/2)/g+O(g)}=\frac{u_1-u_2+{\rm i}}{u_1-u_2-{\rm i}}+O(g^2).$$

The second rational factor is $1+O(g^2)$, because $(x_i^\pm x_j^\pm)^{-1}=O(g^2)$, and the dressing factor contributes $1+O(g^6)$. This proves (100.44).

The weak factor in (100.44) is the compact one-loop exchange phase. It should not be identified with the rank-one $SL(2)$ phase in (98.30) unless the vacuum, edge-crossing path, and scalar-factor split have all been transported to the same convention.

Open Problem 100.16 (Derivation of the hexagon expansion). Give a derivation of the hexagon expansion from a nonperturbatively defined planar gauge-theory path integral, including the emergence of the hexagon form factor, the measure for mirror corrections, and the treatment of operator mixing at finite length. Existing evidence is strong inside the integrability framework. A derivation at the level of a theorem in four-dimensional QFT remains open.

100.8 Maldacena–Wilson Line, Cusp, and Bremsstrahlung

Let C be an oriented smooth curve with parameter s, tangent $\dot{x}^\mu(s)$, and scalar-coupling unit vector $\theta^I(s) \in S^5$. The Maldacena–Wilson line in the fundamental representation is

$$W_{\mathrm{MW}}(C, \theta) = \mathrm{Tr}\ P \exp \int_C \big(\mathrm{i} A_\mu(x(s))\dot{x}^\mu(s) + \Phi_I(x(s))\theta^I(s)|\dot{x}(s)|\big)\,\mathrm{d}s.$$

It is a gauge-invariant line operator after taking the trace and imposing the usual endpoint prescription for closed curves or external heavy sources. A straight line with constant θ is half-BPS and has vanishing cusp anomalous dimension.

For two rays meeting with Euclidean deflection angle φ, define $\Gamma_{\mathrm{cusp}}(\varphi, \theta)$ by the logarithmic divergence of the renormalized cusped line:

$$\log\langle W_{\mathrm{cusp}}\rangle_{\mathrm{ren}} = -\Gamma_{\mathrm{cusp}}(\varphi) \log \frac{R}{\epsilon} + O(1),$$

where R is an infrared distance scale and ϵ is the short-distance cutoff at the cusp. At small geometric angle and fixed scalar coupling,

$$\Gamma_{\mathrm{cusp}}(\varphi) = -B(\lambda)\varphi^2 + O(\varphi^4).$$

The coefficient $B(\lambda)$ is the Bremsstrahlung function. On the straight-line defect, the transverse displacement operators $\mathbb{D}_i(t)$ are defined by the first shape variation of the line; $i = 1, 2, 3$ labels directions normal to the straight Euclidean line. Conformal invariance on the defect fixes their two-point function to

$$\langle \mathbb{D}_i(t)\mathbb{D}_j(0)\rangle = \frac{C_D \delta_{ij}}{(t - \mathrm{i}0)^4}.$$

Displacement normalization of the small cusp. Assume the straight half-BPS line admits the standard defect shape-variation Ward identity: for a small transverse deformation $X^i(t)$ of compact support, the universal nonlocal quadratic part of $\log\langle W_X\rangle$ is, with summation over the transverse index i,

$$\frac{1}{2}\int \frac{\mathrm{d}\omega}{2\pi}\, \frac{\pi C_D}{6} |\omega|^3 \widehat{X}^i(\omega)\widehat{X}^i(-\omega),$$

up to local counterterms polynomial in ω. Equivalently, this fixes the nonlocal part of the finite-part Fourier transform of the displacement two-point distribution,

$$\mathrm{Fp}\int \mathrm{d}t\, \frac{\mathrm{e}^{\mathrm{i}\omega t}}{(t - \mathrm{i}0)^4} = \frac{\pi}{6}|\omega|^3 + \text{a polynomial in } \omega.$$

Then the small-angle cusp coefficient satisfies

$$C_D = 12B(\lambda).$$

Represent a cusp of small angle φ by a deformation of the straight line for which

$$X^1(t) = \varphi t\, \Theta(t)$$

between the scales ϵ and R, with a smooth interpolation outside that window. Different smoothings change only power divergences and finite terms. In the logarithmic momentum window $R^{-1} \ll |\omega| \ll \epsilon^{-1}$,

$$\widehat{X}^1(\omega) = -\frac{\varphi}{(\omega + \mathrm{i}0)^2} + \text{endpoint and zero-frequency terms} + O(R^{-1}, \epsilon).$$

The endpoint terms depend on the infrared smoothing and give only power divergences or finite oscillatory contributions, while the polynomial/contact terms and the $\omega = 0$ terms do not affect the coefficient of $\log(R/\epsilon)$. Hence the universal logarithmic contribution is

$$\frac{1}{2}\int_{R^{-1}<|\omega|<\epsilon^{-1}} \frac{\mathrm{d}\omega}{2\pi}\,\frac{\pi C_D}{6}|\omega|^3\frac{\varphi^2}{\omega^4} = \frac{C_D}{12}\varphi^2 \log\frac{R}{\epsilon}.$$

By the definition of the cusp anomalous dimension,

$$\log\langle W_{\text{cusp}}\rangle_{\text{ren}}\big|_{\log} = -\Gamma_{\text{cusp}}(\varphi)\log\frac{R}{\epsilon}.$$

Using $\Gamma_{\text{cusp}}(\varphi) = -B(\lambda)\varphi^2 + O(\varphi^4)$ and comparing the quadratic logarithmic coefficient gives $B = C_D/12$.

Thus the radiated power of a slowly accelerating heavy probe is

$$\frac{\mathrm{d}E_{\text{rad}}}{\mathrm{d}t} = 2\pi B(\lambda)\,\dot{v}^2.$$

The protected circular-loop matrix model is derived in Theorem 101.22. In the convention where the circular-loop Gaussian coupling of Definition 101.21 is the planar coupling λ used in this chapter, the supersymmetric Ward identity relating the circular loop to the small-angle cusp gives

$$B(\lambda) = \frac{\sqrt{\lambda}}{4\pi^2}\frac{I_2(\sqrt{\lambda})}{I_1(\sqrt{\lambda})} \qquad (N = \infty).$$

The algebraic step from the circular-loop answer $2I_1(\sqrt{\lambda})/\sqrt{\lambda}$ to this expression is Remark 101.23. The genuinely field-theoretic input is the protected Ward identity (101.50); the QSC and mirror-TBA descriptions of the cusped line reproduce the same function with cusp-specific asymptotic data, providing a stringent normalization check on $g = \sqrt{\lambda}/(4\pi)$.

Weak and strong expansions of $B(\lambda)$. Let $z = \sqrt{\lambda}$ and use the planar convention

$$B(\lambda) = \frac{z}{4\pi^2}\frac{I_2(z)}{I_1(z)}.$$

At weak coupling,

$$B(\lambda) = \frac{\lambda}{16\pi^2} - \frac{\lambda^2}{384\pi^2} + \frac{\lambda^3}{6144\pi^2} - \frac{\lambda^4}{92160\pi^2} + O(\lambda^5). \tag{100.45}$$

Equivalently, in the spectral-problem coupling $g = \sqrt{\lambda}/(4\pi)$,

$$B(g) = g^2 - \frac{2\pi^2}{3}g^4 + \frac{2\pi^4}{3}g^6 - \frac{32\pi^6}{45}g^8 + O(g^{10}). \tag{100.46}$$

At strong coupling,

$$B(\lambda) = \frac{\sqrt{\lambda}}{4\pi^2} - \frac{3}{8\pi^2} + \frac{3}{32\pi^2\sqrt{\lambda}} + \frac{3}{32\pi^2\lambda} + \frac{63}{512\pi^2\lambda^{3/2}} + O(\lambda^{-2}). \tag{100.47}$$

The weak expansion follows from the defining power series

$$I_\nu(z) = \sum_{k=0}^{\infty} \frac{1}{k!\,\Gamma(k+\nu+1)} \left(\frac{z}{2}\right)^{2k+\nu}.$$

For the required orders,

$$\begin{aligned} I_1(z) &= \frac{z}{2} + \frac{z^3}{16} + \frac{z^5}{384} + \frac{z^7}{18432} + O(z^9), \\ I_2(z) &= \frac{z^2}{8} + \frac{z^4}{96} + \frac{z^6}{3072} + \frac{z^8}{184320} + O(z^{10}). \end{aligned}$$

Dividing the two series gives

$$\frac{I_2(z)}{I_1(z)} = \frac{z}{4} - \frac{z^3}{96} + \frac{z^5}{1536} - \frac{z^7}{23040} + O(z^9).$$

Multiplication by $z/(4\pi^2)$ and $z^2 = \lambda$ gives (100.45); substituting $\lambda = 16\pi^2 g^2$ gives (100.46).

For the strong expansion use the large-positive-z asymptotic expansion

$$I_\nu(z) \sim \frac{e^z}{\sqrt{2\pi z}} \sum_{k=0}^{\infty} \frac{(-1)^k}{k!(8z)^k} \prod_{j=1}^{k} \big(4\nu^2 - (2j-1)^2\big). \tag{100.48}$$

Let us recall the coefficient derivation, since the signs are a common source of normalization errors. The modified Bessel equation is

$$I_\nu''(z) + \frac{1}{z} I_\nu'(z) - \left(1 + \frac{\nu^2}{z^2}\right) I_\nu(z) = 0.$$

Insert

$$I_\nu(z) \sim \frac{e^z}{\sqrt{2\pi z}} S_\nu(z), \qquad S_\nu(z) = \sum_{k=0}^{\infty} a_k^{(\nu)} z^{-k}, \qquad a_0^{(\nu)} = 1.$$

After cancellation of the leading exponential part, S_ν must satisfy formally

$$2S_\nu'(z) + S_\nu''(z) + \left(\frac{1}{4} - \nu^2\right) z^{-2} S_\nu(z) = 0.$$

Equating the coefficient of z^{-k-1}, for $k \ge 1$, gives

$$a_k^{(\nu)} = -\frac{4\nu^2 - (2k-1)^2}{8k}\, a_{k-1}^{(\nu)},$$

which is precisely (100.48). The classical asymptotic theorem for this ordinary differential equation gives the corresponding remainder after truncation on every closed angular subsector containing the positive real axis and not crossing a Stokes ray; in this proposition only the positive real $z = \sqrt{\lambda}$ ray is used. The common factor $e^z/\sqrt{2\pi z}$ cancels in the ratio. For $\nu = 1, 2$,

$$I_1(z) \sim \frac{e^z}{\sqrt{2\pi z}}\left(1 - \frac{3}{8z} - \frac{15}{128z^2} - \frac{315}{3072z^3} - \frac{4725}{32768z^4} + O(z^{-5})\right),$$
$$I_2(z) \sim \frac{e^z}{\sqrt{2\pi z}}\left(1 - \frac{15}{8z} + \frac{105}{128z^2} + \frac{945}{3072z^3} + \frac{10395}{32768z^4} + O(z^{-5})\right).$$

Series division gives

$$\frac{I_2(z)}{I_1(z)} = 1 - \frac{3}{2z} + \frac{3}{8z^2} + \frac{3}{8z^3} + \frac{63}{128z^4} + O(z^{-5}).$$

Multiplying by $z/(4\pi^2)$ gives (100.47).

These expansions describe a near-BPS Wilson-line observable. The lightlike cusp coefficient of Section 49.24 and the planar large-spin scaling function $f(g)$ of Chapter 98 are cusp data in different analytic limits of the generalized cusp. Their common normalization check is the line-defect definition $C_D = 12B(\lambda)$ together with the protected circular-loop Ward identity.

100.9 Wilson-Line Flux Tube as a Conformal Spectral Datum

Pure Yang–Mills glueball spectroscopy, $\mathcal{N} = 1$ SYM chiral branches, softly broken $\mathcal{N} = 2$ monopole condensation, and planar $\mathcal{N} = 4$ Wilson-line integrability are related examples of gauge-theory spectral data, but the objects being measured differ. In planar $\mathcal{N} = 4$ SYM, conformal invariance supplies no intrinsic mass gap. The analog of a flux-tube spectrum is instead a defect spectrum: the Hamiltonian is the generator of translations along a line or of boosts around a null cusp, and the excitations are states of the defect Hilbert space associated to the Wilson line.

Definition 100.17 (Planar $\mathcal{N} = 4$ Wilson-line flux-tube datum)**.** Fix the planar limit of $\mathcal{N} = 4$ $SU(N)$ SYM with $\lambda = g_{\mathrm{YM}}^2 N$ and $g = \sqrt{\lambda}/(4\pi)$. A Wilson-line flux-tube datum consists of:

(i) a half-BPS straight Maldacena–Wilson line or its analytic continuation to a null cusp, with the scalar coupling normalized as in the preceding section;

(ii) the defect Hilbert space $\mathcal{H}_{\mathrm{def}}$ obtained by radial or boost quantization around the line or cusp, with Hamiltonian H_{def} and spatial momentum P_{def} along the defect;

(iii) local defect fields $\mathbb{O}_a(t)$, including the displacement operators $\mathbb{D}_i(t)$, scalar insertions, fermion insertions, and covariant derivatives along the line;

(iv) a spectral resolution of connected defect two-point functions,

$$\langle \mathbb{O}_a(t)\mathbb{O}_b(0)\rangle_{\mathrm{conn}} = \sum_\alpha \int d\mu_\alpha(u)\, F_{a,\alpha}(u) F_{b,\alpha}(u)^* e^{-E_\alpha(u)|t| + ip_\alpha(u)t}, \tag{100.49}$$

where u denotes rapidity-type spectral coordinates when the integrability description is available;

(v) transition data, such as pentagon form factors or mirror-TBA kernels, that reconstruct multi-particle defect correlators from the one-particle energies, momenta, measures, and scattering phases.

The cusp anomalous dimension is the defect vacuum energy density in the null-cusp frame, while the generalized scaling function and pentagon OPE data are higher spectral coordinates of the same defect system.

Remark 100.18 (Cusp anomalous dimension as defect ground-state energy). Assume the null-cusp Wilson line admits a defect Hamiltonian description on a strip of length $L = \log(R/\epsilon)$, where R and ϵ are the infrared and ultraviolet scales used in the cusp renormalization. If $E_0(\varphi, \theta)$ denotes the extensive ground-state energy in this strip normalization, then

$$E_0(\varphi, \theta) = \Gamma_{\mathrm{cusp}}(\varphi, \theta)\, L + O(1). \tag{100.50}$$

For the lightlike cusp, the coefficient of L is the lightlike cusp anomalous dimension $\Gamma_{\mathrm{cusp}}(\lambda)$. In the large-spin operator problem, the same coefficient controls the leading logarithmic growth

$$\Delta(S) - S = \Gamma_{\mathrm{cusp}}(\lambda) \log S + O(S^0) \qquad (S \to \infty) \tag{100.51}$$

in the normalization of Chapter 98.

The renormalized cusped-line expectation value has the defining logarithmic form

$$\log\langle W_{\mathrm{cusp}}\rangle_{\mathrm{ren}} = -\Gamma_{\mathrm{cusp}}(\varphi, \theta) \log \frac{R}{\epsilon} + O(1).$$

In the defect Hamiltonian representation, the same path integral on the logarithmic strip is

$$\langle W_{\mathrm{cusp}}\rangle_{\mathrm{ren}} = \langle B_{\mathrm{out}}| \mathrm{e}^{-LH_{\mathrm{def}}} |B_{\mathrm{in}}\rangle_{\mathrm{ren}}, \qquad L = \log \frac{R}{\epsilon},$$

with boundary states determined by the ultraviolet and infrared regularizations. If the lowest defect energy is isolated in the sector selected by the cusp boundary conditions, the large-L asymptotic is

$$\log\langle W_{\mathrm{cusp}}\rangle_{\mathrm{ren}} = -E_0(\varphi, \theta) + O(L^0) = -\varepsilon_0(\varphi, \theta)L + O(L^0),$$

where $E_0 = \varepsilon_0 L$ is extensive in the strip length. Comparing the coefficients of L gives $\varepsilon_0 = \Gamma_{\mathrm{cusp}}$, which is (100.50). The large-spin relation (100.51) follows from the same logarithmic renormalization of the lightlike Wilson line that appears in the factorized soft-collinear limit of twist-two operators; in the planar integrability description this coefficient is reproduced by the BES equation and by the large-spin limit of the asymptotic Bethe equations.

100.9.1 Pentagon Channel Expansion as a Defect Spectral Resolution

The pentagon OPE used for null polygonal Wilson loops is a spectral resolution in the defect Hilbert space of the null-cusp flux tube. The word "pentagon" does not replace the Hilbert-space statement: it names the transition amplitude between two adjacent channel decompositions of the same renormalized Wilson-line observable.

Fix a channel of a null polygon whose conformal cross-ratios are parametrized by (τ, σ, ϕ). Here τ is the Euclidean propagation length in the chosen flux-tube channel, σ is the translation coordinate along the defect, and ϕ is the angle conjugate to the transverse rotation charge. The channel evolution operator is

$$U(\tau, \sigma, \phi) = \exp\{-\tau H_{\mathrm{def}} + \mathrm{i}\sigma P_{\mathrm{def}} + \mathrm{i}\phi J_{\mathrm{def}}\}, \tag{100.52}$$

where H_{def}, P_{def}, and J_{def} are the energy, longitudinal momentum, and transverse angular-momentum generators of Definition 100.17. Let $\langle \mathcal{P}_{\mathrm{R}}|$ and $|\mathcal{P}_{\mathrm{L}}\rangle$ denote the right and left boundary states prepared by the adjacent Wilson-line segments in this channel, after the local cusp and edge renormalizations have been fixed. The channel contribution is the matrix element

$$\mathcal{W}_{\mathrm{ch}}(\tau, \sigma, \phi) = \langle \mathcal{P}_{\mathrm{R}}|U(\tau, \sigma, \phi)|\mathcal{P}_{\mathrm{L}}\rangle. \tag{100.53}$$

Pentagon OPE from the defect spectral resolution. Assume the planar Wilson-line defect datum of Definition 100.17 and assume that, in the channel under consideration, the identity on $\mathcal{H}_{\mathrm{def}}$ admits the generalized multiparticle resolution

$$\mathbf{1}_{\mathrm{def}} = |0\rangle\langle 0| + \sum_{k\geq 1} \sum_{a_1,\ldots,a_k} \frac{1}{|\operatorname{Aut}(a_1, \ldots, a_k)|} \int \prod_{r=1}^{k} \frac{\mathrm{d}u_r}{2\pi}\, \mu_{a_r}(u_r)\, |\mathbf{a}, \mathbf{u}\rangle\langle \mathbf{a}, \mathbf{u}|, \tag{100.54}$$

where a_r labels the one-particle species, u_r is its rapidity coordinate, $\mu_a(u)$ is the one-particle spectral measure in this normalization, and $|\operatorname{Aut}(a_1, \ldots, a_k)|$ is the product of factorials of the multiplicities of identical species. Suppose further that these states diagonalize H_{def}, P_{def}, and J_{def} additively:

$$E(\mathbf{a}, \mathbf{u}) = \sum_{r=1}^{k} E_{a_r}(u_r), \quad p(\mathbf{a}, \mathbf{u}) = \sum_{r=1}^{k} p_{a_r}(u_r), \quad m(\mathbf{a}) = \sum_{r=1}^{k} m_{a_r}.$$

Then (100.53) has the expansion

$$\begin{aligned}
\mathcal{W}_{\mathrm{ch}}(\tau, \sigma, \phi) &= \langle \mathcal{P}_{\mathrm{R}}|0\rangle\langle 0|\mathcal{P}_{\mathrm{L}}\rangle \\
&\quad + \sum_{k\geq 1} \sum_{a_1,\ldots,a_k} \frac{1}{|\operatorname{Aut}(a_1, \ldots, a_k)|} \int \prod_{r=1}^{k} \frac{\mathrm{d}u_r}{2\pi}\, \mu_{a_r}(u_r) \\
&\quad \times \exp\left[-\tau \sum_{r=1}^{k} E_{a_r}(u_r) + \mathrm{i}\sigma \sum_{r=1}^{k} p_{a_r}(u_r) + \mathrm{i}\phi \sum_{r=1}^{k} m_{a_r}\right] \\
&\quad \times P_{\mathrm{R}}(\mathbf{a}, \mathbf{u})\, P_{\mathrm{L}}(\mathbf{a}, \mathbf{u})^*,
\end{aligned} \tag{100.55}$$

where

$$P_{\mathrm{R}}(\mathbf{a}, \mathbf{u}) = \langle \mathcal{P}_{\mathrm{R}}|\mathbf{a}, \mathbf{u}\rangle, \qquad P_{\mathrm{L}}(\mathbf{a}, \mathbf{u}) = \langle \mathcal{P}_{\mathrm{L}}|\mathbf{a}, \mathbf{u}\rangle.$$

Insert (100.54) between $\langle \mathcal{P}_{\mathrm{R}}|$ and $U(\tau, \sigma, \phi)|\mathcal{P}_{\mathrm{L}}\rangle$ in (100.53). On the vacuum term, H_{def}, P_{def}, and J_{def} give the chosen vacuum normalization. On a multiparticle eigenstate, the assumed additivity gives

$$U(\tau, \sigma, \phi)|\mathbf{a}, \mathbf{u}\rangle = \exp\left[-\tau \sum_{r} E_{a_r}(u_r) + \mathrm{i}\sigma \sum_{r} p_{a_r}(u_r) + \mathrm{i}\phi \sum_{r} m_{a_r}\right] |\mathbf{a}, \mathbf{u}\rangle.$$

The overlap with the right and left boundary states gives the two transition amplitudes displayed in (100.55). The automorphism factor is the standard quotient by permutations of indistinguishable equal-species particles; without it, the same unordered spectral state would be integrated once for each such permutation. This proves the expansion.

In the integrability solution, the overlaps P_{R} and P_{L} are encoded by elementary pentagon transition functions. For a diagonal scalar component of two ordered one-particle excitations in a fixed rapidity normalization, Watson consistency is the identity

$$P_{a|b}(u|v) = S_{ab}(u, v)\, P_{b|a}(v|u), \tag{100.56}$$

with S_{ab} the flux-tube scattering phase or matrix element in the same rapidity normalization. Mirror moves relate a particle crossing an edge of the pentagon to an excitation in the adjacent channel. These relations are powerful constraints, but they are not substitutes for the spectral datum: the species, rapidity sheets, measures, transition normalizations, and renormalized Wilson-line observable must all be fixed before the formula has a mathematical meaning.

This defect datum is the $\mathcal{N} = 4$ member of the broader gauge-theory family discussed in Section 90.6: the protected local operators, line operators, and spectral measures must be defined before their integrable or semiclassical solution methods are invoked. The integrability problem in planar $\mathcal{N} = 4$ SYM gives an unusually complete solution of the defect spectral data; a derivation from a nonperturbatively defined four-dimensional planar QFT remains part of the proof boundary below.

100.10 Proof Boundary

Planar integrability gives a highly constrained exact spectral structure for four-dimensional interacting QFT. Symmetry fixes matrix scattering, crossing fixes the scalar factor, Bethe equations organize asymptotic spectra, mirror TBA incorporates finite size, and the QSC compresses the exact spectral problem into analytic functional equations. The remaining mathematical task is to derive this structure from a precise nonperturbative formulation of planar $\mathcal{N} = 4$ SYM, including the topology in which local operators, large-N limits, and analytic continuation in λ are controlled.

Chapter 101

Supersymmetric Localization On Compact Manifolds

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Supersymmetric localization is an exact-evaluation method only after the regulated functional integral has been specified with enough information to justify deformation of the integration cycle. This chapter separates the finite-dimensional theorem from the QFT formulae used in four-dimensional $\mathcal{N} = 2$ gauge theory on S^4 and three-dimensional $\mathcal{N} = 2$ Chern–Simons–matter theory on S^3. The formulae below are therefore not introduced as formal replacements for a definition of a QFT: they are consequences of a localization structure in the sense of Definition 86.7, together with the determinant and instanton-sector prescriptions explicitly stated here.

Definition 101.1 (Compact supersymmetric localization structure)**.** A compact supersymmetric localization structure is a tuple

$$\mathfrak{L}_M = \big(M, \mathfrak{B}, \{(\mathfrak{F}_\Lambda, C_\Lambda, \mu_\Lambda)\}_{\Lambda\in I}, Q_\Lambda, B_\Lambda, V_\Lambda, S_\Lambda, \mathcal{O}_\Lambda, \mathfrak{F}_\Lambda^{\mathrm{fix}}, \mathcal{N}_\Lambda^\bullet, \mathfrak{R}_\Lambda, \mathcal{C}_\Lambda\big)$$

with the following meaning.

(i) M is the compact oriented Riemannian manifold on which the QFT is placed, and $\mathfrak{B}$ denotes the chosen rigid-supergravity background: spin or spin-c structure, R-symmetry and flavor bundles, background connections, masses, and any metric or framing data used by the preserved supercharge.

(ii) I is a directed regulator set. For each $\Lambda \in I$, $\mathfrak{F}_\Lambda$ is the regulated super field-variable space, including gauge-fixing or BV variables when gauge symmetry is present; C_Λ is the declared integration cycle, including orientation, boundary, singular strata, and gauge quotient; and μ_Λ is the regulated Berezinian density or BV half-density. Fermionic variables are understood as coordinates on a locally super-ringed space, so μ_Λ is not a Borel measure.

(iii) Q_Λ is an odd derivation of the regulated algebra of observables, and

$$B_\Lambda := Q_\Lambda^2 = \mathcal{L}_{v_\Lambda} + \delta_{\mathrm{gauge}}(\Lambda_Q) + \delta_R(\Theta_R) + \delta_F(\Theta_F)$$

is the specified even transformation: an isometry of M, a gauge transformation, and R- or flavor rotations. In a gauge theory this statement is made in the BV complex; compatibility means that Q_Λ commutes with the gauge-fixed BV differential up to B_Λ-symmetry and that the regulated quantum master equation has the residual boundary terms specified below.

(iv) S_Λ is the regulated action and $\mathcal{O}_\Lambda$ is the regulated protected insertion. They obey

$$Q_\Lambda S_\Lambda = 0, \qquad Q_\Lambda \mathcal{O}_\Lambda = 0, \qquad \mathcal{L}_{Q_\Lambda}\mu_\Lambda = 0$$

in the regulated theory, or else the anomaly term is stated explicitly as a defect of these equations.

(v) V_Λ is an odd localizing functional such that $\mathrm{Re}(Q_\Lambda V_\Lambda) \geq 0$ on the bosonic body of C_Λ, with equality precisely on a stated fixed locus $\mathfrak{F}_\Lambda^{\mathrm{fix}}$. The Q_Λ-Stokes boundary term

$$\int_{\partial C_\Lambda} \mu_\Lambda \, \mathcal{O}_\Lambda V_\Lambda \exp\{-S_\Lambda - tQ_\Lambda V_\Lambda\}$$

is either proved to vanish, canceled by a declared relative-cycle or boundary counterterm, or recorded as an open obstruction.

(vi) $\mathcal{N}_\Lambda^\bullet$ is the normal Q_Λ-complex to the smooth part of $\mathfrak{F}_\Lambda^{\mathrm{fix}}$, with zero modes split off as coordinates or insertion modes. The one-loop determinant is the Berezin Gaussian/Euler class of the acyclic part of this complex, with orientation, phase, zeta or heat-kernel regularization, framing, and local counterterm conventions included in the structure.

(vii) $\mathfrak{R}_\Lambda$ is the residual finite-dimensional integration or summation prescription after normal integration: Cartan contour, residue chamber, Jeffrey–Kirwan vector, instanton compactification, polarization, or equivariant pushforward. Singular fixed strata such as zero-size instantons are part of $\mathfrak{R}_\Lambda$, not automatic consequences of the notation $\int \mathcal{D}\Phi$.

(viii) $\mathcal{C}_\Lambda$ is the continuum comparison structure: topology on protected observables, renormalization and contact-term scheme, convergence or matching statement for the limit $\Lambda \to \infty$, and the precise status of any equality between the regulated localization formula and the underlying QFT observable.

All localization formulae in this chapter are statements about consequences of a structure $\mathfrak{L}_M$. If one of the entries is supplied only by a standard prescription rather than by a regulator theorem, the corresponding formula is a controlled prescription or hypothesis at that entry, even when the finite-dimensional localization identity itself is a theorem.

101.1 Finite-Dimensional Deformation Identity

Let X be an oriented finite-dimensional supermanifold equipped with an integration cycle $C \subset X$ and Berezinian density μ. Let Q be an odd vector field on X, and let B be the even vector field Q^2.

For the following proposition all functions and densities are assumed smooth on a neighborhood of C, and C is assumed to be either compact without boundary or equipped with boundary conditions for which the displayed Stokes term vanishes.

Remark 101.2 (Localization deformation identity). Let $S, V, \mathcal{O}$ be functions on X with parities $|S| = |\mathcal{O}| = 0$, $|V| = 1$. Suppose

$$QS = 0, \qquad Q\mathcal{O} = 0, \qquad BS = B\mathcal{O} = BV = 0,$$

and suppose the Berezinian density is Q-invariant: $\mathcal{L}_Q\mu = 0$. Define

$$I(t) = \int_C \mu\, \mathcal{O}\, \exp\{-S - t\, QV\}.$$

If $Q(\mu\, \mathcal{O}\, V\, \exp\{-S - tQV\})$ has zero integral over C, then $I(t)$ is independent of t. Because Q is an odd derivation and $Q^2V = BV = 0$,

$$\frac{dI}{dt} = -\int_C \mu\, \mathcal{O}\, (QV)\, \exp\{-S - tQV\}.$$

The hypotheses $QS = 0$, $Q\mathcal{O} = 0$, and $Q(QV) = 0$ give

$$\begin{aligned} Q(\mathcal{O}\, V\, \exp\{-S - tQV\}) &= (Q\mathcal{O})V\mathrm{e}^{-S-tQV} + \mathcal{O}(QV)\mathrm{e}^{-S-tQV} \\ &\quad - \mathcal{O}V\, Q(S + tQV)\mathrm{e}^{-S-tQV} \\ &= \mathcal{O}(QV)\mathrm{e}^{-S-tQV}. \end{aligned}$$

Using $\mathcal{L}_Q\mu = 0$, the right hand side integrates to the assumed zero Stokes term. Hence $dI/dt = 0$.

Definition 101.3 (Clean fixed locus and normal complex)**.** Let $F \subset C_{\bar{0}}$ be the common zero locus of the bosonic part of QV on the body of the integration cycle. The fixed locus is called clean for the finite-dimensional localization quadruple (C, μ, Q, V) if F is a submanifold, if the Hessian of $\mathrm{Re}(QV)$ is nondegenerate on a chosen normal bundle $N_{F,\bar{0}}$, and if the linearization of Q in the directions normal to F gives a finite $\mathbb{Z}_2$-graded complex

$$N_F^\bullet : \qquad N_{F,\bar{0}} \xrightarrow{Q_{\mathrm{lin}}} N_{F,\bar{1}} \xrightarrow{Q_{\mathrm{lin}}} N_{F,\bar{0}}$$

whose cohomology has been split off as zero-mode coordinates on F. The one-loop determinant is the Berezin Gaussian of this acyclic normal complex, with orientation and square-root branches inherited from the integration cycle.

Assume, in addition to the deformation identity in Remark 101.2, that $\mathrm{Re}(QV) \geq 0$ on the bosonic body of C, that F is compact and clean, and that the large-t integral is dominated by a tubular neighborhood of F. In local coordinates y along F, bosonic normal coordinates x^i, and fermionic normal coordinates ϑ^A, the even quadratic normal model has the form

$$(QV)_{\mathrm{quad}} = \frac{1}{2}x^i A_{ij}(y)x^j - \frac{1}{2}\vartheta^A \mathsf{F}_{AB}(y)\vartheta^B. \tag{101.1}$$

Here A is symmetric and positive on the declared real normal cycle, and F is antisymmetric. The differential in the normal Q-complex is encoded in the fermion-fermion matrix F, not in an odd-even term: an ordinary even quadratic action cannot contain a term linear in one fermionic normal coordinate and one bosonic normal coordinate with an even numerical coefficient. If, after choosing splittings,

$$\mathsf{F} = \begin{pmatrix} 0 & D \\ -D^T & 0 \end{pmatrix}, \tag{101.2}$$

then the corresponding Pfaffian is $\pm \det D$, with the sign fixed by the orientation of the odd variables. With the conventional finite-dimensional Gaussian normalization absorbed into μ, the local normal factor is therefore

$$Z_{\text{normal}}(y) = \frac{\operatorname{Pf} \mathsf{F}(y)}{\sqrt{\det A(y)}}. \tag{101.3}$$

The finite normal Gaussian factor is fixed by the ordinary Gaussian integral and the defining coefficient of the Pfaffian. Let A be an invertible real symmetric matrix whose real part is positive on the chosen bosonic normal cycle, and let F be an invertible antisymmetric $2m \times 2m$ matrix. With the Berezin orientation $d\vartheta_{2m} \cdots d\vartheta_1$,

$$\int d^{2m}\vartheta \, \exp\!\left(\frac{1}{2}\vartheta^A \mathsf{F}_{AB} \vartheta^B\right) = \operatorname{Pf} \mathsf{F}. \tag{101.4}$$

After absorbing the ordinary factor $(2\pi)^{n/2}$ into the local normalization of the bosonic measure,

$$\int dx \, d\vartheta \, \exp\!\left(-\frac{1}{2}x^i A_{ij} x^j + \frac{1}{2}\vartheta^A \mathsf{F}_{AB} \vartheta^B\right) = \frac{\operatorname{Pf} \mathsf{F}}{\sqrt{\det A}}. \tag{101.5}$$

If A or F has a zero mode, that direction must be split off and integrated on the fixed locus or saturated by insertions; it is not part of the one-loop determinant. The Berezin integral extracts the coefficient of the ordered monomial $\vartheta^1 \cdots \vartheta^{2m}$. By definition of the Pfaffian, this coefficient in $\exp(\frac{1}{2}\vartheta^A \mathsf{F}_{AB} \vartheta^B)$ is $\operatorname{Pf} \mathsf{F}$, proving (101.4). The bosonic Gaussian on the declared cycle is

$$\int_{\mathbb{R}^n} d^n x \, \exp\!\left(-\frac{1}{2}x^i A_{ij} x^j\right) = \frac{(2\pi)^{n/2}}{\sqrt{\det A}}$$

after choosing the square-root branch determined by the cycle. Multiplying the bosonic and fermionic factors and absorbing $(2\pi)^{n/2}$ into the local measure gives (101.5).

If a bosonic zero mode is present, the Gaussian integral diverges or becomes a distribution along that direction; if a fermionic zero mode is present, the top Berezin coefficient is absent unless an insertion supplies the missing odd variable. Thus zero modes are coordinates on F, insertions to be saturated, or obstructions showing that the proposed localized observable vanishes. A determinant formula without this zero-mode statement is not a localization theorem.

Equation (101.3) is the finite model for the one-loop determinants in the compact-space QFT examples below.

101.2 QFT Localization Structure

For a supersymmetric QFT on a compact Riemannian manifold M, the symbol

$$Z_M = \int_{\mathfrak{F}} \mathcal{D}\Phi \, \mathrm{e}^{-S[\Phi]}$$

is shorthand for the regulated data in Definition 101.1. In the minimal notation one keeps only

$$(\mathfrak{F}_\Lambda, C_\Lambda, \mu_\Lambda, S_\Lambda, Q_\Lambda, V_\Lambda)$$

together with the limiting prescription $\Lambda \to \infty$, but the omitted entries of $\mathfrak{L}_M$ remain logically present. Thus the localized expression is justified only when the following conditions are verified or retained as hypotheses:

$$Q_\Lambda S_\Lambda = 0, \qquad \mathcal{L}_{Q_\Lambda}\mu_\Lambda = 0, \qquad Q_\Lambda \mathcal{O}_\Lambda = 0,$$
$$\int_{\partial C_\Lambda} \mu_\Lambda\, \mathcal{O}_\Lambda V_\Lambda \mathrm{e}^{-S_\Lambda - tQ_\Lambda V_\Lambda} = 0,$$
$$\mathrm{Re}(Q_\Lambda V_\Lambda) \geq 0 \quad \text{on the bosonic integration cycle.}$$

The fixed locus, zero modes, determinants, and singular strata must then be included in the limiting prescription. Noncompact Coulomb directions, Jeffrey–Kirwan residues, and point-instanton compactifications are not automatic outputs of the symbol $\int \mathcal{D}\Phi$. They are part of the regulated localization structure. In the formulae below this structure will be stated by naming the finite-dimensional variables, the contour, and the determinant or equivariant-integral prescription.

101.3 S^4 Localization In Four-Dimensional $\mathcal{N} = 2$ Gauge Theory

Let G be compact connected, with Lie algebra $\mathfrak{g}$, maximal torus T, Cartan algebra $\mathfrak{t}$, Weyl group W_G, and root system $\Delta \subset \mathfrak{t}^*$. The monograph convention for non-Abelian gauge theory is

$$\mathrm{tr}_\square(t^a t^b) = \delta^{ab}, \qquad S_{\mathrm{YM}} = \frac{1}{4g_{\mathrm{YM}}^2}\int \mathrm{tr}_\square(F_{\mu\nu}F^{\mu\nu}).$$

With $(a,a) := \mathrm{tr}_\square(a^2)$ for $a \in \mathfrak{t}$, the round S^4_r localization variable is the constant adjoint scalar $a \in \mathfrak{t}$ on the Coulomb locus. The classical Gaussian in this trace-delta convention is

$$Z_{\mathrm{cl}}(a) = \exp\left\{-\frac{4\pi^2 r^2}{g_{\mathrm{YM}}^2}(a,a)\right\}. \tag{101.6}$$

The coefficient equals the familiar half-trace coefficient because $t^a = \sqrt{2}\,T^a$ and $g_{\mathrm{ht}}^2 = 2g_{\mathrm{YM}}^2$, so

$$\frac{8\pi^2}{g_{\mathrm{ht}}^2}\,\mathrm{tr}_{\mathrm{ht}}(a_{\mathrm{ht}}^2) = \frac{4\pi^2}{g_{\mathrm{YM}}^2}(a,a).$$

The localization structure contains more than the Cartan variable. An off-shell $4D$ $\mathcal{N} = 2$ vector multiplet on the round sphere consists of a connection A_μ, complex adjoint scalars $\phi, \bar{\phi}$, gaugini $\lambda_A, \bar{\lambda}_A$ with $A = 1, 2$ an $SU(2)_R$ index, and auxiliary fields $D_{AB} = D_{BA}$. The chosen supercharge is specified by a pair of conformal Killing spinors $(\xi_A, \bar{\xi}_A)$. Its square has the form

$$Q^2 = \mathcal{L}_v + \delta_{\mathrm{gauge}}(\Lambda) + \delta_{SU(2)_R}(\Theta) + \delta_{\mathrm{flavor}}(m), \tag{101.7}$$

where $v^\mu = \xi^A\sigma^\mu\bar{\xi}_A$ is a Killing vector on S^4_r, Λ is an adjoint-valued gauge parameter, Θ is an $SU(2)_R$ rotation, and m denotes background flavor masses when present. For the standard round-sphere choice, v vanishes at the north and south poles and generates rotations in the two tangent planes near each pole.

The bosonic fixed-locus statement used in the matrix model is the following field-theoretic reduction. After choosing the real integration cycle for which the localizing term is nonnegative, all smooth bulk fields on the trivial bundle are gauge-equivalent to

$$A_\mu = 0, \qquad \phi, \bar{\phi} \text{ constant with real-cycle coordinate } a, \qquad D_{AB} = D_{AB}(a), \qquad a \in \mathfrak{t}, \quad (101.8)$$

with the auxiliary field determined algebraically by the Killing-spinor background. Nonzero instanton number is not represented by a smooth global bulk deformation of (101.8); in the large-localizing parameter limit it is concentrated in the two tangent-space models at the poles. The north-pole tangent space contributes an equivariant instanton integral on $\mathbb{C}^2$, and the south pole contributes the anti-instanton factor. This is why the compactification or contour defining Z_{inst} is part of Definition 101.5, rather than an optional interpretation added after the formula.

Define the even entire function

$$H(x) = \prod_{n=1}^{\infty} \left(1 + \frac{x^2}{n^2}\right)^n \exp\!\left(-\frac{x^2}{n}\right), \tag{101.9}$$

where the product is taken in the displayed counterterm convention.

Lemma 101.4 (Local uniform convergence and Barnes representation of H)**.** *The product in* (101.9) *converges locally uniformly on the complex x-plane, defines an even entire function, and satisfies*

$$\frac{d}{dx} \log H(x) = \sum_{n=1}^{\infty} \left(\frac{2nx}{n^2 + x^2} - \frac{2x}{n}\right) \tag{101.10}$$

away from its zeros. If G_B is the Barnes G-function normalized by $G_B(1) = 1$ and $G_B(z+1) = \Gamma(z)G_B(z)$, then

$$H(x) = \exp\!\big(-(1+\gamma_{\mathrm{E}})x^2\big)\, G_B(1 + \mathrm{i}x) G_B(1 - \mathrm{i}x). \tag{101.11}$$

Changing the exponential prefactor $\exp(cx^2)$ is a local quadratic counterterm for the background vector multiplet or the gauge coupling; it is therefore a convention that must be kept fixed when comparing Gaussian coefficients.

Proof. Let $K \subset \mathbb{C}$ be compact and choose N so that $|x|^2/n^2 \leq 1/2$ for $x \in K$ and $n \geq N$. For $n \geq N$, the logarithm of the n-th factor is

$$n \log\!\left(1 + \frac{x^2}{n^2}\right) - \frac{x^2}{n} = -\frac{x^4}{2n^3} + R_n(x), \qquad |R_n(x)| \leq C_K n^{-5},$$

uniformly on K. The series of logarithms therefore converges uniformly on K after the finitely many initial factors are separated. The resulting Weierstrass product converges locally uniformly and defines an entire function. Each factor depends only on x^2, so the function is even; its zeros are at $x = \pm \mathrm{i}n$ with the multiplicities encoded by the exponent n.

On a compact set avoiding these zeros, the differentiated logarithmic series is uniformly convergent because

$$\frac{d}{dx}\left[n \log\!\left(1 + \frac{x^2}{n^2}\right) - \frac{x^2}{n}\right] = \frac{2nx}{n^2 + x^2} - \frac{2x}{n} = O_K(n^{-3}).$$

Termwise differentiation is then justified by the Weierstrass theorem for locally uniformly convergent holomorphic series and gives (101.10).

For the Barnes representation, use the standard Weierstrass product

$$G_B(1+z) = (2\pi)^{z/2} \exp\left[-\frac{1}{2}\big(z + (1+\gamma_{\rm E})z^2\big)\right] \prod_{n=1}^{\infty} \left(1+\frac{z}{n}\right)^n \exp\left(\frac{z^2}{2n} - z\right),$$

which fixes the normalization $G_B(1) = 1$ and the functional equation $G_B(z+1) = \Gamma(z)G_B(z)$. Multiplying the products for $z = \mathrm{i}x$ and $z = -\mathrm{i}x$, the factors $(2\pi)^{\pm \mathrm{i}x/2}$ and $\exp(\mp \mathrm{i}x/2)$ cancel, while

$$\left(1+\frac{\mathrm{i}x}{n}\right)^n \left(1-\frac{\mathrm{i}x}{n}\right)^n \exp\left(-\frac{x^2}{n}\right) = \left(1+\frac{x^2}{n^2}\right)^n \exp\left(-\frac{x^2}{n}\right).$$

The remaining exponential is $\exp((1+\gamma_{\rm E})x^2)$, which gives (101.11). Multiplying H by $\exp(cx^2)$ changes only this local quadratic prefactor. □

The one-loop determinant formula below uses the following finite-part operation. Suppose that, after pairing all acyclic Q-doublets in a fixed root or weight sector, the unpaired finite-cutoff determinant has the form

$$D^{\rm raw}_{\kappa,N}(x) = \prod_{n=1}^{N} (n^2 + x^2)^{\kappa n}, \qquad \kappa \in \mathbb{Z}. \tag{101.12}$$

Here x is the dimensionless equivariant mass in that sector: $x = r\,\alpha(a)$ for a vector root, or $x = r\rho(a) + rm$ for a hypermultiplet weight. The exponent n is the residual cohomological multiplicity of the transversally elliptic complex after the paired boson–fermion modes have cancelled. The constant factor $\prod_{n=1}^{N} n^{2\kappa n}$ is independent of the Coulomb variable and is removed by the normalization of the partition function. The remaining Coulomb-dependent finite part is

$$D^{\rm fp}_{\kappa,N}(x) = \prod_{n=1}^{N} \left(1+\frac{x^2}{n^2}\right)^{\kappa n} \exp\left(-\kappa\frac{x^2}{n}\right) = H_N(x)^{\kappa}, \tag{101.13}$$

where H_N is the N-th partial product of (101.9). The exponential in (101.13) subtracts the logarithmically divergent local term $\kappa x^2 \sum_{n\le N} n^{-1}$. Since x is linear in the background scalar and mass parameters, this subtraction is a quadratic local counterterm in the rigid vector or flavor background. The finite determinant is therefore the finite part specified by the quadratic counterterm convention in Lemma 101.4.

With this convention the perturbative S^4 determinant is obtained from a short sector calculation. A vector root pair $\{\alpha, -\alpha\}$ contributes the Cartan gauge-fixing factor $\alpha(a)^2$ and the finite part with $\kappa = 2$, hence $H(r\alpha(a))^2$ for each positive root. A full hypermultiplet weight ρ contributes the inverse finite part with $\kappa = -1$, hence $H(r\rho(a) + rm)^{-1}$. The formula below is exactly this sector calculation multiplied over the root and weight multisets. A derivation from the infinite-dimensional field theory has to supply the regulated normal complex, the pairing of acyclic modes, the cohomological multiplicity n, and the absence of boundary contributions in the chosen field-variable cycle; those structures are part of Definition 101.1.

For a vector multiplet and hypermultiplets of masses m_ℓ in representations R_ℓ, the perturbative determinant on the round sphere is

$$Z^{S^4}_{1-\rm loop}(a) = \prod_{\alpha\in\Delta_+} \alpha(a)^2 H(r\,\alpha(a))^2 \prod_{\ell} \prod_{\rho\in{\rm wt}(R_\ell)} H(r\,\rho(a) + r\,m_\ell)^{-1}. \tag{101.14}$$

The factor $\prod_{\alpha>0}\alpha(a)^2$ is the Cartan gauge-fixing Jacobian. If the representation is real or pseudoreal, the weights are counted with the multiplicity appropriate to a full hypermultiplet in the chosen convention. A different convention for the hypermultiplet mass shifts the argument of H by the corresponding R-symmetry background; this is a coordinate change in the localization structure, not a change of the underlying determinant complex.

$\mathcal{N}=4$ determinant cancellation on S^4. Let G be compact connected with complexified Lie algebra $\mathfrak{g}_{\mathbb{C}}$, Cartan subalgebra $\mathfrak{t}_{\mathbb{C}}$, root system Δ, chosen positive roots Δ_+, and invariant inner product fixed by the Yang–Mills action $\frac{1}{4g_{\mathrm{YM}}^2}\int \mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$. Consider the $\mathcal{N}=2$ localization formula (101.14) for one vector multiplet and one massless adjoint hypermultiplet, with the hypermultiplet mass coordinate tuned to the point where the field content is an $\mathcal{N}=4$ vector multiplet. Then the non-polynomial H-factors cancel identically and the one-loop factor is only the Cartan gauge-fixing Jacobian:

$$Z_{1-\mathrm{loop}}^{\mathcal{N}=4}(a)=\prod_{\alpha\in\Delta_+}\alpha(a)^2. \tag{101.15}$$

The adjoint representation has weight multiset

$$\mathrm{wt}(\mathfrak{g}_{\mathbb{C}})=\Delta\ \sqcup\ \{0,\dots,0\},$$

where the zero weight occurs $\mathrm{rank}\,G$ times. By Lemma 101.4, H is an even entire function and $H(0)=1$. Therefore the zero weights of the adjoint hypermultiplet contribute the constant $H(0)^{-\mathrm{rank}\,G}=1$, while each pair $\{\alpha,-\alpha\}$ contributes

$$H(r\,\alpha(a))^{-1}H(-r\,\alpha(a))^{-1}=H(r\,\alpha(a))^{-2}.$$

The vector multiplet contributes

$$\prod_{\alpha\in\Delta_+}\alpha(a)^2H(r\,\alpha(a))^2.$$

Multiplying the vector and adjoint-hyper factors root pair by root pair leaves exactly (101.15). No regularization ambiguity is hidden in this cancellation: changing the normalization of H by an even quadratic exponential would multiply the vector and adjoint hypermultiplet factors by inverse local quadratic counterterms at the $\mathcal{N}=4$ point, so the cancellation holds in the determinant convention fixed in (101.11).

Definition 101.5 (Nekrasov factor in the S^4 formula)**.** For the four-dimensional localization formula, $Z_{\mathrm{inst}}(a,\tau;\epsilon_1,\epsilon_2)$ denotes the equivariant integral over the framed instanton moduli space on $\mathbb{C}^2$, with equivariant rotation weights (ϵ_1,ϵ_2), Coulomb parameter a, and

$$\tau=\frac{\theta}{2\pi}+\frac{4\pi\mathrm{i}}{g_{\mathrm{YM}}^2}.$$

For $U(N)$ this can be defined by integration over the smooth framed torsion-free-sheaf compactification. For other gauge groups and matter systems the formula requires the corresponding compactification or an equivalent contour prescription as part of the stated localization structure.

101.4 Singular Instantons And Compactification Choices

The factor Z_{inst} in the S^4 formula is a compactification choice, not a decorative notation. Smooth instantons on $\mathbb{C}^2$ can shrink to zero size. The limiting curvature is then no longer represented by a smooth connection; the lost action is recorded as a point with multiplicity. A localization formula that sums over point instantons must therefore say which compactified moduli space is being integrated over.

Definition 101.6 (Framed instanton compactifications on $\mathbb{C}^2$)**.** Let $\mathcal{M}^{\text{sm}}_{k,N}$ be the framed smooth $U(N)$ k-instanton moduli space on $\mathbb{C}^2$.

1. The Uhlenbeck compactification is stratified by
$$\overline{\mathcal{M}}^{U}_{k,N} = \bigsqcup_{\ell=0}^{k} \mathcal{M}^{\text{sm}}_{k-\ell,N} \times \text{Sym}^{\ell}(\mathbb{C}^2). \tag{101.16}$$
The integer ℓ is the amount of instanton number carried by ideal point instantons.
2. The Gieseker, or framed torsion-free-sheaf, compactification $\mathfrak{M}^{G}_{k,N}$ is the smooth stable ADHM quotient. It carries a proper morphism
$$\pi_{G\to U} : \mathfrak{M}^{G}_{k,N} \longrightarrow \overline{\mathcal{M}}^{U}_{k,N}$$
that resolves the small-instanton strata relevant to equivariant localization.
3. On a compact four-manifold X, the Donaldson–Uhlenbeck compactification of ASD connections is the analogous compactification by weak limits of connections away from finitely many points, together with the lost second Chern class recorded as an effective zero-cycle on X.

These spaces have different meanings. A field-theoretic path integral with a specified regulator must explain which compactification, or which equivalent contour, it produces.

Construction 101.7 (Gieseker-to-Uhlenbeck charge bookkeeping)**.** Work on the framed $U(N)$ instanton compactification on $\mathbb{C}^2$, equivalently on $\mathbb{P}^2$ with a fixed framing along the line at infinity, and take $c_1 = 0$. Let E be a framed torsion-free sheaf in the Gieseker compactification. Its double dual E^{**} is locally free, and there is an exact sequence
$$0 \longrightarrow E \longrightarrow E^{**} \longrightarrow Q \longrightarrow 0 \tag{101.17}$$
with Q a zero-dimensional sheaf of length ℓ. If the instanton number is $k(F) = -\int_{\mathbb{P}^2} \text{ch}_2(F)$ in the framed $c_1 = 0$ convention, then
$$k(E) = k(E^{**}) + \ell. \tag{101.18}$$
Thus the Uhlenbeck morphism sends E to the smooth framed instanton represented by E^{**}, together with the effective length-ℓ zero-cycle supporting Q.

The charge identity in (101.18) is a finite Chern-character calculation. On a smooth complex surface the double dual of a torsion-free sheaf is locally free, and the quotient in (101.17) is supported in complex codimension two. The Chern character is additive in exact sequences, so
$$\text{ch}(E^{**}) = \text{ch}(E) + \text{ch}(Q).$$

Since Q is zero-dimensional of length ℓ, its only nonzero Chern character component is $\mathrm{ch}_2(Q) = \ell[\mathrm{pt}]$. Therefore

$$\mathrm{ch}_2(E) = \mathrm{ch}_2(E^{**}) - \ell[\mathrm{pt}].$$

Integrating and multiplying by the instanton-number sign convention gives

$$k(E) = -\int \mathrm{ch}_2(E) = -\int \mathrm{ch}_2(E^{**}) + \ell = k(E^{**}) + \ell.$$

The support cycle of Q is an element of $\mathrm{Sym}^\ell(\mathbb{C}^2)$. Keeping only $(E^{**}, \operatorname{supp} Q)$ gives the corresponding Uhlenbeck stratum, while the Gieseker space retains the punctual quotient data that resolve that stratum.

Remark 101.8 (Dimension of Uhlenbeck strata). The complex dimension of the top stratum $\mathcal{M}^{\mathrm{sm}}_{k,N}$ is $2kN$. The stratum with ℓ ideal points in (101.16) has complex dimension

$$2(k-\ell)N + 2\ell.$$

Hence its complex codimension inside the top-dimensional instanton component is

$$2\ell(N-1). \tag{101.19}$$

For $N = 2$ and $\ell = 1$, this is real codimension four.

The ADHM dimension count in Chapter 91 gives complex dimension $2rN$ for the smooth framed charge-r moduli space. The symmetric product $\mathrm{Sym}^\ell(\mathbb{C}^2)$ has complex dimension 2ℓ. Adding the two dimensions gives the displayed stratum dimension with $r = k - \ell$. Subtracting from $2kN$ gives

$$2kN - \big(2(k-\ell)N + 2\ell\big) = 2\ell(N-1).$$

Definition 101.9 (ADHM stability and the small-instanton locus)**.** Let $K \simeq \mathbb{C}^k$, $W \simeq \mathbb{C}^N$, and let (B_1, B_2, I, J) obey the complex ADHM equation

$$[B_1, B_2] + IJ = 0.$$

The ADHM tuple is stable if no proper subspace $S \subsetneq K$ satisfies

$$B_1 S \subset S, \qquad B_2 S \subset S, \qquad I(W) \subset S.$$

The Gieseker compactification is the stable GIT quotient by $GL(K)$, or equivalently the positive real-moment-map hyperkähler quotient. The Uhlenbeck compactification is obtained from the affine quotient after discarding the stable framing data carried by punctual quotients. Failure of stability is the ADHM description of the small-instanton stratum.

The geometric content of this definition is as follows. If the cyclic span of $I(W)$ under B_1 and B_2 is all of K, the framing data generate the length-k torsion-free sheaf and the complexified gauge action has the expected stable orbit. If the cyclic span is a proper subspace S, then the quotient K/S carries ADHM length not seen by the framed smooth connection. In the affine quotient this quotient is recorded only by the eigenvalue data of B_1, B_2, hence by points of $\mathbb{C}^2$ with multiplicity. These are precisely the ideal point-instanton coordinates in the Uhlenbeck stratum. The positive real-moment-map quotient forbids this loss by forcing stability; the price is that the singular stratum is replaced by the Gieseker resolution.

Proposition 101.10 (Positive ADHM moment map excludes the small-instanton stratum)**.** *Let K and W be Hermitian vector spaces and let $(B_1, B_2, I, J) \in \mathrm{End}(K)^{\oplus 2} \oplus \mathrm{Hom}(W, K) \oplus \mathrm{Hom}(K, W)$ obey the ADHM equations*

$$[B_1, B_2] + IJ = 0, \tag{101.20}$$

$$[B_1, B_1^\dagger] + [B_2, B_2^\dagger] + II^\dagger - J^\dagger J = \zeta\, \mathbf{1}_K, \qquad \zeta > 0. \tag{101.21}$$

Then the ADHM configuration is stable in the sense of Definition 101.9. Equivalently, the positive real moment-map parameter forbids a quotient K/S that is invisible to the framing $I(W)$, hence forbids the finite-dimensional small-instanton degeneration represented by failure of stability.

Proof. Suppose, for contradiction, that there is a proper subspace $S \subsetneq K$ such that $B_i S \subset S$ for $i = 1, 2$ and $I(W) \subset S$. Let $T = S^\perp$, and write each B_i in block form with respect to $K = S \oplus T$:

$$B_i = \begin{pmatrix} A_i & C_i \\ 0 & D_i \end{pmatrix}.$$

The T-trace of the commutator block is

$$\mathrm{Tr}_T\big([B_i, B_i^\dagger]_{TT}\big) = \mathrm{Tr}(D_i D_i^\dagger) - \mathrm{Tr}(C_i^\dagger C_i + D_i^\dagger D_i) = -\,\mathrm{Tr}(C_i^\dagger C_i). \tag{101.22}$$

Since $I(W) \subset S$, the T-block of $II^\dagger$ is zero. The T-trace of $-J^\dagger J$ is $-\,\mathrm{Tr}_T(J^\dagger J) \le 0$. Taking the trace over T in (101.21) therefore gives

$$-\sum_{i=1}^{2} \mathrm{Tr}(C_i^\dagger C_i) - \mathrm{Tr}_T(J^\dagger J) = \zeta\, \dim T. \tag{101.23}$$

The left hand side is nonpositive and the right hand side is positive because $\zeta > 0$ and $T \neq 0$. This contradiction proves stability. □

Remark 101.11 (What this finite-dimensional statement does not prove)*.* Proposition 101.10 is a theorem inside the ADHM finite-dimensional reduction. It justifies the common statement that a positive ADHM/FI resolution, for example the finite-dimensional resolution induced by noncommutative deformation in the Nekrasov–Schwarz construction, removes the small-instanton stratum. It does not by itself prove that a four-dimensional supersymmetric gauge-theory path integral with a given regulator localizes to this resolved quotient. That identification is the separate regulator theorem, or hypothesis, stated in Hypothesis 101.17.

Definition 101.12 (Tangent Euler class at a Young-diagram fixed point)**.** Let a fixed point of $\mathfrak{M}^G_{k,N}$ be labeled by $\vec{Y} = (Y_1, \ldots, Y_N)$. For a box $s = (i, j) \in Y_\alpha$, define the arm and relative leg lengths by

$$A_{Y_\alpha}(s) = Y_{\alpha,i} - j, \qquad L_{Y_\beta}(s) = Y^T_{\beta,j} - i.$$

With Coulomb weights a_α and rotation weights ϵ_1, ϵ_2, use the orientation convention

$$\begin{aligned} e_T(T_{\vec{Y}}\mathfrak{M}^G_{k,N}) = \prod_{\alpha,\beta=1}^{N} \prod_{s\in Y_\alpha} &\Big(a_\alpha - a_\beta - \epsilon_1 L_{Y_\beta}(s) + \epsilon_2(A_{Y_\alpha}(s) + 1)\Big) \\ &\times \Big(a_\alpha - a_\beta + \epsilon_1(L_{Y_\beta}(s) + 1) - \epsilon_2 A_{Y_\alpha}(s)\Big). \end{aligned} \tag{101.24}$$

The pure vector fixed-point contribution is

$$Z^{\mathrm{vec}}_{\vec{Y}} = e_T(T_{\vec{Y}}\mathfrak{M}^G_{k,N})^{-1}$$

in this convention. Matter multiplets multiply this by the Euler classes of their corresponding equivariant index bundles.

Proposition 101.13 (Rank-one monomial-ideal tangent character)**.** *Let Y be a Young diagram and let $I_Y \subset R = \mathbb{C}[z_1, z_2]$ be the monomial ideal whose quotient has basis*

$$Q_Y = R/I_Y, \qquad \{z_1^{i-1}z_2^{j-1} : (i,j) \in Y\}.$$

Let z_1 and z_2 have torus weights ϵ_1 and ϵ_2, and write $t_a = e^{\epsilon_a}$. At the fixed point $I_Y \in \mathrm{Hilb}^{|Y|}(\mathbb{C}^2)$, the rank-one tangent character is

$$\mathrm{ch}_T\, T_{I_Y}\mathrm{Hilb}^{|Y|}(\mathbb{C}^2) = \sum_{s\in Y}\left(t_1^{-L_Y(s)}t_2^{A_Y(s)+1} + t_1^{L_Y(s)+1}t_2^{-A_Y(s)}\right). \tag{101.25}$$

Equivalently, the additive tangent weights are

$$-L_Y(s)\epsilon_1 + (A_Y(s)+1)\epsilon_2, \qquad (L_Y(s)+1)\epsilon_1 - A_Y(s)\epsilon_2, \qquad s \in Y.$$

Their product is the $N = 1$ specialization of (101.24).

Proof. Set

$$V_Y = \mathrm{ch}_T\, Q_Y = \sum_{(i,j)\in Y} t_1^{i-1}t_2^{j-1}, \qquad V_Y^\vee = \sum_{(i,j)\in Y} t_1^{1-i}t_2^{1-j}.$$

The monomial-ideal deformation complex, equivalently the rank-one ADHM deformation complex with framing character 1, gives the finite equivariant K-theory identity

$$\mathrm{ch}_T\, T_{I_Y}\mathrm{Hilb}^{|Y|}(\mathbb{C}^2) = V_Y^\vee + t_1t_2V_Y - (1-t_1)(1-t_2)V_YV_Y^\vee. \tag{101.26}$$

Here the last term subtracts the gauge and relation part of the two-arrow ADHM complex, while $V_Y^\vee$ and $t_1t_2V_Y$ are the two framing terms. Expanding $(1-t_1)(1-t_2)V_YV_Y^\vee$ is a finite second-difference calculation on the set of box displacements in $Y - Y$: every displacement whose four adjacent translates stay inside the diagram cancels, and the only uncancelled displacements are the two hooks that cross the boundary at each box s. The east hook contributes $t_1^{-L_Y(s)}t_2^{A_Y(s)+1}$, and the south hook contributes $t_1^{L_Y(s)+1}t_2^{-A_Y(s)}$. Summing over boxes gives (101.25). Passing from multiplicative characters to additive weights gives the displayed two weights per box, and their product is exactly (101.24) with $N = 1$ and $a_\alpha - a_\beta = 0$. □

For $k = 1$, the fixed points are the N choices in which one Young diagram Y_α consists of a single box. Formula (101.24) gives

$$Z_1^{U(N)} = \frac{1}{\epsilon_1\epsilon_2}\sum_{\alpha=1}^{N}\prod_{\beta\neq\alpha}\frac{1}{(a_\alpha - a_\beta)(a_\alpha - a_\beta + \epsilon_1 + \epsilon_2)},$$

which is the one-instanton formula used in Definition 91.7. Let $s = (1,1)$ be the single box of Y_α. For $\beta = \alpha$,

$$A_{Y_\alpha}(s) = 0, \qquad L_{Y_\alpha}(s) = 0,$$

so the two tangent weights are ϵ_2 and ϵ_1. For $\beta \neq \alpha$, the diagram Y_β is empty, hence

$$A_{Y_\alpha}(s) = 0, \qquad L_{Y_\beta}(s) = -1.$$

The two weights in (101.24) are then

$$a_\alpha - a_\beta + \epsilon_1 + \epsilon_2, \qquad a_\alpha - a_\beta.$$

Multiplying the weights and summing over the N possible positions of the one box gives the displayed expression.

Example 101.14 (The two-point Gieseker fixed-point laboratory)**.** The first place where the resolved punctual data are not just a projective orientation space is the rank-one length-two Gieseker sector

$$\mathfrak{M}^G_{2,1} \simeq \mathrm{Hilb}^2(\mathbb{C}^2).$$

This is a finite-dimensional model of the resolved ideal-point sector, not a claim that ordinary commutative $U(1)$ Yang–Mills has smooth finite-action instantons. The Uhlenbeck record over a double point at the origin sees only the support cycle $2[0] \in \mathrm{Sym}^2(\mathbb{C}^2)$. The Gieseker space retains the punctual quotient data; over the double point the exceptional fiber is $\mathbb{P}^1$. The torus $T^2_{\epsilon_1,\epsilon_2}$ has two fixed points, corresponding to the partitions (2) and $(1,1)$. Proposition 101.13 computes their tangent characters directly from the monomial ideals.

For the horizontal partition $Y = (2)$, the boxes have

$$(A, L) = ((1,0), (0,0)),$$

and (101.24) gives tangent weights

$$2\epsilon_2, \quad \epsilon_1 - \epsilon_2, \quad \epsilon_2, \quad \epsilon_1.$$

Hence

$$e_T(T_{(2)}\mathrm{Hilb}^2(\mathbb{C}^2)) = 2\epsilon_1\epsilon_2^2(\epsilon_1 - \epsilon_2).$$

For the vertical partition $Y = (1,1)$, the boxes have

$$(A, L) = ((0,1), (0,0)),$$

and the weights are

$$\epsilon_2 - \epsilon_1, \quad 2\epsilon_1, \quad \epsilon_2, \quad \epsilon_1,$$

so

$$e_T(T_{(1,1)}\mathrm{Hilb}^2(\mathbb{C}^2)) = 2\epsilon_1^2\epsilon_2(\epsilon_2 - \epsilon_1).$$

The equivariant integral of 1 over the resolved length-two sector is therefore

$$\begin{aligned}\int_{\mathrm{Hilb}^2(\mathbb{C}^2)} 1 &= \frac{1}{2\epsilon_1\epsilon_2^2(\epsilon_1 - \epsilon_2)} + \frac{1}{2\epsilon_1^2\epsilon_2(\epsilon_2 - \epsilon_1)} \\ &= \frac{1}{2\epsilon_1^2\epsilon_2^2}.\end{aligned} \tag{101.27}$$

This calculation displays the singular-instanton bookkeeping in its smallest nontrivial form. The Uhlenbeck compactification remembers the effective cycle $2[0]$; the Gieseker/Nekrasov resolution remembers which punctual monomial ideal lies over that cycle. A localization formula that uses the two Young-diagram residues is therefore using resolved punctual data, and a field-theoretic regulator must still explain why this resolved sector, rather than the collapsed Uhlenbeck point, is the integration cycle it selects.

Example 101.15 (The charge-one resolution)**.** For $k = 1$, the ADHM matrices B_1, B_2 are complex numbers, hence give the center point in $\mathbb{C}^2$. The remaining data

$$I \in W^*, \qquad J \in W, \qquad IJ = 0$$

modulo the $GL(1)$ action, with positive real moment map, give

$$\mathfrak{M}^G_{1,N} \simeq \mathbb{C}^2 \times T^*\mathbb{CP}^{N-1}.$$

The Uhlenbeck compactification collapses the resolved orientation/size data over the ideal point-instanton stratum. For $N = 2$, the collapsed stratum has real codimension four in the top moduli component, matching Remark 101.8.

Construction 101.16 (Charge-one Uhlenbeck map as a nilpotent-cone resolution)**.** The charge-one example admits a completely explicit map to the Uhlenbeck compactification. Let $W \simeq \mathbb{C}^N$. Since $K = \mathbb{C}$, the complex ADHM equation is the scalar condition

$$I(J) = 0, \qquad I \in W^*, \quad J \in W.$$

Stability is $I \neq 0$. Dividing by $GL(1) = \mathbb{C}^*$ gives

$$(I, J)/\mathbb{C}^* = \{([I], J) : [I] \in \mathbb{P}(W^*),\ I(J) = 0\} \simeq T^*\mathbb{P}(W^*) \simeq T^*\mathbb{CP}^{N-1}.$$

The Uhlenbeck map is the moment-map morphism

$$\mu_{\mathrm{Uh}} : T^*\mathbb{P}(W^*) \longrightarrow \mathfrak{sl}(W), \qquad ([I], J) \longmapsto \nu_{I,J} := J \otimes I, \tag{101.28}$$

where $\nu_{I,J}(w) = I(w)J$. The equation $I(J) = 0$ gives

$$\operatorname{Tr} \nu_{I,J} = I(J) = 0, \qquad \nu_{I,J}^2 = I(J)\nu_{I,J} = 0, \qquad \operatorname{rank} \nu_{I,J} \leq 1.$$

Thus the image is the closure of the minimal nilpotent orbit in $\mathfrak{sl}(W)$. The open subset $J \neq 0$ maps to the smooth rank-one nilpotent orbit; the zero section $J = 0$ maps to the apex $\nu = 0$, which is precisely the ideal point-instanton stratum in the charge-one Uhlenbeck compactification. Including the center $(B_1, B_2) \in \mathbb{C}^2$, one has

$$\mathfrak{M}^G_{1,N} \simeq \mathbb{C}^2 \times T^*\mathbb{CP}^{N-1} \longrightarrow \mathbb{C}^2 \times \overline{\mathcal{O}}_{\min},$$

and the small-instanton boundary is $\mathbb{C}^2 \times \{0\}$. This is the concrete geometric content hidden behind the phrase "point instanton" in the first nontrivial instanton sector.

Hypothesis 101.17 (Field-theoretic matching to the Gieseker integral)**.** The S^4 formula (101.29) uses the Gieseker/Nekrasov equivariant integral at each pole. A theorem-level derivation from the four-dimensional gauge-theory path integral requires a regulator and integration cycle whose localized small-instanton sector is identified with $\mathfrak{M}^G_{k,N}$, with the Uhlenbeck space $\overline{\mathcal{M}}^U_{k,N}$ serving as a boundary compactification rather than as the resolved integration domain. Noncommutative or positive ADHM-moment-map regularization supplies a finite-dimensional resolution of the small-instanton singularity, but the construction-level equivalence between this resolved equivariant integral and the continuum supersymmetric path integral is retained here as a hypothesis unless the regulator has been specified and the limiting argument has been proven.

Definition 101.18 (Regulator selection structure for the Gieseker sector)**.** Fix k, N, equivariant weights (ϵ_1, ϵ_2), Coulomb parameter a, and the trace normalization of this volume. A four-dimensional supersymmetric regulator is said to select the Gieseker instanton sector at charge k if it supplies the following structures.

1. A regulated BV localization problem

$$(\mathfrak{F}_\delta, C_\delta, \rho_\delta, Q_\delta, V_\delta), \qquad \delta > 0,$$

satisfying the finite-regulator quantum master equation and the Q_δ-Stokes condition on the integration cycle. Here δ denotes the regulator parameter, not an equivariant weight.

2. A Q_δ-fixed local model at the pole with coordinates

$$(B_1, B_2, I, J) \in \mathrm{End}(K)^{\oplus 2} \oplus \mathrm{Hom}(W, K) \oplus \mathrm{Hom}(K, W), \qquad \dim K = k, \quad \dim W = N,$$

whose equations reduce, after a controlled finite change of coordinates, to

$$[B_1, B_2] + IJ = 0, \qquad [B_1, B_1^\dagger] + [B_2, B_2^\dagger] + II^\dagger - J^\dagger J = \zeta_\delta \mathbf{1}_K + R_\delta,$$

with $\zeta_\delta > 0$ and $R_\delta \to 0$ in the norm in which the fixed-locus reduction is being taken. Equivalently, the regulator may supply another explicit resolution cycle together with an equivariant proper map to $\overline{\mathcal{M}}^U_{k,N}$; it must then prove that the resolved cycle is isomorphic to $\mathfrak{M}^G_{k,N}$ or give the exact contour replacing it.

3. An orientation and determinant-line comparison between the regulated normal Q_δ-complex and the equivariant tangent/index complex on $\mathfrak{M}^G_{k,N}$. In local fixed-point coordinates this means that the nonzero-mode Berezinian gives the Euler class (101.24), multiplied only by declared one-loop determinants and local counterterms already included in the localization structure.

4. A boundary-cancellation statement for the Uhlenbeck small-instanton collars. In the notation of Chapter 111, the regulator must prove either

$$\sum_\alpha B_{S_\alpha}(\rho_\delta) \longrightarrow 0$$

or an equality of this boundary functional with the difference between the smooth-stratum pushforward and the Gieseker-resolved pushforward. Thus the resolution is part of the BV pushforward structure, not an informal replacement made after the path integral has already been localized.

5. A limiting theorem for equivariantly regular test insertions $\mathcal{O}$:

$$\lim_{\delta \to 0} \int_{C_\delta} \rho_\delta \, \mathcal{O} \, \mathrm{e}^{-tQ_\delta V_\delta} = \int^{\mathrm{equiv}}_{\mathfrak{M}^G_{k,N}} \mathcal{O}_{\mathrm{red}} \, \frac{e_T(E_{\mathrm{matter}})}{e_T(T\mathfrak{M}^G_{k,N})},$$

with the order of the $t \to \infty$ localization limit and the $\delta \to 0$ regulator limit specified. If the result is stated only as a formal power series in the instanton counting parameter, the topology of that formal series must be part of the statement.

This hypothesis is the point at which the monograph refuses the common shortcut. Equivariant localization on $\mathfrak{M}^G_{k,N}$ is a mathematical theorem after the resolved moduli space is chosen. The assertion that the original QFT path integral localizes to that particular resolved integral is an additional field-theoretic statement. A BV pushforward formulation, as in Chapter 111, must include the boundary term at the singular stratum or a regulator that replaces the stratum by a cycle without boundary. The singular-stratum obstruction formula (111.12) is the finite-dimensional statement behind this requirement: a smooth-stratum pushforward satisfies the residual QME only after the small-instanton boundary functional has vanished or has been cancelled by a specified resolution, relative cycle, or residue prescription.

Definition 101.18 is deliberately more structured than the phrase "use the Nekrasov partition function". The finite-dimensional ADHM statement Proposition 101.10 proves the stability part of item 2 once the fixed-locus reduction has already been made. It proves neither the existence of the four-dimensional regulator in item 1, nor the determinant-line comparison in item 3, nor the small-instanton boundary cancellation in item 4, nor the limiting statement in item 5. Conversely, a regulator that selected the Uhlenbeck compactification without a compensating boundary functional would not give the Nekrasov factor appearing in (101.29); it would define a different localized problem.

Open Problem 101.19 (Continuum regulator theorem for Gieseker selection)*.* Construct, for four-dimensional $\mathcal{N}=2$ gauge theory on S^4, a BV-compatible supersymmetric regulator and integration cycle satisfying Definition 101.18 for every instanton charge k, or prove that the standard S^4 localization formula requires an additional nonperturbative definition whose instanton sectors are Gieseker/Nekrasov equivariant integrals by construction. The known finite-dimensional ADHM resolution and the noncommutative positive-moment-map mechanism are necessary local pieces of such a theorem, but they do not by themselves prove the continuum field-theoretic selection statement.

The localized partition function is

$$Z^{\mathcal{N}=2}_{S^4} = \frac{1}{|W_G|}\int_{\mathfrak{t}} da\, Z_{\mathrm{cl}}(a)\, Z^{S^4}_{1-\mathrm{loop}}(a)\, Z_{\mathrm{inst}}\left(a,\tau;\frac{1}{r},\frac{1}{r}\right) Z_{\mathrm{inst}}\left(a,\bar{\tau};\frac{1}{r},\frac{1}{r}\right). \tag{101.29}$$

The north pole contributes instantons and the south pole contributes anti-instantons. The two factors are complex conjugates only when the integration cycle and masses are chosen so that reflection positivity gives the corresponding conjugation property.

Protected-insertion comparison budget. Equation (101.29) is the scalar partition-function case of a functional statement on protected insertions. Fix a finite test space $\mathcal{P}_N$ of Q-closed regulated insertions containing the unit insertion and the protected Wilson-loop insertions under study. On $\mathcal{P}_N$ let

$$\mathcal{Z}_{\mathrm{reg}},\quad \mathcal{Z}_{\mathrm{def}},\quad \mathcal{Z}_{\mathrm{normal}},\quad \mathcal{Z}_{\mathrm{res}},\quad \mathcal{Z}_{\mathrm{Nek}},\quad \mathcal{Z}_{\mathrm{loc}} \in \mathcal{P}_N^\vee$$

denote, respectively, the regulated QFT functional, the functional after the Q-exact deformation, the functional after normal Gaussian integration, the residual Cartan-contour functional, the north/south ADHM–Nekrasov functional, and the final localized expression. Define

$$\begin{aligned} E_{\mathrm{Stokes}} &= \mathcal{Z}_{\mathrm{reg}} - \mathcal{Z}_{\mathrm{def}}, \\ E_{\mathrm{normal}} &= \mathcal{Z}_{\mathrm{def}} - \mathcal{Z}_{\mathrm{normal}}, \\ E_{\mathrm{res}} &= \mathcal{Z}_{\mathrm{normal}} - \mathcal{Z}_{\mathrm{res}}, \\ E_{\mathrm{inst}} &= \mathcal{Z}_{\mathrm{res}} - \mathcal{Z}_{\mathrm{Nek}}, \\ E_{\mathrm{cont}} &= \mathcal{Z}_{\mathrm{Nek}} - \mathcal{Z}_{\mathrm{loc}}. \end{aligned}$$

Then the comparison to the displayed localization formula is the exact telescope

$$\mathcal{Z}_{\mathrm{reg}} - \mathcal{Z}_{\mathrm{loc}} = E_{\mathrm{Stokes}} + E_{\mathrm{normal}} + E_{\mathrm{res}} + E_{\mathrm{inst}} + E_{\mathrm{cont}}. \tag{101.30}$$

Here E_{Stokes} records finite-regulator Q-Stokes, anomaly, and boundary defects; E_{normal} records normal-complex, zero-mode, and determinant-line defects; E_{res} records the residual Cartan contour, Weyl quotient, and fixed-locus restriction of the insertion; E_{inst} records the choice of Gieseker/Nekrasov instanton compactification at the poles; and E_{cont} records the continuum limit and contact-term comparison. For any norm on the finite-dimensional dual space,

$$\|\mathcal{Z}_{\mathrm{reg}} - \mathcal{Z}_{\mathrm{loc}}\| \leq \|E_{\mathrm{Stokes}}\| + \|E_{\mathrm{normal}}\| + \|E_{\mathrm{res}}\| + \|E_{\mathrm{inst}}\| + \|E_{\mathrm{cont}}\|.$$

Thus the usual formula is recovered for this test space only after these five residuals have been killed or bounded. For the half-BPS circular Wilson loop, the fixed-locus restriction is $W_{\square}|_{\mathrm{fix}} = N^{-1}\operatorname{Tr}_{\square} \mathrm{e}^{X}$; the Laguerre and Bessel computations below evaluate $\mathcal{Z}_{\mathrm{loc}}(W_{\square})/\mathcal{Z}_{\mathrm{loc}}(1)$. They do not by themselves prove the continuum field-theoretic vanishing of the five residuals above.

Example 101.20 ($\mathcal{N} = 4$ Yang–Mills degeneration)**.** For an $\mathcal{N} = 2$ vector multiplet plus an adjoint hypermultiplet with the mass coordinate tuned to the $\mathcal{N} = 4$ point, the determinant cancellation above reduces the perturbative one-loop determinant to the Cartan gauge-fixing Jacobian. The remaining matrix model is

$$Z_{S^4}^{\mathcal{N}=4} = \frac{1}{|W_G|} \int_{\mathfrak{t}} da \, \exp\left\{-\frac{4\pi^2 r^2}{g_{\mathrm{YM}}^2}(a,a)\right\} \prod_{\alpha \in \Delta_+} \alpha(a)^2.$$

For $G = U(1)$ there is no root factor and no finite-action instanton sector on $\mathbb{C}^2$. The partition function reduces to the ordinary Gaussian

$$\int_{-\infty}^{\infty} da \, \exp\left(-\frac{4\pi^2 r^2}{g_{\mathrm{YM}}^2} a^2\right) = \frac{g_{\mathrm{YM}}}{2\sqrt{\pi}\, r}. \tag{101.31}$$

Definition 101.21 (Circular Wilson-loop matrix-model coupling)**.** For $G = U(N)$, let X denote the Hermitian matrix whose eigenvalues x_i are the dimensionless arguments that appear in the localized fundamental half-BPS circular Wilson loop,

$$W_{\square}(X) = \frac{1}{N} \operatorname{Tr}_{\square} \mathrm{e}^{X} = \frac{1}{N} \sum_{i=1}^{N} \mathrm{e}^{x_i}. \tag{101.32}$$

The circular-loop Gaussian coupling λ_{circ} is defined by writing the $\mathcal{N} = 4$ localized $U(N)$ Gaussian model in the form

$$\mathrm{d}\mu_{\lambda_{\mathrm{circ}},N}(X) = \frac{1}{Z_{\lambda_{\mathrm{circ}},N}} \exp\left(-\frac{2N}{\lambda_{\mathrm{circ}}} \operatorname{Tr}_{\square} X^2\right) \mathrm{d}X, \tag{101.33}$$

or, after diagonalizing X,

$$\mathrm{d}\mu_{\lambda_{\mathrm{circ}},N}(x) \propto \prod_{i=1}^{N} dx_i \, \exp\left(-\frac{2N}{\lambda_{\mathrm{circ}}}\sum_{i=1}^{N} x_i^2\right) \prod_{i<j}(x_i - x_j)^2. \tag{101.34}$$

This is a definition of the coupling that enters the exact circular-loop answer. Converting it to a Lagrangian symbol such as $g_{\mathrm{YM}}^2 N$ requires using the same fundamental-matrix normalization for the scalar in the Wilson-loop exponent and for the quadratic form in the localized Gaussian. Rescaling the Lie-algebra generators rescales both data; the matrix model (101.33) is the normalization-invariant statement.

Finite-N circular Wilson loop in the Gaussian model. For the $U(N)$ Gaussian matrix model (101.33), the normalized fundamental circular Wilson-loop insertion has the exact finite-N value

$$\left\langle \frac{1}{N}\operatorname{Tr}_{\square} \mathrm{e}^{X} \right\rangle_{\lambda_{\mathrm{circ}},N} = \frac{1}{N}\exp\left(\frac{\lambda_{\mathrm{circ}}}{8N}\right) L_{N-1}^{(1)}\left(-\frac{\lambda_{\mathrm{circ}}}{4N}\right), \tag{101.35}$$

where $L_n^{(1)}$ is the associated Laguerre polynomial.

To derive this formula, put

$$\alpha = \frac{2N}{\lambda_{\mathrm{circ}}}.$$

After diagonalizing X, the one-point density is expressed by the orthogonal-polynomial kernel for the weight $e^{-\alpha x^2}$:

$$\rho_N(x) = \frac{1}{N} e^{-\alpha x^2} \sum_{j=0}^{N-1} \frac{p_j(x)^2}{h_j}, \qquad h_j = \int_{\mathbb{R}} p_j(x)^2 e^{-\alpha x^2}\, dx, \tag{101.36}$$

where p_j is any degree-j polynomial family orthogonal for this weight. Therefore, for an auxiliary parameter s,

$$W_N(s) = \left\langle \frac{1}{N}\operatorname{Tr} \mathrm{e}^{sX} \right\rangle = \frac{1}{N}\sum_{j=0}^{N-1} \frac{1}{h_j}\int_{\mathbb{R}} e^{sx} p_j(x)^2 e^{-\alpha x^2}\, dx. \tag{101.37}$$

Choose $p_j(x) = \alpha^{-j/2} 2^{-j} H_j(\sqrt{\alpha}x)$, where H_j is the physicists' Hermite polynomial. The scale factors cancel in the ratio appearing in (101.37). With $y = \sqrt{\alpha}x$ and $t = s/\sqrt{\alpha}$, the required normalized Hermite integral is

$$\frac{\int_{\mathbb{R}} e^{-y^2+ty} H_j(y)^2\, dy}{\int_{\mathbb{R}} e^{-y^2} H_j(y)^2\, dy} = \exp\left(\frac{t^2}{4}\right) L_j\left(-\frac{t^2}{2}\right). \tag{101.38}$$

For completeness, recall the derivation. The Hermite generating function is

$$\exp(2uy - u^2) = \sum_{j\ge 0} H_j(y)\frac{u^j}{j!}.$$

Multiplying two generating functions and integrating against e^{-y^2+ty} gives

$$\sqrt{\pi}\, \exp\left(\frac{t^2}{4}\right) \exp(2uv + tu + tv)\,.$$

Taking the coefficient of $u^j v^j/(j!)^2$ and dividing by the same coefficient at $t = 0$, namely $2^j j!$, gives (101.38); the remaining finite coefficient sum is the standard Laguerre expansion

$$L_j(z) = \sum_{m=0}^{j} \binom{j}{m} \frac{(-z)^m}{m!}.$$

Substitution into (101.37) yields

$$W_N(s) = \frac{1}{N} \exp\left(\frac{s^2}{4\alpha}\right) \sum_{j=0}^{N-1} L_j\left(-\frac{s^2}{2\alpha}\right). \tag{101.39}$$

The elementary identity

$$\sum_{j=0}^{N-1} L_j(z) = L_{N-1}^{(1)}(z)$$

follows by summing the coefficient formula for L_j and using $\sum_{j=m}^{N-1} \binom{j}{m} = \binom{N}{m+1}$, which is precisely the coefficient formula for $L_{N-1}^{(1)}$. Setting $s = 1$ and $\alpha = 2N/\lambda_{\mathrm{circ}}$ gives (101.35).

Theorem 101.22 (Planar circular Wilson loop from the Gaussian model)**.** *In the large-N limit of* (101.34)*, with $\lambda_{\mathrm{circ}} > 0$ fixed, the normalized eigenvalue density is*

$$\rho_{\lambda_{\mathrm{circ}}}(x) = \frac{2}{\pi \lambda_{\mathrm{circ}}} \sqrt{\lambda_{\mathrm{circ}} - x^2}\, \mathbf{1}_{[-\sqrt{\lambda_{\mathrm{circ}}}, \sqrt{\lambda_{\mathrm{circ}}}]}(x). \tag{101.40}$$

Consequently the planar fundamental circular Wilson loop is

$$\lim_{N\to\infty} \left\langle \frac{1}{N} \operatorname{Tr}_{\Box} \mathrm{e}^X \right\rangle_{\lambda_{\mathrm{circ}},N} = \int dx\, \rho_{\lambda_{\mathrm{circ}}}(x) \mathrm{e}^x = \frac{2}{\sqrt{\lambda_{\mathrm{circ}}}} I_1\left(\sqrt{\lambda_{\mathrm{circ}}}\right), \tag{101.41}$$

where I_1 is the modified Bessel function.

Proof. For an empirical density ρ with $\int \rho(x)dx = 1$, the large-N functional obtained from (101.34) is, up to an additive constant,

$$\mathcal{F}[\rho] = \frac{2}{\lambda_{\mathrm{circ}}} \int x^2 \rho(x) dx - \iint \rho(x)\rho(y) \log|x - y|\, dx\, dy. \tag{101.42}$$

Varying ρ under the normalization constraint gives, on the support of the minimizing density,

$$\frac{2}{\lambda_{\mathrm{circ}}} x^2 - 2 \int \rho(y) \log|x - y|\, dy = \text{constant}. \tag{101.43}$$

Differentiating inside the support gives the singular-integral equation

$$\frac{4x}{\lambda_{\mathrm{circ}}} = 2 \text{ p. v.} \int \frac{\rho(y)}{x - y}\, dy. \tag{101.44}$$

The Cauchy transform of (101.40) is

$$G(z) = \int \frac{\rho_{\lambda_{\mathrm{circ}}}(y)}{z - y}\, dy = \frac{2}{\lambda_{\mathrm{circ}}} \left(z - \sqrt{z^2 - \lambda_{\mathrm{circ}}}\right), \tag{101.45}$$

where the branch is chosen so that $G(z) \sim z^{-1}$ at infinity. The average of the boundary values on the cut is

$$\frac{1}{2}\big(G(x+\mathrm{i}0)+G(x-\mathrm{i}0)\big)=\frac{2x}{\lambda_{\mathrm{circ}}},$$

which is precisely the principal value integral in (101.44). The normalization of (101.40) follows from $\int_{-a}^{a}\sqrt{a^2-x^2}\,dx=\pi a^2/2$, with $a^2=\lambda_{\mathrm{circ}}$. Because the quadratic potential is strictly convex, the logarithmic-energy minimizer is unique. The displayed density satisfies the Euler–Lagrange equation on its support. Outside the support, differentiating the difference between the left side of (101.43) and its constant value gives

$$\frac{4}{\lambda_{\mathrm{circ}}}\sqrt{x^2-\lambda_{\mathrm{circ}}}\quad(x>\sqrt{\lambda_{\mathrm{circ}}})$$

and the corresponding negative derivative on the left component $x<-\sqrt{\lambda_{\mathrm{circ}}}$. Hence the effective potential is larger off the support, so the candidate density is the equilibrium density.

It remains to evaluate the loop insertion. Put $z=\sqrt{\lambda_{\mathrm{circ}}}$ and $x=zt$. Then

$$\int dx\,\rho_{\lambda_{\mathrm{circ}}}(x)\mathrm{e}^{x}=\frac{2}{\pi}\int_{-1}^{1}\mathrm{e}^{zt}\sqrt{1-t^2}\,dt. \tag{101.46}$$

The integral representation

$$I_1(z)=\frac{z}{\pi}\int_{-1}^{1}\mathrm{e}^{zt}\sqrt{1-t^2}\,dt \tag{101.47}$$

gives (101.41). Equivalently, expanding e^{x} and using the even moments

$$\int dx\,\rho_{\lambda_{\mathrm{circ}}}(x)x^{2n}=\frac{1}{n+1}\binom{2n}{n}\left(\frac{\lambda_{\mathrm{circ}}}{4}\right)^{n} \tag{101.48}$$

gives the same series

$$\sum_{n=0}^{\infty}\frac{1}{n!(n+1)!}\left(\frac{\lambda_{\mathrm{circ}}}{4}\right)^{n}=\frac{2}{\sqrt{\lambda_{\mathrm{circ}}}}I_1\Big(\sqrt{\lambda_{\mathrm{circ}}}\Big). \tag{101.49}$$

□

Remark 101.23 (Bremsstrahlung derivative algebra). Assume the protected circular-loop Ward identity

$$B(\lambda_{\mathrm{circ}})=\frac{1}{2\pi^2}\lambda_{\mathrm{circ}}\frac{d}{d\lambda_{\mathrm{circ}}}\log\left\langle\frac{1}{N}\operatorname{Tr}_{\square}\mathrm{e}^{X}\right\rangle_{\mathrm{planar}}. \tag{101.50}$$

Then Theorem 101.22 gives

$$B(\lambda_{\mathrm{circ}})=\frac{\sqrt{\lambda_{\mathrm{circ}}}}{4\pi^2}\frac{I_2(\sqrt{\lambda_{\mathrm{circ}}})}{I_1(\sqrt{\lambda_{\mathrm{circ}}})}. \tag{101.51}$$

Let $z=\sqrt{\lambda_{\mathrm{circ}}}$ and

$$W_0(z)=\frac{2I_1(z)}{z}.$$

Since $\lambda_{\mathrm{circ}}\partial_{\lambda_{\mathrm{circ}}}=(z/2)\partial_z$,

$$\lambda_{\mathrm{circ}}\frac{d}{d\lambda_{\mathrm{circ}}}\log W_0=\frac{z}{2}\left(\frac{I_1'(z)}{I_1(z)}-\frac{1}{z}\right).$$

The modified-Bessel recurrence

$$I_1'(z) = I_2(z) + \frac{1}{z} I_1(z) \tag{101.52}$$

therefore gives

$$\lambda_{\rm circ} \frac{d}{d\lambda_{\rm circ}} \log W_0 = \frac{z}{2} \frac{I_2(z)}{I_1(z)}. \tag{101.53}$$

Substitution into (101.50) proves (101.51).

101.5 S^3 Localization In Three-Dimensional $\mathcal{N}=2$ Theories

Let G, T, $\mathfrak{t}$, W_G, and Δ be as above. On the round S^3_r, the Coulomb-branch localization variable is the constant real scalar $\sigma \in \mathfrak{t}$ in the vector multiplet. With Chern–Simons level k, FI parameter $\zeta \in \mathfrak{t}^*$, chiral multiplets Φ in representations R_Φ, real masses m_Φ, and R-charges Δ_Φ, the Kapustin–Willett–Yaakov matrix integral is

$$Z_{S^3} = \frac{1}{|W_G|} \int_{\mathfrak{t}} d\sigma \, e^{i\pi k r^2(\sigma,\sigma) + 2\pi i r(\zeta,\sigma)} \prod_{\alpha\in\Delta_+} 4\sinh^2\big(\pi r\, \alpha(\sigma)\big) \prod_\Phi Z_\Phi^{S^3}(\sigma), \tag{101.54}$$

where

$$Z_\Phi^{S^3}(\sigma) = \prod_{\rho\in \mathrm{wt}(R_\Phi)} \exp[\ell(1-\Delta_\Phi + i r\,\rho(\sigma) + i r\, m_\Phi)]\,.$$

The function ℓ is fixed, up to an additive constant that changes the overall normalization of Z_{S^3}, by

$$\ell'(z) = -\pi z \cot(\pi z), \qquad \ell\left(\frac{1}{2} + i x\right) + \ell\left(\frac{1}{2} - i x\right) = -\log\big(2\cosh(\pi x)\big). \tag{101.55}$$

Equivalently, the round-sphere determinant is the $b=1$ specialization of the double-sine convention

$$s_b(x) = \prod_{m,n\geq 0} \frac{mb + nb^{-1} + \frac{Q_b}{2} - i x}{mb + nb^{-1} + \frac{Q_b}{2} + i x}, \qquad Q_b = b + b^{-1}, \tag{101.56}$$

defined by zeta regularization or by the corresponding meromorphic continuation. In the convention of (101.54),

$$\exp[\ell(1-\Delta + i x)] = s_1(i(1-\Delta) - x)\,, \qquad x\in\mathbb{R}, \tag{101.57}$$

after fixing the same x-independent normalization on both sides. The reflection identity used for a conjugate R-charge 1/2 pair is

$$s_1\left(\frac{i}{2} - x\right) s_1\left(\frac{i}{2} + x\right) = \frac{1}{2\cosh(\pi x)}. \tag{101.58}$$

The integration contour is the real Cartan in the displayed unitary normalization. This statement includes a convergence hypothesis. If the large-$|\sigma|$ behavior is not damping in every Weyl chamber, then a real mass, FI chamber, analytic continuation, or residue prescription must be declared as part of the theory being evaluated. In abelianized descriptions the possible poles lie on complexified hyperplanes

$$\rho(\sigma) + m_\Phi + i\big(n + \Delta_\Phi\big)/r = 0, \qquad n\in\mathbb{Z}_{\geq 0},$$

up to the convention used for ℓ or s_b. A Jeffrey–Kirwan-type residue prescription is therefore not a decorative evaluation trick: it is a choice of chamber and integration cycle for the regulated localization structure.

Example 101.24 (Abelian Chern–Simons Gaussian)**.** For pure $U(1)_k$ Chern–Simons theory on S^3 with FI parameter ζ, the localized integral is the oscillatory Fresnel integral

$$Z_{U(1)_k}(\zeta) = \int_{\mathbb{R}} d\sigma\, \exp\bigl(\mathrm{i}\pi k\sigma^2 + 2\pi\mathrm{i}\zeta\sigma\bigr)\,.$$

With the contour obtained by rotating the positive quadratic direction by the usual i0 prescription, completing the square gives

$$Z_{U(1)_k}(\zeta) = \frac{\mathrm{e}^{\mathrm{i}\pi\,\mathrm{sgn}(k)/4}}{\sqrt{|k|}}\,\exp\biggl(-\frac{\mathrm{i}\pi\zeta^2}{k}\biggr)\,. \tag{101.59}$$

The phase depends on the framing convention of the Chern–Simons theory; the absolute value and FI dependence follow from the declared contour.

Example 101.25 (A conjugate pair of chirals)**.** For two chiral multiplets of charges $+1$ and -1, both with R-charge $1/2$ and zero real mass, the product of one-loop determinants on the $U(1)$ Coulomb parameter is

$$\exp\biggl[\ell\biggl(\frac{1}{2}+\mathrm{i}\sigma\biggr)+\ell\biggl(\frac{1}{2}-\mathrm{i}\sigma\biggr)\biggr] = \frac{1}{2\cosh(\pi\sigma)}.$$

The elementary integral

$$\int_{-\infty}^{\infty}\frac{d\sigma}{2\cosh(\pi\sigma)} = \frac{1}{2} \tag{101.60}$$

is a finite check on the determinant normalization in (101.54). It is not by itself a definition of a gauge theory; the gauge quotient, possible Chern–Simons contact terms, and background-field couplings remain part of the QFT definition.

101.6 Theorem Boundary And Singular Loci

Equations (101.29) and (101.54) have different mathematical status from Remark 101.2. That remark records the finite-dimensional deformation identity under stated hypotheses. The compact-space QFT formulae additionally require:

- S^4 : a regulator preserving the chosen supercharge, determinant regularization, and an instanton compactification or contour for singular point instantons;
- S^3 : a parity-anomaly regulator, framing convention, real contour or analytic continuation, and a treatment of noncompact Coulomb directions and singular hyperplanes.

When these data are supplied, localization turns a protected observable into an integral over fixed-locus variables. It does not erase the distinction between regularization and renormalization, nor does it make contact terms canonical. Background Chern–Simons terms in three dimensions and local curvature counterterms in four dimensions change phases or local source-dependent factors in the localized answer; they must be tracked as coordinates of the QFT, not discarded as normalization details.

Part VIII

Topological and Cohomological Quantum Field Theory

Chapter 102

Metric Independence and Cohomological Observables

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

A topological sector of a quantum field theory is not defined by the absence of formulas containing a metric. It is defined by correlation functionals whose variation under allowed changes of geometric representatives is controlled and, for the observables under consideration, vanishes in cohomology. The most common mechanism is cohomological: an odd symmetry Q acts on the regulated fields, sources, and insertions; metric variation of the action and of the insertions is Q-exact; and the regulated expectation functional obeys the corresponding Ward identity. This chapter develops that mechanism before any particular example is introduced.

102.1 Proof Status Map for Topological Claims

The topological volumes use several kinds of input, and the status labels are not interchangeable. A finite state-sum identity, a differential-topology classification theorem, and a physical RG comparison do not have the same proof burden. The reader should use the following map while moving through Volumes VIII and IX.

1. A *local finite proof* is a calculation inside a finite-dimensional or finite-groupoid model. Examples include the de Rham Q-Stokes model in this chapter, the ordinary Frobenius-algebra

classification in Chapter 103, the finite gauge groupoid gluing in Chapter 112, and the finite cochain higher-gauging identities in Chapter 123.

2. A *local mechanism under an explicit model hypothesis* proves the algebraic step after the model has been supplied. This is the status of the normal Gaussian/Euler-factor calculation in Chapter 106, the BV collar-boundary formula in Chapter 111, the Müger-center plaquette criterion in Chapter 110, and the finite gauging projector comparison in Chapter 122. These arguments explain what a model must do; they do not construct every continuum or higher-categorical model that could realize the algebra.

3. An *external mathematical theorem boundary* is used with stated hypotheses and a declared role, but is not reproved locally. This includes the fully extended cobordism hypothesis, the full Reshetikhin–Turaev/Crane–Yetter/Walker–Wang theorem packages, Gromov–Witten virtual-cycle technology in Chapter 107, and the Donaldson, Seiberg–Witten, Bauer–Furuta, and Furuta differential-topology inputs in Chapter 109.

4. A *controlled QFT hypothesis* asks for a regulator, BV or Hilbert space construction, anomaly-line convention, compactness statement, and determinant-line normalization. Chern–Simons theory in Chapter 105, continuum cohomological gauge theories, and symmetry-defect systems in Chapters 114 and 121 often sit here until the required construction data have been given.

5. An *open comparison problem* remains when the chapter has exposed the finite or local mechanisms but not built the single continuum framework that identifies them. The Donaldson–Seiberg–Witten comparison is the main example: the finite moduli-space theorems, u-plane wall-normal model, contact terms, and determinant phases test individual arrows, while the full Q-compatible Wilsonian flow from twisted non-Abelian gauge theory to the Abelian monopole theory remains a theorem target rather than a settled local derivation.

This map is a guard against a common source of false depth. Proving a finite cell identity can make a quoted theorem less mysterious, but it closes only the arrow whose hypotheses it actually checks. Conversely, leaving a theorem as external is acceptable only when the surrounding QFT statement has been separated from that theorem and the missing construction has been recorded as a hypothesis or open problem.

102.2 Metric Response as a Renormalized Insertion

Let M be a closed oriented smooth D-manifold and let $\mathcal{G}(M)$ denote the Fréchet manifold of smooth Riemannian metrics on M. A metric-dependent QFT presentation assigns, for $g \in \mathcal{G}(M)$, renormalized correlation functionals

$$\langle X \rangle_g$$

for insertions X in a specified algebra of local, extended, and source dependent observables. The notation includes the regulator, local counterterms, source-coordinate system, and contact-term convention. Different choices can present the same continuum theory, but a metric-variation formula is a statement inside one such presentation.

Definition 102.1 (Stress-tensor response)**.** Let X be a renormalized insertion whose support is disjoint from the support of a compactly supported metric variation $\delta g^{\mu\nu}$. The stress-tensor response of the presentation is the distributional identity

$$\delta_g\langle X\rangle_g = -\frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,\delta g^{\mu\nu}(x)\,\langle T_{\mu\nu}(x)X\rangle_g + \langle C_{\delta g}(X)\rangle_g. \tag{102.1}$$

Here $T_{\mu\nu}$ is the renormalized stress tensor and $C_{\delta g}(X)$ is the sum of contact insertions supported where the metric variation collides with the support or source-dependence of X.

If X is a product of metric-independent local operators at fixed points and δg is supported away from those points, then $C_{\delta g}(X) = 0$. If X includes integrated observables, line operators, boundary conditions, or metric-dependent representatives, the contact term is part of the definition of the observable. Ignoring it is equivalent to changing the problem.

For a one-parameter family g_s, (102.1) becomes

$$\frac{\mathrm{d}}{\mathrm{d}s}\langle X_s\rangle_{g_s} = -\frac{1}{2}\int_M \mathrm{d}^D x\sqrt{g_s}\,\dot{g}_s^{\mu\nu}\langle T_{\mu\nu}(x)X_s\rangle_{g_s} + \left\langle C_{\dot{g}_s}(X_s) + \dot{X}_s\right\rangle_{g_s}. \tag{102.2}$$

The term $\dot{X}_s$ records explicit variation of the chosen insertion representative. Metric independence is the assertion that the right-hand side vanishes for the chosen cohomology classes and for every allowed path g_s.

102.3 Cohomological Ward Systems

The letter Q will denote an odd operator of degree $+1$. If Y is a homogeneous insertion, write $|Y| \in \mathbb{Z}_2$ for its parity. The graded commutator with Q is

$$[Q, Y]_{\mathrm{gr}} = QY - (-1)^{|Y|}YQ.$$

For an odd Y, this is an anticommutator; for an even Y, it is a commutator. In a path-integral presentation it is often clearer to regard Q as an odd derivation δ_Q on the algebra of insertions.

Definition 102.2 (Cohomological Ward system)**.** A cohomological Ward system over a family of metrics g_s consists of:

(i) a graded algebra $\mathcal{A}_s$ of renormalized insertions;

(ii) an odd degree-$+1$ derivation $\delta_Q : \mathcal{A}_s \to \mathcal{A}_s$ satisfying $\delta_Q^2 = 0$;

(iii) expectation functionals $\langle\cdot\rangle_s : \mathcal{A}_s \to \mathbb{C}$;

(iv) a subspace $\mathcal{A}_s^{\mathrm{adm}} \subset \mathcal{A}_s$ of insertions for which metric derivatives and Q-variations are both defined;

(v) the Ward identity

$$\langle\delta_Q Y\rangle_s = 0, \qquad Y \in \mathcal{A}_s^{\mathrm{adm}}. \tag{102.3}$$

The system is anomaly-free on this family if (102.3) holds without additional local or boundary terms. If $\langle\delta_Q Y\rangle_s = \langle\mathcal{A}_Q(Y)\rangle_s$ for a nonzero local functional $\mathcal{A}_Q$, then $\mathcal{A}_Q$ is the cohomological anomaly in the chosen presentation.

The Ward identity is a theorem only after regularization and renormalization are specified. In finite-dimensional compact models it is Stokes' theorem. In gauge theory it is a statement about the BV or BRST measure, the quantum master equation, and boundary behavior at infinity or at singular strata.

Definition 102.3 (Cohomological topological sector)**.** A cohomological topological sector for the family g_s is a cohomological Ward system together with, for every s, a class of Q-closed insertions X_s and an odd insertion V_s such that

$$\frac{\mathrm{d}}{\mathrm{d}s}\langle X_s\rangle_s = \langle \delta_Q V_s\rangle_s\,. \tag{102.4}$$

If the metric response is expressed by a stress tensor, this condition is usually implemented by

$$-\frac{1}{2}\sqrt{g_s}\,\dot{g}_s^{\mu\nu}T_{\mu\nu}\,X_s + C_{\dot{g}_s}(X_s) + \dot{X}_s = \delta_Q V_s \tag{102.5}$$

as an integrated renormalized insertion.

This definition keeps two distinct statements separate. The local formula $T_{\mu\nu} = [Q, G_{\mu\nu}]_{\mathrm{gr}}$ is sufficient only when the contact terms and the explicit variation of X_s are also Q-exact. In examples, the latter terms are often where the nontrivial geometry of the observable enters.

Metric independence from a cohomological Ward system. Let g_s, $0 \le s \le 1$, be a smooth path of metrics on a closed manifold M. Suppose $X_s \in \mathcal{A}_s^{\mathrm{adm}}$ satisfies $\delta_Q X_s = 0$, the one-parameter metric response is defined for all s, and the response insertion is Q-exact as in (102.4). If the Ward identity (102.3) holds for the corresponding V_s, then

$$\langle X_1\rangle_{g_1} = \langle X_0\rangle_{g_0}.$$

The derivation is the integration of the Ward identity along the path:

$$\frac{\mathrm{d}}{\mathrm{d}s}\langle X_s\rangle_s = \langle \delta_Q V_s\rangle_s.$$

The right-hand side vanishes pointwise in s, so $s \mapsto \langle X_s\rangle_s$ is constant on the interval. The load-bearing hypotheses are the existence of the renormalized metric response, the construction of V_s, and the Ward identity for that insertion.

In local stress-tensor language, this criterion is often summarized by saying that $T_{\mu\nu}$ is Q-exact. The precise statement is (102.5): the whole renormalized metric response, including contact terms and moving insertion representatives, must be Q-exact.

102.4 Contact Terms, Anomalies, and Boundaries of Field Space

There are three common mechanisms by which the proof above can fail.

First, the Q-variation of the measure may be anomalous. In BV language, the anomaly is the obstruction to the quantum master equation for the renormalized action. If S is a regulated BV action and Δ is the regulated BV Laplacian, the formal Ward identity follows from

$$\frac{1}{2}(S,S) - \hbar\Delta S = 0.$$

Failure of this equation gives a local functional $\mathcal{A}_Q$ whose cohomology class controls whether a local counterterm can restore the Ward identity. This is why gauge-theoretic cohomological theories must be connected to the BV formalism developed in Chapter 48.

Second, the integration space may have boundaries or noncompact ends. A finite-dimensional model with an odd vector field Q obeys

$$\int_{\mathcal{F}} \delta_Q(\cdots) = \int_{\partial\mathcal{F}} \iota_Q(\cdots)$$

whenever Stokes' theorem applies. Thus the Ward identity requires either $\partial\mathcal{F} = \varnothing$, boundary conditions that kill the boundary term, or compactification data for which the boundary contribution is itself cancelled by other strata. In Donaldson–Witten theory this issue is reflected in compactification of instanton moduli spaces; in localization integrals it appears as contour, Jeffrey–Kirwan, or other cycle choices.

Third, contact terms can change the observable algebra. If a metric variation moves the representative of an integrated observable, its collision with other insertions can generate lower-dimensional descendant operators. A cohomological topological sector therefore contains not only the cohomology of isolated operators but also a contact-term prescription compatible with products and collisions.

Warning 102.4 (Metric independence is not automatic functoriality)*.* Metric-independent closed-manifold numbers do not by themselves define a topological field theory in the Atiyah–Segal sense. A functorial theory must also assign state spaces to codimension-one manifolds, linear maps to bordisms, and gluing isomorphisms. Cohomological Ward identities are a mechanism for producing such data under additional compactness, anomaly, boundary, and finite-dimensionality hypotheses; those hypotheses are part of the construction data.

102.5 Descent and Integrated Observables

Cohomological gauge theories often start from a local Q-closed scalar operator and produce observables supported on cycles. This is the descent construction. It is the source of Donaldson observables, topological sigma-model observables, and many protected line and surface insertions.

Definition 102.5 (Descent equations)**.** Let $O^{(p)}$ be a sequence of renormalized p-form-valued local operators, $0 \le p \le D$, with total parity including form degree. A descent system is

$$\delta_Q O^{(0)} = 0, \qquad \delta_Q O^{(p+1)} + \mathrm{d}O^{(p)} = 0, \quad 0 \le p \le D-1, \tag{102.6}$$

as an identity of renormalized local operator-valued forms, including contact terms when other insertions are present.

For a closed oriented p-cycle $\Sigma_p \subset M$, define

$$O(\Sigma_p) = \int_{\Sigma_p} O^{(p)}.$$

This integral is a renormalized insertion; if Σ_p intersects other operator supports, one must specify the collision prescription.

Homological invariance of descended observables. Assume (102.6) holds and that no contact terms are encountered during the deformations below. If Σ_p is closed, then $O(\Sigma_p)$ is Q-closed. If $\Sigma_p' - \Sigma_p = \partial B_{p+1}$, then

$$O(\Sigma_p') - O(\Sigma_p) = -\delta_Q \int_{B_{p+1}} O^{(p+1)}. \tag{102.7}$$

Thus the Q-cohomology class of $O(\Sigma_p)$ depends only on the homology class $[\Sigma_p]$.

For a closed cycle,

$$\delta_Q O(\Sigma_p) = \int_{\Sigma_p} \delta_Q O^{(p)} = -\int_{\Sigma_p} \mathrm{d}O^{(p-1)} = -\int_{\partial\Sigma_p} O^{(p-1)} = 0.$$

If $\Sigma_p' - \Sigma_p = \partial B_{p+1}$, then Stokes' theorem and the descent equation give

$$O(\Sigma_p') - O(\Sigma_p) = \int_{\partial B_{p+1}} O^{(p)} = \int_{B_{p+1}} \mathrm{d}O^{(p)} = -\delta_Q \int_{B_{p+1}} O^{(p+1)}.$$

The calculation is an identity in the renormalized insertion algebra under the stated no-contact hypothesis.

Example 102.6 (Donaldson-type descent form)**.** In a four-dimensional cohomological gauge theory obtained from a twisted $\mathcal{N} = 2$ vector multiplet, the scalar field ϕ is even and the connection A has an odd one-form partner ψ. With gauge-invariant quadratic polynomial

$$O^{(0)} = \frac{1}{8\pi^2} \operatorname{tr} \phi^2,$$

and with the convention

$$\delta_Q A = \psi, \qquad \delta_Q \psi = -D_A \phi, \qquad \delta_Q \phi = 0,$$

one may choose the first descendants to be

$$O^{(1)} = \frac{1}{4\pi^2} \operatorname{tr}(\phi\psi), \qquad O^{(2)} = \frac{1}{4\pi^2} \operatorname{tr}\left(\phi F + \frac{1}{2}\psi \wedge \psi\right),$$

with higher descendants determined by (102.6). Direct substitution gives

$$\delta_Q O^{(1)} = -\mathrm{d}O^{(0)}, \qquad \delta_Q O^{(2)} = -\mathrm{d}O^{(1)},$$

using the Bianchi identity $D_A F = 0$ and cyclicity of the trace. The normalizations depend on the trace convention and must match the instanton-number normalization of the gauge theory. The integral $\int_{\Sigma_2} O^{(2)}$ is the basic surface observable entering Donaldson–Witten theory; the homological-invariance calculation above explains why its cohomology class depends on the homology class of Σ_2, before compactification and contact-term issues are addressed.

102.6 A Finite-Dimensional Model of the Ward Identity

The following model is not a field theory, but it is the algebraic core of cohomological localization. Let x^i be even coordinates on a compact oriented finite-dimensional manifold X, and let ψ^i be odd coordinates corresponding to $\mathrm{d}x^i$. The de Rham differential is the odd derivation

$$Qx^i = \psi^i, \qquad Q\psi^i = 0.$$

An ordinary differential form α is represented as a function $\alpha(x, \psi)$, and $Q\alpha$ is $\mathrm{d}\alpha$. If X is closed, Stokes' theorem gives

$$\int_X Q\eta = \int_X \mathrm{d}\eta = 0.$$

If α is Q-closed and V_t is an odd family, then

$$\frac{\mathrm{d}}{\mathrm{d}t} \int_X \alpha \, \exp[-QV_t] = -\int_X \alpha \, Q(\dot{V}_t) \, \exp[-QV_t] = -\int_X Q\left(\alpha \, \dot{V}_t \, \exp[-QV_t]\right) = 0,$$

where $Q\alpha = 0$, $Q(QV_t) = 0$, and the graded Leibniz rule fix the sign. This is the finite-dimensional prototype of the cohomological metric-independence criterion above. Infinite-dimensional QFT applications require a regulator, a measure or BV half-density, and a proof that no boundary terms appear from noncompact field directions.

102.7 Functorial Target

The Atiyah–Segal form of a topological field theory assigns a vector space $Z(\Sigma)$ to a closed $(D-1)$-manifold Σ and a linear map

$$Z(M) : Z(\Sigma_{\mathrm{in}}) \to Z(\Sigma_{\mathrm{out}})$$

to a bordism $M : \Sigma_{\mathrm{in}} \to \Sigma_{\mathrm{out}}$, with compatibility under gluing:

$$Z(M_2 \circ M_1) = Z(M_2) Z(M_1).$$

Extended versions refine this assignment to manifolds with corners and higher-categorical targets. The cohomological construction above is one source of such functors after gauge fixing, anomaly cancellation, boundary conditions, compactness, and finite-dimensionality hypotheses have been supplied.

Open Problem 102.7 (From cohomological path integrals to extended functors). Given a cohomological gauge theory with a Q-exact metric response, determine the exact hypotheses under which its correlation functions define an extended topological functor: compactness or properness of the moduli problem, anomaly cancellation, boundary conditions, gluing analysis, orientation data, contact-term compatibility, and compatibility with local operator insertions. The objective is to construct the functorial QFT object from regulated cohomological field theory data while matching known invariants.

Chapter 103

Bordism Functoriality and Extended Topological Field Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The cohomological mechanism of Chapter 102 produces correlation functionals whose metric variation is controlled by a Ward identity. A functorial topological field theory is a stronger object. It assigns state spaces to closed spatial manifolds, linear maps to bordisms, and compatibility maps for cutting and gluing. The purpose of this chapter is to state the functorial data precisely enough that later claims about BF theory, Chern–Simons theory, finite gauge theory, cohomological gauge theory, and topological twists have a definite target.

Throughout this chapter $\Bbbk$ is a field of characteristic zero unless a finite-field example is explicitly declared. The finite-dimensional target is denoted $\mathbf{Vect}_{\Bbbk}^{\mathrm{fd}}$. Infinite-dimensional state spaces, bornological vector spaces, and Hilbert completions occur naturally in non-topological QFT and in some noncompact topological theories; whenever they are used later, the topology on the target is part of the datum and the gluing maps must be continuous for that topology.

103.1 Tangential Structures and Collared Bordisms

A tangential structure in dimension D is a map

$$\theta_\xi : B_\xi \longrightarrow BO(D).$$

Examples are $BSO(D) \to BO(D)$ for oriented manifolds, $BSpin(D) \to BO(D)$ for spin manifolds, and the point $* \to BO(D)$ classifying a framing of the tangent bundle. If N is a smooth d-manifold with $d \leq D$, a ξ-structure on N means a lift, up to homotopy through lifts, of the classifying map of the stabilized tangent bundle

$$TN \oplus \mathbb{R}^{D-d} \longrightarrow BO(D)$$

to B_ξ. This stabilized convention is the one compatible with extended bordisms: a hypersurface, a boundary corner, and a point are all regarded as lower-dimensional strata inside D-dimensional bordisms.

Definition 103.1 (Collared ξ-bordism)**.** Let Σ_0 and Σ_1 be closed compact smooth $(D-1)$-manifolds with ξ-structure. A collared ξ-bordism

$$M : \Sigma_0 \longrightarrow \Sigma_1$$

is a compact smooth D-manifold M with ξ-structure, together with boundary identifications

$$\partial M \simeq \bar{\Sigma}_0 \sqcup \Sigma_1$$

and collar embeddings near the incoming and outgoing components. Here $\bar{\Sigma}_0$ denotes the same underlying manifold with the tangential structure reversed in the sense appropriate to ξ. Two collared bordisms are equivalent if they are related by a ξ-diffeomorphism which respects the collars up to isotopy.

The collars are not decorative. They make composition a smooth operation: if $M_{01} : \Sigma_0 \to \Sigma_1$ and $M_{12} : \Sigma_1 \to \Sigma_2$, then

$$M_{12} \circ M_{01} = M_{01} \cup_{\Sigma_1} M_{12}$$

is obtained by identifying the outgoing collar of M_{01} with the incoming collar of M_{12}, followed by the canonical smoothing determined by the collar product coordinate. The identity of Σ is the cylinder $\Sigma \times [0,1]$ with product ξ-structure.

Definition 103.2 (Ordinary bordism category)**.** The category Bord_D^ξ has:

- objects: closed compact smooth $(D-1)$-manifolds with ξ-structure;
- morphisms: equivalence classes of collared ξ-bordisms;
- composition: collar gluing;
- symmetric monoidal product: disjoint union.

The monoidal unit is the empty manifold $\varnothing$.

Figure 103.1 records the collar-gluing operation in the bordism category: two bordisms sharing the collared boundary Σ_1 compose by identifying that boundary.

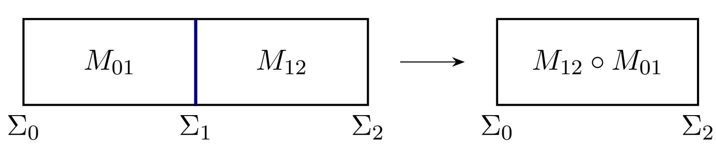

Figure 103.1: Composition in the ordinary bordism category is collar gluing. The intermediate boundary component is not retained as extra data after the composition; extended TQFT keeps track of such cuts through lower-codimension assignments.

Definition 103.2 is the 1-categorical version. A fully smooth functorial QFT normally uses a topologically enriched or higher bordism object in which smooth families of bordisms are also visible. The ordinary category is nevertheless the right first target for finite-dimensional Atiyah–Segal TQFT because it isolates the exact gluing identities on which every refinement must reduce.

103.2 Atiyah–Segal Functoriality

Definition 103.3 (Atiyah–Segal topological field theory)**.** An honest D-dimensional Atiyah–Segal TQFT with tangential structure ξ and finite-dimensional linear target is a symmetric monoidal functor

$$Z : \mathrm{Bord}_D^{\xi} \longrightarrow \mathbf{Vect}_{\Bbbk}^{\mathrm{fd}}.$$

Thus there are canonical isomorphisms

$$Z(\Sigma_1 \sqcup \Sigma_2) \simeq Z(\Sigma_1) \otimes Z(\Sigma_2), \qquad Z(\varnothing) \simeq \Bbbk,$$

and for composable bordisms

$$Z(M_{12} \circ M_{01}) = Z(M_{12})\, Z(M_{01}).$$

The cylinder maps to the identity on $Z(\Sigma)$.

For a closed D-manifold M, regarded as a bordism $\varnothing \to \varnothing$, the value $Z(M)$ is the scalar by which the map $\Bbbk \to \Bbbk$ multiplies. For a bordism $M : \Sigma_0 \to \Sigma_1$, $Z(M)$ is the transition amplitude from the state space $Z(\Sigma_0)$ to $Z(\Sigma_1)$. These words are justified by the gluing axiom, not by an analogy with time evolution: if M is cut along an intermediate closed hypersurface Σ, the amplitude factors through the state space assigned to Σ.

Definition 103.4 (Anomalous or relative functorial theory)**.** Let $\mathcal{L}$ be an invertible $(D+1)$-dimensional field theory, or equivalently in the finite-dimensional setting a compatible system of one-dimensional anomaly lines over boundary data. A D-dimensional theory relative to $\mathcal{L}$ assigns vectors or linear maps valued in those lines. It becomes an honest functor only after the anomaly line has been trivialized, or after the $(D+1)$-dimensional bulk $\mathcal{L}$ is kept as part of the system.

This distinction matters in gauge theory and in theories with gravitational or global anomalies. A path integral may satisfy topological Ward identities on closed manifolds while its boundary Hilbert spaces transform projectively. The functorial object is then relative, not an honest functor $\mathrm{Bord}_D^{\xi} \to \mathbf{Vect}_{\Bbbk}^{\mathrm{fd}}$.

The Atiyah–Segal datum is the metric-independent specialization of the Kontsevich–Segal viewpoint developed in Chapter 13. A Kontsevich–Segal theory keeps admissible complex metrics and analytic dependence as part of the bordism datum. An Atiyah–Segal TQFT is obtained when, after all anomaly and background-structure data have been included, the amplitude is locally constant on the geometric parameters.

103.3 Duality, Pairings, and Reflection

If $\bar{\Sigma}$ is the reversed ξ-manifold, the evaluation bordism

$$\mathrm{ev}_{\Sigma} : \bar{\Sigma} \sqcup \Sigma \longrightarrow \varnothing$$

and coevaluation bordism

$$\mathrm{coev}_\Sigma : \varnothing \longrightarrow \Sigma \sqcup \bar{\Sigma}$$

are the two caps obtained by viewing the cylinder on Σ sideways. Functoriality gives maps

$$Z(\mathrm{ev}_\Sigma) : Z(\bar{\Sigma}) \otimes Z(\Sigma) \to \Bbbk, \qquad Z(\mathrm{coev}_\Sigma) : \Bbbk \to Z(\Sigma) \otimes Z(\bar{\Sigma}).$$

Proposition 103.5 (State-space duality from caps and cylinders)**.** *Let Z be an honest finite-dimensional Atiyah–Segal TQFT. Then $Z(\bar{\Sigma})$ is canonically dual to $Z(\Sigma)$. Equivalently, the pairing $Z(\bar{\Sigma}) \otimes Z(\Sigma) \to \Bbbk$ from the evaluation bordism is nondegenerate, and the coevaluation vector is its inverse tensor.*

Proof. Put $V = Z(\Sigma)$ and $W = Z(\bar{\Sigma})$. The evaluation bordism gives a bilinear form $e : W \otimes V \to \Bbbk$, and the coevaluation bordism gives an element $c \in V \otimes W$. The point of the cap/cylinder argument is that (e, c) is not arbitrary bordism data; it obeys the categorical triangle identities.

The two zig-zag composites

$$\Sigma \xrightarrow{\mathrm{coev}_\Sigma \sqcup \mathrm{id}_\Sigma} \Sigma \sqcup \bar{\Sigma} \sqcup \Sigma \xrightarrow{\mathrm{id}_\Sigma \sqcup \mathrm{ev}_\Sigma} \Sigma$$

and

$$\bar{\Sigma} \xrightarrow{\mathrm{id}_{\bar{\Sigma}} \sqcup \mathrm{coev}_\Sigma} \bar{\Sigma} \sqcup \Sigma \sqcup \bar{\Sigma} \xrightarrow{\mathrm{ev}_\Sigma \sqcup \mathrm{id}_{\bar{\Sigma}}} \bar{\Sigma}$$

are diffeomorphic to the corresponding cylinders. Applying Z, and using the cylinder axiom, gives the triangular identities for a dual pair in $\mathbf{Vect}_\Bbbk^{\mathrm{fd}}$:

$$(\mathrm{id}_V \otimes e)(c \otimes \mathrm{id}_V) = \mathrm{id}_V, \qquad (e \otimes \mathrm{id}_W)(\mathrm{id}_W \otimes c) = \mathrm{id}_W.$$

Write $c = \sum_\alpha v_\alpha \otimes w_\alpha$. If $v \in V$ is annihilated by every functional $e(w, \cdot)$, then the first triangle identity gives

$$v = \sum_\alpha v_\alpha e(w_\alpha, v) = 0.$$

Thus the induced map $W \to V^\vee$ is injective. The second triangle identity similarly shows that $V \to W^\vee$ is injective. Since $\dim W \leq \dim V$ and $\dim V \leq \dim W$, both maps are isomorphisms. Under the resulting identification $W \simeq V^\vee$, the tensor c is the canonical inverse tensor to the pairing e, as expressed by the same two triangle identities. $\square$

A unitary topological theory requires more than the bilinear pairing above. Reflection of bordisms should be implemented by an antilinear involution on state spaces, and the pairing obtained by reflecting a state and gluing it to the original state should be positive. This is the TQFT analogue of reflection positivity in Euclidean QFT. Positivity is therefore not a consequence of Definition 103.3; it is extra structure on the functor.

103.4 The Complete Two-Dimensional Oriented Example

The first nontrivial test of the definition is the classification of ordinary two-dimensional oriented TQFTs by finite-dimensional commutative Frobenius algebras. This theorem gives the exact algebraic form of the gluing law for surfaces, with pair-of-pants multiplication as one piece of the structure.

Definition 103.6 (Commutative Frobenius algebra)**.** A commutative Frobenius algebra over $\Bbbk$ is a finite-dimensional unital associative commutative $\Bbbk$-algebra A, together with a linear functional

$$\epsilon : A \to \Bbbk$$

such that the bilinear form

$$\eta(a, b) = \epsilon(ab) \tag{103.1}$$

is nondegenerate. The unit is denoted 1_A, the multiplication is $m : A \otimes A \to A$, and the counit is ϵ.

Choose a basis $\{e_i\}_{i=1}^N$ of A. Let

$$\eta_{ij} = \epsilon(e_i e_j), \qquad (\eta^{ij}) = (\eta_{ij})^{-1},$$

and define the dual elements

$$e^i = \sum_j \eta^{ij} e_j.$$

Then $\epsilon(e_i e^j) = \delta_i^j$. The inverse of the Frobenius pairing is the tensor

$$C = \sum_i e_i \otimes e^i \in A \otimes A.$$

The comultiplication adjoint to multiplication is

$$\Delta(a) = \sum_i e_i \otimes e^i a = \sum_i a e_i \otimes e^i. \tag{103.2}$$

The equality of the two expressions follows from commutativity. The defining adjointness property is

$$(\epsilon \otimes \epsilon)\big(\Delta(a)(b \otimes c)\big) = \epsilon(abc), \qquad a, b, c \in A. \tag{103.3}$$

Cylinder and neck identities. For a commutative Frobenius algebra A, the inverse-pairing tensor $C = \sum_i e_i \otimes e^i$ and the comultiplication Δ give the two elementary algebraic relations used in the surface-cutting construction:

$$\sum_i e_i \, \epsilon(e^i a) = a, \tag{103.4}$$

$$(m \otimes \mathrm{id}_A)(\mathrm{id}_A \otimes \Delta) = \Delta m = (\mathrm{id}_A \otimes m)(\Delta \otimes \mathrm{id}_A). \tag{103.5}$$

These identities are not separate structure on A; they are the algebraic form of gluing a cap to a cup and sliding a pair-of-pants critical level past another one. For the cylinder identity, pair the left side with an arbitrary $b \in A$:

$$\epsilon\left(b \sum_i e_i \, \epsilon(e^i a)\right) = \sum_i \epsilon(b e_i)\epsilon(e^i a) = \epsilon(ba),$$

because $\{e_i\}$ and $\{e^i\}$ are dual bases for the pairing η. Nondegeneracy of η gives (103.4).

For the first equality in (103.5), the left side on $a \otimes b$ is

$$(m \otimes \mathrm{id})(a \otimes \Delta(b)) = \sum_i ae_i \otimes e^i b.$$

The middle term is

$$\Delta(ab) = \sum_i e_i \otimes e^i ab.$$

To prove equality, pair the first tensor factor with an arbitrary $x \in A$ and the second with an arbitrary $y \in A$. The two pairings give

$$\sum_i \epsilon(xae_i)\epsilon(ye^i b) = \epsilon(xyab) = \sum_i \epsilon(xe_i)\epsilon(ye^i ab),$$

again by the dual-basis identity. Nondegeneracy of $\eta \otimes \eta$ proves the equality. The second equality is identical, or follows by commutativity.

Theorem 103.7 (Oriented 2-dimensional TQFTs and Frobenius algebras)**.** *Finite-dimensional ordinary oriented* 2*-dimensional Atiyah–Segal TQFTs over* $\Bbbk$ *are equivalent to finite-dimensional commutative Frobenius algebras over* $\Bbbk$*. Under this equivalence,*

$$A = Z(S^1), \qquad m = Z(P_{2\to 1}), \qquad 1_A = Z(D_{\varnothing\to 1})(1), \qquad \epsilon = Z(D_{1\to\varnothing}),$$

where $P_{2\to 1}$ *is the oriented pair of pants with two incoming circles and one outgoing circle.*

Proof. First let Z be a 2-dimensional oriented TQFT and set $A = Z(S^1)$. The disk from $\varnothing$ to S^1 gives the unit 1_A, the reversed disk gives $\epsilon : A \to \Bbbk$, and the pair of pants gives $m : A \otimes A \to A$. Associativity follows because the two bordisms

$$P_{2\to 1} \circ (P_{2\to 1} \sqcup \mathrm{id}_{S^1}) \quad \text{and} \quad P_{2\to 1} \circ (\mathrm{id}_{S^1} \sqcup P_{2\to 1})$$

are diffeomorphic as oriented bordisms from three circles to one circle. Commutativity follows from the diffeomorphism of the pair of pants which interchanges the two incoming circles. The unit axiom follows by gluing a disk to one incoming circle of the pair of pants, producing a cylinder. Proposition 103.5, applied to the circle, shows that $\epsilon(ab)$ is nondegenerate. Thus A is a commutative Frobenius algebra.

Conversely, let (A, ϵ) be a commutative Frobenius algebra. Define the value on a disjoint union of n positively oriented circles to be $A^{\otimes n}$; reversed circles are assigned the dual vector space, and the Frobenius pairing identifies it with A when an explicit formula is written using the basis-independent tensor C. Assign to the elementary Morse bordisms the maps

$$D_{\varnothing\to 1} \mapsto 1_A, \qquad D_{1\to\varnothing} \mapsto \epsilon, \qquad P_{2\to 1} \mapsto m, \qquad P_{1\to 2} \mapsto \Delta.$$

For a general compact oriented surface with collared boundary, choose a Morse function constant near the boundary. The critical points decompose the surface into disks and pairs of pants, hence into a composite of the elementary maps above.

It remains to show that the resulting linear map is independent of the Morse decomposition. The differential-topological input is the standard Cerf description of decompositions of compact surfaces: two decompositions are related by isotopy, by creation or cancellation of adjacent critical points, and by interchange of neighboring critical levels. Isotopy gives no change. Cancellation of a birth-death pair gives precisely the cylinder identity (103.4) and the unit/counit identities. Interchange of two pair-of-pants critical levels gives associativity, commutativity, and the neck-exchange Frobenius identity (103.5). Therefore the map depends only on the oriented bordism class, and collar gluing is sent to composition because concatenating Morse functions concatenates the associated elementary maps. The construction is symmetric monoidal by tensor product on disjoint unions.

The two constructions are inverse up to the evident natural isomorphism: a TQFT is generated by disks and pairs of pants modulo the relations just checked, and a Frobenius algebra is recovered from the values of the constructed functor on those generating bordisms. □

Figure 103.2 displays the generating bordisms for the two-dimensional oriented TQFT/Frobenius-algebra equivalence: multiplication, unit, pairing, and the relations imposed by bordism invariance.

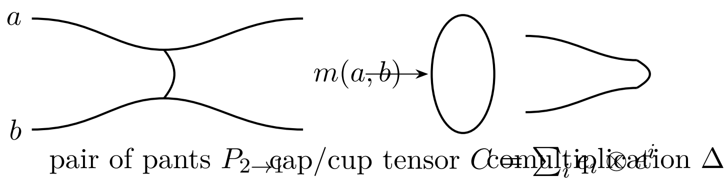

Figure 103.2: In two dimensions the gluing generators are disks, caps, cups, and pairs of pants. The inverse pairing tensor C is what makes gluing along an internal circle a contraction over the intermediate state space.

Example 103.8 (Semisimple idempotent basis)**.** Let

$$A = \Bbbk^r$$

with pointwise multiplication. Let p_α, $1 \le \alpha \le r$, be the primitive idempotents and choose nonzero weights $\lambda_\alpha \in \Bbbk^\times$. Define

$$\epsilon(p_\alpha) = \lambda_\alpha.$$

Then

$$\eta(p_\alpha, p_\beta) = \lambda_\alpha \delta_{\alpha\beta}, \qquad p^\alpha = \lambda_\alpha^{-1} p_\alpha,$$

and the Euler element

$$E = m\Delta(1_A) = \sum_{\alpha=1}^{r} \lambda_\alpha^{-1} p_\alpha$$

is the handle operator. For a closed connected oriented surface Σ_g of genus g,

$$Z(\Sigma_g) = \epsilon(E^g) = \sum_{\alpha=1}^{r} \lambda_\alpha^{1-g}. \tag{103.6}$$

The formula is obtained by cutting Σ_g into a sphere with g handles. Each handle inserts E; the final cap applies ϵ.

103.5 Extended Theories and What Extra Data They Contain

An extended TQFT assigns data not only to closed $(D-1)$-manifolds but also to lower-dimensional strata. Its source is an extended bordism (∞, D)-category

$$\mathrm{Bord}_D^{\xi,\mathrm{ext}},$$

whose objects are points with ξ-structure, whose 1-morphisms are collared intervals and 1-manifolds, whose 2-morphisms are surfaces with corners, and so on up to D-morphisms. The target is a symmetric monoidal higher category $\mathcal{C}$. A fully extended TQFT is a symmetric monoidal higher functor

$$Z : \mathrm{Bord}_D^{\xi,\mathrm{ext}} \to \mathcal{C}.$$

The phrase "locality at all codimensions" means that cutting along corners, defects, junctions, and points is represented by composition in $\mathcal{C}$.

Remark 103.9 (Framed cobordism-hypothesis boundary). The fully general framed cobordism hypothesis is an external higher-categorical classification theorem. In one standard formulation, for a symmetric monoidal (∞, D)-category $\mathcal{C}$ with the duals and adjoints required by framed bordism composition, framed fully extended D-dimensional TQFTs valued in $\mathcal{C}$ are classified by fully D-dualizable objects of $\mathcal{C}$. Here fully D-dualizable means that the object has a dual, its evaluation and coevaluation 1-morphisms have left and right adjoints, those adjunction data have the corresponding adjoints one level higher, and the same adjointability condition continues through level D. This theorem fixes the target data that must be named in a fully extended example: the target higher category, the point object, all duals and adjoints, the tangential-structure action, and any anomaly or boundary decoration. The local calculation below is the part of this structure used in the present chapter.

Definition 103.10 (Finite-dimensional Morita 2-category)**.** Let $\mathbf{Alg}_2^{\mathrm{fd}}$ denote the Morita 2-category over $\Bbbk$. Its objects are finite-dimensional associative unital $\Bbbk$-algebras. A 1-morphism $A \to B$ is a finite-dimensional (B, A)-bimodule. A 2-morphism is a bimodule homomorphism. Composition is relative tensor product over the intermediate algebra, and the symmetric monoidal product is $\otimes_{\Bbbk}$.

Theorem 103.11 (Separable algebras are two-dualizable Morita objects)**.** *Let A be a finite-dimensional separable $\Bbbk$-algebra. Thus there is an element*

$$e = \sum_r x_r \otimes y_r \in A \otimes A^{\mathrm{op}}$$

such that

$$\sum_r x_r y_r = 1_A, \qquad \sum_r a x_r \otimes y_r = \sum_r x_r \otimes y_r a \quad \textit{for every } a \in A. \tag{103.7}$$

In the Morita 2-category Definition 103.10, A has dual A^{op}, and the evaluation and coevaluation bimodules have both left and right adjoints. Hence A is fully 2-dualizable. If, in addition, $\epsilon : A \to \Bbbk$ is a symmetric Frobenius trace, meaning that

$$\epsilon(ab) = \epsilon(ba), \qquad (a, b) \mapsto \epsilon(ab)$$

is nondegenerate, then ϵ is the Calabi–Yau trace datum for the oriented two-dimensional refinement. The circle trace of the Morita object is

$$HH_0(A) = A/[A, A].$$

Proof. The dual object of A is A^{op}. The evaluation 1-morphism

$$\mathrm{ev} : A^{\mathrm{op}} \otimes A \longrightarrow \Bbbk$$

is the vector space A, regarded as a $(\Bbbk, A^{\mathrm{op}} \otimes A)$-bimodule by

$$z \cdot (a^{\mathrm{op}} \otimes b) = azb.$$

The coevaluation

$$\mathrm{coev} : \Bbbk \longrightarrow A \otimes A^{\mathrm{op}}$$

is the same vector space A, now regarded as an $(A \otimes A^{\mathrm{op}}, \Bbbk)$-bimodule by

$$(a \otimes b^{\mathrm{op}}) \cdot z = azb.$$

The two zig-zag composites reduce to the canonical associativity isomorphisms

$$A \otimes_A M \simeq M, \qquad M \otimes_A A \simeq M$$

for finite bimodules M. Thus A^{op} is a Morita dual of A.

It remains to justify adjointability of the evaluation and coevaluation bimodules. Put $A^e = A \otimes A^{\mathrm{op}}$. The multiplication map

$$\mu : A^e \to A, \qquad \mu(a \otimes b^{\mathrm{op}}) = ab$$

is a homomorphism of A-bimodules, equivalently of left A^e-modules. The separability element defines an A^e-linear splitting

$$s : A \to A^e, \qquad s(a) = \sum_r ax_r \otimes y_r = \sum_r x_r \otimes y_r a. \tag{103.8}$$

The equality of the two displayed expressions is precisely the centrality identity in (103.7), and

$$\mu s(a) = \sum_r ax_r y_r = a$$

uses the normalization identity in (103.7). Hence A is a direct summand of the free A^e-module A^e. In particular A is finite projective as a left A^e-module. Applying the same argument to A^{op}, equivalently using the right-module splitting determined by the second expression in (103.8), gives finite projectivity as a right A^e-module as well. These are exactly the enveloping-algebra projectivity statements needed by the coevaluation and evaluation bimodules.

For a finite projective bimodule M representing a 1-morphism $R \to S$, the usual dual modules

$$M^R = \mathrm{Hom}_S(M, S), \qquad M^L = \mathrm{Hom}_R(M, R)$$

carry the opposite bimodule structures and furnish right and left adjoints; the units and counits are the finite dual-basis coevaluation and evaluation maps. Applying this to the evaluation and coevaluation bimodules above gives their adjoints, so A is fully 2-dualizable.

A symmetric Frobenius trace identifies the left and right A-module duals by the nondegenerate pairing $(a, b) \mapsto \epsilon(ab)$. This is the finite-dimensional Calabi–Yau trace datum: it trivializes the Nakayama automorphism and supplies the oriented structure on the Morita object. The value assigned to the circle by the Morita trace is the shadow of the identity (A, A)-bimodule, namely

$$A \otimes_{A^e} A \simeq A/\langle ab - ba : \ a, b \in A\rangle = HH_0(A).$$

$\square$

Example 103.12 (The extended refinement of the semisimple 2-dimensional model)**.** For $A = \Bbbk^r$ with primitive idempotents p_α, the separability element is

$$e = \sum_{\alpha=1}^{r} p_\alpha \otimes p_\alpha.$$

Indeed,

$$\sum_\alpha p_\alpha p_\alpha = 1_A, \qquad a p_\alpha \otimes p_\alpha = p_\alpha \otimes p_\alpha a$$

for every $a \in A$. Choosing nonzero weights $\lambda_\alpha \in \Bbbk^\times$ and

$$\epsilon(p_\alpha) = \lambda_\alpha$$

gives the symmetric Frobenius trace of Example 103.8. Since A is commutative,

$$HH_0(A) = A/[A, A] = A,$$

and the ordinary theory obtained by forgetting point and interval data is the Frobenius-algebra TQFT of Example 103.8.

This example illustrates the conceptual difference between an ordinary and a fully extended theory. In the ordinary theory the circle state space is the primitive datum. In the fully extended Morita-theoretic description the point value is the algebra A, the interval value is the regular bimodule, and the circle state space is obtained by taking the trace of the identity A-bimodule.

103.6 From Local QFT to Functorial Data

A local QFT with a protected topological sector can produce a functorial TQFT only after several independent statements have been proved. The cohomological Ward identity must show metric independence of the selected observables. The state spaces obtained by quantizing on closed spatial manifolds must be identified and completed. Cutting a spacetime along a hypersurface must give an actual contraction over the intermediate state space. Gauge redundancies must be treated by a BV or lattice construction which supplies a gauge-independent integral and a boundary-condition category. Finally, possible anomaly lines must either be trivialized or kept as relative data.

Functorial extraction criterion. Let a regulated local QFT assign, for each collared ξ-bordism $M : \Sigma_0 \to \Sigma_1$, a multilinear amplitude

$$Z_{\mathrm{reg}}(M) : \mathcal{H}_{\mathrm{reg}}(\Sigma_0) \to \mathcal{H}_{\mathrm{reg}}(\Sigma_1)$$

depending on a regulator and auxiliary geometric choices. Suppose:

(i) the selected state spaces have regulator-independent finite-dimensional limits $\mathcal{H}(\Sigma)$;

(ii) for every smooth family of metrics or auxiliary choices, the renormalized variation of the selected amplitudes is zero or is valued in a specified anomaly line;

(iii) for every decomposition $M = M_{12} \circ M_{01}$, the regulated gluing identity converges to

$$Z(M) = Z(M_{12})Z(M_{01})$$

in the operator topology on the finite-dimensional state spaces, with the same anomaly-line convention on both sides;

(iv) the cylinder converges to the identity and disjoint union converges to tensor product.

Then the limiting amplitudes define an honest or relative Atiyah–Segal TQFT, according to whether the anomaly line has been trivialized. Indeed, the limiting assignments are $\Sigma \mapsto \mathcal{H}(\Sigma)$ on objects and $M \mapsto Z(M)$ on morphisms; the four hypotheses are precisely the well-definedness, composition, identity, and symmetric monoidal requirements in Definition 103.3, with the representative dependence recorded as the relative anomaly of Definition 103.4 when the anomaly line is kept.

Open Problem 103.13 (Functorial extraction from interacting QFT). Given a local interacting QFT with a proposed topological sector, construct the associated ordinary or extended bordism functor directly from its Hilbert spaces, local algebras, or Euclidean functional integrals. The construction should identify the precise completion of state spaces, the gluing topology, the anomaly line, the boundary category, and the status of gauge fixing or BV integration cycles.

103.7 Four-Dimensional Cohomological Gauge Theory As A Test Case

Witten–Donaldson theory will be a principal test case for the relation between cohomological path integrals, functorial TQFT data, and ordinary four-dimensional gauge theory. Its ultraviolet presentation is the topological twist of $\mathcal{N} = 2$ Yang–Mills theory. The Donaldson side is organized by the moduli space of anti-self-dual connections, its compactification and orientation data, and the observables obtained from the descent of gauge-invariant polynomials. To define the invariant one must state the gauge group and global form, the four-manifold and its orientation data, the metric dependence and chamber structure, the compactification of the instanton moduli space, and the treatment of reducible connections.

The Seiberg–Witten explanation compares this ultraviolet cohomological gauge theory to an Abelian monopole effective theory on the Coulomb branch. The physical mechanism is an RG statement: after flowing from the non-Abelian $\mathcal{N} = 2$ theory to its low-energy Wilsonian effective action, the singular loci where monopoles or dyons become light supply the Abelian fields and monopole equations that enter the low-energy topological path integral. For the monograph this comparison is not proved by naming the flow. A complete argument must construct the Wilsonian coordinate u, the effective coupling $\tau(u)$, the duality frame near each singular locus, the monopole or dyon hypermultiplet, the contact terms and gravitational couplings, the observable map from Donaldson classes to low-energy observables, and the wall-crossing or u-plane terms when they are present.

Open Problem 103.14 (Donaldson–SW RG comparison). Develop the Donaldson/Seiberg–Witten relation as a theorem-level QFT comparison. The target is to identify which parts follow from rigorous differential geometry of instanton and monopole moduli spaces, which parts follow from finite-dimensional localization or gluing, and which parts depend on a still-unproved RG theorem connecting the twisted non-Abelian $\mathcal{N} = 2$ Yang–Mills theory to the Abelian monopole effective theory. The desired output is an object-level map between correlation functions or cohomological observables, with stated metric, chamber, compactification, contact-term, and anomaly data.

Chapter 104

BF Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

BF theory is the first gauge-theoretic example in this volume. It already displays recurring ingredients of topological gauge theory: fields with form degree, ordinary gauge symmetry, higher-form gauge symmetry, reducibility, metric-free classical action, extended observables, and a BV complex. The abelian compact theory also has a finite cochain model, so some correlation functions reduce to exact finite sums.

Definition 104.1 (closed-manifold BF theory datum)**.** A closed-manifold BF theory datum in dimension D consists of the following objects.

(i) A closed oriented smooth D-manifold M.

(ii) A compact Lie group G, a principal G-bundle $P \to M$, and the adjoint bundle

$$\operatorname{ad} P = P \times_G \mathfrak{g}.$$

(iii) An invariant nondegenerate pairing between the coadjoint and adjoint bundles, written fiberwise as

$$\langle -, - \rangle : \mathfrak{g}^* \otimes \mathfrak{g} \longrightarrow \mathbb{R}.$$

(iv) The classical field space

$$\operatorname{Conn}(P) \times \Omega^{D-2}(M, \operatorname{ad} P^*),$$

with field coordinates (A, B). Here A is a connection on P, B is a $(D-2)$-form valued in the dual adjoint bundle, and $F_A \in \Omega^2(M, \operatorname{ad} P)$ denotes the curvature of A.

(v) The exponentiated classical action

$$\exp S_{\mathrm{BF}}[A,B], \qquad S_{\mathrm{BF}}[A,B] = 2\pi\mathrm{i}\int_M \langle B \wedge F_A\rangle.$$

The factor $2\pi\mathrm{i}$ fixes the convention matched to the compact abelian normalization below.

(vi) Gauge data consisting of the ordinary gauge group $\mathcal{G}(P)$ and the B-field shift parameters $\Omega^{D-3}(M, \mathrm{ad}\, P^*)$. In the nonabelian theory the shift reducibility chain is naturally a derived symmetry over the flat-connection locus $F_A = 0$; in the abelian specialization the same chain is an off-shell cochain complex because $\mathrm{d}^2 = 0$.

(vii) Extended observable data: Wilson observables associated with closed one-cycles and representations or charges, and surface observables associated with closed $(D-2)$-cycles and dual charges. The finite abelian model below makes these observables precise as cochain functionals and computes their linking phase exactly.

(viii) Quantization status. The preceding data define the classical and BV input for continuum BF theory on closed M. A functorial quantum theory additionally requires a BV or BV–BFV regularized semidensity, gauge fixing, anomaly control, and gluing data. The compact finite $\mathbb{Z}_N$ cochain model in Section 104.4 is a fully finite realization of the abelian sector.

104.1 Nonabelian Classical Fields

We first unpack Definition 104.1 in the smooth nonabelian continuum setting. Let M be a closed oriented smooth D-manifold. Let G be a compact Lie group, let $P \to M$ be a principal G-bundle, and let

$$\mathrm{ad}\, P = P \times_G \mathfrak{g}$$

be the adjoint bundle. Choose an invariant nondegenerate pairing

$$\langle -, - \rangle : \mathfrak{g}^* \otimes \mathfrak{g} \longrightarrow \mathbb{R}.$$

The classical fields of D-dimensional nonabelian BF theory are a connection A on P and a B-field

$$B \in \Omega^{D-2}(M, \mathrm{ad}\, P^*).$$

The curvature of A is

$$F_A = \mathrm{d}A + \frac{1}{2}[A, A] \in \Omega^2(M, \mathrm{ad}\, P),$$

where the bracket combines the Lie bracket on $\mathfrak{g}$ with exterior wedge product. The action is

$$S_{\mathrm{BF}}[A,B] = 2\pi\mathrm{i}\int_M \langle B \wedge F_A\rangle. \tag{104.1}$$

The coefficient is fixed so that the compact abelian specialization below has integer periods in the exponent.

Remark 104.2 (Euler–Lagrange equations). On a closed M, the stationary equations of (104.1) are

$$F_A = 0, \qquad \mathrm{d}_A B = 0.$$

Let $\alpha \in \Omega^1(M, \operatorname{ad} P)$ and $\beta \in \Omega^{D-2}(M, \operatorname{ad} P^*)$ be variations of A and B. The curvature variation is

$$\left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} F_{A+t\alpha} = \mathrm{d}_A\alpha.$$

Therefore

$$\delta S_{\mathrm{BF}} = 2\pi\mathrm{i}\int_M \left(\langle\beta \wedge F_A\rangle + \langle B \wedge \mathrm{d}_A\alpha\rangle\right).$$

The first term gives $F_A = 0$ because β is arbitrary. For the second term, use the covariant Leibniz rule

$$\mathrm{d}\langle B \wedge \alpha\rangle = \langle \mathrm{d}_A B \wedge \alpha\rangle + (-1)^{D-2}\langle B \wedge \mathrm{d}_A\alpha\rangle.$$

The integral of the left side vanishes on a closed manifold, so

$$\int_M \langle B \wedge \mathrm{d}_A\alpha\rangle = (-1)^{D-1}\int_M \langle \mathrm{d}_A B \wedge \alpha\rangle.$$

Since α is arbitrary, $\mathrm{d}_A B = 0$.

104.2 Gauge Symmetry And Reducibility

The ordinary gauge group $\mathcal{G}(P)$ acts by

$$A \longmapsto A^g = g^{-1}Ag + g^{-1}\mathrm{d}g, \qquad B \longmapsto B^g = \operatorname{Ad}^*_{g^{-1}} B,$$

where the second formula is the coadjoint action; after choosing an invariant inner product on $\mathfrak{g}$ it is written as $B^g = g^{-1}Bg$. Infinitesimally, for $c \in \Omega^0(M, \operatorname{ad} P)$,

$$\delta_c A = \mathrm{d}_A c, \qquad \delta_c B = [B, c].$$

There is also a B-field shift symmetry. For

$$\eta \in \Omega^{D-3}(M, \operatorname{ad} P^*)$$

define

$$\delta_\eta A = 0, \qquad \delta_\eta B = \mathrm{d}_A\eta.$$

Remark 104.3 (Invariance of the shift symmetry). On a closed manifold,

$$S_{\mathrm{BF}}[A, B + \mathrm{d}_A\eta] - S_{\mathrm{BF}}[A, B] = 2\pi\mathrm{i}\int_M \mathrm{d}\langle\eta \wedge F_A\rangle.$$

Hence the shift is a symmetry on closed M. On a manifold with boundary it produces the boundary term

$$2\pi\mathrm{i}\int_{\partial M} \langle\eta \wedge F_A\rangle.$$

The change in the action is

$$2\pi\mathrm{i}\int_M \langle \mathrm{d}_A\eta \wedge F_A\rangle.$$

The covariant Leibniz rule and Bianchi identity $\mathrm{d}_A F_A = 0$ give

$$\mathrm{d}\langle \eta \wedge F_A \rangle = \langle \mathrm{d}_A \eta \wedge F_A \rangle + (-1)^{D-3} \langle \eta \wedge \mathrm{d}_A F_A \rangle = \langle \mathrm{d}_A \eta \wedge F_A \rangle.$$

This proves the formula. On a closed manifold the integral of this exact top form is zero by Stokes' theorem. When $\partial M \neq \varnothing$, the same Stokes calculation gives the displayed boundary functional, which is the datum that must be cancelled or coupled to boundary degrees of freedom in a theory with boundary.

The shift symmetry is reducible. If $\eta = \mathrm{d}_A \eta_1$, then

$$\delta_\eta B = \mathrm{d}_A^2 \eta_1 = F_A \cdot \eta_1.$$

Thus the transformation vanishes on the flat-connection locus. Continuing,

$$\eta_1 \in \Omega^{D-4}(M, \operatorname{ad} P^*), \quad \eta_1 \sim \eta_1 + \mathrm{d}_A \eta_2, \quad \ldots,$$

ending in degree 0. In the abelian theory $\mathrm{d}_A = \mathrm{d}$ and the reducibility holds off shell because $\mathrm{d}^2 = 0$. The BV field space therefore contains the ordinary ghost c, the B-shift ghost η, the ghosts-for-ghosts $\eta_1, \eta_2, \ldots$, and antifields for all these variables. This is the finite-stage reducible gauge system whose BV integration is modeled by Chapter 111.

104.3 Compact Abelian Normalization

A precise continuum normalization of compact abelian BF theory uses differential characters. For a $U(1)$ one-form gauge field A, the holonomy around a closed one-cycle γ is

$$W_q(\gamma) = \exp\left(2\pi \mathrm{i} q \int_\gamma A\right), \qquad q \in \mathbb{Z}.$$

For a compact $(D-2)$-form gauge field B, the surface operator on a closed $(D-2)$-cycle Σ is

$$V_p(\Sigma) = \exp\left(2\pi \mathrm{i} p \int_\Sigma B\right), \qquad p \in \mathbb{Z}.$$

The local action is

$$S_{\mathrm{BF}}[A, B] = 2\pi \mathrm{i} N \int_M B \wedge \mathrm{d}A, \qquad N \in \mathbb{Z}_{>0}.$$

Large gauge transformations shift the periods of A and B by integers, and the factor N makes the exponent single-valued. The equation obtained by varying B is

$$N \, \mathrm{d}A = 0$$

as a differential character. Thus the theory describes a flat $\mathbb{Z}_N$ one-form gauge sector after the continuous modes and gauge redundancies are accounted for.

104.4 Finite $\mathbb{Z}_N$ Cochain Model

Let K be a finite cell decomposition of a closed connected oriented D-manifold M. Write $C^r = C^r(K;\mathbb{Z}_N)$, and let

$$\delta_r : C^r \longrightarrow C^{r+1}$$

be the cellular coboundary. The finite constraint form of $\mathbb{Z}_N$ BF theory has a one-cochain gauge field $a \in C^1$ and a Lagrange multiplier $b \in \mathrm{Hom}(C^2, \mathbb{Z}_N)$. Its normalized finite sum is

$$Z^{(N)}_{\mathrm{BF}}(K) = \frac{1}{|C^0|\,|C^2|} \sum_{a\in C^1} \sum_{b\in \mathrm{Hom}(C^2,\mathbb{Z}_N)} \exp\!\left(\frac{2\pi \mathrm{i}}{N}\, b(\delta_1 a)\right). \tag{104.2}$$

The factor $|C^0|^{-1}$ divides by ordinary 0-form gauge transformations $a \mapsto a + \delta_0\lambda$. The factor $|C^2|^{-1}$ normalizes the b-sum as a finite Fourier transform.

Finite BF partition function. For a connected K,

$$Z^{(N)}_{\mathrm{BF}}(K) = \frac{|Z^1(K;\mathbb{Z}_N)|}{|C^0(K;\mathbb{Z}_N)|} = \frac{|H^1(K;\mathbb{Z}_N)|}{|H^0(K;\mathbb{Z}_N)|} = \frac{|H^1(M;\mathbb{Z}_N)|}{N}.$$

The finite character identity

$$\frac{1}{|C^2|} \sum_{b\in \mathrm{Hom}(C^2,\mathbb{Z}_N)} \exp\!\left(\frac{2\pi \mathrm{i}}{N}\, b(x)\right) = \begin{cases} 1, & x = 0, \\ 0, & x \neq 0 \end{cases}$$

holds for every $x \in C^2$. Applying it to $x = \delta_1 a$ reduces (104.2) to

$$Z^{(N)}_{\mathrm{BF}}(K) = |C^0|^{-1}\,|\ker \delta_1|.$$

Since

$$H^1(K;\mathbb{Z}_N) = \ker \delta_1 / \operatorname{im} \delta_0,$$

we have $|\ker \delta_1| = |H^1|\,|\operatorname{im}\delta_0|$. Also

$$H^0(K;\mathbb{Z}_N) = \ker \delta_0$$

and $|C^0| = |\ker \delta_0|\,|\operatorname{im}\delta_0|$. Hence

$$|C^0|^{-1}|\ker \delta_1| = |H^1|/|H^0|.$$

For connected K, $H^0(K;\mathbb{Z}_N) \cong \mathbb{Z}_N$, giving the last formula.

The value $|H^1|/N$ is the groupoid cardinality of flat $\mathbb{Z}_N$-bundles on a connected manifold: each flat bundle has automorphism group $\mathbb{Z}_N$, and groupoid cardinality weights each isomorphism class by the reciprocal of the automorphism-group order.

104.5 Wilson Operators And Linking

Let $\gamma \in Z_1(K;\mathbb{Z})$ be a closed cellular one-cycle. Its Wilson operator of charge $q \in \mathbb{Z}_N$ is

$$W_q(\gamma)(a) = \exp\left(\frac{2\pi \mathrm{i} q}{N}\langle a, \gamma\rangle\right).$$

Gauge invariance follows from the cellular Stokes formula:

$$\langle a + \delta_0\lambda, \gamma\rangle = \langle a, \gamma\rangle + \langle \lambda, \partial\gamma\rangle = \langle a, \gamma\rangle.$$

Let Σ be a closed oriented $(D-2)$-cycle, represented on the dual cellulation by a two-cochain $\sigma_\Sigma \in C^2(K;\mathbb{Z}_N)$ through Poincare duality. The B-surface insertion of charge $p \in \mathbb{Z}_N$ shifts the finite Fourier constraint by

$$b(\delta a) \longmapsto b(\delta a + p\,\sigma_\Sigma).$$

Thus the b-sum imposes

$$\delta a = -p\,\sigma_\Sigma.$$

This equation is the finite cochain form of a prescribed surface singularity.

Linking phase in finite BF theory. Assume $M = S^D$ and let γ and Σ be disjoint closed cycles of dimensions 1 and $D-2$. Choose a two-chain C with $\partial C = \gamma$, and define

$$\mathrm{Lk}(\gamma, \Sigma) = \langle \sigma_\Sigma, C\rangle \in \mathbb{Z}.$$

With the sign convention above,

$$\langle W_q(\gamma)V_p(\Sigma)\rangle = \exp\left(-\frac{2\pi \mathrm{i} pq}{N}\,\mathrm{Lk}(\gamma, \Sigma)\right)\langle V_p(\Sigma)\rangle.$$

After inserting $V_p(\Sigma)$, the b-sum enforces

$$\delta a = -p\,\sigma_\Sigma.$$

The hypothesis $M = S^D$ removes the cohomological ambiguity in this constraint in the linking range $D \geq 3$: every closed one-cycle is a boundary, and changing the bounding two-chain changes $\langle \sigma_\Sigma, C\rangle$ by the intersection of Σ with a closed two-cycle, which vanishes because $H_2(S^D;\mathbb{Z}) = 0$. Thus the integer $\mathrm{Lk}(\gamma, \Sigma)$ is well defined.

For any allowed a, cellular Stokes gives

$$\langle a, \gamma\rangle = \langle a, \partial C\rangle = \langle \delta a, C\rangle = -p\,\langle \sigma_\Sigma, C\rangle.$$

Therefore the Wilson insertion contributes the phase

$$\exp\left(-\frac{2\pi \mathrm{i} pq}{N}\,\mathrm{Lk}(\gamma, \Sigma)\right)$$

for every allowed a. The remaining sum is the sum defining $\langle V_p(\Sigma)\rangle$, with the same normalization of the finite path integral. The result is therefore an exact ratio statement inside the same finite sum.

104.6 Metric Independence And Boundary Data

The classical action (104.1) uses the orientation of M, the exterior derivative, wedge product, bundle data, and invariant pairing. It uses no Riemannian metric. Quantum metric independence requires additional data:

BV field space, gauge-fixing Lagrangian, regularized semidensity, anomaly analysis.

If the metric variation of the gauge-fixed integrand is BV-exact and if the BV Stokes boundary term vanishes, then the corresponding BV-closed correlators are metric independent by Remark 111.3. On a manifold with boundary, Remark 104.3 shows that the shift symmetry produces boundary phase-space data. The boundary fields are the restrictions of A and B, and the boundary symplectic pairing is obtained from the boundary term in the variation:

$$\Omega_{\partial M} = 2\pi \mathrm{i} \int_{\partial M} \langle \delta B \wedge \delta A \rangle.$$

A functorial BF theory must choose a boundary polarization or boundary condition, then prove compatibility with gluing.

Open Problem 104.4 (Continuum nonabelian BF theory with boundaries)*.* Construct nonabelian continuum BF theory on manifolds with boundary as a functorial BV-BFV theory. The construction must specify the boundary phase space, residual fields, gauge fixing, anomaly line, gluing pairing, and the relationship between Wilson, surface, and boundary observables.

Chapter 105

Chern–Simons Theory

Conventions in this chapter.

- **Signature.** oriented smooth three-manifold M.
- **Metric sign.** no metric is part of the classical action.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** a vacuum vector appears only after choosing a Hamiltonian splitting or a boundary state space.
- **Generator convention.** gauge transformations act on connections by pullback and conjugation.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Let G be a compact Lie group with Lie algebra $\mathfrak{g}$. Fix an invariant symmetric bilinear form tr on $\mathfrak{g}$. For a connection A on a principal G-bundle over an oriented three-manifold M, the Chern–Simons functional in a local trivialization is

$$S_{\mathrm{CS}}(A) = \frac{k}{4\pi}\int_M \mathrm{tr}\Big(A \wedge dA + \frac{2}{3}A \wedge A \wedge A\Big).$$

Large gauge transformations quantize the allowed values of the level k.

Definition 105.1 (Chern–Simons defining structure)**.** A Chern–Simons defining structure is a tuple

$$\mathfrak{C} = (G, \lambda, \mathfrak{f}, \mathfrak{L}, \mathfrak{b})$$

with the following constituents.

(i) G is a compact Lie group with Lie algebra $\mathfrak{g}$.

(ii) λ is an integral level: equivalently, a class in $H^4(BG;\mathbb{Z})$ together with a de Rham representative determined by an invariant symmetric bilinear form on $\mathfrak{g}$. In the simply connected compact simple normalization used below, this is the assertion that

$$\frac{1}{24\pi^2}\int_{S^3} \mathrm{tr}(g^{-1}dg)^3 \in \mathbb{Z}$$

for a generator $g : S^3 \to G$, and the level is an integer k multiplying this normalized bilinear form. For general compact G, the phrase "integral level" means the corresponding differential-cohomology lift $\check{\lambda} \in \widehat{H}^4(BG;\mathbb{Z})$ has been chosen, so that the exponentiated action is a globally defined $U(1)$-valued functional on connections on all principal G-bundles. The displayed local expression is the trivial-bundle representative of this global functional.

(iii) $\mathfrak{f}$ is the framing anomaly specification. Depending on the chosen normalization of the quantum theory, this is specified either by a three-dimensional framing or two-framing convention for closed manifolds, or equivalently by the gravitational Chern–Simons counterterm/central-charge anomaly needed to make partition functions and Wilson-line expectations unambiguous.

(iv) $\mathfrak{L}$ is the allowed line-operator sector: oriented framed link components are labelled by admissible representations or, after quantization, by the simple objects of the associated line category. The framing of each line is part of the operator insertion, because coincident point-splitting of the holonomy has a local self-linking ambiguity.

(v) $\mathfrak{b}$ is boundary and polarization structure. If manifolds with boundary are admitted, $\mathfrak{b}$ specifies the boundary condition or boundary theory, the polarization of the boundary phase space, and the allowed boundary line endpoints. On closed three-manifolds this entry is empty.

The structure $\mathfrak{C}$ is the object used below. The integral level controls large-gauge invariance; the framing specification controls the gravitational/framing anomaly; and the line and boundary structures specify which observables and state spaces are being assigned.

Hypothesis 105.2 (Quantum Chern–Simons theory associated to a defining structure)**.** Given a Chern–Simons defining structure $\mathfrak{C} = (G, \lambda, \mathfrak{f}, \mathfrak{L}, \mathfrak{b})$, the notation

$$Z_{\mathfrak{C}}$$

denotes a quantum Chern–Simons theory only when a construction or hypothesis supplies the following structures.

(i) To each closed oriented surface Σ, with the boundary data required by $\mathfrak{b}$, it assigns a finite-dimensional state space $\mathcal{H}_{\mathfrak{C}}(\Sigma)$.

(ii) To each compact oriented three-dimensional cobordism M, equipped with the required framing specification and with framed labelled links from $\mathfrak{L}$, it assigns a vector or linear map between the boundary state spaces.

(iii) The assignments satisfy functorial gluing: cutting along Σ corresponds to contraction with the pairing on $\mathcal{H}_{\mathfrak{C}}(\Sigma)$, including the anomaly phases fixed by $\mathfrak{f}$.

(iv) On a closed manifold, in a semiclassical regime where stationary phase is meaningful, the critical points are flat G-connections and the local phase is the exponentiated Chern–Simons action determined by $\check{\lambda}$.

(v) The line sector realizes the framed Wilson-line observables specified by $\mathfrak{L}$. In a modular case, the simple line labels, fusion, braiding, twists, and mapping-class-group matrices agree with the associated modular tensor category or modular functor.

(vi) If a holomorphic boundary polarization is used, the boundary variation is cancelled by the corresponding chiral Wess–Zumino–Witten boundary theory at the same integral level.

This hypothesis is intentionally conditional. Perturbative configuration space integrals, geometric quantization, WZW conformal blocks, and modular tensor categories provide constructions in important regimes. The comparison maps among these constructions are part of Open Problem 105.9.

105.1 Variation and Classical Equations

Let $F_A = dA + A \wedge A$. For a compactly supported variation δA on a closed manifold,

$$\delta S_{\mathrm{CS}} = \frac{k}{2\pi} \int_M \mathrm{tr}(\delta A \wedge F_A).$$

Thus the Euler–Lagrange equation is

$$F_A = 0.$$

On a manifold with boundary, the integration by parts also gives

$$\frac{k}{4\pi} \int_{\partial M} \mathrm{tr}(A \wedge \delta A),$$

so a boundary condition, boundary action, or boundary phase space must be part of the definition.

105.2 Level Quantization

For simply connected compact simple G, choose the bilinear form so that

$$\frac{1}{24\pi^2} \int_{S^3} \mathrm{tr}\big(g^{-1}dg\big)^3 \in \mathbb{Z}$$

for maps $g : S^3 \to G$ representing the generator of $\pi_3(G)$. Under a gauge transformation $g : M \to G$, use the right action convention

$$A^g = gAg^{-1} - (dg)g^{-1}.$$

Put $\theta_g = dg\, g^{-1}$. The right Maurer–Cartan equation is

$$d\theta_g = \theta_g \wedge \theta_g.$$

Chern–Simons transgression under a finite gauge transformation. With

$$\mathrm{cs}(A) = \mathrm{tr}\left(A \wedge dA + \frac{2}{3} A \wedge A \wedge A\right),$$

one has the identity of three-forms

$$\mathrm{cs}(A^g) - \mathrm{cs}(A) = d\, \mathrm{tr}(\theta_g \wedge A) + \frac{1}{3} \mathrm{tr}(\theta_g \wedge \theta_g \wedge \theta_g). \tag{105.1}$$

Write $B = gAg^{-1}$. Then $A^g = B - \theta_g$,

$$dB = g(dA)g^{-1} + \theta_g \wedge B - B \wedge \theta_g, \qquad d\theta_g = \theta_g \wedge \theta_g.$$

Substitute these two identities into $\mathrm{tr}((B-\theta_g)\wedge d(B-\theta_g)+\frac{2}{3}(B-\theta_g)^3)$. The terms containing only B give $\mathrm{cs}(A)$ by invariance of tr. The terms with two B's and one θ_g cancel after cyclic permutation inside the invariant trace. Conjugating the remaining one-θ_g mixed terms back to the original A-frame by invariance of tr, they combine as

$$\mathrm{tr}(d\theta_g\wedge A)-\mathrm{tr}(\theta_g\wedge dA)=d\ \mathrm{tr}(\theta_g\wedge A),$$

and the pure Maurer–Cartan terms give $\frac{1}{3}\,\mathrm{tr}(\theta_g^3)$. This is (105.1).

Therefore, on closed M,

$$S_{\mathrm{CS}}(A^g)-S_{\mathrm{CS}}(A)=2\pi k\,n(g)$$

where

$$n(g)=\frac{1}{24\pi^2}\int_M \mathrm{tr}(\theta_g\wedge\theta_g\wedge\theta_g)\in\mathbb{Z}$$

is the winding number with the chosen normalization. The two displayed three-forms define the same integral because $\theta_g=dg\,g^{-1}=g(g^{-1}dg)g^{-1}$ and the bilinear form is invariant. The sign in this formula is tied to the displayed right-action convention for A^g.

Remark 105.3 (Gauge invariance of the exponentiated action). With the integral normalization above, $\exp(\mathrm{i}S_{\mathrm{CS}})$ is invariant under all gauge transformations on closed M if $k\in\mathbb{Z}$.

The transformation formula gives $\exp(\mathrm{i}S_{\mathrm{CS}}(A^g))=\exp(\mathrm{i}S_{\mathrm{CS}}(A))\exp(2\pi\mathrm{i}kn(g))$. This equals $\exp(\mathrm{i}S_{\mathrm{CS}}(A))$ for all $n(g)\in\mathbb{Z}$ exactly when k is integral in the normalization used for the bilinear form. The closed-manifold hypothesis removes boundary terms from the gauge-variation formula. With a boundary, the gauge-variation formula contains the boundary term obtained by restricting the transgression form to ∂M; its cancellation requires boundary degrees of freedom, boundary conditions, or a specified anomalous boundary theory together with the integral level.

The same integrality controls the Wess–Zumino term that appears below. If $g:\Sigma\to G$ extends to two oriented three-manifolds B_1 and B_2 with $\partial B_i=\Sigma$, glue B_1 to $-B_2$ along the boundary. The resulting closed three-manifold $X=B_1\cup_\Sigma(-B_2)$, equipped with the glued map to G, gives

$$\frac{k}{12\pi}\left(\int_{B_1}\mathrm{tr}(g^{-1}dg)^3-\int_{B_2}\mathrm{tr}(g^{-1}dg)^3\right)=2\pi k\,\frac{1}{24\pi^2}\int_X \mathrm{tr}(g^{-1}dg)^3.$$

Thus the ambiguity of the Wess–Zumino functional is an integral multiple of $2\pi k$, and $\exp(\mathrm{i}S)$ is independent of the chosen extension for integer level. The boundary statement is the same integral class λ in Definition 105.1 viewed through a boundary extension.

105.3 Phase Space on a Surface

Let $M=\mathbb{R}\times\Sigma$. Write $A=A_0dt+A_\Sigma$. The term linear in time derivatives is

$$\frac{k}{4\pi}\int_{\mathbb{R}}dt\int_\Sigma \mathrm{tr}(A_\Sigma\wedge\partial_tA_\Sigma).$$

The field A_0 is a Lagrange multiplier imposing $F_{A_\Sigma}=0$. Therefore the classical phase space is the moduli space

$$\mathcal{M}_{\mathrm{flat}}(\Sigma,G)=\{A_\Sigma:F_{A_\Sigma}=0\}/\mathcal{G}_\Sigma$$

with symplectic form

$$\omega_{\rm CS} = \frac{k}{4\pi}\int_\Sigma \mathrm{tr}(\delta A_\Sigma \wedge \delta A_\Sigma).$$

In a quantum Chern–Simons theory satisfying Hypothesis 105.2, the quantization of this phase space is the state space assigned to Σ. In compact semisimple modular examples this state space is finite-dimensional after the integral level, framing convention, and boundary data are fixed.

105.4 Wilson Lines and Framing

For an oriented knot or link component $K \subset M$ and a representation R of G, the Wilson line is

$$W_R(K) = \mathrm{Tr}_R\,\mathrm{Pexp}\int_K A.$$

The quantum expectation value of Wilson links in Hypothesis 105.2 requires precisely the line-framing datum included in Definition 105.1: a nonvanishing normal vector field along each component, or equivalently a choice of point-splitting direction. The framing dependence is a local counterterm effect for the self-linking singularity of the line operator.

105.5 $SU(2)_k$ Modular Data and Link Invariants

The first fully explicit compact simple example of the conditional quantum datum in Hypothesis 105.2 is $G = SU(2)$ at positive integer level k. In the Hamiltonian/modular-functor normalization, the simple Wilson-line labels are

$$a = 0, 1, \ldots, k, \qquad \mathrm{spin}(a) = \frac{a}{2}.$$

These are the integrable highest weights of the affine algebra $\widehat{\mathfrak{su}}(2)_k$. Define

$$K = k+2, \qquad S_{ab} = \sqrt{\frac{2}{K}}\sin\left(\frac{(a+1)(b+1)\pi}{K}\right), \qquad 0 \le a, b \le k. \tag{105.2}$$

The matrix S is the modular S-transformation on the torus state space in the basis determined by core Wilson lines in a solid torus.

Remark 105.4 (Orthogonality of the $SU(2)_k$ modular S-matrix)*.* The matrix (105.2) is real, symmetric, and orthogonal:

$$\sum_{b=0}^{k} S_{ab}S_{cb} = \delta_{ac}.$$

Put $r = a+1$, $s = c+1$, and $K = k+2$. The required identity is

$$\frac{2}{K}\sum_{m=1}^{K-1}\sin\left(\frac{rm\pi}{K}\right)\sin\left(\frac{sm\pi}{K}\right) = \delta_{rs}, \qquad 1 \le r, s \le K-1.$$

Using $2\sin x \sin y = \cos(x-y) - \cos(x+y)$, the sum reduces to finite geometric sums of K-th roots of unity. For $r = s$, it gives $\sum_{m=1}^{K-1}\sin^2(rm\pi/K) = K/2$. For $r \neq s$, the two cosine sums cancel. This proves the orthogonality relation.

The quantum dimension of the label a is

$$d_a = \frac{S_{0a}}{S_{00}} = \frac{\sin((a+1)\pi/K)}{\sin(\pi/K)}. \tag{105.3}$$

This number is the normalized expectation value of a 0-framed unknot in S^3 colored by a, in the convention in which the empty normalized expectation value on S^3 is 1:

$$\langle W_a(\text{unknot})\rangle_{S^3} = d_a. \tag{105.4}$$

The corresponding 0-framed Hopf link with components colored by a and b is

$$\langle W_a(K_1)W_b(K_2)\rangle_{S^3,\text{Hopf}} = \frac{S_{ab}}{S_{00}}. \tag{105.5}$$

Equation (105.5) is the basic bridge between the path integral and the modular category: the two linked Wilson loops compute the matrix element of the modular S-transformation, normalized by the vacuum amplitude.

Example 105.5 ($SU(2)_1$)**.** At $k=1$, there are two labels $0,1$ and

$$S = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

The nontrivial line has quantum dimension $d_1 = 1$, and the Hopf link with both components colored by 1 has normalized value

$$\frac{S_{11}}{S_{00}} = -1.$$

Thus $SU(2)_1$ is an abelian topological order in this line basis: the nontrivial line is invertible and has nontrivial mutual braiding with itself as measured by the Hopf link.

Example 105.6 ($SU(2)_2$)**.** At $k=2$, the labels $0,1,2$ have quantum dimensions

$$d_0 = 1, \qquad d_1 = \sqrt{2}, \qquad d_2 = 1.$$

The label 1, the spin-$\frac{1}{2}$ Wilson line, is non-invertible. This is the Chern–Simons modular tensor category underlying the Ising fusion rules after the conventional identification of labels.

105.6 Verlinde Formula

The same modular data determine the fusion coefficients. For $SU(2)_k$, the Verlinde formula reads

$$N_{ab}{}^{c} = \sum_{x=0}^{k} \frac{S_{ax}S_{bx}S_{cx}}{S_{0x}}, \tag{105.6}$$

where all labels are self-dual. The result is the truncated $SU(2)$ Clebsch–Gordan rule:

$$N_{ab}{}^{c} = 1$$

exactly when

$$|a-b| \le c \le \min(a+b,\, 2k-a-b), \qquad a+b+c \in 2\mathbb{Z},$$

and $N_{ab}{}^{c} = 0$ otherwise. The truncation $c \le 2k-a-b$ is the finite-level effect: tensor products that would exceed the affine alcove are reflected back by the quantum Weyl symmetry.

Remark 105.7 (Verlinde dimensions from the modular-functor input). Let Σ_g be a closed oriented genus-g surface. The $SU(2)_k$ Chern–Simons state-space dimension assigned by the modular functor is

$$\dim \mathcal{H}_{SU(2)_k}(\Sigma_g) = \sum_{x=0}^{k} (S_{0x})^{2-2g}. \tag{105.7}$$

In particular,

$$\dim \mathcal{H}(S^2) = 1, \qquad \dim \mathcal{H}(T^2) = k+1.$$

The dimension formula is the zero-puncture specialization of the Verlinde formula for conformal blocks,

$$\dim \mathcal{H}(\Sigma_g; a_1, \dots, a_n) = \sum_{x=0}^{k} (S_{0x})^{2-2g-n} \prod_{j=1}^{n} S_{a_j x}.$$

For $g = 0, n = 0$, orthogonality of the first row of S gives $\sum_x S_{0x}^2 = 1$. For $g = 1, n = 0$, the exponent vanishes, so the sum has $k+1$ terms. Higher genus follows from pair-of-pants gluing: each handle contraction inserts a sum over an intermediate label weighted by the inverse square of S_{0x}, which is exactly the displayed exponent. This paragraph records the modular-functor consequence used below; it is not a derivation of the modular functor from the Chern–Simons path integral.

105.7 Boundary Theory

If M has boundary, the boundary term in the variation is the first datum. Let $\partial M = \Sigma$, choose a complex coordinate $z, \bar{z}$ on Σ, and write

$$A_\Sigma = A_z \, \mathrm{d}z + A_{\bar{z}} \, \mathrm{d}\bar{z}, \qquad \mathrm{d}^2 z := \mathrm{d}z \wedge \mathrm{d}\bar{z}.$$

On solutions of $F_A = 0$, the variation of the bulk Chern–Simons action is

$$\delta S_{\mathrm{CS}}\big|_{F=0} = \frac{k}{4\pi} \int_\Sigma \mathrm{tr}(A_\Sigma \wedge \delta A_\Sigma) = \frac{k}{4\pi} \int_\Sigma \mathrm{d}^2 z \ \mathrm{tr}\left(A_z \delta A_{\bar{z}} - A_{\bar{z}} \delta A_z\right).$$

The holomorphic polarization fixes $A_{\bar{z}}$ as the source and adds

$$S_{\mathrm{pol}} = \frac{k}{4\pi} \int_\Sigma \mathrm{d}^2 z \ \mathrm{tr}(A_z A_{\bar{z}}).$$

Then

$$\delta(S_{\mathrm{CS}} + S_{\mathrm{pol}})\big|_{F=0} = \frac{k}{2\pi} \int_\Sigma \mathrm{d}^2 z \ \mathrm{tr}(A_z \, \delta A_{\bar{z}}). \tag{105.8}$$

Thus $kA_z/(2\pi)$ is the current conjugate to $A_{\bar{z}}$ in this polarization.

The corresponding boundary field is a map $g : \Sigma \to G$. For an extension of g to a three-manifold B with $\partial B = \Sigma$, set

$$S_{\mathrm{WZW},k}(g) = \frac{k}{4\pi} \int_\Sigma \mathrm{d}^2 z \ \mathrm{tr}\left(g^{-1} \partial_z g \, g^{-1} \partial_{\bar{z}} g\right) + \frac{k}{12\pi} \int_B \mathrm{tr}(g^{-1} \mathrm{d}g)^3. \tag{105.9}$$

The Wess–Zumino term is defined modulo $2\pi\mathbb{Z}$ in $\exp(\mathrm{i}S)$ exactly when the same integral normalization that quantizes the Chern–Simons level is used. The extension-independence calculation in the level-quantization section is the global input behind this sentence; the Polyakov–Wiegmann identity below is the local product formula in the same normalization.

Lemma 105.8 (Polyakov–Wiegmann identity)**.** *With the convention* (105.9),

$$S_{\mathrm{WZW},k}(gh) = S_{\mathrm{WZW},k}(g) + S_{\mathrm{WZW},k}(h) + \frac{k}{2\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}\left(g^{-1}\partial_{\bar z} g\,\partial_z h\,h^{-1}\right).$$

Proof. The Maurer–Cartan form of the product is

$$(gh)^{-1}\mathrm{d}(gh) = h^{-1}(g^{-1}\mathrm{d}g)h + h^{-1}\mathrm{d}h.$$

Cyclicity and invariance of tr give the three-form identity

$$\mathrm{tr}\big((gh)^{-1}\mathrm{d}(gh)\big)^3 = \mathrm{tr}(g^{-1}\mathrm{d}g)^3 + \mathrm{tr}(h^{-1}\mathrm{d}h)^3 - 3\,\mathrm{d}\,\mathrm{tr}\left(g^{-1}\mathrm{d}g \wedge \mathrm{d}h\,h^{-1}\right).$$

Stokes' theorem converts the final term to a boundary integral on Σ. To see the coefficient and sign, put

$$X_z = g^{-1}\partial_z g, \qquad X_{\bar z} = g^{-1}\partial_{\bar z} g, \qquad Y_z = \partial_z h\,h^{-1}, \qquad Y_{\bar z} = \partial_{\bar z} h\,h^{-1}.$$

The kinetic term of gh has the cross contribution

$$\frac{k}{4\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}(X_z Y_{\bar z} + X_{\bar z} Y_z).$$

The boundary contribution from the Wess–Zumino three-form identity is

$$\frac{k}{4\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}(-X_z Y_{\bar z} + X_{\bar z} Y_z).$$

Adding the two cross contributions cancels the $X_z Y_{\bar z}$ term and doubles the $X_{\bar z} Y_z$ term:

$$\frac{k}{2\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}(g^{-1}\partial_{\bar z} g\,\partial_z h\,h^{-1}).$$

The non-cross terms are exactly $S_{\mathrm{WZW},k}(g)$ and $S_{\mathrm{WZW},k}(h)$. This proves the identity. ☐

The gauged chiral boundary action in the same polarization is

$$S_{\partial,k}(g; A_{\bar z}) = S_{\mathrm{WZW},k}(g) + \frac{k}{2\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}\left(\partial_z g\,g^{-1} A_{\bar z}\right). \tag{105.10}$$

If a flat bulk connection is written near the boundary as

$$A_z = -\partial_z g\,g^{-1},$$

then

$$\delta_{A_{\bar z}} S_{\partial,k} = -\frac{k}{2\pi}\int_\Sigma \mathrm{d}^2 z\ \mathrm{tr}(A_z\,\delta A_{\bar z}),$$

which cancels the polarized Chern–Simons variation (105.8). This is the precise sense in which the chiral Wess–Zumino–Witten boundary degree of freedom supplies the boundary term needed by the Chern–Simons variational problem.

The holomorphic current is

$$J(z) = -\frac{k}{2\pi}\,\partial_z g\,g^{-1}.$$

Writing $J = J^a t_a$, with $\mathrm{tr}(t_a t_b) = \kappa_{ab}$ and $[t_a, t_b] = \mathrm{i} f^c{}_{ab} t_c$, quantization gives the affine current algebra at level k,

$$J^a(z) J^b(w) \sim \frac{k\,\kappa^{ab}}{(z-w)^2} + \frac{\mathrm{i} f^{ab}{}_c J^c(w)}{z-w},$$

where the double pole is the local expression of the same integral level that entered the bulk action. The mode form is obtained by the contour-residue calculation, not by an additional convention. Define

$$J^a_m = \oint_0 \frac{\mathrm{d}z}{2\pi\mathrm{i}}\, z^m J^a(z), \qquad J^a(z) = \sum_{m\in\mathbb{Z}} J^a_m z^{-m-1}.$$

With the z-contour around w and the w-contour around the origin, the double and simple poles give

$$\operatorname*{Res}_{z=w} \frac{z^m}{(z-w)^2} = m\, w^{m-1}, \qquad \operatorname*{Res}_{z=w} \frac{z^m}{z-w} = w^m.$$

Therefore

$$[J^a_m, J^b_n] = \mathrm{i} f^{ab}{}_c J^c_{m+n} + k\, m\, \kappa^{ab} \delta_{m+n,0}.$$

The central term is the loop-algebra cocycle

$$\Omega(X_m, Y_n) = k\, m\, \kappa(X, Y) \delta_{m+n,0}.$$

Its Jacobi compatibility follows from invariance of κ:

$$\Omega([X_m, Y_n], Z_\ell) + \Omega([Y_n, Z_\ell], X_m) + \Omega([Z_\ell, X_m], Y_n) = 0.$$

Indeed, when the Kronecker deltas are nonzero, $m+n+\ell = 0$, and the three invariant trace factors are cyclic permutations of $\kappa([X, Y], Z)$; their coefficient is $(m+n) + (n+\ell) + (\ell+m) = 0$. Thus the mode algebra is a genuine central extension of the boundary loop algebra with level k. The precise Hilbert space still depends on the boundary polarization and global boundary condition, but the local current algebra and its level are fixed by the same integer k that quantizes the bulk Chern–Simons action.

Open Problem 105.9 (Chern–Simons path integral as a QFT object)*.* Give a regulator-level construction of Chern–Simons theory that simultaneously controls gauge fixing, framing, Wilson-line renormalization, boundary conditions, and functorial gluing. Perturbative configuration-space integrals, geometric quantization, and modular tensor category constructions each capture part of this structure; a single local-QFT construction should state the comparison maps among them.

Chapter 106

Cohomological Field Theories

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

A cohomological field theory is a quantum field theory equipped with an odd symmetry Q whose cohomology controls a protected class of observables. Its data include the regulated fields, the algebra on which Q acts, the closure relation for Q^2, the integration cycle or state, and the anomaly-free Q-Ward identity. Once those entries are supplied, metric independence and localization are consequences of Stokes' theorem in the regulated field space or of the BV quantum master equation.

This chapter gives the abstract cohomological mechanism in a form usable by the later Donaldson–Witten, topological sigma-model, and twisted supersymmetric examples. The finite-dimensional statements are proved directly. Infinite-dimensional QFT examples are presented as constructions that must be implemented at regulator level; the later chapters identify which parts are theorem-level mathematics and which parts still depend on unproved continuum-QFT input.

106.1 Regulated Cohomological Datum

Let Λ denote a finite regulator: a lattice, a finite-dimensional mode cutoff, a finite-dimensional approximation to a BV complex, or any other scheme for which the integral is an actual finite-dimensional integral or a finite trace. The regulator is part of the notation because the Ward identity is false until it has been proved at some regulator and shown to survive the continuum limit.

Definition 106.1 (Regulated cohomological QFT data)**.** Regulated cohomological QFT data consist of:

(i) a $\mathbb{Z}_2$-graded algebra $\mathcal{A}_\Lambda$ of regulated insertions;

(ii) an odd derivation
$$Q_\Lambda : \mathcal{A}_\Lambda \to \mathcal{A}_\Lambda;$$

(iii) a distinguished even element S_Λ, or more generally a regulated state/weight, defining expectation functionals
$$\langle X \rangle_\Lambda = Z_\Lambda^{-1} \int_{\Gamma_\Lambda} X \, \exp(-S_\Lambda);$$

(iv) a declared integration cycle Γ_Λ, contour, BV Lagrangian, or Hilbert-space trace;

(v) an even derivation B_Λ such that
$$Q_\Lambda^2 = B_\Lambda \tag{106.1}$$
on $\mathcal{A}_\Lambda$;

(vi) a B_Λ-invariant subalgebra
$$\mathcal{A}_\Lambda^B = \ker B_\Lambda$$
on which $Q_\Lambda^2 = 0$;

(vii) the Ward identity
$$\langle Q_\Lambda Y \rangle_\Lambda = 0 \tag{106.2}$$
for every admissible insertion Y used in the argument.

The regulated cohomological observables are the classes
$$H_{Q_\Lambda}(\mathcal{A}_\Lambda^B) = \frac{\ker(Q_\Lambda : \mathcal{A}_\Lambda^B \to \mathcal{A}_\Lambda^B)}{\operatorname{im}(Q_\Lambda : \mathcal{A}_\Lambda^B \to \mathcal{A}_\Lambda^B)}.$$

The even derivation B_Λ may be zero. In important examples it is the infinitesimal action of a compact bosonic symmetry, a gauge transformation, a flavor transformation, or a combination of these. The restriction to $\mathcal{A}_\Lambda^B$ is the Cartan-model step: Q is a cohomological differential on invariant observables even when it is not nilpotent on all fields.

If the data are presented by a finite-dimensional supermanifold, the odd coordinates are coordinates in the structure sheaf of a locally super-ringed space; they are not points of an ordinary set. Berezin integration is the algebraic operation extracting the top odd coefficient, possibly after multiplication by a Berezinian density. It is not a Borel measure. This distinction is harmless in finite-dimensional algebraic manipulations but becomes important when one discusses continuum "fermionic field configurations."

Definition 106.2 (Anomaly and boundary term)**.** If instead of (106.2) one has
$$\langle Q_\Lambda Y \rangle_\Lambda = \langle \mathcal{A}_\Lambda(Y) \rangle_\Lambda + \langle \partial_\Lambda(Y) \rangle_\Lambda,$$
then $\mathcal{A}_\Lambda$ is the local cohomological anomaly and ∂_Λ is the boundary contribution from the integration cycle, compactification, contour endpoint, or singular stratum. A cohomological statement is anomaly-free for the chosen observables only when both terms vanish or cancel by a stated inflow or boundary prescription.

106.2 Ward Identities and Metric Independence

Let g be a background metric, and write δ_g for a tangent vector to the space of metrics. A metric variation formula is a statement in a fixed renormalization and contact-term scheme:

$$\delta_g\langle X\rangle_\Lambda = \langle \delta_g X - (\delta_g S_\Lambda)X\rangle_\Lambda - \langle X\rangle_\Lambda\langle -\delta_g S_\Lambda\rangle_\Lambda, \tag{106.3}$$

with additional contact insertions included in $\delta_g X$ when the representative of X depends on the metric.

Metric-independence criterion. Let $X_g \in \mathcal{A}_\Lambda^B$ be a smooth family of Q_Λ-closed insertions. Suppose the normalized metric variation can be written as

$$\delta_g\langle X_g\rangle_\Lambda = \langle Q_\Lambda Y_{\delta g}\rangle_\Lambda \tag{106.4}$$

for an admissible insertion $Y_{\delta g}$. If the Ward identity (106.2) holds for $Y_{\delta g}$, then

$$\delta_g\langle X_g\rangle_\Lambda = 0.$$

Indeed, equation (106.4) identifies the metric derivative with $\langle Q_\Lambda Y_{\delta g}\rangle_\Lambda$, and the regulated Ward identity evaluates this expectation value to zero. The substantive part of using the criterion is constructing $Y_{\delta g}$ with all contact terms and metric dependence of X_g included in the regulated insertion algebra.

The familiar condition that the stress tensor is Q-exact is a sufficient local mechanism, not the full statement. In the notation of Chapter 102, the complete condition is that the full renormalized metric response, including contact terms and explicit variation of the insertion representative, is a Q-variation. This is the condition expressed by (106.4).

106.3 Exact Deformations and Localization

Let $V \in \mathcal{A}_\Lambda$ be odd and B_Λ-invariant. If

$$S_{\Lambda,t} = S_\Lambda + t\, Q_\Lambda V \tag{106.5}$$

is an allowed family of regulated actions and X is Q_Λ-closed, then t-independence is the same Ward identity.

***Q*-exact deformation independence.** Assume $Q_\Lambda S_\Lambda = 0$, $Q_\Lambda X = 0$, $Q_\Lambda^2 V = 0$, and the Ward identity holds for

$$Y = V X \exp(-tQ_\Lambda V)$$

for every t in the interval under consideration. Then

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle X\rangle_{\Lambda,t} = 0.$$

For the unnormalized integral

$$I_t(X) = \int_{\Gamma_\Lambda} X \exp(-S_\Lambda - tQ_\Lambda V),$$

one has

$$\frac{\mathrm{d}}{\mathrm{d}t}I_t(X) = -\int_{\Gamma_\Lambda} X(Q_\Lambda V)\exp(-S_\Lambda - tQ_\Lambda V).$$

Since $Q_\Lambda X = 0$, $Q_\Lambda S_\Lambda = 0$, and $Q_\Lambda^2 V = 0$, the integrand is

$$-Q_\Lambda(VX\exp(-S_\Lambda - tQ_\Lambda V))\,.$$

The Ward identity makes the derivative of $I_t(X)$ vanish. Applying the calculation above with $X = 1$ gives

$$\frac{\mathrm{d}}{\mathrm{d}t}I_t(1) = -\int_{\Gamma_\Lambda} Q_\Lambda(V\exp(-S_\Lambda - tQ_\Lambda V)) = 0,$$

so the normalization is also t-independent. The quotient $\langle X\rangle_{\Lambda,t} = I_t(X)/I_t(1)$ is therefore independent of t.

This calculation is the algebraic part of localization. It does not by itself identify the locus, the determinant, or the boundary contribution. Those require positivity or contour information for the bosonic part of $Q_\Lambda V$, a compactness statement, and a normal-mode analysis.

106.4 Finite-Dimensional Localization Theorem

The following theorem is the precise finite-dimensional model used by cohomological path integrals. It is intentionally stated with hypotheses that are checkable in finite dimension.

Theorem 106.3 (Compact nondegenerate localization)**.** *Let $\mathcal{X}$ be an oriented finite-dimensional supermanifold with compact even integration cycle Γ, Berezinian density μ, and an odd vector field Q. Let $S \in C^\infty(\mathcal{X})_{\bar 0}$ be an even action, $X \in C^\infty(\mathcal{X})$ an insertion, and $V \in C^\infty(\mathcal{X})_{\bar 1}$ an odd deformation functional. Suppose:*

- *(i) Q^2 generates a compact even symmetry whose invariant subalgebra is used for observables;*
- *(ii) $L_Q\mu = 0$ and Q has no boundary flux through $\partial\Gamma$;*
- *(iii) $QS = 0$, $QX = 0$, and S and X are invariant under Q^2;*
- *(iv) V is invariant under Q^2;*
- *(v) the even part $h = (QV)_{\mathrm{bos}}$ satisfies $h \geq 0$, and $F = h^{-1}(0) \subset \Gamma_{\mathrm{red}}$ is a compact smooth submanifold;*
- *(vi) in a tubular neighborhood of F, the normal expansion of QV has a nondegenerate quadratic normal super-Gaussian whose local inverse Euler factors patch to a smooth density-valued section $e_{Q^2}(N_F)^{-1}$ on F.*

More explicitly, the last condition means the following. For each $y \in F$, after choosing even normal coordinates $u \in N_{\bar 0,y}$ and odd normal coordinates $\eta \in N_{\bar 1,y}$, the quadratic normal part is

$$(QV)_2(y;u,\eta) = \frac{1}{2}u^i A_{ij}(y)u^j + \frac{1}{2}\eta^\alpha C_{\alpha\beta}(y)\eta^\beta, \tag{106.6}$$

where A_y is positive definite on the chosen real normal contour and C_y is nondegenerate on the odd normal variables. The leading Berezinian degree is assumed to be balanced: after the normal *rescaling $u = t^{-1/2}\xi$, $\eta = t^{-1/2}\zeta$, the product of the even Jacobian, the odd Berezinian, and the degree of the normal Berezin polynomial has a finite t^0 limit. If this balance fails, the right large-t statement is a different asymptotic expansion rather than the simple fixed-locus formula below. Under this balance condition, the normal Gaussian*

$$\mathcal{G}(y) = \int_{N_y} \exp[-(QV)_2(y; u, \eta)]\; Du\, D\eta = (2\pi)^{\dim N_{\bar{0}}/2} \frac{\mathrm{Pf}(C_y)}{\det(A_y)^{1/2}} \tag{106.7}$$

with the chosen orientation and square-root convention is the local value of $e_{Q^2}(N_F)^{-1}$. Changes of normal coordinates act on the numerator, denominator, and Berezinian in the compensating way, so the patched object is a density on F. Then

$$I_t(X) = \int_\Gamma X \exp(-S - tQV)\, \mu$$

is independent of $t \geq 0$, and its large-t value is

$$\int_F \frac{X|_F \, \exp(-S|_F)}{e_{Q^2}(N_F)} \tag{106.8}$$

with the orientation line and equivariant Euler class determined by the normal Gaussian datum (106.6).

Proof. The t-independence is the Q-exact deformation calculation above in finite dimension, with $\langle QY \rangle = 0$ following from Stokes' theorem for the divergence-free odd vector field Q. In detail,

$$\frac{\mathrm{d}I_t(X)}{\mathrm{d}t} = -\int_\Gamma X(QV)e^{-S-tQV}\,\mu = -\int_\Gamma Q\big(VXe^{-S-tQV}\big)\,\mu = 0,$$

because $QS = 0$, $QX = 0$, $Q^2V = 0$ on the invariant subalgebra, and the boundary flux of Q through $\partial\Gamma$ vanishes.

It remains to identify the common value by the limit $t \to +\infty$. Since Γ_{red} is compact and $h^{-1}(0) = F$, for every sufficiently small tubular neighborhood U of F there is a constant $c_U > 0$ with $h \geq c_U$ on $\Gamma_{\mathrm{red}} \setminus U$. The even body of the integrand outside U is therefore bounded by $\exp(-tc_U)$ times a fixed smooth density, and the odd part is a finite polynomial. Hence the complement of U does not contribute to the limit.

Work in one coordinate patch of the tubular neighborhood and write a point as (y, u, η), with $y \in F$, even normal coordinate u, and odd normal coordinate η. Taylor expansion gives

$$QV = (QV)_2 + R_3,$$

where $(QV)_2$ is the quadratic expression (106.6) and R_3 has total normal degree at least three. Put $u = t^{-1/2}\xi$ and $\eta = t^{-1/2}\zeta$. In Berezin integration the odd change of variables contributes the inverse determinant of the odd scaling, while the even change of variables contributes the ordinary Jacobian; these are exactly the factors included in the super-Gaussian density (106.7). The remainder satisfies

$$t\,R_3(y, t^{-1/2}\xi, t^{-1/2}\zeta) = O(t^{-1/2})$$

on every bounded normal set, and the positive quadratic form A_y gives a uniform Gaussian majorant after shrinking the tubular neighborhood and using a finite cover of F. Dominated convergence therefore replaces the normal integral by the fiberwise Gaussian $\mathcal{G}(y)$.

The local Gaussian factors transform by the Berezinian of changes of normal coordinates, so they glue to the inverse Euler density $e_{Q^2}(N_F)^{-1}$. Summing the finite partition of unity on F gives (106.8). The orientation line and the square root of $\det A_y$ are not decoration: without these choices the local Gaussian factors do not define a global integrand on F. □

106.5 Mathai–Quillen Form of a Cohomological Theory

Many cohomological field theories are infinite-dimensional analogues of the Mathai–Quillen representative of the Euler class of a vector bundle. The finite-dimensional model is as follows.

Let $\pi : E \to X$ be an oriented real vector bundle with metric $(\cdot,\cdot)_E$, compatible connection ∇^E, and smooth section

$$s : X \to E.$$

The zero locus is

$$Z(s) = \{x \in X : s(x) = 0\}.$$

Introduce local even coordinates x^i, odd tangent variables ψ^i representing dx^i, odd fiber variables χ_a, and even auxiliary fiber variables H_a. The cohomological differential is

$$Qx^i = \psi^i, \qquad Q\psi^i = 0, \qquad Q\chi_a = H_a, \qquad QH_a = 0 \tag{106.9}$$

in a local trivialization. The connection-covariant version adds the standard connection terms so that the expression below globalizes.

Choose the standard oscillatory auxiliary-field representative

$$V_{\mathrm{MQ}} = \frac{1}{2}(\chi, H)_E + \mathrm{i}(\chi, s)_E.$$

Then

$$QV_{\mathrm{MQ}} = \frac{1}{2}(H, H)_E + \mathrm{i}(H, s)_E - \mathrm{i}(\chi, \nabla^E_\psi s)_E + \text{curvature term.} \tag{106.10}$$

With the real Gaussian contour for H, completing the square gives

$$\int \mathrm{d}H \, \exp\left[-\frac{1}{2}(H, H)_E - \mathrm{i}(H, s)_E\right] = \text{const.} \exp\left[-\frac{1}{2}\|s\|^2\right].$$

The remaining Berezin polynomial, including the connection and curvature terms suppressed in (106.10), has top fiber-degree component equal to the Mathai–Quillen Thom form. Pulling this Thom form back by the section s gives a de Rham representative of $e(E)$. If the section is transverse, the large-deformation limit localizes the integral to $Z(s)$, with sign determined by the orientation of $\det(ds)$.

Proposition 106.4 (Mathai–Quillen localization for a transverse section)**.** *Let X be compact and s transverse to the zero section. For any closed differential form α on X of degree* $\dim X - \operatorname{rank} E$*,*

$$\int_X \alpha \wedge e(E) = \int_{Z(s)} \alpha|_{Z(s)}$$

where $Z(s)$ is oriented by the isomorphism

$$N_{Z(s)/X} \simeq s^*E$$

induced by ds and by the given orientations of X and E. When $\operatorname{rank} E = \dim X$ *it is the signed sum of zeros of s.*

Proof. Let $\tau_{\mathrm{MQ}} \in \Omega^{\operatorname{rank} E}_{\mathrm{cpt}}(E)$ denote the Mathai–Quillen Thom form in the convention described above. Its pullback $s^*\tau_{\mathrm{MQ}}$ represents $e(E)$. Replacing s by $t^{1/2}s$ does not change this cohomology class: differentiating the Gaussian representative with respect to t gives an exact form, equivalently a Q-exact variation in the finite-dimensional supersymmetric notation. Since X is compact and α is closed,

$$I(t) := \int_X \alpha \wedge (t^{1/2}s)^*\tau_{\mathrm{MQ}}$$

is independent of $t > 0$.

It remains to identify the common value by the limit $t \to +\infty$. Transversality makes $Z(s)$ a compact submanifold of codimension $\operatorname{rank} E$, and

$$ds : N_{Z(s)/X} \longrightarrow s^*E$$

is a vector-bundle isomorphism. Choose a tubular neighborhood of $Z(s)$ with base coordinate $y \in Z(s)$ and normal coordinate $n \in N_{Z(s)/X,y}$. In this neighborhood

$$s(y, n) = ds_y(n) + O(|n|^2).$$

On the complement of any smaller tubular neighborhood, $\|s\|$ is bounded below by a positive constant, so the Gaussian part of the pulled-back Mathai–Quillen form is exponentially small in t. Thus only $|n| = O(t^{-1/2})$ contributes. Put $n = t^{-1/2}\xi$. The leading normal part of the Mathai–Quillen density is

$$(2\pi)^{-r/2} \exp\left[-\frac{1}{2}\|ds_y(\xi)\|^2\right] \det(ds_y)\, d^r\xi, \qquad r = \operatorname{rank} E,$$

where the determinant is computed after oriented bases of $N_{Z(s)/X,y}$ and E_y are chosen. The ordinary Gaussian integral contributes $|\det(ds_y)|^{-1}$, while the Berezin fiber integration contributes $\det(ds_y)$. Their quotient is the sign of ds_y. The orientation on $Z(s)$ is exactly the orientation for which the decomposition

$$T_xX \simeq T_xZ(s) \oplus N_{Z(s)/X,x} \simeq T_xZ(s) \oplus E_x$$

has the prescribed orientations of X and E. With this convention the sign is absorbed into the oriented integration over $Z(s)$. The terms omitted in $s(y, t^{-1/2}\xi)$ and in the pulled-back form give negative powers of $t^{1/2}$ after the rescaling and vanish by the Gaussian bound. Therefore

$$\lim_{t\to+\infty} I(t) = \int_{Z(s)} \alpha|_{Z(s)}.$$

The equality follows because $I(t)$ is independent of t. When $\operatorname{rank} E = \dim X$, $Z(s)$ is a finite oriented zero-manifold, so the last integral is the signed sum over its points. □

The proposition is the finite-dimensional ancestor of statements such as "Donaldson–Witten theory localizes to anti-self-dual connections" and "the A-model localizes to holomorphic maps." In field theory, X is an infinite-dimensional field space, E is an infinite-dimensional bundle of equations, and $s = 0$ is the PDE defining the moduli problem. The theorem then requires regularization, compactness, orientation, and determinant-line control.

106.6 Descent and Integrated Observables

Let M be a smooth D-manifold. A local cohomological observable is not only a Q-closed local density. If it is to be integrated over cycles of different dimensions, it must come with a descent package.

Definition 106.5 (Descent package)**.** A descent package is a sequence of local p-form insertions

$$\mathcal{O}^{(p)} \in \Omega^p(M) \otimes \mathcal{A}, \qquad 0 \le p \le D,$$

such that

$$Q\mathcal{O}^{(0)} = 0, \qquad Q\mathcal{O}^{(p)} + \mathrm{d}\mathcal{O}^{(p-1)} = 0 \quad (1 \le p \le D). \tag{106.11}$$

If γ_p is a closed p-cycle, then

$$I_{\gamma_p}(\mathcal{O}) = \int_{\gamma_p} \mathcal{O}^{(p)} \tag{106.12}$$

is Q-closed: using (106.11) and $\partial\gamma_p = 0$,

$$QI_{\gamma_p}(\mathcal{O}) = \int_{\gamma_p} Q\mathcal{O}^{(p)} = -\int_{\gamma_p} \mathrm{d}\mathcal{O}^{(p-1)} = -\int_{\partial\gamma_p} \mathcal{O}^{(p-1)} = 0.$$

If γ_p is changed by a boundary, $\gamma_p \mapsto \gamma_p + \partial C_{p+1}$, then

$$I_{\gamma_p+\partial C_{p+1}}(\mathcal{O}) - I_{\gamma_p}(\mathcal{O}) = \int_{C_{p+1}} \mathrm{d}\mathcal{O}^{(p)} = -Q\int_{C_{p+1}} \mathcal{O}^{(p+1)}. \tag{106.13}$$

Thus integrated descendants depend only on the homology class of the cycle in Q-cohomology, subject to the specified contact-term qualification when cycles collide with other insertions.

In Donaldson–Witten theory, the descent package is generated from invariant polynomials in the universal equivariant curvature. With

$$QA = \psi, \qquad Q\psi = -d_A\phi, \qquad Q\phi = 0, \qquad Q^2 = \delta_{\text{gauge}}(-\phi), \tag{106.14}$$

gauge-invariant polynomials of ϕ define local Q-classes, and their descendants give observables integrated over cycles in the four-manifold. The detailed four-dimensional field content, instanton moduli space, and orientation data are developed in Chapter 109.

106.7 Cartan Model and Equivariant Closure

When Q^2 is an even symmetry, the finite-dimensional model is the Cartan model of equivariant cohomology. Let a compact Lie group K act on a manifold X with infinitesimal vector fields v_ξ, $\xi \in \mathfrak{k}$. On K-invariant polynomial maps

$$\alpha : \mathfrak{k} \to \Omega^\bullet(X)$$

define

$$d_K\alpha(\xi) = d\alpha(\xi) - \iota_{v_\xi}\alpha(\xi). \tag{106.15}$$

Then

$$d_K^2\alpha(\xi) = -\mathcal{L}_{v_\xi}\alpha(\xi), \tag{106.16}$$

so $d_K^2 = 0$ on invariant forms.

Example 106.6 (Hamiltonian S^1 model)**.** Let $X = \mathbb{R}^2$ with coordinates x, y, symplectic form $\omega = dx \wedge dy$, and rotation vector field

$$v = -y\partial_x + x\partial_y.$$

The moment map in the sign convention of (106.15) is

$$\mu = -\frac{1}{2}(x^2 + y^2), \qquad d\mu = \iota_v\omega.$$

Therefore

$$d_{S^1}(\omega + \mu) = 0.$$

This is the elementary algebra behind equivariant localization: the deformation can be made by an equivariantly exact term without changing the equivariant cohomology class.

106.8 Gauge Theories and BV Closure

For a gauge theory, replacing Q by a formal odd symmetry on fields is not enough. Gauge fixing, ghosts, antifields, and the integration cycle must be part of the construction. The correct compatibility condition is the BV master equation. In finite-dimensional notation, let $(\mathcal{F}, \omega_{\mathrm{BV}})$ be an odd symplectic supermanifold, let $(\,\cdot\,,\,\cdot\,)$ be the BV bracket, and let Δ be the regulated BV Laplacian. A quantum BV action satisfies

$$\frac{1}{2}(S, S) - \hbar\Delta S = 0. \tag{106.17}$$

The corresponding BV differential on insertions is

$$\widehat{Q}X = (S, X) - \hbar\Delta X. \tag{106.18}$$

If $X = \widehat{Q}Y$ and the BV Stokes theorem holds on the chosen Lagrangian integration cycle $\mathcal{L}$, then

$$\int_{\mathcal{L}} X\, \exp(-S/\hbar) = 0.$$

A cohomological gauge theory is therefore a BV theory together with an extra odd symmetry, or with a BV differential whose cohomology contains the desired topological observables. The equality $Q^2 = \delta_{\mathrm{gauge}}(\phi)$ must be interpreted inside the BV complex. A Q-exact deformation is legitimate only if it preserves the quantum master equation, or equivalently if it is generated by a BV-canonical deformation plus allowed gauge-fixing data.

106.9 Donaldson–Witten as the Guiding Gauge-Theory Model

The universal finite-dimensional template for Donaldson–Witten theory is the Mathai–Quillen model applied to the bundle of self-dual two-forms over the space of connections modulo gauge. Let X be a closed oriented Riemannian four-manifold and $P \to X$ a principal $SU(2)$ bundle. The configuration space before quotient is the affine space $\mathcal{A}(P)$. The equation bundle is

$$\Omega^{2,+}(X, \mathrm{ad}\, P) \longrightarrow \mathcal{A}(P),$$

and the section is

$$s(A) = F_A^+.$$

The zero locus $s^{-1}(0)$ is the space of anti-self-dual connections. After quotient by the gauge group, the virtual tangent-obstruction complex is

$$\Omega^0(X, \operatorname{ad} P) \xrightarrow{d_A} \Omega^1(X, \operatorname{ad} P) \xrightarrow{d_A^+} \Omega^{2,+}(X, \operatorname{ad} P).$$

The twisted fields

$$\psi \in \Omega^1(X, \operatorname{ad} P), \qquad \chi^+ \in \Omega^{2,+}(X, \operatorname{ad} P), \qquad H^+ \in \Omega^{2,+}(X, \operatorname{ad} P)$$

are the tangent odd variable, antighost, and auxiliary variable in this Mathai–Quillen construction. The scalar ϕ is the equivariant gauge parameter appearing in $Q^2 = \delta_{\mathrm{gauge}}(-\phi)$. Thus localization to $F_A^+ = 0$ is the infinite-dimensional, gauge-equivariant Mathai–Quillen localization mechanism, with all analytic and compactness issues still to be supplied.

This perspective also explains why contact terms are unavoidable. The Donaldson observables are descendants integrated over cycles. Products of integrated descendants require a prescription for collisions of cycles and for boundary strata of the instanton compactification. A cohomological Ward identity controls these contact terms only after they have been included in the regulated observable algebra.

106.10 What Must Be Proved in Infinite Dimension

The finite-dimensional statements above reduce the infinite-dimensional problem to a clear list of mathematical obligations:

(i) construct the regulated field/BV space and integration cycle;

(ii) prove the Q-Ward identity or quantum master equation at the regulator;

(iii) prove that the continuum limit exists for the selected observables;

(iv) identify the fixed locus and its virtual normal complex;

(v) prove compactness or describe boundary strata and their contributions;

(vi) orient the determinant line and compute the one-loop or Euler factor;

(vii) define contact terms for integrated descendants and show that the descent equations survive renormalization.

Only after these steps are complete does a formal localization computation become a theorem about a QFT.

Open Problem 106.7 (Cohomological QFT beyond formal localization)*.* Develop regulator-level cohomological QFT constructions in which Q-Stokes theorem, BV gauge fixing, compactness of fixed loci, orientation lines, one-loop determinants, contact terms, and boundary strata are all controlled. This is the prerequisite for using cohomological field theory as a theorem-level bridge between quantum field theory and topological invariants.

Chapter 107

Topological Sigma Models

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Let Σ be a compact oriented smooth surface equipped with a complex structure j_Σ, and let X be a compact smooth manifold. A two-dimensional sigma model has bosonic field $\phi : \Sigma \to X$. A topological sigma model is a cohomological sigma model in the sense of Chapter 106: it has an odd differential Q, Q-closed observables, and a stress-tensor or metric-response insertion which is Q-exact after the anomaly and boundary terms have been accounted for. The central examples are the A-model and the B-model obtained from two-dimensional $\mathcal{N} = (2, 2)$ sigma models by two distinct twists.
