and $P_a(\eta)$ is a local polynomial in the continuum sources and their derivatives. The linear part of $\mathcal{Z}_a$ fixes field normalization and operator mixing. Its higher local Taylor coefficients fix the contact extension of products of continuum fields.

The term $P_a(\eta)$ removes vacuum terms such as powers of the volume and local source self-contractions. It has no effect on separated normalized correlators, but it is part of the definition of the full distributional generating functional.

Separated kernels in a source-dependent scaling limit. Assume the source-dependent scaling limit (38.9) exists for two microscopic realizations X and Y and that their continuum source coordinates have been identified by the same fixed-point operator normalization. Then their noncoincident continuum correlators of the corresponding scaling fields agree. Their contact-term extensions may differ by local distributions supported on collision diagonals.

The point is a consequence of the source-functional definition. Functional derivatives of (38.9) at $\eta = 0$ give the scaling limits of smeared inserted correlators. Restricting the resulting distributions to the configuration space of distinct insertion points removes all terms supported on collision diagonals. By the source-coordinate partition formula of Section 34.5, only the linear source jet contributes on this configuration space. Once the linear jet has been fixed by the common operator normalization, the two realizations have the same separated-point correlators. Higher source jets and the local polynomials P_a change only the extension across collision diagonals.

Thus microscopic observables enter the continuum theory through renormalized source derivatives whose limits are operator-valued distributions. The universal data are the separated-point kernels obtained after the relevant scaling coordinates and linear operator normalizations have been fixed. These kernels are the source-coordinate input for the fixed-point operator data constructed in Chapter 56.

38.6 A Lattice Scalar Path Integral

The Ising variables may be enlarged from two values to a real local variable without changing the long-distance fixed point, provided the relevant $\mathbb{Z}_2$-even coupling is tuned. Let $P : \mathbb{R} \to \mathbb{R}$ be an even single-site potential with sufficient growth at infinity. The generalized Ising partition function is

$$\widetilde{Z}_\Lambda = \int \prod_{x\in\Lambda} \mathrm{d}s_x \, \exp\left[-\sum_{x\in\Lambda} P(s_x) + \beta \sum_{\langle xy\rangle} s_x s_y \right].$$

For P real and bounded below with sufficient growth and for $\beta \geq 0$, this nearest-neighbor scalar measure is in the reflection-positive class of Proposition 38.4. This assertion uses the positivity of the cross-reflection nearest-neighbor coupling. It would not follow for an arbitrary lattice regularization with negative next-nearest-neighbor terms or other cross-plane kernels that are not positive in the sense used in the proof of that proposition. Equivalently,

$$\widetilde{Z}_\Lambda = \int \prod_{x\in\Lambda} \mathrm{d}s_x \, \mathrm{e}^{-S_\Lambda(s)}$$

with

$$S_\Lambda(s) = \frac{\beta}{2} \sum_{\langle xy\rangle} (s_x - s_y)^2 + \sum_{x\in\Lambda} \big(P(s_x) - \beta D \, s_x^2\big),$$

where each positive lattice direction is counted once. The identity follows from

$$\sum_{\langle xy\rangle} (s_x - s_y)^2 = 2D \sum_x s_x^2 - 2 \sum_{\langle xy\rangle} s_x s_y$$

on a periodic hypercubic lattice.

For an infinite hypercubic lattice with unit spacing, introduce the Brillouin zone

$$B = [-\pi, \pi]^D$$

and write

$$s_x = \int_B \frac{\mathrm{d}^D k}{(2\pi)^D} \, \widetilde{\phi}(k) \, \mathrm{e}^{\mathrm{i}k\cdot x}, \qquad \widetilde{\phi}(k + 2\pi n) = \widetilde{\phi}(k), \quad n \in \mathbb{Z}^D.$$

The cutoff $|k^\mu| \leq \pi$ is a finite ultraviolet cutoff. The nearest neighbor kinetic term becomes

$$\sum_{\langle xy\rangle} (s_x - s_y)^2 = \int_B \frac{\mathrm{d}^D k}{(2\pi)^D} \, \widetilde{\phi}(-k)\widetilde{\phi}(k) \sum_{\mu=1}^{D} \left| \mathrm{e}^{\mathrm{i}k_\mu} - 1 \right|^2.$$

For lattice spacing a, the dimensionful momentum is $p = k/a$, and the Brillouin-zone edge is therefore

$$\Lambda_{\mathrm{BZ}} = \frac{\pi}{a}.$$

In the finite-cutoff Wilsonian estimates below, $\Lambda_0 = a^{-1}$ denotes the inverse lattice spacing rather than the Brillouin-zone edge. The two conventions are related by the fixed conversion

$$\Lambda_{\mathrm{BZ}} = \pi\Lambda_0.$$

Replacing Λ_0 by Λ_{BZ} in a cutoff-suppressed estimate only multiplies the corresponding constant by a power of π; it does not change the exponent or the continuum limit. For small momentum,

$$\sum_{\mu=1}^{D} \left| \mathrm{e}^{\mathrm{i}k_\mu} - 1 \right|^2 = k^2 - \frac{1}{12}\sum_{\mu=1}^{D} k_\mu^4 + O(k^6).$$

Thus the long-distance action has the form

$$S[\phi] = \int \mathrm{d}^D x \left[\frac{\beta}{2}\sum_{\mu=1}^{D}(\partial_\mu\phi)^2 + V_\beta(\phi) - \frac{\beta}{24}\sum_{\mu=1}^{D}(\partial_\mu^2\phi)^2 + \cdots \right],$$

with $V_\beta(\phi) = P(\phi) - \beta D\phi^2$ plus local terms generated by the field normalization convention. The higher-derivative terms reflect the lattice cutoff and the breaking of continuous rotations to the hypercubic lattice symmetry.

Figure 38.4 shows the local scalar action generated from the lattice ensemble: the single-site measure supplies $V_\beta(\phi)$, the nearest-neighbor term supplies the gradient term, and higher-derivative operators record the cutoff symmetry.

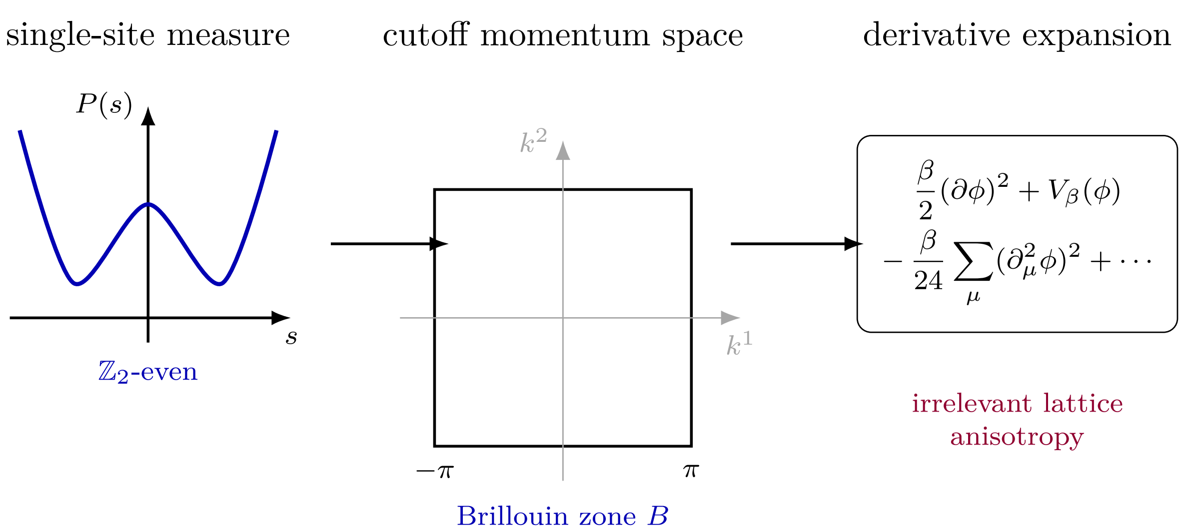

Figure 38.4: The generalized Ising model may be rewritten as a scalar lattice path integral. The single-site measure supplies the potential, the nearest neighbor interaction supplies the kinetic term, and the Brillouin zone gives a finite ultraviolet cutoff.

38.7 Universality Classes and Relevant Coordinates

The lattice scalar action just constructed and the continuum quartic scalar action differ in their short-distance coordinates. The lattice action has a finite cutoff, lattice-anisotropic derivative terms, and many allowed local couplings such as ϕ^6 and higher powers or derivatives. These differences define distinct points in the same local theory space. The universality statement is that, in $D = 2, 3$ and under the existence of the scaling limit described above, these distinct ultraviolet points have long-distance trajectories that approach the same Ising fixed point after the relevant coordinates are tuned.

Near the fixed point, write a general local deformation as

$$\Delta S = \int \mathrm{d}^D x \left(u_h\, \sigma(x) + u_t\, \varepsilon(x) + \sum_I u_I\, O_I(x) \right), \qquad \Delta_I = \dim O_I.$$

The coefficient u_I has mass dimension $D - \Delta_I$. At a physical mass scale μ, the dimensionless strength of this perturbation is

$$\lambda_I(\mu) = u_I\, \mu^{\Delta_I - D}.$$

To linear order at the fixed point,

$$\frac{\mathrm{d}\lambda_I}{\mathrm{d}\log\mu} = (\Delta_I - D)\lambda_I + O(\lambda^2).$$

If $\Delta_I > D$, the dimensionless strength tends to zero as $\mu \to 0$. These are the irrelevant perturbations. They account for microscopic differences such as the choice of square or hexagonal lattice, the details of $P(s)$, and higher-derivative cutoff terms.

The fixed-point spectral input used in the Ising universality statement is that, after omitting the identity, total derivatives, equation-of-motion descendants, and metric deformations, the only relevant scalar action deformations are the $\mathbb{Z}_2$-odd spin field σ and the $\mathbb{Z}_2$-even energy field ε:

$$\Delta_\sigma < D, \qquad \Delta_\varepsilon = D - \frac{1}{\nu} < D.$$

Their linear RG eigenvalues are

$$y_h = D - \Delta_\sigma, \qquad y_t = D - \Delta_\varepsilon = \frac{1}{\nu}.$$

The magnetic field couples to u_h. If the microscopic $\mathbb{Z}_2$ symmetry is imposed, then $u_h = 0$ and the displayed theory-space slice has only the thermal relevant direction. The temperature deviation determines the thermal scaling coordinate by

$$u_t = c_T(T - T_c) + O((T - T_c)^2), \qquad c_T \neq 0,$$

after a choice of temperature coordinate near T_c. Since u_t has dimension $D - \Delta_\varepsilon$, it generates the correlation length

$$\xi(T) \propto |u_t|^{-1/(D-\Delta_\varepsilon)} \propto |T - T_c|^{-\nu}.$$

The coefficient c_T and the amplitude of ξ are not universal; the exponent is.

Figure 38.5 gives the local RG picture of the Ising universality statement: the temperature coordinate follows the relevant direction, and microscopic data along irrelevant directions are forgotten in the scaling limit.

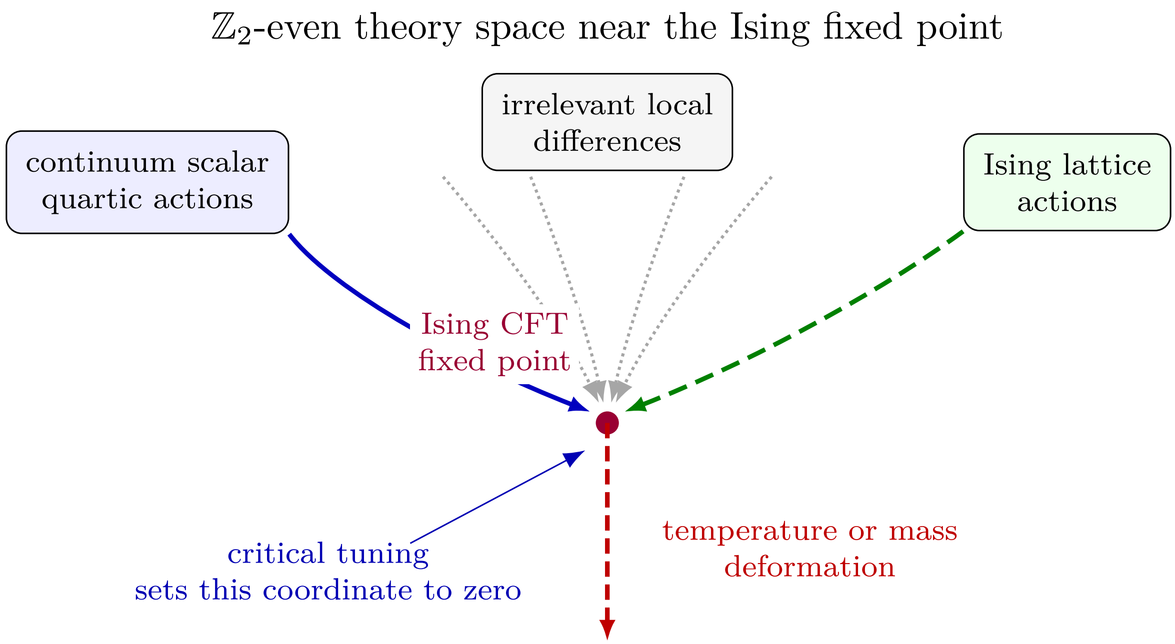

Figure 38.5: A local $\mathbb{Z}_2$-even theory-space chart for an Ising universality statement. Solid and dashed arrows distinguish continuum scalar and lattice representatives after critical tuning; dotted arrows indicate irrelevant differences whose effects must be controlled in a declared observable topology. Relevant thermal deformations move the theory away from criticality and produce massive scaling limits.

Thus the statistical Ising model supplies a constructive route from microscopic lattice ensembles to continuum Euclidean QFT. The construction is by correlators: after tuning the relevant coordinates and rescaling fields, the large-distance spin correlators define correlators of local fields at, or near, the Ising fixed point.

Definition 38.7 (Scaling-limit universality structure)**.** For the purposes of this chapter, a scaling-limit universality structure is the following collection of objects.

(i) A class $\mathfrak{U}$ of microscopic regulators X, each with a finite or Banach parameter space P_X, a cutoff a^{-1}, a reflection-positive Euclidean state or finite-volume measure, and a selected family of microscopic local observables A_I^X.

(ii) For each relevant endpoint u_R at a fixed reference scale μ_R, families of tuned microscopic parameters

$$p_X(a, u_R) \in P_X, \qquad X \in \mathfrak{U},$$

defined for all sufficiently small a.

(iii) Local normalization and source-renormalization maps

$$A_I^X \longmapsto Z_{I,a}^X A_I^X, \qquad \eta \longmapsto \mathcal{Z}_a^X(\eta),$$

together with source-local counterterms $P_a^X(\eta)$, where source-local means a polynomial functional supported on collision diagonals of the inserted sources.

(iv) A directed family of observation domains $\mathfrak{W}$. An element $W \in \mathfrak{W}$ may be a bounded set of test sources, a finite list of separated smeared correlators, or a finite observation window in the observable-germ sense of Chapter 142. Each W carries seminorms in which convergence is to be stated.

(v) A limiting source functional $W_*(\eta; u_R)$, modulo source-local polynomials, such that for every $X \in \mathfrak{U}$ and every $W \in \mathfrak{W}$,

$$W^X_{a,p_X(a,u_R)}[\mathcal{Z}_a^X(\eta)] - W^X_{a,p_X(a,u_R)}[0] - P_a^X(\eta) \longrightarrow W_*(\eta; u_R) \tag{38.10}$$

in the seminorms attached to W.

Two microscopic regulators $X, Y \in \mathfrak{U}$ are in the same scaling-limit universality class, relative to the selected observables, normalization freedom, tuning maps, and observation topology above, when they belong to a common structure with the same W_*. The relation is therefore an equivalence relation only after these normalizations, tuning maps, observation topologies, and convergence statements have been specified: equality of W_* is reflexive and symmetric, and transitivity is composition through the common limiting source functional with the permitted local source redefinitions.

The definition is deliberately source-functional. It records the object that can reconstruct separated Schwinger functions and, after positivity and regularity hypotheses, local QFT data. A Wilsonian coordinate basin supplies one possible mechanism for proving (38.10), but it is not the definition of the universality class: the definition is the common limiting observable structure with its tuning, normalization, and topology.

38.8 Finite-Cutoff Universality in a Local Chart

The preceding paragraph can be made into a local finite-cutoff statement. Let $\Lambda_0 = a^{-1}$ be the lattice cutoff and let μ_R be a fixed reference momentum scale with $\mu_R < \Lambda_0$. Choose a finite local RG chart near the Ising fixed point and write the projected Wilsonian coordinates at μ_R as

$$z(\mu_R; \Lambda_0) = (u(\mu_R; \Lambda_0), v(\mu_R; \Lambda_0)).$$

Here u denotes the relevant coordinates and v denotes the retained irrelevant coordinates. In the full scalar chart

$$u = (\lambda_h, \lambda_t),$$

where λ_h is the dimensionless coordinate coupled to the spin field σ, and λ_t is the dimensionless coordinate coupled to the energy field ε. In the $\mathbb{Z}_2$-even chart λ_h is absent. The target value

$$u_R = (\lambda_{h,R}, \lambda_{t,R})$$

specifies either the critical theory, when $u_R = 0$, or a massive scaling limit, when one of the relevant coordinates is held at a fixed nonzero value at the scale μ_R.

Let X label a microscopic realization in the same proposed universality class: a nearest-neighbor Ising model, a generalized single-site potential, or a lattice scalar action with different short-distance couplings. Let p_X denote the microscopic parameters available for tuning, such as temperature and magnetic field. The endpoint map in the finite chart is

$$E_X(\Lambda_0, p_X) = u_X(\mu_R; \Lambda_0, p_X).$$

The local tuning problem is to solve

$$E_X(\Lambda_0, p_X) = u_R.$$

In the $\mathbb{Z}_2$-even one-parameter case this is the precise version of tuning the temperature: if $p_X = T$, then the condition at criticality is $\lambda_t(\mu_R; \Lambda_0, T) = 0$.

Local RG-coordinate consequence. Fix a finite local RG chart near the Ising fixed point and a target relevant coordinate u_R. Suppose that, for every sufficiently large Λ_0 and for each microscopic realization X under consideration, the following conditions hold.

(i) The endpoint equation $E_X(\Lambda_0, p_X) = u_R$ has a solution $p_X(\Lambda_0, u_R)$, and the corresponding trajectory remains in the chosen chart between Λ_0 and μ_R.

(ii) The retained irrelevant block obeys the same backward contraction estimate used in the Wilsonian cutoff-removal theorem.

(iii) The microscopic irrelevant coordinates are uniformly bounded after expressing the ultraviolet-regulated microscopic action in the chosen local coordinates.

(iv) The generated integral along the tuned trajectory converges uniformly as $\Lambda_0 \to \infty$.

Then there is a graph $v = V_{\mu_R}(u_R)$, depending on the fixed point and on the chosen RG coordinates but not on the microscopic label X, such that

$$v_X(\mu_R; \Lambda_0, p_X(\Lambda_0, u_R)) = V_{\mu_R}(u_R) + O\left[\left(\frac{\mu_R}{\Lambda_0}\right)^{\kappa}\right]$$

for some $\kappa > 0$ determined by the irrelevant exponents and by the convergence rate of the generated integral.

This follows by applying the finite-coordinate cutoff-removal estimate of Chapter 36 to the RG trajectory whose relevant endpoint coordinate is fixed to be u_R. The irrelevant part of the bare coordinate contributes at order $(\mu_R/\Lambda_0)^{\omega}$, where ω is the smallest retained irrelevant exponent in the chart. The generated integral has the assumed cutoff limit and a convergence rate, say ω_F. Taking $\kappa = \min(\omega, \omega_F)$ gives the displayed estimate. The limiting graph is independent of X because all dependence on X has been placed either in the solved relevant-coordinate tuning or in bounded irrelevant bare coordinates whose direct memory is power-suppressed.

This coordinate form of universality separates three kinds of objects. First, the fixed point and its scaling operators determine Δ_σ, Δ_ε, y_h, y_t, and the limiting operator algebra. Second, the microscopic model determines nonuniversal coordinate maps, such as

$$\lambda_t(\Lambda_0) = A_X\,(T - T_{c,X}) + O((T - T_{c,X})^2), \qquad A_X \neq 0.$$

Third, the irrelevant microscopic coordinates determine finite-cutoff corrections. At linear order the tuning relation for a fixed thermal target $\lambda_{t,R}$ is

$$\lambda_t(\Lambda_0) = \left(\frac{\mu_R}{\Lambda_0}\right)^{y_t} \lambda_{t,R} + \text{higher-order terms},$$

so

$$T - T_{c,X} = A_X^{-1} \left(\frac{\mu_R}{\Lambda_0}\right)^{y_t} \lambda_{t,R} + \cdots .$$

The factor A_X is not fixed-point data. The exponent $y_t = D - \Delta_\varepsilon$ is.

Remark 38.8 (Coordinate universality versus scaling-limit existence). The local RG-coordinate consequence above is a statement about convergence of finitely many projected RG coordinates at the reference scale μ_R. It does not, by itself, construct a continuum probability measure, a Euclidean source functional, or a Wightman theory. To upgrade the coordinate statement to a continuum universality theorem one must additionally establish the existence of the scaling limit of the relevant Schwinger functions or, equivalently in a source-functional formulation, convergence of the renormalized lattice source functionals on a source domain large enough to determine the desired correlators. The limiting Schwinger functions must also satisfy the positivity, covariance, locality, regularity, and clustering hypotheses needed for the intended reconstruction or structural theorem.

Indeed, the local RG proposition controls the finite vector $z(\mu_R; \Lambda_0)$ after projecting the exact cutoff action to the chosen coordinate chart. A continuum measure or source functional contains infinitely many correlation data and their positivity properties. Convergence of a finite coordinate vector does not imply tightness of the underlying measures, convergence of all moments or distributions, reflection positivity in the limit, locality of the reconstructed fields, or uniqueness of the continuum state. Each of these is an additional analytic assertion about the regulated models. Hence scaling-limit existence is an independent hypothesis or theorem, not a conclusion of the coordinate estimate.

Hypothesis 38.9 (Continuum universality data)**.** Let X range over a class of reflection-positive microscopic lattice models with the same global symmetries as the Ising fixed point, and let $p_X(a, u_R)$ be microscopic parameters tuned so that the relevant endpoint coordinate at the reference scale μ_R is the same fixed value u_R. Assume the following hypotheses.

(i) The finite-coordinate RG hypotheses of the local RG-coordinate consequence above hold uniformly for the class X, so that the retained Wilsonian coordinates satisfy

$$z_X(a, u_R) \longrightarrow z_*(u_R) := (u_R, V_{\mu_R}(u_R)).$$

(ii) For the selected microscopic observables and sources, there are local source renormalization maps $\mathcal{Z}_a^X$ and source-local vacuum counterterms P_a^X on a common test-source neighborhood such that the renormalized source functionals have the representation

$$W_a^X[\mathcal{Z}_a^X(\eta)] - W_a^X[0] - P_a^X(\eta) = \mathcal{W}_X(z_X(a, u_R), \eta) + r_a^X(\eta),$$

where $r_a^X(\eta) \to 0$ as a distributional functional of η.

(iii) The continuum source coordinate has been fixed by a common normalization of the leading scaling fields, and the maps $\mathcal{W}_X(z, \eta)$ are sequentially continuous at $z = z_*(u_R)$ with the same limiting functional:

$$\lim_{z \to z_*(u_R)} \mathcal{W}_X(z, \eta) = W_*(\eta; u_R)$$

for every X in the class, modulo source-local polynomials.

(iv) The reflection-positive lattice quadratic forms for the renormalized observables converge on the positive-time test-function domain, and the limiting source functional has the Euclidean covariance, locality, regularity, and clustering properties required for the intended Osterwalder–Schrader reconstruction.

Consequence of the continuum-universality data. Under Hypothesis 38.9, the continuum separated-point Schwinger functions of the normalized scaling fields are independent of X. More precisely, functional derivatives of $W_*(\eta; u_R)$ give a common distribution on the configuration space of distinct insertion points, while the source-local polynomials in Hypothesis 38.9(iii) can change only contact terms on collision diagonals. Under the positivity and regularity hypotheses in Hypothesis 38.9(iv), the common Schwinger functions reconstruct the same Euclidean-to-Lorentzian QFT data in the observable sector generated by these fields. At $u_R = 0$, if the additional stress-tensor hypothesis stated after Hypothesis 38.2 holds, this common fixed point is the corresponding Ising CFT.

Here the substance is in the hypothesis. By Hypothesis 38.9(i), all tuned microscopic realizations approach the same retained-coordinate point $z_*(u_R)$ at the reference scale. Hypothesis 38.9(ii) separates the dependence of the renormalized source functional into a coordinate-dependent part, a vanishing remainder, and source-local vacuum terms. Hypothesis 38.9(iii) then gives

$$W_a^X[\mathcal{Z}_a^X(\eta)] - W_a^X[0] - P_a^X(\eta) \longrightarrow W_*(\eta; u_R)$$

for every X, modulo source-local polynomials. Taking functional derivatives at $\eta = 0$ gives the limiting distributions of inserted renormalized observables. Source-local polynomial differences are supported on collision diagonals, so they vanish after restriction to pairwise distinct insertion points. This proves equality of separated-point Schwinger functions. Hypothesis 38.9(iv) is precisely the additional closedness and regularity input needed to pass from equality of separated kernels to a common reconstructed Euclidean/Lorentzian theory; it is not supplied by the finite-dimensional RG coordinate estimate.

Hypothesis 38.10 (Ising lattice-to-CFT universality data)**.** Fix a spatial dimension D and a class $\mathfrak{U}$ of reflection-positive $\mathbb{Z}_2$-invariant microscopic lattice models whose thermodynamic limits exist in the pure-state convention used above. Let $A_{\sigma,a}^X$ and $A_{\varepsilon,a}^X$ be odd and even microscopic observables in a model $X \in \mathfrak{U}$, normalized by nonzero constants so that their leading scaling fields are σ and ε. Assume the following data and hypotheses.

(i) The tuned finite-coordinate Wilsonian hypotheses of the local RG-coordinate consequence above hold uniformly for $\mathfrak{U}$, with relevant endpoint coordinate $u_R = (\lambda_{h,R}, \lambda_{t,R})$. In the $\mathbb{Z}_2$-even critical slice this means $\lambda_{h,R} = \lambda_{t,R} = 0$.

(ii) The source-dependent scaling-limit hypotheses of the continuum-universality data above hold for the source coordinates coupled to $A_{\sigma,a}^X$, $A_{\varepsilon,a}^X$, and the other selected scaling observables. The reflected OS quadratic forms converge on the positive-time test-function domain.

(iii) At $u_R = 0$, the common limiting Schwinger hierarchy $W_*(\eta; 0)$ satisfies Euclidean covariance, reflection positivity, regularity, clustering, and the radial reconstruction hypotheses of Hypothesis 59.1. It has a conserved symmetric stress tensor improvable to traceless form, so the fixed point is a CFT in the sense of Chapter 56.

(iv) The fixed-point local CFT data include the local scaling-operator spectrum, two-point pairings, OPE coefficients, stress-tensor Ward data, and the OPE convergence hypotheses of Definition 64.1. For nonzero u_R, the corresponding relevant deformation of the fixed-point source functional by

$$\int \mathrm{d}^D x \left(\lambda_{h,R}\mu_R^{D-\Delta_\sigma}\sigma(x) + \lambda_{t,R}\mu_R^{D-\Delta_\varepsilon}\varepsilon(x)\right)$$

is constructed in a source-functional neighborhood large enough to determine the separated scaling functions under discussion.

Conditional Ising scaling functions. Under Hypothesis 38.10, for every $X \in \mathfrak{U}$, every list of selected microscopic observables, and every configuration of pairwise distinct continuum points $x_1, \ldots, x_n$, the normalized thermodynamic lattice correlators have the common scaling limit

$$\lim_{a \downarrow 0} \left\langle \prod_{j=1}^{n} a^{-\Delta_{I_j}} (b_{I_j}^X)^{-1} A_{I_j,a}^X(x_j) \right\rangle_{X, p_X(a,u_R)} = S_{I_1 \ldots I_n}^{\text{Ising}}(x_1, \ldots, x_n; u_R), \tag{38.11}$$

where I_j labels σ, ε, or another selected scaling operator, $b_{I_j}^X \neq 0$ is the leading microscopic normalization, and $p_X(a, u_R)$ is the tuned microscopic parameter supplied by Hypothesis 38.10(i). At $u_R = 0$, the functions on the right are the separated-point correlators of the Ising CFT. They are determined by the fixed-point CFT data in Hypothesis 38.10(iv) through radial OPE convergence and the Ward identities. At nonzero u_R inside the constructed relevant-deformation neighborhood, the same fixed-point data together with the specified relevant coordinates determine the massive or magnetized scaling functions.

The quantities $T_{c,X}$, metric factors relating $T - T_{c,X}$ and the magnetic field to $\lambda_{t,R}$ and $\lambda_{h,R}$, the constants b_I^X, finite-cutoff corrections, and contact-term extensions are not part of the universal separated-point functions (38.11).

The argument should be read as an unpacking of the hypotheses. The thermodynamic limit supplies the infinite-volume lattice state for each fixed cutoff and tuned microscopic parameter. Hypothesis 38.10(i), by the local RG-coordinate consequence above, sends every tuned microscopic realization to the same retained Wilsonian coordinate

$$z_*(u_R) = (u_R, V_{\mu_R}(u_R))$$

at the reference scale. Hypothesis 38.10(ii), by the continuum-universality consequence above, upgrades that coordinate convergence to convergence of the renormalized source functionals: after the local source maps and source-local vacuum subtractions are applied, all $X \in \mathfrak{U}$ have the same limiting functional $W_*(\eta; u_R)$ modulo source-local polynomials. Functional derivatives with respect to the normalized sources give (38.11). Source-local polynomials are supported on collision diagonals, so they vanish on the configuration space $x_i \neq x_j$.

At $u_R = 0$, Hypothesis 38.10(iii) gives the OS/radial reconstruction data and the stress-tensor condition needed to regard $W_*(\eta; 0)$ as the source functional of a unitary CFT. Hypothesis 38.10(iv) supplies the local CFT data and OPE convergence. The radial OPE theorem then reconstructs separated-point correlators from the local scaling spectrum, two-point pairings, OPE coefficients, and Ward data, with the contact chart fixed by the source functional. For $u_R \neq 0$ in the stated source-functional neighborhood, the deformation by σ and ε is part of the constructed functional data: differentiating the limiting deformed functional $W_*(\eta; u_R)$ at fixed u_R gives the corresponding separated-point scaling functions with the relevant coordinates held fixed. The last sentence lists parameters removed either by tuning, by field normalization, or by restriction to separated points; the preceding argument never identifies them with CFT data.

The same separation applies to observables. Let A^X_{spin} be a microscopic odd lattice observable and A^X_{eng} a microscopic even energy-density observable with identity part subtracted. Their scaling-field expansions have the form

$$A^X_{\mathrm{spin}} = b^X_\sigma a^{\Delta_\sigma}\sigma + \sum_J b^X_J a^{\Delta_J} O_J, \qquad A^X_{\mathrm{eng}} = b^X_\varepsilon a^{\Delta_\varepsilon}\varepsilon + \sum_K c^X_K a^{\Delta_K} O_K,$$

where the sums contain fields with larger scaling dimensions in the same symmetry sector, and $b^X_\sigma, b^X_\varepsilon$ are nonzero for the chosen observables.

Assume now, in addition to the coordinate hypotheses above, that the renormalized separated-point lattice correlators for the selected observables have scaling limits as distributions and that the coordinate-to-correlator map is continuous at the limiting graph $v = V_{\mu_R}(u_R)$. For separated continuum points x_i, the normalized lattice correlators then have the common limit

$$\lim_{a\to 0}\prod_i \left((b^X_i)^{-1}a^{-\Delta_i}\right)\left\langle \prod_i A^X_i([x_i/a])\right\rangle_{X,a,p_X(a,u_R)} = \left\langle \prod_i O_i(x_i)\right\rangle_{u_R},$$

with the same limiting continuum correlator for all X satisfying the coordinate hypotheses and the additional scaling-limit hypotheses. The constants b^X_i, the critical temperature $T_{c,X}$, and finite-cutoff corrections are microscopic. The dimensions, RG eigenvalues, and normalized continuum correlators are fixed-point data once the continuum limit has been constructed.

If the coordinate-to-correlator map is differentiable in the retained irrelevant coordinates, the same estimate gives the standard correction structure with all symbols fixed. Let

$$G^X_a(x_1, \ldots, x_n)$$

denote a normalized separated-point lattice correlator after solving the relevant endpoint equation for u_R. In the finite chart,

$$G^X_a = G_{u_R} + \sum_\rho \left(v^\rho_X(\mu_R; \Lambda_0) - V^\rho_{\mu_R}(u_R)\right) \left.\frac{\partial G}{\partial v^\rho}\right|_{v=V_{\mu_R}(u_R)} + \cdots .$$

For bounded microscopic irrelevant coordinates this gives

$$G^X_a(x_1, \ldots, x_n) = G_{u_R}(x_1, \ldots, x_n) + O((\mu_R a)^\kappa), \qquad a = \Lambda_0^{-1}.$$

When the generated-integral convergence is faster than the leading irrelevant correction, the smallest irrelevant exponent in the symmetry sector gives the leading correction-to-scaling exponent. The amplitudes multiplying these corrections depend on X; the exponents and the limiting correlator do not, under the hypotheses stated above.

39.1 Scaling Limits and Finite-Cutoff Effective Theories

This chapter separates two constructions that are often conflated. A lattice or many-body system may have a critical scaling limit which is a continuum QFT, or it may have only a finite-cutoff long-distance effective description. The first case can produce a UV-complete relativistic theory. The second case is an effective theory whose validity is tied to the microscopic cutoff and to a specified range of observables.

Definition 39.1 (Critical scaling limit)**.** Let $a > 0$ be a lattice spacing, let $\mu_{a,\kappa}$ be a finite- or infinite-volume Euclidean lattice probability measure with couplings κ, and let $\mathcal{O}_{a,i}(x)$ be lattice observables. A critical scaling limit consists of:

1. a tuning $\kappa(a)$ for which the correlation length in lattice units diverges;
2. normalization factors $Z_i(a)$ and continuum coordinates $x = an$;

3. limits of separated Euclidean correlators

$$\lim_{a\downarrow 0}\left\langle \prod_{j=1}^{k} Z_{i_j}(a)\mathcal{O}_{a,i_j}(n_j)\right\rangle_{\mu_{a,\kappa(a)}};$$

4. Euclidean covariance, locality, reflection positivity, clustering, and regularity estimates sufficient for OS or another stated reconstruction theorem.

When these data are supplied, the limiting continuum QFT is the scaling-limit object constructed from the lattice system.

Definition 39.2 (Finite-cutoff effective theory)**.** A finite-cutoff effective theory is a tuple

$$(\Lambda_{\mathrm{UV}}, \mathcal{A}_\Lambda, S_\Lambda, \mathcal{O}_\Lambda, \mathcal{R}, E_{\max})$$

where Λ_{UV} is a physical ultraviolet scale, $\mathcal{A}_\Lambda$ is the algebra or field-variable space retained below that scale, S_Λ is the regulated action or Hamiltonian, $\mathcal{O}_\Lambda$ is the declared operator-insertion prescription, $\mathcal{R}$ is the set of observables to be matched, and $E_{\max} \ll \Lambda_{\mathrm{UV}}$ is the energy or momentum domain in which the error estimate is claimed. It is a QFT technique only after the regulator, matching observables, and error class have been stated.

The two definitions have different logical content. A critical scaling limit aims to remove the microscopic cutoff. A finite-cutoff effective theory keeps the cutoff as part of its meaning, even when its formulas resemble a relativistic continuum Lagrangian.

Remark 39.3 (Scaling limit as continuum QFT). Suppose the limits in Definition 39.1 exist for a set of local lattice observables closed under the operator products needed to generate the limiting Schwinger functions, and suppose the limiting Schwinger functions satisfy the OS hypotheses with Euclidean covariance. Then the reconstructed theory is a continuum local QFT. If the limiting Euclidean group enhances to the full Euclidean rotation group and the OS linear-growth hypothesis needed for continuation is verified, the Lorentzian reconstruction is a Poincare-covariant Wightman theory.

The OS reconstruction theorem applies to the limiting Schwinger functions, not to the finite lattice variables themselves. Reflection positivity gives a positive Hilbert-space inner product after quotienting null vectors; Euclidean time translations give a positive Hamiltonian; Euclidean covariance and the required analytic-growth bound give the Lorentzian representation of the Poincare group; and locality follows from Euclidean symmetry and the OS permutation/reflection structure after analytic continuation. The microscopic lattice remains a regulator for the construction, while the Hilbert space, fields, and correlation functions are those of the limiting object.

Thus the two-dimensional Ising scaling limit and, conjecturally, the three-dimensional Ising critical point belong to the first category. Away from criticality, a gapped lattice system may still be described at long distances by a continuum effective action, but the continuum action is then a finite-cutoff description of selected observables, not a removed-cutoff definition of a Poincare-invariant QFT.

39.2 What Must Be Revalidated

Let $\mathcal{T}_{\rm rel}$ be a theorem whose proof in earlier volumes used Poincare covariance, the spectral condition, local commutativity, and the existence of asymptotic particle states. Applying the same theorem to a condensed-matter EFT with microscopic cutoff a^{-1} requires a replacement proof or a matching argument.

Definition 39.4 (Validation map for borrowed QFT technology)**.** A validation map from a relativistic theorem or construction $\mathcal{T}_{\rm rel}$ to a finite-cutoff effective theory consists of:

1. the precise hypotheses $H_1, \dots, H_n$ used in the relativistic proof;
2. finite-cutoff replacements H_i^Λ or a proof that H_i is emergent with a stated error bound;
3. the observable class $\mathcal{R}$ on which the conclusion is claimed;
4. an estimate comparing the microscopic observable and the effective observable in that class;
5. a statement of which parts of the relativistic conclusion are retained, modified, or unavailable.

The following table records typical outcomes.

Relativistic tool	Finite-cutoff status
Wilsonian integration	Available after the cutoff, fields, and blocking map are stated.
Power counting	Available with the correct dynamical exponent and symmetries.
OS/Wightman analyticity	Requires an independent Euclidean-to-real-time argument.
LSZ scattering	Requires stable quasiparticles and an asymptotic dynamics.
Spin-statistics and CPT	Do not transfer without Lorentz/locality hypotheses.
Wedge modular flow	Requires a relativistic wedge or a replacement modular theorem.
Anomaly matching	Transfers only for the specified symmetry and regulator response.

The entries are not restrictions on using effective field theory. They are the data needed to know what the calculation proves.

39.3 Examples

39.3.1 Fermi Liquid

A Fermi liquid is organized around a codimension-one Fermi surface Σ_F in momentum space, not around the Lorentz-invariant point $p_\mu p^\mu = m^2$. A local patch with outward normal $\hat{n}$ has linearized dispersion

$$\epsilon(k_F\hat{n} + \ell\hat{n} + q_\parallel) = v_F\ell + O(\ell^2, q_\parallel^2),$$

where $q_\parallel$ is tangent to Σ_F. The scaling that keeps the kinetic term fixed scales ℓ and frequency differently from tangential momenta. Hence relativistic spin-statistics, crossing, and LSZ are not the primitive logic. The primitive data are the microscopic Hamiltonian, the Fermi surface, quasiparticle lifetime estimates, Landau parameters, and the range of frequencies and momenta for which quasiparticles are sharp.

39.3.2 Lifshitz Fixed Points

A Lifshitz scalar with dynamical exponent z has a quadratic action of the form

$$S = \frac{1}{2}\int \mathrm{d}\tau\,\mathrm{d}^d x\,\left[(\partial_\tau\phi)^2 + \kappa^2(\Delta^{z/2}\phi)^2\right]$$

when z is even, with the obvious Fourier-symbol replacement for general integer z. The scaling is

$$x \mapsto bx, \qquad \tau \mapsto b^z\tau.$$

Power counting is meaningful, but it is not relativistic power counting. If a Lorentz-invariant relativistic action appears in the infrared, the Lorentz-violating operators must be shown to be irrelevant or tuned small in the stated scaling regime.

39.3.3 Quantum Hall Effective Theory

The integer or fractional quantum Hall response at long distances may be encoded by a Chern–Simons effective action

$$S_{\mathrm{CS}}[a, A] = \frac{K_{IJ}}{4\pi}\int a^I \mathrm{d}a^J + \frac{q_I}{2\pi}\int A\mathrm{d}a^I + \cdots .$$

This is a topological response theory for a gapped many-body phase with a microscopic non-relativistic Hamiltonian and background electromagnetic field. Its gauge invariance, boundary anomaly, and line-operator data are real low-energy statements, but they do not imply a local Poincare-invariant UV completion. The correct validation map matches ground-state response, edge anomaly, quasiparticle braiding, and finite-size gaps, not an asymptotic-particle S-matrix.

39.4 Controlled Use of Emergent Relativistic Language

Controlled Approximation 39.5 (Emergent relativistic EFT)**.** Let a microscopic system with cutoff Λ_{UV} have low-energy observables $\mathcal{R}$. A relativistic EFT with action S_{rel} is a controlled emergent description on $\mathcal{R}$ if there exists a matching map M_Λ and constants $C, \Delta > 0$ such that for every observable $O \in \mathcal{R}$ with characteristic scale $E \le E_{\max}$,

$$|\langle O\rangle_{\mathrm{micro}} - \langle M_\Lambda O\rangle_{S_{\mathrm{rel}}}| \le C_O\left(\frac{E}{\Lambda_{\mathrm{UV}}}\right)^{\Delta}$$

after the stated renormalizations. The exponent Δ is the smallest scaling dimension gap between retained operators and omitted symmetry-allowed Lorentz-violating operators in the chosen RG chart.

This formulation is deliberately observable-based. It does not require that the microscopic system possess a Lorentzian spacetime symmetry. It requires only that the selected observables are approximated by a relativistic continuum theory with a quantitative error bound. In contrast, a critical scaling limit satisfying Remark 39.3 constructs the continuum QFT as its limiting object.

Open Problem 39.6 (Validated condensed-matter EFT atlas). For each major class of condensed-matter effective theory, construct an atlas of validation maps in the sense of Definition 39.4: Fermi liquids, non-Fermi liquids, superconductors, deconfined critical points, fractional quantum Hall states, spin liquids, fracton phases, and systems with emergent gauge fields. The goal is not to force these systems into Poincare-invariant axioms, but to state exactly which QFT techniques are justified for which observables.

Part IV

Gauge Theory, Infrared Structure, and Anomalies

Chapter 40

Spinor Fields, Fermionic Statistics, and Grassmann Path Integrals

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

40.1 The Free Dirac Field

Definition 40.1 (Spinor convention and massive intertwiners)**.** Work in $D = 4$ with

$$\eta_{\mu\nu} = \mathrm{diag}(-,+,+,+), \qquad \{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}.$$

The convention is the one fixed globally in Section 40.16. In particular, the Dirac adjoint, chirality matrix, Majorana conjugation, and later anomaly traces are not independent sign choices. Set

$$\partial\!\!\!/ = \gamma^\mu \partial_\mu, \qquad p\!\!\!/ = p_\mu \gamma^\mu, \qquad \beta = \mathrm{i}\gamma^0.$$

For a spinor s, its Dirac adjoint is

$$\bar{s} = s^\dagger \beta.$$

Let $u^\sigma(p)$ and $v^\sigma(p)$, $\sigma = 1, 2$, be the spinor intertwiners on the positive-energy mass shell Σ_m^+ constructed in Chapter 20:

$$(p\!\!\!/ - \mathrm{i}m)u^\sigma(p) = 0, \qquad (p\!\!\!/ + \mathrm{i}m)v^\sigma(p) = 0.$$

The delta-normalized spinors used below inherit the normalization

$$\bar{u}^\sigma(p)u^\tau(p) = \frac{m}{\omega_{\vec{p}}}\delta^{\sigma\tau}, \qquad \bar{v}^\sigma(p)v^\tau(p) = -\frac{m}{\omega_{\vec{p}}}\delta^{\sigma\tau}, \qquad \bar{u}^\sigma(p)v^\tau(p) = 0,$$

where $\bar{u} = u^\dagger\beta$, $\bar{v} = v^\dagger\beta$, and $p^0 = \omega_{\vec{p}}$ on Σ_m^+. The corresponding individual completeness relations are

$$\sum_{\sigma=1}^{2} u_\alpha^\sigma(p)\bar{u}^{\sigma,\beta}(p) = \frac{(m - \mathrm{i}\, \not{p})_\alpha{}^\beta}{2\omega_{\vec{p}}}, \qquad \sum_{\sigma=1}^{2} v_\alpha^\sigma(p)\bar{v}^{\sigma,\beta}(p) = -\frac{(m + \mathrm{i}\, \not{p})_\alpha{}^\beta}{2\omega_{\vec{p}}}. \tag{40.1}$$

At the reference momentum $p_R = (m, \vec{0})$, $\not{p}_R = \mathrm{i}m\beta$, so

$$\sum_\sigma u^\sigma(p_R)\bar{u}^\sigma(p_R) = \frac{1+\beta}{2}, \qquad \sum_\sigma v^\sigma(p_R)\bar{v}^\sigma(p_R) = -\frac{1-\beta}{2}.$$

These rest-frame matrices obey

$$(\not{p}_R - \mathrm{i}m)\frac{1+\beta}{2} = 0, \qquad (\not{p}_R + \mathrm{i}m)\left[-\frac{1-\beta}{2}\right] = 0,$$

and have traces 2 and -2, reproducing the summed Dirac-adjoint normalizations at $p^0 = m$. Lorentz covariance of the intertwiners transports the identities to all $p \in \Sigma_m^+$. Let

$$\mathrm{d}\mu_m(p) = \frac{\mathrm{d}^3\vec{p}}{(2\pi)^3\, 2\omega_{\vec{p}}}, \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^2 + m^2}, \qquad p^0 = \omega_{\vec{p}}.$$

Definition 40.2 (Free charged Dirac field and CAR)**.** Introduce two independent families of fermionic creation and annihilation operators

$$b_\sigma(\vec{p}),\ b_\sigma^\dagger(\vec{p}), \qquad d_\sigma(\vec{p}),\ d_\sigma^\dagger(\vec{p}),$$

with canonical anticommutation relations

$$\{b_\sigma(\vec{p}), b_\tau^\dagger(\vec{q})\} = (2\pi)^3\, 2\omega_{\vec{p}}\, \delta_{\sigma\tau}\delta^{(3)}(\vec{p} - \vec{q}),$$

$$\{d_\sigma(\vec{p}), d_\tau^\dagger(\vec{q})\} = (2\pi)^3\, 2\omega_{\vec{p}}\, \delta_{\sigma\tau}\delta^{(3)}(\vec{p} - \vec{q}),$$

all other anticommutators being zero. The vacuum vector Ω is annihilated by all $b_\sigma(\vec{p})$ and $d_\sigma(\vec{p})$.

The charged Dirac field is the operator-valued distribution

$$\widehat{\psi}_\alpha(x) = \sum_{\sigma=1}^{2}\int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\ \left[v_\alpha^\sigma(p)b_\sigma^\dagger(\vec{p})\mathrm{e}^{-\mathrm{i}p\cdot x} + u_\alpha^\sigma(p)d_\sigma(\vec{p})\mathrm{e}^{\mathrm{i}p\cdot x}\right].$$

Its adjoint field is

$$\widehat{\bar{\psi}}^\alpha(x) = \left(\widehat{\psi}^\dagger(x)\beta\right)^\alpha.$$

The field equation and charge convention are immediate consequences of the chosen momentum-space intertwiners and oscillator charges. Because of the two momentum-space Dirac equations above,

$$(\not{\partial} + m)\widehat{\psi}(x) = 0, \qquad \widehat{\bar{\psi}}(x)(-\overleftarrow{\not{\partial}} + m) = 0,$$

where the arrow indicates that the derivative acts on the field to its left.

The convention in this chapter assigns charge $+1$ to the one-particle states created by $b^\dagger$ and charge -1 to the states created by $d^\dagger$. If

$$U_\theta = \mathrm{e}^{\mathrm{i}\theta\widehat{Q}}, \qquad U_\theta\Omega = \Omega,$$

then

$$U_\theta\widehat{\psi}_\alpha(x)U_\theta^{-1} = \mathrm{e}^{\mathrm{i}\theta}\widehat{\psi}_\alpha(x), \qquad U_\theta\widehat{\overline{\psi}}^{\alpha}(x)U_\theta^{-1} = \mathrm{e}^{-\mathrm{i}\theta}\widehat{\overline{\psi}}^{\alpha}(x).$$

For the creation part of $\widehat{\psi}$,

$$(\not{\partial} + m)\big(v^\sigma(p)\mathrm{e}^{-\mathrm{i}p\cdot x}\big) = (-\mathrm{i}\not{p} + m)v^\sigma(p)\mathrm{e}^{-\mathrm{i}p\cdot x} = 0,$$

because $(\not{p} + \mathrm{i}m)v^\sigma(p) = 0$. For the annihilation part,

$$(\not{\partial} + m)\big(u^\sigma(p)\mathrm{e}^{\mathrm{i}p\cdot x}\big) = (\mathrm{i}\not{p} + m)u^\sigma(p)\mathrm{e}^{\mathrm{i}p\cdot x} = 0,$$

because $(\not{p} - \mathrm{i}m)u^\sigma(p) = 0$. The adjoint equation follows by taking the Dirac adjoint and using $(\gamma^\mu)^\dagger\beta = -\beta\gamma^\mu$, with the derivative acting on the field to its left.

The charge convention is fixed on the oscillator algebra by

$$[\widehat{Q}, b_\sigma^\dagger(\vec{p})] = b_\sigma^\dagger(\vec{p}), \qquad [\widehat{Q}, d_\sigma^\dagger(\vec{p})] = -d_\sigma^\dagger(\vec{p}).$$

Taking adjoints gives

$$[\widehat{Q}, b_\sigma(\vec{p})] = -b_\sigma(\vec{p}), \qquad [\widehat{Q}, d_\sigma(\vec{p})] = d_\sigma(\vec{p}).$$

Both terms in $\widehat{\psi}$ therefore have charge $+1$, while $\widehat{\overline{\psi}}$ has charge -1. Exponentiating the commutators gives the displayed U_θ-transformation laws.

40.2 The Statistics Sign from Locality

Proposition 40.3 (Free spinor locality selects the CAR sign)**.** *Once the spin-$\frac{1}{2}$ one-particle representation and the covariant spinor intertwiners have been chosen, the local free field is obtained from canonical anticommutators rather than ordinary commutators. Use the delta-normalized polarizations $\mathcal{U}, \mathcal{V}$ of Chapter 20. Let*

$$\Delta_+(z; m^2) = \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, \mathrm{e}^{\mathrm{i}p\cdot z}$$

be the positive-frequency scalar distribution, and form the trial field

$$\widehat{\Phi}_\alpha(x) = \sum_{\sigma=1}^{2} \int \frac{d^3\vec{p}}{(2\pi)^{3/2}} \Big[\mathcal{V}_\alpha^\sigma(p)a_\sigma^\dagger(\vec{p})\mathrm{e}^{-\mathrm{i}p\cdot x} + \mathcal{U}_\alpha^\sigma(p)c_\sigma(\vec{p})\mathrm{e}^{\mathrm{i}p\cdot x}\Big].$$

Suppose first that the oscillator algebra used ordinary commutators,

$$[a_\sigma(\vec{p}), a_\tau^\dagger(\vec{q})] = [c_\sigma(\vec{p}), c_\tau^\dagger(\vec{q})] = \delta_{\sigma\tau}\delta^{(3)}(\vec{p} - \vec{q}),$$

with all other commutators zero. Using (40.1) gives

$$[\widehat{\Phi}_\alpha(x), \widehat{\overline{\Phi}}^\beta(y)] = \int \frac{d^3\vec{p}}{(2\pi)^3} \left[\mathrm{e}^{-\mathrm{i}p\cdot(x-y)} \frac{m + \mathrm{i}\not{p}}{2p^0} + \mathrm{e}^{\mathrm{i}p\cdot(x-y)} \frac{m - \mathrm{i}\not{p}}{2p^0} \right]_\alpha{}^\beta.$$

The scalar part contains

$$m\big(\Delta_+(x-y;m^2) + \Delta_+(y-x;m^2)\big),$$

which has nonzero spacelike values. For example, at equal times and $\vec{x} \neq \vec{y}$ it equals the distribution

$$2m \int \frac{d^3\vec{p}}{(2\pi)^3\, 2\omega_{\vec{p}}}\, \mathrm{e}^{\mathrm{i}\vec{p}\cdot(\vec{x}-\vec{y})}.$$

Thus the field obtained with the commutator sign is nonlocal.

If instead the oscillator algebra is the canonical anticommutator algebra, (40.1) gives

$$\{\widehat{\psi}_\alpha(x), \widehat{\overline{\psi}}^\beta(y)\} = (-\not{\partial}_x + m)_\alpha{}^\beta \left[\Delta_+(x-y;m^2) - \Delta_+(y-x;m^2)\right].$$

The bracket is the Pauli–Jordan distribution. It vanishes for spacelike separation, so the spinor field is local as an odd field in a graded local algebra. This computation is the free-field derivation of the statistics sign used in the rest of the chapter.

Proof. Only the oscillator pairings $aa^\dagger$ and $cc^\dagger$, or their CAR counterparts, contribute. Inserting the mode expansion and using the spin sums (40.1) gives the two displayed kernels. For ordinary commutators the scalar part is the even combination

$$m\big(\Delta_+(x-y;m^2) + \Delta_+(y-x;m^2)\big).$$

At equal time and $\vec{x} \neq \vec{y}$ this is the Fourier transform of the positive mass-shell density $(2\omega_{\vec{p}})^{-1} d^3\vec{p}$ plus its reflected copy. It is not the zero distribution; for example smearing by a nonzero real test function supported in an equal-time ball gives a strictly positive quadratic form. Thus ordinary commutators violate locality.

For CAR, the creation and annihilation contributions enter with the relative minus sign shown above, and the scalar factor is the Pauli–Jordan distribution

$$\Delta(x-y;m^2) = \Delta_+(x-y;m^2) - \Delta_+(y-x;m^2).$$

The scalar chapter proves that $\Delta(z;m^2)$ has support in the closed light cone. Applying the local differential operator $(-\not{\partial}_x + m)_\alpha{}^\beta$ cannot enlarge support, so the anticommutator vanishes at spacelike separation. This is precisely graded locality for an odd field. □

40.3 Locality and the CAR

With the same positive-frequency scalar distribution

$$\Delta_+(x;m^2) = \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, \mathrm{e}^{\mathrm{i}p\cdot x}.$$

With the spinor normalizations fixed by the one-particle inner product, the field anticommutator is

$$\{\widehat{\psi}_\alpha(x), \widehat{\overline{\psi}}^{\beta}(y)\} = (-\not{\partial}_x + m)_\alpha{}^\beta \left[\Delta_+(x-y;m^2) - \Delta_+(y-x;m^2)\right].$$

The bracketed distribution is the Pauli–Jordan distribution in the normalization convention already used for the scalar field. It vanishes at spacelike separation. Hence

$$\{\widehat{\psi}_\alpha(x), \widehat{\overline{\psi}}^{\beta}(y)\} = 0 \qquad \text{when } (x-y)^2 > 0.$$

The equal-time anticommutator is obtained by differentiating the Pauli–Jordan distribution:

$$\{\widehat{\psi}_\alpha(t,\vec{x}), \widehat{\overline{\psi}}^{\beta}(t,\vec{y})\} = \mathrm{i}(\gamma^0)_\alpha{}^\beta \delta^{(3)}(\vec{x}-\vec{y}),$$

and

$$\{\widehat{\psi}_\alpha(t,\vec{x}), \widehat{\psi}_\beta(t,\vec{y})\} = 0, \qquad \{\widehat{\overline{\psi}}^{\alpha}(t,\vec{x}), \widehat{\overline{\psi}}^{\beta}(t,\vec{y})\} = 0.$$

The local algebra is therefore a graded local algebra. If $|A| \in \{0,1\}$ is the fermion parity of a homogeneous operator A, the graded commutator is

$$[A,B]_{\mathrm{g}} = AB - (-1)^{|A||B|}BA.$$

Locality is the vanishing of this graded commutator for spacelike separated smeared fields. The Dirac field has parity 1, while bosonic local fields have parity 0.

Remark 40.4. The preceding computation is the free spin-$\frac{1}{2}$ instance of the spin-statistics connection. A theorem-level spin-statistics statement requires a specified Wightman framework: a common invariant dense domain for the smeared fields, a positive-energy unitary representation of the spin cover of the proper orthochronous Poincare group, covariance of the fields as operator-valued tempered distributions, locality on the common domain, positivity of the Hilbert-space inner product, and the stated adjoint compatibility between fields and their conjugates. Under those hypotheses, integer-spin fields have even local commutation and half-integer-spin fields have odd local anticommutation, except for fields that vanish in the physical Hilbert space. This chapter does not use that theorem as an input; the displayed anticommutator is the direct verification needed for the free Dirac field used below.

40.4 Dirac, Weyl, and Majorana Fields

Definition 40.5 (Dirac, Weyl, and Majorana local spinor data)**.** The Dirac field transforms in the spinor representation:

$$U(\Lambda)\widehat{\psi}_\alpha(x)U(\Lambda)^{-1} = R_\alpha{}^\beta(\Lambda)\widehat{\psi}_\beta(\Lambda x),$$

where

$$R(\Lambda) = \exp\left(-\frac{\mathrm{i}}{2}\omega_{\mu\nu}S^{\mu\nu}\right), \qquad S^{\mu\nu} = -\frac{\mathrm{i}}{4}[\gamma^\mu, \gamma^\nu],$$

for $\Lambda = \exp\omega$. The field $\widehat{\psi}$ has four complex components before additional Lorentz-covariant conditions are imposed.

Define

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3.$$

It obeys

$$\gamma_5^2 = 1, \qquad \{\gamma_5, \gamma^\mu\} = 0, \qquad [\gamma_5, S^{\mu\nu}] = 0.$$

Therefore

$$P_\pm = \frac{1 \pm \gamma_5}{2}$$

are Lorentz-covariant projectors. A Weyl spinor field is a Dirac spinor field subject to

$$\widehat{\chi}_\pm = P_\pm \widehat{\chi}_\pm.$$

In the explicit Clifford basis used in Chapter 20,

$$\gamma_5 = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix}, \qquad P_+ = \begin{pmatrix} I_2 & 0 \\ 0 & 0 \end{pmatrix}, \qquad P_- = \begin{pmatrix} 0 & 0 \\ 0 & I_2 \end{pmatrix}.$$

Thus a Weyl condition removes two of the four complex Dirac components while preserving Lorentz covariance. The two chiralities are inequivalent complex representations of $\mathrm{Spin}^+(1,3)$. The Dirac mass term couples them because γ^μ maps one chirality to the other.

A Majorana condition is a Lorentz-covariant reality condition. Suppose a matrix B is chosen so that

$$(\gamma^\mu)^* = B\gamma^\mu B^{-1}, \qquad B^{-1}(B^{-1})^* = 1.$$

Here $*$ denotes the antilinear operation on spinor components, combined with componentwise adjunction when it is applied to operator-valued spinor fields. In the displayed gamma basis one may take $B = \gamma_2$. Since $\sigma_2^* = -\sigma_2$, this choice obeys the two identities above. Then

$$\widehat{\psi}^c = B^{-1}\widehat{\psi}^*$$

transforms in the same Lorentz representation as $\widehat{\psi}$. A Majorana field satisfies

$$\widehat{\xi} = \widehat{\xi}^c.$$

Lorentz covariance of chiral and Majorana reductions. The projectors $P_\pm = (1 \pm \gamma_5)/2$ define Lorentz-covariant Weyl subfields. If B obeys the two identities in Definition 40.5, then charge conjugation $\psi \mapsto \psi^c = B^{-1}\psi^*$ is Lorentz covariant and involutive. In four dimensions a Weyl field $\widehat{\chi}_+$ determines a Majorana field

$$\widehat{\xi} = \widehat{\chi}_+ + B^*\widehat{\chi}_+^*,$$

whose P_+-projection is $\widehat{\chi}_+$. The commutator $[\gamma_5, S^{\mu\nu}] = 0$ implies $[P_\pm, R(\Lambda)] = 0$ for the connected spin group, hence the Weyl conditions $P_\pm\chi_\pm = \chi_\pm$ are preserved by Lorentz transformations. The charge-conjugation covariance check is direct:

$$\begin{aligned} U(\Lambda)\widehat{\psi}^c(x)U(\Lambda)^{-1} &= B^{-1}\left(R(\Lambda)\widehat{\psi}(\Lambda x)\right)^* \\ &= B^{-1}BR(\Lambda)B^{-1}\widehat{\psi}^*(\Lambda x) = R(\Lambda)\widehat{\psi}^c(\Lambda x). \end{aligned}$$

The second identity for B gives $(\psi^c)^c = \psi$, so the Majorana condition is a genuine reality condition on the complex Dirac module. If $\widehat{\chi}_+ = P_+\widehat{\chi}_+$ is a Weyl field, then

$$\widehat{\xi} = \widehat{\chi}_+ + B^*\widehat{\chi}_+^*$$

is Majorana, and

$$P_+\widehat{\xi} = \widehat{\chi}_+.$$

Indeed $P_+B^* = B^*P_-^*$, so

$$P_+B^*\widehat{\chi}_+^* = B^*P_-^*\widehat{\chi}_+^* = B^*(P_-\widehat{\chi}_+)^* = 0.$$

Moreover $B^*\widehat{\chi}_+^*$ is anti-chiral:

$$\gamma_5 B^*\widehat{\chi}_+^* = -B^*\gamma_5^*\widehat{\chi}_+^* = -B^*\widehat{\chi}_+^*.$$

Thus in four dimensions a Majorana spinor is equivalent, as Lorentz representation data, to one Weyl spinor together with its conjugate. These are statements about local field representations. Particle content is determined separately by the spectral and asymptotic data of the theory.

40.5 Odd Field Variables and Configuration Superspaces

Definition 40.6 (Finite fermionic configuration superspace)**.** There are two distinct meanings of the word "fermionic field" in this chapter. The operator field $\widehat{\psi}_\alpha(x)$ is an operator-valued distribution on a $\mathbb{Z}_2$-graded Hilbert space. After smearing by test functions, it gives conventional linear operators on a common dense domain, with parity 1. Its locality property is the vanishing of the graded commutator at spacelike separation. This is a statement about the local operator algebra.

The variables $\psi_\alpha(x)$, $\bar{\psi}^\alpha(x)$ appearing in a fermionic path integral are different objects. In a finite-dimensional regularization they are odd coordinates on a supermanifold. Let V be a finite-dimensional complex vector space carrying the cutoff spinor labels, including spacetime lattice points, spinor indices, and any internal indices. The purely odd affine superspace with those labels is ΠV. As a locally super-ringed space it is

$$\Pi V = \big(\{*\}, \mathcal{O}_{\Pi V}\big), \qquad \mathcal{O}_{\Pi V} = \Lambda(V^\vee),$$

where $V^\vee$ is placed in odd degree. Equivalently, for every supercommutative test algebra $R = R_{\bar{0}} \oplus R_{\bar{1}}$, its R-points are

$$(\Pi V)(R) = R_{\bar{1}} \otimes_{\mathbb{C}} V.$$

Thus a Grassmann field variable is an odd coordinate in the structure sheaf, or equivalently an $R_{\bar{1}}$-valued component in the functor-of-points description. It is not an ordinary function on spacetime and it is not a point of an underlying set of configurations. For independent Dirac variables the finite-dimensional configuration superspace is

$$\Pi(V_\psi \oplus V_{\bar{\psi}}), \qquad \mathcal{O} = \Lambda(V_\psi^\vee \oplus V_{\bar{\psi}}^\vee),$$

with ψ and $\bar{\psi}$ treated as independent odd coordinates until a real or adjoint structure is imposed by the operator theory.

If bosonic cutoff fields are present, their configuration space is an ordinary affine or smooth space B. Fermionic directions are then encoded by an odd vector bundle $E \to B$, and the corresponding configuration supermanifold is the locally super-ringed space

$$\big(B, \mathcal{O}_B \otimes \Lambda(E^\vee)\big)$$

in a local trivialization. This description is the finite-dimensional geometric meaning of the formal phrase "integration over fermionic fields."

Purely odd Berezinian transformation. Berezin integration is the associated algebraic integration on the Berezinian line. For a purely odd coordinate system $(\eta_1, \ldots, \eta_N)$, choosing the ordered Berezinian element $\mathrm{d}\eta_N \cdots \mathrm{d}\eta_1$ defines the linear functional which extracts the coefficient of $\eta_1 \cdots \eta_N$. Under a change of odd coordinates $\eta' = A\eta$, this ordered Berezinian transforms as

$$\mathrm{d}\eta'_N \cdots \mathrm{d}\eta'_1 = (\det A)^{-1} \mathrm{d}\eta_N \cdots \mathrm{d}\eta_1.$$

This inverse determinant is the odd part of the Berezinian transformation law. The operative object is the coordinate-independent algebraic functional on Berezinian densities; positivity and countable additivity belong to Borel integration and play no role in this odd integration operation. The continuum symbol

$$\int [\mathrm{d}\bar{\psi}\, \mathrm{d}\psi]\ (\cdots)$$

used below denotes a compatible family of such finite-dimensional Berezin integrals after a regulator has supplied finitely many odd coordinates. All determinants, Pfaffians, source contractions, and fermionic signs in the formal continuum notation are inherited from these finite-dimensional Berezinian operations.

The ordered integral with density $\mathrm{d}\eta_N \cdots \mathrm{d}\eta_1$ extracts the coefficient of the ordered monomial $\eta_1 \cdots \eta_N$. If $\eta'_a = A_a{}^b \eta_b$, then antisymmetry of the odd coordinates gives

$$\eta'_1 \cdots \eta'_N = (\det A) \eta_1 \cdots \eta_N.$$

For the coefficient extracted from $f(\eta)\mathrm{d}\eta_N \cdots \mathrm{d}\eta_1$ to be coordinate independent, the ordered Berezinian element must transform by the inverse factor:

$$\mathrm{d}\eta'_N \cdots \mathrm{d}\eta'_1 = (\det A)^{-1} \mathrm{d}\eta_N \cdots \mathrm{d}\eta_1.$$

This is the odd part of the Berezinian. The construction uses only the finite-dimensional exterior algebra and its top coefficient. No underlying set of odd values, sigma-algebra, or positivity structure enters.

40.6 Classical Grassmann Mechanics and Dirac Brackets

Definition 40.7 (Finite odd first-order mechanical datum)**.** The finite-dimensional model underlying fermion path integrals is specified by its coordinate superalgebra. Let η_α, $\alpha = 1, \ldots, N$, be odd generators of a Grassmann algebra,

$$\eta_\alpha \eta_\beta = -\eta_\beta \eta_\alpha, \qquad \eta_\alpha^2 = 0.$$

Functions of the formal coordinates are elements of this algebra. Consider the first-order action

$$S[\eta] = \int \mathrm{d}t\, M_{\alpha\beta}\eta_\alpha\dot{\eta}_\beta, \qquad M_{\alpha\beta} = M_{\beta\alpha},$$

where M is nondegenerate. The symmetry of M is compatible with the odd nature of the coordinates because integration by parts gives

$$-\int \mathrm{d}t\, M_{\alpha\beta}\dot{\eta}_\alpha\eta_\beta = \int \mathrm{d}t\, M_{\alpha\beta}\eta_\beta\dot{\eta}_\alpha.$$

Using the right derivative with respect to $\dot{\eta}_\alpha$, the canonical momenta are

$$\pi_\alpha = L\frac{\overleftarrow{\partial}}{\partial\dot{\eta}_\alpha} = M_{\alpha\beta}\eta_\beta.$$

Thus the phase-space variables obey primary constraints

$$\chi_\alpha = \pi_\alpha - M_{\alpha\beta}\eta_\beta = 0.$$

For odd canonical variables use the graded Poisson brackets

$$\{\eta_\alpha, \eta_\beta\}_{\mathrm{P}} = 0, \qquad \{\pi_\alpha, \pi_\beta\}_{\mathrm{P}} = 0, \qquad \{\eta_\alpha, \pi_\beta\}_{\mathrm{P}} = \{\pi_\beta, \eta_\alpha\}_{\mathrm{P}} = \delta_{\alpha\beta}.$$

Odd second-class constraints and Dirac brackets. For the datum of Definition 40.7, the constraints $\chi_\alpha = \pi_\alpha - M_{\alpha\beta}\eta_\beta$ are second class with constraint matrix

$$K_{\alpha\beta} = \{\chi_\alpha, \chi_\beta\}_{\mathrm{P}} = -2M_{\alpha\beta},$$

and the Dirac bracket

$$\{f, g\}_{\mathrm{D}} = \{f, g\}_{\mathrm{P}} - \{f, \chi_\alpha\}_{\mathrm{P}}(K^{-1})^{\alpha\beta}\{\chi_\beta, g\}_{\mathrm{P}}.$$

annihilates the constraints:

$$\{f, \chi_\alpha\}_{\mathrm{D}} = 0.$$

For the odd coordinates,

$$\begin{aligned}\{\eta_\alpha, \eta_\beta\}_{\mathrm{D}} &= -(K^{-1})_{\alpha\beta} = \frac{1}{2}(M^{-1})_{\alpha\beta},\\ \{\eta_\alpha, \pi_\beta\}_{\mathrm{D}} &= \frac{1}{2}\delta_{\alpha\beta}.\end{aligned}$$

In the $N = 2$ model below, quantization gives a two-state Hilbert space with Hamiltonian eigenvalues $-\omega/4$ and $+\omega/4$.

Using the graded Poisson brackets in the definition,

$$\begin{aligned}\{\chi_\alpha, \chi_\beta\}_{\mathrm{P}} &= \{\pi_\alpha - M_{\alpha\gamma}\eta_\gamma, \pi_\beta - M_{\beta\delta}\eta_\delta\}_{\mathrm{P}}\\ &= -M_{\beta\alpha} - M_{\alpha\beta} = -2M_{\alpha\beta},\end{aligned}$$

because $M_{\alpha\beta} = M_{\beta\alpha}$. Nondegeneracy of M makes K invertible, hence the constraints are second class. The displayed Dirac bracket is the usual Schur-complement correction of the graded Poisson bracket by the inverse constraint matrix. Substituting one argument χ_α gives zero because $\{\chi_\rho, \chi_\alpha\}_{\mathrm{P}} = K_{\rho\alpha}$. For the coordinates, $\{\eta_\alpha, \chi_\rho\}_{\mathrm{P}} = \delta_{\alpha\rho}$, so

$$\{\eta_\alpha, \eta_\beta\}_{\mathrm{D}} = -\delta_{\alpha\rho}(K^{-1})^{\rho\sigma}\delta_{\sigma\beta} = \frac{1}{2}(M^{-1})_{\alpha\beta}.$$

The same substitution gives $\{\eta_\alpha, \pi_\beta\}_{\mathrm{D}} = \delta_{\alpha\beta}/2$.

For $N = 2$, take

$$S = \int \mathrm{d}t\, \mathrm{i}(\eta_1\dot\eta_1 + \eta_2\dot\eta_2).$$

Equivalently, with

$$\eta = \eta_1 + \mathrm{i}\eta_2, \qquad \chi = \eta_1 - \mathrm{i}\eta_2,$$

the difference between $\int \mathrm{d}t\, \mathrm{i}(\eta_1\dot\eta_1 + \eta_2\dot\eta_2)$ and $\int \mathrm{d}t\, \mathrm{i}\chi\dot\eta$ is a total derivative. The endpoint convention fixes which representative of the first-order action is used. The Dirac brackets are

$$\{\eta, \chi\}_{\mathrm{D}} = -\mathrm{i}, \qquad \{\eta, \eta\}_{\mathrm{D}} = 0 = \{\chi, \chi\}_{\mathrm{D}}.$$

Quantization replaces η_α by operators satisfying

$$\{\widehat\eta_\alpha, \widehat\eta_\beta\} = \frac{\mathrm{i}\hbar}{2}(M^{-1})_{\alpha\beta}.$$

In units $\hbar = 1$, the oscillator with

$$L = \mathrm{i}\eta_1\dot\eta_1 + \mathrm{i}\eta_2\dot\eta_2 - \mathrm{i}\omega\eta_1\eta_2$$

has Hamiltonian $H = \mathrm{i}\omega\eta_1\eta_2$. A minimal representation is

$$\widehat\eta_1 = \frac{1}{2}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \widehat\eta_2 = \frac{1}{2}\begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix},$$

so that

$$\widehat H = \mathrm{i}\omega\widehat\eta_1\widehat\eta_2 = \begin{pmatrix} -\omega/4 & 0 \\ 0 & \omega/4 \end{pmatrix}.$$

The finite Grassmann system therefore quantizes to a two-state Hilbert space.

40.7 Berezin Calculus

Convention 40.8 (Berezin normalization and ordering)**.** For one odd coordinate θ, the Berezin integral is normalized by

$$\int \mathrm{d}\theta\, 1 = 0, \qquad \int \mathrm{d}\theta\, \theta = 1.$$

For ordered odd coordinates $(\theta_1, \ldots, \theta_N)$, the ordered Berezinian density $\mathrm{d}\theta_N \cdots \mathrm{d}\theta_1$ is normalized by

$$\int \mathrm{d}\theta_N \cdots \mathrm{d}\theta_1\, \theta_1\theta_2 \cdots \theta_N = 1.$$

All signs below, including the sign of a closed fermion loop and the determinant obtained from a fermionic Gaussian, use this ordering together with the Koszul rule for moving odd variables and odd differentials past one another.

Definition 40.9 (Finite Grassmann algebra and Berezin derivative)**.** Let Λ_N be the complex Grassmann algebra generated by

$$\eta_1, \ldots, \eta_N$$

with relations

$$\eta_a\eta_b = -\eta_b\eta_a, \qquad \eta_a^2 = 0.$$

A homogeneous monomial has parity equal to its degree modulo 2. If X and Y are homogeneous, then

$$XY = (-1)^{|X||Y|}YX$$

when every generator appearing in X is distinct from every generator appearing in Y. Berezin differentials are treated as odd symbols, so

$$\eta_a\, \mathrm{d}\eta_b = -\mathrm{d}\eta_b\, \eta_a.$$

The left derivative $\partial^L/\partial\eta_a$ is defined by

$$\frac{\partial^L}{\partial\eta_a}\eta_b = \delta_{ab}, \qquad \frac{\partial^L}{\partial\eta_a}(XY) = \frac{\partial^L X}{\partial\eta_a}Y + (-1)^{|X|}X\frac{\partial^L Y}{\partial\eta_a}$$

for homogeneous X. Berezin integration is the same algebraic operation, with the normalization of Convention 40.8:

$$\int \mathrm{d}\eta_a\, 1 = 0, \qquad \int \mathrm{d}\eta_a\, \eta_a = 1.$$

For N generators the ordered integral is fixed by

$$\int \mathrm{d}\eta_N \cdots \mathrm{d}\eta_1\, \eta_1\eta_2\cdots\eta_N = 1.$$

Lemma 40.10 (Finite Berezin Gaussian and contractions)**.** *For independent pairs $\eta_a, \bar\eta_a$, $a = 1, \dots, N$, and an invertible $N \times N$ complex matrix A, use the ordered measure*

$$[\mathrm{d}\bar\eta\, \mathrm{d}\eta] = \prod_{a=1}^{N} \mathrm{d}\bar\eta_a\, \mathrm{d}\eta_a.$$

With this convention,

$$\int [\mathrm{d}\bar\eta\, \mathrm{d}\eta]\, \exp\left(-\bar\eta_a A^a{}_b\eta_b\right) = \det A.$$

Adding Grassmann sources $J, \bar J$,

$$\begin{aligned}\int [\mathrm{d}\bar\eta\, \mathrm{d}\eta]\, &\exp\left(-\bar\eta_a A^a{}_b\eta_b + \bar J\eta + \bar\eta J\right) \\ &= \det A\, \exp\left(\bar J A^{-1} J\right).\end{aligned}$$

The normalized two-point contraction is

$$\langle \eta_a\bar\eta_b\rangle_A = (A^{-1})_a{}^b.$$

This identity follows from Berezin integration by parts. Since

$$0 = \int [\mathrm{d}\bar\eta\, \mathrm{d}\eta]\, \frac{\partial^L}{\partial\bar\eta_b}\left[\bar\eta_c \exp(-\bar\eta_a A^a{}_d\eta_d)\right],$$

the normalized integral obeys

$$\delta_c{}^b = A^b{}_d\langle \eta_d\bar\eta_c\rangle_A.$$

Higher Gaussian moments are obtained by repeated contractions, with the sign determined by the number of odd variables moved past one another to bring a contracted pair together.

Proof. The Gaussian identity is an identity in the finite exterior algebra generated by the $2N$ odd variables. The Berezin integral extracts one fixed top coefficient. The coefficient of the top monomial in $\exp(-\bar{\eta}_a A^a{}_b \eta_b)$ is multilinear and alternating in the columns of A, and the declared ordering normalizes the identity matrix case to 1. Hence the coefficient is $\det A$.

For the source identity, use the odd translation

$$\eta \mapsto \eta - A^{-1}J, \qquad \bar{\eta} \mapsto \bar{\eta} - \bar{J}A^{-1}.$$

Berezinian densities are invariant under translations, and the exponent becomes

$$-\bar{\eta}A\eta + \bar{J}A^{-1}J.$$

The source-free Gaussian integral then gives the factor $\det A \exp(\bar{J}A^{-1}J)$. Differentiating the source identity with the same left/right derivative convention gives $\langle \eta_a \bar{\eta}_b \rangle_A = (A^{-1})_a{}^b$. Equivalently, the integration-by-parts identity displayed above gives

$$\delta_c{}^b = A^b{}_d \langle \eta_d \bar{\eta}_c \rangle_A,$$

which is the same statement after multiplication by A^{-1}. Repeated differentiation gives Wick contractions, with Koszul signs determined by the permutation needed to place each contracted pair next to the source derivatives. □

40.8 The Fermionic Coherent-State Path Integral

The one-mode complex fermionic system has two operators

$$\hat{\eta}, \qquad \hat{\chi},$$

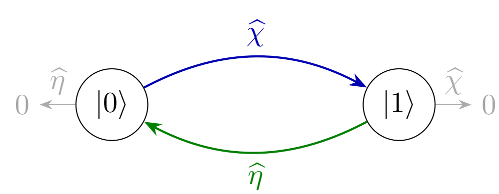
obeying

$$\{\hat{\eta}, \hat{\chi}\} = 1, \qquad \hat{\eta}^2 = \hat{\chi}^2 = 0.$$

On the two-dimensional Hilbert space with basis $|0\rangle, |1\rangle$, choose

$$\hat{\eta}|0\rangle = 0, \qquad \hat{\eta}|1\rangle = |0\rangle, \qquad \hat{\chi}|0\rangle = |1\rangle, \qquad \hat{\chi}|1\rangle = 0.$$

One-mode coherent-state resolution and time slicing.



For a Grassmann parameter η, define the right coherent ket

$$|\eta\rangle = |0\rangle + |1\rangle\eta,$$

so that

$$\widehat{\eta}|\eta\rangle = |\eta\rangle\eta.$$

Define the dual coherent bra by

$$\langle\!\langle\chi| = -\langle 1| + \chi\langle 0|.$$

It satisfies

$$\langle\!\langle\chi|\eta\rangle = \chi - \eta.$$

It also gives the left action

$$\langle\!\langle\chi|\widehat{\eta} = -\chi\,\langle\!\langle\chi|.$$

The resolution of the identity is

$$\int |\eta\rangle\,\mathrm{d}\eta\,\langle\!\langle\eta| = \mathbf{1}.$$

The sign in this formula is part of the ordered Berezin convention. Written with the differential moved to the left, it is

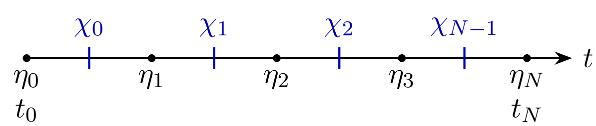
$$\begin{aligned}
\int |\eta\rangle\,\mathrm{d}\eta\,\langle\!\langle\eta| &= \int \mathrm{d}\eta\,|-\eta\rangle\,\langle\!\langle\eta| \\
&= \int \mathrm{d}\eta\,(-|1\rangle\eta + |0\rangle)(-\langle 1| + \eta\langle 0|) \\
&= |1\rangle\langle 1| + |0\rangle\langle 0|.
\end{aligned}$$

Let

$$U(T) = \mathrm{e}^{-\mathrm{i}\widehat{H}T}.$$

Insert the coherent-state resolution of identity at times

$$0 = t_0 < t_1 < \cdots < t_N = T, \qquad t_{n+1} - t_n = \varepsilon = T/N.$$



The one-step overlap identities are

$$\langle\!\langle\eta_{n+1}|\eta_n\rangle = -\int \mathrm{d}\chi_n\,\exp[-\chi_n(\eta_{n+1} - \eta_n)]\,,$$

and

$$\langle\!\langle\eta_{n+1}|\widehat{\chi}|\eta_n\rangle = -\int \mathrm{d}\chi_n\,\chi_n\,\exp[-\chi_n(\eta_{n+1} - \eta_n)]\,.$$

The endpoint convention fixes the signs in these formulas. With $\eta_0 = \eta_i$, $\eta_N = \eta_f$, and the ordered measure displayed below, the finite-N kernel is

$$\begin{aligned}
K_N(\eta_f, T; \eta_i, 0) = -\int \mathrm{d}\chi_0 \prod_{n=1}^{N-1} \mathrm{d}\eta_n\,\mathrm{d}\chi_n \\
\times \exp \sum_{n=0}^{N-1} \left[-\chi_n(\eta_{n+1} - \eta_n) - \mathrm{i}\varepsilon H(\chi_n, \eta_n)\right].
\end{aligned}$$

The kernel itself is the continuum limit of these regulated Berezin integrals,

$$\langle\!\langle \eta_f | U(T) | \eta_i \rangle = \lim_{N\to\infty} K_N(\eta_f, T; \eta_i, 0),$$

when that limit exists in the chosen topology. Equivalently, the global sign may be absorbed into the definition of the ordered finite-dimensional measure. The continuum notation for the same construction is

$$\int D\chi\, D\eta\, \exp\left\{ \int_0^T \mathrm{d}t\, \left[-\chi\dot{\eta} - \mathrm{i}H(\chi,\eta)\right] \right\}.$$

Equivalently, with the first-order action

$$S[\chi,\eta] = \int_0^T \mathrm{d}t\, \left[\mathrm{i}\chi\dot{\eta} - H(\chi,\eta)\right],$$

the continuum Grassmann path-integral notation assigns the weight $\mathrm{e}^{\mathrm{i}S}$ to the kernel. This expression denotes the limit, when it exists, of the finite time-sliced Berezin integrals displayed above; the time-sliced expression is the regulated meaning of the notation. In this first-order odd system the Hamiltonian and Lagrangian forms coincide: χ is the odd conjugate variable of η, and it remains in the first-order action rather than being removed by a nondegenerate even Gaussian integration.

The identities above are finite two-state Berezin calculations. The eigenket identity follows directly from the two-state action:

$$\widehat{\eta}(|0\rangle + |1\rangle\eta) = |0\rangle\eta = (|0\rangle + |1\rangle\eta)\eta,$$

because $\eta^2 = 0$. The dual coherent bra gives

$$\langle\!\langle \chi|\eta\rangle = (-\langle 1| + \chi\langle 0|)(|0\rangle + |1\rangle\eta) = \chi - \eta,$$

and

$$\langle\!\langle \chi|\widehat{\eta} = -\chi\langle\!\langle \chi|$$

by the same basis calculation. The displayed Berezin computation of $\int |\eta\rangle\, \mathrm{d}\eta\, \langle\!\langle \eta|$ extracts the coefficient of η and gives $|0\rangle\langle 0| + |1\rangle\langle 1|$. Inserting this identity between short-time evolution factors gives the finite-N kernel. The overlap identities follow by applying the same one-variable Berezin integral to $\langle\!\langle \eta_{n+1}|\eta_n\rangle$ and $\langle\!\langle \eta_{n+1}|\widehat{\chi}|\eta_n\rangle$.

40.9 Fermionic Traces and Thermal Boundary Conditions

Fermionic trace endpoint signs. The trace of a fermionic Hilbert-space operator carries one extra sign from the odd coherent-state resolution. For inverse temperature $\beta_{\mathrm{T}} > 0$,

$$\begin{aligned}
Z(\beta_{\mathrm{T}}) &= \mathrm{Tr}_{\mathcal{H}}\, \mathrm{e}^{-\beta_{\mathrm{T}}\widehat{H}} \\
&= \int \mathrm{Tr}_{\mathcal{H}} \left(|\eta\rangle\, \mathrm{d}\eta\, \langle\!\langle \eta|\, \mathrm{e}^{-\beta_{\mathrm{T}}\widehat{H}} \right) \\
&= \int \mathrm{d}\eta\, \langle\!\langle \eta|\mathrm{e}^{-\beta_{\mathrm{T}}\widehat{H}}|{-\eta}\rangle.
\end{aligned}$$

The state $|-\eta\rangle$ appears because moving the odd ket $|\eta\rangle = |0\rangle + |1\rangle\eta$ through the odd differential $\mathrm{d}\eta$ changes the sign of its odd component. After Euclidean time slicing this identity becomes the finite-dimensional Berezin integral with boundary condition

$$\eta(\tau + \beta_{\mathrm{T}}) = -\eta(\tau).$$

Thus ordinary thermal traces impose anti-periodic boundary conditions on fermionic variables. The supertrace

$$\mathrm{Tr}_{\mathcal{H}}\left((-1)^F \mathrm{e}^{-\beta_{\mathrm{T}}\widehat{H}}\right)$$

replaces the final $|-\eta\rangle$ by $|\eta\rangle$, and therefore imposes periodic fermionic boundary conditions. This distinction is the finite-dimensional origin of the spin-structure choice for fermionic fields on a Euclidean time circle.

For the trace sign, let A be the matrix

$$A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

in the ordered basis $|0\rangle, |1\rangle$. Then

$$\int \mathrm{d}\eta \, \langle\!\langle \eta | A | -\eta \rangle = a + d = \mathrm{Tr}\, A,$$

whereas

$$\int \mathrm{d}\eta \, \langle\!\langle \eta | A | \eta \rangle = a - d = \mathrm{Tr}((-1)^F A).$$

Thus an ordinary trace identifies the endpoint coherent variable with a minus sign, while the insertion of $(-1)^F$ removes that sign. Time slicing carries this endpoint algebra into anti-periodic and periodic Euclidean fermion boundary conditions, respectively.

40.10 Berezin Integration as Functorial Pushforward

Definition 40.11 (Finite Berezin pushforward)**.** Let V be a finite-dimensional complex vector space and let ΠV denote the purely odd affine superspace with structure sheaf $\Lambda(V^\vee)$. A basis $e_1, \ldots, e_N$ of V determines odd coordinates $\theta_1, \ldots, \theta_N$ and the ordered Berezinian density

$$[\mathrm{d}\theta] = \mathrm{d}\theta_N \cdots \mathrm{d}\theta_1.$$

The integral of $f(\theta)[\mathrm{d}\theta]$ is the coefficient of $\theta_1 \cdots \theta_N$ in f. If $\theta'_a = A_a{}^b \theta_b$, then

$$\theta'_1 \cdots \theta'_N = (\det A)\theta_1 \cdots \theta_N, \qquad [\mathrm{d}\theta'] = (\det A)^{-1}[\mathrm{d}\theta].$$

Thus the product $f(\theta)[\mathrm{d}\theta]$ is the coordinate-independent object, and Berezin integration is the linear functional on compactly supported algebraic Berezinian densities in this finite model.

For a direct sum $V \oplus W$, choose ordered coordinates θ on ΠV and η on ΠW, with total density

$$[\mathrm{d}\eta][\mathrm{d}\theta] = \mathrm{d}\eta_M \cdots \mathrm{d}\eta_1 \, \mathrm{d}\theta_N \cdots \mathrm{d}\theta_1.$$

The projection

$$p : \Pi(V \oplus W) \longrightarrow \Pi V$$

has a pushforward

$$p_! : \Gamma(\mathrm{Ber}_{\Pi(V\oplus W)}) \longrightarrow \Gamma(\mathrm{Ber}_{\Pi V})$$

defined by

$$p_!\big(F(\theta,\eta)[\mathrm{d}\eta][\mathrm{d}\theta]\big) = \left(\int \mathrm{d}\eta_M \cdots \mathrm{d}\eta_1 \, F(\theta,\eta)\right)[\mathrm{d}\theta].$$

This finite-dimensional pushforward is the prototype of a fermionic path integral: it is a fiberwise algebraic pushforward of Berezinian densities.

For

$$\Pi(V \oplus W \oplus U) \xrightarrow{q} \Pi(V \oplus W) \xrightarrow{p} \Pi V,$$

the equality

$$(p \circ q)_! = p_! \circ q_!$$

holds when the Berezinian orders are the induced product orders. Thus a finite regulator may integrate fermionic modes in stages without changing the value, provided the induced Berezinian order is carried along. Choose ordered odd coordinates θ on V, η on W, and ζ on U, with total Berezinian density $[\mathrm{d}\zeta][\mathrm{d}\eta][\mathrm{d}\theta]$. Applying $(p\circ q)_!$ extracts first the coefficient of $\zeta_1 \cdots \zeta_{\dim U}\eta_1 \cdots \eta_{\dim W}$ from the coefficient polynomial over $\Lambda(V^\vee)$. Applying $q_!$ extracts the ζ-top coefficient and leaves a Berezinian density on $\Pi(V \oplus W)$; applying $p_!$ then extracts the η-top coefficient. Since coefficient extraction in a finite exterior algebra is associative once the ordered monomial is fixed, the two operations agree.

40.11 Supersymmetric Quantum Mechanics and the Witten Index

Definition 40.12 (One-dimensional supersymmetric quantum-mechanics datum)**.** Let $W : \mathbb{R} \to \mathbb{R}$ be a smooth function for which the operators below are essentially self-adjoint on the Schwartz domain and have discrete low-energy spectrum. The Hilbert space is

$$\mathcal{H} = L^2(\mathbb{R}) \otimes \Lambda^\bullet\mathbb{C},$$

with fermion operators $\psi, \psi^\dagger$ obeying

$$\{\psi, \psi^\dagger\} = 1, \qquad F = \psi^\dagger\psi.$$

Define

$$Q = \psi^\dagger(\partial_x + W'(x)), \qquad Q^\dagger = \psi(-\partial_x + W'(x)), \qquad H = \frac{1}{2}\{Q, Q^\dagger\}.$$

Then $Q^2 = (Q^\dagger)^2 = 0$, $[H,Q] = [H,Q^\dagger] = 0$, and

$$H = \frac{1}{2}\left[-\partial_x^2 + W'(x)^2 + W''(x)(2F-1)\right]. \tag{40.2}$$

The Witten index is

$$I_W(\beta_{\mathrm{T}}) = \mathrm{Tr}_{\mathcal{H}}\left((-1)^F \mathrm{e}^{-\beta_{\mathrm{T}} H}\right)$$

whenever this trace is defined by the finite-volume or confining regularization under discussion.

Pairing of positive-energy states. Assume $H \geq 0$, the nonzero spectrum in the regulated problem is discrete, and $Q, Q^\dagger$ preserve the domain of H. Then

$$I_W(\beta_{\mathrm{T}}) = \dim\ker H|_{F=0} - \dim\ker H|_{F=1}, \qquad \frac{d}{d\beta_{\mathrm{T}}} I_W(\beta_{\mathrm{T}}) = 0.$$

Let $E > 0$ and let $\mathcal{H}_E$ be the finite-dimensional eigenspace of energy E. Since $H = \frac{1}{2}(QQ^\dagger + Q^\dagger Q)$, a vector $\Psi \in \mathcal{H}_E$ with $E > 0$ cannot be annihilated by both Q and $Q^\dagger$. The maps Q and $Q^\dagger$ commute with H and change fermion parity. The operator

$$\frac{1}{2E}(QQ^\dagger + Q^\dagger Q)$$

is the identity on $\mathcal{H}_E$, so the even and odd parts of $\mathcal{H}_E$ have equal dimension: $Q + Q^\dagger$ gives an invertible odd map on $\mathcal{H}_E$ after division by $\sqrt{2E}$. Therefore the supertrace of $\mathrm{e}^{-\beta_{\mathrm{T}} H}$ vanishes on every positive-energy eigenspace. Only $\ker H$ remains, where $Q\Psi = Q^\dagger\Psi = 0$. The displayed formula and β_{T}-independence follow.

For the harmonic superpotential

$$W(x) = \frac{m}{2}x^2, \qquad m > 0,$$

Harmonic supersymmetric oscillator index. For $W(x) = mx^2/2$ with $m > 0$, the regulated Witten index is

$$I_W = 1.$$

The zero-mode equations are

$$(\partial_x + mx)f_0(x) = 0, \qquad (-\partial_x + mx)f_1(x) = 0.$$

Their solutions are

$$f_0(x) = C_0\mathrm{e}^{-mx^2/2}, \qquad f_1(x) = C_1\mathrm{e}^{mx^2/2}.$$

Only f_0 lies in $L^2(\mathbb{R})$. Hence

$$I_W = 1.$$

The oscillator spectrum makes the cancellation explicit. With

$$q = \mathrm{e}^{-\beta_{\mathrm{T}} m},$$

the even contribution is

$$Z_{\text{even}} = \sum_{n\geq 0} q^n = \frac{1}{1-q},$$

and the odd contribution is

$$Z_{\text{odd}} = \sum_{n\geq 0} q^{n+1} = \frac{q}{1-q}.$$

Thus

$$\operatorname{Str}\mathrm{e}^{-\beta_{\mathrm{T}} H} = Z_{\text{even}} - Z_{\text{odd}} = 1.$$

In the coherent-state path integral this is the same supertrace discussed in the previous section, so the fermionic variable is periodic on the Euclidean time circle.

40.12 Worldline Index Density from Periodic Fermions

Definition 40.13 (Twisted Dirac index and periodic worldline datum)**.** Let M be a compact oriented Riemannian spin manifold of dimension $2n$, let $E \to M$ be a Hermitian vector bundle with unitary connection, and let

$$D_E : \Gamma(S^+ \otimes E) \longrightarrow \Gamma(S^- \otimes E)$$

be the chiral Dirac operator. The analytic index is

$$\operatorname{ind} D_E = \dim\ker D_E - \dim\ker D_E^\dagger = \operatorname{Str}_{L^2(S\otimes E)} \mathrm{e}^{-\beta_{\mathrm{T}} D_E^2}.$$

The last equality follows from the same positive-spectrum pairing as in the supersymmetric quantum-mechanical index discussion above, with $(-1)^F$ replaced by chirality.

The worldline path integral for this supertrace has periodic bosonic and fermionic loops:

$$x(\tau + \beta_{\mathrm{T}}) = x(\tau), \qquad \psi^a(\tau + \beta_{\mathrm{T}}) = \psi^a(\tau),$$

where a is an orthonormal tangent-frame index. In normal coordinates at a point $x_0 \in M$, split

$$x(\tau) = x_0 + \sqrt{\beta_{\mathrm{T}}}\, y(\tau), \qquad \psi^a(\tau) = \psi_0^a + \psi_\perp^a(\tau),$$

with y and $\psi_\perp$ having zero average. The finite-mode Gaussian calculation is performed around this zero-mode decomposition.

Example 40.14 (Finite-mode periodic-fermion index density)**.** For the preceding periodic worldline datum, the finite-mode nonzero-mode calculation and the fermion zero-mode Berezin integral give the local index density

$$\left[\widehat{A}(TM)\,\mathrm{ch}(E)\right]_{2n}.$$

When the heat-kernel proof of the McKean–Singer formula is supplied, integration over the bosonic zero mode gives

$$\operatorname{ind} D_E = \int_M \widehat{A}(TM)\,\mathrm{ch}(E).$$

The calculation is finite-dimensional after mode truncation. The nonzero-mode Gaussian ratio gives one factor for each skew-eigenvalue r_j of the curvature two-form $R/(2\pi\mathrm{i})$:

$$\prod_{j=1}^{n} \frac{r_j/2}{\sinh(r_j/2)}. \tag{40.3}$$

Indeed, in a curvature two-plane the bosonic nonzero modes carry eigenvalues $(2\pi k)^2$ shifted by the curvature matrix, while the periodic fermionic nonzero modes carry first-order eigenvalues $2\pi k$ shifted by the same skew-eigenvalue. Taking the finite-mode determinant ratio and then the symmetric product limit gives

$$\frac{z}{\sinh z} = \prod_{k=1}^{\infty} \left(1 + \frac{z^2}{\pi^2 k^2}\right)^{-1}.$$

With $z = r_j/2$, this gives the factor in (40.3). The connection on E contributes

$$\mathrm{tr}_E \exp\left(\frac{F_E}{2\pi \mathrm{i}}\right),$$

because the fermion zero modes represent exterior multiplication by tangent one-forms and the Berezin integral over $\psi_0^1, \ldots, \psi_0^{2n}$ extracts the top-degree component. Therefore the local density produced by the finite-mode worldline supertrace is

$$\left[\widehat{A}(TM)\,\mathrm{ch}(E)\right]_{2n}, \qquad \widehat{A}(TM) = \prod_{j=1}^{n} \frac{r_j/2}{\sinh(r_j/2)}, \qquad \mathrm{ch}(E) = \mathrm{tr}_E \exp\left(\frac{F_E}{2\pi \mathrm{i}}\right). \tag{40.4}$$

The equality with the Fredholm index of D_E additionally uses the McKean–Singer supertrace identity and the heat-kernel asymptotic expansion for D_E^2 on a compact manifold. With those analytic inputs established, the bosonic zero-mode integral gives

$$\mathrm{ind}\, D_E = \int_M \widehat{A}(TM)\,\mathrm{ch}(E).$$

40.13 Dirac Functional Integrals and Propagators

Definition 40.15 (Free Dirac functional-integral datum)**.** For a classical Grassmann spinor field $\psi_\alpha(x)$, define

$$\bar{\psi}^\alpha(x) = \big(\psi^\dagger(x)\beta\big)^\alpha.$$

Here $\beta = \mathrm{i}\gamma^0$, so

$$(\gamma^\mu)^\dagger \beta = -\beta\gamma^\mu.$$

This is the adjoint convention for which $\bar{\psi}(\not{\partial} + m)\psi$ is a Lorentz scalar density. The free Dirac Lagrangian density in the conventions of this volume is

$$\mathcal{L}_{\mathrm{D}} = -\bar{\psi}(\not{\partial} + m)\psi.$$

Its Euler–Lagrange equation is

$$(\not{\partial} + m)\psi = 0.$$

The momentum conjugate to ψ, using the right derivative appropriate for odd variables, is

$$\Pi_\psi{}^\alpha = \mathcal{L}_{\mathrm{D}} \frac{\overleftarrow{\partial}}{\partial(\partial_0 \psi_\alpha)} = -\bar{\psi}^\beta (\gamma^0)_\beta{}^\alpha.$$

The equal-time anticommutator computed from the mode expansion above,

$$\{\widehat{\psi}_\alpha(t,\vec{x}), \widehat{\bar{\psi}}^\beta(t,\vec{y})\} = \mathrm{i}(\gamma^0)_\alpha{}^\beta\, \delta^{(3)}(\vec{x} - \vec{y}),$$

therefore gives the canonical odd bracket

$$\{\widehat{\psi}_\alpha(t,\vec{x}), \widehat{\Pi}_\psi{}^\beta(t,\vec{y})\} = \mathrm{i}\delta_\alpha{}^\beta\, \delta^{(3)}(\vec{x} - \vec{y}).$$

The regulated Lorentzian generating functional, written in continuum shorthand, is normalized so that

$$Z[\bar{J}, J] = \int D\bar{\psi}\, D\psi\, \exp\left[\mathrm{i}\int \mathrm{d}^4x\, \mathcal{L}_{\mathrm{D}} + \mathrm{i}\int \mathrm{d}^4x\, \left(\bar{J}\psi + \bar{\psi}J\right)\right]$$
$$= Z[0,0]\, \exp\left[-\mathrm{i}\int \mathrm{d}^4x\, \mathrm{d}^4y\, \bar{J}^{\alpha}(x) S_{F,\alpha}{}^{\beta}(x-y) J_{\beta}(y)\right],$$

where J and $\bar{J}$ are Grassmann sources. The Feynman two-point function is

$$S_{F,\alpha}{}^{\beta}(x-y) = \langle\Omega|\, \mathrm{T}\{\widehat{\psi}_{\alpha}(x)\widehat{\bar{\psi}}^{\beta}(y)\}|\Omega\rangle.$$

Charge conservation gives

$$\langle\Omega|\, \mathrm{T}\{\widehat{\psi}_{\alpha}(x)\widehat{\psi}_{\beta}(y)\}|\Omega\rangle = 0, \qquad \langle\Omega|\, \mathrm{T}\{\widehat{\bar{\psi}}^{\alpha}(x)\widehat{\bar{\psi}}^{\beta}(y)\}|\Omega\rangle = 0$$

for the free charged Dirac field.

Free Dirac propagator as Feynman inverse. The free charged Dirac two-point function in Definition 40.15 is the Feynman inverse of $\not{\partial} + m$:

$$S_F(x;m) = (-\not{\partial}_x + m)\Delta_F(x;m^2).$$

Using the scalar convention

$$\Delta_F(x;m^2) = -\mathrm{i}\int \frac{\mathrm{d}^4k}{(2\pi)^4} \frac{\mathrm{e}^{\mathrm{i}k\cdot x}}{k^2 + m^2 - \mathrm{i}\epsilon},$$

one obtains

$$S_F(k) = \frac{-\mathrm{i}(-\mathrm{i}\not{k} + m)}{k^2 + m^2 - \mathrm{i}\epsilon}.$$

The numerator is the spinor projector algebra of Chapter 20, while the denominator is the scalar mass-shell pole with the Feynman boundary value.

Since Δ_F is the scalar Feynman inverse in the convention

$$(-\partial^2 + m^2)\Delta_F(x;m^2) = -\mathrm{i}\delta^{(4)}(x),$$

and the Clifford relation gives

$$(\not{\partial} + m)(-\not{\partial} + m) = -\not{\partial}^2 + m^2 = -\partial^2 + m^2,$$

the distribution $S_F = (-\not{\partial} + m)\Delta_F$ obeys the Dirac inverse equation with the same Feynman boundary value. Fourier transforming $\partial_\mu \mapsto \mathrm{i}k_\mu$ in the convention used in the scalar chapter gives the displayed numerator $-\mathrm{i}(-\mathrm{i}\not{k} + m)$ over $k^2 + m^2 - \mathrm{i}0$.

40.14 Spinor Spectral Poles and LSZ

Definition 40.16 (Isolated spinor one-particle pole datum)**.** Let an interacting theory have a global $U(1)$ charge $\widehat{Q}$, a vacuum satisfying $\widehat{Q}\Omega = 0$, and an isolated massive spin-$\frac{1}{2}$ one-particle sector of mass m and charge $+1$. Let $\widehat{\psi}_\alpha$ be a local spinor field of charge $+1$ with nonzero overlap with this sector:

$$[\widehat{Q}, \widehat{\psi}_\alpha] = \widehat{\psi}_\alpha, \qquad [\widehat{Q}, \widehat{\bar{\psi}}^\alpha] = -\widehat{\bar{\psi}}^\alpha.$$

In the delta-normalized one-particle convention, Lorentz covariance permits the matrix element

$$\langle \vec{p}, \sigma, +|\widehat{\psi}_\alpha(x)|\Omega\rangle = \frac{\mathrm{e}^{-\mathrm{i}p\cdot x}}{(2\pi)^{3/2}} \left[Z_v^{1/2} \mathcal{V}^\sigma_\alpha(p) + Z_u^{1/2} \mathcal{U}^\sigma_\alpha(p) \right],$$

where $\mathcal{U}, \mathcal{V}$ are the two massive spinor intertwiners constructed from the one-particle representation. A constant local redefinition inside the span of ψ and $\gamma_5\psi$, together with a phase convention for one-particle states, chooses an interpolating field whose isolated pole residue is proportional to one chosen intertwiner. After making that choice and passing to the covariant one-particle normalization used in the LSZ formulas, write

$$\langle \vec{p}, \sigma, +|\widehat{\psi}_\alpha(x)|\Omega\rangle = Z_\psi^{1/2}\, \mathrm{e}^{-\mathrm{i}p\cdot x} v^\sigma_\alpha(p), \qquad Z_\psi \geq 0.$$

Proposition 40.17 (Locality fixes conjugate spinor pole residue)**.** *The conjugate field has the corresponding overlap with the charge -1 sector,*

$$\langle \vec{p}, \sigma, -|\widehat{\bar{\psi}}^\alpha(x)|\Omega\rangle = Z_\psi^{1/2}\, \mathrm{e}^{-\mathrm{i}p\cdot x} \bar{u}^{\sigma,\alpha}(p),$$

with the same pole residue after the phase convention is fixed. The time-ordered two-point function then has the one-particle pole

$$Z_\psi(-\not{\partial}_x + m)_\alpha{}^\beta \Delta_F(x-y; m^2).$$

Proof. Let $Z_{\bar{\psi}}$ denote the conjugate-sector residue before imposing locality. The one-particle contribution to the vacuum anticommutator has the form

$$C_\alpha{}^\beta(x-y) = \sum_\sigma \int \mathrm{d}\Pi_p \left[Z_\psi\, \mathrm{e}^{-\mathrm{i}p\cdot(x-y)} v^\sigma_\alpha(p) \bar{v}^{\sigma,\beta}(p) \right. \\ \left. + Z_{\bar{\psi}}\, \mathrm{e}^{\mathrm{i}p\cdot(x-y)} u^\sigma_\alpha(p) \bar{u}^{\sigma,\beta}(p) \right].$$

The spin sums of Chapter 20 convert this to

$$C_\alpha{}^\beta(x-y) = Z_\psi(-\not{\partial}_x + m)_\alpha{}^\beta \Delta(x-y; m^2)$$

precisely when $Z_{\bar{\psi}} = Z_\psi$. Here Δ is the scalar Pauli–Jordan distribution, hence the pole contribution has support in the closed light cone. The positive- and negative-frequency terms separately do not have this support property, so the equality of residues is fixed by locality and the chosen normalization.

The time-ordered two-point function then has the one-particle pole

$$\langle \Omega|\, \mathrm{T}\{\widehat{\psi}_\alpha(x) \widehat{\bar{\psi}}^\beta(y)\}|\Omega\rangle = Z_\psi(-\not{\partial}_x + m)_\alpha{}^\beta \Delta_F(x-y; m^2) + G_\alpha{}^{\beta,\mathrm{cont}}(x-y),$$

where G^{cont} is the contribution from states outside the isolated one-particle mass shell. In momentum space the pole term is

$$Z_\psi \frac{-\mathrm{i}(-\mathrm{i}\not{k} + m)_\alpha{}^\beta}{k^2 + m^2 - \mathrm{i}\epsilon}.$$

□

Spinor mass-shell residue and external factors. The normalization content of this pole fixes the external spinor factor. Put $p = (\omega_{\vec{p}}, \vec{p})$. The delta-normalized spinor intertwiners obey

$$\sum_{\sigma=1}^{2} u^\sigma_\alpha(p)\bar{u}^{\sigma,\beta}(p) = \frac{(m - \mathrm{i}\ \not{p})_\alpha{}^\beta}{2\omega_{\vec{p}}}, \qquad \sum_{\sigma=1}^{2} v^\sigma_\alpha(p)\bar{v}^{\sigma,\beta}(p) = -\frac{(m + \mathrm{i}\ \not{p})_\alpha{}^\beta}{2\omega_{\vec{p}}}. \tag{40.5}$$

Thus the numerator of the Dirac pole contains the mass-shell Jacobian:

$$m - \mathrm{i}\ \not{p} = 2\omega_{\vec{p}} \sum_{\sigma=1}^{2} u^\sigma(p)\bar{u}^\sigma(p), \qquad m + \mathrm{i}\ \not{p} = -2\omega_{\vec{p}} \sum_{\sigma=1}^{2} v^\sigma(p)\bar{v}^\sigma(p). \tag{40.6}$$

Since

$$k^2 + m^2 - \mathrm{i}0 = -2\omega_{\vec{k}}\big(k^0 - \omega_{\vec{k}} + \mathrm{i}0\big) + O\big((k^0 - \omega_{\vec{k}})^2\big)$$

near the positive-energy pole, the pole contribution is

$$Z_\psi \frac{-\mathrm{i}(m - \mathrm{i}\ \not{k})_\alpha{}^\beta}{k^2 + m^2 - \mathrm{i}0} = \frac{\mathrm{i}Z_\psi}{k^0 - \omega_{\vec{k}} + \mathrm{i}0} \sum_{\sigma=1}^{2} u^\sigma_\alpha(k)\bar{u}^{\sigma,\beta}(k) + \text{terms regular at } k^0 = \omega_{\vec{k}}. \tag{40.7}$$

The negative-energy pole has the same form with v^σ and $k^0 + \omega_{\vec{k}} - \mathrm{i}0$. Therefore the factor $2\omega_{\vec{k}}$ from the mass-shell denominator is already accounted for by the spinor completeness relation (40.5). In the $\delta^{(3)}(\vec{p} - \vec{q})$-normalized external basis, each external wavefunction carries the Fourier factor $(2\pi)^{-3/2}$, while the spinor intertwiner carries the energy normalization in $\bar{u}^\sigma u^\tau = (m/\omega_{\vec{p}})\delta^{\sigma\tau}$ and $\bar{v}^\sigma v^\tau = -(m/\omega_{\vec{p}})\delta^{\sigma\tau}$. Hence a spinor external leg contributes

$$\frac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\, u^\sigma_\alpha(p), \qquad \frac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\, \bar{u}^{\sigma,\alpha}(p), \qquad \frac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\, v^\sigma_\alpha(p), \qquad \frac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\, \bar{v}^{\sigma,\alpha}(p), \tag{40.8}$$

with the choice among them fixed by charge and by the in/out convention. This is the spinorial normalization counterpart of the scalar one-particle normalization in Chapter 23. The spin sums (40.5) express the Dirac numerator as the mass-shell projector together with the Jacobian $2\omega_{\vec{p}}$, giving (40.6). Expanding the scalar denominator near the positive-energy shell gives the linear factor displayed before (40.7); substituting the projector identity gives the residue formula (40.7). At the negative-energy pole one expands

$$k^2 + m^2 - \mathrm{i}0 = (k^0 + \omega_{\vec{k}} - \mathrm{i}0)(k^0 - \omega_{\vec{k}} + \mathrm{i}0)$$

near $k^0 = -\omega_{\vec{k}}$, and uses the v-spin completeness relation in (40.5). The factor $(k^0 - \omega_{\vec{k}} + \mathrm{i}0)$ evaluates to $-2\omega_{\vec{k}}$ on this shell, while the v-spin sum carries the corresponding sign in the Dirac numerator. This gives the antiparticle residue with the same external normalization convention as the particle residue. Therefore no additional factor of $2\omega_{\vec{p}}$ is inserted by hand in the external spinor; it has already appeared in the projector identity. The remaining Fourier normalization of the delta-normalized one-particle wavefunction is $(2\pi)^{-3/2}$, yielding (40.8).

Definition 40.18 (Spinorial LSZ pole assignment)**.** Spinorial LSZ reduction applies the same Haag–Ruelle and pole-extraction logic as the scalar case. The difference is that the residue has spinor indices. With Fourier transform convention

$$F(k) = \int \mathrm{d}^4x\, \mathrm{e}^{\mathrm{i}k\cdot x} F(x),$$

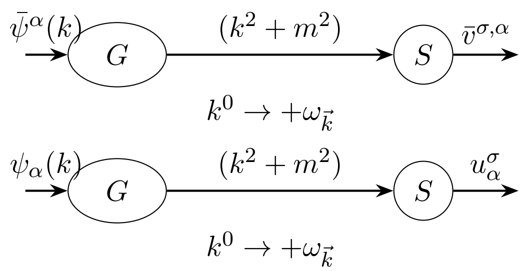
the pole assignments are:

field insertion	mass-shell limit	external one-particle state and residue
$\widehat{\bar\psi}^{\alpha}(k)$	$k^0 \to +\omega_{\vec k}$	outgoing charge $+$, $\quad Z_\psi^{1/2}\bar v^{\sigma,\alpha}(k)$
$\widehat{\bar\psi}^{\alpha}(k)$	$k^0 \to -\omega_{\vec k}$	incoming charge $-$, $\quad Z_\psi^{1/2}\bar u^{\sigma,\alpha}(k)$
$\widehat{\psi}_{\alpha}(k)$	$k^0 \to +\omega_{\vec k}$	outgoing charge $-$, $\quad Z_\psi^{1/2}u^{\sigma}_{\alpha}(k)$
$\widehat{\psi}_{\alpha}(k)$	$k^0 \to -\omega_{\vec k}$	incoming charge $+$, $\quad Z_\psi^{1/2}v^{\sigma}_{\alpha}(k)$.

Thus amputation of an external spinor leg consists of:

$$\text{multiply by } (k^2+m^2), \qquad \text{take } k^0 \to \omega_{\vec k}, \qquad \text{contract with } u^\sigma(p) \text{ or } v^\sigma(p),$$

with the choice of u or v determined by the external charge and by whether the particle is incoming or outgoing. Thus external spinor factors in perturbative scattering are the one-particle pole intertwiners of local spinor fields.



40.15 A First Fermionic Vertex

At this point the S-matrix has already been defined through asymptotic one-particle states, and LSZ has related its matrix elements to pole residues of time-ordered Green functions. Perturbation theory now enters as a method for computing those Green functions.

First four-fermion direct-minus-exchange vertex. Consider

$$\mathcal{L} = -\bar\psi(\partial\!\!\!/ + m)\psi - \frac{g}{2}(\bar\psi\psi)^2.$$

To first order in g, the connected four-point function has one local vertex. With all propagators oriented from ψ to $\bar\psi$, the spinor-index kernel of the vertex is

$$K_{\alpha\beta}{}^{\gamma\delta} = \mathrm{i}g\left(\delta_\alpha{}^\gamma\delta_\beta{}^\delta - \delta_\alpha{}^\delta\delta_\beta{}^\gamma\right).$$

The two terms are the direct and exchange contractions. Their relative sign is the sign obtained by moving odd fields through one another before applying the Gaussian contraction. Figure 40.1 draws the two index contractions; the arrows are a bookkeeping convention for the ordered contraction from ψ to $\bar\psi$, not an additional dynamical orientation.

For external spinors ζ_i selected by the LSZ table, the corresponding tree-level four-fermion amplitude has the index contraction

$$\mathcal{M} = \bar{\zeta}_3{}^{\gamma}\bar{\zeta}_4{}^{\delta}\, K_{\alpha\beta}{}^{\gamma\delta}\, \zeta_1^{\alpha}\zeta_2^{\beta}.$$

For two identical incoming and two identical outgoing charge-+ particles this reads

$$\mathcal{M} = \mathrm{i}g\left[(\bar{\zeta}_3\zeta_1)(\bar{\zeta}_4\zeta_2) - (\bar{\zeta}_4\zeta_1)(\bar{\zeta}_3\zeta_2)\right],$$

with ζ_i replaced by the charge and in/out spinors appropriate to the chosen process. This example is the first template for fermionic Feynman diagrams: every vertex has a local index tensor, every internal line is the time-ordered two-point function, and every exchange of odd fields contributes its parity sign. At first order in g, the interaction insertion is the local product $-\frac{g}{2}(\bar{\psi}\psi)(\bar{\psi}\psi)$. Contracting two incoming ψ-fields with two outgoing $\bar{\psi}$-fields gives two pairings. The first pairs (α, γ) and (β, δ) and gives $\delta_{\alpha}{}^{\gamma}\delta_{\beta}{}^{\delta}$. The second pairs (α, δ) and (β, γ). To put the odd fields in that pairing order one transposes one pair of fermionic variables, producing the minus sign. The factor $1/2$ in the Lagrangian cancels the two identical ways of choosing the two $\bar{\psi}\psi$ factors, leaving the displayed vertex normalization. The external expression is obtained by contracting this local kernel with the spinorial LSZ residues from Definition 40.18.

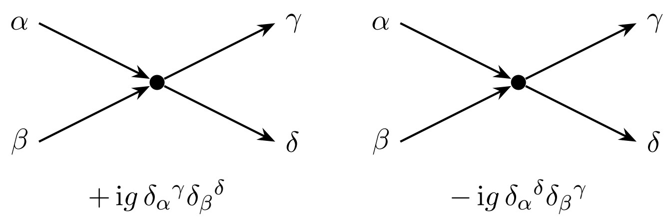


Figure 40.1: Direct and exchange contractions in the first local four-fermion vertex. The exchange contraction differs by the transposition of the two outgoing spinor indices and by the Berezin sign from moving odd variables into the contracted order.

The next chapter turns to massless particles. The logical input will again be the one-particle representation theory, now with the massless little group and helicity replacing the massive $SU(2)$ spin label.

40.16 Spinor and Gamma-Matrix Conventions

This section records the spinor conventions used throughout the monograph. The convention is the Weinberg-compatible four-dimensional gamma-matrix basis, adapted to the mostly-plus metric used in this monograph. The section fixes the data that determine signs in the Dirac adjoint, current normalization, chirality, Majorana conjugation, anomaly traces, and supersymmetry formulae. All comparisons below keep the Lorentzian metric fixed as $\eta = \mathrm{diag}(-,+,+,+)$.

40.17 Four-Dimensional Lorentzian Clifford Algebra

Definition 40.19 (Four-dimensional mostly-plus spinor convention)**.** The Lorentzian metric is

$$\eta_{\mu\nu} = \mathrm{diag}(-,+,+,+), \qquad \eta^{\mu\rho}\eta_{\rho\nu} = \delta^{\mu}{}_{\nu}.$$

Gamma matrices are endomorphisms of a complex four-dimensional vector space S and obey

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}\mathbf{1}_S. \tag{40.9}$$

Consequently

$$(\gamma^0)^2 = -\mathbf{1}_S, \qquad (\gamma^i)^2 = \mathbf{1}_S, \quad i = 1, 2, 3.$$

For a covector p_μ we write

$$\not{p} = p_\mu \gamma^\mu.$$

If $p^2 = \eta^{\mu\nu} p_\mu p_\nu$, then

$$\not{p}^2 = p^2 \mathbf{1}_S.$$

The explicit basis used for sign checks in the monograph is

$$\gamma^0 = -\mathrm{i}\begin{pmatrix} 0 & I_2 \\ I_2 & 0 \end{pmatrix}, \qquad \gamma^j = -\mathrm{i}\begin{pmatrix} 0 & \sigma_j \\ -\sigma_j & 0 \end{pmatrix}, \qquad j = 1, 2, 3, \tag{40.10}$$

where

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The hermiticity identities are

$$(\gamma^0)^\dagger = -\gamma^0, \qquad (\gamma^i)^\dagger = \gamma^i.$$

Define

$$\beta = \mathrm{i}\gamma^0, \qquad \bar{\psi} = \psi^\dagger \beta. \tag{40.11}$$

Then

$$\beta^\dagger = \beta, \qquad \beta^2 = \mathbf{1}_S, \qquad (\gamma^\mu)^\dagger \beta = -\beta\gamma^\mu.$$

Thus the bilinear $\bar{\psi}\psi$ is Lorentz invariant and $\bar{\psi}\gamma^\mu\psi$ transforms as a Lorentz vector, with the Lorentz action of Definition 40.20. In these conventions the free Lorentzian Dirac density used in the monograph is

$$\mathcal{L}_{\mathrm{D}} = -\bar{\psi}(\gamma^\mu \partial_\mu + m)\psi.$$

For a real Abelian charge q, the Hermitian vector current is

$$j^\mu = \mathrm{i}q\,\bar{\psi}\gamma^\mu\psi.$$

The explicit factor of i is not optional: it follows from (40.11) and the anti-Hermitian nature of $\bar{\psi}\gamma^\mu\psi$ in the mostly-plus convention.

Basic Clifford, adjoint, and current identities. The data in Definition 40.19 obey

$$\not{p}^2 = p^2 \mathbf{1}_S, \qquad \beta^\dagger = \beta, \qquad \beta^2 = \mathbf{1}_S, \qquad (\gamma^\mu)^\dagger\beta = -\beta\gamma^\mu.$$

Consequently the pairing $s, t \mapsto s^\dagger \beta t$ is the invariant Dirac pairing used throughout the monograph, and $\mathrm{i}\bar{\psi}\gamma^\mu\psi$ is Hermitian for an even classical spinor field or for the corresponding normal-ordered quantum current. The square of $\not{p} = p_\mu\gamma^\mu$ is

$$p_\mu p_\nu \gamma^\mu \gamma^\nu = \frac{1}{2} p_\mu p_\nu \{\gamma^\mu, \gamma^\nu\} = p_\mu p_\nu \eta^{\mu\nu} \mathbf{1}_S.$$

The explicit matrices give $(\gamma^0)^\dagger = -\gamma^0$ and $(\gamma^i)^\dagger = \gamma^i$. Since $\beta = \mathrm{i}\gamma^0$ and $(\gamma^0)^2 = -1$, this gives $\beta^\dagger = \beta$ and $\beta^2 = 1$. For $\mu = 0$,

$$(\gamma^0)^\dagger\beta = -\gamma^0\mathrm{i}\gamma^0 = \mathrm{i} = -\mathrm{i}\gamma^0\gamma^0 = -\beta\gamma^0,$$

and for $i = 1, 2, 3$,

$$(\gamma^i)^\dagger\beta = \gamma^i\mathrm{i}\gamma^0 = -\mathrm{i}\gamma^0\gamma^i = -\beta\gamma^i.$$

Thus $\beta\gamma^\mu$ is anti-Hermitian. With the adjoint convention $\bar{\psi} = \psi^\dagger\beta$, the bilinear $\bar{\psi}\gamma^\mu\psi$ is anti-Hermitian in the even finite-dimensional model. Multiplication by i gives the Hermitian current normalization. The quantum statement follows after imposing the same adjoint convention on the operator-valued distribution and using normal ordering when products at the same point are represented in a regulator.

40.18 Spin Representation and Chirality

Definition 40.20 (Spin representation and chirality)**.** The spinor Lorentz generators are

$$S^{\mu\nu} = -\frac{\mathrm{i}}{4}[\gamma^\mu, \gamma^\nu]. \tag{40.12}$$

For $\Lambda = \exp\omega \in SO^+(1,3)$, with $\omega_{\mu\nu} = -\omega_{\nu\mu}$, the corresponding element in the spinor representation is

$$R(\Lambda) = \exp\left(-\frac{\mathrm{i}}{2}\omega_{\mu\nu}S^{\mu\nu}\right).$$

The Clifford relation gives

$$[S^{\mu\nu}, \gamma^\rho] = -\mathrm{i}\gamma^\mu\eta^{\nu\rho} + \mathrm{i}\gamma^\nu\eta^{\mu\rho},$$

and hence

$$R(\Lambda)\gamma^\mu R(\Lambda)^{-1} = \Lambda^\mu{}_\nu\gamma^\nu.$$

The β-pairing is invariant:

$$R(\Lambda)^\dagger\beta R(\Lambda) = \beta.$$

The chirality matrix is

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3. \tag{40.13}$$

It obeys

$$\gamma_5^2 = \mathbf{1}_S, \qquad \{\gamma_5, \gamma^\mu\} = 0, \qquad [\gamma_5, S^{\mu\nu}] = 0.$$

In the explicit basis (40.10),

$$\gamma_5 = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix}, \qquad P_\pm = \frac{1 \pm \gamma_5}{2}.$$

Thus a spinor $s \in S$ decomposes as

$$s = \begin{pmatrix} \chi_a \\ \widetilde{\chi}_{\dot{a}} \end{pmatrix}, \qquad \chi \in S_+ := P_+S, \qquad \widetilde{\chi} \in S_- := P_-S, \qquad a, \dot{a} = 1, 2.$$

The matrix γ^μ maps S_+ to S_- and S_- to S_+.

With the orientation convention

$$\epsilon^{0123} = +1,$$

the four-dimensional trace convention is

$$\operatorname{tr}(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = 4\mathrm{i}\,\epsilon^{\mu\nu\rho\sigma}. \tag{40.14}$$

This is the convention used in the anomaly chapter.

Spin covariance and chirality trace. The generators in Definition 40.20 satisfy

$$[S^{\mu\nu}, \gamma^\rho] = -\mathrm{i}\gamma^\mu\eta^{\nu\rho} + \mathrm{i}\gamma^\nu\eta^{\mu\rho}.$$

Consequently

$$R(\Lambda)\gamma^\mu R(\Lambda)^{-1} = \Lambda^\mu{}_\nu\gamma^\nu, \qquad R(\Lambda)^\dagger\beta R(\Lambda) = \beta.$$

The chirality matrix obeys

$$\gamma_5^2 = 1, \qquad \{\gamma_5, \gamma^\mu\} = 0, \qquad [\gamma_5, S^{\mu\nu}] = 0,$$

and, with $\epsilon^{0123} = +1$,

$$\operatorname{tr}(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma) = 4\mathrm{i}\,\epsilon^{\mu\nu\rho\sigma}.$$

For any Clifford generators,

$$[[\gamma^\mu, \gamma^\nu], \gamma^\rho] = 4(\eta^{\nu\rho}\gamma^\mu - \eta^{\mu\rho}\gamma^\nu).$$

Multiplying by $-\mathrm{i}/4$ gives the displayed commutator for $S^{\mu\nu}$. Exponentiating this infinitesimal identity gives the Clifford covariance of $R(\Lambda)\gamma^\mu R(\Lambda)^{-1}$. The infinitesimal derivative of $R^\dagger\beta R$ is zero because $(S^{\mu\nu})^\dagger\beta = \beta S^{\mu\nu}$, which follows from the adjoint identities above; the value at the identity is β.

Let $\Gamma = \gamma^0\gamma^1\gamma^2\gamma^3$. Moving each γ^μ through the other three Clifford generators shows that Γ anticommutes with every γ^μ. Since

$$\Gamma^2 = (-1)^6(\gamma^0)^2(\gamma^1)^2(\gamma^2)^2(\gamma^3)^2 = -1,$$

$\gamma_5 = -\mathrm{i}\Gamma$ squares to 1. Anticommutation with every γ^μ implies commutation with every even commutator $[\gamma^\mu, \gamma^\nu]$, hence with $S^{\mu\nu}$.

The trace with γ_5 is totally antisymmetric in the four vector indices: moving adjacent Clifford generators past one another changes the sign, while the metric term produced by the anticommutator has a repeated index and gives zero in the fully antisymmetric part. It is therefore enough to evaluate the ordered component:

$$\operatorname{tr}(\gamma_5\gamma^0\gamma^1\gamma^2\gamma^3) = -\mathrm{i}\operatorname{tr}(\Gamma^2) = 4\mathrm{i}.$$

This gives the stated $\epsilon^{0123} = +1$ normalization.

40.19 Two-Component Blocks and Index Conventions

Definition 40.21 (Two-component block and epsilon conventions)**.** Let

$$\gamma^\mu = \begin{pmatrix} 0 & \rho^\mu_{+-} \\ \rho^\mu_{-+} & 0 \end{pmatrix}$$

with respect to $S = S_+ \oplus S_-$. In the basis (40.10),

$$\rho^0_{+-} = -\mathrm{i}I_2, \qquad \rho^j_{+-} = -\mathrm{i}\sigma_j, \qquad \rho^0_{-+} = -\mathrm{i}I_2, \qquad \rho^j_{-+} = +\mathrm{i}\sigma_j.$$

Equivalently,

$$(\gamma^\mu s)_a = (\rho^\mu_{+-})_a{}^{\dot b}\widetilde{\chi}_{\dot b}, \qquad (\gamma^\mu s)_{\dot a} = (\rho^\mu_{-+})_{\dot a}{}^{b}\chi_b.$$

Spinor $SU(2)$ indices are raised and lowered by

$$\chi^a = \epsilon^{ab}\chi_b, \qquad \widetilde{\chi}^{\dot a} = \epsilon^{\dot a\dot b}\widetilde{\chi}_{\dot b}, \qquad \epsilon^{12} = \epsilon_{12} = 1, \qquad \epsilon^{\dot 1\dot 2} = \epsilon_{\dot 1\dot 2} = 1.$$

With this convention, the two chiral blocks obey the sign relation

$$(\rho^\mu_{+-})_a{}^{\dot b} = -(\rho^\mu_{-+})^{\dot b}{}_a = -\epsilon^{\dot b\dot c}(\rho^\mu_{-+})_{\dot c}{}^d\epsilon_{da}. \tag{40.15}$$

In lowered form,

$$(\rho_\mu)_{a\dot b}(\rho_\nu)^{a\dot b} = 2\eta_{\mu\nu}.$$

Complex conjugation exchanges the chiral and antichiral components:

$$\overline{\chi}^{\dot a} = (\chi_a)^*, \qquad \overline{\widetilde{\chi}}^a = (\widetilde{\chi}_{\dot a})^*.$$

The two-component sign relation is a convention check rather than an independent structural theorem. It is nevertheless worth recording explicitly because it fixes the minus sign that often changes when formulae are copied between spinor conventions. Let

$$\epsilon = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

The matrices in the two chiral blocks are

$$\rho^0_{+-} = -\mathrm{i}I_2, \quad \rho^j_{+-} = -\mathrm{i}\sigma_j, \qquad \rho^0_{-+} = -\mathrm{i}I_2, \quad \rho^j_{-+} = +\mathrm{i}\sigma_j.$$

Substituting the Pauli matrices gives the finite matrix identity

$$\rho^\mu_{+-} = \left(-\epsilon\,\rho^\mu_{-+}\,\epsilon\right)^T,$$

which is precisely the displayed index formula. For the contraction, lower the vector index with $\eta_{\mu\nu}$ and raise the two spinor indices with the same epsilon matrix:

$$M^{a\dot b} = \epsilon^{ac}\epsilon^{\dot b\dot d}M_{c\dot d}.$$

Direct multiplication of the four displayed 2×2 matrices gives

$$\sum_{a,\dot b}(\rho_\mu)_{a\dot b}(\rho_\nu)^{a\dot b} = -2\,\delta_{\mu 0}\delta_{\nu 0} + 2\sum_{j=1}^{3}\delta_{\mu j}\delta_{\nu j} = 2\eta_{\mu\nu}.$$

40.20 Majorana Conjugation

Definition 40.22 (Majorana conjugation in the Weinberg-compatible basis)**.** A Majorana condition is a Lorentz-covariant reality condition on the complex spinor representation. In the explicit basis (40.10), set

$$B = \gamma_2. \tag{40.16}$$

Here $\gamma_2 = \eta_{2\nu}\gamma^\nu = \gamma^2$. Directly from the Pauli matrices,

$$(\gamma^\mu)^* = B\gamma^\mu B^{-1}, \qquad B^* B = \mathbf{1}_S.$$

For a spinor s, define

$$s^c = B^{-1}s^*.$$

Then s^c transforms in the same Lorentz representation as s, and $(s^c)^c = s$. A Majorana spinor is a spinor satisfying

$$s = s^c, \qquad \text{equivalently} \qquad s^* = Bs.$$

If $\chi = P_+ s$ is the chiral component, then the Majorana spinor may be written

$$s = \chi + B^*\chi^*.$$

The charge-conjugation matrix in the convention often used for transposed spinor contractions is

$$C = B\gamma^0.$$

For a Majorana spinor s,

$$\bar{s} = s^\dagger \mathrm{i}\gamma^0 = \mathrm{i}s^T C.$$

For two Grassmann-even Majorana spinors s_1, s_2, with chiral components χ_1, χ_2, the Lorentz vector bilinear decomposes as

$$\bar{s}_1\gamma^\mu s_2 = \overline{\chi}_1\, \rho^\mu_{+-}\chi_2 + \overline{\chi}_2\, \rho^\mu_{+-}\chi_1,$$

where the precise matrix placement is the one fixed in (40.15). For Grassmann-odd spinors the same formula must be combined with the sign rules for moving odd coefficients through one another.

Lorentz covariance of Majorana conjugation. The anti-linear map $s \mapsto s^c = B^{-1}s^*$ obeys

$$(s^c)^c = s, \qquad (R(\Lambda)s)^c = R(\Lambda)s^c.$$

The Majorana condition $s = s^c$ is therefore a Lorentz-covariant real structure on the complex spinor representation. If s is Majorana, then

$$\bar{s} = \mathrm{i}s^T C, \qquad C = B\gamma^0.$$

The explicit matrices give

$$(\gamma^\mu)^* = B\gamma^\mu B^{-1}, \qquad B^* B = 1.$$

The second identity gives

$$(s^c)^c = B^{-1}(B^{-1}s^*)^* = B^{-1}(B^*)^{-1}s = s.$$

The first identity implies $(S^{\mu\nu})^* = -BS^{\mu\nu}B^{-1}$. The minus sign is exactly canceled by complex conjugating the factor $-\mathrm{i}$ in the exponential, hence $R(\Lambda)^* = BR(\Lambda)B^{-1}$. Therefore

$$(R(\Lambda)s)^c = B^{-1}R(\Lambda)^*s^* = R(\Lambda)B^{-1}s^* = R(\Lambda)s^c.$$

If $s = s^c$, then $s^* = Bs$, and

$$\bar{s} = s^\dagger \mathrm{i}\gamma^0 = (s^*)^T\mathrm{i}\gamma^0 = s^T B^T \mathrm{i}\gamma^0.$$

For the displayed basis $B^T = B$, so the last expression is $\mathrm{i}s^T B\gamma^0 = \mathrm{i}s^T C$.

40.21 Comparison with Wess-Bagger-Type Conventions

At fixed Lorentzian metric $\eta = \mathrm{diag}(-,+,+,+)$, a common chiral gamma-matrix basis, used for example in Wess-Bagger-style supersymmetry formulae, is

$$\gamma^0_{\mathrm{WB}} = \begin{pmatrix} 0 & I_2 \\ -I_2 & 0 \end{pmatrix}, \qquad \gamma^j_{\mathrm{WB}} = \begin{pmatrix} 0 & \sigma_j \\ \sigma_j & 0 \end{pmatrix}. \tag{40.17}$$

These matrices obey the same Clifford relation

$$\{\gamma^\mu_{\mathrm{WB}}, \gamma^\nu_{\mathrm{WB}}\} = 2\eta^{\mu\nu}.$$

The Weinberg-compatible basis used in the monograph is related to (40.17) by the chiral phase change

$$U_{\mathrm{ch}} = \begin{pmatrix} I_2 & 0 \\ 0 & \mathrm{i}I_2 \end{pmatrix}, \qquad \gamma^\mu = U_{\mathrm{ch}}\gamma^\mu_{\mathrm{WB}}U_{\mathrm{ch}}^{-1}. \tag{40.18}$$

Thus if s_{WB} and s are coordinate columns for the same abstract spinor in the two bases, then

$$s = U_{\mathrm{ch}}s_{\mathrm{WB}}.$$

The chiral component is unchanged, while the antichiral component is multiplied by i. This basis change is the source of many sign differences in two-component supersymmetry formulae. In particular, with the index-raising convention used in this section, the monograph has the minus sign in (40.15); in the Wess-Bagger-type basis one often writes the corresponding relation without that minus sign, together with a different convention for upper and lower ϵ-symbols and dotted-index contractions. Formulae copied between the two systems must therefore translate both the gamma matrices and the index algebra.

The chirality matrix defined by

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$$

is unchanged by the similarity transformation (40.18). The Dirac adjoint is also the same abstract Hermitian pairing after the basis change:

$$\bar{s} = s^\dagger(\mathrm{i}\gamma^0) = s^\dagger_{\mathrm{WB}}\left(U^\dagger_{\mathrm{ch}}\mathrm{i}\gamma^0 U_{\mathrm{ch}}\right)s_{\mathrm{WB}}.$$

The displayed matrix in the last expression is the Wess-Bagger-basis matrix for the same invariant pairing.

At the fixed metric $\eta = \mathrm{diag}(-,+,+,+)$, the Wess–Bagger-type matrices used here are related to the Weinberg-compatible matrices by a finite chiral phase change. The matrix

$$U_{\mathrm{ch}} = \begin{pmatrix} I_2 & 0 \\ 0 & \mathrm{i}I_2 \end{pmatrix}$$

relates the Wess-Bagger-type basis (40.17) to the Weinberg-compatible basis by

$$\gamma^\mu = U_{\mathrm{ch}} \gamma^\mu_{\mathrm{WB}} U_{\mathrm{ch}}^{-1}.$$

The chirality operator is unchanged as an endomorphism of the abstract spinor module, while the antichiral coordinate column is multiplied by i. Hence any formula imported from Wess-Bagger-type notation must translate both the gamma matrices and the epsilon-index convention. Since $U_{\mathrm{ch}}^{-1} = \mathrm{diag}(I_2, -\mathrm{i}I_2)$, direct block multiplication gives

$$U_{\mathrm{ch}} \begin{pmatrix} 0 & I_2 \\ -I_2 & 0 \end{pmatrix} U_{\mathrm{ch}}^{-1} = -\mathrm{i} \begin{pmatrix} 0 & I_2 \\ I_2 & 0 \end{pmatrix} = \gamma^0$$

and, for $j = 1, 2, 3$,

$$U_{\mathrm{ch}} \begin{pmatrix} 0 & \sigma_j \\ \sigma_j & 0 \end{pmatrix} U_{\mathrm{ch}}^{-1} = -\mathrm{i} \begin{pmatrix} 0 & \sigma_j \\ -\sigma_j & 0 \end{pmatrix} = \gamma^j.$$

Both bases are block-off-diagonal with the same chiral splitting, so γ_5 remains $\mathrm{diag}(I_2, -I_2)$. The coordinate relation $s = U_{\mathrm{ch}} s_{\mathrm{WB}}$ gives $(\chi, \widetilde{\chi})^T = (\chi_{\mathrm{WB}}, \mathrm{i}\widetilde{\chi}_{\mathrm{WB}})^T$, which is the stated antichiral phase. The epsilon symbols determine how lowered and raised two-component indices are identified; therefore the matrix phase alone is insufficient for translating two-component formulae.

40.22 Dimensional Continuation and γ_5

Definition 40.23 (Dimensional-reduction chiral trace prescription)**.** Dimensional regularization and dimensional reduction are perturbative schemes; they are not definitions of a non-perturbative fermionic path integral. Whenever a chiral trace is present, the finite-dimensional four-dimensional data must be specified before continuing loop momenta. The convention used in the anomaly chapter is:

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$$

is a strictly four-dimensional matrix. In a split $D = 4 - \varepsilon$ momentum algebra, write

$$\ell = \ell_{\parallel} + \ell_{\perp},$$

where $\ell_{\parallel}$ lies in the physical four-dimensional subspace and $\ell_{\perp}$ lies in the continued complement. Then

$$\{\gamma_5, \not{\ell}_{\parallel}\} = 0, \qquad [\gamma_5, \not{\ell}_{\perp}] = 0.$$

Together with (40.14), these rules define the chiral trace algebra used in the dimensional-reduction anomaly calculation. Changing this prescription changes intermediate contact terms and must be compensated by an explicit finite local counterterm if the same renormalized Ward identity is to be recovered.

40.23 Three-Dimensional Lorentzian Spinors

Definition 40.24 (Three-dimensional mostly-plus Majorana convention)**.** For later use in lower-dimensional QFT, take

$$\eta_{\mu\nu} = \mathrm{diag}(-,+,+), \qquad \Gamma^0 = \mathrm{i}\sigma^2, \qquad \Gamma^1 = \sigma^1, \qquad \Gamma^2 = \sigma^3.$$

Then

$$\{\Gamma^\mu, \Gamma^\nu\} = 2\eta^{\mu\nu},$$

and all three matrices are real. Therefore a Majorana spinor may be taken to have real components. Raise and lower two-component indices by

$$\chi^a = \epsilon^{ab}\chi_b, \qquad \epsilon^{12} = \epsilon_{12} = 1.$$

The lowered gamma matrices

$$\Gamma^\mu_{ab} := (\Gamma^\mu)_a{}^c\epsilon_{cb}$$

are symmetric in a, b. For two Grassmann-even Majorana spinors ζ_1, ζ_2,

$$\bar{\zeta}_1\Gamma^\mu\zeta_2 = \zeta_1^T \mathrm{i}\Gamma^0\Gamma^\mu\zeta_2 = \mathrm{i}\,\zeta_1^a\Gamma^\mu_{ab}\zeta_2^b.$$

Remark 40.25 (Three-dimensional Clifford and symmetric block identities). The matrices in Definition 40.24 obey

$$\{\Gamma^\mu, \Gamma^\nu\} = 2\eta^{\mu\nu},$$

and $\Gamma^\mu_{ab} = (\Gamma^\mu)_a{}^c\epsilon_{cb}$ is symmetric in a, b. This is a finite convention check: The Pauli identities $\sigma_i\sigma_j + \sigma_j\sigma_i = 2\delta_{ij}$ give $(\mathrm{i}\sigma^2)^2 = -1$, $(\sigma^1)^2 = (\sigma^3)^2 = 1$, and zero anticommutators between distinct displayed matrices. With $\epsilon = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$,

$$\Gamma^0\epsilon = -I_2, \qquad \Gamma^1\epsilon = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad \Gamma^2\epsilon = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

which are all symmetric.

40.24 Two-Dimensional Lorentzian Spinors

Definition 40.26 (Two-dimensional mostly-plus spinor trace convention)**.** In two-dimensional Lorentzian calculations the monograph uses

$$\eta_{\mu\nu} = \mathrm{diag}(-,+), \qquad \{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}, \qquad \epsilon^{01} = +1.$$

The chirality matrix is

$$\gamma = \gamma^0\gamma^1, \qquad \gamma^2 = 1, \qquad \{\gamma, \gamma^\mu\} = 0.$$

The trace convention compatible with the anomaly calculation is

$$\mathrm{tr}(\gamma^\nu\gamma\,\gamma^\rho) = 2\epsilon^{\rho\nu}.$$

Thus

$$\mathrm{tr}(\gamma^\nu\gamma\ \not{p}) = 2\epsilon^{\rho\nu}p_\rho.$$

As in four dimensions, $\bar{\psi} = \mathrm{i}\psi^\dagger\gamma^0$ in the mostly-plus convention.

Remark 40.27 (Two-dimensional chirality trace). The convention in the preceding definition is realized by

$$\gamma^0 = \mathrm{i}\sigma^2, \qquad \gamma^1 = \sigma^1, \qquad \gamma = \gamma^0\gamma^1 = \sigma^3.$$

It satisfies

$$\mathrm{tr}(\gamma^\nu \gamma\, \gamma^\rho) = 2\epsilon^{\rho\nu}.$$

The Clifford relation follows from $(\mathrm{i}\sigma^2)^2 = -\mathbf{1}$, $(\sigma^1)^2 = \mathbf{1}$, and $\sigma^2\sigma^1 = -\sigma^1\sigma^2$, so $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$ in mostly-plus signature. Also

$$\gamma^0\gamma^1 = \mathrm{i}\sigma^2\sigma^1 = \sigma^3.$$

With $\epsilon^{01} = +1$, the two nonzero traces are

$$\mathrm{tr}(\gamma^0\gamma\gamma^1) = -2, \qquad \mathrm{tr}(\gamma^1\gamma\gamma^0) = 2,$$

which equal $2\epsilon^{10}$ and $2\epsilon^{01}$, respectively; repeated indices vanish because $\gamma^\nu\gamma\gamma^\nu$ is proportional to γ, whose trace is zero.

Definition 40.28 (Two-dimensional chiral-component Majorana convention)**.** For comparison with two-dimensional CFT component conventions, it is useful to use a Majorana basis adapted to light-cone components. In flat coordinates $x^0 = t$, $x^1 = \sigma$, set

$$\widehat{\Gamma}^0 = -\mathrm{i}\sigma^1, \qquad \widehat{\Gamma}^1 = \sigma^2, \qquad \widehat{\Gamma} = \widehat{\Gamma}^0\widehat{\Gamma}^1 = \sigma^3.$$

Let $\sigma^\pm = \sigma \pm t$, so that

$$\widehat{\Gamma}^+ = \widehat{\Gamma}^1 + \widehat{\Gamma}^0, \qquad \widehat{\Gamma}^- = \widehat{\Gamma}^1 - \widehat{\Gamma}^0.$$

Spinor indices $A, B = \pm$ are raised and lowered by

$$\epsilon^{+-} = \epsilon_{+-} = 1, \qquad v^A = \epsilon^{AB} v_B.$$

The lowered light-cone gamma matrices are

$$(\widehat{\Gamma}^\pm)_{AB} := (\widehat{\Gamma}^\pm)_A{}^C \epsilon_{CB}.$$

This basis gives

$$(\widehat{\Gamma}^+)_{++} = 2\mathrm{i}, \qquad (\widehat{\Gamma}^-)_{--} = 2\mathrm{i},$$

with all other lowered light-cone components zero. It is the convention that reduces the covariant Majorana action

$$-\frac{\mathrm{i}}{4\pi} \int d^2\sigma \sqrt{-g}\, \psi \Gamma^a \nabla_a^{\mathrm{spin}} \psi$$

to

$$-\frac{1}{2\pi} \int d^2\sigma \left(\psi_+ \partial_- \psi_+ + \psi_- \partial_+ \psi_-\right)$$

in flat coordinates, with the same spinor-index contraction convention. Its role in this monograph is translational: it is the convenient bridge to the chiral free-fermion fields of two-dimensional CFT. After Wick rotation, ψ_- and ψ_+ become the holomorphic and antiholomorphic spin fields on a Riemann surface, and the global information is carried by a spin structure rather than by a preferred global spinor frame. Most two-dimensional CFT computations are therefore done directly with these components, their OPEs, and their Szego kernels. No ghost system or integration over moduli space is part of this convention; those are separate structures that are outside the fixed-surface two-dimensional QFT/CFT framework being recorded here.

Remark 40.29 (Compatibility of the two-dimensional spinor bases)*.* The Dirac-anomaly basis of Remark 40.27 and the Majorana basis of Definition 40.28 are similar representations of the same mostly-plus Clifford algebra. Explicitly, with

$$U_2 = \begin{pmatrix} -\mathrm{i} & 0 \\ 0 & 1 \end{pmatrix},$$

one has

$$\widehat{\Gamma}^0 = U_2\gamma^0 U_2^{-1}, \qquad \widehat{\Gamma}^1 = U_2\gamma^1 U_2^{-1}, \qquad \widehat{\Gamma} = U_2\gamma U_2^{-1}.$$

Consequently the two bases define the same invariant Clifford algebra and the same chirality splitting, while the free-fermion light-cone component normalization and the Dirac-anomaly trace normalization are different coordinate realizations of that algebra. The monograph uses the Dirac-anomaly basis when evaluating spinor traces and uses the chiral-component Majorana basis when comparing to two-dimensional CFT component conventions. Direct multiplication gives

$$U_2(\mathrm{i}\sigma^2)U_2^{-1} = -\mathrm{i}\sigma^1, \qquad U_2\sigma^1 U_2^{-1} = \sigma^2.$$

The chirality relation follows by multiplying the two identities. Lowering the spinor index of

$$\widehat{\Gamma}^+ = \begin{pmatrix} 0 & -2\mathrm{i} \\ 0 & 0 \end{pmatrix}, \qquad \widehat{\Gamma}^- = \begin{pmatrix} 0 & 0 \\ 2\mathrm{i} & 0 \end{pmatrix}$$

with $\epsilon = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ gives

$$\widehat{\Gamma}^+\epsilon = \begin{pmatrix} 2\mathrm{i} & 0 \\ 0 & 0 \end{pmatrix}, \qquad \widehat{\Gamma}^-\epsilon = \begin{pmatrix} 0 & 0 \\ 0 & 2\mathrm{i} \end{pmatrix}.$$

Thus the light-cone components have the stated chiral-component normalization. Since U_2 is invertible, all Clifford, chirality, and trace identities are transported between the two bases after transforming the coordinate components of the spinors.

40.25 Euclidean Spinors

Definition 40.30 (Recursive Euclidean Clifford basis)**.** Euclidean gamma matrices in even dimension d are denoted $\Gamma^1, \dots, \Gamma^d$ and obey

$$\{\Gamma^i, \Gamma^j\} = 2\delta^{ij}.$$

A concrete recursive construction starts in $d = 2$ with

$$\Gamma^1_{(2)} = \sigma_1, \qquad \Gamma^2_{(2)} = \sigma_2,$$

and for even $d > 2$ sets

$$\Gamma^\mu_{(d)} = \Gamma^\mu_{(d-2)} \otimes (-\sigma_3), \qquad \mu = 1, \dots, d-2,$$

$$\Gamma^{d-1}_{(d)} = I_{2^{d/2-1}} \otimes \sigma_1, \qquad \Gamma^d_{(d)} = I_{2^{d/2-1}} \otimes \sigma_2.$$

The Euclidean chirality matrix is

$$\Gamma_E = \mathrm{i}^{-d/2}\Gamma^1 \cdots \Gamma^d, \qquad \Gamma_E^2 = 1.$$

One convenient charge-conjugation matrix is

$$C_E = \Gamma^1\Gamma^3\cdots\Gamma^{d-1}, \qquad d \equiv 0 \pmod 4,$$

and

$$C_E = \Gamma_E\Gamma^1\Gamma^3\cdots\Gamma^{d-1}, \qquad d \equiv 2 \pmod 4.$$

These formulae fix a basis; invariant statements should be phrased in terms of the corresponding real, complex, or quaternionic structure on the Euclidean spinor module.

The recursive construction in Definition 40.30 gives

$$\{\Gamma^i_{(d)}, \Gamma^j_{(d)}\} = 2\delta^{ij}, \qquad \Gamma_E^2 = 1$$

in every even dimension d. The $d = 2$ matrices are the Pauli matrices σ_1, σ_2, so the claim holds at the initial step. Assume it holds in dimension $d-2$. For $i, j \le d-2$, tensoring both matrices with $-\sigma_3$ preserves the anticommutator because $(-\sigma_3)^2 = 1$. The two new matrices $I \otimes \sigma_1$ and $I \otimes \sigma_2$ anticommute with each other and square to 1. They also anticommute with the old matrices because σ_1 and σ_2 anticommute with σ_3. Hence the Clifford relation holds in dimension d.

Let $\Omega_d = \Gamma^1\cdots\Gamma^d$. In Euclidean signature, $\Omega_d^2 = (-1)^{d(d-1)/2}$. For even $d = 2r$, this is $(-1)^r$. Since $\Gamma_E = \mathrm{i}^{-r}\Omega_d$,

$$\Gamma_E^2 = \mathrm{i}^{-2r}(-1)^r = (-1)^{-r}(-1)^r = 1.$$

40.26 Six- and Eight-Dimensional Euclidean Blocks

Definition 40.31 (Six- and eight-dimensional Euclidean spinor blocks)**.** For later supersymmetric and internal-symmetry applications, it is useful to record block conventions for Euclidean $SO(6)$ and $SO(8)$ spinors.

In $d = 8$, the chiral and antichiral spinor representations are both real eight-dimensional. In a basis in which the charge-conjugation matrix is the identity, write the off-diagonal gamma-matrix components as

$$(\Gamma^i)^{a\dot b} = \mathcal{C}^{ia\dot b}, \qquad (\Gamma^i)^{\dot b a} = \mathcal{C}^{i\dot b a}, \qquad \mathcal{C}^{i\dot b a} = -\mathcal{C}^{ia\dot b}.$$

They obey

$$\begin{aligned}
\mathcal{C}^{ia\dot c}\mathcal{C}^{j\dot c b} + \mathcal{C}^{ja\dot c}\mathcal{C}^{i\dot c b} &= 2\delta^{ij}\delta^{ab},\\
\mathcal{C}^{i\dot a c}\mathcal{C}^{jc\dot b} + \mathcal{C}^{j\dot a c}\mathcal{C}^{ic\dot b} &= 2\delta^{ij}\delta^{\dot a\dot b},\\
\mathcal{C}^{ia\dot c}\mathcal{C}^{i\dot d b} + \mathcal{C}^{ib\dot c}\mathcal{C}^{i\dot d a} &= 2\delta^{ab}\delta^{\dot c\dot d}.
\end{aligned}$$

The first two identities are the Clifford relations; the third records the triality symmetry that exchanges vector and spinor representations.

In $d = 6$, use $\mathrm{Spin}(6) \simeq SU(4)$. Chiral and antichiral spinors are the fundamental and antifundamental representations of $SU(4)$. Let $I, J, K, L = 1, \ldots, 4$. The gamma-matrix blocks are antisymmetric tensors

$$\mathcal{C}^i_{IJ} = -\mathcal{C}^i_{JI}, \qquad \mathcal{C}^{iIJ} = \frac{1}{2}\epsilon^{IJKL}\mathcal{C}^i_{KL} = \left(\mathcal{C}^i_{JI}\right)^*.$$

They satisfy

$$\sum_{i=1}^{6} \mathcal{C}^i_{IJ} \mathcal{C}^{iKL} = -2 \left(\delta_I{}^K \delta_J{}^L - \delta_I{}^L \delta_J{}^K \right) .$$

These identities are the ones used when four-dimensional supersymmetry or higher-dimensional reductions are translated into $SU(4)$ index notation.

Chapter 41

Maxwell Theory, Constraints, and Gauge Fixing

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

41.1 Representative Fields and Field Strength

Definition 41.1 (Local Maxwell representative datum)**.** Work on four-dimensional Minkowski space with mostly-plus metric. A Maxwell configuration in this local discussion is represented by a real one-form

$$A = A_\mu(x)\,\mathrm{d}x^\mu.$$

Two representatives related by

$$A_\mu(x) \longmapsto A_\mu(x) + \partial_\mu \xi(x)$$

describe the same electromagnetic field. Here ξ is a real scalar gauge parameter in the same boundary-condition class as A_μ. We assume throughout this chapter that fields are either smeared with compactly supported test functions or obey boundary conditions for which integrations by parts have no boundary term. Zero modes of the gauge-fixing operators are then removed separately; this is part of the definition of the local gauge slice used below.

The local gauge-invariant field strength is

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

Maxwell action and Euler–Lagrange equation. The free Maxwell action is

$$S[A] = -\frac{1}{4}\int \mathrm{d}^4x\, F_{\mu\nu}F^{\mu\nu}.$$

Its Euler–Lagrange equation is

$$\partial_\mu F^{\mu\nu} = 0.$$

The variation of the field strength is $\delta F_{\mu\nu} = \partial_\mu \delta A_\nu - \partial_\nu \delta A_\mu$. Using antisymmetry of $F^{\mu\nu}$,

$$\delta S = -\frac{1}{2}\int \mathrm{d}^4x\, F^{\mu\nu}\delta F_{\mu\nu} = -\int \mathrm{d}^4x\, F^{\mu\nu}\partial_\mu \delta A_\nu.$$

The boundary condition convention of Definition 41.1 gives

$$\delta S = \int \mathrm{d}^4x\, (\partial_\mu F^{\mu\nu})\delta A_\nu.$$

Since δA_ν is arbitrary within the chosen test-function class, the Euler–Lagrange equation is $\partial_\mu F^{\mu\nu} = 0$. The same calculation shows gauge invariance of $S[A]$, because $\delta_\xi F_{\mu\nu} = 0$ for $\delta_\xi A_\mu = \partial_\mu \xi$.

With $x^0 = t$ and spatial indices $i, j = 1, 2, 3$, the Lagrangian density is

$$\mathcal{L} = \frac{1}{2}\sum_{i=1}^{3}(\partial_0 A_i - \partial_i A_0)^2 - \frac{1}{4}\sum_{i,j=1}^{3}(\partial_i A_j - \partial_j A_i)^2.$$

The absence of $\partial_0 A_0$ is the first sign that the vector potential is a redundant representative rather than four independent propagating fields.

41.2 Canonical Constraint Analysis

Definition 41.2 (Maxwell canonical Poisson structure)**.** At fixed time let $A_\mu(t, \vec{x})$ be canonical coordinates. For functionals F, G of A_μ, Π^μ, use the equal-time Poisson bracket

$$\{F, G\}_{\mathrm{P}} = \int \mathrm{d}^3\vec{x}\, \left(\frac{\delta F}{\delta A_\mu(\vec{x})}\frac{\delta G}{\delta \Pi^\mu(\vec{x})} - \frac{\delta F}{\delta \Pi^\mu(\vec{x})}\frac{\delta G}{\delta A_\mu(\vec{x})}\right).$$

Equivalently,

$$\{A_\mu(\vec{x}), \Pi^\nu(\vec{y})\}_{\mathrm{P}} = \delta_\mu{}^\nu \delta^{(3)}(\vec{x} - \vec{y}),$$

with all A-A and Π-Π brackets zero.

Primary constraint, Gauss constraint, and canonical Hamiltonian. The canonical momenta are

$$\Pi^\mu(\vec{x}) = \frac{\partial \mathcal{L}}{\partial(\partial_0 A_\mu(t, \vec{x}))},$$

so

$$\Pi^0(\vec{x}) = 0, \qquad \Pi^i(\vec{x}) = \partial_0 A_i - \partial_i A_0.$$

The equation

$$\chi_1(\vec{x}) = \Pi^0(\vec{x}) = 0$$

is the primary constraint. The canonical Hamiltonian is

$$H_{\mathrm{c}} = \int \mathrm{d}^3\vec{x}\, \left[\frac{1}{2}\Pi^i\Pi^i + \frac{1}{4}F_{ij}F_{ij} - A_0\, \partial_i\Pi^i\right],$$

after integrating $\Pi^i\partial_i A_0$ by parts. Preserving the primary constraint under time evolution gives

$$\dot{\Pi}^0(\vec{x}) = \{\Pi^0(\vec{x}), H_{\mathrm{c}}\}_{\mathrm{P}} = \partial_i\Pi^i(\vec{x}),$$

hence the secondary constraint

$$\chi_2(\vec{x}) = \partial_i\Pi^i(\vec{x}) = 0.$$

This is Gauss' law in the absence of charges.

These formulae are the canonical Legendre transform. The Lagrangian density contains $\partial_0 A_i$ only through $\partial_0 A_i - \partial_i A_0$, and contains no $\partial_0 A_0$. This gives the displayed momenta and the primary constraint $\Pi^0 = 0$. Solving $\partial_0 A_i = \Pi^i + \partial_i A_0$, the Legendre transform gives

$$\Pi^i\partial_0 A_i - \mathcal{L} = \frac{1}{2}\Pi^i\Pi^i + \frac{1}{4}F_{ij}F_{ij} + \Pi^i\partial_i A_0.$$

Integrating the last term by parts gives H_{c}. Finally,

$$\{\Pi^0(\vec{x}), H_{\mathrm{c}}\}_{\mathrm{P}} = -\frac{\delta H_{\mathrm{c}}}{\delta A_0(\vec{x})} = \partial_i\Pi^i(\vec{x}),$$

so preservation of $\Pi^0 = 0$ imposes Gauss' law.

Hamiltonian generator of Maxwell gauge transformations. The constraints obey

$$\{\chi_a(\vec{x}), \chi_b(\vec{y})\}_{\mathrm{P}} = 0, \qquad a, b = 1, 2.$$

They are first-class constraints. Their relation to gauge redundancy is direct. For a spacetime function ζ, define at time t

$$G[\zeta] = \int \mathrm{d}^3\vec{y}\, \left[(\partial_0\zeta)(t,\vec{y})\, \Pi^0(\vec{y}) - \zeta(t,\vec{y})\, \partial_i\Pi^i(\vec{y})\right].$$

Then

$$\{A_0(\vec{x}), G[\zeta]\}_{\mathrm{P}} = \partial_0\zeta(t,\vec{x}), \qquad \{A_i(\vec{x}), G[\zeta]\}_{\mathrm{P}} = \partial_i\zeta(t,\vec{x}).$$

Thus the first-class constraints generate

$$\delta_\zeta A_\mu(t,\vec{x}) = \partial_\mu\zeta(t,\vec{x})$$

on the vector-potential representative. The gauge-invariant phase space is obtained by restricting to the constraint surface and quotienting by these gauge orbits, or equivalently by choosing a regular slice through the orbits.

The bracket calculation is elementary but fixes an important convention. The constraints depend only on momenta, hence their mutual Poisson brackets vanish. For the generator $G[\zeta]$,

$$\{A_0(\vec{x}), G[\zeta]\}_{\mathrm{P}} = \int \mathrm{d}^3\vec{y}\, \partial_0\zeta(t,\vec{y})\delta^{(3)}(\vec{x}-\vec{y}) = \partial_0\zeta(t,\vec{x}).$$

For A_i, integrate the derivative in the Gauss term against the delta function:

$$\{A_i(\vec{x}), G[\zeta]\}_{\mathrm{P}} = -\int \mathrm{d}^3\vec{y}\, \zeta(t,\vec{y})\partial_i^{\vec{y}}\delta^{(3)}(\vec{x}-\vec{y}) = \partial_i\zeta(t,\vec{x}).$$

The transformed field strength is unchanged because mixed partial derivatives commute. Thus the Hamiltonian first-class flow is precisely the Maxwell representative redundancy.

41.3 Axial Gauge and Reduced Phase Space

Definition 41.3 (Axial gauge local chart)**.** Axial gauge chooses the representative satisfying

$$A_3 = 0.$$

Locally along an orbit,

$$A_3 \longmapsto A_3 + \partial_3\xi,$$

so this is a regular gauge condition for modes on which ∂_3 is invertible. Modes with $\partial_3\xi = 0$ are residual gauge parameters for this slice and must be treated separately by boundary conditions or an additional gauge condition.

Axial gauge leaves two canonical degrees of freedom. There are two equivalent local descriptions. In canonical language the condition $A_3 = 0$ pairs with Gauss' law and allows one to solve

$$\partial_3\Pi^3 = -\partial_a\Pi^a, \qquad a = 1, 2,$$

for the longitudinal momentum Π^3, again modulo ∂_3 zero modes. In Lagrangian language one imposes $A_3 = 0$ before eliminating the non-dynamical field A_0. The gauge-fixed Lagrangian density is

$$\begin{aligned}\mathcal{L}_{\mathrm{ax}} = {} & \frac{1}{2}\sum_{a=1}^{2}(\partial_0 A_a - \partial_a A_0)^2 + \frac{1}{2}(\partial_3 A_0)^2 \\ & - \frac{1}{2}(\partial_1 A_2 - \partial_2 A_1)^2 - \frac{1}{2}\sum_{a=1}^{2}(\partial_3 A_a)^2.\end{aligned}$$

The A_0 equation is

$$\sum_{a=1}^{2}\partial_a(\partial_a A_0 - \partial_0 A_a) + \partial_3^2 A_0 = 0.$$

With

$$\Pi^a = \partial_0 A_a - \partial_a A_0,$$

this becomes

$$\sum_{a=1}^{2}\partial_a\Pi^a + \partial_3^2 A_0 = 0.$$

The pair

$$\Pi^0(\vec{x}) = 0, \qquad \sum_{a=1}^{2} \partial_a \Pi^a(\vec{x}) + \partial_3^2 A_0(\vec{x}) = 0$$

is second-class for nonzero k_3, since

$$\left\{ \Pi^0(\vec{x}), \sum_{a=1}^{2} \partial_a \Pi^a(\vec{y}) + \partial_3^2 A_0(\vec{y}) \right\}_{\mathrm{P}} = \partial_3^2 \delta^{(3)}(\vec{x} - \vec{y}).$$

Hence one may either introduce the corresponding Dirac bracket or solve

$$\partial_3^2 A_0 = -\sum_{a=1}^{2} \partial_a \Pi^a$$

and eliminate A_0, Π^0. For the regular modes of the axial slice the remaining canonical variables are

$$A_a(\vec{x}), \Pi^a(\vec{x}), \qquad a = 1, 2.$$

They are the two canonical degrees of freedom of the free photon. On modes where ∂_3 is invertible, Gauss' law gives $\Pi^3 = -\partial_3^{-1} \partial_a \Pi^a$, so (A_3, Π^3) is removed after imposing the axial condition and the constraint. In the Lagrangian description, A_0 has no time derivative. Its equation of motion is the displayed elliptic equation along the x^3-direction once $A_3 = 0$ is imposed. The Poisson bracket

$$\{\Pi^0(\vec{x}), \partial_3^2 A_0(\vec{y})\}_{\mathrm{P}} = \partial_3^2 \delta^{(3)}(\vec{x} - \vec{y})$$

is invertible on the same nonzero-k_3 modes, so (A_0, Π^0) is a second-class pair there and may be eliminated. The only regular canonical variables left are A_a, Π^a, $a = 1, 2$.

41.4 Gauge Slices and the Faddeev–Popov Factor

Definition 41.4 (Local Faddeev–Popov chart)**.** Before gauge fixing, the path-integral shorthand

$$Z_{\text{unfixed}} = \int DA_\mu \, \mathrm{e}^{\mathrm{i}S[A]}$$

integrates over all representatives on each gauge orbit. Let $\mathcal{G}(A)$ be a gauge condition. Locally in field space, and after removing zero modes, the Faddeev–Popov identity is

$$1 = \Delta_{\mathcal{G}}[A] \int D\xi \, \delta\big(\mathcal{G}(A + \partial\xi)\big),$$

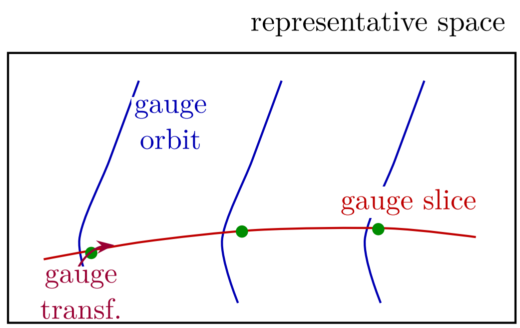
where

$$\Delta_{\mathcal{G}}[A] = \det M_{\mathcal{G}}[A], \qquad M_{\mathcal{G}}[A]\xi = \frac{\mathrm{d}}{\mathrm{d}s} \mathcal{G}(A + s\,\partial\xi) \bigg|_{s=0}.$$

Abelian linear FP determinant. For abelian Maxwell theory with a linear gauge condition, $M_{\mathcal{G}}$ is independent of A_μ. Its determinant is then an overall normalization in the free theory. This special simplification is not a definition of gauge fixing; it is a property of the abelian linear examples used in this chapter. The corresponding nonabelian construction is developed later as a local coordinate system on gauge orbits. There the analogue of $M_{\mathcal{G}}$ depends on the gauge potential, can acquire zero modes, and therefore cannot be promoted to a single global Faddeev–Popov chart without additional geometric data. If $\mathcal{G}$ is linear, then

$$\mathcal{G}(A + \partial\xi) = \mathcal{G}(A) + \mathcal{G}(\partial\xi).$$

Therefore the derivative with respect to s at $s = 0$ is simply $M_{\mathcal{G}}\xi = \mathcal{G}(\partial\xi)$, independent of A. The determinant is consequently independent of the integration variable in the free abelian representative integral and factors from normalized correlators.



Example 41.5 (Finite-dimensional gauge-slice independence model)**.** A finite-dimensional model isolates the logic. Let

$$S(x, y) = (x - y)^2$$

on $\mathbb{R}^2$, with gauge orbits

$$(x, y) \longmapsto (x + \alpha, y + \alpha).$$

The ungauged Gaussian integral diverges by the orbit volume. Choose the linear slice

$$\ell(x, y) = y + ax + b = 0, \qquad a \neq -1.$$

The Faddeev–Popov factor is the absolute value of the derivative of $\ell(x + \alpha, y + \alpha)$ with respect to α,

$$\Delta_\ell = |1 + a|.$$

For a gauge-invariant observable $O(x, y) = O(x + \alpha, y + \alpha)$,

$$\frac{\int \mathrm{d}x\, \Delta_\ell\, \mathrm{e}^{-(x+ax+b)^2} O(x, -ax - b)}{\int \mathrm{d}x\, \Delta_\ell\, \mathrm{e}^{-(x+ax+b)^2}}$$

is independent of a, b. This is the finite-dimensional form of gauge-slice independence for gauge-invariant quantities in a region where the slice is regular. On the slice $y = -ax - b$, the gauge-invariant coordinate is

$$u = x - y = (1 + a)x + b.$$

The measure changes by $\mathrm{d}u = |1 + a|\mathrm{d}x$. The factor $\Delta_\ell = |1 + a|$ therefore cancels the Jacobian in both numerator and denominator. Because O is constant on gauge orbits, $O(x, -ax - b)$ depends only on u. Both normalized integrals are thus the same Gaussian average in u, independent of a, b.

41.5 Axial-Gauge Gaussian and Propagator

Axial-gauge quadratic inverse. For axial gauge,

$$\mathcal{G}_{\mathrm{ax}}(A) = A_3, \qquad M_{\mathrm{ax}} = \partial_3.$$

After removing the ∂_3 zero modes, the determinant is independent of A_μ, and the gauge-fixed Maxwell integral may be written as

$$Z_{\mathrm{ax}} = \int DA_\mu\, \delta(A_3)\, \mathrm{e}^{\mathrm{i}S[A]}.$$

Integrating the Maxwell action by parts gives

$$S[A] = \frac{1}{2}\int \mathrm{d}^4x\, A_\mu \left(\eta^{\mu\nu}\Box - \partial^\mu\partial^\nu\right) A_\nu, \qquad \Box = \partial^\rho\partial_\rho.$$

The unfixed quadratic operator has zero directions $A_\mu = \partial_\mu\xi$. On the axial slice $A_3 = 0$, the remaining block has indices $\mu, \nu = 0, 1, 2$. With

$$A_\mu(x) = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\, \mathrm{e}^{\mathrm{i}k\cdot x}\widetilde{A}_\mu(k),$$

the quadratic form is

$$S_{\mathrm{ax}} = \frac{1}{2}\int \frac{\mathrm{d}^4k}{(2\pi)^4}\, \widetilde{A}_\mu(-k)\, \widetilde{D}^{\mu\nu}_{\mathrm{ax}}(k)\, \widetilde{A}_\nu(k),$$

where

$$\widetilde{D}^{\mu\nu}_{\mathrm{ax}}(k) = -\eta^{\mu\nu}k^2 + k^\mu k^\nu, \qquad \mu, \nu = 0, 1, 2.$$

For $k^2 \neq 0$ and $k_3 \neq 0$, its inverse on this 3×3 block is

$$\left(\widetilde{D}_{\mathrm{ax}}(k)^{-1}\right)_{\mu\nu} = -\frac{1}{k^2}\left(\eta_{\mu\nu} + \frac{k_\mu k_\nu}{k_3^2}\right), \qquad \mu, \nu = 0, 1, 2.$$

The abelian Faddeev–Popov operator is $M_{\mathrm{ax}}\xi = \partial_3\xi$, so its determinant is field independent after the ∂_3 zero modes are removed. Integration by parts gives the displayed quadratic operator. On the axial slice $A_3 = 0$, only the $\mu, \nu = 0, 1, 2$ block remains. Multiplying the proposed inverse by the quadratic block gives

$$\begin{aligned}
&\sum_{\rho=0}^{2}\left(-\eta^{\mu\rho}k^2 + k^\mu k^\rho\right)\left[-\frac{1}{k^2}\left(\eta_{\rho\nu} + \frac{k_\rho k_\nu}{k_3^2}\right)\right] \\
&\qquad = \delta^\mu{}_\nu - \frac{k^\mu k_\nu}{k^2} + \frac{k^\mu k_\nu}{k_3^2} - \frac{k^\mu k_\nu}{k^2 k_3^2}\sum_{\rho=0}^{2} k^\rho k_\rho = \delta^\mu{}_\nu,
\end{aligned}$$

because

$$\sum_{\rho=0}^{2} k^\rho k_\rho = k^2 - k_3^2.$$

Corollary 41.6 (Axial-gauge representative propagator and field strength)**.** *The Lorentzian Feynman boundary value therefore gives, for $\mu, \nu = 0, 1, 2$,*

$$\begin{aligned}&\langle\Omega|\,\mathrm{T}\{\widehat{A}_\mu(x)\widehat{A}_\nu(y)\}|\Omega\rangle_{\mathrm{ax}}\\ &= \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\mathrm{e}^{\mathrm{i}k\cdot(x-y)}\frac{-\mathrm{i}}{k^2-\mathrm{i}\epsilon}\left(\eta_{\mu\nu}+\frac{k_\mu k_\nu}{k_3^2}\right),\end{aligned}$$

with components involving A_3 set to zero in this gauge. The displayed kernel is singular at $k_3 = 0$, precisely where the axial slice has residual gauge directions.

The field-strength two-point function is obtained by antisymmetrizing momentum factors. Away from coincident points, equivalently modulo local contact terms fixed by the definition of time ordering, the $k_\mu k_\nu$ part of the axial propagator cancels:

$$\begin{aligned}&\langle\Omega|\,\mathrm{T}\{\widehat{F}_{\mu\nu}(x)\widehat{F}_{\rho\sigma}(y)\}|\Omega\rangle\\ &= \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\mathrm{e}^{\mathrm{i}k\cdot(x-y)}\frac{-\mathrm{i}}{k^2-\mathrm{i}\epsilon}\big(k_\mu k_\rho\eta_{\nu\sigma}-k_\nu k_\rho\eta_{\mu\sigma}-k_\mu k_\sigma\eta_{\nu\rho}+k_\nu k_\sigma\eta_{\mu\rho}\big).\end{aligned}$$

Thus the local gauge-invariant correlator has a Lorentz-covariant kernel although the axial representative propagator does not.

41.6 Covariant Gauges

Definition 41.7 (Lorenz gauge and covariant gauge parameter)**.** For perturbative calculations it is often useful to preserve manifest Lorentz covariance in the representative propagator. The Lorenz gauge condition is

$$\mathcal{G}_{\mathrm{L}}(A) = \partial_\mu A^\mu.$$

Along a gauge orbit,

$$\partial_\mu(A^\mu + \partial^\mu\xi) = \partial_\mu A^\mu + \Box\xi,$$

so the abelian Faddeev–Popov operator is $M_{\mathrm{L}} = \Box$. In the free abelian theory its determinant is field independent.

Remark 41.8 (Gaussian averaging of the Lorenz gauge condition). Instead of imposing $\partial_\mu A^\mu = 0$ sharply, introduce an auxiliary function φ and average the condition

$$\partial_\mu A^\mu = \varphi$$

with a Gaussian weight. In Euclidean signature the insertion is

$$\int D\varphi\,\exp\left[-\frac{1}{2\xi_{\mathrm{g}}}\int \mathrm{d}^4x_E\,\varphi^2\right]\delta(\partial_\mu A^\mu - \varphi), \qquad \xi_{\mathrm{g}} > 0.$$

Equivalently, writing the delta-functional with a real Lagrange multiplier λ,

$$\begin{aligned}&\int D\varphi\,D\lambda\,\exp\left[-\frac{1}{2\xi_{\mathrm{g}}}\int\varphi^2 + \mathrm{i}\int\lambda(\partial_\mu A^\mu - \varphi)\right]\\ &\propto \exp\left[-\frac{1}{2\xi_{\mathrm{g}}}\int(\partial_\mu A^\mu)^2\right].\end{aligned}$$

The Euclidean gauge-fixing term is therefore

$$\Delta S_E = \frac{1}{2\xi_{\mathrm{g}}} \int \mathrm{d}^4 x_E \, (\partial_\mu A^\mu)^2.$$

The delta-functional sets $\varphi = \partial_\mu A^\mu$. Integrating first over λ implements this constraint, and the remaining Gaussian weight in φ becomes exactly the displayed quadratic term in $\partial_\mu A^\mu$. Conversely, integrating first over φ completes the square and produces the same local quadratic functional of the Lagrange multiplier; the two orders express the same finite-mode Gaussian identity before the regulator is removed.

Covariant-gauge quadratic inverse. The corresponding Lorentzian gauge-fixed action is

$$S_{\xi_{\mathrm{g}}}[A] = \int \mathrm{d}^4 x \left[-\frac{1}{4} F_{\mu\nu} F^{\mu\nu} - \frac{1}{2\xi_{\mathrm{g}}} (\partial_\mu A^\mu)^2 \right].$$

After integration by parts,

$$S_{\xi_{\mathrm{g}}}[A] = \frac{1}{2} \int \mathrm{d}^4 x \, A_\mu \left[\eta^{\mu\nu} \Box - \left(1 - \frac{1}{\xi_{\mathrm{g}}} \right) \partial^\mu \partial^\nu \right] A_\nu.$$

In momentum space,

$$\widetilde{D}^{\mu\nu}_{\xi_{\mathrm{g}}}(k) = -\eta^{\mu\nu} k^2 + \left(1 - \frac{1}{\xi_{\mathrm{g}}} \right) k^\mu k^\nu.$$

For $\xi_{\mathrm{g}} \neq 0$, its inverse is

$$\big(\widetilde{D}^{-1}_{\xi_{\mathrm{g}}}(k) \big)_{\mu\nu} = -\frac{\eta_{\mu\nu}}{k^2} + (1 - \xi_{\mathrm{g}}) \frac{k_\mu k_\nu}{(k^2)^2}.$$

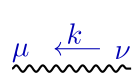
The gauge-fixed action is obtained from the Maxwell action and the Lorentzian continuation of the Euclidean term in Proposition 41.8. Integrating by parts gives the displayed quadratic operator. The inverse is verified by

$$\left[-\eta^{\mu\rho} k^2 + \left(1 - \frac{1}{\xi_{\mathrm{g}}} \right) k^\mu k^\rho \right] \left[-\frac{\eta_{\rho\nu}}{k^2} + (1 - \xi_{\mathrm{g}}) \frac{k_\rho k_\nu}{(k^2)^2} \right]$$
$$= \delta^\mu{}_\nu.$$

Corollary 41.9 (Covariant representative propagator)**.** *The Feynman two-point function of the representative field is*

$$\langle \Omega | \, \mathrm{T}\{ \widehat{A}_\mu(x) \widehat{A}_\nu(y) \} | \Omega \rangle_{\xi_{\mathrm{g}}}$$
$$= \int \frac{\mathrm{d}^4 k}{(2\pi)^4} \mathrm{e}^{\mathrm{i}k\cdot(x-y)} \frac{-\mathrm{i}}{k^2 - \mathrm{i}\epsilon} \left[\eta_{\mu\nu} - (1 - \xi_{\mathrm{g}}) \frac{k_\mu k_\nu}{k^2 - \mathrm{i}\epsilon} \right].$$

The value $\xi_{\mathrm{g}} = 1$ is Feynman gauge:



$$= \frac{-\mathrm{i}\eta_{\mu\nu}}{k^2 - \mathrm{i}\epsilon}.$$

The value $\xi_{\mathrm{g}} \to 0$ is Landau gauge.

41.7 Gupta–Bleuler Fock Space in Lorenz Gauge

Definition 41.10 (Covariant Maxwell Krein-Fock representative)**.** The covariant representative propagator has a direct operator realization in a Krein-Fock space. The construction keeps Lorentz covariance manifest at the level of representative fields and recovers the positive physical photon space by a null quotient.

Let

$$\mathrm{d}\mu_0(k) = \frac{\mathrm{d}^3\vec{k}}{(2\pi)^3\, 2|\vec{k}|}, \qquad k^0 = |\vec{k}|,$$

be the positive-energy massless measure. Define the one-particle covariant test space $\mathcal{K}_1^0$ to consist of smooth rapidly decreasing complex vector wavefunctions $f_\mu(k)$ on the forward light cone. It is equipped with the indefinite Hermitian form

$$[f, g]_1 = \int \mathrm{d}\mu_0(k)\, \eta^{\mu\nu}\, \overline{f_\mu(k)}\, g_\nu(k).$$

The time-like component contributes with the opposite sign because $\eta^{00} = -1$. Choosing a time-like polarization and three space-like polarizations gives a fundamental symmetry and hence a Hilbert majorant topology; the completion is a Krein space $\mathcal{K}_1$. The covariant Fock space is the symmetric Krein-Fock space

$$\mathcal{K} = \mathcal{F}_s(\mathcal{K}_1).$$

On the algebraic finite-particle domain define annihilation and creation operator-valued distributions by

$$[a_\mu(\vec{k}), a_\nu^\dagger(\vec{q})] = (2\pi)^3\, 2|\vec{k}|\, \eta_{\mu\nu}\, \delta^{(3)}(\vec{k} - \vec{q}), \qquad a_\mu(\vec{k})\Omega = 0.$$

The Lorenz-gauge representative field in Feynman gauge is

$$A_\mu(x) = \int \mathrm{d}\mu_0(k)\, \left[a_\mu(\vec{k})\mathrm{e}^{-\mathrm{i}k\cdot x} + a_\mu^\dagger(\vec{k})\mathrm{e}^{\mathrm{i}k\cdot x}\right].$$

It satisfies the free wave equation $\Box A_\mu = 0$ and has two-point function

$$\langle\Omega|\, \mathrm{T}\, A_\mu(x) A_\nu(y)|\Omega\rangle = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\, \mathrm{e}^{\mathrm{i}k\cdot(x-y)}\, \frac{-\mathrm{i}\eta_{\mu\nu}}{k^2 - \mathrm{i}0},$$

which is the $\xi_{\mathrm{g}} = 1$ propagator above. The price of this covariant representative is the indefinite form on $\mathcal{K}$.

Definition 41.11 (Gupta–Bleuler physical subspace)**.** Write

$$B(x) = \partial^\mu A_\mu(x), \qquad B^{(+)}(x) = -\mathrm{i}\int \mathrm{d}\mu_0(k)\, k^\mu a_\mu(\vec{k})\mathrm{e}^{-\mathrm{i}k\cdot x}.$$

The Gupta–Bleuler physical subspace is

$$\mathcal{K}_{\mathrm{GB}} = \{\Psi \in \mathcal{K} :\ B^{(+)}(f)\Psi = 0 \text{ for every test function } f\}.$$

Equivalently, on wavefunctions this condition is the mass-shell Lorenz condition

$$k^\mu f_\mu(k) = 0.$$

Remark 41.12 (Weak Lorenz condition). If $\Phi, \Psi \in \mathcal{K}_{\mathrm{GB}}$, then

$$\langle \Phi | B(x) | \Psi \rangle = 0.$$

Indeed $B^{(+)}(x)\Psi = 0$ by the definition of $\mathcal{K}_{\mathrm{GB}}$, while $B^{(-)}(x)$ is the Krein adjoint of $B^{(+)}(x)$, so $\langle \Phi | B^{(-)}(x) = 0$ for $\Phi \in \mathcal{K}_{\mathrm{GB}}$. Since $B = B^{(+)} + B^{(-)}$, the Lorenz condition is imposed weakly, as a condition on matrix elements between physical vectors.

Construction 41.13 (One-particle Gupta–Bleuler quotient)**.** The quotient that removes null gauge vectors can be described already at one-particle level. Let

$$\mathcal{K}_{1,\mathrm{GB}} = \{ f \in \mathcal{K}_1 : \ k^\mu f_\mu(k) = 0 \}.$$

The subspace

$$\mathcal{N}_1 = \{ f_\mu(k) = k_\mu h(k) \}$$

lies in $\mathcal{K}_{1,\mathrm{GB}}$ and is null:

$$[kh, kh']_1 = \int \mathrm{d}\mu_0(k)\, k^2\, \overline{h(k)} h'(k) = 0.$$

It is also orthogonal to every $f \in \mathcal{K}_{1,\mathrm{GB}}$, since

$$[kh, f]_1 = \int \mathrm{d}\mu_0(k)\, \overline{h(k)}\, k^\mu f_\mu(k) = 0.$$

For each null k, the quotient $k^\perp / \mathbb{C}k$ is a two-dimensional positive Hermitian space. Choosing two transverse polarization representatives $\epsilon^h_\mu(k)$, $h = \pm 1$, gives the isometry

$$[f] \longmapsto f_h(k) = \epsilon^{h\mu}(k) f_\mu(k)$$

from

$$\mathcal{H}_1^\gamma := \mathcal{K}_{1,\mathrm{GB}} / \mathcal{N}_1$$

onto the two-helicity one-photon Hilbert space

$$\bigoplus_{h=\pm 1} L^2(\mathcal{N}_+, \mathrm{d}\mu_0).$$

The positive inner product is

$$\langle [f], [g] \rangle_\gamma = \sum_{h=\pm 1} \int \mathrm{d}\mu_0(k)\, \overline{f_h(k)} g_h(k).$$

Gupta–Bleuler quotient as the two-helicity photon Fock space. With the one-particle quotient $\mathcal{H}_1^\gamma$ constructed in Construction 41.13, the many-particle physical Hilbert space is

$$\mathcal{H}_{\mathrm{GB}} = \mathcal{K}_{\mathrm{GB}} / \mathcal{N} \simeq \mathcal{F}_s(\mathcal{H}_1^\gamma),$$

where $\mathcal{N}$ is the closed subspace generated by finite-particle vectors with at least one one-particle factor in $\mathcal{N}_1$. Equivalently, on every n-particle sector,

$$\mathrm{Sym}^n(\mathcal{K}_{1,\mathrm{GB}}) / \sum_{r=1}^{n} \mathrm{Sym}^{r-1}(\mathcal{K}_{1,\mathrm{GB}}) \odot \mathcal{N}_1 \odot \mathrm{Sym}^{n-r}(\mathcal{K}_{1,\mathrm{GB}}) \cong \mathrm{Sym}^n(\mathcal{H}_1^\gamma).$$

Thus Gupta–Bleuler quantization and reduced two-helicity quantization give the same positive free-photon Hilbert space after quotienting null vectors. This is the functorial quotient calculation following the one-particle construction. Construction 41.13 identifies $\mathcal{K}_{1,\mathrm{GB}}/\mathcal{N}_1$ with the two-helicity one-photon Hilbert space. The symmetric tensor functor sends a quotient by a subspace to the quotient of each symmetric tensor power by the sum of tensors with one factor in that subspace:

$$\mathrm{Sym}^n(V/N) \cong \mathrm{Sym}^n(V)/\sum_{r=1}^{n} \mathrm{Sym}^{r-1}(V) \odot N \odot \mathrm{Sym}^{n-r}(V).$$

Taking $V = \mathcal{K}_{1,\mathrm{GB}}$ and $N = \mathcal{N}_1$ gives the displayed n-particle identification. The finite-particle direct sum therefore quotients to the symmetric Fock space over $\mathcal{H}_1^\gamma$, and completion gives $\mathcal{F}_s(\mathcal{H}_1^\gamma)$.

Proposition 41.14 (Field strengths descend to the Gupta–Bleuler quotient). *Let $u_{\mu\nu}(x)$ be a compactly supported test two-form and smear the field strength:*

$$F(u) = \int \mathrm{d}^4x\, u^{\mu\nu}(x)\big(\partial_\mu A_\nu - \partial_\nu A_\mu\big)(x).$$

Then $F(u)\Omega$ lies in $\mathcal{K}_{1,\mathrm{GB}}$, and $F(u)$ descends to a well-defined operator on $\mathcal{H}_{\mathrm{GB}} \simeq \mathcal{F}_s(\mathcal{H}_1^\gamma)$. Every free time-ordered correlator of field strengths computed in the covariant Gupta–Bleuler Fock representation agrees with the corresponding correlator computed in the reduced positive two-helicity Fock representation.

Proof. The one-particle wavefunction of $F(u)\Omega$ is proportional on the light cone to

$$f_\nu(k) = 2\mathrm{i}\, k_\mu \widetilde{u}^\mu{}_\nu(k), \qquad k^\nu f_\nu(k) = 0,$$

because $k^\mu k^\nu \widetilde{u}_{\mu\nu} = 0$. Therefore $F(u)\Omega$ lies in $\mathcal{K}_{1,\mathrm{GB}}$. If the representative field is shifted by $A_\mu \mapsto A_\mu + \partial_\mu \xi$, the field-strength smearing changes by zero; at the one-particle level this is the statement that adding $k_\mu h(k)$ changes only the null class. Consequently field-strength operators descend to well-defined operators on $\mathcal{H}_{\mathrm{GB}} \simeq \mathcal{F}_s(\mathcal{H}_1^\gamma)$.

The equality of observable correlators follows by Wick's theorem from the two-point statement. The Feynman-gauge vector propagator and the two-helicity time-ordered vector kernel differ by terms whose external vector indices are longitudinal on the light cone, together with local contact terms fixed by the time-ordering prescription. Applying the antisymmetric derivatives that form $F_{\mu\nu}$ kills the longitudinal terms. Hence every free correlator of field strengths computed in the covariant Gupta–Bleuler Fock representation agrees with the correlator computed in the reduced positive two-helicity Fock representation. The same cancellation explains why the ξ_{g}-dependent term in the covariant path-integral propagator drops out of gauge-invariant field-strength correlators. □

41.8 Field Strength and One-Photon States

Field-strength two-point function and photon helicity data. The gauge-fixed path integral defines Green functions of the representative variable A_μ. In a positive-metric physical Hilbert space the local observable obtained from the free Maxwell field is the field strength $\widehat{F}_{\mu\nu}$. The field-strength two-point function is independent of ξ_{g}, because the gauge-parameter term in the representative propagator is proportional to $k_\mu k_\nu$ and is killed by antisymmetrization.

The Wightman two-point function has the one-photon spectral form

$$\begin{aligned}&\langle\Omega|\widehat{F}_{\mu\nu}(x)\widehat{F}_{\rho\sigma}(y)|\Omega\rangle\\&=\sum_{h=\pm1}\int\frac{\mathrm{d}^3\vec{k}}{(2\pi)^3\,2|\vec{k}|}\langle\Omega|\widehat{F}_{\mu\nu}(x)|k,h\rangle\langle k,h|\widehat{F}_{\rho\sigma}(y)|\Omega\rangle,\end{aligned}$$

where the sharp states are generalized one-particle vectors in the sense of Section 5.2. With the helicity representatives of Chapter 21,

$$\langle k,h|\widehat{F}_{\mu\nu}(x)|\Omega\rangle=Z_A^{1/2}\mathrm{e}^{-\mathrm{i}k\cdot x}\left(-\mathrm{i}k_\mu\epsilon_\nu^{h*}(k)+\mathrm{i}k_\nu\epsilon_\mu^{h*}(k)\right).$$

The representative shift

$$\epsilon_\mu^h(k)\longmapsto\epsilon_\mu^h(k)+c(k)k_\mu$$

does not change this matrix element.

For a fixed null momentum k, choose a null covector $C_\mu(k)$ satisfying

$$C^2=0,\qquad k^\mu C_\mu=-1.$$

The two transverse helicity representatives may be normalized so that

$$\epsilon_\mu^h(k)\epsilon^{h'*\mu}(k)=\delta_{hh'},\qquad k^\mu\epsilon_\mu^h(k)=0,$$

and obey the completeness relation

$$\sum_{h=\pm1}\epsilon_\mu^h(k)\epsilon_\nu^{h*}(k)=\eta_{\mu\nu}+k_\mu C_\nu+k_\nu C_\mu.$$

For example, when $k^\mu=(|\vec{k}|,\vec{k})$, one may take

$$C^\mu(k)=\frac{1}{2|\vec{k}|^2}\big(|\vec{k}|,-\vec{k}\big).$$

In the field-strength spectral sum all terms involving C_μ cancel by antisymmetrization. Comparison with the explicit Wightman boundary value of the free field-strength correlator fixes the free normalization

$$Z_A=1.$$

The verification is explicit. The ξ_{g}-dependent term of the representative propagator is proportional to $k_\alpha k_\beta$. Applying the two field-strength antisymmetrizers gives the factor

$$(k_\mu\delta_\nu{}^\alpha-k_\nu\delta_\mu{}^\alpha)k_\alpha k_\beta(k_\rho\delta_\sigma{}^\beta-k_\sigma\delta_\rho{}^\beta),$$

which vanishes because $k_\mu k_\nu-k_\nu k_\mu=0$. Thus the gauge-parameter part of the representative two-point function is invisible to $F_{\mu\nu}$.

The spectral representation is the one-particle part of the Wightman two-point function for the positive photon Hilbert space constructed above by quotienting the Gupta–Bleuler space; sharp $|k,h\rangle$ are used as generalized vectors in the rigged-Hilbert-space sense. The matrix element of the field strength is obtained by applying $\partial_\mu A_\nu-\partial_\nu A_\mu$ to a one-photon vector-potential matrix element. The replacement $\epsilon^h_\mu \mapsto \epsilon^h_\mu + c\,k_\mu$ changes the parent vector potential representative, but it contributes

$$-\mathrm{i}c\,k_\mu k_\nu + \mathrm{i}c\,k_\nu k_\mu = 0$$

to the field-strength matrix element.

For the completeness relation, the tensor $\eta_{\mu\nu} + k_\mu C_\nu + k_\nu C_\mu$ annihilates k^ν, has zero components along the null complement modulo the line $\mathbb{C}k$, and restricts to the positive Euclidean metric on the two-dimensional transverse quotient $k^\perp/\mathbb{C}k$. Hence it is the sum of the two normalized helicity projectors. Substituting this completeness relation into the field-strength spectral sum, every term containing C has two symmetric factors of k entering one of the antisymmetrizers, so those terms vanish. The remaining $\eta_{\mu\nu}$ term is exactly the explicit free field-strength Wightman kernel obtained from the Feynman-gauge representative propagator. With the normalization of the photon creation and annihilation operators in Definition 41.10, this comparison gives $Z_A = 1$.

The next chapter couples this representative gauge field to a charged spinor field. The perturbative Green functions will be written using gauge-fixed representatives, while local gauge-invariant operators and external photon states are read through the field strength and helicity data constructed here.

Chapter 42

Quantum Electrodynamics and External States

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

42.1 Charged Spinors and Abelian Gauge Representatives

Definition 42.1 (QED representative datum)**.** A local representative datum for four-dimensional QED consists of a real Abelian vector-potential representative $A_\mu(x)$, a Dirac spinor representative $\psi_\alpha(x)$, its mostly-plus Dirac adjoint $\bar{\psi}^\alpha(x) = \psi^\dagger \beta$, and a real charge coordinate $g \in \mathbb{R}$. For the electron convention used below,

$$g = -e, \qquad e > 0.$$

The representative fields are therefore

$$A_\mu(x), \qquad \psi_\alpha(x), \qquad \bar{\psi}^\alpha(x),$$

with $\bar{\psi}$ defined as in Chapter 40. A real function $\xi(x)$ changes representatives by

$$A_\mu \mapsto A_\mu + \partial_\mu \xi, \qquad \psi \mapsto \mathrm{e}^{\mathrm{i}g\xi}\psi, \qquad \bar{\psi} \mapsto \bar{\psi}\,\mathrm{e}^{-\mathrm{i}g\xi}.$$

The Abelian covariant derivative is

$$D_\mu \psi = \partial_\mu \psi - \mathrm{i}g A_\mu \psi.$$

Covariance of the Abelian Dirac coupling. For the representative change of Definition 42.1, the covariant derivative transforms as

$$D_\mu(\mathrm{e}^{\mathrm{i}g\xi}\psi) = \mathrm{e}^{\mathrm{i}g\xi}D_\mu\psi.$$

Consequently the local action

$$S_{\mathrm{QED}}[A,\bar{\psi},\psi] = \int \mathrm{d}^4x \left[-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \bar{\psi}(\gamma^\mu D_\mu + m)\psi\right]$$

is invariant under compactly supported changes of Abelian representative, where

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \qquad \not{a} = a_\mu\gamma^\mu.$$

In the monograph's mostly-plus gamma convention the current represented by the coupling to A_μ is

$$j^\mu = \mathrm{i}g\,\bar{\psi}\gamma^\mu\psi.$$

It transforms with the same charge as ψ:

$$\begin{aligned} D_\mu(\mathrm{e}^{\mathrm{i}g\xi}\psi) &= \partial_\mu(\mathrm{e}^{\mathrm{i}g\xi}\psi) - \mathrm{i}g(A_\mu + \partial_\mu\xi)\mathrm{e}^{\mathrm{i}g\xi}\psi \\ &= \mathrm{e}^{\mathrm{i}g\xi}D_\mu\psi. \end{aligned}$$

The curvature $F_{\mu\nu}$ is unchanged because $\partial_\mu\partial_\nu\xi = \partial_\nu\partial_\mu\xi$. The Dirac term is invariant because the phase of $D_\mu\psi$ cancels the opposite phase of $\bar{\psi}$. Expanding the covariant derivative gives

$$\mathcal{L}_{\mathrm{QED}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \bar{\psi}(\not{\partial} + m)\psi + \mathrm{i}gA_\mu\bar{\psi}\gamma^\mu\psi.$$

The last term is the interaction. In these gamma-matrix conventions the electric current represented by the coupling to A_μ is

$$j^\mu = \mathrm{i}g\,\bar{\psi}\gamma^\mu\psi.$$

The leading factor of i is fixed by the mostly-plus Dirac adjoint $\bar{\psi} = \psi^\dagger\beta$, $\beta = \mathrm{i}\gamma^0$, together with $D_\mu = \partial_\mu - \mathrm{i}gA_\mu$. It is invariant under the local Abelian representative change because the endpoint phases of $\bar{\psi}$ and ψ cancel.

42.2 Local Observables and Charged Insertions

Definition 42.2 (Local Abelian charge of a representative monomial)**.** A local observable is represented by a local expression in the fields that is invariant under all compactly supported changes of gauge representative. Examples are

$$F_{\mu\nu}, \qquad \bar{\psi}\psi, \qquad \mathrm{i}g\,\bar{\psi}\gamma^\mu\psi.$$

A local monomial containing N_ψ factors of ψ and $N_{\bar{\psi}}$ factors of $\bar{\psi}$ has local charge

$$g(N_\psi - N_{\bar{\psi}}).$$

Remark 42.3 (Neutrality criterion for pointlike local monomials). Gauge invariance of a pointlike local monomial therefore requires the net local charge in Definition 42.2 to vanish. Under a compactly supported representative change the monomial is multiplied by

$$\exp\bigl(\mathrm{i}g(N_\psi - N_{\bar\psi})\xi(x)\bigr)$$

at the point of insertion. Since $\xi(x)$ can be chosen arbitrarily while remaining compactly supported, invariance for all representative changes forces $g(N_\psi - N_{\bar\psi}) = 0$. For nonzero charge coordinate g this is precisely $N_\psi = N_{\bar\psi}$.

Definition 42.4 (Wilson-line dressed charged insertion)**.** Charged insertions are represented by adding dressing data. Let C_x be an oriented curve beginning at x and ending at a prescribed asymptotic endpoint. For gauge parameters that vanish at that endpoint, set

$$\Psi_{C_x}(x) = \exp\left(\mathrm{i}g\int_{C_x} A_\mu(y)\,\mathrm{d}y^\mu\right)\psi(x).$$

Similarly, for a path $C_{y\to x}$ from y to x, set

$$\mathcal{O}_\alpha{}^\beta(x,y;C_{y\to x}) = \psi_\alpha(x)\exp\left(-\mathrm{i}g\int_{C_{y\to x}} A_\mu(z)\,\mathrm{d}z^\mu\right)\bar\psi^\beta(y).$$

The curve is part of the insertion datum; these are not pointlike local observables.

Remark 42.5 (Endpoint cancellation for Abelian Wilson dressings). The dressed operators in Definition 42.4 are invariant under compactly supported Abelian representative changes compatible with the stated endpoint convention. For the half-infinite dressing,

$$\int_{C_x}\partial_\mu\xi(y)\,\mathrm{d}y^\mu = \xi(\infty)-\xi(x) = -\xi(x),$$

so the phase acquired by the line integral cancels the phase of $\psi(x)$. For the finite bilocal dressing the Wilson-line phase changes by

$$\exp\{-\mathrm{i}g(\xi(x)-\xi(y))\}.$$

This cancels the endpoint phases of $\psi_\alpha(x)$ and $\bar\psi^\beta(y)$.

The line operator itself may require short-distance renormalization when it is defined as an operator-valued distribution. That renormalization question is separate from the finite gauge-covariance calculation displayed here.

Remark 42.6. Gauge-fixed perturbation theory uses $A_\mu, \psi, \bar\psi$ Green functions as representative correlators. After gauge fixing these correlators have propagators and vertices. Gauge-invariant local observables and physical external photon states are read from $F_{\mu\nu}$, helicity representatives, and LSZ pole data.

42.3 Gauge-Fixed Generating Functional

For perturbation theory choose the covariant gauge parameter ξ_g and add

$$\Delta\mathcal{L} = -\frac{1}{2\xi_\mathrm{g}}(\partial_\mu A^\mu)^2.$$

The Abelian Faddeev–Popov determinant for the condition $\partial_\mu A^\mu = \varphi$ is $\det\Box$, independent of A_μ; it is absorbed into the normalization of the generating functional.

Abelian Faddeev–Popov specialization. Let

$$F_\varphi[A](x) = \partial_\mu A^\mu(x) - \varphi(x)$$

be the covariant gauge condition, with φ an auxiliary scalar function in the same regulator and boundary-condition class as $\partial_\mu A^\mu$. Along the Abelian gauge orbit

$$A_\mu^\xi = A_\mu + \partial_\mu \xi, \qquad \psi^\xi = \mathrm{e}^{\mathrm{i}g\xi}\psi, \qquad \bar\psi^\xi = \bar\psi\,\mathrm{e}^{-\mathrm{i}g\xi},$$

the linearized orbit-slice map is

$$\mathcal{M}_{\mathrm{QED}}(x,y) = \left.\frac{\delta F_\varphi[A^\xi](x)}{\delta\xi(y)}\right|_{\xi=0} = \Box_x \delta^{(4)}(x-y). \tag{42.1}$$

After residual zero modes have been removed or separately fixed,

$$\Delta_{\mathrm{FP}}^{U(1)} = \det{}'\Box.$$

This determinant is independent of $A_\mu, \psi, \bar\psi$. Hence it cancels from normalized representative Green functions and may be absorbed into the normalization of Z. If it is represented by anti-commuting ghosts, the ghost action is the free decoupled quadratic action

$$S_{\mathrm{gh}}^{U(1)} = \int \mathrm{d}^4x\, \bar c\,\Box c,$$

so there is no QED ghost vertex in the perturbative rules below.

The gauge condition depends only on the vector-potential representative, so the matter-field phases do not enter the Faddeev–Popov operator. Directly,

$$F_\varphi[A^\xi](x) = \partial_\mu A^\mu(x) + \Box\xi(x) - \varphi(x).$$

Taking the functional derivative with respect to $\xi(y)$ gives (42.1). Since the result contains no field, the Jacobian is a constant determinant on the regular gauge-parameter subspace. The prime on $\det{}'\Box$ records the same zero-mode separation already needed for the gauge slice itself: constant gauge parameters, or any residual modes allowed by the chosen boundary conditions, do not change $\partial_\mu A^\mu$. For normalized correlators the same determinant multiplies numerator and denominator. The Grassmann representation follows from the finite-dimensional Berezin identity $\int D\bar c\, Dc\, \exp(\mathrm{i}\bar c M c) \propto \det M$, applied to $M = \Box$.

This is the Abelian, linear-gauge specialization of the general local orbit-measure construction in Proposition 47.2 and (47.11). In a nonabelian gauge theory the orbit map is instead

$$\delta_\zeta A_\mu^a = (D_\mu(A)\zeta)^a, \qquad \mathcal{M}^{ab}(A;x,y) = \partial_x^\mu D_\mu^{ab}(A;x)\,\delta^{(4)}(x-y)$$

for Lorenz gauge. The determinant then depends on the gauge representative and its ghost representation produces interacting ghost vertices. Moreover, outside a sufficiently small regular chart the Faddeev–Popov operator can develop zero modes and a single gauge condition can meet an orbit more than once. Those issues are not QED Feynman-rule details; they belong to the nonabelian local-coordinate and BRST analysis of Chapter 47, especially Quoted Theorem 47.5.

Definition 42.7 (Regulated gauge-fixed QED source functional)**.** Introduce an ordinary source J^μ for A_μ, and Grassmann sources $\eta_\alpha, \bar{\eta}^\alpha$ for $\bar{\psi}^\alpha, \psi_\alpha$. The regulated Lorentzian generating functional, written in continuum shorthand, is

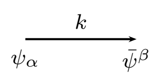
$$Z[J,\bar{\eta},\eta] = \int DA\, D\bar{\psi}\, D\psi\, \exp\Big\{ \mathrm{i} \int \mathrm{d}^4x \left(\mathcal{L}_{\mathrm{QED}} + \Delta\mathcal{L}\right) + \mathrm{i} \int \mathrm{d}^4x \left(J^\mu A_\mu + \bar{\eta}\psi + \bar{\psi}\eta\right) \Big\}.$$

As in the preceding finite-dimensional Berezin discussion, this notation is shorthand for a regulated Gaussian integral followed by perturbative expansion of the interaction term

$$\mathrm{i}g A_\mu \bar{\psi}\gamma^\mu\psi$$

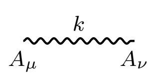
around the Gaussian Maxwell and Dirac functionals already constructed. The covariant gauge parameter ξ_{g} changes representative correlators; the local gauge-invariant correlators obtained from neutral operators and field strengths do not depend on this representative choice.

Representative QED Feynman rules. The coefficientwise expansion of Definition 42.7 gives the following momentum-space representative rules. A directed fermion line from ψ_α to $\bar{\psi}^\beta$ carries



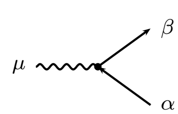
$$= \frac{-\mathrm{i}(-\mathrm{i}\,\not{k} + m)_\alpha{}^\beta}{k^2 + m^2 - \mathrm{i}\epsilon}.$$

The photon representative propagator is



$$= \frac{-\mathrm{i}}{k^2 - \mathrm{i}\epsilon}\left[\eta_{\mu\nu} - (1-\xi_{\mathrm{g}})\frac{k_\mu k_\nu}{k^2 - \mathrm{i}\epsilon}\right].$$

The cubic vertex with one photon representative and two spinor representatives is



$$= -g(\gamma^\mu)_\beta{}^\alpha.$$

For the electron convention $g = -e$, the vertex factor is $e(\gamma^\mu)_\beta{}^\alpha$. The gauge parameter ξ_{g} appears only in the representative photon propagator. Amplitudes between physical photon helicity states are obtained after LSZ projection and are independent of the longitudinal representative.

The fermion propagator is the inverse of the free Dirac kernel in the conventions of Chapter 40; the displayed numerator is the adjugate of $\not{k} + \mathrm{i}m$ in the mostly-plus spinor convention, with the Feynman boundary value fixed by $-\mathrm{i}\epsilon$. The photon representative propagator is the inverse of the quadratic Maxwell operator after adding $-(\partial_\mu A^\mu)^2/(2\xi_{\mathrm{g}})$, as derived in Chapter 41. The Abelian Faddeev–Popov determinant is field independent by the Abelian specialization above, so no ghost vertex occurs. Finally, differentiating the interaction $\mathrm{i}\int \mathrm{i}gA_\mu\bar{\psi}\gamma^\mu\psi$ with respect to one photon source and the two Grassmann sources gives the cubic representative vertex $-g\gamma^\mu$, with the displayed index placement inherited from the ordered source convention in Definition 42.7.

42.4 External Factors as Pole Data

Definition 42.8 (QED external pole-residue factors)**.** External factors in a diagrammatic amplitude are residues of poles already identified by LSZ. The particle definitions have already been supplied by the one-particle spectral data and scattering construction. With the normalizations of Chapters 18, 40, and 41, the factors are

external state	LSZ factor
$e^-_{\mathrm{out}}(\vec{p},\sigma)$	$\dfrac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\,(\bar{u}^\sigma)^\alpha(\vec{p})$
$e^+_{\mathrm{out}}(\vec{p},\sigma)$	$\dfrac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\,v^\sigma_\alpha(\vec{p})$
$\gamma_{\mathrm{out}}(\vec{k},h)$	$\dfrac{Z_A^{1/2}}{(2\pi)^{3/2}\sqrt{2\lvert\vec{k}\rvert}}\,e^{h*}_\mu(\vec{k})$
$e^-_{\mathrm{in}}(\vec{p},\sigma)$	$\dfrac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\,u^\sigma_\alpha(\vec{p})$
$e^+_{\mathrm{in}}(\vec{p},\sigma)$	$\dfrac{Z_\psi^{1/2}}{(2\pi)^{3/2}}\,(\bar{v}^\sigma)^\alpha(\vec{p})$
$\gamma_{\mathrm{in}}(\vec{k},h)$	$\dfrac{Z_A^{1/2}}{(2\pi)^{3/2}\sqrt{2\lvert\vec{k}\rvert}}\,e^{h}_\mu(\vec{k}).$

Remark 42.9 (Status of the charged entries)*.* The electron and positron rows are literal LSZ residues only in a sector whose charged spectrum contains an isolated massive one-particle shell. This is the case for an infrared-deformed theory, for instance a theory with a small gauge-invariant photon mass regulator, and it is the pole bookkeeping used in the hard part of perturbation theory. It is not an exact statement about massless four-dimensional QED after the infrared regulator is removed. Gauss' law ties nonzero electric charge to an electromagnetic field at spatial infinity, while the massless photon allows arbitrarily soft excitations with the same total charge and arbitrarily nearby energy-momentum. The charged threshold is therefore not separated from a continuum of charge plus soft photon states, and the hypothesis needed by ordinary LSZ–a delta atom or isolated pole associated with a normalizable one-electron Wigner subspace–is absent. The spinor factors below should consequently be read as hard-kernel data whose physical completion is supplied by the inclusive and dressed constructions of Chapter 44.

Proposition 42.10 (Residue origin of the external factors)**.** *Assume the spinor and photon representative two-point functions have the isolated one-particle pole data specified in Chapters 18, 40, and 41. Then the factors in Definition 42.8 are exactly the coefficients obtained by applying the LSZ boundary-value operation to the corresponding amputated kernel. A change*

$$e^h_\mu(\vec{k}) \mapsto e^h_\mu(\vec{k}) + \alpha k_\mu$$

does not change the physical photon state; it changes only the representative used before the final helicity quotient.

Proof. The spinor entries use the normalization derived in (40.8): the $2\omega_{\vec{p}}$ factor in the covariant one-particle measure is paired with the $1/(2\omega_{\vec{p}})$ in the spinor completeness relation, leaving the Fourier factor $(2\pi)^{-3/2}$ and the pole residue $Z_\psi^{1/2}$. The free spinor or photon line adjacent to the external leg is not retained: the LSZ operator removes that propagator and evaluates the residue at the one-particle pole. The displayed spinor index is contracted with the corresponding open index of the amputated Green-function kernel. In a Fourier convention in which all momenta flow into a Green function, outgoing massive particles are represented by the boundary value with the opposite energy sign; the table above is written directly in terms of the physical future-directed external momenta.

The massive spinor momenta satisfy

$$p^0 = \omega_{\vec{p}} = \sqrt{\vec{p}^2 + m^2},$$

and the photon momentum satisfies

$$k^0 = |\vec{k}|, \qquad k^2 = 0.$$

The spinors obey

$$(\not{p} - \mathrm{i}m)u^\sigma(\vec{p}) = 0, \qquad (\not{p} + \mathrm{i}m)v^\sigma(\vec{p}) = 0,$$

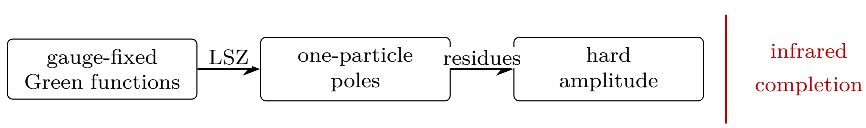
with the corresponding adjoint equations for $\bar{u}, \bar{v}$. The photon polarization representatives obey

$$k^\mu e^h_\mu(\vec{k}) = 0, \qquad e^h_\mu(\vec{k}) \sim e^h_\mu(\vec{k}) + \alpha k_\mu.$$

For any polarization representative,

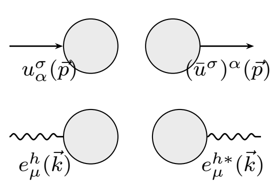
$$\not{e}^{\,h}(\vec{k}) = e^h_\mu(\vec{k})\gamma^\mu.$$

The LSZ operation removes the adjacent free propagator and leaves precisely the displayed residue vector or covector. For the photon, the quotient by longitudinal representatives is the helicity quotient constructed in Chapter 21; replacing e^h_μ by $e^h_\mu + \alpha k_\mu$ changes the representative but not the resulting one-photon helicity state. □



The vertical mark in the diagram indicates a boundary of this chapter. The hard-amplitude rules are perturbative rules for fixed external momenta and helicities. The infrared completion of charged scattering is a further construction.

Diagrammatically, the external factors attach to amputated kernels as follows:



with the common normalization factors displayed in the table.

42.5 Compton Scattering at Tree Level

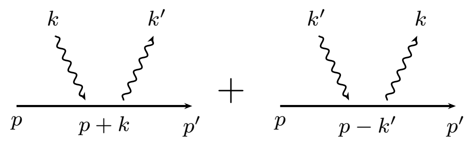
Tree-level Compton hard kernel. Consider the process

$$e^-(p,\sigma) + \gamma(k,h) \longrightarrow e^-(p',\sigma') + \gamma(k',h')$$

with

$$p + k = p' + k'.$$

At tree level two diagrams contribute:



After removing the factor

$$(2\pi)^4 \delta^{(4)}(p + k - p' - k')$$

from the scattering matrix element, the reduced amplitude is

$$\mathrm{i}\mathcal{M} = \frac{-\mathrm{i}e^2}{(2\pi)^6\sqrt{2|\vec{k}|}\sqrt{2|\vec{k}'|}}\,\bar{u}^{\sigma'}(\vec{p}')\Bigg[\not{\epsilon}^{\,h'*}(\vec{k}')\,\frac{-\mathrm{i}(\not{p}+\not{k})+m}{(p+k)^2+m^2-\mathrm{i}\epsilon}\;\not{\epsilon}^{\,h}(\vec{k})$$
$$+\;\not{\epsilon}^{\,h}(\vec{k})\,\frac{-\mathrm{i}(\not{p}-\not{k}')+m}{(p-k')^2+m^2-\mathrm{i}\epsilon}\;\not{\epsilon}^{\,h'*}(\vec{k}')\Bigg]u^{\sigma}(\vec{p}).$$

At tree level the source expansion of the representative QED Feynman rules above has exactly two connected diagrams with one internal electron line: the channel with internal momentum $p + k$ and the channel with internal momentum $p - k'$. The photon external factors are the helicity representatives in Definition 42.8; the adjacent photon propagators have already been removed by LSZ. The two cubic vertices contribute the factor e^2 in the electron convention $g = -e$, while the single internal spinor propagator contributes the displayed numerator and denominator in each channel. Removing the overall $(2\pi)^4\delta^{(4)}(p + k - p' - k')$ gives the stated reduced kernel.

In an infrared-deformed theory with ordinary charged one-particle poles, this is an LSZ-reduced expression: the external spinors and polarization vectors are the pole residues listed above. In massless QED it is the Born hard kernel. It becomes part of a physical charged-scattering prediction only after the infrared completion has been specified. At higher orders, virtual soft photons and real photons below detector resolution cannot be separated into an exact fixed-photon-number electron S-matrix element; they are combined in the inclusive or dressed constructions developed in Chapter 44.

Lemma 42.11 (Tree-level Ward identity for the Compton hard kernel)**.** *The tree-level Compton hard kernel displayed above descends from photon polarization representatives to photon helicity states. Equivalently, replacing either external photon polarization representative by that representative plus a multiple of its null momentum leaves the sum of the two tree diagrams unchanged.*

Proof. The expression descends from photon representatives to photon helicity states. Let

$$N(q) = -\mathrm{i}\,\not{q} + m, \qquad D(q) = q^2 + m^2 - \mathrm{i}\epsilon.$$

If the incoming polarization is shifted by

$$e^h_\mu(k) \mapsto e^h_\mu(k) + \alpha k_\mu,$$

then the first diagram changes by a factor proportional to

$$\frac{N(p+k)\ \not{k}}{D(p+k)} u^\sigma(p).$$

Using $p^2 = -m^2$, $k^2 = 0$, and $(\not{p} - \mathrm{i}m)u^\sigma(p) = 0$, one obtains

$$N(p+k)\ \not{k}\, u^\sigma(p) = -2\mathrm{i}(p \cdot k)u^\sigma(p), \qquad D(p+k) = 2p \cdot k - \mathrm{i}\epsilon.$$

Thus the first diagram contributes

$$-\mathrm{i}\alpha\, \bar{u}^{\sigma'}(p')\ \not{e}^{h'*}(k')u^\sigma(p)$$

up to the common prefactor. For the second diagram, momentum conservation gives $p-k' = p'-k$, and the adjoint Dirac equation gives

$$\bar{u}^{\sigma'}(p')\ \not{k}\, N(p-k') = -2\mathrm{i}(p' \cdot k)\bar{u}^{\sigma'}(p'), \qquad D(p-k') = -2p' \cdot k - \mathrm{i}\epsilon.$$

The second diagram therefore contributes

$$+\mathrm{i}\alpha\, \bar{u}^{\sigma'}(p')\ \not{e}^{h'*}(k')u^\sigma(p)$$

with the same common prefactor. The two incoming-polarization shifts cancel.

Now shift the outgoing representative by

$$e^{h'*}_\mu(k') \mapsto e^{h'*}_\mu(k') + \beta k'_\mu.$$

In the first diagram, $p + k = p' + k'$, and

$$\bar{u}^{\sigma'}(p')\ \not{k}'\, N(p+k) = -2\mathrm{i}(p' \cdot k')\bar{u}^{\sigma'}(p'), \qquad D(p+k) = 2p' \cdot k' - \mathrm{i}\epsilon.$$

It contributes

$$-\mathrm{i}\beta\, \bar{u}^{\sigma'}(p')\ \not{e}^{h}(k)u^\sigma(p)$$

up to the common prefactor. In the second diagram,

$$N(p-k')\ \not{k}'\, u^\sigma(p) = -2\mathrm{i}(p \cdot k')u^\sigma(p), \qquad D(p-k') = -2p \cdot k' - \mathrm{i}\epsilon,$$

so the contribution is

$$+\mathrm{i}\beta\, \bar{u}^{\sigma'}(p')\ \not{e}^{h}(k)u^\sigma(p).$$

The outgoing-polarization shifts cancel as well. This cancellation is the tree-level Ward identity for the Compton amplitude. □

With the cross-section normalization of Chapter 19, the total cross section for fixed incoming spin and helicity is

$$\sigma = \frac{(2\pi)^6}{v} \int \mathrm{d}^3\vec{k}'\, \mathrm{d}^3\vec{p}'\, (2\pi)^4 \delta^{(4)}(k + p - k' - p') \\ \times \sum_{\substack{h'=\pm 1 \\ \sigma'=1,2}} \left| \mathcal{M}(\vec{p}', \sigma'; \vec{k}', h' \mid \vec{p}, \sigma; \vec{k}, h) \right|^2,$$

where v is the incoming relative velocity. The spin and polarization sums are obtained from the completeness relations of Chapters 40 and 21. The reduced Compton kernel $\mathcal{M}$ is the connected on-shell matrix element after removal of the total momentum-conservation delta distribution. In the sharp-kernel event-probability formula, the final electron and photon momenta are integrated with the normalization used in the external-state chapters, while the remaining $(2\pi)^4\delta^{(4)}(k + p - k' - p')$ imposes energy-momentum conservation on the event. Summing over h' and σ' implements the inclusive measurement over final physical helicity and spin labels. The incoming spin and helicity are specified rather than averaged, so no factor averaging over initial labels appears.

42.6 Infrared Boundary of Charged Scattering

Remark 42.12 (Infrared boundary of charged QED scattering). The perturbative rules above are rules for hard Green-function residues. They are valid order by order once an infrared regulator or an inclusive prescription has been specified. The exact long-range theory has an additional constraint: Gauss' law ties electric charge to an electromagnetic field extending to arbitrarily large distances. Consequently the charged-sector asymptotic data is infrared-sensitive: its spectral support is tied to the charged mass threshold together with arbitrarily soft radiation. This lies outside the isolated massive-particle hypothesis used in the basic Haag–Ruelle construction.

This boundary is already visible in the charged dressing $\Psi_{C_x}(x)$. A dressing that retains nonzero electric charge extends to infinity. In scattering, the same long-range field is represented perturbatively by arbitrarily soft photons.

For a gauge parameter that approaches a nonzero constant on a large sphere, Gauss' law relates the total electric charge inside the sphere to the asymptotic electric flux. Thus a charged vector cannot be created from the vacuum by a compactly supported gauge-invariant operator, and a charged insertion must carry dressing data extending to the boundary as in Definition 42.4. Because the photon is massless, adding arbitrarily low-energy photons to a charged hard configuration changes the state while changing the total energy-momentum by an arbitrarily small amount. The charged mass threshold is therefore not an isolated one-particle mass shell separated by a gap from the rest of the charged spectrum. This is precisely the hypothesis ordinary massive Haag–Ruelle and the pole form of LSZ require, so the representative hard kernel must be completed by an infrared-aware construction.

The physical completions are inclusive transition probabilities, where soft photons below a resolution threshold are summed over, or dressed asymptotic charged states. Those constructions belong after renormalization and the analysis of infrared singularities. The present chapter supplies the gauge-fixed hard-amplitude rules on which that later analysis acts.

Chapter 43

QED Renormalization and Electromagnetic Form Factors

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

43.1 Regulated Variables and Ward Organization

Definition 43.1 (Regulated explicit-coupling QED coordinates)**.** Use the electron convention of Chapter 42. At a chosen perturbative regulator, use regulator-dependent representative fields and parameters

$$A^B_\mu, \qquad \psi^B, \qquad \bar{\psi}^B, \qquad m^B, \qquad e^B,$$

where the superscript B labels this cutoff-dependent coordinate system. It does not denote a second Lagrangian separate from the regulated path integral. The regulated QED Lagrangian in these coordinates is

$$\mathcal{L}_B = -\frac{1}{4} F^B_{\mu\nu} F^{\mu\nu}_B - \bar{\psi}^B \left[\gamma^\mu(\partial_\mu + \mathrm{i}e^B A^B_\mu) + m^B\right] \psi^B.$$

This is the explicit-coupling QED normalization: the photon representative has a canonical kinetic term, and the electric charge appears in the covariant derivative. It differs from the coupling-absorbed Yang–Mills normalization of Chapter 45. In the notation of (45.6), the electron convention $g = -e$ gives $A^{\mathrm{YM}}_\mu = -eA^{\mathrm{QED}}_\mu$ and $F^{\mathrm{YM}}_{\mu\nu} = -eF^{\mathrm{QED}}_{\mu\nu}$. Therefore the photon renormalization constant Z_A below is a field-residue constant in explicit-coupling coordinates; after the rescaling to Yang–Mills coordinates the same running is read from the coefficient of $(F^{\mathrm{YM}}_{\mu\nu})^2/e^2$. Introduce renormalized representative fields by

$$A^B_\mu = Z_A^{1/2} A_\mu, \qquad \psi^B = Z_\psi^{1/2}\psi, \qquad \bar\psi^B = Z_\psi^{1/2}\bar\psi.$$

The constants Z_A and Z_ψ are fixed by pole-residue normalizations in the infrared-regulated hard theory: Z_A normalizes the one-photon component of $\widehat{F}_{\mu\nu}|\Omega\rangle$, and Z_ψ normalizes the one-electron and one-positron spinor poles before the long-distance regulator is removed. In exact massless QED, Z_ψ is not a physical residue of an isolated electron Wigner particle; its infrared dependence is part of the hard-kernel bookkeeping that is combined with soft radiation in Chapter 44. Write

$$m^B = m + \delta m.$$

The renormalized charge parameter e is fixed by the electromagnetic current matrix element at zero momentum transfer. Gauge covariance of the renormalized representative derivative requires

$$e = e^B Z_A^{1/2},$$

so that

$$\partial_\mu + \mathrm{i}e^B A^B_\mu = \partial_\mu + \mathrm{i}eA_\mu.$$

Equivalently, if a separate vertex constant Z_1 is introduced by

$$e^B Z_A^{1/2} Z_\psi = eZ_1,$$

then Abelian gauge covariance gives the Ward organization

$$Z_1 = Z_\psi.$$

The same statement can be read from the renormalized representative gauge transformation,

$$A_\mu \mapsto A_\mu + \partial_\mu\xi, \qquad \psi \mapsto \mathrm{e}^{-\mathrm{i}e\xi}\psi, \qquad \bar\psi \mapsto \bar\psi\,\mathrm{e}^{\mathrm{i}e\xi}.$$

The coefficient e, not eZ_ψ, is the charge appearing in this transformation law. The common factor Z_ψ multiplies the whole spinor covariant derivative and therefore belongs to the spinor residue normalization. Thus

$$\mathcal{L}_B = -\frac{1}{4}Z_A F_{\mu\nu}F^{\mu\nu} - Z_\psi\bar\psi\left[\gamma^\mu(\partial_\mu + \mathrm{i}eA_\mu) + m + \delta m\right]\psi.$$

Equivalently, write the same regulated Lagrangian in the finite field and charge coordinates as a finite reference part plus regulator-dependent local coordinates:

$$\begin{aligned}\mathcal{L}_B = {}&\underbrace{-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \bar\psi(\gamma^\mu\partial_\mu + m)\psi - \mathrm{i}eA_\mu\bar\psi\gamma^\mu\psi}_{\mathcal{L}_{\mathrm{ren}}}\\ &- \frac{1}{4}(Z_A - 1)F_{\mu\nu}F^{\mu\nu} - (Z_\psi - 1)\bar\psi(\gamma^\mu\partial_\mu + m)\psi - Z_\psi\delta m\,\bar\psi\psi\\ &- \mathrm{i}e(Z_\psi - 1)A_\mu\bar\psi\gamma^\mu\psi.\end{aligned}$$

The last line is the vertex counterterm tied to the spinor wavefunction counterterm by the Abelian Ward identity. The mass counterterm is independent because $m\bar\psi\psi$ is gauge-invariant. These counterterm vertices are not added to a separate bare theory; they are the regulator-dependent part of the single local Lagrangian $\mathcal{L}_B$ after it has been expressed in the renormalized coordinates $A_\mu, \psi, \bar\psi, m, e$.

Ward organization of the renormalized current. In the coordinate system of Definition 43.1, the coefficient e in the renormalized gauge transformation is the same coefficient fixed by the zero-momentum electromagnetic current matrix element. If a vertex constant Z_1 is introduced by $e^B Z_A^{1/2} Z_\psi = eZ_1$, Abelian gauge covariance gives $Z_1 = Z_\psi$, and the current normalized by the renormalized field strength is

$$\partial_\nu F^{\mu\nu} = -\mathrm{i} Z_A^{-1} e Z_\psi \,\bar{\psi}\gamma^\mu\psi \equiv j^\mu.$$

The equality $e = e^B Z_A^{1/2}$ is the condition that the covariant derivative written in regulator fields, $\partial_\mu + \mathrm{i}e^B A_\mu^B$, becomes $\partial_\mu + \mathrm{i}eA_\mu$ after the field-residue change $A_\mu^B = Z_A^{1/2} A_\mu$. Therefore the renormalized representative transformation $A_\mu \mapsto A_\mu + \partial_\mu\xi$, $\psi \mapsto \exp(-\mathrm{i}e\xi)\psi$ fixes e before the spinor residue normalization is chosen. Substituting $e = e^B Z_A^{1/2}$ into $e^B Z_A^{1/2} Z_\psi = eZ_1$ gives $Z_1 = Z_\psi$. Finally vary $\mathcal{L}_B$, expressed in the finite fields of Definition 43.1, with respect to A_μ. The Maxwell term contributes $Z_A \partial_\nu F^{\mu\nu}$ and the interaction term contributes $\mathrm{i}eZ_\psi\bar{\psi}\gamma^\mu\psi$, which gives the displayed operator identity after division by Z_A.

This identity is an operator identity at separated insertions in the regulated theory. In time-ordered products, differentiating the ordering symbols may also produce local contact terms; the nonlocal momentum dependence discussed below is insensitive to such polynomial contact terms.

43.2 Photon Self-Energy and Transversality

Let

$$\langle\Omega|\,\mathrm{T}\{\widehat{A}_\mu(x)\widehat{A}_\nu(0)\}|\Omega\rangle = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\,\mathrm{e}^{\mathrm{i}k\cdot x}\,\widetilde{G}_{\mu\nu}(k).$$

The full photon representative two-point function is obtained by inserting one-particle-irreducible photon self-energies into the free propagator:

Let $\mathrm{i}\Pi^{\mu\nu}(k)$ denote the sum of amputated one-particle irreducible photon two-point insertions.

Proposition 43.2 (Transversality of the photon self-energy)**.** *Modulo local contact terms in time-ordered products, Abelian current conservation implies*

$$k_\mu \Pi^{\mu\nu}(k) = 0, \qquad k_\nu \Pi^{\mu\nu}(k) = 0.$$

The statement is about the amputated nonlocal 1PI two-point kernel and is independent of the longitudinal representative chosen for the photon propagator.

Proof. The Maxwell equation with the renormalized current has the form

$$\partial_\nu \widehat{F}^{\mu\nu} = \widehat{j}^\mu, \qquad \partial_\mu \widehat{j}^\mu = 0$$

at separated points. Let $M^{\mu\nu}(k)$ be the noncontact coefficient in the Fourier transform of $\langle\Omega|\,\mathrm{T}\,\widehat{j}^\mu(x)\widehat{j}^\nu(0)|\Omega\rangle$. Then

$$k_\mu M^{\mu\nu}(k) = 0, \qquad k_\nu M^{\mu\nu}(k) = 0.$$

On the other hand, applying $\partial_\alpha F^{\mu\alpha}$ to the photon Dyson series acts on each external photon line by the transverse differential operator

$$k^2\eta^{\mu\rho} - k^\mu k^\rho.$$

The local contact terms are polynomials in k. The nonlocal part is therefore transverse only if the amputated 1PI insertion obeys

$$k_\mu \Pi^{\mu\nu}(k) = 0.$$

This is the two-photon consequence of a linear Ward–Takahashi identity. If $\Gamma_{\mathrm{inv}}[A,\psi,\bar\psi]$ denotes the gauge-invariant part of the QED 1PI functional, the infinitesimal transformation

$$\delta_\alpha A_\mu = \partial_\mu\alpha, \qquad \delta_\alpha\psi = -\mathrm{i}e\alpha\psi, \qquad \delta_\alpha\bar\psi = \mathrm{i}e\alpha\bar\psi$$

gives

$$\mathcal{W}_\alpha\Gamma_{\mathrm{inv}} := \int \left[\partial_\mu\alpha\,\frac{\delta\Gamma_{\mathrm{inv}}}{\delta A_\mu} - \mathrm{i}e\alpha\psi\,\frac{\delta_L\Gamma_{\mathrm{inv}}}{\delta\psi} + \mathrm{i}e\alpha\bar\psi\,\frac{\delta_R\Gamma_{\mathrm{inv}}}{\delta\bar\psi}\right]\mathrm{d}^4x = 0.$$

The operator $\mathcal{W}_\alpha$ is fixed before Γ_{inv} is known; hence the identity is linear in Γ_{inv}. Differentiating twice with respect to A and then setting the fields to zero gives transversality of the photon 1PI two-point kernel, up to the local contact terms already separated above. The nonabelian Slavnov–Taylor identity in Chapter 47 has a different mathematical form: because the BRST variations of A_μ and c are composite local fields, the corresponding 1PI identity is quadratic in Γ, as in (47.44). □

Lorentz covariance then gives the tensor decomposition

$$\Pi^{\mu\nu}(k) = (\eta^{\mu\nu}k^2 - k^\mu k^\nu)\pi(k^2)$$

for a scalar function π.

In covariant gauge, with gauge parameter ξ_{g}, the resummed propagator is

$$\widetilde{G}_{\mu\nu}(k) = \frac{-\mathrm{i}}{k^2 - \mathrm{i}\epsilon}\left[\frac{\eta_{\mu\nu}}{1-\pi(k^2)} - \frac{k_\mu k_\nu}{k^2 - \mathrm{i}\epsilon}\left(1 - \xi_{\mathrm{g}} + \frac{\pi(k^2)}{1-\pi(k^2)}\right)\right].$$

The longitudinal part depends on the representative gauge choice. The transverse pole is normalized by imposing

$$\pi(0) = 0$$

for the massive-electron theory, where the loop function is regular at the photon point $k^2 = 0$.

43.3 One-Loop Vacuum Polarization

Lemma 43.3 (One-loop QED vacuum polarization in explicit-coupling coordinates)**.** *In the regulator convention of Definition 43.1, dimensional continuation to $D = 4 - \epsilon$ and the pole normalization $\pi(0) = 0$ give*

$$Z_A = 1 - \frac{e^2}{6\pi^2}\frac{1}{\epsilon} + \text{finite},$$

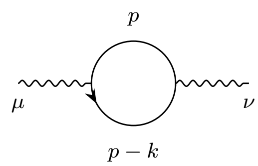
and the cutoff-removed one-loop transverse photon form factor is

$$\pi(k^2) = \frac{e^2}{2\pi^2}\int_0^1 \mathrm{d}x\, x(1-x)\log\frac{m^2 + x(1-x)k^2}{m^2}.$$

Proof. The photon counterterm contributes

$$= -\mathrm{i}(Z_A - 1)(k^2\eta_{\mu\nu} - k_\mu k_\nu),$$

which contributes $1 - Z_A$ to $\pi(k^2)$. The one-loop electron diagram is



and equals

$$\mathrm{i}\Pi^{(1)}_{\mu\nu}(k) = -\int \frac{\mathrm{d}^4p}{(2\pi)^4}\,\mathrm{Tr}\left[e\gamma_\mu\,\frac{-\mathrm{i}(-\mathrm{i}\,\not{p} + m)}{p^2 + m^2 - \mathrm{i}\epsilon}\,e\gamma_\nu\,\frac{-\mathrm{i}(-\mathrm{i}(\not{p} - \not{k}) + m)}{(p-k)^2 + m^2 - \mathrm{i}\epsilon}\right].$$

The minus sign is the closed fermion loop. Continue the integral to $D = 4-\epsilon$ dimensions, keeping

$$\{\gamma_\mu, \gamma_\nu\} = 2\eta_{\mu\nu}, \qquad \eta^{\mu\nu}\eta_{\mu\nu} = D, \qquad \mathrm{Tr}\,\mathbf{1} = 4.$$

After Wick rotation and the Feynman-parameter identity

$$\frac{1}{ab} = \int_0^1 \mathrm{d}x\,\frac{1}{\bigl(xa + (1-x)b\bigr)^2},$$

shift

$$p \mapsto p + xk.$$

The denominator becomes

$$\bigl(p^2 + x(1-x)k^2 + m^2\bigr)^2.$$

The trace identity

$$\mathrm{Tr}(\gamma_\mu\gamma_\alpha\gamma_\nu\gamma_\beta) = 4(\eta_{\mu\alpha}\eta_{\nu\beta} - \eta_{\mu\nu}\eta_{\alpha\beta} + \eta_{\mu\beta}\eta_{\nu\alpha})$$

reduces the numerator. Rotational symmetry in the continued loop momentum allows

$$p_\mu p_\nu \mapsto \frac{1}{D}\eta_{\mu\nu}p^2$$

inside the integral, and all terms linear in p vanish. With

$$M_x^2 = m^2 + x(1-x)k^2,$$

the angularly averaged numerator can be written as

$$\begin{aligned} N_{\mu\nu} = 4\Bigl[\eta_{\mu\nu}\bigl(p^2 - x(1-x)k^2 + m^2\bigr) - \frac{2}{D}\eta_{\mu\nu}p^2 \\ + 2x(1-x)k_\mu k_\nu\Bigr]. \end{aligned}$$

The two scalar integrals needed are

$$\begin{aligned} \int \frac{\mathrm{d}^Dp}{(2\pi)^D}\frac{1}{(p^2 + M_x^2)^2} &= \frac{1}{(4\pi)^{D/2}}\Gamma(2 - D/2)(M_x^2)^{D/2-2}, \\ \int \frac{\mathrm{d}^Dp}{(2\pi)^D}\frac{p^2}{(p^2 + M_x^2)^2} &= \frac{D}{2}\frac{1}{(4\pi)^{D/2}}\Gamma(1 - D/2)(M_x^2)^{D/2-1}, \end{aligned}$$

where the second formula is defined by analytic continuation in D. Substitution cancels the nontransverse local-looking pieces and leaves the transverse tensor

$$\Pi^{(1)}_{\mu\nu}(k) = -(\eta_{\mu\nu}k^2 - k_\mu k_\nu)\frac{8e^2}{(4\pi)^{D/2}}\Gamma(2-D/2)\int_0^1 \mathrm{d}x\, x(1-x)\big(m^2 + x(1-x)k^2\big)^{D/2-2}.$$

With the counterterm included,

$$\pi(k^2) = 1 - Z_A - \frac{8e^2}{(4\pi)^{D/2}}\Gamma(2-D/2)\int_0^1 \mathrm{d}x\, x(1-x)\big(m^2 + x(1-x)k^2\big)^{D/2-2}.$$

The pole normalization $\pi(0) = 0$ fixes

$$Z_A = 1 - \frac{8e^2}{(4\pi)^{D/2}}\Gamma(2-D/2)\frac{1}{6}\, m^{D-4}.$$

For $D = 4 - \epsilon$, this has the pole part

$$Z_A = 1 - \frac{e^2}{6\pi^2}\frac{1}{\epsilon} + \text{finite}.$$

Subtracting the value at $k^2 = 0$ and taking $D \to 4$ gives the finite one-loop vacuum-polarization function

$$\pi(k^2) = \frac{e^2}{2\pi^2}\int_0^1 \mathrm{d}x\, x(1-x)\log\frac{m^2 + x(1-x)k^2}{m^2}.$$

This $\pi(k^2)$ is the cutoff-removed form factor: in a cutoff realization it is the $\Lambda \to \infty$ limit of the renormalized transverse coefficient in the photon two-point matrix element, with the charge normalization $\pi(0) = 0$ held fixed. In dimensional regularization the same statement is represented by the analytic continuation to $D = 4$ after the local counterterm Z_A has subtracted the ultraviolet pole. □

43.4 The Electron Current Matrix Element

Definition 43.4 (Electron electromagnetic form factors)**.** Let $|\vec{p}, \sigma\rangle$ be a one-electron state of charge $q = -e$. Translation covariance gives

$$\langle \vec{p}\,', \sigma'|\widehat{j}^{\mu}(x)|\vec{p}, \sigma\rangle = \mathrm{e}^{\mathrm{i}(p-p')\cdot x}\langle \vec{p}\,', \sigma'|\widehat{j}^{\mu}(0)|\vec{p}, \sigma\rangle.$$

Write the matrix element as

$$\langle \vec{p}\,', \sigma'|\widehat{j}^{\mu}(0)|\vec{p}, \sigma\rangle = \frac{\mathrm{i}q}{(2\pi)^3}\bar{u}^{\sigma'}(\vec{p}\,')M^{\mu}(p', p)u^{\sigma}(\vec{p}).$$

Modulo the on-shell Dirac equations

$$(\not{p} - \mathrm{i}m)u^{\sigma}(\vec{p}) = 0, \qquad \bar{u}^{\sigma'}(\vec{p}\,')(\not{p}' - \mathrm{i}m) = 0,$$

a parity-even Lorentz vector between spinor solutions can be reduced, by the Clifford algebra, to the span of

$$\gamma^{\mu}, \qquad (p + p')^{\mu}, \qquad (p - p')^{\mu}.$$

Terms with γ_5 are excluded by parity, and terms with $[\gamma^\mu, \gamma^\nu]$ are equivalent to the displayed basis by the Gordon identity. Current conservation removes the component proportional to $(p-p')^\mu$. Therefore

$$M^\mu(p', p) = \gamma^\mu F(k^2) - \frac{\mathrm{i}}{2m}(p+p')^\mu G(k^2), \qquad k = p - p'.$$

The scalar functions F and G are the electromagnetic form factors in the present gamma-matrix convention and in the $(p+p')^\mu$ basis. For comparison with the Dirac–Pauli basis, let F_1^{DP} and F_2^{DP} be defined in this same gamma-matrix convention by

$$\bar{u}(p')M^\mu u(p) = \bar{u}(p')\left[\gamma^\mu F_1^{\mathrm{DP}}(k^2) + \left(\gamma^\mu + \frac{\mathrm{i}}{2m}(p+p')^\mu\right) F_2^{\mathrm{DP}}(k^2)\right] u(p).$$

The second structure is the Gordon-identity form of the Pauli tensor structure. Indeed, with

$$S^{\mu\nu} = -\frac{\mathrm{i}}{4}[\gamma^\mu, \gamma^\nu], \qquad k = p - p',$$

the on-shell identity displayed below gives

$$\bar{u}(p')\frac{1}{m}S^{\mu\nu}k_\nu u(p) = \bar{u}(p')\left(\gamma^\mu + \frac{\mathrm{i}}{2m}(p+p')^\mu\right) u(p). \tag{43.1}$$

Thus F_2^{DP} is the coefficient of the Pauli tensor $m^{-1}S^{\mu\nu}k_\nu$, not the coefficient of $(p+p')^\mu$ alone. Its matrix element vanishes at $p' = p$. Comparing coefficients with the displayed (F, G) decomposition gives

$$F_1^{\mathrm{DP}} = F + G, \qquad F_2^{\mathrm{DP}} = -G, \qquad F = F_1^{\mathrm{DP}} + F_2^{\mathrm{DP}}.$$

Thus the charge normalization below, $F(0) + G(0) = 1$, is precisely $F_1^{\mathrm{DP}}(0) = 1$, while the anomalous magnetic moment is $F_2^{\mathrm{DP}}(0) = -G(0)$.

With the plane-wave normalization and current normalization used in Definition 43.4, charge normalization fixes one combination at zero momentum transfer. The condition $\widehat{Q}|\vec{p}, \sigma\rangle = q|\vec{p}, \sigma\rangle$, where $\widehat{Q} = \int \mathrm{d}^3\vec{x}\,\widehat{j}^0(x)$, is equivalent to

$$F(0) + G(0) = 1. \tag{43.2}$$

Indeed, taking $p' \to p$, using

$$\bar{u}^{\sigma'}(\vec{p})u^\sigma(\vec{p}) = \frac{m}{p^0}\delta_{\sigma\sigma'},$$

and using the Dirac equations to rewrite

$$p^\mu \bar{u}^{\sigma'}(\vec{p})u^\sigma(\vec{p}) = \mathrm{i}m\,\bar{u}^{\sigma'}(\vec{p})\gamma^\mu u^\sigma(\vec{p}),$$

one obtains

$$\langle\vec{p}, \sigma'|\widehat{j}^\mu(0)|\vec{p}, \sigma\rangle = \frac{q}{(2\pi)^3}\frac{p^\mu}{p^0}\delta_{\sigma\sigma'}\big(F(0) + G(0)\big).$$

The charge operator

$$\widehat{Q} = \int \mathrm{d}^3\vec{x}\,\widehat{j}^0(x)$$

acts by

$$\widehat{Q}|\vec{p}, \sigma\rangle = q|\vec{p}, \sigma\rangle.$$

Thus

$$F(0) + G(0) = 1.$$

The equality is a distributional momentum-state identity: after smearing the external plane waves by a common wave packet and then removing the smearing, the spatial integral supplies the same $\delta^{(3)}(\vec{p}' - \vec{p})$ on both sides.

43.5 Magnetic Moment from the Form Factor

Proposition 43.5 (Magnetic factor in the (F, G) basis)**.** *For an electron current matrix element written in the basis of Definition 43.4, the spin-dependent coupling to a slowly varying external magnetic field is*

$$\Delta H_{\text{spin}} = -g_{\text{mag}} \frac{q}{2m} \vec{B} \cdot \frac{\vec{\sigma}}{2}, \qquad g_{\text{mag}} = 2F(0) = 2\bigl(1 - G(0)\bigr).$$

Proof. Couple the current to a weak classical background:

$$\Delta H = -\int \mathrm{d}^3\vec{x}\, A^{\text{cl}}_\mu(x) \widehat{j}^\mu(x).$$

For a slowly varying magnetic field choose

$$A^{\text{cl}}_0 = 0, \qquad \nabla \times \vec{A}^{\text{cl}} = \vec{B}.$$

The part of the form-factor matrix element proportional to $(p + p')^\mu$ gives the spin-independent Lorentz-force contribution in the nonrelativistic limit. The spin-dependent term is exposed by writing the $\gamma^\mu F$ term with the Gordon identity. Equivalently, after an integration by parts,

$$\int \mathrm{d}^3\vec{x}\, A^{\text{cl}}_i(x)\, \mathrm{e}^{\mathrm{i}(\vec{p}-\vec{p}')\cdot\vec{x}} (p' - p)_j S^{ij} = \frac{\mathrm{i}}{2} \int \mathrm{d}^3\vec{x}\, \mathrm{e}^{\mathrm{i}(\vec{p}-\vec{p}')\cdot\vec{x}} F^{\text{cl}}_{ij}(x) S^{ij},$$

up to terms higher order in the spatial momentum transfer; only the antisymmetric part contributes to the spin coupling. The spin-dependent part of $\langle \vec{p}', \sigma' | \Delta H | \vec{p}, \sigma \rangle$ is obtained from the identity

$$\begin{aligned} &\bar{u}^{\sigma'}(\vec{p}')[\gamma^\mu, \gamma^\nu](p' - p)_\nu u^\sigma(\vec{p}) \\ &\quad = -4\mathrm{i}m\, \bar{u}^{\sigma'}(\vec{p}')\gamma^\mu u^\sigma(\vec{p}) + 2(p^\mu + p'^\mu)\bar{u}^{\sigma'}(\vec{p}')u^\sigma(\vec{p}), \end{aligned}$$

with

$$S^{\mu\nu} = -\frac{\mathrm{i}}{4}[\gamma^\mu, \gamma^\nu].$$

In the nonrelativistic limit $|\vec{p}|, |\vec{p}'| \ll m$, the spin coupling becomes

$$\Delta H_{\text{spin}} = -\frac{qF(0)}{2m} \vec{B} \cdot \vec{\sigma}.$$

Writing this as

$$\Delta H_{\text{spin}} = -g_{\text{mag}} \frac{q}{2m} \vec{B} \cdot \frac{\vec{\sigma}}{2},$$

the magnetic factor is

$$g_{\text{mag}} = 2F(0).$$

Together with $F(0) + G(0) = 1$, this gives

$$g_{\text{mag}} = 2\bigl(1 - G(0)\bigr).$$

□

43.6 One-Loop Vertex Correction

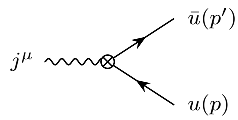
Proposition 43.6 (Schwinger term in the electron magnetic factor)**.** *In the same ultraviolet and infrared hard-kernel convention used for Lemma 43.3, the one-loop vertex correction gives*

$$G(0) = -\frac{e^2}{8\pi^2} = -\frac{\alpha}{2\pi}, \qquad g_{\mathrm{mag}} = 2 + \frac{\alpha}{\pi} + O(\alpha^2), \qquad \alpha = \frac{e^2}{4\pi}.$$

Proof. The current is represented by

$$\widehat{j}^\mu = -\mathrm{i} Z_A^{-1} e\, Z_\psi\, \bar{\psi}\gamma^\mu\psi = -\mathrm{i} e^B Z_A^{-1/2} Z_\psi\, \bar{\psi}\gamma^\mu\psi.$$

Within the same infrared-regulated hard-kernel convention, the current insertion between external electron labels is computed by reducing the external spinor legs by LSZ:



If the three-point function is written in bare fields, each external fermion leg supplies a factor $Z_\psi^{1/2}$ in the LSZ residue. If it is written in renormalized fields, those factors are absent from the external residues but reappear through the counterterm vertices. These two bookkeepings give the same matrix element. After removing the infrared regulator in massless QED, this exclusive one-electron matrix element is not an autonomous physical scattering amplitude. The hard form factor is one factor in either an inclusive probability, where unresolved photons are summed over, or a dressed-state matrix element whose charged asymptotic state already contains the soft electromagnetic field.

The tree current vertex gives

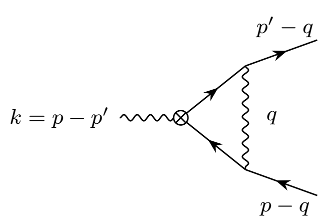
$$-\mathrm{i} Z_A^{-1} e\, \frac{Z_\psi}{(2\pi)^3} \bar{u}^{\sigma'}(\vec{p}')\gamma^\mu u^\sigma(\vec{p}).$$

The current insertion can also be followed by any number of photon self-energy insertions before the photon attaches to the electron line. The transverse photon chain contributes $Z_A/(1-\pi(k^2))$, so the whole tree-plus-vacuum-polarization chain contributes

$$-\mathrm{i} e\, \frac{Z_\psi}{(2\pi)^3} \frac{1}{1-\pi(k^2)} \bar{u}^{\sigma'}(\vec{p}')\gamma^\mu u^\sigma(\vec{p}).$$

This changes only the coefficient of γ^μ, hence only $F(k^2)$. It does not contribute to $G(k^2)$.

At order e^2, the contribution to $G(k^2)$ comes from the vertex correction



in Feynman gauge. Its integrand is

$$-\,\mathrm{i}Z_A^{-1}e\,\frac{Z_\psi}{(2\pi)^3}\int\frac{\mathrm{d}^4q}{(2\pi)^4}\frac{-\mathrm{i}}{q^2-\mathrm{i}\epsilon}\,\bar u(p')\,e\gamma^\rho\frac{-\mathrm{i}[-\mathrm{i}(\not p'-\not q)+m]}{(p'-q)^2+m^2-\mathrm{i}\epsilon}$$
$$\times\,\gamma^\mu\frac{-\mathrm{i}[-\mathrm{i}(\not p-\not q)+m]}{(p-q)^2+m^2-\mathrm{i}\epsilon}e\gamma_\rho\,u(p).$$

To isolate the term that affects the magnetic moment, Wick rotate, continue the loop integral dimensionally, and combine the three denominators

$$D_0=q^2,\qquad D_1=(p'-q)^2+m^2,\qquad D_2=(p-q)^2+m^2$$

by the simplex coordinates

$$z_0=1-x,\qquad z_1=y,\qquad z_2=x-y,\qquad 0\le y\le x\le 1.$$

On the external mass shell $p^2=p'^2=-m^2$, $k=p-p'$, one has

$$z_0D_0+z_1D_1+z_2D_2=\ell^2+m^2x^2+k^2y(x-y),\qquad q=\ell+yp'+(x-y)p.$$

Thus

$$\frac{1}{D_0D_1D_2}=2\int_0^1\mathrm{d}x\int_0^x\mathrm{d}y\,\frac{1}{\big(\ell^2+m^2x^2+k^2y(x-y)\big)^3}.$$

The external Dirac equations and the Clifford algebra reduce every parity-even vector bilinear between the on-shell spinors to the two-basis form

$$\bar u(p')\gamma^\mu u(p)\,A(k^2)+(p+p')^\mu\bar u(p')u(p)\,B(k^2).$$

The scalar $B(k^2)$ is the coefficient of the second basis vector in this on-shell quotient; for $k^2\neq 0$ it is obtained by solving the resulting two-by-two Gram system, and the $k^2=0$ value used below is the regular limit. Terms odd in ℓ vanish, and the $\ell_\alpha\ell_\beta$ terms are replaced by $D^{-1}\eta_{\alpha\beta}\ell^2$ before the scalar integrals are evaluated. The Pauli-coordinate projection of the finite part gives

$$B(k^2)=\frac{\mathrm{i}e^2m}{8\pi^2}\int_0^1\mathrm{d}x\int_0^x\mathrm{d}y\,\frac{x(1-x)}{m^2x^2+k^2y(x-y)}.$$

Since the form-factor definition is $B(k^2)=-\mathrm{i}G(k^2)/(2m)$, this is equivalent to the formula below. The scalar $A(k^2)$ contains ultraviolet and infrared singular terms whose contribution is fixed by the charge normalization and the spinor wavefunction counterterm. The scalar $B(k^2)$ is finite at this order and determines $G(k^2)$. The resulting coefficient is

$$G(k^2)=-\frac{e^2m^2}{4\pi^2}\int_0^1\mathrm{d}x\int_0^x\mathrm{d}y\,\frac{x(1-x)}{m^2x^2+k^2y(x-y)}.$$

The displayed $G(k^2)$ is again the cutoff-removed form factor: for fixed external on-shell wave packets and fixed nonzero momentum-transfer invariant away from infrared singular loci, it is the ultraviolet-regulator removal limit of the renormalized coefficient multiplying $(p+p')^\mu\bar u(p')u(p)$ in the current matrix element. The charge normalization and the wavefunction counterterm determine the accompanying γ^μ coefficient, while no additional ultraviolet subtraction is needed for this one-loop $G(k^2)$. At zero momentum transfer,

$$\int_0^1\mathrm{d}x\int_0^x\mathrm{d}y\,\frac{x(1-x)}{m^2x^2}=\frac{1}{2m^2},\qquad G(0)=-\frac{e^2}{8\pi^2}.$$

With

$$\alpha = \frac{e^2}{4\pi},$$

the one-loop magnetic factor is

$$g_{\text{mag}} = 2\big(1 - G(0)\big) = 2 + \frac{\alpha}{\pi} + O(\alpha^2).$$

44.1 Soft Radiation Data

The scattering constructions developed earlier are simplest when all asymptotic particles are massive. Four-dimensional QED has a massless stable photon, and a charged particle may emit photons of arbitrarily small energy. This chapter constructs the scattering quantities adapted to that long-distance structure. The ordinary LSZ theorem for a charged external electron would require an isolated massive charged pole. Massless QED instead has charged threshold data accompanied by arbitrarily soft electromagnetic radiation. The fixed hard charged labels used below are therefore not exact fixed-photon-number Wigner-particle S-matrix labels. They are hard data in an infrared-regulated factorization problem; physical charged scattering is attached either to detector-inclusive probabilities or to asymptotic states dressed by their soft electromagnetic fields.

Throughout the chapter, spacetime is $D = 4$ Minkowski space with metric

$$\eta_{\mu\nu} = \mathrm{diag}(-1, +1, +1, +1).$$

Consider a hard transition

$$\alpha \longrightarrow \beta$$

between massive charged particles. The hard external charged lines are labelled by n. Their momenta are p_n, their charges are g_n, and

$$p_n^2 = -m_n^2, \qquad p_n^0 > 0.$$

The sign

$$\eta_n = \begin{cases} +1, & n \in \beta \quad \text{outgoing}, \\ -1, & n \in \alpha \quad \text{incoming} \end{cases}$$

records whether the line is outgoing or incoming. Charge conservation for the hard process is

$$\sum_n \eta_n g_n = 0.$$

The charge symbols used in the QED chapters are related as follows.

context	symbol	meaning
Chapter 42	g	signed Abelian charge in $D_\mu = \partial_\mu - \mathrm{i}gA_\mu$; for an electron $g = -e$, with $e > 0$.
Chapter 43	$e,\ e^B$	positive magnitude of the electron charge and its bare counterpart; the electron covariant derivative is $\partial_\mu + \mathrm{i}eA_\mu$, and $e = e^B Z_A^{1/2}$.
this chapter	g_n	signed physical charge of the n-th hard external line; an electron has $g_n = -e$, a positron has $g_n = +e$, and an external scalar of charge g in the scalar-QED example has $g_n = g$.

Thus η_n records whether the charged line is incoming or outgoing, whereas g_n records the physical sign of the charge carried by that line.

A soft photon has momentum

$$k^\mu = (\omega, \vec{k}), \qquad \omega = |\vec{k}|,$$

and physical helicity $h = \pm$. The detector threshold is denoted by E_T: photons below this energy are included in the same observed hard event. An auxiliary infrared cutoff μ will regulate intermediate formulas, and M denotes a soft upper scale below which the eikonal approximation is valid:

$$0 < \mu < E_T < M.$$

Definition 44.1 (Regulated resolution-inclusive transition probability)**.** Let $S^{(\mu)}_{\beta;\{k_r,h_r\}|\alpha}$ denote an infrared-regulated hard kernel with hard charged configuration β, incoming hard charged configuration α, and additional photons (k_r, h_r). The superscript (μ) records the auxiliary long-distance regulator. The object $S^{(\mu)}$ may be obtained from a regulated LSZ computation, but it is not assumed to have a regulator-independent fixed-photon-number limit. The regulated resolution-inclusive probability at threshold E_T is the sum

$$P^{(\mu)}_{\beta|\alpha}(E_T) = \sum_{N=0}^{\infty} \frac{1}{N!} \sum_{h_1,\ldots,h_N} \int_{\mathcal{R}_{E_T}} \prod_{r=1}^{N} \frac{\mathrm{d}^3\vec{k}_r}{(2\pi)^3\, 2\omega_r} \left| S^{(\mu)}_{\beta;\{k_r,h_r\}|\alpha} \right|^2,$$

where $\mathcal{R}_{E_T}$ is the detector-degenerate soft region. At leading soft logarithmic order one may take $\mu < \omega_r < E_T$ independently for each unresolved photon. Refining the detector model changes finite functions of E_T/M, but not the cancellation of the regulator μ. The regulator-free inclusive probability is not the termwise limit of the summands at fixed N; it is the ordered limit constructed in Section 44.5.

44.2 External-Line Soft Factors

In scalar QED, attach an outgoing photon of momentum k and polarization vector $e_h^\mu(k)$ to an outgoing external scalar line of momentum p. The factor multiplying the hard amplitude is

$$(-\mathrm{i})\,\frac{1}{(p+k)^2+m^2-\mathrm{i}\epsilon}\,\mathrm{i}g(2p+k)^\mu e^*_{h,\mu}(k).$$

Since $p^2+m^2=0$ and $k^2=0$, the leading term as $k\to 0$ is

$$g\,\frac{p\cdot e_h^*(k)}{p\cdot k-\mathrm{i}\epsilon}.$$

The denominator is linear in the photon energy. The soft photon therefore couples to the charge and momentum of the external line, while the internal structure of the hard subdiagram is unresolved at leading order.

For the hard transition $\alpha\to\beta$, the one-soft-photon amplitude is

$$\mathcal{M}_{\beta;k,h|\alpha}=\mathcal{M}_{\beta|\alpha}\left[\sum_n \frac{g_n\,p_n\cdot e_h^*(k)}{\eta_n p_n\cdot k-\mathrm{i}\epsilon}\right]+O(k^0).$$

The same leading factor is obtained in spinor QED. The numerator of the nearly on-shell fermion propagator acts on the external spinor and reduces to the corresponding momentum factor; spin first enters in subleading soft terms. Indeed, for an outgoing fermion line the soft attachment contains

$$\left[\bar u^\sigma(p)(-g\gamma^\mu)\frac{-\mathrm{i}[-\mathrm{i}(\not p+\not k)+m]}{(p+k)^2+m^2-\mathrm{i}\epsilon}\right]e^*_{h,\mu}(k).$$

The denominator is $2p\cdot k-\mathrm{i}\epsilon+O(k^2)$. In the numerator, using the on-shell equation for the external spinor and moving γ^μ through the Dirac numerator gives

$$\bar u^\sigma(p)\gamma^\mu(-\mathrm{i}\not p+m)=\bar u^\sigma(p)(\mathrm{i}\not p+m)\gamma^\mu-2\mathrm{i}p^\mu\bar u^\sigma(p)=-2\mathrm{i}p^\mu\bar u^\sigma(p).$$

Thus the leading soft limit is

$$g\,\frac{p\cdot e_h^*(k)}{p\cdot k-\mathrm{i}\epsilon}\,\bar u^\sigma(p),$$

the same eikonal factor multiplying the original spinor amplitude.

Theorem 44.2 (Weinberg leading soft photon theorem)**.** *Fix an infrared regulator and hard external data for which the hard kernel $\mathcal{M}_{\beta|\alpha}$ is defined and smooth under the addition of one photon of momentum $k^\mu=\omega(1,\widehat{k})$ with $\omega\to 0^+$, away from nonsoft singular surfaces. Then the hard kernel with one additional outgoing physical photon of helicity h satisfies*

$$\mathcal{M}_{\beta;k,h|\alpha}=S_\gamma^{(0)}(k,h)\,\mathcal{M}_{\beta|\alpha}+O(\omega^0),\qquad S_\gamma^{(0)}(k,h)=\sum_n \eta_n g_n\,\frac{p_n\cdot e_h^*(k)}{p_n\cdot k}. \tag{44.1}$$

The sum runs over all hard charged external lines, with $\eta_n = +1$ for outgoing and $\eta_n = -1$ for incoming hard lines. The $i\epsilon$ prescription in the preceding external-line formula specifies the boundary value of the regulated kernel; the theorem displays the homogeneous leading soft factor.

Proof. The scalar and spinor calculations above show that attaching the soft photon to an external hard line produces the pole

$$\eta_n g_n \frac{p_n \cdot e_h^*(k)}{p_n \cdot k} \mathcal{M}_{\beta|\alpha}.$$

The sign η_n is the crossing sign: an incoming charged line is equivalently an outgoing line with momentum and charge flow reversed in the all-outgoing Ward identity. Attachments to internal lines are less singular in the uniform soft limit at fixed nonexceptional hard kinematics, because no internal propagator is forced onto a new mass shell by adding a momentum k of order ω. Summing the external-line poles gives (44.1).

Gauge invariance fixes the allowed leading pole. A physical photon polarization representative is defined modulo

$$e_h^\mu(k) \sim e_h^\mu(k) + c\, k^\mu.$$

Under this replacement, the leading factor shifts by

$$\delta S_\gamma^{(0)} = c^* \sum_n \eta_n g_n.$$

Thus the unphysical longitudinal polarization decouples precisely when the hard process obeys charge conservation,

$$\sum_n \eta_n g_n = 0.$$

This is the Ward identity for the global $U(1)$ charge written in the external hard basis. Conversely, a nonzero coefficient of the longitudinal soft pole would mean that the regulated hard kernel had not descended to a physical photon helicity amplitude. $\square$

Figure 44.1 records this leading-soft Ward identity: attaching a soft photon to the charged hard external lines gives the eikonal factor, and the longitudinal part cancels precisely by charge conservation.

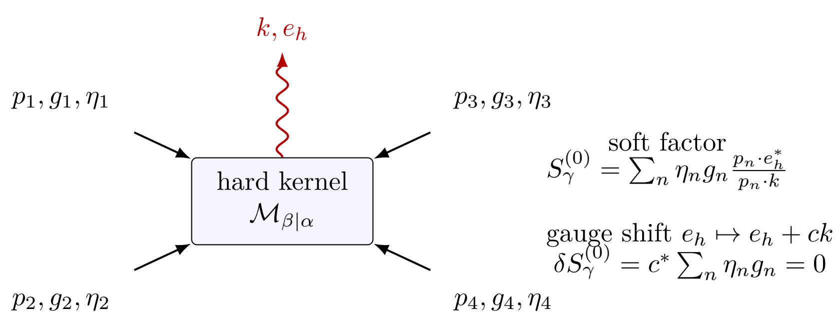

Figure 44.1: The leading soft photon factor is the sum of external-line poles. Replacing the polarization by a pure gauge vector tests the Ward identity; the pole descends to the physical photon helicity space exactly when the hard charges are conserved.

Theorem 44.3 (Weinberg leading soft graviton theorem)**.** *Consider an infrared-regulated theory with a massless spin-two gauge field whose representative is normalized by*

$$g_{\mu\nu} = \eta_{\mu\nu} + \kappa h_{\mu\nu}, \qquad \mathcal{L}_{\text{int}} = -\frac{\kappa}{2} h_{\mu\nu} T^{\mu\nu}.$$

For one additional outgoing graviton of momentum k and physical polarization tensor $\varepsilon^{(\lambda)}_{\mu\nu}(k)$, the leading soft limit is

$$\mathcal{M}^{\text{grav}}_{\beta;k,\lambda|\alpha} = S^{(0)}_{\text{grav}}(k,\lambda)\,\mathcal{M}_{\beta|\alpha} + O(\omega^0), \qquad S^{(0)}_{\text{grav}} = \frac{\kappa}{2}\sum_n \eta_n \frac{p_n^\mu p_n^\nu \varepsilon^{(\lambda)*}_{\mu\nu}(k)}{p_n \cdot k}. \tag{44.2}$$

Proof. The stress-tensor vertex on an external massive line contains, at leading order in the soft momentum, the matrix element of the hard momentum carried by that line. For a scalar line, the one-graviton vertex contracted with a transverse traceless polarization gives

$$\kappa\, p^\mu p^\nu \varepsilon^*_{\mu\nu}(k)$$

up to terms less singular in k, while the adjacent nearly on-shell propagator gives $(2\eta_n p_n \cdot k)^{-1}$. Their product is the $(\kappa/2)\eta_n p_n^\mu p_n^\nu \varepsilon^*_{\mu\nu}/(p_n \cdot k)$ term in (44.2). Spin-dependent terms in the stress tensor contain an additional power of the soft momentum or the Lorentz generator and therefore begin at subleading order. Summing over the hard external lines gives (44.2).

The physical spin-two polarization is defined modulo the linearized diffeomorphism shift

$$\varepsilon_{\mu\nu} \sim \varepsilon_{\mu\nu} + k_\mu \xi_\nu + k_\nu \xi_\mu, \qquad k \cdot \xi = 0$$

on the null momentum k. The leading soft factor changes by

$$\delta S^{(0)}_{\text{grav}} = \kappa \xi^*_\nu \sum_n \eta_n p_n^\nu.$$

This vanishes by hard momentum conservation. If the coefficient of $h_{\mu\nu}T^{\mu\nu}$ depended on the species, the same gauge variation would contain

$$\sum_n \eta_n \kappa_n p_n^\nu,$$

which does not vanish for arbitrary allowed hard reactions unless all κ_n are the same constant. The leading soft spin-two theorem therefore packages both the external-line pole and the universality of the gravitational coupling. □

The photon theorem is the input used in the rest of this chapter. The graviton theorem is recorded here because it is the same infrared consequence of a massless gauge particle and gauge-invariant factorization. A complete quantum theory containing the spin-two field requires additional ultraviolet and nonperturbative input not used in the soft argument.

For N real soft photons the leading factors multiply:

$$\mathcal{M}_{\beta;\{k_r,h_r\}|\alpha} = \mathcal{M}_{\beta|\alpha} \prod_{r=1}^{N} \left[\sum_n \frac{g_n\, p_n \cdot e^*_{h_r}(k_r)}{\eta_n p_n \cdot k_r - \mathrm{i}\epsilon} \right] + O(k_r^0).$$

For two photons emitted from the same line, the two possible orderings of the emissions turn the nested eikonal denominators into the product displayed above. For an outgoing scalar line this is the elementary identity

$$\frac{g\,p\cdot e^*_{h_2}(k_2)}{p\cdot k_2-\mathrm{i}\epsilon}\,\frac{g\,p\cdot e^*_{h_1}(k_1)}{p\cdot(k_1+k_2)-\mathrm{i}\epsilon}+(1\leftrightarrow 2)$$
$$=\frac{g\,p\cdot e^*_{h_1}(k_1)}{p\cdot k_1-\mathrm{i}\epsilon}\,\frac{g\,p\cdot e^*_{h_2}(k_2)}{p\cdot k_2-\mathrm{i}\epsilon}.$$

Corrections from the non-eikonal parts of the propagators and vertices are less singular in the soft scaling. The same combinatorics gives the product for any finite number of soft photons.

Remark 44.4 (Subleading soft photons). The preceding product formula uses only the leading eikonal term. For a single additional photon, under the perturbative hypotheses of massive charged external particles, a smooth hard amplitude near $k=0$, and a fixed infrared regulator, the Low soft expansion has the form

$$\mathcal{M}_{\beta;k,h|\alpha}=\left(S^{(0)}_h(k)+S^{(1)}_h(k)\right)\mathcal{M}_{\beta|\alpha}+O(\omega),$$

where

$$S^{(0)}_h(k)=\sum_n\frac{g_n\,p_n\cdot e^*_h(k)}{\eta_n p_n\cdot k}$$

is the leading factor used above, and the subleading operator is

$$S^{(1)}_h(k)=-\mathrm{i}\sum_n\frac{g_n\,e^*_{h,\mu}(k)k_\nu J^{\mu\nu}_n}{\eta_n p_n\cdot k}.$$

Here $J^{\mu\nu}_n$ is the total Lorentz generator acting on the n-th hard external datum. For a scalar external line its orbital part is

$$J^{\mu\nu}_{n,\mathrm{orb}}=-\mathrm{i}\left(p^\mu_n\frac{\partial}{\partial p_{n,\nu}}-p^\nu_n\frac{\partial}{\partial p_{n,\mu}}\right),$$

and for spinning particles one adds the spin matrix $\Sigma^{\mu\nu}_n$. The formula is a distributional statement on the mass shell and momentum-conservation surface: the differential operator acts on the hard amplitude together with its conservation delta function, or equivalently on a chosen smooth local representative before restricting to the physical surface.

The subleading factor is homogeneous of degree ω^0, whereas $S^{(0)}_h$ is homogeneous of degree ω^{-1}. Consequently the real-emission integral built from $S^{(0)}_h S^{(0)*}_h$ contains $\mathrm{d}\omega/\omega$, while the interference between $S^{(0)}_h$ and $S^{(1)}_h$ contains $\mathrm{d}\omega$ and is finite at the lower endpoint in the massive case. This is why the Bloch–Nordsieck logarithm and its Poisson exponentiation are governed by $S^{(0)}$. At subleading order the soft insertion is a differential operator, and multiple soft emissions produce ordered products and contact terms. The independent one-photon multiplication factors used in the leading-log proof are a property of the leading eikonal term.

The same soft statements have an asymptotic-symmetry formulation. In four-dimensional QED, the leading soft photon theorem is equivalent, under the assumptions on null-infinity limits and charged-state sectors, to a Ward identity for large $U(1)$ gauge transformations; its classical counterpart is electromagnetic memory. In gravity, the analogous leading and subleading soft-graviton statements are tied to BMS supertranslations and to the more delicate superrotation story. These asymptotic-symmetry interpretations delimit the leading eikonal approximation used in this chapter; the inclusive cancellation above uses the exponentiation of $S^{(0)}$.

Figure 44.2 shows the leading eikonal factorization used in the inclusive calculation: soft photons attach to the external charged lines, while the hard kernel is unchanged at leading soft order.

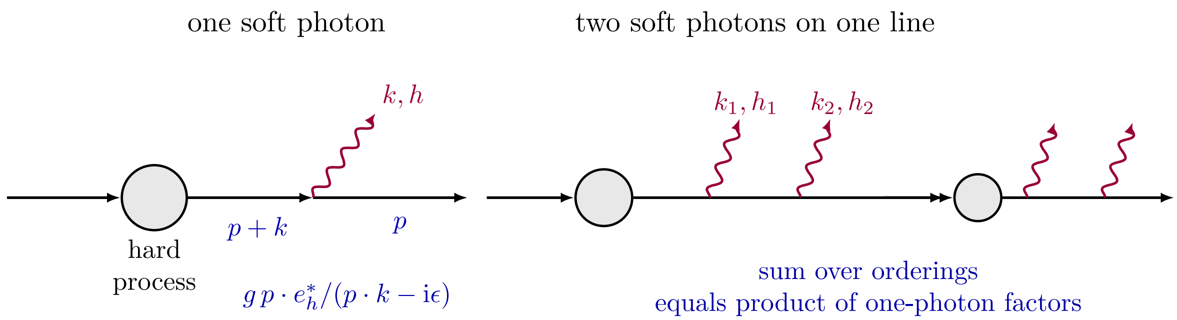

Figure 44.2: Soft factorization on external charged lines. A photon with wavelength much larger than the hard interaction region resolves only the external charge and momentum.

44.3 Real Soft Emission

Divide the real-emission contribution by the hard rate with no unresolved photons. Using the leading soft factor gives

$$R_{\text{real}}(E_T, \mu) = \sum_{N=0}^{\infty} \frac{1}{N!} \prod_{r=1}^{N} \int_{\mu<\omega_r<E_T} \frac{\mathrm{d}^3\vec{k}_r}{(2\pi)^3\, 2\omega_r} \sum_{h_r=\pm} \left| \sum_n \frac{g_n\, p_n \cdot e_{h_r}^*(k_r)}{\eta_n p_n \cdot k_r} \right|^2 .$$

For a single soft photon, define the nonnegative angular kernel

$$\mathcal{S}(k) = \sum_{h=\pm} \left| \sum_n \frac{g_n\, p_n \cdot e_h^*(k)}{\eta_n p_n \cdot k} \right|^2 .$$

A covariant physical-polarization sum may be written as

$$\sum_{h=\pm} e_{h,\mu}(k) e_{h,\nu}^*(k) = \eta_{\mu\nu} + k_\mu c_\nu + k_\nu c_\mu, \qquad k \cdot c = -1, \qquad c^2 = 0.$$

The terms involving c_μ vanish after using $\sum_n \eta_n g_n = 0$. Thus

$$\mathcal{S}(k) = \sum_{n,m} \frac{\eta_n \eta_m g_n g_m\, p_n \cdot p_m}{(p_n \cdot k)(p_m \cdot k)}.$$

Writing $k^\mu = \omega(1, \hat{k})$, the energy integral separates from the angular integral:

$$\int_\mu^{E_T} \frac{\mathrm{d}^3\vec{k}}{(2\pi)^3\, 2\omega} \mathcal{S}(k) = \frac{1}{2(2\pi)^3} \int_\mu^{E_T} \frac{\mathrm{d}\omega}{\omega} \int \mathrm{d}^2\hat{k} \sum_{n,m} \frac{\eta_n \eta_m g_n g_m\, p_n \cdot p_m}{(p_n^0 - \vec{p}_n \cdot \hat{k})(p_m^0 - \vec{p}_m \cdot \hat{k})}.$$

For massive external particles, define the relative-velocity parameter

$$\beta_{nm} = \sqrt{1 - \frac{m_n^2 m_m^2}{(p_n \cdot p_m)^2}}.$$

The diagonal term $n = m$ is understood as the $\beta_{nm} \to 0$ limit. The angular integral may be evaluated directly by combining the two denominators:

$$\begin{aligned}
&\int \mathrm{d}^2\hat{k}\, \frac{1}{(p_n^0 - \vec{p}_n \cdot \hat{k})(p_m^0 - \vec{p}_m \cdot \hat{k})} \\
&= \int_0^1 \mathrm{d}x \int \mathrm{d}^2\hat{k}\, \frac{1}{\left[p_n^0 x + p_m^0(1-x) - (\vec{p}_n x + \vec{p}_m(1-x)) \cdot \hat{k}\right]^2}.
\end{aligned}$$

Choose the polar axis along $\vec{p}_n x + \vec{p}_m(1-x)$. The $\hat{k}$-integral becomes an elementary integral of

$$\frac{2\pi \sin\theta\, \mathrm{d}\theta}{\left[p_n^0 x + p_m^0(1-x) - |\vec{p}_n x + \vec{p}_m(1-x)| \cos\theta\right]^2}.$$

Performing the x-integral gives

$$\int \mathrm{d}^2\hat{k}\, \frac{1}{(p_n^0 - \vec{p}_n \cdot \hat{k})(p_m^0 - \vec{p}_m \cdot \hat{k})} = -\frac{2\pi}{p_n \cdot p_m} \frac{1}{\beta_{nm}} \log \frac{1+\beta_{nm}}{1-\beta_{nm}}.$$

It is useful to introduce

$$A_{\beta\alpha} = -\frac{1}{8\pi^2} \sum_{n,m} \frac{\eta_n \eta_m g_n g_m}{\beta_{nm}} \log \frac{1+\beta_{nm}}{1-\beta_{nm}}.$$

The representation by $\mathcal{S}(k)$ shows $A_{\beta\alpha} \geq 0$ for the massive charged scattering considered here. The real unresolved photons therefore give

$$R_{\text{real}}(E_T, \mu) = \sum_{N=0}^{\infty} \frac{1}{N!} \left[A_{\beta\alpha} \log \frac{E_T}{\mu}\right]^N = \left(\frac{E_T}{\mu}\right)^{A_{\beta\alpha}}$$

at leading soft logarithmic order.

44.4 Virtual Soft Photons and External Factors

A virtual soft photon exchanged between two distinct external charged lines also factorizes. For external lines n and m, set

$$J_{nm} = -\mathrm{i}\, p_n \cdot p_m \int_{\mu < |\vec{k}| < M} \frac{\mathrm{d}^4k}{(2\pi)^4} \frac{1}{(k^2 - \mathrm{i}\epsilon)(\eta_n p_n \cdot k - \mathrm{i}\epsilon)(-\eta_m p_m \cdot k - \mathrm{i}\epsilon)}.$$

The virtual soft photons exchanged among distinct external lines exponentiate:

$$\exp\left[\frac{1}{2} \sum_{n \neq m} g_n g_m J_{nm}\right].$$

This expression omits the soft photons whose two endpoints lie on the same external charged line. Those terms are tied to the infrared part of the LSZ normalization factors. A direct way to see the accounting is to insert the electromagnetic current

$$\widehat{j}^{\mu}(x) = \partial_\nu \widehat{F}^{\mu\nu}(x)$$

between one-particle states. In scalar QED, with $k = p_2 - p_1$ and $\omega_p = \sqrt{\vec{p}^2 + m^2}$,

$$\langle \vec{p}_2 | \widehat{j}^\mu(0) | \vec{p}_1 \rangle = \frac{g}{(2\pi)^3 \sqrt{2\omega_{p_1}}\sqrt{2\omega_{p_2}}} (p_1 + p_2)^\mu F(k^2), \qquad F(0) = 1.$$

In spinor QED the corresponding decomposition is

$$\begin{aligned} &\langle \vec{p}_2, \sigma_2 | \widehat{j}^\mu(0) | \vec{p}_1, \sigma_1 \rangle \\ &\quad = \frac{\mathrm{i}g}{(2\pi)^3}\, \bar{u}^{\sigma_2}(\vec{p}_2) \left[\gamma^\mu F(k^2) - \frac{\mathrm{i}}{2m}(p_1 + p_2)^\mu G(k^2) \right] u^{\sigma_1}(\vec{p}_1), \qquad F(0) + G(0) = 1. \end{aligned}$$

In these conventions the one-loop value $G(0) = -g^2/(8\pi^2) + O(g^4)$ is a finite contribution to the magnetic form factor. The electromagnetic matrix element at $k^2 = 0$ is free of infrared divergence, although derivatives such as $\mathrm{d}F/\mathrm{d}k^2\big|_{k^2=0}$ need not be. Thus the soft virtual photons attached to the current insertion must be accompanied by the same infrared part of the LSZ factors. In the current form factor, soft photons connecting the two charged legs exponentiate as $e^{g^2 J_{12}}$. Finiteness at $k^2 = 0$ then fixes the infrared factor in Z:

$$Z_{\mathrm{IR}} = e^{-g^2 J_{12}} \Big|_{p_2 = p_1,\ \eta_2 = -\eta_1} .$$

Equivalently, compare this with the same-line expression obtained by setting the two eikonal velocities equal before interpreting the self-contraction:

$$\text{“}J_{11}\text{”} = -\mathrm{i} p_1^2 \int_{\mu < |\vec{q}| < M} \frac{\mathrm{d}^4 q}{(2\pi)^4} \frac{1}{(q^2 - \mathrm{i}\epsilon)(p_1 \cdot q - \mathrm{i}\epsilon)(-p_1 \cdot q - \mathrm{i}\epsilon)}.$$

The two matter poles in the q^0-plane contribute to the imaginary part. The real part satisfies

$$\operatorname{Re} J_{11} = -\operatorname{Re} J_{12}\big|_{p_2 = p_1,\ \eta_2 = -\eta_1}, \qquad Z_{\mathrm{IR}} = e^{g^2 \operatorname{Re} J_{11}}.$$

At one-loop order this same statement follows directly from the scalar-QED self-energy. The soft part is

$$\mathrm{i}\Sigma(p) = \int \frac{\mathrm{d}^4 k}{(2\pi)^4} \frac{-\mathrm{i}}{(p+k)^2 + m^2 - \mathrm{i}\epsilon} \frac{-\mathrm{i}}{k^2 - \mathrm{i}\epsilon} (\mathrm{i}g)^2 (2p + k)^2 + \cdots ,$$

whose infrared approximation is

$$\mathrm{i}\Sigma(p)\big|_{\mathrm{soft}} = 4g^2 p^2 \int_{|\vec{k}| < M} \frac{\mathrm{d}^4 k}{(2\pi)^4} \frac{1}{p^2 + m^2 + 2p \cdot k - \mathrm{i}\epsilon} \frac{1}{k^2 - \mathrm{i}\epsilon}.$$

The corresponding external factor

$$Z = \left(1 - \frac{\partial \Sigma}{\partial p^2} \bigg|_{p^2 = -m^2} \right)^{-1}$$

contains the same soft logarithm as the same-line eikonal loop. In the infrared region,

$$\log Z_{\mathrm{IR}} = \mathrm{i}g^2\, 4p^2 \int_{|\vec{k}| < M} \frac{\mathrm{d}^4 k}{(2\pi)^4} \frac{1}{(2p \cdot k - \mathrm{i}\epsilon)^2 (k^2 - \mathrm{i}\epsilon)} = g^2 \operatorname{Re} J_{11} + O(g^4).$$

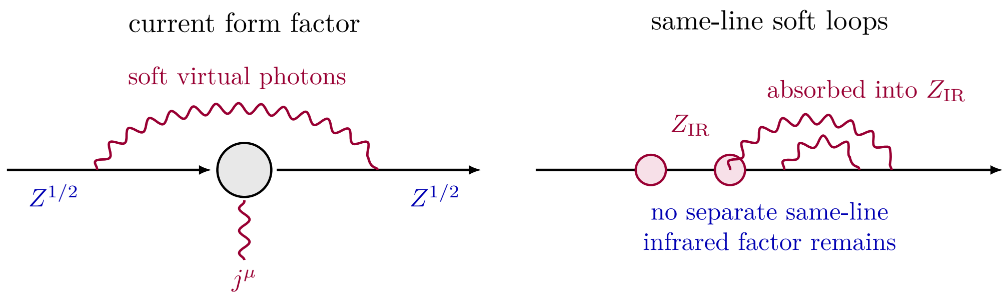

Figure 44.3: The infrared part of the external LSZ factor accounts for soft virtual photons whose two endpoints lie on the same charged external line.

Thus soft loops beginning and ending on a single external charged line are not additional uncancelled infrared factors; they are already included in the LSZ normalization of that charged external line.

Figure 44.3 identifies the same-line soft loop contribution and its placement in the external-line normalization factor rather than as a separate inclusive-rate correction.

Combining the distinct-line soft loops with the infrared parts of the $Z_n^{1/2}$ factors gives

$$\exp\left[\frac{1}{2}\sum_{n\neq m} g_n g_m J_{nm}\right]\prod_n (Z_n^{\rm IR})^{1/2} = (\text{phase})\,\exp\left[\frac{1}{2}\sum_{n,m} g_n g_m\ \mathrm{Re}\,J_{nm}\right].$$

The k^0-plane poles of J_{nm}, including only the denominators that control the contour placement, are

$$-|\vec{k}|+\mathrm{i}\epsilon,\qquad |\vec{k}|-\mathrm{i}\epsilon,\qquad \frac{\vec{p}_n\cdot\vec{k}}{p_n^0}-\mathrm{i}\eta_n\epsilon,\qquad \frac{\vec{p}_m\cdot\vec{k}}{p_m^0}+\mathrm{i}\eta_m\epsilon.$$

The photon poles give the real part of the eikonal integral, while the matter poles may contribute to its phase. Evaluating the photon-pole contribution gives

$$\mathrm{Re}\,J_{nm} = -\eta_n\eta_m\,\frac{p_n\cdot p_m}{2}\int_{\mu<|\vec{k}|<M}\frac{\mathrm{d}^3\vec{k}}{(2\pi)^3}\frac{1}{|\vec{k}|^3(p_n^0-\vec{p}_n\cdot\hat{k})(p_m^0-\vec{p}_m\cdot\hat{k})}.$$

Using the same angular integral as for real emission,

$$\mathrm{Re}\,J_{nm} = \eta_n\eta_m\,\frac{1}{8\pi^2\beta_{nm}}\log\frac{1+\beta_{nm}}{1-\beta_{nm}}\log\frac{M}{\mu}.$$

Therefore the virtual factor in the amplitude has modulus

$$\left(\frac{\mu}{M}\right)^{A_{\beta\alpha}/2},$$

and its contribution to a rate is

$$R_{\rm virt}(M,\mu) = \left(\frac{\mu}{M}\right)^{A_{\beta\alpha}}.$$

Figure 44.4 displays the Bloch–Nordsieck cancellation in the notation above: the virtual factor and the real-emission inclusive factor carry opposite powers of the soft regulator.

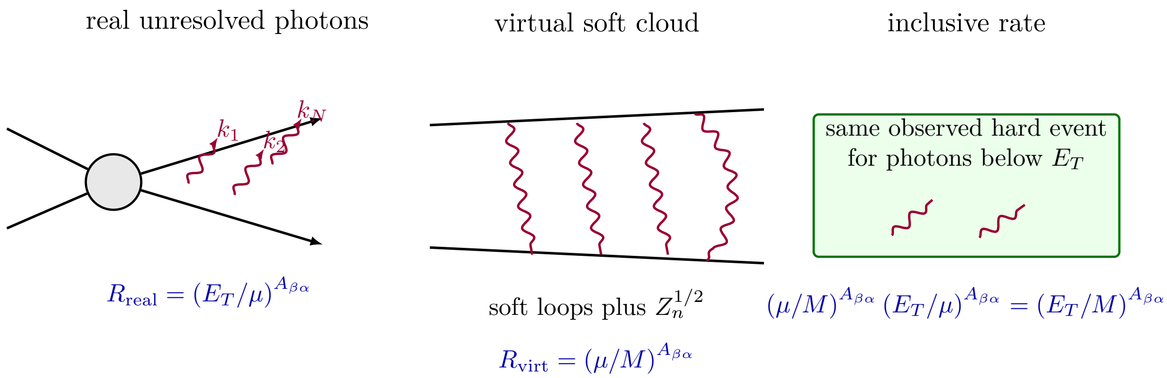

Figure 44.4: Real unresolved photons and virtual soft photons carry opposite powers of the auxiliary infrared cutoff. The product is finite for a fixed detector threshold.

44.5 Inclusive Probabilities

The cancellation of the auxiliary photon-mass regulator between real unresolved emission and virtual soft exchange is the Bloch–Nordsieck cancellation. Equivalently, real soft emission cancels virtual infrared divergences at the level of inclusive probabilities. The order of operations is part of the statement. Fix

$$0 < \mu < E_T < M$$

and compute in the regulated theory. At fixed μ, first include all detector-degenerate unresolved photons, or, coefficientwise in perturbation theory, all detector-degenerate terms contributing to the chosen coefficient. Only after that inclusive sum has been formed is the regulator $\mu \downarrow 0$ removed.

In the leading soft approximation this ordered construction is completely explicit. Put

$$\ell_T(\mu) = \log \frac{E_T}{\mu}, \qquad \ell_M(\mu) = \log \frac{M}{\mu}.$$

The real contribution with exactly N unresolved photons is

$$R_N(E_T, \mu) = \frac{1}{N!} \left[A_{\beta\alpha} \ell_T(\mu)\right]^N ,$$

and the virtual soft factor in the rate is

$$R_{\text{virt}}(M, \mu) = \exp\{-A_{\beta\alpha} \ell_M(\mu)\}.$$

Thus the leading-soft regulated inclusive factor is

$$R^{(\mu)}_{\text{incl}}(E_T, M) = R_{\text{virt}}(M, \mu) \sum_{N=0}^{\infty} R_N(E_T, \mu).$$

The infinite sum over N is taken at fixed positive μ, where it is an ordinary exponential series. It gives

$$R^{(\mu)}_{\text{incl}}(E_T, M) = \exp\{-A_{\beta\alpha} \ell_M(\mu)\} \exp\{A_{\beta\alpha} \ell_T(\mu)\} = \left(\frac{E_T}{M}\right)^{A_{\beta\alpha}},$$

which is independent of μ. Multiplying by the hard finite factor gives the leading soft result

$$P_{\beta|\alpha}(E_T) = P^{\mathrm{hard}}_{\beta|\alpha}(M) \left(\frac{E_T}{M}\right)^{A_{\beta\alpha}} \times F_{\beta\alpha}(E_T/M),$$

where $F_{\beta\alpha}$ is finite as $\mu \to 0$ and equals 1 in the leading logarithmic approximation. The scale M separates hard and soft physics; dependence on it cancels once the hard finite correction is computed to the same order.

Remark 44.5 (Coefficientwise Bloch–Nordsieck cancellation). Let $A_{\beta\alpha}$ be regarded as a formal quantity of order g^2. At every fixed power $A^L_{\beta\alpha}$, the coefficient of the inclusive leading-soft rate has a regulator-independent limit after the sum over unresolved photon numbers contributing to that coefficient is taken. More precisely,

$$\begin{aligned}
[A^L_{\beta\alpha}] & \left[\exp\{-A_{\beta\alpha}\ell_M(\mu)\} \sum_{N=0}^{\infty} \frac{[A_{\beta\alpha}\ell_T(\mu)]^N}{N!}\right] \\
&= \sum_{N=0}^{L} \frac{[-\ell_M(\mu)]^{L-N}}{(L-N)!} \frac{\ell_T(\mu)^N}{N!} = \frac{1}{L!}\left(\ell_T(\mu) - \ell_M(\mu)\right)^L \\
&= \frac{1}{L!}\left(\log\frac{E_T}{M}\right)^L.
\end{aligned}$$

Thus the cancellation is not a statement about an individual fixed photon number. It is a statement about the inclusive coefficient obtained after the degenerate real-emission terms and the virtual terms at the same perturbative order are combined.

At fixed $\mu > 0$, the product of the virtual exponential and the real emission exponential is an identity of formal power series in $A_{\beta\alpha}$. The coefficient of $A^L_{\beta\alpha}$ receives contributions from N real photons and $L - N$ powers of the virtual exponential, with $0 \le N \le L$. This gives the displayed binomial sum. Since

$$\ell_T(\mu) - \ell_M(\mu) = \log\frac{E_T}{\mu} - \log\frac{M}{\mu} = \log\frac{E_T}{M},$$

all dependence on the auxiliary regulator cancels before the limit $\mu \downarrow 0$ is taken.

For a fixed finite number N of photons, by contrast, the rate contains

$$\left(\frac{\mu}{M}\right)^{A_{\beta\alpha}} \frac{1}{N!}\left[A_{\beta\alpha}\log\frac{E_T}{\mu}\right]^N,$$

which tends to zero as $\mu \to 0$ when $A_{\beta\alpha} > 0$. The resolution-inclusive sum remains finite because arbitrarily many unresolved soft photons are included.

The coupling expansion and the infrared limit are therefore nonuniform in the exclusive fixed-N decomposition. The perturbative statement is the coefficientwise one in Remark 44.5: coefficient extraction is performed at fixed regulator, all degenerate real and virtual terms at that coefficient are added, and only then is μ removed. The exponentiated leading-soft expression is a resummation of these coefficientwise cancellations, not a license to take the regulator limit term by term in photon number.

Remark 44.6. The fixed-photon-number matrix elements are exclusive kernels for an idealized measurement that specifies the exact number of photons down to zero energy. The inclusive probability above is the transition probability associated with a finite energy resolution. In a charged sector of massless QED, the exclusive kernels should not be reinterpreted as ordinary regulator-independent LSZ S-matrix elements for bare electron states. Both the vanishing of fixed-N probabilities and the finiteness of the inclusive probability follow from the same soft factorization formulas.

The discussion so far treated massive charged particles, where the angular integral is finite. If massless charged particles occur, photon emission collinear to a charged external line produces additional singularities. The soft Bloch–Nordsieck sum is then only part of the required inclusive construction. The finite-degeneracy statement behind the Kinoshita–Lee–Nauenberg prescription is the following.

Remark 44.7 (Finite-degeneracy KLN trace identity). Let $\mathcal{H}_0$ be a Hilbert space with unperturbed Hamiltonian H_0. Let P_A and P_B be the orthogonal projectors onto two finite-dimensional degenerate subspaces of H_0, with

$$d_A = \operatorname{rank} P_A < \infty, \qquad d_B = \operatorname{rank} P_B < \infty.$$

Let $H = H_0 + V$, where V is a bounded self-adjoint perturbation, and let

$$U_T = \mathcal{T} \exp\left\{-\mathrm{i}\int_{-T}^{T} e^{\mathrm{i}H_0 t} V e^{-\mathrm{i}H_0 t}\,\mathrm{d}t\right\}$$

be the interaction-picture evolution, possibly with an adiabatic switch-on understood. Assume that, after introducing whatever ultraviolet and infrared regulators are being used, the inclusive long-time limit

$$\mathcal{P}^{(\rho)}_{B|A} = \lim_{T\to\infty} \frac{1}{d_A} \operatorname{Tr}_{\mathcal{H}_0}\left(P_B U_T P_A U_T^\dagger P_B\right)$$

exists coefficientwise in the perturbation expansion. Finally assume that the regulator-singular factors associated with exact degeneracy act by unitary rotations inside the degenerate subspaces: for the $P_A \to P_B$ block of the regulated scattering operator,

$$P_B S_\rho P_A = U_B(\rho)\, S_{\mathrm{fin}}(\rho)\, U_A(\rho)^\dagger,$$

where $U_A(\rho)$ and $U_B(\rho)$ are unitary on $P_A\mathcal{H}_0$ and $P_B\mathcal{H}_0$, respectively, and $S_{\mathrm{fin}}(\rho)$ has a finite coefficientwise limit as the regulator $\rho \downarrow 0$. Then

$$\lim_{\rho\downarrow 0} \mathcal{P}^{(\rho)}_{B|A} = \frac{1}{d_A} \operatorname{Tr}_{P_B\mathcal{H}_0}\left(S_{\mathrm{fin}} S_{\mathrm{fin}}^\dagger\right)$$

exists coefficientwise. The final-state sum removes the outgoing degenerate rotation $U_B(\rho)$, and the initial-state average removes the incoming degenerate rotation $U_A(\rho)$.

The normalized incoming density matrix for an unresolved initial degeneracy class is

$$\varrho_A = \frac{P_A}{d_A}.$$

The inclusive probability of finding the outgoing state in $P_B\mathcal{H}_0$ is

$$\operatorname{Tr}_{\mathcal{H}_0}\left(P_B S_\rho \varrho_A S_\rho^\dagger P_B\right) = \frac{1}{d_A} \operatorname{Tr}_{P_B\mathcal{H}_0}\left(P_B S_\rho P_A S_\rho^\dagger P_B\right).$$

Insert

$$P_B S_\rho P_A = U_B(\rho) S_{\mathrm{fin}}(\rho) U_A(\rho)^\dagger.$$

Because $U_A(\rho)^\dagger U_A(\rho) = P_A$ on the incoming degenerate subspace and $U_B(\rho)^\dagger U_B(\rho) = P_B$ on the outgoing degenerate subspace, cyclicity of the finite-dimensional trace gives

$$\begin{aligned}\mathcal{P}^{(\rho)}_{B|A} &= \frac{1}{d_A} \operatorname{Tr}_{P_B\mathcal{H}_0} \left[U_B(\rho) S_{\mathrm{fin}}(\rho) S_{\mathrm{fin}}(\rho)^\dagger U_B(\rho)^\dagger\right] \\ &= \frac{1}{d_A} \operatorname{Tr}_{P_B\mathcal{H}_0} \left[S_{\mathrm{fin}}(\rho) S_{\mathrm{fin}}(\rho)^\dagger\right].\end{aligned}$$

The assumed coefficientwise limit of $S_{\mathrm{fin}}(\rho)$ therefore gives the claimed coefficientwise limit of the inclusive probability.

The theorem is an abstract finite-regulator statement. In a relativistic field theory the interaction is generally an unbounded operator-valued distribution on the physical Hilbert space, and exact massless degeneracy is typically continuous rather than finite-dimensional. The theorem identifies the finite-volume, energy-resolution, and regulator structure that must be implemented before the regulator limits are taken. After those regularizations have turned detector-degenerate sectors into finite subspaces, the inclusive construction sums over final states and averages over initial states inside the same detector degeneracy class. In symbols, if $[\alpha]$ and $[\beta]$ are the incoming and outgoing equivalence classes defined by the detector resolution, one considers

$$P([\alpha] \to [\beta]) = \sum_{\alpha' \in [\alpha]} \omega_{\alpha'} \sum_{\beta' \in [\beta]} \left| S^{(\mu)}_{\beta'\alpha'} \right|^2,$$

with nonnegative weights $\omega_{\alpha'}$ normalized on the incoming degenerate class. Soft degeneracy and collinear degeneracy are therefore handled by the same operational rule: the transition probability is attached to what the detector distinguishes.

Remark 44.8 (Abelian scope of Bloch–Nordsieck cancellation). The Bloch–Nordsieck exponentiation derived in this chapter is an Abelian soft-photon statement. Its leading real-emission factor is a scalar function of the hard charges and momenta, and different soft photons multiply by commuting factors. Nonabelian gauge theory changes this algebraic input: soft gluons couple through color generators, and the soft factors are operators in color space, naturally organized by Wilson lines and color ordered products.

Consequently, the QED formula above should not be transplanted directly to partonic QCD. In perturbative QCD, final-state soft and collinear singularities cancel in sufficiently inclusive color-singlet observables or factor into universal jet and soft functions, but initial-state collinear singularities of colored partons are absorbed into the renormalization of parton distributions. The finite hadronic observable is then obtained from renormalized light-ray matrix elements and short-distance kernels, as in the DIS factorization formula (49.313) and DGLAP equation (49.314) of Chapter 49. This is the precise replacement, in QCD factorization, for an abelian fixed-charge Bloch–Nordsieck cancellation.

44.6 Soft Photon Number Distribution

The leading soft formula also determines the unresolved photon multiplicity distribution. Let

$$\overline{N}_{\beta\alpha}(\mu, E_T) = A_{\beta\alpha} \log \frac{E_T}{\mu}$$

be the mean number of photons in the energy window $\mu < \omega < E_T$ generated by the eikonal current. The probability for emitting exactly N photons in this unresolved window has the Poisson form

$$P_N(\mu, E_T) = \exp\{-\overline{N}_{\beta\alpha}\}\frac{\overline{N}_{\beta\alpha}^{\,N}}{N!}$$

at leading soft order, multiplied by the hard probability and finite corrections. The exponential factor is the virtual soft factor together with the no-resolved-emission probability. Summing over N gives unity for the soft probability distribution, while the hard probability is multiplied by the finite detector-resolution factor

$$\left(\frac{E_T}{M}\right)^{A_{\beta\alpha}}.$$

As $\mu \to 0$, the mean $\overline{N}_{\beta\alpha}$ diverges when $A_{\beta\alpha} > 0$. The inclusive probability is finite because the detector state is a distribution over arbitrarily many unresolved photons. The exclusive fixed-N probability tends to zero because it samples a set of vanishing measure inside the infrared cloud selected by the long-range electromagnetic field.

44.7 Charged Asymptotic Sectors and Infraparticles

The preceding formulas describe a scattering problem whose charged asymptotic representation is fixed by Gauss' law. Let $\mathfrak{A}_{\mathrm{loc}}$ denote the algebra of gauge-invariant observables localized in bounded spacetime regions, and let

$$E^i = F^{i0}$$

be the electric field. At a fixed time, for a smooth function f on the unit sphere, define the large-radius electric-flux observable formally by

$$\Phi_R(f) = \int_{S^2} \mathrm{d}\Omega(\mathbf{n})\, R^2 f(\mathbf{n})\, n_i E^i(0, R\mathbf{n}).$$

The constant test function gives the total electric charge in the limit

$$Q = \lim_{R\to\infty} \Phi_R(1),$$

when the limit exists in the representation under consideration. More generally, the limiting angular flux functional

$$\Phi_\infty(f) = \lim_{R\to\infty} \Phi_R(f)$$

records the electromagnetic field at spacelike infinity. Local observables cannot change this limiting flux. The precise operator statement uses a shell-smearing before the limit is taken. Choose $\chi \in C_c^\infty(\mathbb{R})$ with $\int_{\mathbb{R}} \chi(s)\mathrm{d}s = 1$, and put

$$\Phi_{R,\chi}(f) = \int_{\mathbb{R}^3} \mathrm{d}^3\mathbf{x}\, \chi(|\mathbf{x}| - R)\, f(\mathbf{x}/|\mathbf{x}|)\, \frac{x_i}{|\mathbf{x}|}\, E^i(0, \mathbf{x}).$$

This is a local field smeared in the annular shell $|\,|\mathbf{x}| - R\,| \le C_\chi$. If $A \in \mathfrak{A}_{\mathrm{loc}}$ is localized in a bounded spacetime region whose time-zero spatial projection is contained in $|\mathbf{x}| \le R_0$, then for $R > R_0 + C_\chi$ every point in the smearing shell is spacelike to that region. Locality gives

$$[\Phi_{R,\chi}(f), A] = 0$$

on the common field domain, and the same statement holds for bounded functions of $\Phi_{R,\chi}(f)$. Hence, whenever $\Phi_{R,\chi}(f)$ has a sharp limiting self-adjoint observable $\Phi_\infty(f)$ in the representation under study, the spectral projections of $\Phi_\infty(f)$ commute with every bounded local observable. The limiting angular flux is then a superselection datum for the charged sector.

The constant mode $f = 1$ is the total electric charge. The higher spherical modes are independent asymptotic data: a neutral configuration may have zero total charge while still carrying nontrivial angular flux if its charged constituents have different asymptotic velocities. Thus charge neutrality alone does not return the sector to the vacuum infrared representation; the angular Coulomb field is part of the asymptotic charged datum.

There are two logically separate consequences. First, a bounded local gauge-invariant observable cannot change the limiting surface charge: for a large sphere spacelike to its localization region it commutes with the surface-flux operator before the $R \to \infty$ limit. This is the localization obstruction to creating a charged particle by ordinary local observable Haag–Ruelle operators. Second, in massless QED the charged sector also carries velocity-dependent soft electromagnetic flux, so its spectral support is not an ordinary sharp Wigner mass shell. The next theorem concerns this second statement. The Wilson-line and Coulomb dressings needed for the first statement are formulated as a scattering-theory problem in Chapter 22.

Quoted Theorem 44.9 (Buchholz infraparticle obstruction)**.** *In a local relativistic quantum field theory satisfying Maxwell's equations and Gauss' law, a pure state carrying nonzero abelian gauge charge cannot be a Wigner one-particle state with a sharp mass shell. More precisely, charged particle weights are accompanied by asymptotic electromagnetic flux, and the representations induced by different charged velocities need not be unitarily equivalent. In particular, the charged sector is not an ordinary tensor product of a Wigner electron one-particle representation with the vacuum photon Fock representation, and Lorentz boosts of a charged particle change the flux sector rather than acting inside one fixed Fock sector.*

The electron in four-dimensional QED is therefore an infraparticle. The conclusion is an algebraic consequence of locality and Gauss' law.[1]

The mechanism behind the quoted theorem is the following. If a massive charged particle were an ordinary Wigner particle, boosts would move its one-particle vector through a single massive one-particle representation. In a theory with Gauss' law the same boost also changes the angular flux functional at spacelike infinity. Since the sharp limiting flux commutes with all bounded local observables and labels a superselection datum, the boosted charged state cannot remain a vector in one fixed photon Fock representation unless the change of flux is implemented by a square-integrable soft-photon displacement. The latter implementation fails for the Coulomb tail: the displacement has logarithmically divergent one-photon norm.

Perturbation theory displays this obstruction in a direct way. Work in a frame where $\mathbf{v} = \beta\widehat{\mathbf{z}}$. The boosted Coulomb field has radial flux density

$$\mathcal{E}_{g,\beta}(\mathbf{n}) = \frac{g}{4\pi}\frac{1-\beta^2}{(1-\beta\cos\theta)^2}, \qquad \cos\theta = \widehat{\mathbf{z}}\cdot\mathbf{n}.$$

[1] The theorem-level result used here is Buchholz's Gauss-law analysis of the infraparticle problem. The spectral analysis of charged infraparticles was developed by Fröhlich–Morchio–Strocchi, while the coherent asymptotic construction used in perturbation theory is the Faddeev–Kulish construction. The review of Buchholz–Dybalski gives a modern scattering-theoretic account of these relations.

The total flux is still g, because

$$2\pi(1-\beta^2)\int_{-1}^{1}\frac{\mathrm{d}z}{(1-\beta z)^2} = 2\pi(1-\beta^2)\left[\frac{1}{\beta(1-\beta z)}\right]_{z=-1}^{z=1} = 4\pi. \tag{44.3}$$

The angular distribution, however, determines the velocity: its value in the forward direction divided by its value in the backward direction is

$$\frac{\mathcal{E}_{g,\beta}(\widehat{\mathbf{z}})}{\mathcal{E}_{g,\beta}(-\widehat{\mathbf{z}})} = \left(\frac{1+\beta}{1-\beta}\right)^2. \tag{44.4}$$

For a charged particle of velocity

$$\mathbf{v} = \frac{\mathbf{p}}{p^0},$$

the Coulomb field boosted to that velocity has radial flux density

$$\mathcal{E}_{g,\mathbf{v}}(\mathbf{n}) = \frac{g}{4\pi}\frac{1-|\mathbf{v}|^2}{(1-\mathbf{v}\cdot\mathbf{n})^2}, \qquad \int_{S^2}\mathrm{d}\Omega(\mathbf{n})\,\mathcal{E}_{g,\mathbf{v}}(\mathbf{n}) = g. \tag{44.5}$$

Different velocities give different angular flux functionals. A multiparticle charged configuration carries the sum of the corresponding flux densities. This flux data is what the soft photon cloud implements.

The non-Fock nature of the dressing can already be read from the one-photon Hilbert norm. The physical photon one-particle space has norm

$$\|f\|_\gamma^2 = \sum_h \int \frac{\mathrm{d}^3\mathbf{k}}{(2\pi)^3\,2\omega}\,|f^h(k)|^2.$$

For the leading charged soft profile

$$f_p^h(k) \sim g\,\frac{p\cdot e_h^*(k)}{p\cdot k}, \qquad \omega = |\mathbf{k}|,$$

one has $p\cdot k = \omega(p^0 - \mathbf{p}\cdot\mathbf{n})$ and therefore

$$\|f_p\|_\gamma^2 \sim C(p,g)\int_0^\Lambda \frac{\mathrm{d}\omega}{\omega}, \qquad C(p,g) > 0 \quad (g\neq 0).$$

Thus $f_p \notin \mathcal{H}_{1,\gamma}$ after the infrared cutoff is removed. More invariantly, choose transverse polarization vectors and write

$$V_\mathbf{v}(\mathbf{n}) = \frac{\mathbf{v}-(\mathbf{v}\cdot\mathbf{n})\mathbf{n}}{1-\mathbf{v}\cdot\mathbf{n}}.$$

This profile determines the velocity: for $\mathbf{v}\neq 0$ its zeros on the unit sphere are $\mathbf{n} = \pm\mathbf{v}/|\mathbf{v}|$, and on the great circle $\mathbf{v}\cdot\mathbf{n} = 0$ its norm is $|\mathbf{v}|$; the zero-velocity profile is identically zero. For two velocities $\mathbf{v}\neq\mathbf{w}$, the difference of the two soft profiles has norm

$$\|f_\mathbf{v} - f_\mathbf{w}\|_\gamma^2 = \frac{g^2}{2(2\pi)^3}\log\frac{\Lambda}{\mu}\int_{S^2}\mathrm{d}\Omega(\mathbf{n})\,|V_\mathbf{v}(\mathbf{n}) - V_\mathbf{w}(\mathbf{n})|^2 + O(1), \tag{44.6}$$

where μ and Λ are infrared and soft ultraviolet cutoffs. The angular integral vanishes exactly when the velocities coincide. Therefore distinct sharp charged velocities define inequivalent infrared coherent directions in the limit $\mu \to 0$. At finite cutoff the coherent operator below is a unitary Weyl operator on photon Fock space; in the limit it defines an inequivalent representation labelled by the asymptotic flux. If two dressings have different limiting flux, their difference is not square-integrable in the same norm, so they are assigned to inequivalent infrared representations rather than to two vectors in one common photon Fock representation. The inclusive construction avoids choosing a sharp charged flux sector by summing over detector-unresolved radiation; the dressed construction chooses a sector adapted to the hard charged asymptotic data.

The elementary flux-normalization, velocity-extraction, half-line Fourier, and soft-profile norm checks behind (44.3), (44.4), and (44.6) are collected in `calculation-checks/charged_flux_dressing_checks.py`. They are not a replacement for Buchholz's theorem; they are the explicit perturbative mechanism that explains why the theorem has the physical content stated above.

Open Problem 44.10 (Charged asymptotic completeness in massless QED). Give a nonperturbative Hilbert-space construction of charged scattering in four-dimensional QED with the following data and conclusions. For each charged superselection sector $\mathcal{H}^{\mathrm{ch}}_{\mathrm{phys}}$, construct an asymptotic space

$$\mathcal{H}^{\mathrm{ch}}_{\mathrm{as}}$$

whose labels include hard charged velocity and spin data, ordinary transverse photon radiation, and the limiting angular electric-flux data required by Gauss' law. Construct large-time wave operators

$$\Omega^{\mathrm{ch}}_{\mathrm{in/out}} : \mathcal{H}^{\mathrm{ch}}_{\mathrm{as}} \longrightarrow \mathcal{H}^{\mathrm{ch}}_{\mathrm{phys}}$$

which intertwine spacetime translations with the total asymptotic energy-momentum, represent the limiting electromagnetic flux consistently with Φ_∞, and are isometric after the appropriate infrared identifications of zero-resolution photon clouds. The asymptotic-completeness claim is the equality

$$\overline{\mathrm{Ran}\,\Omega^{\mathrm{ch}}_{\mathrm{in}}} = \overline{\mathrm{Ran}\,\Omega^{\mathrm{ch}}_{\mathrm{out}}} = \mathcal{H}^{\mathrm{ch}}_{\mathrm{phys}}$$

in the chosen charged sector, together with a scattering operator on $\mathcal{H}^{\mathrm{ch}}_{\mathrm{as}}$ whose detector-inclusive probabilities agree with the regulator-independent inclusive probabilities constructed above from Bloch–Nordsieck and KLN degeneracy sums.

The theorem above identifies the obstruction that fixes the form of the problem: the asymptotic space cannot be the tensor product of a Wigner one-electron Fock space with the vacuum photon Fock space. A charged creator must carry electromagnetic flux to infinity; in a gauge-invariant description this requires a noncompact dressing, for example a Dirac-Coulomb dressing or a Wilson-line dressing, and a corresponding replacement for the ordinary local-field LSZ limit. The Faddeev–Kulish construction supplies the perturbative coherent soft datum suggested by the leading eikonal factor, and the inclusive construction supplies finite detector probabilities. The open problem is to put these structures into a single nonperturbative large-time scattering theorem.

44.8 Dressed Charged States

The same eikonal data can also be incorporated into the asymptotic states. For a charged particle of momentum p, a soft coherent dressing has the leading soft form

$$\mathcal{W}_p = \exp\left[\sum_h \int_{\omega<\Lambda} \frac{\mathrm{d}^3\vec{k}}{(2\pi)^3\,2\omega} \left(f^h_p(k)a^\dagger_h(k) - \overline{f^h_p(k)}a_h(k)\right)\right],$$

with leading coefficient

$$f_p^h(k) \sim g\,\frac{p \cdot e_h^*(k)}{p \cdot k}.$$

The operator $\mathcal{W}_p$ attaches the long-range electromagnetic field carried by the charged particle. With a positive infrared cutoff it is a well-defined Fock-space Weyl operator. Removing the cutoff is the representation-changing step described in the preceding section: the limiting state is a charged hard datum together with a coherent soft electromagnetic field in the corresponding asymptotic flux sector. This is the leading Faddeev–Kulish dressing datum. Dressed-state and inclusive descriptions use the same soft factor. The inclusive construction sums over unresolved radiation in probabilities, while the dressed construction builds part of the soft cloud into the state representation.

44.9 A Gauge-Invariant Infrared Regulator

The cutoff μ in the formulas above can be realized by deforming the theory so that the photon has a small mass, and then removing the deformation. If the same soft region is regulated dimensionally instead, the logarithms $\log(\mu/M)$ are replaced by infrared poles $1/\epsilon_{\mathrm{IR}}$ plus scheme-dependent finite constants; the coefficient multiplying the logarithm or pole is the same eikonal coefficient $A_{\beta\alpha}$, so the real–virtual cancellation is identical coefficient by coefficient. A convenient gauge-invariant deformation is an Abelian-Higgs regulator. Introduce a complex scalar φ, charged under the gauge field A_μ, with

$$D_\mu\varphi = (\partial_\mu + \mathrm{i}g_H A_\mu)\varphi$$

and Lagrangian terms

$$\mathcal{L}_{\mathrm{reg}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - |D_\mu\varphi|^2 - V(|\varphi|).$$

Choose the potential so that its vacuum satisfies

$$|\langle\varphi\rangle| = v \neq 0.$$

Expanding around this vacuum gives

$$-|D_\mu\varphi|^2 \supset -g_H^2 v^2 A_\mu A^\mu,$$

so the gauge boson acquires a mass proportional to $g_H v$. Taking v to zero after forming inclusive quantities gives a consistent version of the infrared-regulated calculation.

Figure 44.5 records the Abelian-Higgs infrared regulator used for this comparison: the gauge boson mass is generated by a regulated Higgs expectation value and is taken to zero only after inclusive quantities have been formed.

The infrared analysis will be used later whenever massless gauge fields occur. The next step in the logical development is the generating functional formalism, which packages connected Green functions and one-particle irreducible vertices in a form suitable for renormalization.

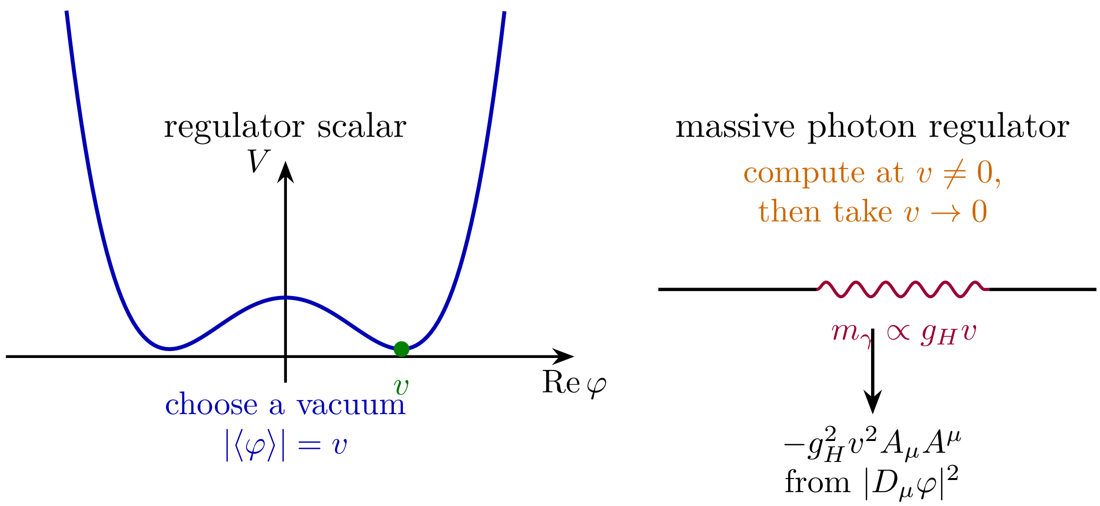

Figure 44.5: A small photon mass may be introduced through a Higgs deformation while keeping gauge invariance manifest.

Classical Yang-Mills Theory and Matter Fields

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

45.1 Local Gauge Fields

This chapter formulates the local classical field theory of nonabelian gauge fields. We work first on a spacetime region over which the relevant principal G-bundle has been trivialized. In such a local trivialization, a gauge field is represented by a Hermitian matrix-valued one-form

$$A = A_\mu(x)\,\mathrm{d}x^\mu, \qquad A_\mu(x) = A^a_\mu(x) t^a.$$

The index $\mu = 0, \dots, D-1$ is a spacetime index. The index a labels a basis of the gauge algebra in the Hermitian-generator convention. If $\mathfrak{g}_{\mathrm{ah}} = \mathrm{Lie}(G)$ is realized by anti-Hermitian matrices in a unitary representation, then the Hermitian generators used here span $i\,\mathfrak{g}_{\mathrm{ah}}$. The associated anti-Hermitian connection one-form, denoted A_{ah}, is $\mathsf{A}_{\mathrm{ah}} = -\mathrm{i}A$. We write $\mathfrak{g} := i\,\mathfrak{g}_{\mathrm{ah}}$ for this Hermitian coordinate space. Throughout this chapter $[X, Y]$ denotes the ordinary matrix commutator of Hermitian representatives, while the real compact Lie bracket in Hermitian coordinates is

$$[X, Y]_{\mathrm{H}} := -\mathrm{i}[X, Y].$$

With this convention,

$$[t^a, t^b] = \mathrm{i}f^c{}_{ab} t^c. \tag{45.1}$$

The real constants ${f^c}_{ab}$ are the structure constants of $[\ ,\ ]_{\mathrm{H}}$ in this basis, with the output Lie-algebra label written first. Thus ${f^c}_{ab} = -{f^c}_{ba}$ and the Jacobi identity is

$$ {f^e}_{ab}{f^d}_{ec} + {f^e}_{bc}{f^d}_{ea} + {f^e}_{ca}{f^d}_{eb} = 0. $$

Formulas below include explicit factors of i so that A_μ, ζ, and $F_{\mu\nu}$ remain Hermitian matrix fields.

The infinitesimal local transformation with parameter $\zeta(x) = \zeta^a(x)t^a$ is

$$ \delta_\zeta A_\mu = \partial_\mu \zeta - \mathrm{i}[A_\mu, \zeta]. \tag{45.2} $$

In components,

$$ \delta_\zeta A^a_\mu = \partial_\mu \zeta^a + {f^a}_{bc} A^b_\mu \zeta^c, \tag{45.3} $$

The derivative term records the freedom to change local trivialization from point to point, while the commutator term records the adjoint action of the Lie algebra on itself.

Figure 45.1 fixes the index conventions in this gauge-potential formula: the spacetime index labels the one-form component, and the Lie-algebra index labels the chosen generator basis.

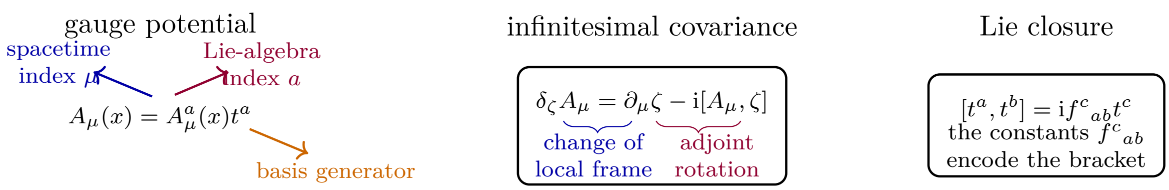

Figure 45.1: The local gauge field carries a spacetime vector index and a Lie-algebra index. The infinitesimal transformation combines the derivative of the local parameter with the adjoint action of the Lie algebra.

The finite transformation is most cleanly stated using a smooth G-valued function $g(x)$. With

$$ g(x) = \exp\{\mathrm{i}\zeta^a(x)t^a\}, $$

define

$$ A'_\mu = gA_\mu g^{-1} + \mathrm{i}g\,\partial_\mu g^{-1}. \tag{45.4} $$

The Baker-Campbell-Hausdorff formula

$$ \log(\mathrm{e}^X \mathrm{e}^Y) = X + Y + \frac{1}{2}[X, Y] + \frac{1}{12}[X, [X, Y]] - \frac{1}{12}[Y, [X, Y]] + \cdots $$

shows how products of exponentials are controlled by the Lie bracket. The identity

$$ \mathrm{e}^X Y \mathrm{e}^{-X} = Y + [X, Y] + \frac{1}{2!}[X, [X, Y]] + \cdots $$

then shows that conjugation by $g(x)$ maps $\mathfrak{g}$ to $\mathfrak{g}$. Thus (45.4) produces another local representative $A'_\mu = A'^a_\mu t^a$.

The same formula is also the transition law between local trivializations. If U_i and U_j are two coordinate patches and $h_{ji} : U_i \cap U_j \to G$ is the transition function, then their local connection representatives satisfy

$$ A^{(j)}_\mu = h_{ji}A^{(i)}_\mu h^{-1}_{ji} + \mathrm{i}h_{ji}\partial_\mu h^{-1}_{ji}. $$

Thus the local field A_μ is not itself a globally defined tensor on a nontrivial bundle. The curvature constructed below does glue covariantly:

$$F^{(j)}_{\mu\nu} = h_{ji} F^{(i)}_{\mu\nu} h_{ji}^{-1}.$$

The local formulas therefore describe a connection on a principal bundle; they do not assume that the bundle is globally trivial.

45.2 Curvature and the Yang-Mills Action

Define the covariant differential operator

$$\nabla_\mu := \partial_\mu - \mathrm{i} A_\mu. \tag{45.5}$$

The gauge coupling has been absorbed into the connection in this chapter: if g_{el} denotes the Abelian charge called g in Chapter 42, then relative to the QED convention $\partial_\mu - \mathrm{i} g_{\mathrm{el}} A_\mu^{\mathrm{QED}}$ the present connection is $A_\mu^{\mathrm{here}} = g_{\mathrm{el}} A_\mu^{\mathrm{QED}}$. With this choice the curvature and the action carry the coupling in the Yang–Mills kinetic term rather than in the covariant derivative. In the $U(1)$ specialization,

$$A_\mu^{\mathrm{here}} = g_{\mathrm{el}} A_\mu^{\mathrm{QED}}, \qquad F_{\mu\nu}^{\mathrm{here}} = \partial_\mu A_\nu^{\mathrm{here}} - \partial_\nu A_\mu^{\mathrm{here}} = g_{\mathrm{el}} F_{\mu\nu}^{\mathrm{QED}}. \tag{45.6}$$

This is a change of field normalization, not a new physical assumption; every occurrence of $F_{\mu\nu}$ below is in the coupling-absorbed Yang–Mills normalization. The finite transformation law (45.4) is equivalent to

$$\nabla'_\mu = g \nabla_\mu g^{-1}, \tag{45.7}$$

where the factors are multiplied as differential operators. The curvature is

$$F_{\mu\nu} := \mathrm{i}[\nabla_\mu, \nabla_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu - \mathrm{i}[A_\mu, A_\nu] = F^a_{\mu\nu} t^a. \tag{45.8}$$

It follows from (45.7) that

$$F'_{\mu\nu} = g F_{\mu\nu} g^{-1}. \tag{45.9}$$

Connection, curvature, and Bianchi identities. In the Hermitian convention of this chapter, the finite transformation law (45.4) is equivalent to (45.7). Consequently the curvature transforms covariantly as in (45.9). Its components are

$$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^a{}_{bc} A^b_\mu A^c_\nu. \tag{45.10}$$

For an adjoint-valued field X, define

$$D_\mu X := \partial_\mu X - \mathrm{i}[A_\mu, X].$$

Then the curvature obeys the Bianchi identity

$$D_\lambda F_{\mu\nu} + D_\mu F_{\nu\lambda} + D_\nu F_{\lambda\mu} = 0. \tag{45.11}$$

Let s be a test section in the local trivialization. Using $\partial_\mu(g^{-1}s) = (\partial_\mu g^{-1})s + g^{-1}\partial_\mu s$,

$$\begin{aligned}(g\nabla_\mu g^{-1})s &= g\big(\partial_\mu - \mathrm{i}A_\mu\big)(g^{-1}s)\\ &= \partial_\mu s + g(\partial_\mu g^{-1})s - \mathrm{i}gA_\mu g^{-1}s.\end{aligned}$$

Since $A'_\mu = gA_\mu g^{-1} + \mathrm{i}g\partial_\mu g^{-1}$, the last line is $(\partial_\mu - \mathrm{i}A'_\mu)s$. This proves $\nabla'_\mu = g\nabla_\mu g^{-1}$. Therefore

$$[\nabla'_\mu, \nabla'_\nu] = g[\nabla_\mu, \nabla_\nu]g^{-1},$$

and multiplication by i gives (45.9).

For the component formula, substitute $A_\mu = A^a_\mu t^a$ into (45.8) and use $[t^b, t^c] = \mathrm{i}f^a{}_{bc}t^a$. The commutator term contributes $-\mathrm{i}A^b_\mu A^c_\nu[t^b, t^c] = f^a{}_{bc}A^b_\mu A^c_\nu t^a$, which gives (45.10).

Finally, the Jacobi identity for the differential operators ∇_μ is

$$[\nabla_\lambda, [\nabla_\mu, \nabla_\nu]] + [\nabla_\mu, [\nabla_\nu, \nabla_\lambda]] + [\nabla_\nu, [\nabla_\lambda, \nabla_\mu]] = 0.$$

Since $[\nabla_\mu, \nabla_\nu] = -\mathrm{i}F_{\mu\nu}$ and $[\nabla_\lambda, X] = D_\lambda X$ for multiplication by an adjoint field X, the Jacobi identity is precisely (45.11).

Figure 45.2 shows the geometric content of the commutator formula. For a small oriented rectangle based at x, with side lengths a in the x^μ direction and b in the x^ν direction, let

$$U_\mu(x, a) = \mathcal{P}\exp\left\{\mathrm{i}\int_0^a A_\mu(x + se_\mu)\,\mathrm{d}s\right\}$$

be the parallel-transport operator for $\dot{x}^\rho\nabla_\rho s = 0$ along the horizontal side. The oriented loop holonomy is

$$U_\square(x; \mu, \nu) = U_\nu(x, b)^{-1}U_\mu(x + be_\nu, a)^{-1}U_\nu(x + ae_\mu, b)U_\mu(x, a).$$

Expanding the path-ordered exponentials and using the Baker–Campbell–Hausdorff formula gives

$$U_\square(x; \mu, \nu) = 1 + \mathrm{i}F_{\mu\nu}(x)\,ab + O(a^2b + ab^2).$$

Thus $F_{\mu\nu}$ is the infinitesimal failure of parallel transports in the two coordinate directions to commute.

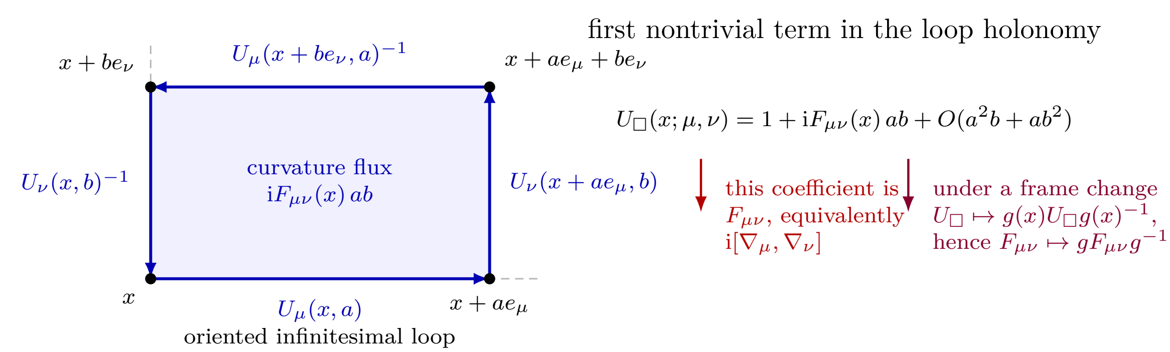

Figure 45.2: Curvature as infinitesimal loop holonomy. Parallel transport around the small rectangle returns a section to the same base point with $U_\square = 1 + \mathrm{i}F_{\mu\nu}ab + O(a^2b + ab^2)$. A change of local frame conjugates the based loop holonomy, so the curvature transforms by $F_{\mu\nu} \mapsto gF_{\mu\nu}g^{-1}$; invariant traces used in the Yang–Mills action remove this conjugation.

An invariant trace is a symmetric bilinear form on $\mathfrak{g}$, written in a chosen representation as

$$\operatorname{tr}(t^a t^b) = \kappa^{ab}. \tag{45.12}$$

Cyclicity gives

$$\operatorname{tr}([t^a, t^b]t^c) = \operatorname{tr}(t^a[t^b, t^c])$$

and, equivalently,

$$\operatorname{tr}(gXg^{-1}gYg^{-1}) = \operatorname{tr}(XY)$$

for Lie-algebra-valued X, Y. It also gives the invariant tensor

$$f_{abc} := \kappa^{ad} f^d{}_{bc} = -\mathrm{i}\ \operatorname{tr}\big(t^a[t^b, t^c]\big), \tag{45.13}$$

which is completely antisymmetric in a, b, c. Here $\kappa^{ab} := \operatorname{tr}(t^a t^b)$, while κ_{ab} denotes the inverse matrix:

$$\kappa_{ac}\kappa^{cb} = \delta_a{}^b. \tag{45.14}$$

Consequently the output-first structure constants are recovered from the trace-lowered constants by

$$f^a{}_{bc} = \kappa_{ad} f_{dbc}. \tag{45.15}$$

The trace normalization used for the Yang–Mills coupling below is $\kappa^{ab} = \delta^{ab}$ unless another normalization is explicitly declared. In that convention $f_{abc} = f^a{}_{bc}$ after the obvious identification of labels. If instead one uses the common fundamental-matrix normalization $\operatorname{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$, then $\kappa_{ab} = 2\delta_{ab}$ and

$$f^a{}_{bc} = 2\delta_{ad} f_{dbc}.$$

This factor of 2 is a normalization consequence of the chosen trace pairing, not a separate convention for the Lie bracket.

The Lorentzian Yang-Mills Lagrangian density is

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4g_{\mathrm{YM}}^2} \operatorname{tr}(F_{\mu\nu}F^{\mu\nu}). \tag{45.16}$$

With the default normalization $\operatorname{tr}(t^a t^b) = \delta^{ab}$, this is

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4g_{\mathrm{YM}}^2} F^a_{\mu\nu} F^{a\mu\nu}.$$

Changing the invariant bilinear rescales the component expression and hence the coordinate called g_{YM}; the trace-form equation above is the definition of the coupling convention used in this monograph.

Warning 45.1 (Trace-form coupling convention). The Yang–Mills coupling used in this monograph is defined by the trace-form coefficient in (45.16). Changing from $\operatorname{tr}(t^a t^b) = \delta^{ab}$ to $\operatorname{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$ changes the component coordinates $F^a_{\mu\nu}$ and the component coordinate called g_{YM}. It is not a legitimate convention change to keep the same component fields, the same trace symbol, and the same coupling while inserting or removing a factor of $1/2$. The invariant datum is the matrix-valued curvature F together with the displayed trace coefficient.

Yang–Mills variation in the trace-form convention. Let

$$S_{\mathrm{YM}}[A] = -\frac{1}{4g_{\mathrm{YM}}^2}\int_M \mathrm{d}^D x\ \mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$$

on a Lorentzian spacetime region M, and assume boundary conditions for which integrations by parts have no boundary contribution. For a variation δA_μ,

$$\delta F_{\mu\nu} = D_\mu \delta A_\nu - D_\nu \delta A_\mu, \tag{45.17}$$

and

$$\delta S_{\mathrm{YM}} = \frac{1}{g_{\mathrm{YM}}^2}\int_M \mathrm{d}^D x\ \mathrm{tr}\big((D_\mu F^{\mu\nu})\delta A_\nu\big). \tag{45.18}$$

If matter coupled to the same connection has current j^ν defined by

$$\delta S_{\mathrm{matter}} = -\int_M \mathrm{d}^D x\ \mathrm{tr}(j^\nu \delta A_\nu), \tag{45.19}$$

then the classical gauge-field equation is

$$D_\mu F^{\mu\nu} = g_{\mathrm{YM}}^2 j^\nu. \tag{45.20}$$

For pure Yang–Mills, $j^\nu = 0$.

Using the definition of $F_{\mu\nu}$,

$$\begin{aligned}\delta F_{\mu\nu} &= \partial_\mu \delta A_\nu - \partial_\nu \delta A_\mu - \mathrm{i}[\delta A_\mu, A_\nu] - \mathrm{i}[A_\mu, \delta A_\nu]\\ &= D_\mu \delta A_\nu - D_\nu \delta A_\mu.\end{aligned}$$

Then

$$\delta S_{\mathrm{YM}} = -\frac{1}{2g_{\mathrm{YM}}^2}\int \mathrm{d}^D x\ \mathrm{tr}(F^{\mu\nu}\delta F_{\mu\nu}).$$

Substituting (45.17) and using antisymmetry of $F^{\mu\nu}$ gives

$$\delta S_{\mathrm{YM}} = -\frac{1}{g_{\mathrm{YM}}^2}\int \mathrm{d}^D x\ \mathrm{tr}(F^{\mu\nu} D_\mu \delta A_\nu).$$

The invariant trace satisfies $\mathrm{tr}(X D_\mu Y) = \partial_\mu \mathrm{tr}(XY) - \mathrm{tr}((D_\mu X)Y)$. After dropping the boundary term, this is (45.18). Adding (45.19) and requiring the variation to vanish for arbitrary δA_ν gives (45.20).

For a unitary Lorentzian quantum theory built from these fields, the invariant quadratic form on the gauge algebra is chosen positive definite. Equivalently, the local gauge algebra is a compact reductive Lie algebra: a direct sum of abelian $\mathbb{R}$ factors and compact simple factors. The compact simple factors are the simple Lie algebras of Cartan type

$$A,\ B,\ C,\ D,\ E,\ F,\ G.$$

For these algebras one may choose a linear basis in which

$$\kappa^{ab} = \mathrm{tr}(t^a t^b) = \delta^{ab},$$

which is the normalization used unless another normalization is explicitly declared.

Remark 45.2 (Status of four-dimensional quantum Yang–Mills). The construction in this chapter is classical and local. It supplies the connection, curvature, invariant action, and matter couplings used later in perturbation theory and in regulated path integrals. For a compact simple gauge group in four Euclidean dimensions, the nonperturbative construction of pure Yang–Mills theory on $\mathbb{R}^4$, together with a proof that the resulting quantum theory has a positive mass gap, is the Yang–Mills existence and mass-gap problem of the Clay Millennium list. A theorem at that level would construct continuum correlation functions or an equivalent operator-algebraic theory satisfying the standard structural axioms and would prove that the spectrum above the vacuum begins at a strictly positive mass.

Consequently, the local Lagrangian (45.16), its BRST gauge-fixed perturbation theory, and finite-cutoff lattice regularizations are different mathematical objects from a completed four-dimensional continuum quantum Yang–Mills theory with mass gap. Whenever later chapters use a mass gap, glueball spectrum, or confinement property in four-dimensional Yang–Mills, that input is explicitly a nonperturbative hypothesis, a lattice-supported expectation, or a statement inside a regulated approximation until the continuum existence problem has been solved. The finite-cutoff lattice formulation itself is developed in Chapter 46, where the continuum-limit hypothesis and its relation to covariant perturbation theory are stated separately.

The basic example $SU(2)$ can be written in the default trace convention as

$$t^a = \frac{\sigma^a}{\sqrt{2}}, \qquad a = 1, 2, 3,$$

where σ^a are the Pauli matrices. Then $\operatorname{tr}(t^a t^b) = \delta^{ab}$ and

$$[t^a, t^b] = \mathrm{i}\sqrt{2}\,\epsilon^c{}_{ab} t^c, \qquad f^c{}_{ab} = \sqrt{2}\,\epsilon^c{}_{ab}.$$

The frequently used basis $\sigma^a/2$ is the alternate half-trace coordinate system discussed above; it is not the default normalization of this monograph. More generally, the Hermitian coordinate space $i\,\mathfrak{su}(N)$ is represented by traceless Hermitian $N \times N$ matrices, and

$$SU(N) = \{g \in U(N) : \det g = 1\}.$$

In four spacetime dimensions there is another local gauge-invariant Lorentz scalar of power-counting dimension four, written in the trace convention just fixed.[1]

$$\Delta\mathcal{L}_\theta = \frac{\theta}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}(F_{\mu\nu}F_{\rho\sigma}). \tag{45.21}$$

With $\operatorname{tr}(t^a t^b) = \delta^{ab}$, this equals

$$\frac{\theta}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}F^a_{\mu\nu}F^a_{\rho\sigma}.$$

Authors using a basis with $\operatorname{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$ write the same trace-form density with half this component coefficient, because their components of $F_{\mu\nu}$ are rescaled relative to the basis used

[1] With $F_{\mu\nu} = F^a_{\mu\nu}t^a$ and the default $\operatorname{tr}(t^a t^b) = \delta^{ab}$, $\operatorname{tr}(F_{\mu\nu}F_{\rho\sigma}) = F^a_{\mu\nu}F^a_{\rho\sigma}$. If one instead uses generators normalized by $\operatorname{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$, the components of the same matrix-valued curvature and the component form of the coupling must be rescaled accordingly. The trace-form equations are the convention-independent statements. Here and below the trace is the actual matrix trace in the chosen representation applied to the matrix-valued curvature F; it is not an independent component contraction that may be rescaled while F is held fixed.

here. The normalization is fixed by the Chern–Weil integer. For an $SU(N)$ bundle over an oriented compact four-manifold M, with

$$F = \frac{1}{2} F_{\mu\nu}\, \mathrm{d}x^\mu \wedge \mathrm{d}x^\nu,$$

the number

$$Q(P, A) := \frac{1}{8\pi^2} \int_M \mathrm{tr}(F \wedge F) = \frac{1}{32\pi^2} \int_M \mathrm{d}^4x\, \epsilon^{\mu\nu\rho\sigma}\, \mathrm{tr}(F_{\mu\nu} F_{\rho\sigma}) \in \mathbb{Z} \tag{45.22}$$

is the integral characteristic number determined by the second Chern class, with the overall sign fixed by the Hermitian curvature convention. For finite-action $SU(N)$ fields on $\mathbb{R}^4$, compactification by the point at infinity gives the same integer; equivalently, it is the degree of the limiting pure gauge map $S^3_\infty \to SU(N)$. This density is odd under parity and time reversal. In local coordinates it is a total derivative, so it does not change the local Euler-Lagrange equations under boundary conditions that keep the boundary variation fixed. Perturbation theory around the trivial gauge-field sector consequently has no local Feynman vertex associated with (45.21). Finite-action gauge fields may approach nontrivial pure gauges at spatial infinity, and then the spacetime integral of (45.21) equals $\theta Q(P, A)$. Thus θ enters through global topological sectors of the gauge field, and the Lorentzian path-integral phase is invariant under $\theta \mapsto \theta + 2\pi$. The explicit $Q = 1$ $SU(2)$ BPST representative, its action saturation, zero modes, and the resulting fermionic instanton vertex are constructed in Section 51.17.

45.3 Higher-Form Symmetry Data in Gauge Theory

Ordinary internal global symmetries act on local operators. Gauge theories also contain symmetries whose charged objects are extended operators. The basic example needed later is the center one-form symmetry of pure Yang–Mills theory. We record the definition here because it fixes the meaning of phrases such as center charge, screening, string breaking, and Wilson-loop order parameter in the QCD chapters.

Definition 45.3 (Invertible p-form symmetry, operational form)**.** Let the spacetime dimension be D, and let A be an abelian group. An invertible p-form global symmetry with group A, in the sector of the theory under discussion, consists of topological operators

$$U_a(\Sigma^{D-p-1}), \qquad a \in A,$$

assigned to closed oriented submanifolds Σ^{D-p-1} of codimension $p+1$, together with p-dimensional charged operators $\mathcal{W}_q(C^p)$. The operators satisfy

$$U_a(\Sigma) U_b(\Sigma) = U_{a+b}(\Sigma), \qquad U_0(\Sigma) = 1,$$

and are invariant under smooth deformations of Σ that do not cross charged insertions. If Σ links C, the symmetry action is

$$U_a(\Sigma)\, \mathcal{W}_q(C)\, U_a(\Sigma)^{-1} = \chi_q(a)^{\mathrm{Lk}(\Sigma, C)} \mathcal{W}_q(C), \tag{45.23}$$

where $\chi_q : A \to U(1)$ is the character carried by $\mathcal{W}_q$, and $\mathrm{Lk}(\Sigma, C)$ is the oriented linking number when the dimensions are complementary as above.

For $p = 0$, the topological operator is codimension one and separates space into two regions; moving it past a local operator implements the ordinary global symmetry action on that local operator. For $p = 1$ in four dimensions, $U_a(\Sigma)$ is a surface operator, and the charged objects are line operators. Invertibility means that the symmetry operators have inverses. More general topological defects may have non-group-like fusion; those categorical and noninvertible structures are part of the later global structure volume, after line and surface operators have been developed as QFT observables.

Consider pure $SU(N)$ Yang–Mills theory with no dynamical matter in representations of nonzero N-ality. The center is

$$Z(SU(N)) = \{\mathrm{e}^{2\pi \mathrm{i} m/N}\mathbf{1}_N : m \in \mathbb{Z}_N\}.$$

All local gauge-invariant operators built from $F_{\mu\nu}$, covariant derivatives, and adjoint fields are neutral under this center, because the adjoint representation has zero N-ality. A Wilson line in a representation R,

$$W_R(C) = \mathrm{tr}_R\, P \exp\left\{\mathrm{i}\int_C A_\mu\, \mathrm{d}x^\mu\right\},$$

has center charge $k_R \in \mathbb{Z}_N$, defined by

$$z\,\mathbf{1}_N \text{ acts on } R \text{ as } z^{k_R}.$$

The electric center one-form symmetry is the $\mathbb{Z}_N$ one-form symmetry whose charged operators are precisely these Wilson lines.

One concrete construction of the symmetry surface is as follows. Let Σ be a closed oriented two-surface in four-dimensional spacetime, and choose a three-chain V with $\partial V = \Sigma$ locally. Across V, perform a gauge transformation which is single-valued up to the center element $z_m = \mathrm{e}^{2\pi \mathrm{i} m/N}\mathbf{1}_N$. Adjoint fields and the connection in the adjoint bundle are unchanged as local gauge-invariant data; a Wilson line crossing V acquires the center phase seen by its representation. The resulting topological surface operator $U_m(\Sigma)$ obeys

$$U_m(\Sigma)W_R(C)U_m(\Sigma)^{-1} = \exp\left\{\frac{2\pi \mathrm{i}\, m k_R}{N}\,\mathrm{Lk}(\Sigma, C)\right\} W_R(C). \tag{45.24}$$

This equation is the definition of the center charge used later. The topological character of $U_m(\Sigma)$ says that deforming Σ while keeping it away from C leaves the correlation function unchanged; crossing C changes the linking number and produces exactly the displayed phase.

Dynamical matter determines the unbroken subgroup. Suppose the theory contains matter fields in representations R_α of $SU(N)$, with N-alities k_α. A Wilson line in R_α can end on a dynamical local field only when that field is present in the operator algebra. Then a center surface linked with the line endpoint fails to define a topological operation on the full set of insertions unless its phase on every dynamical endpoint is trivial. The surviving electric one-form symmetry is

$$A_{\mathrm{el}} = \{m \in \mathbb{Z}_N : \exp(2\pi \mathrm{i} m k_\alpha/N) = 1 \text{ for every dynamical } R_\alpha\}. \tag{45.25}$$

Thus pure Yang–Mills has $A_{\mathrm{el}} = \mathbb{Z}_N$, adjoint matter preserves the same electric center one-form symmetry, and dynamical fundamental quarks break it completely.

The behavior of large Wilson loops is a dynamical question, but the symmetry data determine what can serve as a sharp diagnostic. In a massive pure Yang–Mills theory, a Wilson loop with nonzero N-ality is charged under A_{el}, so its area or perimeter behavior distinguishes phases of the one-form symmetry. With dynamical fundamental quarks the same loop can be screened by pair creation; the QCD chapter therefore treats the Wilson loop as a static-source observable, while the one-form-symmetry order-parameter interpretation applies to the unbroken center subgroup.

Remark 45.4 (Higher groups, noninvertible symmetries, and placement). The definition above covers the invertible higher-form symmetry needed for the center symmetry of pure Yang–Mills. More refined global structures include mixed ordinary/higher-form symmetries organized by higher groups, background $p+1$-form gauge fields and their Postnikov constraints, and noninvertible topological defects with categorical fusion. Those structures are QFT data about extended operators and background couplings, and they are conceptually distinct from the local gauge redundancy used to coordinatize the field space. They belong to the later volume on global structure, phases, and extended operators. The present gauge-theory volume uses only the definitions required for Wilson lines, screening, confinement diagnostics, and anomaly statements.

45.4 Matter Representations

Let R be a finite-dimensional representation of G on a vector space V_R. The matter fields below use complex V_R; real representations, such as the adjoint representation, are included by complexification when they are compared with complex representations. The representation is a homomorphism

$$\rho_R : G \longrightarrow GL(V_R), \qquad \rho_R(gh) = \rho_R(g)\rho_R(h). \tag{45.26}$$

Its derived Lie-algebra representation is the linear map $\widetilde{\rho}_R : \mathfrak{g} \to \mathrm{End}(V_R)$ determined by

$$\rho_R(\mathrm{e}^{\mathrm{i}\zeta^a t^a}) = \mathrm{e}^{\mathrm{i}\zeta^a t^a_R}, \qquad t^a_R := \widetilde{\rho}_R(t^a). \tag{45.27}$$

The matrices t^a_R obey

$$[t^a_R, t^b_R] = \mathrm{i} f^c{}_{ab} t^c_R. \tag{45.28}$$

For compact G, every finite-dimensional complex representation used in a unitary theory may be equipped with a G-invariant Hermitian inner product. In such a basis the matrices t^a_R are Hermitian. This is the matter-field version of the same Hermitian convention used for the gauge potential.

For $G = SU(N)$, three representations recur throughout gauge theory:

representation	V_R	infinitesimal generators
fundamental $\square$	$\mathbb{C}^N$	$t^a_\square = t^a$
anti-fundamental $\overline{\square}$	$\mathbb{C}^N$	$t^a_{\overline{\square}} = -(t^a)^*$
adjoint	$\mathfrak{g}_\mathbb{C}$	$t^a_{\mathrm{adj}}(t^b) = \mathrm{i} f^c{}_{ab} t^c$

In the fundamental representation, $\rho_\square(g) = g$ and $t^a_\square = t^a$. In the anti-fundamental representation,

$$\rho_{\overline{\square}}(g) = g^* \qquad \text{complex conjugation, without transposition,}$$

so differentiating $\rho_{\overline{\square}}(\mathrm{e}^{\mathrm{i}\zeta^a t^a}) = \mathrm{e}^{\mathrm{i}\zeta^a t^a_{\overline{\square}}}$ gives $t^a_{\overline{\square}} = -(t^a)^*$. Here $\mathfrak{g}_\mathbb{C}$ denotes the complexification of the real Hermitian coordinate space. A real adjoint-valued field is obtained by imposing the corresponding reality condition on its components. The finite adjoint representation is conjugation on the algebra:

$$v \mapsto gvg^{-1}, \qquad \rho_{\mathrm{adj}}(g)v = gvg^{-1}.$$

Its infinitesimal form is consistent with the convention differentiating $v \mapsto e^{i\zeta^a t^a} v e^{-i\zeta^a t^a}$:

$$\delta v = i\zeta^a [t^a, v] = i\zeta^a t^a_{\mathrm{adj}} v.$$

Figure 45.3 gathers the $SU(N)$ representation data used in the matter-coupling formulas: fundamental, antifundamental, adjoint, and tensor-product conventions.

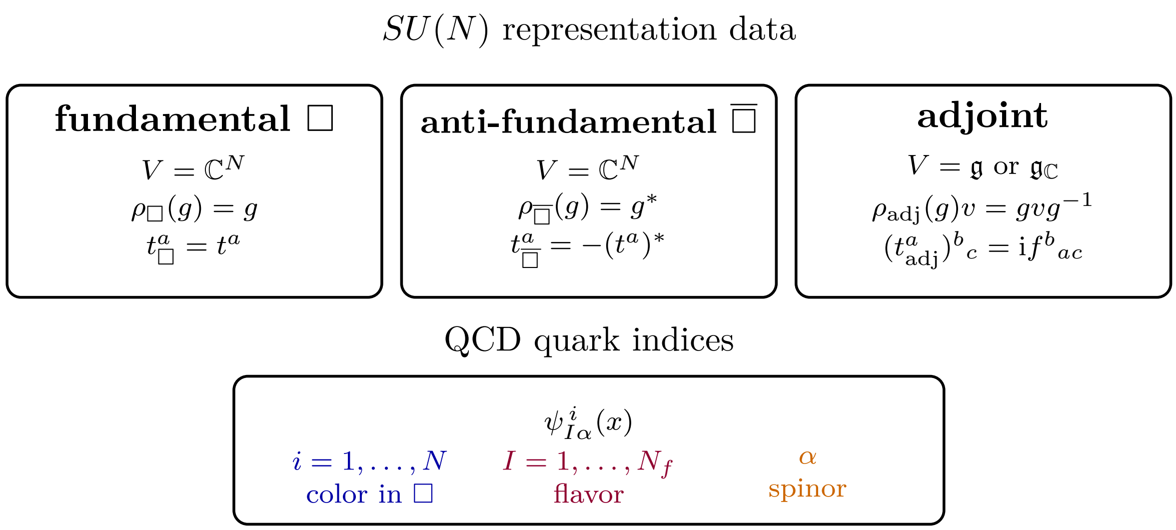

Figure 45.3: The fundamental, anti-fundamental, and adjoint representations of $SU(N)$ used in Yang-Mills theory and QCD. The anti-fundamental finite action is complex conjugation of the matrix entries, not Hermitian conjugation.

If $\psi(x) \in V_R$, its finite gauge transformation is

$$\psi'(x) = \rho_R(g(x))\psi(x). \tag{45.29}$$

The covariant derivative acting on ψ is

$$D_\mu \psi = \partial_\mu \psi - iA^a_\mu t^a_R \psi. \tag{45.30}$$

Using (45.4) and (45.26), one obtains

$$(D_\mu \psi)' = \rho_R(g) D_\mu \psi. \tag{45.31}$$

This covariance is the algebraic reason that replacing ordinary derivatives by D_μ produces gauge-invariant matter kinetic terms. For example, if $(\ , \ )_R$ is the invariant Hermitian pairing on V_R, then $(D_\mu\psi, D^\mu\psi)_R$ is gauge invariant for scalar matter. For Dirac matter, the gauge index contraction in $\bar{\psi}\gamma^\mu D_\mu \psi$ uses the pairing between R^* and R. Mass and Yukawa couplings are gauge invariant only when their flavor and representation tensors define intertwiners from the tensor product of fields to the trivial representation.

Figure 45.4 displays the geometric meaning of the same covariance statement. The matter field is a section of the associated bundle $P \times_G V_R$. Parallel transport along a curve $\gamma : x \to y$ is the representation R applied to the gauge-field parallel transport, and infinitesimal loop transport acts on matter by the represented curvature:

$$U_R(\partial\square)\psi(x) = \psi(x) + iF^a_{\mu\nu}(x) t^a_R \psi(x)\, ab + O(a^2 b + ab^2).$$

The invariant pairings used in kinetic, mass, and Yukawa terms are pairings of associated fibers.

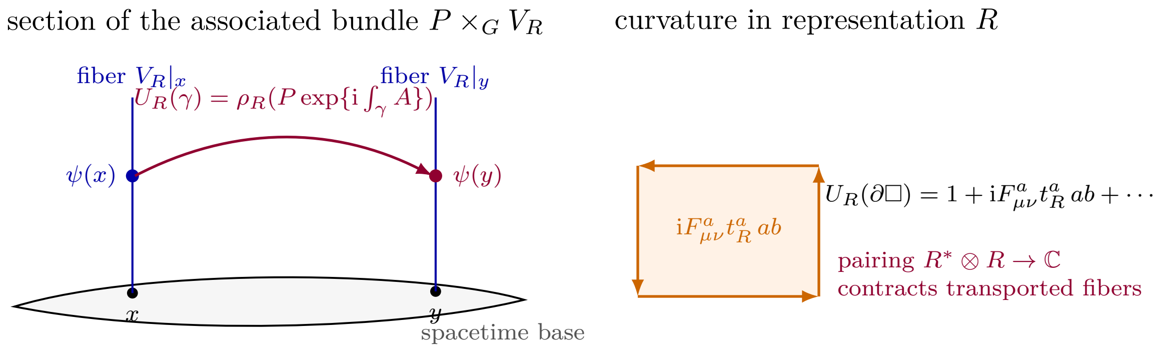

Figure 45.4: Matter covariance as associated-bundle parallel transport. A section value $\psi(x) \in V_R|_x$ is transported by applying the representation R to the gauge holonomy. Around an infinitesimal loop the first nontrivial term is the represented curvature $F^a_{\mu\nu}t^a_R$. Gauge-invariant matter contractions are pairings of associated fibers, for instance $R^* \otimes R \to \mathbb{C}$.

45.5 The Brout–Englert–Higgs Mechanism

Gauge redundancy is not a physical global symmetry acting faithfully on the Hilbert space. A gauge-theory phase with a scalar expectation value is therefore not defined by a gauge-variant order parameter. Its perturbative description is defined by choosing a coordinate chart on field space near a minimum of the gauge-invariant potential, then fixing the gauge or passing to gauge-invariant variables. The Brout–Englert–Higgs mechanism is the local quadratic statement that scalar fluctuations tangent to the gauge orbit supply the longitudinal polarizations of gauge bosons whose generators do not stabilize the chosen vacuum. The physical formulation is spectral: the BRST-invariant or gauge-invariant Hilbert space contains massive vector particles and scalar excitations, while the would-be Goldstone coordinates are not independent physical massless particles.

45.5.1 Abelian Higgs Model

Use the coupling-absorbed Abelian convention inherited from (45.6). Thus

$$D_\mu\phi = \partial_\mu\phi - \mathrm{i}A_\mu\phi,$$

$$\mathcal{L} = -\frac{1}{4e^2}F_{\mu\nu}F^{\mu\nu} + (D_\mu\phi)^* D^\mu\phi - \lambda\left(|\phi|^2 - \frac{v^2}{2}\right)^2. \tag{45.32}$$

The finite gauge transformation is

$$A_\mu \mapsto A_\mu + \partial_\mu\alpha, \qquad \phi \mapsto e^{\mathrm{i}\alpha}\phi.$$

Choose a local Cartesian coordinate chart near the minimum

$$\phi(x) = \frac{1}{\sqrt{2}}\big(v + h(x) + \mathrm{i}\pi(x)\big).$$

The scalar kinetic term gives, to quadratic order,

$$(D_\mu\phi)^* D^\mu\phi = \frac{1}{2}\partial_\mu h\,\partial^\mu h + \frac{1}{2}(\partial_\mu\pi - vA_\mu)(\partial^\mu\pi - vA^\mu) + O(\text{cubic}). \tag{45.33}$$

The potential gives

$$\lambda\left(|\phi|^2 - \frac{v^2}{2}\right)^2 = \lambda v^2 h^2 + O(\text{cubic}), \qquad m_h^2 = 2\lambda v^2.$$

The gauge field A_μ is not canonically normalized; the canonical vector is $\mathcal{A}_\mu = A_\mu/e$. Therefore the vector mass is

$$m_A = ev.$$

Equation (45.33) displays the mechanism: the derivative of the orbit coordinate π appears only through the combination $\partial_\mu\pi - vA_\mu$ at quadratic order.

On the open set where $v + h \neq 0$, write polar coordinates

$$\phi(x) = \frac{v + H(x)}{\sqrt{2}}\exp\!\left(\frac{\mathrm{i}\theta(x)}{v}\right).$$

The gauge-invariant local vector coordinate

$$B_\mu := A_\mu - \frac{1}{v}\partial_\mu\theta \tag{45.34}$$

is invariant under $A_\mu \mapsto A_\mu + \partial_\mu\alpha$, $\theta \mapsto \theta + v\alpha$. In these coordinates

$$(D_\mu\phi)^* D^\mu\phi = \frac{1}{2}\partial_\mu H\,\partial^\mu H + \frac{1}{2}(v + H)^2 B_\mu B^\mu.$$

This is the unitary-gauge description: the orbit coordinate has been removed from the local chart and the vector has a mass term. It is useful for classical mode counting, but its vector propagator has poor ultraviolet power-counting behavior. Perturbative renormalizability is most transparent in R_ξ gauges.

The R_ξ gauge-fixing functional in the coupling-absorbed convention is

$$\mathcal{F}_\xi = \partial_\mu A^\mu + \xi e^2 v\pi. \tag{45.35}$$

Adding

$$\mathcal{L}_{\text{gf}} = -\frac{1}{2e^2\xi}\mathcal{F}_\xi^2$$

cancels the quadratic mixing term $v(\partial_\mu A^\mu)\pi$ obtained from (45.33) after integrating by parts. The quadratic Lagrangian becomes

$$\mathcal{L}_2 = -\frac{1}{4e^2}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2e^2\xi}(\partial_\mu A^\mu)^2 + \frac{1}{2}v^2 A_\mu A^\mu + \frac{1}{2}(\partial h)^2 - \frac{1}{2}m_h^2 h^2 + \frac{1}{2}(\partial\pi)^2 - \frac{1}{2}\xi m_A^2\pi^2.$$

In terms of the canonical vector $\mathcal{A}_\mu = A_\mu/e$, the propagator is

$$D_{\mu\nu}(p) = \frac{-\mathrm{i}}{p^2 - m_A^2 + \mathrm{i}0}\left[\eta_{\mu\nu} - \frac{(1-\xi)p_\mu p_\nu}{p^2 - \xi m_A^2 + \mathrm{i}0}\right]. \tag{45.36}$$

It decays as p^{-2} at large momentum for fixed ξ. The field π and the ghosts have gauge-dependent mass $\sqrt{\xi}\, m_A$; they are not physical particles. The Faddeev–Popov operator follows by varying (45.35) under the infinitesimal gauge transformation. Since

$$\delta_\alpha A_\mu = \partial_\mu \alpha, \qquad \delta_\alpha \pi = (v+h)\alpha + O(\pi\alpha),$$

one obtains

$$\delta_\alpha \mathcal{F}_\xi = \left(\Box + \xi e^2 v(v+h)\right)\alpha + O(\pi\alpha).$$

Thus the ghost action contains the quadratic mass ξm_A^2 and a local ghost–ghost–h vertex. In an Abelian unbroken gauge theory ghosts decouple; in the R_ξ chart of the Abelian Higgs model this field dependence of the gauge condition makes their BRST role visible.

Figure 45.5 separates the two pieces of the Abelian BEH calculation. The angular coordinate on the circle of scalar minima is a gauge-orbit coordinate, and the physical local mode count is the same before and after rewriting the fields.

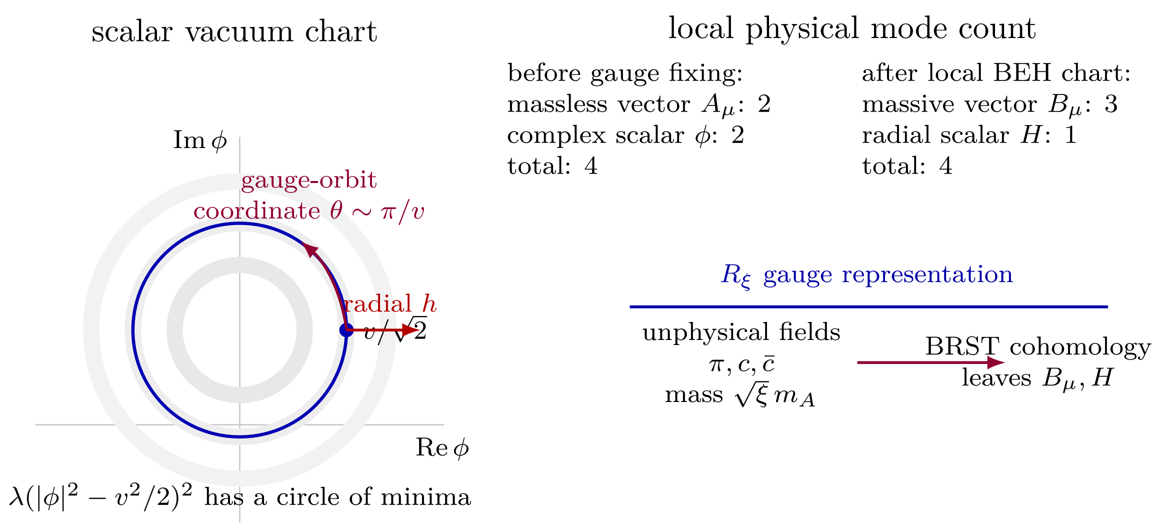

Figure 45.5: Abelian BEH geometry and mode accounting. The angular coordinate along the circle of minima is a gauge-orbit coordinate; locally it is the would-be Goldstone field. The local field variables reorganize $2+2$ degrees of freedom into a massive vector with three physical polarizations and one radial scalar. R_ξ gauges keep the orbit coordinate and ghosts as gauge-dependent representatives, but the BRST cohomology contains the same physical modes.

45.5.2 Nonabelian Mass Matrix and the $SU(2) \to U(1)$ Pattern

Let a scalar field Φ take values in a unitary representation V_R of a compact gauge group G, and let $v \in V_R$ be a minimum of a gauge-invariant potential. The stabilizer subgroup is

$$H = \{g \in G : \rho_R(g)v = v\}, \qquad \mathfrak{h} = \{X \in \mathfrak{g} : t_R(X)v = 0\}.$$

The tangent space to the gauge orbit at v is

$$T_v(G \cdot v) = \{\, \mathrm{i} t_R(X) v : X \in \mathfrak{g}\,\} \simeq \mathfrak{g}/\mathfrak{h}.$$

It is useful to isolate the finite-dimensional linear map

$$q_v : \mathfrak{g} \longrightarrow T_v V_R, \qquad q_v(X) = \mathrm{i}t_R(X)v. \tag{45.37}$$

The kernel of q_v is $\mathfrak{h}$. Thus q_v is the differential of the gauge-orbit map at the chosen vacuum, and all local mode counting in the Brout–Englert–Higgs mechanism is the mode counting of this linear map. Expanding the scalar kinetic term around $\Phi = v + \eta$ gives the gauge-boson mass bilinear

$$(D_\mu v, D^\mu v)_R = A^a_\mu A^{b\mu}\,(t^a_R v, t^b_R v)_R. \tag{45.38}$$

The Hermitian matrix

$$K_{ab} := \mathrm{Re}(t^a_R v, t^b_R v)_R \tag{45.39}$$

is positive semidefinite, and its kernel is exactly the unbroken Lie algebra:

$$K_{ab}X^b = 0 \quad \Longleftrightarrow \quad t_R(X)v = 0 \quad \Longleftrightarrow \quad X \in \mathfrak{h}.$$

Equivalently, $K = q_v^\dagger q_v$, where the adjoint is taken with respect to the invariant inner product on V_R and the invariant trace form on $\mathfrak{g}$.

Proposition 45.5 (Local BEH mode count)**.** *At a smooth vacuum v with compact stabilizer H, the scalar kinetic term gives nonzero masses to exactly* $\dim G - \dim H$ *gauge bosons. In four-dimensional Minkowski space these massive vector particles carry* $3(\dim G - \dim H)$ *physical polarizations. The scalar coordinates removed from a local unitary-gauge slice are exactly the tangent coordinates to the orbit G/H. The remaining scalar coordinates are coordinates normal to the gauge orbit, subject to the Hessian of the gauge-invariant potential on a local slice.*

Proof. Choose an H-invariant orthogonal decomposition of scalar fluctuations near v,

$$T_v V_R = \mathrm{im}\, q_v \oplus N_v,$$

where N_v is the orthogonal complement of the orbit tangent space. The existence of such a complement follows by averaging the Hermitian inner product over the compact group H. To quadratic order in fields,

$$D_\mu(v + \eta) = \partial_\mu \eta - q_v(A_\mu) + O(A_\mu \eta), \qquad A_\mu = A^a_\mu t^a.$$

If the orbit component of η is written as $q_v(\chi)$, then the quadratic expression depends on A_μ and χ through

$$\partial_\mu q_v(\chi) - q_v(A_\mu) = q_v(\partial_\mu \chi - A_\mu).$$

This identity is the precise local statement behind the phrase that the would-be Goldstone coordinate supplies the longitudinal vector polarization: the scalar orbit coordinate and the gauge potential appear in the same gauge-orbit differential. Since $\mathrm{rank}\, q_v = \dim \mathfrak{g} - \dim \mathfrak{h}$, exactly that many vector fields have nonzero mass eigenvalues. A massive vector particle in four spacetime dimensions has three physical polarizations after the BRST or gauge-invariant quotient. The normal scalar coordinates in N_v are not gauge-orbit coordinates; their quadratic masses are the eigenvalues of the potential Hessian restricted to a local slice transverse to the orbit. $\square$

After canonical normalization of the gauge kinetic term, the vector mass-squared matrix is $2g_{\mathrm{YM}}^2 K$, with the invariant trace form used to identify gauge-algebra indices. Hence precisely $\dim G - \dim H$ gauge bosons acquire mass. The same number of scalar coordinates tangent to G/H are gauge-orbit coordinates. A covariant R_ξ gauge keeps these coordinates in the field algebra but gives them gauge-dependent masses; a unitary-gauge chart removes them locally.

The nonabelian R_ξ construction is the adjoint of the same orbit differential. In a local linear chart, let $q_v^\dagger \eta \in \mathfrak{g}$ be the adjoint projection of the scalar fluctuation onto the broken gauge directions. The gauge-fixing functional

$$\mathcal{F}_\xi = \partial^\mu A_\mu + \xi g_{\mathrm{YM}}^2 q_v^\dagger \eta \tag{45.40}$$

is the nonabelian analogue of (45.35). Its quadratic cross term cancels the integration-by-parts mixing from $\|\partial_\mu \eta - q_v(A_\mu)\|^2$. In a basis of broken generators diagonalizing K, (45.40) becomes a direct sum of Abelian R_ξ gauges, with unphysical scalar and ghost masses $\sqrt{\xi}$ times the corresponding vector masses. The unbroken $\mathfrak{h}$ directions have no $q_v^\dagger \eta$ term and remain ordinary massless gauge directions at this stage.

For the adjoint $SU(2)$ model, take an adjoint scalar $\Phi = \Phi^a t^a$ and a vacuum $\Phi_0 = v t^3$. The stabilizer of Φ_0 is the $U(1)$ generated by t^3. The directions t^1, t^2 do not stabilize the vacuum, so the corresponding two gauge bosons are massive and the t^3 gauge boson remains massless. In electroweak $SU(2) \times U(1)$ with a fundamental scalar doublet, the same mass-matrix logic leaves the diagonal electromagnetic $U(1)$ unbroken and gives masses to the orthogonal charged and neutral vector combinations. The detailed electroweak parameter conventions belong to the Standard Model chapter; the structural statement is already contained in (45.38).

The perturbative renormalizability statement is also local in field space. An R_ξ gauge-fixed action for the shifted fields contains only local operators of power-counting dimension at most four when the original Yang–Mills–scalar action is renormalizable. The propagators have the large-momentum behavior required for power counting, and the BRST identities restrict counterterms to gauge-invariant deformations together with BRST-exact gauge-fixing and field-coordinate terms, as in Chapter 47. Unitary gauge is a useful reduced coordinate description of the classical spectrum, but it is not the gauge in which the renormalizability proof is manifest.

45.6 Finite-Energy Gauge-Higgs Solitons

The finite-energy configuration space of a nonabelian gauge-Higgs theory has connected components, asymptotic winding data, and nontrivial critical points of the energy functional. A classical soliton in this section is such a finite-energy critical point, together with its boundary sector and its localized energy density. Quantizing small fluctuations about such a critical point gives a semiclassical expansion with different background data from the translation-invariant vacuum expansion.

We formulate the discussion in the same Hermitian-generator convention and trace-form coupling convention used above. Let G be compact, let $\Phi(x)$ be an adjoint scalar field, and let

$$D_i \Phi := \partial_i \Phi - \mathrm{i}[A_i, \Phi], \qquad B_i := \frac{1}{2}\varepsilon_{ijk} F_{jk}$$

on a time slice $\mathbb{R}^3$. The index $i = 1, 2, 3$ is spatial and $\varepsilon_{123} = 1$. A simple gauge-Higgs energy functional is

$$E[A,\Phi] = \frac{1}{2g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\ \mathrm{tr}\big(B_iB_i + D_i\Phi D_i\Phi\big) + \frac{1}{g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\, U(\Phi), \tag{45.41}$$

where $U(\Phi) \geq 0$ is gauge invariant. For example, for $G = SU(2)$ one may take

$$U(\Phi) = \frac{\lambda}{4}\big(\mathrm{tr}\,\Phi^2 - v^2\big)^2, \qquad v > 0, \quad \lambda \geq 0.$$

The scalar Φ and the connection A_i are in the coupling-absorbed normalization of this chapter. If one instead writes the covariant derivative as $\partial_i - \mathrm{i}g_{\mathrm{phys}}A_i^{\mathrm{phys}}$, then $A_i = g_{\mathrm{phys}}A_i^{\mathrm{phys}}$; the trace-form energy (45.41) is the convention used below.

Definition 45.6 (Smooth finite-energy sector)**.** Fix a vacuum orbit

$$\mathcal{O}_v := \{\Phi \in \mathfrak{g} : U(\Phi) = 0\}.$$

In the smooth classical sector used in this section, a static configuration (A_i, Φ) is finite energy if the integral (45.41) is finite and if, after a gauge choice on the complement of a compact set,

$$U(\Phi(x)) \to 0, \qquad D_i\Phi(x) \to 0, \qquad B_i(x) \to 0 \quad \text{fast enough as } |x| \to \infty$$

to make the surface integrals below finite. The limiting Higgs field defines a map

$$\Phi_\infty : S^2_\infty \longrightarrow \mathcal{O}_v.$$

Two configurations are in the same asymptotic sector if their maps Φ_∞ are homotopic through finite-energy boundary data, modulo gauge transformations which extend over the bulk.

A more analytic treatment replaces smooth fields by Sobolev completions and states the boundary conditions as weighted norm conditions. The topological classification and the Bogomolny argument below are already visible in the smooth sector, where all integrations by parts can be justified by decay and then extended by completion when the appropriate functional-analytic hypotheses are imposed.

Let $\Phi_0 \in \mathcal{O}_v$ and let

$$H := \mathrm{Stab}_G(\Phi_0) = \{h \in G : h\Phi_0h^{-1} = \Phi_0\}.$$

For an adjoint orbit $\mathcal{O}_v \simeq G/H$, the asymptotic Higgs field is a map $S^2_\infty \to G/H$. Hence possible magnetic sectors are measured by $\pi_2(G/H)$. When G is simply connected, the long exact homotopy sequence of

$$H \longrightarrow G \longrightarrow G/H$$

gives

$$\pi_2(G/H) \simeq \pi_1(H),$$

because $\pi_2(G) = 0$ for compact connected Lie groups and $\pi_1(G) = 0$ for simply connected G. Thus the magnetic charge is the winding of the transition function of the unbroken group H seen at spatial infinity.

Example 45.7 $(SU(2) \to U(1))$**.** For $G = SU(2)$ and a nonzero adjoint vacuum value, the stabilizer is $H = U(1)$, so

$$\mathcal{O}_v \simeq SU(2)/U(1) \simeq S^2, \qquad \pi_2(\mathcal{O}_v) \simeq \mathbb{Z}.$$

The integer is the degree of the normalized asymptotic Higgs field

$$\widehat{\Phi}_\infty : S^2_\infty \to S^2, \qquad \widehat{\Phi}_\infty(\hat{x}) = \Phi_\infty(\hat{x})/v$$

when $\operatorname{tr}\Phi_\infty^2 = v^2$. This integer is invariant under gauge transformations which extend over the bulk. In a gauge where Φ_∞ is made constant separately on the northern and southern hemispheres of S^2_∞, the two gauges differ on the equator by a $U(1)$-valued transition function of the same winding.

Figure 45.6 displays the finite-energy boundary data for the monopole sector: the normalized Higgs field maps S^2_∞ to the vacuum sphere, and its equatorial transition function records the magnetic winding.

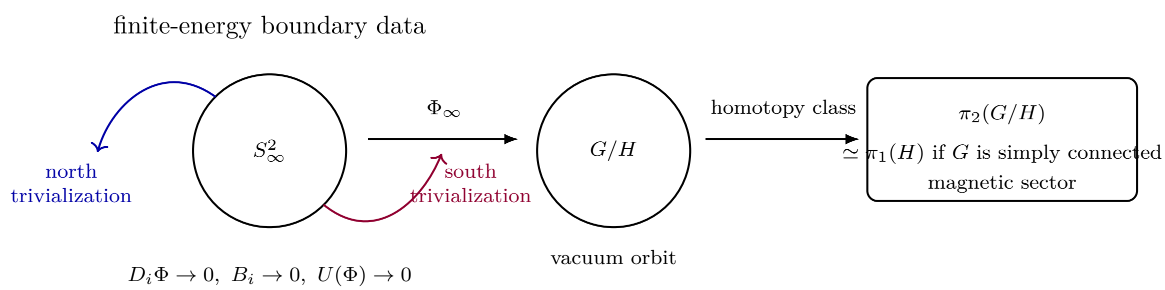

Figure 45.6: Finite energy turns spatial infinity into a two-sphere mapped to the vacuum orbit. For $SU(2) \to U(1)$, the degree of this map is the magnetic charge of the smooth monopole sector.

The Bogomolny bound is the simplest place where the topology enters the energy in addition to labeling boundary data. Set $U = 0$. This is the Prasad–Sommerfield or BPS limit of the adjoint Higgs model. Completing the square gives

$$E[A,\Phi] = \frac{1}{2g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\ \operatorname{tr}\big(B_i \mp D_i\Phi\big)^2 \pm \frac{1}{g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\ \operatorname{tr}(B_i D_i \Phi). \tag{45.42}$$

The Bianchi identity $D_iB_i = 0$ implies

$$\operatorname{tr}(B_iD_i\Phi) = \partial_i \operatorname{tr}(\Phi B_i).$$

Therefore

$$E[A,\Phi] \geq \frac{4\pi}{g_{\mathrm{YM}}^2}|\Gamma_{\mathrm{m}}(A,\Phi)|, \qquad \Gamma_{\mathrm{m}}(A,\Phi) := \frac{1}{4\pi}\int_{S^2_\infty} \mathrm{d}S_i\ \operatorname{tr}(\Phi B_i). \tag{45.43}$$

The number Γ_{m} is the magnetic central charge seen by the chosen asymptotic Higgs field. It is the trace pairing of the Higgs vacuum with the magnetic cocharacter determined by the $U(1)$ bundle at infinity. In a primitive $SU(2) \to U(1)$ sector one may write $\Gamma_{\mathrm{m}} = v_{\mathrm{m}}n$, $n \in \mathbb{Z}$, where v_{m} is the trace pairing of Φ_∞ with the primitive magnetic generator. The value of v_{m} changes if one rescales the matrix generator basis; the trace-form equation (45.43) does not. The inequality is saturated precisely when

$$B_i = \pm D_i \Phi. \tag{45.44}$$

These first-order equations imply the second-order Euler–Lagrange equations in the BPS limit: applying D_i to $B_i = \pm D_i\Phi$ gives $D_i D_i \Phi = 0$, while the variation of A_i gives $D_j F_{ji} = \mathrm{i}[\Phi, D_i\Phi]$, which follows by differentiating $B_i = \pm D_i\Phi$, using the Bianchi identity, and using $[D_i, D_j]\Phi = -\mathrm{i}[F_{ij}, \Phi]$.

Proposition 45.8 (Topological lower bound for adjoint $SU(2)$ monopoles)**.** *Consider smooth finite-energy $SU(2)$ adjoint-Higgs configurations in the BPS limit $U = 0$. Fix the asymptotic Higgs value and the primitive magnetic cocharacter so that $\Gamma_{\mathrm{m}} = v_{\mathrm{m}} n$ on the sector of degree $n \in \mathbb{Z}$. Then*

$$E \geq \frac{4\pi v_{\mathrm{m}}}{g_{\mathrm{YM}}^2}|n|.$$

Equality holds if and only if the Bogomolny equation (45.44) holds with the sign chosen to match the sign of n.

Proof. The square completion (45.42) gives, for either sign,

$$E = \frac{1}{2g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\ \mathrm{tr}(B_i \mp D_i\Phi)^2 \pm \frac{1}{g_{\mathrm{YM}}^2}\int_{\mathbb{R}^3} \mathrm{d}^3x\ \mathrm{tr}(B_i D_i \Phi).$$

The first term is nonnegative because the trace form is positive on the compact real Lie algebra. For the second term,

$$\mathrm{tr}(B_i D_i\Phi) = \partial_i\,\mathrm{tr}(B_i\Phi) - \mathrm{tr}((D_iB_i)\Phi).$$

The covariant Bianchi identity gives $D_iB_i = 0$, so the cross term is the surface integral in (45.43).

It remains to identify that surface integral with the magnetic cocharacter. Finite energy implies that, on the sphere at infinity, Φ has fixed length and $D_i\Phi \to 0$. Hence the structure group of the asymptotic bundle reduces to the stabilizer $U(1)$ of the limiting Higgs direction. Choose northern and southern patches on S^2_∞ in which Φ_∞ is gauge rotated to a fixed Cartan element H. On their equatorial overlap the transition map is

$$g_{NS}(\varphi) = \exp(\mathrm{i}n\varphi H_{\mathrm{m}})$$

for the primitive magnetic generator H_{m} and an integer winding n. In these patches the asymptotic connection is Abelian in the same Cartan direction, and Stokes' theorem gives a flux proportional to this winding:

$$\frac{1}{4\pi}\int_{S^2_\infty} \mathrm{d}S_i\ \mathrm{tr}(\Phi B_i) = \left[\frac{1}{4\pi}\int_{S^2_\infty}^{\text{primitive}} \mathrm{d}S_i\ \mathrm{tr}(\Phi B_i)\right] n = v_{\mathrm{m}} n.$$

The bracketed primitive flux is the normalization called v_{m} in the statement. This form keeps the trace-form convention explicit rather than hiding a generator normalization in H_{m}. Choosing the sign in the square completion to match the sign of n gives the lower bound

$$E \geq \frac{4\pi v_{\mathrm{m}}}{g_{\mathrm{YM}}^2}|n|.$$

Equality can hold only if the nonnegative square term vanishes almost everywhere. Smoothness makes this equivalent to the pointwise Bogomolny equation $B_i = \pm D_i\Phi$, with the same sign as the magnetic charge. $\square$

An explicit unit monopole is obtained from the hedgehog ansatz. To avoid embedding normalization factors in every radial equation, let

$$T_a := \frac{t_a}{\sqrt{2}} = \frac{\sigma_a}{2}, \qquad [T_a, T_b] = \mathrm{i}\epsilon^c{}_{ab} T_c, \qquad \mathrm{tr}(T_a T_b) = \frac{1}{2}\delta_{ab}.$$

This T_a is only an auxiliary $SU(2)$ basis for the following explicit solution; the action and coupling convention remain the trace-form convention (45.16). With $\rho := ur$, $u > 0$, $r = |x|$, and $\hat{x}^a = x^a/r$, write

$$\Phi(x) = u\, H(\rho)\, \hat{x}^a T_a, \qquad A_i(x) = \frac{1 - K(\rho)}{r}\, \epsilon_{aij} \hat{x}^j T_a. \tag{45.45}$$

Regularity at the origin and finite energy at infinity require

$$K(0) = 1, \qquad H(0) = 0, \qquad K(\infty) = 0, \qquad H(\infty) = 1.$$

Substitution into $B_i = D_i \Phi$ gives the ordinary differential equations

$$K'(\rho) = -K(\rho)H(\rho), \qquad H'(\rho) = \frac{1 - K(\rho)^2}{\rho^2}, \tag{45.46}$$

where the prime denotes $\mathrm{d}/\mathrm{d}\rho$. The Prasad–Sommerfield solution is

$$K(\rho) = \frac{\rho}{\sinh \rho}, \qquad H(\rho) = \coth \rho - \frac{1}{\rho}. \tag{45.47}$$

Indeed,

$$\frac{\mathrm{d}}{\mathrm{d}\rho}\left(\frac{\rho}{\sinh \rho}\right) = -\frac{\rho}{\sinh \rho}\left(\coth \rho - \frac{1}{\rho}\right),$$

and

$$\frac{\mathrm{d}}{\mathrm{d}\rho}\left(\coth \rho - \frac{1}{\rho}\right) = \frac{1 - \rho^2/\sinh^2 \rho}{\rho^2}.$$

Thus (45.47) solves (45.46), is smooth at the origin, approaches the vacuum orbit at infinity, and saturates the bound (45.43) in the unit magnetic sector. Translating the parameter u to the default trace basis amounts only to replacing it by the corresponding v_{m} in the surface charge Γ_{m}.

For $\lambda > 0$ the square completion is no longer exact, but the same topological sector persists. The second-order radial equations for the profile functions have a smooth solution with a nonzero core size of order u^{-1} times a function of λ. Its mass is larger than the BPS value. The nonsingular nonabelian core replaces the singularity of a Dirac monopole: after gauge fixing Φ_∞ to a constant Cartan generator on patches, the asymptotic field is described by a $U(1)$ magnetic bundle, while the full $SU(2)$ fields remain smooth at the origin.

Figure 45.7 shows the explicit Prasad–Sommerfield profiles. This is the quantitative content hidden by the square completion: the nonabelian core is smooth, the Higgs field approaches the vacuum orbit at infinity, and the gauge profile decays to the unbroken $U(1)$ magnetic bundle.

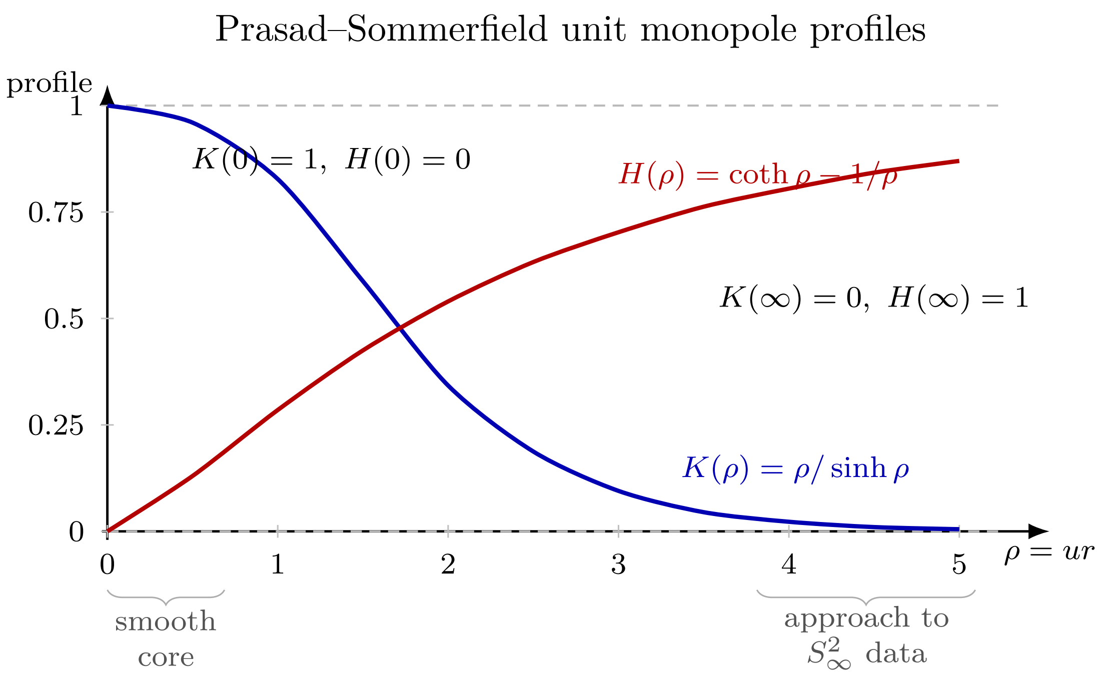

Figure 45.7: Profiles of the explicit unit BPS monopole in the auxiliary $T_a = \sigma_a/2$ basis of (45.45). The gauge profile $K(\rho) = \rho/\sinh\rho$ removes the would-be Dirac singularity at the origin and decays to zero, while $H(\rho) = \coth\rho - 1/\rho$ carries the adjoint Higgs field from the smooth core to the vacuum orbit at infinity. The first-order equations force these boundary behaviors and saturate the Bogomolny surface bound.

45.6.1 Framed Monopole Moduli Data and Low-Velocity Dynamics

The monopole also has collective coordinates, but these coordinates are not extra variables appended to the field theory. They are coordinates on the solution space of the Bogomolny equation modulo the gauge transformations declared to be redundancies. The declaration matters. To retain the electric phase whose quantization gives dyons, one divides by based gauge transformations which approach the identity at infinity; the residual constant unbroken $U(1)$ at infinity then acts on the resulting framed moduli space.

Definition 45.9 (Framed BPS monopole moduli datum)**.** Fix an $SU(2) \to U(1)$ adjoint-Higgs theory in the BPS limit and a magnetic sector n. Let $\mathcal{B}_n$ be the set of smooth finite-energy pairs (A_i, Φ) in that sector satisfying

$$B_i = D_i\Phi.$$

Let $\mathcal{G}_0$ be the group of smooth gauge transformations which tend to the identity element at spatial infinity with the decay needed to preserve the finite-energy sector. The framed monopole moduli space is the quotient

$$\mathcal{M}_n^{\mathrm{fr}} := \mathcal{B}_n/\mathcal{G}_0.$$

The unbroken asymptotic group $U(1)_\infty$ acts on $\mathcal{M}_n^{\mathrm{fr}}$. Quotienting further by this action gives the unframed moduli space. The framed version is the one used for dyonic quantization, because the primitive $U(1)_\infty$ orbit is the phase coordinate χ of Subsection 45.6.2.

Let z^a be local coordinates on a smooth chart of $\mathcal{M}_n^{\mathrm{fr}}$, and let

$$(a_{ai}, \varphi_a) = \left(\frac{\partial A_i(z)}{\partial z^a}, \frac{\partial \Phi(z)}{\partial z^a} \right)$$

be a representative tangent vector. In the Hermitian convention $D_i X = \partial_i X - \mathrm{i}[A_i, X]$, linearizing the Bogomolny equation gives

$$\varepsilon_{ijk} D_j a_{ak} - D_i \varphi_a + \mathrm{i}[a_{ai}, \Phi] = 0. \tag{45.48}$$

The infinitesimal gauge orbit through (A_i, Φ) is

$$(a_i, \varphi) = (D_i \epsilon, \mathrm{i}[\epsilon, \Phi]).$$

With respect to the kinetic inner product below, orthogonality to all such based gauge directions is exactly the background-gauge condition

$$D_i a_{ai} - \mathrm{i}[\Phi, \varphi_a] = 0. \tag{45.49}$$

Indeed, after integrating by parts and using the decay of the based parameter ϵ,

$$\int_{\mathbb{R}^3} \mathrm{tr}\big(a_i D_i \epsilon + \varphi\, \mathrm{i}[\epsilon, \Phi]\big) = \int_{\mathbb{R}^3} \mathrm{tr}\big((-D_i a_i + \mathrm{i}[\Phi, \varphi])\epsilon\big).$$

Thus a tangent vector to the quotient is represented by a pair satisfying (45.48) and (45.49), modulo based gauge parameters solving the homogeneous horizontal condition.

The metric used in the semiclassical approximation is the restriction of the real-time kinetic energy to these horizontal zero modes:

$$g_{ab}^{\mathrm{mon}}(z) = \frac{1}{g_{\mathrm{YM}}^2} \int_{\mathbb{R}^3} \mathrm{d}^3 x \; \mathrm{tr}\big(a_{ai} a_{bi} + \varphi_a \varphi_b\big). \tag{45.50}$$

The dimension assertion for $\mathcal{M}_n^{\mathrm{fr}}$ is the index statement for the elliptic complex defined by (45.48) together with (45.49). In the smooth charge $n > 0$ sector the framed dimension is $4n$: three center coordinates and one primitive phase coordinate for the total monopole, plus $4n - 4$ relative coordinates. The metric is hyperkähler in the smooth BPS sector because the linearized equations can be written as a quaternionic Dirac-type equation and the three complex structures act on the spatial one-form/scalar pair while preserving the horizontal slice. A full analytic construction of the multi-monopole moduli spaces uses the corresponding Fredholm theory and, equivalently, Nahm data; the local semiclassical formulae below require precisely the smooth chart, the horizontal tangent space, and the metric (45.50).

The low-velocity Lagrangian follows directly from Gauss' law. Let $(A_i(z(t)), \Phi(z(t)))$ be a path in a smooth moduli chart. The time-component A_0 is a Lagrange multiplier; varying it gives Gauss' law. Choosing A_0 so that the velocity is horizontal is equivalent, at linear order in $\dot{z}$, to imposing (45.49). Then

$$E_i = \dot{z}^a a_{ai} + O(\dot{z}^2), \qquad D_0 \Phi = \dot{z}^a \varphi_a + O(\dot{z}^2).$$

The magnetic and Higgs-gradient energy remains the BPS mass on the moduli space, since the topological sector and the Bogomolny equation are unchanged. The real-time kinetic terms therefore give

$$L_{\mathrm{eff}} = \frac{1}{2}\, g_{ab}^{\mathrm{mon}}(z) \dot{z}^a \dot{z}^b - M_{\mathrm{BPS}} + O(\dot{z}^3), \tag{45.51}$$

so the leading classical motion is geodesic motion for (45.50). The error term records the adiabatic expansion: massive fluctuation modes and radiation are solved for perturbatively and first affect the reduced dynamics beyond the quadratic zero-mode kinetic energy.

For the primitive unit monopole there are no relative coordinates. A framed chart is

$$(X^1, X^2, X^3, \chi) \in \mathbb{R}^3 \times S^1, \qquad \chi \sim \chi + 2\pi,$$

where X translates the core and χ is the primitive asymptotic $U(1)_\infty$ angle. In this chart the metric has the block form

$$\mathrm{d}s^2_{\mathcal{M}_1^{\mathrm{fr}}} = M_{\mathrm{BPS}}\,\delta_{ij}\mathrm{d}X^i\mathrm{d}X^j + I_\chi\,\mathrm{d}\chi^2, \qquad I_\chi > 0. \tag{45.52}$$

The translation coefficient is the soliton mass, fixed by the stress-tensor normalization of the center-of-mass kinetic energy. The phase moment of inertia I_χ is the $\chi\chi$-component of (45.50); its precise value depends on the trace and phase-coordinate normalization, while the electric-charge lattice derived below depends only on the primitive periodicity of χ.

45.6.2 Phase Coordinate, Dyonic Charge, and the Theta Angle

The unit BPS monopole has an S^1-valued phase coordinate

$$\chi \in \mathbb{R}/2\pi\mathbb{Z}.$$

The normalization used here is that $\chi \mapsto \chi + 2\pi$ is the primitive loop of the unbroken $U(1)$ gauge transformations at spatial infinity. Let $n_{\mathrm{m}} \in \mathbb{Z}$ be the magnetic charge in the same primitive cocharacter normalization. The phase coordinate is the finite-dimensional part of the gauge field which becomes electric after time dependence is allowed.

The theta density (45.21) contributes a total derivative on a path in the monopole moduli space. With the orientation convention in which a positive phase loop of a positive monopole obeys

$$\frac{1}{8\pi^2}\int_{\mathbb{R}_t\times\mathbb{R}^3} \mathrm{tr}(F\wedge F) = -\frac{n_{\mathrm{m}}}{2\pi}\int \dot\chi\,\mathrm{d}t, \tag{45.53}$$

the phase-sector effective Lagrangian has the form

$$L_\chi = \frac{1}{2}I_\chi\dot\chi^2 - \frac{\theta n_{\mathrm{m}}}{2\pi}\dot\chi, \qquad I_\chi > 0. \tag{45.54}$$

The positive constant I_χ is the $\chi\chi$-component of the monopole moduli-space metric. Its value is determined by the zero-mode inner product in (45.50); the charge-lattice shift below uses only the periodicity of χ and the topological coefficient in (45.53).

Proposition 45.10 (Dyonic tower from the monopole phase coordinate)**.** *Quantize the phase coordinate χ with Hilbert space $L^2(S^1, \mathrm{d}\chi/2\pi)$. The operator*

$$\widehat{n}_{\mathrm{e}} := -\mathrm{i}\frac{\partial}{\partial\chi}$$

has spectrum $\mathbb{Z}$. For a state $\psi_{n_{\mathrm{e}}}(\chi) = e^{\mathrm{i}n_{\mathrm{e}}\chi}$, the phase-sector Hamiltonian derived from (45.54) is

$$H_\chi(n_{\mathrm{e}}, n_{\mathrm{m}}; \theta) = \frac{1}{2I_\chi}\left(n_{\mathrm{e}} + \frac{\theta n_{\mathrm{m}}}{2\pi}\right)^2. \tag{45.55}$$

Thus the electric field carried by a charge-n_{m} monopole is graded by the shifted real coordinate

$$q_{\mathrm{E}} = n_{\mathrm{e}} + \frac{\theta n_{\mathrm{m}}}{2\pi}. \tag{45.56}$$

The periodicity $\theta \mapsto \theta + 2\pi$ preserves q_{E} after the integer electric label is relabelled by

$$n_{\mathrm{e}} \longmapsto n_{\mathrm{e}} - n_{\mathrm{m}}. \tag{45.57}$$

Proof. The canonical momentum conjugate to χ is

$$p_\chi = \frac{\partial L_\chi}{\partial \dot{\chi}} = I_\chi \dot{\chi} - \frac{\theta n_{\mathrm{m}}}{2\pi}. \tag{45.58}$$

The Legendre transform gives

$$H_\chi = p_\chi \dot{\chi} - L_\chi = \frac{1}{2I_\chi}\left(p_\chi + \frac{\theta n_{\mathrm{m}}}{2\pi}\right)^2. \tag{45.59}$$

Because χ is a coordinate on S^1, single-valued wave functions are expanded in the orthonormal Fourier basis $e^{\mathrm{i}n\chi}$, $n \in \mathbb{Z}$. Replacing p_χ by the self-adjoint generator $-\mathrm{i}\partial_\chi$ therefore gives (45.55). The combination multiplying $I_\chi^{-1/2}$ in the Hamiltonian is the electric-field coordinate (45.56). Under $\theta \mapsto \theta + 2\pi$, the relabelling (45.57) leaves this real coordinate and hence the spectrum of H_χ unchanged.

It remains to justify the topological term used in (45.54). On a slab $[t_0, t_1] \times \mathbb{R}^3$, the Chern–Weil identity gives

$$\frac{1}{8\pi^2}\int \mathrm{tr}(F \wedge F) = N_{\mathrm{CS}}[A(t_1)] - N_{\mathrm{CS}}[A(t_0)] \quad \text{plus the boundary contribution at } S^2_\infty. \tag{45.60}$$

For a path which changes only the asymptotic $U(1)$ phase, this boundary contribution is the pairing of the magnetic transition function on S^2_∞ with the $U(1)$ loop $\chi(t_0) \to \chi(t_1)$. In the primitive normalization of this subsection that pairing is

$$-\, n_{\mathrm{m}} \frac{\chi(t_1) - \chi(t_0)}{2\pi}.$$

Differentiating in time gives (45.53). The sign follows from the chosen orientation convention for a positive phase loop; reversing either the magnetic-charge orientation or the phase orientation reverses both sides and leaves (45.56) as the invariant charge-lattice statement. □

45.6.3 Collective Coordinates and the Regularized Semiclassical Measure

The word "collective coordinate" will mean a coordinate on a finite dimensional manifold of gauge-equivalence classes of classical solutions, not a new field added by hand. The measure on this manifold is not guessed from the number of zero modes. It is obtained by first defining a regulated path integral, choosing a gauge slice or working directly on the quotient, and then applying stationary phase in a neighborhood of the critical manifold. This is the point at which the distinction between a classical moduli space and the quantum weight assigned to that moduli space enters.

Definition 45.11 (Regulated collective-coordinate data)**.** Fix a finite regulator Λ. A regulated bosonic collective-coordinate data consist of the following objects.

1. A finite-dimensional smooth manifold $\mathcal{C}_\Lambda$ of regulated field variables, equipped with a smooth positive density $\mathrm{D}_\Lambda\varphi$.
2. A compact Lie group $\mathcal{G}_\Lambda$ acting smoothly on $\mathcal{C}_\Lambda$, preserving the action S_Λ and the density.
3. A gauge slice $\Sigma_\Lambda \subset \mathcal{C}_\Lambda$ meeting the gauge orbits under consideration transversely, with Faddeev–Popov Jacobian $\Delta_{\mathrm{FP},\Lambda}$. Equivalently, one may replace this item by a smooth density on the local quotient $\mathcal{C}_\Lambda/\mathcal{G}_\Lambda$.
4. A connected m-dimensional submanifold $\mathcal{M}_\Lambda \subset \Sigma_\Lambda$ of critical points of S_Λ, parametrized locally by $z = (z^1, \ldots, z^m)$, such that
$$S_\Lambda(\varphi_z) = S_0 \qquad \text{for all } z \in \mathcal{M}_\Lambda.$$
5. A regulator inner product $\langle\ ,\ \rangle_{\Lambda,z}$ on $T_{\varphi_z}\Sigma_\Lambda$. The tangent vectors
$$Z_a(z) := \frac{\partial \varphi_z}{\partial z^a}$$
define the zero-mode Gram matrix
$$G^{(\Lambda)}_{ab}(z) := \langle Z_a(z), Z_b(z)\rangle_{\Lambda,z}. \tag{45.61}$$

The data are nondegenerate if the Hessian $L_{\Lambda,z}$ of $S_\Lambda|_{\Sigma_\Lambda}$ has kernel exactly $T_{\varphi_z}\mathcal{M}_\Lambda$ and is positive on a chosen normal bundle $N_z\mathcal{M}_\Lambda$. If the residual stabilizer of φ_z in $\mathcal{G}_\Lambda$ is a compact group Γ_z, its volume is computed using the same normalization of the gauge-group density that was used to define $\Delta_{\mathrm{FP},\Lambda}$.

For a monopole, z includes center-of-mass and phase coordinates. For a BPST instanton, z includes center, size, and gauge-orientation coordinates. In both cases, the formula below is a statement at fixed regulator. The continuum semiclassical formula is obtained only after the renormalized nonzero-mode determinant and the moduli integral have been given a limit in the chosen scheme.

Theorem 45.12 (Collective-coordinate stationary phase)**.** *Let $\mathfrak{D}_\Lambda$ be a nondegenerate regulated collective-coordinate data in the sense of Definition 45.11. Denote its field space, gauge slice, critical manifold, and action by $\mathcal{C}_\Lambda$, Σ_Λ, $\mathcal{M}_\Lambda$, and S_Λ. Let $\epsilon_{\mathrm{sc}} > 0$ be the semiclassical parameter multiplying the action, and let O be a smooth gauge-invariant observable supported in a tubular neighborhood of $\mathcal{M}_\Lambda$ inside the gauge slice. Then, for each coordinate patch on $\mathcal{M}_\Lambda$,*
$$\begin{aligned}&\int_{\Sigma_\Lambda} O(\varphi)\, \exp[-S_\Lambda(\varphi)/\epsilon_{\mathrm{sc}}]\ \Delta_{\mathrm{FP},\Lambda}(\varphi)\,\mathrm{D}_\Lambda\varphi \\ &\quad = \exp(-S_0/\epsilon_{\mathrm{sc}})\,(2\pi\epsilon_{\mathrm{sc}})^{r/2} \int_{\mathcal{M}_\Lambda} \frac{O(\varphi_z)\,\Delta_{\mathrm{FP},\Lambda}(\varphi_z)}{\mathrm{Vol}(\Gamma_z)\ {\det}'_\Lambda(L_{\Lambda,z})^{1/2}}\,\mathrm{d}\nu_{\Lambda,\mathcal{M}}(z) + O\Big(\epsilon_{\mathrm{sc}}^{r/2+1}\Big),\end{aligned} \tag{45.62}$$
where $r = \dim N_z\mathcal{M}_\Lambda$ is the number of nonzero bosonic normal directions in the regulated slice, ${\det}'_\Lambda(L_{\Lambda,z})$ is the determinant of the Hessian on $N_z\mathcal{M}_\Lambda$ with respect to the regulator inner product, and
$$\mathrm{d}\nu_{\Lambda,\mathcal{M}}(z) = \sqrt{\det G^{(\Lambda)}_{ab}(z)}\,\mathrm{d}z^1\cdots\mathrm{d}z^m. \tag{45.63}$$

The product $\sqrt{\det G^{(\Lambda)}}\,\mathrm{d}^m z$ *is invariant under changes of collective-coordinate chart. If the path integral is formulated directly on the local quotient rather than on a gauge slice, the factor* $\Delta_{\mathrm{FP},\Lambda}/\operatorname{Vol}(\Gamma_z)$ *is absent and* $\mathrm{d}\nu_{\Lambda,\mathcal{M}}$ *is computed from the quotient metric.*

Proof. The proof is finite dimensional. Choose a tubular-neighborhood map

$$(z,\eta)\longmapsto\varphi(z,\eta),\qquad z\in\mathcal{M}_\Lambda,\quad \eta\in N_z\mathcal{M}_\Lambda,$$

with $\varphi(z,0)=\varphi_z$. The density in these coordinates has the form

$$\mathrm{D}_\Lambda\varphi=J_\Lambda(z,\eta)\,\mathrm{d}^m z\,\mathrm{d}^r\eta,\qquad J_\Lambda(z,0)=\sqrt{\det G^{(\Lambda)}_{ab}(z)}$$

after the normal coordinates are chosen orthonormally in $N_z\mathcal{M}_\Lambda$. This equality is precisely the definition of the Riemannian density induced on the critical manifold by the regulator inner product.

Because every φ_z is critical and the tangent directions are exactly the kernel of the Hessian,

$$S_\Lambda(\varphi(z,\eta))=S_0+\frac{1}{2}\langle\eta,L_{\Lambda,z}\eta\rangle_{\Lambda,z}+O(\|\eta\|^3).$$

By nondegeneracy, $L_{\Lambda,z}$ is positive on the normal space. For an observable with support in a fixed tubular neighborhood, the part $\|\eta\|\geq c$ is exponentially smaller than any power of ϵ_{sc}, after possibly shrinking the neighborhood. In the remaining region set $\eta=\epsilon_{\mathrm{sc}}^{1/2}\xi$. Taylor expand

$$O(\varphi(z,\epsilon_{\mathrm{sc}}^{1/2}\xi))\,\Delta_{\mathrm{FP},\Lambda}(\varphi(z,\epsilon_{\mathrm{sc}}^{1/2}\xi))\,J_\Lambda(z,\epsilon_{\mathrm{sc}}^{1/2}\xi)$$

and the cubic remainder in the action. Odd Gaussian moments vanish and the leading normal integral is

$$\int_{N_z\mathcal{M}_\Lambda}\exp\left[-\frac{1}{2}\langle\xi,L_{\Lambda,z}\xi\rangle_{\Lambda,z}\right]\mathrm{d}^r\xi=(2\pi)^{r/2}\,{\det}'_\Lambda(L_{\Lambda,z})^{-1/2}.$$

Multiplying by the Jacobian $\epsilon_{\mathrm{sc}}^{r/2}$ from $\mathrm{d}^r\eta=\epsilon_{\mathrm{sc}}^{r/2}\mathrm{d}^r\xi$ gives (45.62). The factor $\operatorname{Vol}(\Gamma_z)^{-1}$ removes the residual gauge copies left inside the slice. Under a chart change $z=z(z')$, the Gram matrix transforms as $G'=(\partial z/\partial z')^T G(\partial z/\partial z')$; hence $\sqrt{\det G'}\,\mathrm{d}^m z'=\sqrt{\det G}\,\mathrm{d}^m z$. The displayed measure is therefore intrinsic. □

For BPS monopoles, the moduli-space metric and the low-velocity geodesic Lagrangian obtained from this stationary-phase measure were derived in Subsection 45.6.1. The finite stationary-phase formula above supplies the accompanying quantum collective-coordinate density once the nonzero-mode determinant and the chosen regulator have been specified.

Construction 45.13 (Fermion zero modes and Berezin saturation)**.** At finite regulator, suppose the quadratic fermion action in a bosonic background φ_z is

$$S_F=\frac{1}{2}\Psi^T\mathcal{D}_z\Psi,$$

where Ψ is a finite list of odd variables and $\mathcal{D}_z$ is the antisymmetric matrix representing the regulated Dirac operator in the chosen pairing. Split

$$\Psi=\sum_{\alpha=1}^{n_0}\zeta^\alpha\Psi_{0,\alpha}+\Psi_\perp,\qquad \mathcal{D}_z\Psi_{0,\alpha}=0.$$

The nonzero modes give $\mathrm{Pf}'(\mathcal{D}_z)$. The zero-mode part of the Berezin integral is

$$\int \mathrm{d}\zeta^{n_0}\cdots \mathrm{d}\zeta^1\, F(\zeta^1,\ldots,\zeta^{n_0}),$$

which extracts the coefficient of $\zeta^1\cdots\zeta^{n_0}$. Therefore a correlation function in this background vanishes unless the operator insertions or mass terms supply all fermion zero-mode variables. This is the regulated algebraic origin of the 't Hooft vertex; the index theorem counts how many such variables are present, while the zero-mode wavefunctions determine the gauge, spin, and flavor tensor multiplying them.

The same finite-energy logic also produces codimension-two vortices. In the Abelian Higgs model on $\mathbb{R}^2$, with

$$D_i\phi = \partial_i\phi - \mathrm{i}A_i\phi, \qquad B = F_{12},$$

use the energy per unit length

$$T[A,\phi] = \int_{\mathbb{R}^2} \mathrm{d}^2x \left[\frac{1}{2e^2}B^2 + |D_i\phi|^2 + \frac{e^2}{2}\left(|\phi|^2 - v^2\right)^2\right]. \tag{45.64}$$

Finite energy implies $|\phi| \to v$ and $D_i\phi \to 0$ at infinity, so $\phi/|\phi| : S^1_\infty \to U(1)$ has winding n. Equivalently,

$$\int_{\mathbb{R}^2} B\,\mathrm{d}^2x = 2\pi n.$$

At the critical coupling displayed in (45.64),

$$T = \int_{\mathbb{R}^2} \mathrm{d}^2x \left[\frac{1}{2e^2}\left(B \mp e^2(v^2 - |\phi|^2)\right)^2 + |(D_1 \pm \mathrm{i}D_2)\phi|^2\right] \pm v^2 \int_{\mathbb{R}^2} B\,\mathrm{d}^2x. \tag{45.65}$$

Hence

$$T \geq 2\pi v^2 |n|,$$

with equality precisely for the Nielsen–Olesen vortex equations

$$(D_1 \pm \mathrm{i}D_2)\phi = 0, \qquad B = \pm e^2(v^2 - |\phi|^2).$$

The vortex is therefore the codimension-two analogue of the monopole: finite energy converts infinity to a sphere of one lower dimension, topological winding fixes a flux, and a first-order system appears at a special value of the scalar potential.

Finite-energy critical points also include unstable saddles. In four-dimensional $SU(2)$-Higgs theory with a fundamental Higgs doublet, the finite-energy configuration space contains a saddle point called the sphaleron. Its distinguishing data are its position between neighboring vacua of different Chern–Simons number and its single negative fluctuation mode. With the Hermitian connection convention of this chapter, the spatial Chern–Simons functional is

$$N_{\mathrm{CS}}[A] = \frac{1}{8\pi^2}\int_{\mathbb{R}^3} \mathrm{tr}\left(A\wedge \mathrm{d}A - \frac{2\mathrm{i}}{3}A\wedge A\wedge A\right), \tag{45.66}$$

defined modulo integers under large gauge transformations when the boundary conditions compactify space to S^3. The sphaleron sits, in an appropriate one-parameter minimax construction, at half-integer Chern–Simons number and has one negative fluctuation mode. It controls the height of the classical barrier between adjacent electroweak vacua; real-time transitions at finite temperature and tunneling transitions at zero temperature require additional quantum and statistical analysis. Thus the sphaleron is an unstable static saddle of the classical energy.

Solitons enter the theory as critical points or sectors of the same classical field space, selected by finite-energy boundary conditions and by the topology of gauge and Higgs data at infinity. Their quantum interpretation requires a separate construction of states, collective coordinates, fluctuation determinants, and possible fermion zero modes. In gauge theories this construction is phrased in terms of gauge-invariant observables and superselection sectors; the local gauge potential itself remains a coordinate on a redundant description.

45.7 QCD Notation and Chiral Masses

For QCD with gauge group $SU(N)$, a quark field carries three kinds of indices:

$$\psi^i_{I\alpha}(x), \qquad i = 1, \dots, N, \quad I = 1, \dots, N_f.$$

Here i is the color index in the fundamental representation, I is a flavor index, and α is a spinor index. The conjugate field $\bar{\psi}$ carries the anti-fundamental color representation.

For these quarks, the local four-dimensional terms that are Poincare invariant, gauge invariant, and power-counting renormalizable have the gauge part

$$-\frac{1}{4g^2_{\mathrm{YM}}}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu}) + \frac{\theta}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma})$$

and the fermion part

$$\mathcal{L}_\psi = -\bar{\psi}_I\gamma^\mu D_\mu\psi_I - m_{IJ}\bar{\psi}_I\psi_J - \widetilde{m}_{IJ}\bar{\psi}_I\gamma_5\psi_J. \tag{45.67}$$

The matrices m and $\widetilde{m}$ act on flavor and are Hermitian in a Hermitian Lorentzian action.

For chiral notation, use the convention fixed in Chapter 40, $\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$; with this sign the left-handed subspace is the $+1$ eigenspace of γ_5:

$$P_L = \frac{1+\gamma_5}{2}, \qquad P_R = \frac{1-\gamma_5}{2}, \qquad \psi_{IL} = P_L\psi_I, \quad \psi_{IR} = P_R\psi_I.$$

Then the fermion Lagrangian can be written

$$\mathcal{L}_\psi = -\bar{\psi}_{IL}\gamma^\mu D_\mu\psi_{IL} - \bar{\psi}_{IR}\gamma^\mu D_\mu\psi_{IR} - M_{IJ}\bar{\psi}_{IL}\psi_{JR} - M^*_{IJ}\bar{\psi}_{JR}\psi_{IL}. \tag{45.68}$$

The complex mass matrix M is the coefficient matrix of the left-right bilinear in (45.68); M^*_{IJ} denotes the entrywise complex conjugate of M_{IJ}. Equivalently, after substituting $\psi_{IL} = P_L\psi_I$, $\psi_{IR} = P_R\psi_I$, and the corresponding Dirac-adjoint projectors, M is defined by the identity

$$m_{IJ}\bar{\psi}_I\psi_J + \widetilde{m}_{IJ}\bar{\psi}_I\gamma_5\psi_J = M_{IJ}\bar{\psi}_{IL}\psi_{JR} + M^*_{IJ}\bar{\psi}_{JR}\psi_{IL}.$$

Thus M is the same mass data expressed in the chiral basis. The reason this package is useful is that it exposes the phase affected by anomalous axial rotations. Under a common vector rotation $\psi_L \mapsto \mathrm{e}^{\mathrm{i}\beta}\psi_L$, $\psi_R \mapsto \mathrm{e}^{\mathrm{i}\beta}\psi_R$, M is unchanged. Under a common axial rotation

$$\psi_L \mapsto \mathrm{e}^{\mathrm{i}\alpha}\psi_L, \qquad \psi_R \mapsto \mathrm{e}^{-\mathrm{i}\alpha}\psi_R,$$

the left-right bilinear transforms as $\bar{\psi}_L\psi_R \mapsto \mathrm{e}^{-2\mathrm{i}\alpha}\bar{\psi}_L\psi_R$, so the spurion transformation preserving the mass term is

$$M \mapsto \mathrm{e}^{2\mathrm{i}\alpha}M.$$

For N_f fundamental Dirac quarks the anomalous Jacobian shifts $\theta \mapsto \theta - 2N_f\alpha$ in the normalization (45.21). Hence the combination

$$\bar{\theta} := \theta + \arg\det M$$

is invariant under this common axial change of variables, provided $\det M \neq 0$. If a quark mass vanishes, $\arg\det M$ is not defined and the chiral rotation must be treated on the rank-deficient mass matrix itself.

Figure 45.8 records this invariant phase relation, which is the reason for using the complex chiral mass matrix in the QCD chiral-symmetry discussion.

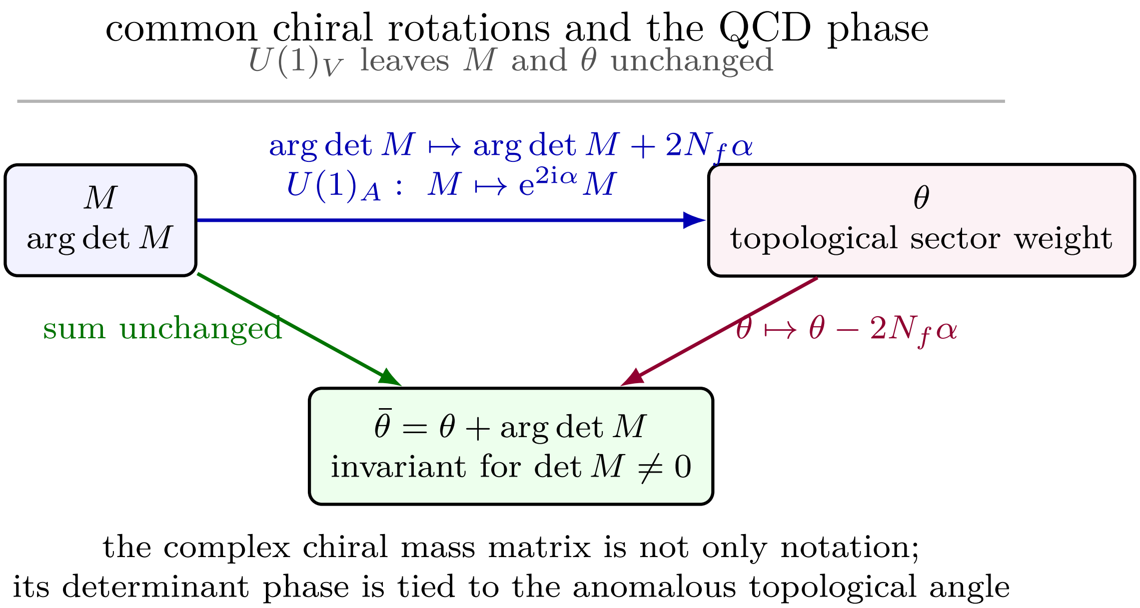

Figure 45.8: Phase information in the chiral mass matrix. With the γ_5 convention used here, a common axial field redefinition sends $M \mapsto e^{2i\alpha}M$ and shifts the topological angle by $\theta \mapsto \theta - 2N_f\alpha$. Therefore $\bar{\theta} = \theta + \arg\det M$ is the invariant phase when M is nonsingular. The vector $U(1)$ rotation leaves both quantities unchanged.

This notation prepares two later developments. Gauge fixing and BRST will quantize the gauge theory while preserving the gauge-covariant local data defined here. Anomalous chiral rotations will relate phases of the mass matrix to the θ-angle.

Chapter 46

Lattice Yang–Mills as a Nonperturbative Formulation

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter gives a regulator-level construction of pure Yang–Mills theory which does not begin by choosing a covariant gauge. The construction is a finite-dimensional integral over compact groups at finite lattice spacing and finite volume. Its continuum limit is a separate problem: one must prove, or assume with stated evidence, that a sequence of finite-cutoff theories has gauge-invariant Schwinger functions with a limit satisfying the Euclidean axioms and yielding a positive-energy Hilbert-space theory after Osterwalder–Schrader reconstruction.

46.1 Finite Lattice Gauge Fields

Fix a compact Lie group G. For most formulas below $G = SU(N)$, and tr denotes the trace in the fundamental representation with $\mathrm{tr}(t^a t^b) = \delta^{ab}$, matching the continuum Yang–Mills convention of Chapter 45. Let

$$\Lambda_{a,L} = (a\mathbb{Z}/L\mathbb{Z})^4$$

be a four-dimensional periodic hypercubic lattice, where $a > 0$ is the lattice spacing and L/a is an integer. The positively oriented links are

$$E^+(\Lambda_{a,L}) = \{(x, \mu) \mid x \in \Lambda_{a,L},\ \mu = 1, \dots, 4\}.$$

The link (x, μ) joins x to $x + a\widehat{\mu}$. A lattice gauge field is a function

$$U : E^+(\Lambda_{a,L}) \longrightarrow G, \qquad (x, \mu) \longmapsto U_\mu(x).$$

The inverse orientation is assigned the inverse group element,

$$U_{-\mu}(x + a\widehat{\mu}) = U_\mu(x)^{-1}.$$

Thus a lattice gauge field is a point of the compact manifold

$$\mathcal{A}_\Lambda = G^{E^+(\Lambda_{a,L})}.$$

The lattice gauge group is

$$\mathcal{G}_\Lambda = G^{\Lambda_{a,L}}.$$

An element $\Omega \in \mathcal{G}_\Lambda$ acts by

$$U_\mu(x) \longmapsto U_\mu^\Omega(x) = \Omega(x) U_\mu(x) \Omega(x + a\widehat{\mu})^{-1}. \tag{46.1}$$

This convention matches the Hermitian continuum convention of Chapter 45. For a smooth field with

$$U_\mu(x) = \exp\bigl(-\mathrm{i}aA_\mu(x) + O(a^2)\bigr),$$

the endpoint rule (46.1) gives

$$A_\mu^\Omega = \Omega A_\mu \Omega^{-1} + \mathrm{i}\, \Omega \partial_\mu \Omega^{-1} + O(a).$$

For $\mu < \nu$, define the oriented plaquette based at x by

$$U_{\mu\nu}(x) = U_\mu(x) U_\nu(x + a\widehat{\mu}) U_\mu(x + a\widehat{\nu})^{-1} U_\nu(x)^{-1}. \tag{46.2}$$

Under (46.1),

$$U_{\mu\nu}(x) \longmapsto \Omega(x) U_{\mu\nu}(x) \Omega(x)^{-1}. \tag{46.3}$$

Therefore every class function of $U_{\mu\nu}(x)$, and in particular $\mathrm{Re}\,\mathrm{tr}\, U_{\mu\nu}(x)$, is gauge invariant.

Figure 46.1 records the oriented plaquette convention and its based-loop gauge covariance (46.3), the input for the Wilson action.

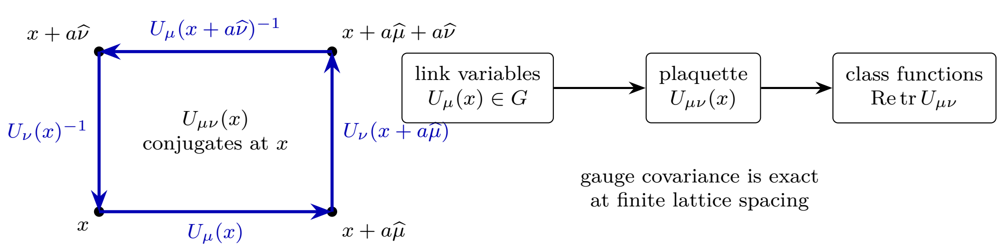

Figure 46.1: The plaquette is the elementary lattice curvature. Link variables transform at their endpoints; around a closed elementary square the endpoint factors cancel except for conjugation at the basepoint.

46.2 Wilson Action and the Finite Haar Integral

For $G = SU(N)$ the Wilson action is

$$S_{W,\Lambda}[U] = \frac{\beta}{N} \sum_{x\in\Lambda_{a,L}} \sum_{1\le\mu<\nu\le4} \operatorname{Re}\operatorname{tr}\big(\mathbf{1} - U_{\mu\nu}(x)\big), \qquad \beta = \frac{N}{g_0^2}. \tag{46.4}$$

Here g_0 is the lattice coupling parameter in the trace-form continuum normalization

$$S_{\text{cont}}[A] = \frac{1}{4g_0^2} \int \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}).$$

With the more common generator normalization $\operatorname{tr}(t^a t^b) = \frac{1}{2}\delta^{ab}$, the same Wilson action is often written with $\beta = 2N/g_0^2$. The difference is a coordinate change in the generator and coupling normalization, not a different lattice integral. The integrand $\operatorname{Re}\operatorname{tr}(\mathbf{1}-U_{\mu\nu})$ is nonnegative, because each eigenvalue of $U_{\mu\nu}$ lies on the unit circle and hence $\operatorname{Re}\operatorname{tr} U_{\mu\nu} \le N$. Gauge invariance of $S_{W,\Lambda}$ follows from (46.3).

Let $\mathrm{d}U$ be normalized Haar measure on G. At finite a and finite L, the lattice partition function is the finite-dimensional compact integral

$$Z_\Lambda(\beta) = \int_{\mathcal{A}_\Lambda} \prod_{\ell\in E^+(\Lambda_{a,L})} \mathrm{d}U_\ell \, \exp\{-S_{W,\Lambda}[U]\}. \tag{46.5}$$

Since $\mathcal{A}_\Lambda$ is compact and the integrand is continuous, $Z_\Lambda(\beta)$ is finite and strictly positive. For a bounded gauge-invariant function $O : \mathcal{A}_\Lambda \to \mathbb{C}$,

$$\langle O\rangle_{\Lambda,\beta} = Z_\Lambda(\beta)^{-1} \int_{\mathcal{A}_\Lambda} \prod_\ell \mathrm{d}U_\ell \, O[U] \, \exp\{-S_{W,\Lambda}[U]\} \tag{46.6}$$

is a completely defined number. No division by an infinite gauge-group volume and no Faddeev–Popov determinant enter this finite-cutoff definition.

The relation to the continuum Yang–Mills action is obtained by evaluating the plaquette on a smooth continuum connection. Let $x_c = x + \frac{a}{2}\widehat{\mu} + \frac{a}{2}\widehat{\nu}$ be the plaquette center. With

$$U_\mu(x) = \exp\big(-\mathrm{i}aA_\mu(x + \tfrac{a}{2}\widehat{\mu}) + O(a^3)\big),$$

the Baker–Campbell–Hausdorff expansion gives

$$U_{\mu\nu}(x) = \exp\big(-\mathrm{i}a^2 F_{\mu\nu}(x_c) + O(a^4)\big), \tag{46.7}$$

where $F_{\mu\nu}$ is the Hermitian-coordinate curvature of Chapter 45. For $SU(N)$, $\operatorname{tr} F_{\mu\nu} = 0$, and hence

$$\operatorname{Re}\operatorname{tr}(\mathbf{1} - U_{\mu\nu}) = \frac{a^4}{2} \operatorname{tr}(F_{\mu\nu}(x_c)F_{\mu\nu}(x_c)) + O(a^6).$$

Substitution in (46.4) gives

$$\sum_{\mu<\nu} \frac{a^4}{2} \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) = \frac{a^4}{4} \sum_{\mu,\nu} \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}),$$

because $F_{\nu\mu} = -F_{\mu\nu}$. Therefore

$$S_{W,\Lambda}[U(A)] = \frac{1}{4g_0^2} \int_{\mathbb{T}_L^4} \operatorname{tr}(F_{\mu\nu} F_{\mu\nu}) \, \mathrm{d}^4 x + O(a^2), \tag{46.8}$$

for smooth fields on the torus of side L. Equation (46.8) is an expansion of the classical lattice action on smooth configurations. The quantum continuum limit also requires control of the measure as $a \downarrow 0$, L is sent to the desired infrared limit, and $\beta \to \infty$ along a trajectory that keeps a physical scale fixed.

46.3 Reflection Positivity and the Transfer Matrix

The Wilson lattice theory is Euclidean from the start. To connect it to a Hilbert-space theory one uses the lattice version of reflection positivity, the discrete precursor of the Osterwalder–Schrader condition developed in Chapter 12.

Choose the reflection ϑ which sends the Euclidean time coordinate x_4 to $-x_4$ and reverses the orientation of reflected links. Let $\mathcal{B}_+$ be the algebra generated by gauge-invariant functions of link variables whose support lies in the positive-time half lattice. For $F \in \mathcal{B}_+$, set

$$\Theta F[U] = \overline{F[\vartheta U]}.$$

Theorem 46.1 (Osterwalder–Seiler reflection positivity for the Wilson action)**.** *On a reflection-invariant finite hypercubic lattice, the Wilson measure*

$$\mathrm{d}\mu_{\Lambda,\beta}(U) = Z_\Lambda(\beta)^{-1} \prod_\ell \mathrm{d}U_\ell \, \mathrm{e}^{-S_{W,\Lambda}[U]}$$

satisfies

$$\int \Theta F[U] \, F[U] \, \mathrm{d}\mu_{\Lambda,\beta}(U) \geq 0, \qquad F \in \mathcal{B}_+. \tag{46.9}$$

Proof. The proof is finite-dimensional. Haar measure is invariant under reflection, inversion, and left and right multiplication. The Wilson action splits into a positive-time part, its reflected part, and plaquette factors crossing the reflection plane. A crossing plaquette factor is a continuous central function of a group element V:

$$K_\beta(V) = \exp\left\{ \frac{\beta}{N} \operatorname{Re} \operatorname{tr} V \right\}.$$

Peter–Weyl theory expands it as

$$K_\beta(V) = \sum_{\lambda \in \widehat{G}} c_\lambda(\beta) \chi_\lambda(V), \qquad c_\lambda(\beta) = \int_G K_\beta(V) \overline{\chi_\lambda(V)} \, \mathrm{d}V. \tag{46.10}$$

For $G = SU(N)$ with the fundamental Wilson kernel this positivity is explicit. Write

$$K_\beta(V) = \exp\left[\frac{\beta}{2N} \big(\operatorname{tr} V + \operatorname{tr} V^{-1} \big) \right] = \sum_{r,s \geq 0} \frac{(\beta/2N)^{r+s}}{r! \, s!} (\operatorname{tr} V)^r (\operatorname{tr} V^{-1})^s.$$

The product $(\operatorname{tr} V)^r(\operatorname{tr} V^{-1})^s$ is the character of $(\mathbb{C}^N)^{\otimes r} \otimes (\overline{\mathbb{C}^N})^{\otimes s}$. Decomposing this finite-dimensional representation into irreducibles gives

$$(\operatorname{tr} V)^r(\operatorname{tr} V^{-1})^s = \sum_{\lambda \in \widehat{SU(N)}} m_{\lambda;r,s}\chi_\lambda(V), \qquad m_{\lambda;r,s} \in \mathbb{Z}_{\geq 0}.$$

The exponential series is absolutely and uniformly convergent on the compact group, so its character coefficients are

$$c_\lambda(\beta) = \sum_{r,s \geq 0} \frac{(\beta/2N)^{r+s}}{r!\, s!}\, m_{\lambda;r,s} \geq 0.$$

The same argument applies to a Wilson kernel built from a unitary representation R and its conjugate, with $R^{\otimes r} \otimes \overline{R}^{\otimes s}$ replacing the fundamental tensor powers. Matrix-coefficient orthogonality rewrites each crossing contribution as a finite or absolutely convergent sum of terms

$$c_\lambda(\beta)\, F_{\lambda,i}[U_+]\, \overline{F_{\lambda,i}[\vartheta U_+]}, \qquad c_\lambda(\beta) \geq 0,$$

after the links on the reflection plane have been integrated. Multiplication by the positive-time Boltzmann weight and summation over λ, i turns (46.9) into a sum of squared absolute values with nonnegative coefficients. □

Reflection positivity produces a Hilbert space at finite lattice spacing by quotienting $\mathcal{B}_+$ by the null vectors of (46.9) and completing. Translation by one lattice unit in Euclidean time gives a positive transfer matrix

$$T_a = \mathrm{e}^{-aH_a}.$$

Thus the finite lattice theory has a genuine Hilbert-space interpretation with a nonnegative lattice Hamiltonian H_a. The continuum question is whether a family of such OS-positive finite-cutoff theories has a scaling limit whose Schwinger functions satisfy the continuum hypotheses of Chapter 12.

46.4 Thermal Center Symmetry and the Polyakov Loop

The Wilson lattice also gives a precise finite-cutoff formulation of the thermal center-symmetry order parameter. This subsection is kinematic: it defines the symmetry, the charged operator, and the order of limits needed for spontaneous symmetry breaking. It does not assume a continuum proof of confinement or of a deconfinement transition.

Let the Euclidean lattice have the form

$$\Lambda_{a,N_s,N_t} = (a\mathbb{Z}/N_s a\mathbb{Z})^3 \times (a\mathbb{Z}/N_t a\mathbb{Z}), \qquad \beta_{\mathrm{T}} = aN_t.$$

The last circle is the thermal circle of inverse temperature β_{T}. To avoid confusion, the Wilson coupling parameter in (46.4) will be denoted by $\beta_{\mathrm{lat}} = N/g_0^2$ in this subsection.

For $G = SU(N)$, choose a center element

$$z_m = \mathrm{e}^{2\pi \mathrm{i} m/N}\mathbf{1}_N, \qquad m \in \mathbb{Z}_N.$$

Fix one Euclidean-time slice τ_0. The thermal center transformation acts on temporal links crossing that slice by

$$U_4(\mathbf{x},\tau_0) \longmapsto z_m\, U_4(\mathbf{x},\tau_0), \qquad U_i(\mathbf{x},\tau) \longmapsto U_i(\mathbf{x},\tau), \qquad U_4(\mathbf{x},\tau \neq \tau_0) \longmapsto U_4(\mathbf{x},\tau). \tag{46.11}$$

It is the finite thermal-lattice representative of the electric center one-form symmetry of Section 45.3 after the Euclidean time direction has been compactified.

Lemma 46.2 (Exact center symmetry of pure thermal lattice Yang–Mills)**.** *For pure $SU(N)$ Wilson lattice gauge theory on Λ_{a,N_s,N_t}, the transformation (46.11) preserves the Haar measure and the Wilson action. If dynamical matter of N-ality k_α is added, the unbroken subgroup is*

$$\{m \in \mathbb{Z}_N : \exp(2\pi \mathrm{i} m k_\alpha/N) = 1 \textit{ for every dynamical } \alpha\},$$

the same subgroup as in (45.25).

Proof. Haar measure is invariant under left multiplication by the fixed group element z_m. A spatial plaquette contains no transformed temporal link. A temporal plaquette crossing the slice contains one transformed temporal link $U_4(\mathbf{x},\tau_0)$ and one inverse transformed temporal link $U_4(\mathbf{x}+a\hat{i},\tau_0)^{-1}$. Because z_m is central, the phases cancel:

$$z_m U_4(\mathbf{x},\tau_0)\cdots\left(z_m U_4(\mathbf{x}+a\hat{i},\tau_0)\right)^{-1} = z_m U_4(\mathbf{x},\tau_0)\cdots U_4(\mathbf{x}+a\hat{i},\tau_0)^{-1} z_m^{-1}.$$

The center factors commute through the remaining links and disappear inside $\mathrm{Re}\,\mathrm{tr}$. Thus every plaquette term and the product Haar measure are invariant.

A dynamical matter hopping term in representation R_α and N-ality k_α crossing the thermal slice acquires the phase $z_m^{k_\alpha}$. Such a term is invariant for all dynamical fields precisely when the displayed phase is one for every R_α. □

The Polyakov line at spatial position $\mathbf{x}$ is the temporal holonomy around the thermal circle,

$$\mathcal{P}(\mathbf{x}) = U_4(\mathbf{x},0)U_4(\mathbf{x},a)\cdots U_4(\mathbf{x},(N_t-1)a). \tag{46.12}$$

For an irreducible representation R, define the normalized Polyakov loop

$$P_R(\mathbf{x}) = d_R^{-1}\chi_R(\mathcal{P}(\mathbf{x})). \tag{46.13}$$

Under a periodic lattice gauge transformation, $\mathcal{P}(\mathbf{x})$ is conjugated at the basepoint, so $P_R(\mathbf{x})$ is gauge invariant. Under the center transformation (46.11),

$$P_R(\mathbf{x}) \longmapsto \exp\left(\frac{2\pi \mathrm{i} m k_R}{N}\right) P_R(\mathbf{x}), \tag{46.14}$$

where k_R is the N-ality of R. The fundamental Polyakov loop is therefore a charged local operator of the three-dimensional thermal theory. Equivalently, it is a line operator of the four-dimensional Euclidean theory wrapping the thermal circle.

Figure 46.2 shows the center transformation on a thermal slice and the resulting N-ality charge of a Polyakov loop in representation R.

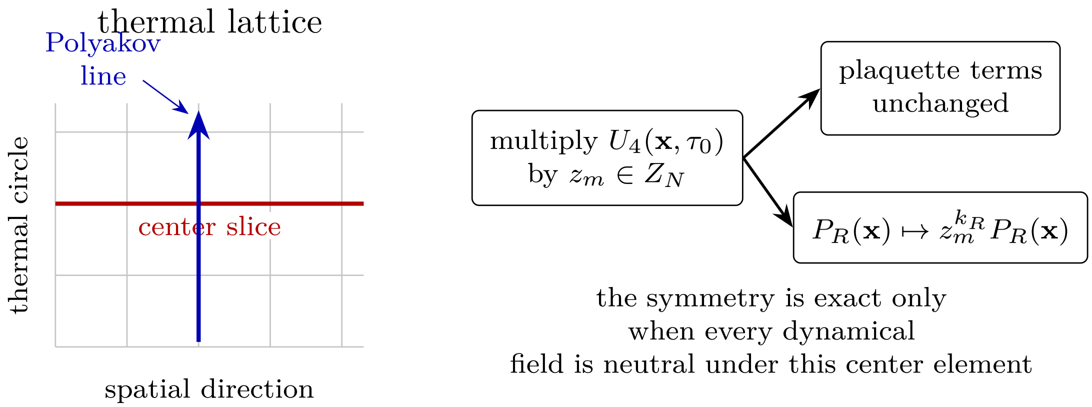

Figure 46.2: Thermal center symmetry on the lattice. Multiplying all temporal links crossing one time slice by a center element leaves plaquettes invariant, while a Polyakov loop winding the thermal circle acquires the center phase of its representation.

At finite spatial volume and with no explicit center-breaking source,

$$\langle P_\Box(\mathbf{x}) \rangle_{\Lambda, \beta_{\text{lat}}} = 0$$

in pure $SU(N)$ Yang–Mills. Indeed, averaging the expectation value over the exact $\mathbb{Z}_N$ transformations gives $\langle P_\Box \rangle = z_m \langle P_\Box \rangle$ for every m, and the only complex number with this property for a nontrivial center character is zero. A nonzero order parameter is therefore an infinite-volume spontaneous-symmetry-breaking statement, not a finite-volume expectation at zero source.

Definition 46.3 (Polyakov-loop order parameter)**.** Let

$$\overline{P}_\Box = N_s^{-3} \sum_{\mathbf{x}} P_\Box(\mathbf{x}).$$

Choose a small source h selecting one center sector, for example by adding $-hN_s^3 \operatorname{Re} \overline{P}_\Box$ to the lattice action. The fundamental Polyakov-loop order parameter is

$$\ell = \lim_{h \downarrow 0} \lim_{N_s \to \infty} \langle \overline{P}_\Box \rangle_{h, N_s, N_t, \beta_{\text{lat}}}, \tag{46.15}$$

with the continuum thermal limit, if desired, taken afterward along a scaling trajectory with $aN_t = \beta_{\text{T}}$ fixed. Center symmetry is unbroken when $\ell = 0$ and broken when $\ell \neq 0$.

The order of limits in (46.15) is part of the definition. Reversing the limits gives zero in a finite volume because the exact finite-volume measure is center invariant.

The same operator has a static-source interpretation. After a center sector has been selected, or with the small source used in (46.15), insertion of $P_R(\mathbf{x})$ at finite lattice spacing computes the partition function in the presence of a static external source in representation R, divided by the vacuum partition function:

$$\langle P_R(\mathbf{x}) \rangle_{\text{bare}} = \exp\{-\beta_{\text{T}}(F_R^{\text{bare}} - F_0)\}. \tag{46.16}$$

The adjective “bare” matters. In the continuum limit a static line has a self-energy divergence, so a renormalized Polyakov loop is obtained by a multiplicative line renormalization,

$$P_R^{\mathrm{ren}} = Z_R(a)^{N_t} P_R^{\mathrm{bare}},$$

or equivalently by subtracting the static-source self-energy from F_R^{bare}. This renormalization changes the numerical value of ℓ, but it does not change the center charge (46.14) or whether ℓ vanishes.

Similarly, the Polyakov-loop two-point function gives the free energy of a static source and anti-source pair:

$$\langle P_R(\mathbf{x}) P_{\overline{R}}(\mathbf{y})\rangle = \exp\{-\beta_{\mathrm{T}}(F_{R\overline{R}}(|\mathbf{x}-\mathbf{y}|) - F_0)\}, \tag{46.17}$$

after the same line renormalization. This correlator is center neutral even when each individual Polyakov loop is charged. If the infinite-volume thermal state satisfies clustering, then a center-broken phase has

$$\lim_{|\mathbf{x}-\mathbf{y}|\to\infty} \langle P_{\square}(\mathbf{x}) P_{\overline{\square}}(\mathbf{y})\rangle = |\ell|^2, \tag{46.18}$$

whereas a center-symmetric phase has $\ell = 0$.

Definition 46.4 (Deconfinement in the center-symmetry sense)**.** For pure $SU(N)$ Yang–Mills, a thermal phase is center confined when the thermal center symmetry is unbroken, $\ell = 0$, and center deconfined when the thermal center symmetry is spontaneously broken, $\ell \neq 0$. A deconfinement transition is a nonanalytic change, in the infinite-volume thermal free energy or its derivatives, across which this center order parameter changes its symmetry-realization pattern.

This definition is sharp for pure Yang–Mills and for theories whose dynamical matter preserves a nontrivial center subgroup. With dynamical fundamental quarks the fundamental center symmetry is explicitly broken, so the fundamental Polyakov loop is no longer a strict order parameter. It remains a useful static-source observable, and rapid finite-temperature changes in it may diagnose a crossover, but the exact symmetry statement has been lost.

The center-symmetry order parameter is logically distinct from the zero-temperature Wilson-loop area law. The latter concerns large spacelike or spacetime Wilson loops and static-source potentials at $T = 0$; the former concerns the realization of the thermal center symmetry and the free energy of a single static source at $T > 0$. In a theory where both are under control they are related by physical continuity, but neither finite-cutoff definition is a substitute for proving the other’s continuum dynamics.

46.5 Wilson Loops and the Strong-Coupling Area Law

Let C be a closed oriented lattice path. If C traverses the oriented link ℓ with sign $\epsilon_\ell = \pm 1$, set

$$U(C) = \prod_{\ell \in C} U_\ell^{\epsilon_\ell},$$

with the product ordered along the path. For an irreducible representation R of G with character χ_R and dimension d_R, define the normalized Wilson loop

$$W_R(C) = d_R^{-1} \chi_R(U(C)). \tag{46.19}$$

Gauge factors at adjacent endpoints cancel around the closed curve, so $W_R(C)$ is gauge invariant.

The strong-coupling expansion is the character expansion of each plaquette Boltzmann factor. Write

$$\exp\left\{\frac{\beta}{N}\operatorname{Re}\operatorname{tr}U_P\right\} = c_0(\beta)\left[1+\sum_{\lambda\neq 0} d_\lambda u_\lambda(\beta)\chi_\lambda(U_P)\right], \qquad u_\lambda(\beta) = O(\beta^{n_\lambda}), \tag{46.20}$$

where $n_\lambda > 0$ for every nontrivial representation. The Haar orthogonality relation

$$\int_G R^\lambda(U)_{ij} R^\mu(U^{-1})_{kl}\,\mathrm{d}U = \frac{\delta_{\lambda\mu}}{d_\lambda}\delta_{il}\delta_{jk} \tag{46.21}$$

implies a local constraint: after integrating a link, the representation matrices carried by the plaquettes and by the Wilson loop must combine to the trivial representation on that link.

For a fundamental Wilson loop in $SU(N)$, the lowest nonzero contribution is therefore obtained by filling a surface Σ with boundary C by fundamental plaquettes. If $A_{\min}(C)$ is the minimal number of plaquettes in such a surface, then

$$\langle W_\square(C)\rangle_{\Lambda,\beta} = K_C\, u_\square(\beta)^{A_{\min}(C)}\big(1+O(\beta)\big) \tag{46.22}$$

for sufficiently small β, with $K_C > 0$ determined by boundary group integrals and by the normalization of $W_\square$. More precisely, the polymer expansion obtained from (46.20) converges absolutely when β is small enough; its polymer activities obey a bound of the form

$$\sum_{\Gamma\ni P} |z(\Gamma)|\mathrm{e}^{\alpha|\Gamma|} \le \alpha$$

for a positive α, after decreasing β if necessary. This Kotecky–Preiss type estimate gives constants $C(\beta)$ and $\sigma(\beta) > 0$ such that

$$|\langle W_\square(C)\rangle_{\Lambda,\beta}| \le C(\beta)\,\exp\{-\sigma(\beta)A_{\min}(C)\} \tag{46.23}$$

uniformly in the finite volume, away from boundary effects.

For a rectangular loop with spatial length $R = na$ and Euclidean time length $T = ma$, (46.23) gives

$$\langle W_\square(C_{R,T})\rangle \sim \exp\{-\sigma_{\mathrm{lat}}(\beta)nm\} = \exp\{-[\sigma_{\mathrm{lat}}(\beta)R/a]\,T/a\}.$$

The transfer-matrix interpretation therefore gives a static-source potential which grows linearly with separation in the strong-coupling lattice theory. This is a rigorous confinement diagnostic at finite lattice cutoff for small β. The four-dimensional continuum confinement problem asks for control along a scaling trajectory with $\beta \to \infty$.

46.6 Scaling Trajectories and Dimensional Transmutation

The continuum limit is not obtained by fixing β and sending $a \downarrow 0$. One must choose a trajectory $g_0(a)$, equivalently $\beta(a) = N/g_0(a)^2$ in the trace normalization of this chapter, so that dimensionless lattice observables scale in a way compatible with finite physical observables. For example, if the continuum theory has a string tension σ_{phys}, a scaling trajectory would satisfy

$$a^2\sigma_{\mathrm{lat}}(\beta(a)) \longrightarrow a^2\sigma_{\mathrm{phys}} \quad \text{with} \quad a^2\sigma_{\mathrm{phys}} \downarrow 0.$$

Equivalently, the correlation length in lattice units must diverge.

Perturbation theory around the Gaussian ultraviolet fixed point predicts the large-β relation between a and the lattice coupling. For pure $SU(N)$, define β_0, β_1 by

$$\mu \frac{\mathrm{d}g}{\mathrm{d}\mu} = -\beta_0 g^3 - \beta_1 g^5 + O(g^7), \qquad \beta_0 = \frac{11N}{48\pi^2}, \qquad \beta_1 = \frac{34N^2}{3(16\pi^2)^2}. \tag{46.24}$$

Then the associated lattice scale Λ_L is characterized by

$$a\Lambda_L = \exp\left\{-\frac{1}{2\beta_0 g_0^2}\right\} (\beta_0 g_0^2)^{-\beta_1/(2\beta_0^2)} \big(1 + O(g_0^2)\big), \qquad g_0^2 = \frac{2N}{\beta}. \tag{46.25}$$

The numerical value of Λ_L depends on the lattice action and on the definition of the bare coupling. Ratios between Λ_L and scales in other schemes, such as $\Lambda_{\overline{\mathrm{MS}}}$, are determined by matching a short-distance observable in the overlap of the two regularized perturbation theories.

The formula (46.25) gives the perturbative tangent to the scaling trajectory near $g_0 = 0$. A construction of four-dimensional Yang–Mills theory must also show that the gauge-invariant Schwinger functions or an equivalent algebraic object converge along such a trajectory and that the reconstructed Hilbert-space theory has the desired spectral properties.

46.7 Local Operators, Counterterms, and Lattice Symmetries

The Wilson lattice action has exact gauge invariance, lattice translations, hypercubic rotations and reflections, and charge conjugation when the θ-angle is set to zero. The continuum local terms that can be generated by the lattice regulator must respect these symmetries. This gives the Symanzik form of a local long-distance effective action:

$$S_{\mathrm{Sym}} = \int \mathrm{d}^4x \left[\mathcal{E}_0(a) + \frac{1}{4g_R(a)^2} \operatorname{tr}(F_{\mu\nu}F_{\mu\nu}) + \sum_i a^{d_i-4} c_i(a)\mathcal{O}_i(x)\right] + \mathrm{i}\theta \frac{1}{8\pi^2} \int \operatorname{tr}(F \wedge F). \tag{46.26}$$

Here $\mathcal{E}_0(a)$ is a vacuum-energy density, $d_i > 4$, and $\mathcal{O}_i$ are gauge-invariant local operators compatible with the lattice symmetries. In pure $SU(N)$ Yang–Mills, with CP imposed, the only nontrivial gauge-invariant dimension-four term is $\operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$. If CP is not imposed, the topological density $\operatorname{tr}(F \wedge F)$ supplies the separate θ-parameter. Gauge invariance forbids a gluon mass term, and hypercubic symmetry makes the coefficient of $F_{\mu\nu}F_{\mu\nu}$ the same for every coordinate two-plane on an isotropic lattice.

Definition 46.5 (Tuning for a lattice continuum limit)**.** A lattice parameter is tuned when it must be chosen as a function of a in order to keep a specified renormalized observable finite and nonzero as $a \downarrow 0$. Parameters multiplying operators with dimension below four are relevant at the Gaussian fixed point; parameters multiplying dimension-four operators are marginal at tree level and must be classified by the beta function and by symmetry.

For pure CP-even $SU(N)$ Yang–Mills on an isotropic Wilson lattice, this power-counting and symmetry analysis leaves one running parameter, $g_0(a)$. The mass gap, glueball spectrum, and string tension are then outputs of the continuum theory, if the continuum limit exists. Different gauge-invariant lattice actions with the same symmetries change the coefficients of irrelevant operators in (46.26) and change the relation between their lattice scales. Symanzik improvement chooses additional irrelevant plaquette and loop terms so that the leading lattice artifacts begin at higher powers of a.

For theories whose ultraviolet flow is not asymptotically free, the preceding one-parameter mechanism may fail to produce an interacting continuum theory. Four-dimensional scalar ϕ^4 theory and four-dimensional QED are the basic cautionary examples: perturbation theory points toward a Landau-pole obstruction, and rigorous triviality results constrain large classes of lattice scalar limits. Those results do not settle every possible UV-complete theory that has the same formal perturbative expansion around the Gaussian point. The monograph therefore treats triviality and asymptotic non-freedom as theory-specific continuum-limit questions, not as consequences of formal power series alone.

46.8 Glueball Spectrum and Flux-Tube Observables

The preceding sections define finite-regulator expectation values. To discuss the pure Yang–Mills spectrum one must say which gauge-invariant Hilbert-space object is being extracted from those expectations. At finite spatial volume and finite lattice spacing, reflection positivity supplies a transfer matrix $\mathbb{T} = \exp(-aH_{\rm lat})$ on the gauge-invariant Hilbert space. A glueball is an eigenstate of $H_{\rm lat}$ in the vacuum superselection sector, created with nonzero overlap by a gauge-invariant local operator built from closed Wilson loops or lattice field-strength composites. This is a finite-regulator definition. A continuum glueball mass is a limit of energy differences along a scaling trajectory, if the limit exists.

Let $\mathcal{O}_i(t)$, $i = 1, \dots, m$, be gauge-invariant operators projected to a chosen zero-momentum lattice symmetry channel and with vacuum expectation subtracted when the channel permits it. The Euclidean correlation matrix is

$$C_{ij}(t) = \langle \mathcal{O}_i(t)\mathcal{O}_j(0)\rangle - \langle \mathcal{O}_i\rangle\langle \mathcal{O}_j\rangle. \tag{46.27}$$

If $0 = E_0 < E_1 \le E_2 \le \cdots$ are transfer-matrix energies in this channel, then the spectral theorem gives

$$C_{ij}(t) = \sum_{n\ge 1} Z_i^{(n)}\overline{Z_j^{(n)}}\,\mathrm{e}^{-aE_n t}, \qquad Z_i^{(n)} = \langle \Omega|\mathcal{O}_i|n\rangle. \tag{46.28}$$

The integer t is Euclidean time in lattice units. The connected subtraction removes the vacuum term; without it the scalar 0^{++} channel would be dominated by the identity.

Equation (46.28) is the Yang–Mills datum needed here. A finite-volume calculation must declare how the energies appearing in this spectral representation are estimated, but the estimator is not part of the definition of a glueball state. The Yang–Mills-specific content is the construction of gauge-invariant Wilson-loop source spaces, the cubic-group channel assignment, reflection positivity of the chosen lattice regulator, and the continuum/infinite-volume limit that turns finite-regulator energies into pure-glue spectral data. Correlator-matrix algebra and residual diagnostics are numerical-analysis data, not additional pure-Yang–Mills definitions.

The continuum spin labels J^{PC} are recovered only after the cubic lattice irreducible representations have been compared across lattice spacings and volumes. The following table records the operator meaning of the lowest pure-glue channels; it is not a phenomenological assignment to

QCD-with-quarks resonances.

continuum channel	typical continuum operator	cubic-lattice channel
0^{++}	$\operatorname{tr}(F_{\mu\nu}F_{\mu\nu})$	A_1^{++}
2^{++}	$\operatorname{tr}\big(F_{\mu\alpha}F_{\nu\alpha} - \frac{1}{4}\delta_{\mu\nu}F_{\rho\sigma}F_{\rho\sigma}\big)$	$E^{++} \oplus T_2^{++}$
0^{-+}	$\operatorname{tr}(F_{\mu\nu}\widetilde{F}_{\mu\nu})$	A_1^{-+}
0^{+-}	multi-loop CP-odd scalar combinations	A_1^{+-}
1^{+-}, 1^{-+}	hypercubic vector loop combinations	T_1^{+-}, T_1^{-+}

At nonzero lattice spacing the cubic irreducible representation is the exact label. A continuum spin claim is supported when the expected degeneracies among cubic irreducibles emerge under continuum extrapolation; for example a continuum $J = 2$ state splits into the E and T_2 representations of the cubic group at finite a.

Definition 46.6 (Pure-glue spectral continuum datum)**.** A pure-glue spectral continuum datum consists of:

1. a choice of gauge group and global form;
2. a reflection-positive lattice action and scaling trajectory;
3. a basis of gauge-invariant operators in each cubic PC channel, together with smearing or blocking maps stated as regulator definitions;
4. finite-volume energy estimates, with the estimator, time windows, source-basis conditioning, and stability diagnostics declared as regulator data;
5. continuum and infinite-volume extrapolations of dimensionless ratios such as $M_{J^{PC}}/\sqrt{\sigma}$ or $M_{J^{PC}}/\Lambda_{\overline{\mathrm{MS}}}$;
6. a systematic-error budget for excited-state contamination, volume effects, lattice-spacing artifacts, topological freezing, and operator-basis conditioning.

Only after these data are stated is a numerical glueball spectrum a statement about pure Yang–Mills theory rather than about a particular finite lattice calculation.

The static flux-tube sector is extracted from rectangular Wilson loops or from Polyakov-line correlators. For two static sources in a representation R, the finite-regulator static energy is

$$E_R(L) = -\lim_{T\to\infty} \frac{1}{aT} \log\langle W_R(L,T)\rangle_{\mathrm{conn}}, \tag{46.29}$$

when the limit exists. The string tension in a stable center-charge sector is

$$\sigma_R = \lim_{L\to\infty} \frac{E_R(L)}{L}.$$

Chapter 49 develops the long-string effective expansion: the Luscher term, excited open and closed flux-tube levels, k-string sectors, baryonic flux networks, and the distinction between winding closed flux tubes and contractible glueball states. The role of the present chapter is the regulator-level extraction: the operators are well-defined finite Haar-integral observables, and the continuum question is whether their dimensionless spectral data converge.

Controlled Approximation 46.7 (Large-N glueball width counting)**.** Normalize single-trace glueball operators formally by

$$\mathcal{O}_N(x) = \frac{1}{N} \operatorname{tr} \mathcal{P}(F, D)(x),$$

so that connected two-point functions are $O(N^0)$ in the confining large-N scaling regime. If the topological large-N expansion has isolated single-glueball poles with LSZ residues of order one, then connected k-glueball amplitudes scale as N^{2-k}. In particular a three-glueball coupling is $O(N^{-1})$, and a glueball decay width into two glueballs is $O(N^{-2})$, when the decay is kinematically allowed. The double-line expansion for connected correlators of k normalized single-trace insertions has leading sphere topology with k marked boundaries, hence N^{2-k}. Isolated poles with order-one residues do not change the N-power when the external legs are amputated. A decay width is quadratic in the on-shell three-point coupling and includes no compensating positive power of N in the density of a fixed number of color-singlet final states, so it is $O(N^{-2})$.

None of the preceding statements proves the four-dimensional continuum existence and mass-gap theorem for Yang–Mills theory. They give the precise finite-regulator and continuum-extrapolation language in which the expected mass gap, glueball spectrum, and confining flux-string data are formulated. The rigorous construction problem remains the one stated at the end of this chapter: produce a continuum local quantum field theory, prove positivity and locality after reconstruction, and prove a strictly positive lowest color-singlet excitation above the vacuum.

46.9 The θ-Term and Lattice Topology

For a smooth continuum $SU(N)$ connection on a closed four-manifold,

$$Q[A] = \frac{1}{8\pi^2} \int \operatorname{tr}(F \wedge F) \in \mathbb{Z}$$

is the second Chern number. The Euclidean action may include $\mathrm{i}\theta Q[A]$, and the integer-valuedness of Q gives 2π-periodicity in θ.

At finite lattice spacing, a generic lattice gauge field is only an assignment of group elements to links. There is no literal smooth bundle connection from which Q can be read without an additional construction. A plaquette discretization of the density $\operatorname{tr}(F \wedge F)$ has the correct classical limit on smooth fields, but it is not integer-valued on arbitrary lattice fields. Consequently $\exp(\mathrm{i}\theta Q_{\mathrm{plaq}})$ need not be 2π-periodic at finite a.

There are several regulator-level ways to define topological charge more carefully. A geometric definition interpolates admissible lattice fields to a bundle over the torus and evaluates the corresponding Chern number. With Ginsparg–Wilson fermions, the index of the lattice Dirac operator gives an integer

$$Q_{\mathrm{GW}} = \operatorname{Tr} \gamma_5 \left(1 - \frac{aD_{\mathrm{GW}}}{2}\right)$$

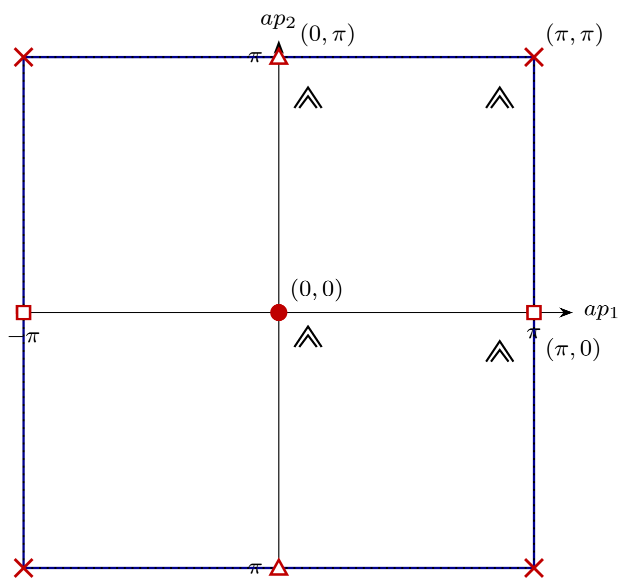
under the usual admissibility hypotheses. Gradient-flow definitions smooth the gauge field before evaluating a lattice density and are designed to have a controlled continuum limit. These choices agree in the continuum scaling regime when the required estimates hold, but they are distinct finite-cutoff definitions. Thus the θ-angle is an additional parameter whose nonperturbative lattice definition requires its own regulator convention.

46.10 Fermions: Doubling and Chiral Lattice Actions

A vectorlike gauge theory with fermions requires a lattice Dirac operator coupled to the link variables. The naive free lattice Dirac operator is

$$D_{\mathrm{n}}(p) = \frac{\mathrm{i}}{a}\sum_{\mu=1}^{4}\gamma_\mu \sin(ap_\mu), \qquad p_\mu \in [-\pi/a, \pi/a). \tag{46.30}$$

Its zeros occur whenever every ap_μ is 0 or π. In four dimensions this gives $2^4 = 16$ light species near the corners of the Brillouin zone. Figure 46.3 displays the two-dimensional Brillouin-torus version, where edge identifications turn nine drawn zeros into four inequivalent continuum cones.



edge identifications of the Brillouin torus group the nine displayed zeros into four inequivalent two-dimensional Dirac species; four dimensions have 2^4 species

Figure 46.3: The naive lattice derivative vanishes at every Brillouin-zone corner. In two dimensions the center, the two identified horizontal-edge zeros, the two identified vertical-edge zeros, and the four identified corners give four inequivalent continuum Dirac cones.

Theorem 46.8 (Degree obstruction for chiral lattice symbols)**.** *Let $f = (f_1, \dots, f_D) : \mathbb{T}^D \to \mathbb{R}^D$ be a smooth periodic map whose zeros are isolated and nondegenerate, and let*

$$D_f(p) = \mathrm{i}\sum_{\mu=1}^{D}\gamma_\mu f_\mu(p)$$

with Euclidean gamma matrices satisfying $\{\gamma_\mu, \gamma_\nu\} = 2\delta_{\mu\nu}$. This symbol anticommutes with the fixed chirality matrix γ_{D+1}. Assign to a zero p_* the chirality sign

$$\chi(p_*) = \operatorname{sign}\det\left(\frac{\partial f_\mu}{\partial p_\nu}(p_*)\right).$$

Then

$$\sum_{f(p_*)=0}\chi(p_*) = 0.$$

Consequently a chirally symmetric periodic symbol of this form cannot contain only one nondegenerate continuum Weyl cone.

Proof. For a regular value $y \in \mathbb{R}^D$ of f, define the signed preimage count

$$I(y) = \sum_{f(p)=y} \operatorname{sign}\det\left(\frac{\partial f_\mu}{\partial p_\nu}(p)\right).$$

Sard's theorem makes the regular values dense. On a connected open set of regular values, $I(y)$ is locally constant: if $y(s)$ is a small path of regular values and $f(p_0) = y(0)$, the inverse function theorem gives a unique smooth branch $p(s)$ with $f(p(s)) = y(s)$, and the determinant sign cannot change along the branch because it never vanishes.

The image $f(\mathbb{T}^D)$ is compact, so there exists a regular value y_∞ outside the image; for it $I(y_\infty) = 0$. Join 0 to y_∞ by a smooth path and perturb it, with endpoints fixed, so that it meets the critical-value set only in isolated birth–death crossings. At such a crossing the local normal form creates or annihilates two simple preimages with opposite determinant signs. Hence the signed count is unchanged across the crossing. Therefore $I(0) = I(y_\infty) = 0$, which is the displayed chirality-sum identity.

Near a nondegenerate zero, $D_f(p)$ linearizes to $\mathrm{i}\gamma_\mu A^\mu{}_\nu(p - p_*)^\nu$. The sign of $\det A$ is exactly the orientation, hence chirality, of that continuum cone relative to the chosen gamma-matrix orientation. A single Weyl cone would have total chirality ± 1, contradicting the zero sum. □

The full Nielsen–Ninomiya theorem treats broader local, translation-invariant, chirally symmetric lattice Dirac operators by replacing $f/|f|$ with the appropriate normalized symbol on the Brillouin torus with small neighborhoods of the zeros removed. The obstruction is the same degree identity: a compact momentum torus has no boundary, so the local winding numbers of all zeros must sum to zero. Later lattice-fermion chapters spell out how Wilson and Ginsparg–Wilson constructions evade different hypotheses.

Standard lattice fermion constructions evade different hypotheses of this theorem.

Wilson fermions
: Add $ra\,\Delta/2$, giving doublers masses of order $1/a$. The Wilson term breaks chiral symmetry and produces additive mass renormalization, so the chiral limit requires tuning $m_0(a)$ to a critical value $m_c(a)$.

Staggered fermions
: Diagonalize part of the spin structure and reduce the number of tastes. The residual taste symmetry and rooting questions must be treated as finite-cutoff regularization issues.

Domain-wall fermions
: Place chiral modes on separated boundaries of an auxiliary fifth direction. Finite fifth-dimensional size produces residual chiral-symmetry breaking.

Overlap and Ginsparg–Wilson fermions
: Replace $\{\gamma_5, D\} = 0$ by $\gamma_5 D + D\gamma_5 = aD\gamma_5 D$, giving an exact modified lattice chiral symmetry and an index theorem at finite cutoff under admissibility hypotheses.

For vectorlike QCD, these formulations provide regulator choices for gauge-invariant correlation functions. Their continuum equivalence requires the same kind of scaling-limit control as in the pure gauge theory, together with the relevant mass and chiral-symmetry tunings.

46.11 Status of the Four-Dimensional Continuum Construction

Hypothesis 46.9 (Four-dimensional lattice Yang–Mills continuum limit)**.** Let $G = SU(N)$ and let the Wilson lattice measures $d\mu_{\Lambda,\beta}$ be defined by (46.5). There exists a scaling trajectory $\beta(a) \to \infty$ and an infinite-volume limit such that the gauge-invariant Schwinger functions of local and loop observables converge, after the required field and operator normalizations, to Schwinger functions satisfying the continuum Osterwalder–Schrader hypotheses. The reconstructed Hilbert-space theory has a unique vacuum and a positive mass gap.

This hypothesis is the constructive content of four-dimensional pure Yang–Mills theory. The finite lattice theory is rigorous; the hypothesis is the assertion that the rigorous finite-cutoff objects have the required continuum limit and spectral gap. Renormalization-group analyses of lattice gauge theory, including Bałaban's multiscale program, prove substantial estimates toward such a construction. Other constructive results in related models and dimensions give additional control of particular mechanisms. A complete proof of Hypothesis 46.9 for four-dimensional nonabelian Yang–Mills theory remains the Yang–Mills existence and mass-gap problem.

The strong-coupling area law is a theorem inside the small-β lattice regime. The weak-coupling continuum regime lies at $\beta \to \infty$. For four-dimensional pure $SU(2)$ and $SU(3)$ Wilson gauge theory, numerical and analytic evidence support a confining continuum limit connected to the strong-coupling phase without a physical deconfining transition at zero temperature. For other groups and lattice actions, bulk lattice-artifact transitions may occur and must be distinguished from continuum physics. The logical role of the lattice construction is therefore precise: it supplies a finite, gauge-invariant nonperturbative regulator and a clear continuum-limit problem; it does not by itself solve the mass-gap problem.

Covariant gauge fixing, Faddeev–Popov ghosts, BRST cohomology, and the BV formalism developed in the following chapters are indispensable perturbative and cohomological tools. Their nonperturbative identification with the continuum theory constructed from the lattice rests on two further inputs: first, the lattice continuum limit in Hypothesis 46.9; second, agreement of short-distance gauge-invariant observables with the covariant perturbative expansion order by order after matching the renormalized coupling and local operator normalizations.

Chapter 47

Gauge Fixing, Ghosts, and BRST Cohomology

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Remark 47.1 (Regulator-level status of covariant gauge fixing). The gauge-fixing, ghost, and BRST constructions in this chapter are local coordinate systems for perturbative gauge theory and for the cohomological classification of local operators, counterterms, and anomalies. The finite-dimensional nonperturbative regulator used in this volume for pure Yang–Mills theory is the lattice construction of Chapter 46. The identification of the covariant BRST expansion with that lattice-based continuum theory is made through gauge-invariant observables and order-by-order short-distance matching, together with the continuum-limit hypothesis stated in Hypothesis 46.9.

47.1 Gauge Orbits and Local Coordinates

Let M be the spacetime manifold and let G be the compact gauge group whose Lie algebra conventions were fixed in Chapter 45. On a fixed local trivialization, the space of gauge potentials is the affine space

$$\mathcal{A} = \Omega^1(M, \mathfrak{g}).$$

Here $\mathfrak{g} = i\,\mathfrak{g}_{\mathrm{ah}}$ is the Hermitian coordinate space associated with the anti-Hermitian Lie algebra $\mathfrak{g}_{\mathrm{ah}} = \mathrm{Lie}(G)$ in a unitary representation. If $X, Y \in \mathfrak{g}$, the compact real Lie bracket is

$$[X, Y]_{\mathrm{H}} := -\mathrm{i}[X, Y],$$

where the bracket on the right is the matrix commutator in a unitary representation. The gauge transformations form the infinite-dimensional group

$$\mathcal{G} = C^{\infty}(M, G).$$

This group must be distinguished from the finite-dimensional internal group G. In local coordinates near the identity, a gauge transformation can be written as

$$g(x) = \exp\bigl(\mathrm{i}\zeta^{a}(x)t^{a}\bigr), \qquad \xi^{\alpha} \equiv \zeta^{a}(x), \qquad \alpha = (a, x).$$

Repeated condensed indices include sums over Lie algebra labels and integrals over spacetime; for example

$$f_{\alpha}g^{\alpha} = \sum_{a} \int_{M} f_{a}(x)g^{a}(x)\,\mathrm{d}^{D}x. \tag{47.1}$$

The action of $g \in \mathcal{G}$ on $A \in \mathcal{A}$ is

$$A_{\mu} \longmapsto A_{\mu}^{g} = gA_{\mu}g^{-1} + \mathrm{i}g\partial_{\mu}g^{-1}.$$

The infinitesimal action associated with $\zeta = \zeta^{a}t^{a} \in C^{\infty}(M, \mathfrak{g})$ is

$$\delta_{\zeta}A_{\mu} = D_{\mu}(A)\zeta, \qquad D_{\mu}(A)\zeta = \partial_{\mu}\zeta + [A_{\mu}, \zeta]_{\mathrm{H}}, \qquad (D_{\mu}(A)\zeta)^{a} = \partial_{\mu}\zeta^{a} + f^{a}{}_{bc}A_{\mu}^{b}\zeta^{c}.$$

Let ϕ denote the complete list of fields: gauge potentials and, when present, matter fields. At a fixed ultraviolet and infrared regulator, before the gauge orbits are divided out, the gauge-field integral is an integral over a regulated field space $\mathcal{F}_{\Lambda}$,

$$Z_{\mathrm{unfixed},\Lambda} = \int_{\mathcal{F}_{\Lambda}} \mathrm{d}\mu_{\Lambda}(\phi)\, \exp(\mathrm{i}S_{\Lambda}[\phi]), \qquad S[\phi^{\xi}] = S[\phi], \qquad \mathrm{d}\mu_{\Lambda}(\phi^{\xi}) = \mathrm{d}\mu_{\Lambda}(\phi). \tag{47.2}$$

Here $\mathrm{d}\mu_{\Lambda}$ is the regulator measure induced by the chosen regularization of the bosonic and fermionic variables. Equation (47.2) is not a definition of a gauge theory by itself: if the gauge group acts freely, it integrates separately over orbit directions and over directions transverse to the orbits; if stabilizers or Gribov phenomena are present, the same statement holds only in sufficiently small coordinate charts. In canonical language the orbit directions are the directions generated by first-class constraints. Covariant perturbation theory therefore chooses local coordinates transverse to the orbits and keeps track of the corresponding Jacobian.

A gauge condition is a collection of functionals $F^{A}[\phi]$, with the index A carrying the same number of local degrees of freedom as the gauge parameter index α. The intended local slice is $F^{A}[\phi] = 0$. Figure 47.1 records the geometric content.

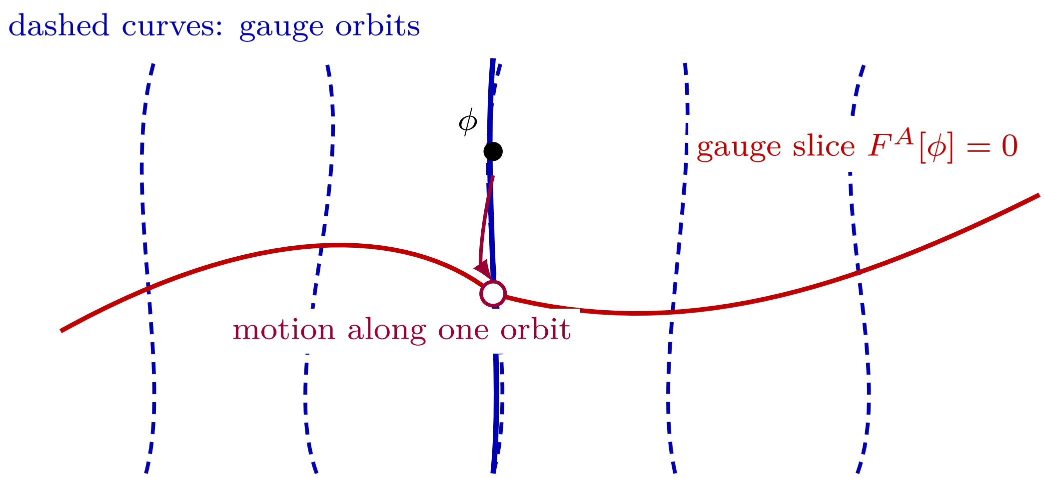


Figure 47.1: A local gauge condition is a slice through field space. The blue dashed curves are gauge orbits, the heavier red curve is the surface $F^A[\phi] = 0$, and the filled point ϕ and open point ϕ^ξ lie on the same highlighted gauge orbit. The Faddeev–Popov determinant is the Jacobian that converts integration along the orbit to integration through the slice.

The infinitesimal variation of the gauge condition along the orbit defines the Faddeev–Popov matrix

$$\mathcal{M}^A{}_\alpha[\phi] := \left.\frac{\partial F^A[\phi^\xi]}{\partial \xi^\alpha}\right|_{\xi=\mathrm{id}}. \tag{47.3}$$

For Yang–Mills gauge potentials alone this is the distributional operator

$$\mathcal{M}_F^{ab}(A; x, y) = \left.\frac{\delta F^a(A^{\exp(\mathrm{i}\zeta)})(x)}{\delta \zeta^b(y)}\right|_{\zeta=0}. \tag{47.4}$$

Proposition 47.2 (Orbit measure and the Faddeev–Popov density)**.** *Let $U \subset \mathcal{F}_\Lambda$ be a finite-regulator field-space region, or a Sobolev local Hilbert-manifold chart with determinant regularization specified, on which the gauge group $\mathcal{G}_\Lambda$ acts freely and properly. Let*

$$q : U \longrightarrow B_U := U/\mathcal{G}_\Lambda$$

be the quotient map, and let $F : U \to E$ be a gauge condition such that

$$\mathcal{S}_F = \{\phi \in U : F(\phi) = 0\}$$

is the image of a local section $s_F : B_U \to U$ of q. Equivalently, the map

$$\Theta : \mathcal{S}_F \times \mathcal{G}_\Lambda \longrightarrow U, \qquad (\sigma, \xi) \longmapsto \sigma^\xi$$

is a diffeomorphism onto U. Suppose $\mathrm{d}\mu_\Lambda$ is a $\mathcal{G}_\Lambda$-invariant density on U, and let $\mathrm{d}\xi_{\mathrm{H}}$ be a right Haar density on $\mathcal{G}_\Lambda$. For each $\phi \in U$, the orbit measure $\mathrm{d}\mu_{\mathcal{O}_\phi}$ is the pushforward of $\mathrm{d}\xi_{\mathrm{H}}$ by $\xi \mapsto \phi^\xi$. The restriction of F to the orbit has differential

$$\mathrm{d}(F|_{\mathcal{O}_\phi})_\phi = \mathcal{M}_F[\phi] : T_{\mathrm{id}}\mathcal{G}_\Lambda \longrightarrow E.$$

If the orbit intersects $\mathcal{S}_F$ once in the chart, then

$$\int_{\mathcal{O}_\phi} \mathrm{d}\mu_{\mathcal{O}_\phi}(\psi)\, \delta_E(F(\psi))\, \big|\det \mathcal{M}_F[\psi]\big| = 1. \tag{47.5}$$

Consequently the quotient measure represented in the section $\mathcal{S}_F$ is characterized by the pushed-forward density

$$(s_F)_*\mathrm{d}\nu_F = \delta_E(F(\phi))\, \big|\det \mathcal{M}_F[\phi]\big|\, \mathrm{d}\mu_\Lambda(\phi) \tag{47.6}$$

on U, as an identity of densities tested against functions supported in the coordinate chart. Equivalently, for every gauge-invariant test function H,

$$\int_{B_U} \mathrm{d}\nu_F([\,\phi\,])\, H([\,\phi\,]) = \int_U \mathrm{d}\mu_\Lambda(\phi)\, \delta_E(F(\phi))\, \big|\det \mathcal{M}_F[\phi]\big|\, H(q(\phi)). \tag{47.7}$$

The oriented perturbative Faddeev–Popov formula replaces the absolute value by $\det \mathcal{M}_F$ after choosing an orientation of the determinant line on the chart. The ghost path integral represents this oriented determinant. If $\det \mathcal{M}_F$ vanishes, or if an orbit intersects the section more than once, the single-chart quotient-measure formula has left its domain of validity.

Proof. Fix an orbit in U and write $\psi = \sigma^\xi$ with $\sigma \in \mathcal{S}_F$. The map

$$\chi_\sigma : \mathcal{G}_\Lambda \longrightarrow E, \qquad \chi_\sigma(\xi) = F(\sigma^\xi)$$

has derivative $\mathcal{M}_F[\sigma^\xi]$ in the orbit directions. Since the slice is transverse and intersects the orbit once, χ_σ is a local diffeomorphism from a neighborhood of the relevant group element to a neighborhood of $0 \in E$. The ordinary change-of-variables formula gives

$$\mathrm{d}\chi_\sigma = \big|\det \mathcal{M}_F[\sigma^\xi]\big|\, \mathrm{d}\xi_{\mathrm{H}}$$

in these coordinates, and therefore

$$\int_{\mathcal{G}_\Lambda} \mathrm{d}\xi_{\mathrm{H}}\, \delta_E(F(\sigma^\xi))\, \big|\det \mathcal{M}_F[\sigma^\xi]\big| = \int_E \mathrm{d}u\, \delta_E(u) = 1.$$

This proves (47.5). The action is free and proper on U, so $q : U \to B_U$ is a local principal bundle and the invariant density disintegrates in the product coordinates supplied by Θ into a quotient density times the Haar density on the orbit. Inserting (47.5) into the orbit factor of this disintegration gives (47.7). Multiple intersections replace the right-hand side of (47.5) by the intersection number, and zero modes of $\mathcal{M}_F$ are precisely the failure of the change of variables. □

In a field-space region where the slice is transverse to the orbit, and after separating zero modes associated with unfixed global transformations, the oriented perturbative Faddeev–Popov identity is

$$1 = \int_{\mathcal{G}} D\xi\, \delta\big(F^A[\phi^\xi]\big) \det\left(\frac{\partial F^A[\phi^\xi]}{\partial \xi^\alpha}\right). \tag{47.8}$$

Inserting (47.8) in (47.2) and changing variables $\phi \mapsto \phi^{\xi^{-1}}$ gives a factor depending only on integration over the gauge group. More explicitly, the determinant at a general point ξ on the orbit splits as

$$\det \frac{\partial F^A[\phi^{\xi'}]}{\partial \xi'^\alpha}\bigg|_{\xi'=\xi} = \det \frac{\partial(\xi'' \circ \xi)^\alpha}{\partial \xi''^\beta}\bigg|_{\xi''=\mathrm{id}} \det \frac{\partial F^A[\phi^{\xi''}]}{\partial \xi''^\alpha}\bigg|_{\xi''=\mathrm{id}}.$$

The first factor converts the coordinate measure $D\xi$ to the right Haar measure $[D\xi]_{\mathrm{H}}$, characterized formally by

$$[D(\xi \circ \xi_1)]_{\mathrm{H}} = [D\xi]_{\mathrm{H}}, \qquad \xi_1 \in \mathcal{G} \text{ fixed.} \tag{47.9}$$

Thus

$$\int_{\mathcal{G}} [D\xi]_{\mathrm{H}}$$

is the formal volume of the gauge-transformation group, and the normalized gauge-theory path integral is

$$Z = \frac{1}{\int_{\mathcal{G}} [D\xi]_{\mathrm{H}}} \int [D\phi] \exp(\mathrm{i}S[\phi]). \tag{47.10}$$

The same expression, written in local gauge-fixed coordinates, is

$$Z = \int [D\phi]\, \delta\big(F^A[\phi]\big) \Delta_{\mathrm{FP}}[\phi] \exp(\mathrm{i}S[\phi]), \qquad \Delta_{\mathrm{FP}}[\phi] = \det \mathcal{M}[\phi]. \tag{47.11}$$

Definition 47.3 (Local gauge slice and global section)**.** A local gauge slice in a region $U \subset \mathcal{F}_\Lambda$ is a subspace $\mathcal{S}_F = \{\phi \in U : F^A[\phi] = 0\}$ such that the map

$$\mathcal{S}_F \times \mathcal{G} \longrightarrow U, \qquad (\phi, \xi) \longmapsto \phi^\xi$$

is locally invertible after zero modes and stabilizers have been separated. Equivalently, the Faddeev–Popov operator ${\mathcal{M}^A}_\alpha[\phi]$ is invertible on the nonzero gauge directions. A global smooth gauge fixing would be a smooth section of the quotient map $\mathcal{F}_\Lambda \to \mathcal{F}_\Lambda/\mathcal{G}$, or of the corresponding irreducible-connection quotient after stabilizers are removed.

Proposition 47.4 (Coulomb-slice atlas on irreducible connections)**.** *Let X be a compact Euclidean spacetime, let $P \to X$ be a smooth principal G-bundle with G compact, and fix an integer $k >$* $\dim X/2 + 1$. *Write*

$$\mathcal{A}_k(P) = A_0 + L^2_k(T^*X \otimes \operatorname{ad} P), \qquad \mathcal{G}_{k+1}(P) = L^2_{k+1}\Gamma(\operatorname{Ad} P)$$

for the Sobolev-completed space of connections and gauge group. Let $A \in \mathcal{A}_k(P)$ be irreducible, and divide by a based gauge group, or equivalently remove the finite stabilizer, so that the gauge action is free at A. Denote by

$$d_A : L^2_{k+1}(\operatorname{ad} P) \longrightarrow L^2_k(T^*X \otimes \operatorname{ad} P)$$

the infinitesimal gauge action and by d_A^* its L^2-adjoint. After the stabilizer directions have been removed, the elliptic operator

$$\mathcal{M}_A = d_A^* d_A$$

has trivial kernel. Hence, for sufficiently small $\epsilon > 0$,

$$\mathcal{S}_A(\epsilon) = \{\, A + a : \ d_A^* a = 0, \ \|a\|_{L^2_k} < \epsilon \,\}$$

is a local slice: the map

$$\mathcal{S}_A(\epsilon) \times \mathcal{U}_{\mathrm{id}} \longrightarrow \mathcal{A}_k(P), \qquad (B, g) \longmapsto B^g,$$

with $\mathcal{U}_{\mathrm{id}}$ a small neighborhood of the identity in the based gauge group, is a Hilbert-manifold coordinate chart onto a neighborhood of the orbit of A. In these coordinates $\mathcal{M}_A$ is the Faddeev–Popov operator of the background Coulomb gauge condition $d_A^*(B - A) = 0$.

Proof. The derivative of the displayed map at (A, id) sends a transverse variation a and an infinitesimal gauge parameter ζ to

$$a + d_A\zeta.$$

The tangent space to the proposed slice is $\ker d_A^*$, because the Coulomb condition $d_A^*(B - A) = 0$ linearizes to $d_A^* a = 0$. Elliptic Fredholm theory gives the Hodge-type decomposition

$$L^2_k(T^*X \otimes \mathrm{ad}\, P) = \ker d_A^* \oplus \mathrm{im}\, d_A$$

after the finite-dimensional kernel of d_A has been removed. The orthogonality follows from the adjoint relation $\langle a, d_A\zeta\rangle = \langle d_A^* a, \zeta\rangle$, and closedness of $\mathrm{im}\, d_A$ follows from ellipticity of $d_A^* d_A$ on the stabilizer-free gauge algebra.

The inverse on the orbit directions is obtained explicitly. Given a one-form u, solve

$$d_A^* d_A \zeta = d_A^* u$$

for ζ; invertibility of $\mathcal{M}_A = d_A^* d_A$ is precisely the irreducibility condition with stabilizer directions removed. Then

$$u = (u - d_A\zeta) + d_A\zeta, \qquad d_A^*(u - d_A\zeta) = 0,$$

so the derivative

$$\ker d_A^* \oplus L^2_{k+1}(\mathrm{ad}\, P)_{\mathrm{free}} \longrightarrow L^2_k(T^*X \otimes \mathrm{ad}\, P)$$

is a Banach-space isomorphism. The Sobolev condition $k > \dim X/2 + 1$ makes L^2_{k+1} gauge transformations at least C^1 and makes multiplication/composition smooth in the Hilbert-manifold category. The Banach inverse function theorem therefore gives a local diffeomorphism from a neighborhood of (A, id) in $\mathcal{S}_A(\epsilon) \times \mathcal{U}_{\mathrm{id}}$ onto a neighborhood of the orbit of A. In this chart the linearization of the gauge condition along the orbit is $d_A^* d_A$, hence the background Coulomb Faddeev–Popov operator is $\mathcal{M}_A$. □

The word "local" in the Faddeev–Popov formulae below means precisely this kind of chart, or its finite-regulator analogue. Perturbation theory around a background uses one such chart and expands the resulting local Jacobian. A nonperturbative continuum gauge-fixed measure would require compatible integration data on an atlas of such charts, with boundary and overlap contributions controlled. The elementary Faddeev–Popov formula is not that global construction.

Quoted Theorem 47.5 (Singer obstruction, structural form)**.** *Let $P \to M$ be a principal bundle over a compact smooth Euclidean spacetime, let G be compact and nonabelian, let $\mathcal{A}_{\mathrm{irr}}$ be the space of irreducible connections, and divide by a based gauge group $\mathcal{G}_*$ so that the action is free. In the standard Yang–Mills cases covered by Singer's theorem, the principal $\mathcal{G}_*$-bundle*

$$\mathcal{A}_{\mathrm{irr}} \longrightarrow \mathcal{A}_{\mathrm{irr}}/\mathcal{G}_*$$

is not globally trivial. Consequently there is no smooth gauge condition that supplies one representative on every gauge orbit and is everywhere transverse to the orbit. Any Faddeev–Popov gauge condition must therefore fail globally either by encountering zero modes of $\mathcal{M}$, by intersecting some orbits more than once, or by requiring multiple coordinate charts on orbit space.

This quoted theorem is a global topological statement rather than a perturbative loop calculation.[1] The proof mechanism is the following. A smooth global gauge condition selecting exactly one point on each orbit is a smooth section

$$\sigma : \mathcal{A}_{\mathrm{irr}}/\mathcal{G}_* \longrightarrow \mathcal{A}_{\mathrm{irr}}$$

of the quotient map. Such a section is equivalent to a trivialization of the principal bundle:

$$\Theta_\sigma : (\mathcal{A}_{\mathrm{irr}}/\mathcal{G}_*) \times \mathcal{G}_* \longrightarrow \mathcal{A}_{\mathrm{irr}}, \qquad ([A], g) \longmapsto \sigma([A])^g. \tag{47.12}$$

Conversely, a trivialization gives a section by setting $g = \mathrm{id}$. Thus the existence of a global transverse gauge slice is exactly the triviality problem for the principal $\mathcal{G}_*$-bundle of connections.

In the Sobolev completions used for the local slice theorem, the full space of connections is affine and contractible. After removing stabilizers by passing to the irreducible locus and by using the based gauge group, Singer's standard Yang–Mills cases give the same universal-bundle homotopy mechanism: $\mathcal{A}_{\mathrm{irr}}$ is a free model for $E\mathcal{G}_*$ in the range relevant to the obstruction, and $\mathcal{A}_{\mathrm{irr}}/\mathcal{G}_*$ is the corresponding model for $B\mathcal{G}_*$. A principal H-bundle with contractible total space is trivial only if H is weakly contractible. Indeed, if

$$P \cong B \times H$$

and P is contractible, then H is a homotopy retract of the contractible space P by fixing a point of B, hence all homotopy groups of H vanish.

The based gauge group in nonabelian Yang–Mills theory has nonzero homotopy. For the trivial bundle over a compactified four-dimensional patch one sees the essential source already in

$$\mathcal{G}_* \simeq \mathrm{Map}_*(S^4, G), \qquad \pi_r(\mathcal{G}_*) \cong \pi_{r+4}(G), \tag{47.13}$$

with the displayed equivalence replaced by the corresponding section space for a nontrivial bundle. Compact nonabelian Lie groups have nonvanishing higher homotopy groups, for instance by Bott periodicity in the classical families. Thus $\mathcal{G}_*$ is not weakly contractible in the cases at issue, and the orbit bundle cannot be globally trivial. This is the mathematical reason why (47.11) gives a local Faddeev–Popov coordinate formula rather than a single global nonperturbative definition of the nonabelian gauge-field integral.

Definition 47.6 (Gribov region and fundamental modular domain)**.** For Landau gauge on a compact Euclidean manifold, write the gauge condition as

$$\partial^\mu A_\mu = 0$$

in a local trivialization and remove the constant gauge zero modes. The Landau Faddeev–Popov operator is

$$\mathcal{M}_L(A) = -\partial^\mu D_\mu(A).$$

The first Gribov region is

$$\Omega_{\mathrm{G}} = \{\, A : \partial^\mu A_\mu = 0,\ \mathcal{M}_L(A) \geq 0 \,\}.$$

[1]See I. M. Singer, "Some remarks on the Gribov ambiguity," *Commun. Math. Phys.* **60** (1978) 7–12, and V. N. Gribov, "Quantization of non-Abelian gauge theories," *Nucl. Phys. B* **139** (1978) 1–19.

Its boundary, where $\mathcal{M}_L(A)$ has a zero mode, is the Gribov horizon. The fundamental modular domain is the set of absolute minima along each gauge orbit of the norm functional

$$\|A\|^2 = \int_M \mathrm{d}^D x \ \mathrm{tr}(A_\mu A^\mu) : \qquad \mathfrak{F} = \{\, A : \|A\|^2 \leq \|A^g\|^2 \text{ for all } g \in \mathcal{G} \,\}.$$

The domain $\mathfrak{F}$ lies inside Ω_{G}, but boundary points of $\mathfrak{F}$ can still be gauge-equivalent. Thus even this sharper domain is not a smooth global slice without boundary identifications.

Proposition 47.7 (Where the Landau Faddeev–Popov chart is Gribov-free)**.** *On a compact flat Euclidean spacetime with constant gauge zero modes removed, the interior*

$$\Omega_{\mathrm{G}}^\circ = \{\, A : \partial^\mu A_\mu = 0, \langle \zeta, \mathcal{M}_L(A)\zeta\rangle_{L^2} > 0 \textit{ for all } 0 \neq \zeta \,\}$$

is the Landau-gauge region where the infinitesimal Faddeev–Popov chart is transverse to the gauge orbit. The Gribov horizon $\partial\Omega_{\mathrm{G}}$ is the locus where this infinitesimal chart loses invertibility. The fundamental modular domain $\mathfrak{F}$ selects absolute minima of $\|A^g\|^2$ on each orbit, but its boundary identifications mean that it is not a smooth global coordinate slice.

Proof. For a fixed connection A, define the orbit norm functional

$$N_A(g) = \|A^g\|^2 = \int_X \mathrm{d}^D x \ \mathrm{tr}(A^g_\mu A^g_\mu).$$

Let $g(t) = \exp(\mathrm{i}t\zeta)$. With the conventions of this chapter,

$$\frac{\mathrm{d}}{\mathrm{d}t} A_\mu^{g(t)}\bigg|_{t=0} = D_\mu(A)\zeta.$$

Using invariance of the trace and integrating by parts on the compact manifold gives

$$\frac{\mathrm{d}}{\mathrm{d}t} N_A(g(t))\bigg|_{t=0} = 2\int_X \mathrm{tr}(A_\mu D_\mu(A)\zeta)\,\mathrm{d}^D x = -2\int_X \mathrm{tr}((\partial^\mu A_\mu)\zeta)\,\mathrm{d}^D x.$$

Thus the stationary points of N_A on the orbit are precisely the Landau representatives. At such a stationary point,

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2} N_A(g(t))\bigg|_{t=0} = 2\int_X \mathrm{tr}\big(\zeta\,[-\partial^\mu D_\mu(A)]\zeta\big)\,\mathrm{d}^D x = 2\langle \zeta, \mathcal{M}_L(A)\zeta\rangle_{L^2}.$$

Therefore strict positivity of $\mathcal{M}_L(A)$ on the nonzero gauge directions is exactly the nondegeneracy condition for the Landau slice to be a local transverse chart. When a zero mode appears, the derivative of the gauge condition along the orbit is singular, and the Faddeev–Popov coordinate formula ceases to be locally invertible. Absolute minima of N_A define $\mathfrak{F}$, but two absolute minima on the boundary may be related by a gauge transformation; such boundary identifications are quotient data, not ordinary smooth coordinates. □

Figure 47.2 records the geometry behind this proof: the Landau slice, the Gribov region where the Faddeev–Popov operator is positive, the fundamental modular region of absolute minima, and the boundary identifications left by gauge equivalence.

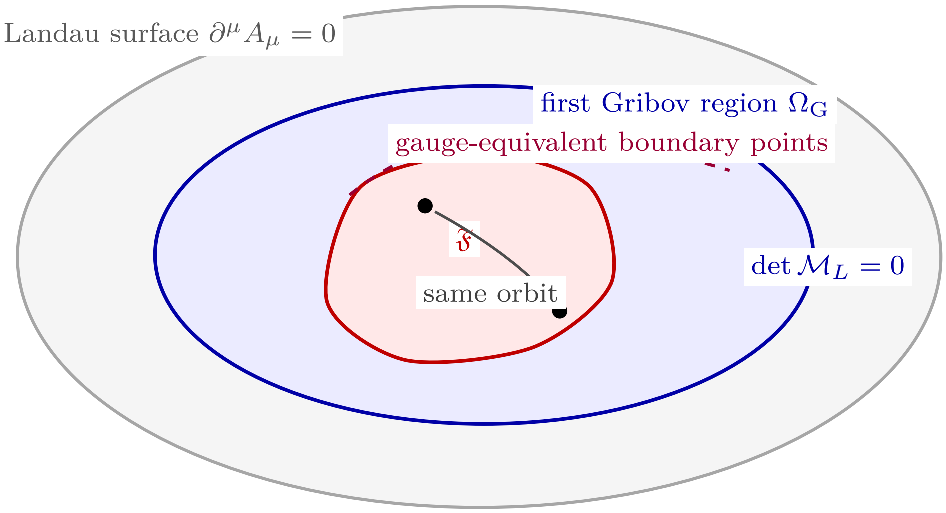

Figure 47.2: Landau gauge does not define a single global coordinate system on nonabelian orbit space. The interior of Ω_{G} is the infinitesimal Gribov-free regime where $\mathcal{M}_L$ is positive after zero modes are removed. The fundamental modular domain $\mathfrak{F}$ lies inside it but carries boundary identifications.

The perturbative Faddeev–Popov construction used in this chapter is the local construction near a chosen background, usually $A = 0$ or a fixed classical solution. Near $A = 0$, after global gauge zero modes are removed, $\mathcal{M}_L(0) = -\partial^2$ is positive on nonconstant modes, so the implicit-function theorem gives a local transverse slice. Ghost fields then represent the local Jacobian of this coordinate change. BRST symmetry, in the form used below, is the corresponding local algebraic symmetry of the gauge-fixed perturbative integrand. A global nonperturbative measure on $\mathcal{F}_\Lambda/\mathcal{G}$ requires additional data: gauge-invariant variables, patched local slices, a lattice formulation before gauge fixing, or a Gribov-region/fundamental-domain restriction with the additional boundary and BRST questions that such a restriction creates.

47.1.1 The Gribov–Zwanziger Horizon Functional

The first Gribov region gives a precise finite-regulator coordinate domain for Landau gauge, but it is still a domain with a boundary in field space. The Gribov–Zwanziger construction is a way of representing the influence of that boundary by a nonlocal functional built from the inverse Faddeev–Popov operator. The construction is used here as a controlled gauge-fixed infrared model and as a diagnostic of the failure of global covariant BRST assumptions. The gauge-invariant lattice construction remains the nonperturbative definition of Yang–Mills theory used in this volume.

Work on a compact Euclidean torus of volume V, remove the constant gauge zero modes, and impose Landau gauge. Let

$$\mathcal{M}_L(A) = -\partial^\mu D_\mu(A)$$

act on the zero-mode-removed adjoint scalar test functions. In the interior of the first Gribov region, $\mathcal{M}_L(A)$ is strictly positive and has a bounded inverse on this finite-regulator space. Define

$$B^a_{\mu,c}(x; A) := f^a{}_{bc} A^b_\mu(x), \qquad f^a{}_{cd} f^b{}_{cd} = C_A \delta^{ab}.$$

For $G = SU(N_c)$ in the trace-delta convention of this monograph, $C_A = 2N_c$. The horizon functional is

$$H(A) := \sum_{\mu,c} \left\langle B_{\mu,c}(A), \mathcal{M}_L(A)^{-1} B_{\mu,c}(A) \right\rangle_{L^2}. \tag{47.14}$$

Equivalently,

$$H(A) = \int_{M\times M} \mathrm{d}^d x\, \mathrm{d}^d y\, f^a{}_{bc} A^b_\mu(x)\, [\mathcal{M}_L(A)^{-1}]^{ad}(x,y)\, f^d{}_{ec} A^e_\mu(y),$$

where the inverse is taken after the separated zero modes have been removed. The functional is finite on $\Omega^\circ_{\mathrm{G}}$ and becomes singular along directions that approach the horizon with a nonzero projection onto a vanishing Faddeev–Popov eigenmode.

Let $A \in \Omega^\circ_{\mathrm{G}}$ at finite regulator, and let $\{e_j\}$ be an L^2-orthonormal eigenbasis of $\mathcal{M}_L(A)$ with eigenvalues $\lambda_j(A) > 0$. Then

$$H(A) = \sum_{\mu,c} \sum_j \frac{|\langle e_j, B_{\mu,c}(A)\rangle_{L^2}|^2}{\lambda_j(A)}. \tag{47.15}$$

If a path $A(s) \in \Omega^\circ_{\mathrm{G}}$ approaches a horizon point and one eigenvalue satisfies $\lambda_0(A(s)) \downarrow 0$, while

$$\liminf_s \sum_{\mu,c} |\langle e_0(s), B_{\mu,c}(A(s))\rangle|^2 > 0,$$

then $H(A(s)) \to +\infty$. Strict positivity of $\mathcal{M}_L(A)$ gives the spectral decomposition

$$\mathcal{M}_L(A)^{-1} u = \sum_j \lambda_j(A)^{-1} \langle e_j, u\rangle e_j.$$

Substituting $u = B_{\mu,c}(A)$ and summing over the displayed Lorentz and spectator color labels gives (47.15). The divergence statement follows from the single $j = 0$ term and positivity of all the other terms.

Introduce a nonnegative mass parameter γ_{G}. The nonlocal horizon-modified Landau-gauge Euclidean action is

$$S^{\mathrm{nl}}_{\mathrm{GZ}} = S^{\xi=0}_{\mathrm{FP}} + \gamma_{\mathrm{G}}^4 H(A) - \gamma_{\mathrm{G}}^4\, d\, (\dim G)\, V, \tag{47.16}$$

where $d = \dim M$, $S^{\xi=0}_{\mathrm{FP}}$ is the Landau-gauge Faddeev–Popov action, and the final term fixes the usual horizon normalization. The gap condition obtained by stationarity of the regulated vacuum functional with respect to γ_{G}^4 is

$$\langle H(A)\rangle_{\gamma_{\mathrm{G}}} = d\, (\dim G)\, V. \tag{47.17}$$

Equation (47.17) is a condition selecting the horizon parameter inside a specified finite-regulator gauge-fixed model. Its continuum and infinite-volume uses require a limiting construction for the corresponding gauge-fixed correlation functions.

The nonlocal factor $\exp[-\gamma_{\mathrm{G}}^4 H(A)]$ has a local finite-regulator representation. Introduce complex commuting fields $\varphi^{ac}_\mu, \bar\varphi^{ac}_\mu$ and Grassmann-odd fields $\omega^{ac}_\mu, \bar\omega^{ac}_\mu$, where the first adjoint index is acted on by $\mathcal{M}_L(A)$ and the second adjoint index is the spectator index c in $B_{\mu,c}$. With the contour for the bosonic fields chosen so that the Gaussian is convergent,

$$\begin{aligned}\int D\bar\varphi\, D\varphi\, D\bar\omega\, D\omega\, \exp\Big[-\bar\varphi\, \mathcal{M}_L(A)\varphi + \bar\omega\, \mathcal{M}_L(A)\omega - \mathrm{i}\gamma_{\mathrm{G}}^2 B(A)(\varphi + \bar\varphi)\Big] \\ = \mathcal{N}\, \exp[-\gamma_{\mathrm{G}}^4 H(A)].\end{aligned} \tag{47.18}$$

Here the products mean the L^2 pairing together with the sums over μ, a, c, and $\mathcal{N}$ is independent of A. The factor $\bar{\omega}\mathcal{M}_L\omega$ cancels the determinant from the commuting φ-Gaussian, leaving only the shifted source term. The factor of i records the contour convention that localizes a positive horizon functional in the Euclidean action.

The localized action at $\gamma_{\mathrm{G}} = 0$ admits the doublet assignment

$$s\varphi = \omega, \qquad s\omega = 0, \qquad s\bar{\omega} = \bar{\varphi}, \qquad s\bar{\varphi} = 0,$$

after adding the standard $s\mathcal{M}_L(A)$ term generated by applying s to $\bar{\omega}\mathcal{M}_L(A)\varphi$. Hence the auxiliary quartet does not change the local BRST cohomology when $\gamma_{\mathrm{G}} = 0$. The horizon source

$$\mathrm{i}\gamma_{\mathrm{G}}^2 B(A)(\varphi + \bar{\varphi})$$

has a nonzero s-variation for $\gamma_{\mathrm{G}} > 0$. Therefore the Gribov–Zwanziger horizon implementation and the perturbative local BRST charge are compatible only after one specifies an enlarged non-perturbative BRST or BV datum. The elementary Kugo–Ojima assumptions below, which require a global covariant BRST charge in Landau gauge, are consequently independent hypotheses rather than consequences of the horizon-restricted integral.

At the quadratic level around $A = 0$, the inverse Faddeev–Popov operator is $(-\partial^2)^{-1}$. The color contraction above gives

$$\sum_{a,c} f^a{}_{bc} f^a{}_{dc} = C_A \delta_{bd}.$$

After projecting to transverse gauge fields, the quadratic action has the form

$$S_{\mathrm{GZ},2} = \frac{1}{2} \int \frac{\mathrm{d}^d p}{(2\pi)^d}\, A_\mu^a(-p) \left[\frac{p^2}{g_{\mathrm{YM}}^2} + \frac{\lambda_{\mathrm{G}}^4}{g_{\mathrm{YM}}^2 p^2} \right] P_{\mu\nu}(p)\, A_\nu^a(p), \tag{47.19}$$

where

$$P_{\mu\nu}(p) = \delta_{\mu\nu} - \frac{p_\mu p_\nu}{p^2}$$

and λ_{G}^4 is the positive horizon scale obtained from $\gamma_{\mathrm{G}}^4 C_A$ with the normalization of the quadratic action absorbed into its definition. The corresponding tree-level transverse two-point kernel is

$$\langle A_\mu^a(p) A_\nu^b(-p) \rangle_{\mathrm{GZ},2} = \delta^{ab} g_{\mathrm{YM}}^2 \frac{p^2}{p^4 + \lambda_{\mathrm{G}}^4}\, P_{\mu\nu}(p). \tag{47.20}$$

The denominator has complex p^2-plane poles at

$$p^2 = \pm \mathrm{i}\lambda_{\mathrm{G}}^2.$$

Thus the elementary tree-level horizon model already prevents the transverse gauge potential from having a positive Källén–Lehmann spectral measure. This statement concerns the gauge-fixed potential two-point function. Gauge-invariant color-singlet correlators and Wilson-loop observables remain the objects used for physical spectral questions.

Controlled Approximation 47.8 (Status of the Gribov–Zwanziger construction)**.** The Gribov–Zwanziger action is a finite-regulator Landau-gauge construction that encodes a restriction to the first Gribov region through the horizon functional (47.14). It supplies a precise infrared ansatz for gauge-fixed Green functions and a concrete test of covariant BRST assumptions. A proof that it is equivalent to the gauge-invariant Yang–Mills continuum theory requires a separate comparison of gauge-invariant observables or a construction of the gauge-fixed measure as a pushforward of the lattice continuum limit. Refined Gribov–Zwanziger models add condensates of dimension-two local fields; those refinements change the gauge-fixed infrared ansatz and require their own renormalization and BRST/BV analysis.

The determinant in (47.11) is represented by Grassmann-odd variables b_A and c^α:

$$\Delta_{\mathrm{FP}}[\phi] = \int [Db][Dc]\, \exp\left[-\mathrm{i} b_A\, \frac{\partial F^A[\phi^\xi]}{\partial \xi^\alpha}\bigg|_{\xi=\mathrm{id}} c^\alpha\right]. \tag{47.21}$$

The field c^α is the ghost associated with the gauge parameter ξ^α, and b_A is the antighost associated with the gauge condition F^A. The delta functional is represented by a commuting auxiliary field B_A:

$$\delta\big(F^A[\phi]\big) = \int [DB]\, \exp\big(\mathrm{i} B_A F^A[\phi]\big). \tag{47.22}$$

The field B_A is not an external background field or a new physical degree of freedom. It is an integrated auxiliary variable in the local gauge-fixed functional integral. Keeping it in the formula gives a polynomial local action and off-shell BRST nilpotency; carrying out the B-integration returns the delta functional imposing the sharp slice $F^A[\phi] = 0$. The gauge-fixed action in these condensed variables is therefore

$$S_{\mathrm{tot}}[\phi, B, b, c] = S[\phi] + S_{\mathrm{GF}}[\phi, B, b, c], \qquad S_{\mathrm{GF}} = B_A F^A[\phi] - b_A \mathcal{M}^A{}_\alpha[\phi] c^\alpha. \tag{47.23}$$

The term S_{GF} is not gauge invariant; its controlling symmetry is the nilpotent BRST symmetry constructed below.

47.2 Covariant Gauges and Ghost Fields

The covariant linear gauge condition is

$$F^a(A) = \partial^\mu A^a_\mu.$$

For this choice,

$$\mathcal{M}^{ab}(A) = \partial^\mu D^{ab}_\mu(A), \qquad (D_\mu c)^a = \partial_\mu c^a + f^a{}_{bc} A^b_\mu c^c. \tag{47.24}$$

For this local gauge condition the condensed labels are

$$A = (a, x), \qquad \alpha = (b, y),$$

and $\mathcal{M}^{ab}(A; x, y) = \partial^\mu D^{ab}_\mu(A)\delta^{(D)}(x - y)$. This A-dependence is the structural difference from the abelian Maxwell case discussed in Chapter 41. If the gauge group is abelian and the gauge condition is linear, $D_\mu = \partial_\mu$, the Faddeev–Popov determinant is independent of the gauge field and contributes only a field-independent factor. For a nonabelian group,

$$\partial^\mu D^{ab}_\mu(A) = \delta^{ab}\partial^2 + f^a{}_{cb}\, \partial^\mu(A^c_\mu\, \cdot),$$

so $\det \mathcal{M}(A)$ is a functional of A. The ghost fields below are therefore dynamical scalar fermions in perturbation theory; their interactions are the local representation of this A-dependent Jacobian. The b_A notation used in (47.21) is related to the conventional antighost by

$$\bar{c}_A = b_A.$$

With this convention the ghost term in the Lagrangian has the sign displayed below, while the BRST transformation of the antighost is $sb_A = B_A$. The determinant of $\mathcal{M}(A)$ is represented by Grassmann-valued scalar fields $c^a(x)$ and $\bar{c}^a(x)$ in the adjoint representation:

$$\det \mathcal{M}(A) = \int [D\bar{c}\, Dc] \exp\left\{ -\mathrm{i} \int_M \bar{c}^a \mathcal{M}^{ab}(A) c^b \,\mathrm{d}^D x \right\}. \tag{47.25}$$

This equality is understood up to a field-independent normalization and phase: in a finite-dimensional Grassmann Gaussian, changing the sign multiplying $\bar{c}\mathcal{M}c$ multiplies the integral by a power of -1 and i, but does not change its dependence on A. The sign in (47.25) is chosen so that the ghost term agrees with the BRST gauge-fixing fermion below in the Minkowski weight $\exp(\mathrm{i}S)$. The field c is called the ghost and $\bar{c}$ the antighost. They are Lorentz scalars with fermionic statistics. Their role is determined by (47.25): they encode the Jacobian of gauge fixing and produce the loop contributions required by gauge covariance of the renormalized theory.

It is useful to introduce an auxiliary real field $B^a(x)$, the Nakanishi–Lautrup field. For a real parameter ξ, and for the Yang–Mills normalization

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4g_{\mathrm{YM}}^2} F^a_{\mu\nu} F^{a\mu\nu},$$

the gauge-fixing and ghost Lagrangian density can be written

$$\mathcal{L}_{\text{gf+gh}} = B^a \partial^\mu A^a_\mu + \frac{g_{\mathrm{YM}}^2 \xi}{2} B^a B^a - \bar{c}^a\, \partial^\mu D^{ab}_\mu(A) c^b. \tag{47.26}$$

At fixed regulator the covariant-gauge functional integral contains the ordinary auxiliary integration over B:

$$\int [DB] \exp\left\{ \mathrm{i} \int_M \left[B^a \partial^\mu A^a_\mu + \frac{g_{\mathrm{YM}}^2 \xi}{2} B^a B^a \right] \mathrm{d}^D x \right\} = \mathcal{N}_B(\xi) \exp\left\{ -\frac{\mathrm{i}}{2g_{\mathrm{YM}}^2 \xi} \int_M (\partial^\mu A^a_\mu)^2 \,\mathrm{d}^D x \right\}, \tag{47.27}$$

with the oscillatory Gaussian contour, or its Wick-rotated regulator-level version, fixed as part of the path integral. The factor $\mathcal{N}_B(\xi)$ is independent of A and cancels from normalized correlators. Equivalently, completing the square and using the algebraic stationary equation gives

$$B^a = -\frac{1}{g_{\mathrm{YM}}^2 \xi} \partial^\mu A^a_\mu, \qquad \mathcal{L}_{\mathrm{gf}} = -\frac{1}{2g_{\mathrm{YM}}^2 \xi} (\partial^\mu A^a_\mu)(\partial^\nu A^a_\nu),$$

so the B-field has been Gaussian-integrated out and no longer appears among the remaining integration variables. Landau gauge is the limiting gauge condition obtained by taking $\xi \to 0$ after the regulated Gaussian B-field integral has been defined; in that limit the Gaussian becomes the Fourier representation of the delta functional imposing $\partial^\mu A^a_\mu = 0$. Setting $g_{\mathrm{YM}} = 1$, or rescaling the gauge potential to canonical quadratic normalization, gives the more common version without the displayed factor of g_{YM}^2 in the B^2 term.

47.3 The BRST Differential

The gauge-fixed field algebra is a graded-commutative algebra generated by

$$A^a_\mu, \qquad c^a, \qquad \bar{c}^a, \qquad B^a,$$

and by matter fields when present. Assign ghost numbers

$$\mathrm{gh}(A_\mu) = 0, \qquad \mathrm{gh}(B) = 0, \qquad \mathrm{gh}(c) = 1, \qquad \mathrm{gh}(\bar{c}) = -1.$$

The BRST differential s is an odd derivation of ghost number $+1$. On the Yang–Mills sector it is defined by

$$sA^a_\mu = (D_\mu c)^a, \qquad sc^a = -\frac{1}{2} f^a{}_{bc} c^b c^c, \qquad s\bar{c}^a = B^a, \qquad sB^a = 0. \tag{47.28}$$

The construction in this section uses the off-shell closure of the Yang–Mills gauge algebra. In field-space language, the infinitesimal generators S_α satisfy a Lie-bracket identity as vector fields on the space of fields,

$$[S_\beta, S_\gamma] = f^\alpha{}_{\beta\gamma} S_\alpha,$$

without imposing the Euler–Lagrange equations. Therefore $s^2 = 0$ is an identity on the algebra generated by fields and ghosts. This is a genuine hypothesis of the elementary Faddeev–Popov/BRST construction used here. For gauge systems whose commutator closes only modulo the classical equations of motion, the same formulae define at most an on-shell nilpotent operation on the original fields; the corresponding off-shell differential is obtained in the BV field-antifield formalism, where the equation-of-motion terms are recorded by higher antifield-number terms in the master action.

In condensed field-space notation this reads

$$s\phi = c^\alpha S_\alpha \phi, \qquad sB_A = 0, \qquad sb_A = B_A, \qquad sc^\alpha = -\frac{1}{2} f^\alpha{}_{\beta\gamma} c^\beta c^\gamma, \tag{47.29}$$

where

$$S_\alpha \phi = \left.\frac{\partial \phi^\xi}{\partial \xi^\alpha}\right|_{\xi = \mathrm{id}}, \qquad [S_\beta, S_\gamma] = f^\alpha{}_{\beta\gamma} S_\alpha.$$

For the gauge-transformation group of maps $M \to G$, the condensed structure constants are the distributional kernel

$$f^{(a,x)}{}_{(b,y)(c,z)} = f^a{}_{bc}\, \delta^{(D)}(x-y) \delta^{(D)}(x-z),$$

with the same output-first finite-dimensional convention as in Chapter 45. Thus the Greek-index formula is condensed notation, not a second convention for raising Lie-algebra indices. The two notations agree because $b_A = \bar{c}_A$. If ϵ is a constant Grassmann-odd parameter, the finite-parity infinitesimal variation is $\delta_B X = \epsilon\, sX$; in particular ϵc^α is even, as a gauge parameter must be. The ghost $c = c^a t^a$ is an odd field valued in the same Hermitian coordinate space as the infinitesimal gauge parameter. For an odd $\mathfrak{g}$-valued field, the expression $[c, c]_{\mathrm{H}}$ is defined by combining the Lie bracket with the Grassmann product:

$$[c, c]^a_{\mathrm{H}} = f^a{}_{bc} c^b c^c.$$

Thus $sc = -\frac{1}{2}[c, c]_{\mathrm{H}}$. The antighost $\bar{c}$ is an independent odd adjoint-valued scalar of ghost number -1, and B is an even adjoint-valued scalar of ghost number 0. For a matter field $\psi \in V_R$, with representation matrices t^a_R,

$$s\psi = \mathrm{i} c^a t^a_R \psi, \qquad s\bar{\psi} = -\mathrm{i}\bar{\psi}\, c^a t^a_R. \tag{47.30}$$

The derivation rule is graded:

$$s(XY) = (sX)Y + (-1)^{|X|}X(sY),$$

where $|X|$ is the Grassmann parity of X.

Nilpotency is an algebraic consequence of the Jacobi identity. For any original field ϕ, the condensed notation gives

$$\begin{aligned} s^2\phi &= -\frac{1}{2}f^{\alpha}{}_{\beta\gamma}c^{\beta}c^{\gamma}S_{\alpha}\phi - c^{\alpha}c^{\beta}S_{\beta}S_{\alpha}\phi \\ &= -\frac{1}{2}f^{\alpha}{}_{\beta\gamma}c^{\beta}c^{\gamma}S_{\alpha}\phi + \frac{1}{2}c^{\alpha}c^{\beta}[S_{\alpha}, S_{\beta}]\phi = 0. \end{aligned}$$

For the ghost, using the graded derivation rule gives

$$s^2c^a = \frac{1}{4}f^a{}_{bc}f^b{}_{de}c^dc^ec^c - \frac{1}{4}f^a{}_{bc}f^c{}_{de}c^bc^dc^e.$$

After antisymmetrizing over the three odd ghost factors, this is

$$s^2c^a = -\frac{1}{12}\left(f^a{}_{be}f^e{}_{cd} + f^a{}_{ce}f^e{}_{db} + f^a{}_{de}f^e{}_{bc}\right)c^bc^cc^d = 0.$$

For the gauge field, the matrix form of the same computation is

$$s^2A_{\mu} = D_{\mu}(sc) + [D_{\mu}c, c]_{\mathrm{H}} = -\frac{1}{2}D_{\mu}[c, c]_{\mathrm{H}} + [D_{\mu}c, c]_{\mathrm{H}} = 0,$$

because $D_{\mu}[c, c]_{\mathrm{H}} = 2[D_{\mu}c, c]_{\mathrm{H}}$ for odd c. For a matter field, the representation identity $[t_R^a, t_R^b] = \mathrm{i}f^c{}_{ab}t_R^c$ gives

$$s^2\psi = \mathrm{i}(sc^a)t_R^a\psi + c^ac^bt_R^at_R^b\psi = -\frac{\mathrm{i}}{2}f^a{}_{bc}c^bc^ct_R^a\psi + \frac{1}{2}c^ac^b[t_R^a, t_R^b]\psi = 0,$$

and similarly for $\bar{\psi}$. Hence

$$s^2 = 0. \tag{47.31}$$

Thus s is the infinitesimal gauge-orbit differential with the even gauge parameter replaced by the odd field c, combined with the Chevalley–Eilenberg differential of the gauge algebra and the nonminimal contractible pair $(\bar{c}, B)$.

Let

$$\Psi = \int_M \bar{c}^a\left(\partial^{\mu}A_{\mu}^a + \frac{g_{\mathrm{YM}}^2\xi}{2}B^a\right)\mathrm{d}^Dx.$$

Using (47.28),

$$s\Psi = \int_M \left[B^a\partial^{\mu}A_{\mu}^a + \frac{g_{\mathrm{YM}}^2\xi}{2}B^aB^a - \bar{c}^a\partial^{\mu}D_{\mu}^{ab}(A)c^b\right]\mathrm{d}^Dx. \tag{47.32}$$

For $\xi = 0$, this is the covariant-gauge specialization of the condensed formula

$$S_{\mathrm{GF}} = s\big(b_AF^A[\phi]\big) = B_AF^A[\phi] - b_A\mathcal{M}^A{}_{\alpha}[\phi]c^{\alpha}.$$

Equivalently, if the BRST charge Q_B is defined by the convention

$$\delta_BX = \mathrm{i}\epsilon\, Q_B \cdot X, \qquad Q_B = -\mathrm{i}s, \tag{47.33}$$

then

$$S_{\text{GF}} = \mathrm{i}Q_B \cdot \big(b_A F^A[\phi]\big), \qquad Q_B^2 = 0. \tag{47.34}$$

The ξB^2 term in (47.32) is an additional BRST-exact deformation of the same gauge-fixing fermion and does not alter the cohomology. The full gauge-fixed action is therefore

$$S_{\text{gf}} = S_{\text{YM}} + S_{\text{matter}} + s\Psi.$$

Since $S_{\text{YM}} + S_{\text{matter}}$ is gauge invariant and $s^2 = 0$, one obtains $sS_{\text{gf}} = 0$. The gauge-fixed action is therefore controlled by a nilpotent fermionic symmetry acting on the enlarged field space, including ghosts, antighosts, and the Nakanishi–Lautrup field.

47.4 Local BRST Cohomology

The BRST differential acts on local expressions before any functional integral is evaluated. Let $\mathcal{F}_{\text{loc}}$ denote the graded-commutative algebra of local functions: polynomials or formal power series in the fields

$$A_\mu, \quad c, \quad \bar{c}, \quad B, \quad \psi, \quad \bar{\psi}$$

and finitely many of their spacetime derivatives, with coefficients smooth in the spacetime point when explicit x-dependence is allowed. The differential s is extended to derivatives by

$$s(\partial_{\nu_1} \cdots \partial_{\nu_r} \Phi) = \partial_{\nu_1} \cdots \partial_{\nu_r} (s\Phi)$$

for every generator Φ. The local BRST cohomology at ghost number g is

$$H^g(s; \mathcal{F}_{\text{loc}}) = \frac{\{a \in \mathcal{F}_{\text{loc}} : \text{gh}(a) = g,\ sa = 0\}}{\{a = sb : \text{gh}(b) = g - 1\}}.$$

At ghost number zero, this cohomology is the local algebraic form of gauge-invariant composite operators, with BRST-exact representatives removed.

Integrated local functionals require a second quotient because Lagrangian densities differing by total derivatives define the same action on manifolds without boundary, or the same bulk functional after boundary data have been specified. Let Ω^p_{loc} be the space of local p-forms and let

$$d = dx^\mu \partial_\mu$$

be the spacetime exterior derivative. With the convention that s and d are odd derivations on local forms, they anticommute:

$$sd + ds = 0.$$

For a D-dimensional spacetime, an integrated local functional is represented by a local D-form a. The cohomology relevant for local functionals is the relative cohomology $H^{g,D}(s \mid d)$. Its cocycles and coboundaries are

$$sa + dm = 0, \qquad a \sim a + sb + dn,$$

where

$$a \in \Omega^D_{\text{loc}}, \quad m, n \in \Omega^{D-1}_{\text{loc}}, \quad b \in \Omega^D_{\text{loc}},$$

with ghost numbers chosen so that all displayed terms have ghost number $g+1$ in the first equation and ghost number g in the equivalence relation. Thus $H^{0,D}(s \mid d)$ classifies BRST-invariant local counterterm densities modulo field redefinitions and total derivatives, while $H^{1,D}(s \mid d)$ is the algebraic home of possible local gauge anomalies. The anomaly chapters will compute the relevant representatives in four-dimensional chiral gauge theories; the present chapter fixes the cohomological language.

The pair $(\bar{c}, B)$ belongs to the nonminimal gauge-fixing sector. Since

$$s\bar{c}^a = B^a, \qquad sB^a = 0,$$

and the BRST transformations of the minimal variables $A, c, \psi, \bar{\psi}$ do not depend on $\bar{c}$ or B, this pair is contractible in local BRST cohomology. The doublet lemma below gives the explicit homotopy. Consequently, the nonminimal variables are essential for writing local propagators and Slavnov–Taylor identities, but the cohomology classes of gauge-invariant local operators, counterterms, and anomalies may be represented in the minimal sector under the standard regularity assumptions used in perturbative Yang–Mills theory.

47.5 Krein Space Structure of Covariant Gauge Quantization

Before the BRST quotient, covariant gauge quantization uses an indefinite-metric state space with a specified topology. The functional-analytic structure used here is a Krein space.[2]

Definition 47.9 (Krein space and fundamental symmetry)**.** A Krein space is a complex vector space $\mathcal{K}$ equipped with a nondegenerate Hermitian form $[\cdot,\cdot]$ and a direct decomposition

$$\mathcal{K} = \mathcal{K}_+ \oplus \mathcal{K}_-,$$

such that $[\cdot,\cdot]$ is positive definite on $\mathcal{K}_+$, negative definite on $\mathcal{K}_-$, and both summands are complete for the associated positive norms. The fundamental symmetry is

$$J(\psi_+ + \psi_-) = \psi_+ - \psi_-, \qquad \psi_\pm \in \mathcal{K}_\pm.$$

It defines a Hilbert inner product

$$(\psi,\chi)_J = [\psi, J\chi] = [\psi_+, \chi_+] - [\psi_-, \chi_-],$$

and the topology of $\mathcal{K}$ is the Hilbert topology determined by $(\cdot,\cdot)_J$. Different fundamental decompositions may give different fundamental symmetries; a statement about domains, closures, adjoints, or continuity is meaningful only after such a Hilbert majorant topology has been specified.

Let T be a densely defined operator on $\mathcal{K}$. Its Krein adjoint $T^\times$ is defined by

$$[T\psi, \chi] = [\psi, T^\times \chi]$$

[2] For the operator theory of Krein spaces, see J. Bognar, *Indefinite Inner Product Spaces*, Ergebnisse der Mathematik und ihrer Grenzgebiete **78**, Springer, 1974. For product-integral technology useful in controlling operator evolutions, see J. D. Dollard and C. N. Friedman, *Product Integration with Applications to Differential Equations*, Encyclopedia of Mathematics and its Applications **10**, Addison–Wesley, 1979. For the indefinite-metric framework in local covariant gauge QFT and QED, see F. Strocchi and A. S. Wightman, "Proof of the charge superselection rule in local relativistic quantum field theory," *Journal of Mathematical Physics* **15** (1974), 2198–2224, and F. Strocchi, "Local and covariant gauge quantum field theories. Cluster property, superselection rules, and the infrared problem," *Physical Review D* **17** (1978), 2010–2021.

for all $\psi \in \mathcal{D}(T)$ and all χ in the domain for which the right-hand side is represented continuously. If T_J^* denotes the Hilbert adjoint with respect to $(\cdot,\cdot)_J$, then formally

$$T^\times = JT_J^*J$$

with the corresponding transformed domain. Thus an assertion that a BRST charge is "Hermitian" in covariant gauge means Krein symmetry or Krein self-adjointness, not Hilbert self-adjointness in a positive inner product.

Hypothesis 47.10 (Krein-domain data for the BRST charge)**.** The canonical covariant-gauge construction supplies:

$$(\mathcal{K}, [\cdot,\cdot], J), \qquad N_{\mathrm{gh}}, \qquad Q : \mathcal{D}(Q) \subset \mathcal{K} \to \mathcal{K},$$

where N_{gh} is the ghost-number operator and Q is a densely defined closed odd operator of ghost number $+1$. There is a common dense invariant domain $\mathcal{D} \subset \mathcal{D}(Q)$ containing the finite particle states, stable under the fields used in the BRST construction, such that

$$Q\mathcal{D} \subset \mathcal{D}, \qquad Q^2\psi = 0 \quad (\psi \in \mathcal{D}), \qquad [Q\psi, \chi] = [\psi, Q\chi] \quad (\psi, \chi \in \mathcal{D}).$$

Equivalently, $Q \subset Q^\times$ on the stated domain; when a Krein self-adjoint closure exists, this inclusion is replaced by equality for that closure. The physical quotient below is formed first on this controlled domain and then completed only after positivity of the induced form has been proved.

The free Gupta–Bleuler and perturbative BRST Fock constructions provide the model example of this structure: longitudinal and timelike oscillator modes create the negative directions, the fundamental symmetry J records the chosen positive majorant Hilbert topology, and the BRST charge is symmetric for the indefinite form. In an interacting nonperturbative gauge theory, Hypothesis 47.10 is an additional construction problem. The path-integral Slavnov–Taylor identities derived later are formal consequences of the regularized BRST symmetry; the Krein-space operator domain is separate analytic data.

47.6 Cohomology of States and Observables

In canonical quantization of the gauge-fixed theory, the state space before the BRST quotient is the Krein space $\mathcal{K}$ described above. At a fixed time a state can be represented, in a Schrodinger notation, by a wavefunctional

$$\Psi[\phi, B, b, c]\big|_{x^0=t}.$$

The first-order functional differential operator Q_B in (47.33) is promoted to an operator $\widehat{Q}_B$ on $\mathcal{K}$:

$$\widehat{Q}_B|\Psi\rangle = |Q_B \cdot \Psi\rangle, \qquad \widehat{Q}_B^2 = 0.$$

Insertion of a functional $R[\Phi]$, where $\Phi = (\phi, B, b, c)$, corresponds to an operator $\widehat{R}$, and the insertion $Q_B \cdot R$ corresponds to the graded commutator with $\widehat{Q}_B$, with the sign fixed by the parity of R. In the rest of this section we write Q for $\widehat{Q}_B$.

A state is admissible when

$$Q|\Psi\rangle = 0. \tag{47.35}$$

This condition is selected by gauge-fixing independence. Consider the transition amplitude between two admissible boundary states,

$$\mathcal{A}_F(\Psi_f, \Psi_i) = \int [D\Phi]_{t_i}^{t_f} \, \Psi_f^*[\Phi(t_f)] \, \exp(\mathrm{i}S_F[\Phi]) \, \Psi_i[\Phi(t_i)],$$

where the subscript F records the chosen gauge condition. If $F^A[\phi]$ is deformed to $F^A[\phi]+\bar{\delta}F^A[\phi]$, then (47.34) gives

$$\bar{\delta}S_F[\Phi] = \mathrm{i}Q_B \cdot \big(b_A \bar{\delta}F^A[\phi]\big).$$

Therefore, to first order in the deformation,

$$\begin{aligned}\bar{\delta}\, \mathcal{A}_F(\Psi_f, \Psi_i) &= -\int [D\Phi] \, \Psi_f^* \, \exp(\mathrm{i}S_F) \, \Psi_i \, Q_B \cdot \big(b_A \bar{\delta}F^A\big) \\ &= -\int [D\Phi] \, Q_B \cdot \big(\Psi_f^* \, \exp(\mathrm{i}S_F) \, \Psi_i \, b_A \bar{\delta}F^A\big) = 0. \end{aligned} \tag{47.36}$$

The last equality assumes that the functional measure is BRST invariant and that the BRST integration by parts has no boundary contribution in field space. The equalities also use $Q|\Psi_i\rangle = 0$, the corresponding condition on the final bra, and $Q_B \cdot S_F = 0$.

Nilpotency implies that $Q|\chi\rangle$ is admissible for every $|\chi\rangle$. Such a state has zero matrix element against any admissible state when Q is symmetric with respect to the Krein form:

$$\langle\Psi|Q|\chi\rangle = 0, \qquad Q|\Psi\rangle = 0.$$

Thus

$$|\Psi\rangle \sim |\Psi\rangle + Q|\chi\rangle$$

is the equivalence relation on admissible states. The physical state space is the ghost-number-zero BRST cohomology

$$\mathcal{H}_{\mathrm{phys}} = H^0(Q, \mathcal{K}) = \frac{\ker(Q : \mathcal{K}^0 \to \mathcal{K}^1)}{\mathrm{im}(Q : \mathcal{K}^{-1} \to \mathcal{K}^0)}. \tag{47.37}$$

Here $\mathcal{K}^n$ is the subspace of ghost number n. Gauge-invariant local operators define classes in the ghost-number-zero cohomology of s, while BRST-exact insertions have vanishing matrix elements between physical states when the BRST symmetry is preserved by the regulator and renormalization.

The perturbative S-matrix of a gauge-fixed nonabelian theory is an operator first constructed on $\mathcal{K}$ and then descended to $\mathcal{H}_{\mathrm{phys}}$. Asymptotic states and LSZ define scattering; gauge fixing supplies local Green-function rules whose matrix elements are well defined on BRST cohomology classes.

47.7 Positivity of the BRST Quotient

The quotient in (47.37) is a Hilbert-space construction only after positivity has been checked. Assume the Krein form $[\cdot,\cdot]$ on $\mathcal{K}$ is nondegenerate and that Q is symmetric with respect to it:

$$[Q\chi, \psi] = [\chi, Q\psi].$$

If $\psi \in \ker Q$ and $\eta = Q\chi$, then

$$[\eta, \psi] = [Q\chi, \psi] = [\chi, Q\psi] = 0.$$

Thus exact states are orthogonal to all closed states, including themselves. The inner product therefore descends to the quotient $\ker Q / \operatorname{im} Q$. The remaining requirement is that the induced form on ghost number zero cohomology be positive and that zero-norm closed states represent the zero cohomology class. When this holds, completing the quotient gives the physical Hilbert space.

Positivity criterion for a BRST doublet sector. Let $Q^2 = 0$ be symmetric for the non-degenerate Krein form on the ghost-graded space $\mathcal{K}$. Assume that the ghost-number-zero closed subspace admits a direct decomposition

$$\ker(Q : \mathcal{K}^0 \to \mathcal{K}^1) = \mathcal{P} \oplus \operatorname{im}(Q : \mathcal{K}^{-1} \to \mathcal{K}^0),$$

where the restriction of the inner product to $\mathcal{P}$ is positive definite. Assume further that every closed state with zero norm lies in $\operatorname{im} Q$. Then

$$H^0(Q, \mathcal{K}) = \frac{\ker(Q : \mathcal{K}^0 \to \mathcal{K}^1)}{\operatorname{im}(Q : \mathcal{K}^{-1} \to \mathcal{K}^0)}$$

inherits a positive-definite inner product and is isometric to the positive subspace $\mathcal{P}$ by the map that sends a closed state to its $\mathcal{P}$-component. Exact states are orthogonal to closed states by the calculation above, so the inner product is independent of the representative of a cohomology class. The displayed decomposition says that each class has a unique representative in $\mathcal{P}$. The induced norm of the class is therefore the norm of this $\mathcal{P}$-representative. Positivity on $\mathcal{P}$ gives a nonnegative norm, and the additional zero-norm assumption says that a class of zero norm has an exact representative, hence is the zero class. The quotient argument itself is formal; the substantive physics and mathematics are the hypotheses. In an interacting gauge theory one must construct a common domain for Q, prove $Q^2 = 0$ after renormalization, identify the closed zero-ghost subspace, and verify the absence of nonexact zero-norm closed states. These are the Kugo–Ojima/quartet-type inputs, not consequences of nilpotency alone.

Perturbatively, the unphysical polarizations, ghosts, antighosts, and Nakanishi–Lautrup modes organize into Q-doublets. A doublet has the form

$$Qu = v, \qquad Qv = 0.$$

Any state obtained by acting with such paired excitations is either exact or paired with an exact state and does not contribute to cohomology. The cohomology is then represented by transverse physical polarizations and gauge-invariant matter states. This is the cohomological version of the statement that the physical content of the gauge-fixed construction is carried by Q-cohomology classes.

47.8 Kugo–Ojima Quartets and the Color-Confinement Criterion

The preceding doublet argument is an algebraic statement about a given BRST complex. The Kugo–Ojima mechanism is the stronger covariant-gauge scenario in which all states carrying nontrivial color belong to quartets and hence have no representatives in $H^0(Q,\mathcal{K})$.[3]

Definition 47.11 (BRST quartet)**.** Let Q be a nilpotent symmetric BRST charge on a Krein space with ghost-number operator. A BRST quartet is a four-dimensional subcomplex generated by two BRST doublets related by the conjugation structure of the indefinite metric. In a basis

$$u, \quad v, \quad \widetilde{v}, \quad \widetilde{u},$$

one has

$$Qu = v, \qquad Qv = 0, \qquad Q\widetilde{v} = \widetilde{u}, \qquad Q\widetilde{u} = 0,$$

with ghost numbers chosen so that the indefinite form pairs the two doublets nondegenerately. The quartet contributes no physical state: v and $\widetilde{u}$ are exact, while u and $\widetilde{v}$ are not closed.

For perturbative Yang–Mills theory around the trivial vacuum, the longitudinal and timelike gauge modes, together with the Faddeev–Popov ghost and antighost excitations, form such quartets mode by mode. This is the operator version of the local doublet lemma below. It proves perturbative decoupling of the unphysical gauge-fixing sector once the BRST charge is constructed on the asymptotic Fock space and the quotient is positive. It does not by itself identify which nonperturbative colored excitations, if any, exist in the state space before the quotient.

The nonperturbative Kugo–Ojima confinement criterion is most sharply stated in Landau gauge. Work in a covariantly gauge-fixed Yang–Mills theory whose BRST charge Q exists as an operator, whose global color charges exist as operators on a common invariant domain, and whose indefinite state space has a positive BRST cohomology quotient. Let

$$(X \times Y)^a = f^a{}_{bc} X^b Y^c,$$

and define, for Euclidean momentum $p \neq 0$, the Kugo–Ojima two-point function by

$$\int \mathrm{d}^D x\, \mathrm{e}^{\mathrm{i}p\cdot x} \left\langle (D_\mu c)^a(x) \left(g_{\mathrm{YM}}(A_\nu \times \bar{c})\right)^b(0) \right\rangle = \delta^{ab} P_{\mu\nu}(p)\, u(p^2) + \delta^{ab} \frac{p_\mu p_\nu}{p^2}\, w(p^2), \tag{47.38}$$

where

$$P_{\mu\nu}(p) = \delta_{\mu\nu} - \frac{p_\mu p_\nu}{p^2}$$

is the transverse projector and w records a possible longitudinal component. In strict Landau gauge the transverse part $u(p^2)$ is the quantity usually called the Kugo–Ojima function. If one instead writes

$$F_{\mathrm{KO}}(p^2) = -u(p^2),$$

then the Kugo–Ojima infrared condition is

$$\lim_{p^2 \downarrow 0} F_{\mathrm{KO}}(p^2) = 1, \qquad \text{equivalently} \qquad u(0) = -1, \tag{47.39}$$

provided the limit exists.

[3]The canonical operator formulation and confinement criterion are developed in T. Kugo and I. Ojima, "Local covariant operator formalism of non-Abelian gauge theories and quark confinement problem," *Progress of Theoretical Physics Supplement* **66** (1979), 1–130. Lattice tests and modern infrared status include H. Nakajima and S. Furui, "Test of the Kugo-Ojima confinement criterion in the lattice Landau gauge," *Nuclear Physics B Proceedings Supplements* **83–84** (2000), 521–523; K.-I. Kondo, "Infrared behavior of the ghost propagator in the Landau gauge Yang-Mills theory," *Progress of Theoretical Physics* **122** (2009), 1455–1475; and N. M. R. Brito, "Lattice computation of the Kugo-Ojima correlation function," arXiv:2310.09010.

Conjecture 47.12 (Kugo–Ojima confinement criterion)**.** *Assume that the covariant-gauge BRST construction above exists nonperturbatively in Landau gauge, that the BRST charge is unbroken, that the spacetime integral defining the global color charge has no massless boundary contribution from $\partial^\nu F^a_{\mu\nu}$, and that (47.39) holds with no compensating singular longitudinal term in $w(p^2)$. Then the global color charge is represented on physical states by a BRST-exact operator. Consequently every BRST-closed state of ghost number zero has vanishing physical matrix elements of the color charge, and colored states, if present in the indefinite space, occur in BRST quartets rather than in the physical Hilbert space.*

The relation to the ghost propagator is conditional and should be stated with the same hypotheses. If the Landau-gauge ghost two-point function is written

$$\left\langle c^a(p)\bar{c}^b(-p)\right\rangle = \delta^{ab}\frac{G_{\rm gh}(p^2)}{p^2},$$

and if the longitudinal remainder in (47.38) has a regular infrared limit in the combination entering the ghost Ward identity, then

$$G_{\rm gh}(p^2)^{-1} = 1 + u(p^2) + p^2 v(p^2) \tag{47.40}$$

for another scalar form factor v. Under this regularity assumption, $u(0) = -1$ is equivalent to an infrared-divergent ghost dressing function. This equivalence is often the form in which the criterion is compared with Dyson–Schwinger or lattice Landau-gauge data.

This is a conditional Kugo–Ojima scenario, not a theorem for four-dimensional Yang–Mills theory. It assumes a global BRST charge and a covariant-gauge state space precisely in the regime where Gribov copies and possible fundamental-domain boundaries make the nonperturbative BRST construction delicate. Moreover, large-volume lattice studies of minimal Landau gauge and Gribov–Zwanziger infrared analyses generally find a finite infrared ghost dressing function and a Kugo–Ojima function that does not approach $u(0) = -1$. These results are evidence that the original Kugo–Ojima scenario is not realized in the standard lattice Landau-gauge implementation. They are not evidence against color confinement itself, whose gauge-invariant diagnostics in this monograph are formulated through the spectrum, Wilson loops, center symmetry when available, and the nonperturbative lattice construction.

47.9 The Doublet Lemma

The decoupling of unphysical variables has a simple algebraic form. Suppose a graded commutative differential algebra contains pairs

$$u^i, \qquad v^i,$$

with

$$su^i = v^i, \qquad sv^i = 0.$$

Let N count the total number of u's and v's in a polynomial, and define a homotopy operator h by

$$hv^i = u^i, \qquad hu^i = 0,$$

extended as a graded derivation with the appropriate signs. On the subalgebra generated by the doublets one has

$$sh + hs = N.$$

If X is s-closed and homogeneous with $NX = rX$, $r > 0$, then

$$X = \frac{1}{r}(sh + hs)X = s\left(\frac{1}{r}hX\right).$$

Thus every s-closed expression with positive doublet number is s-exact. The cohomology is represented by expressions independent of the doublet variables.

In perturbative gauge theory the longitudinal gauge modes, antighosts, Nakanishi–Lautrup variables, and their paired ghost excitations are organized in precisely this way after linearization around the perturbative vacuum. The lemma explains why physical cohomology depends on gauge-invariant transverse and matter data, while the doublet variables remain necessary in intermediate local formulas for propagators, counterterms, and Slavnov–Taylor identities.

47.10 Dimensional Regularization in Perturbative Gauge Theory

Dimensional regularization is a perturbative rule for assigning meromorphic functions of a complex dimension parameter to Feynman graph distributions. It is specified graph by graph, together with algebraic rules for tensor indices, spinors, internal polarizations, and external states. The datum is this meromorphic graph-distribution assignment; the field variables remain the fields of the physical-dimensional theory whose perturbative graphs are being regularized.

Definition 47.13 (Dimensional analytic regularization of graph integrals)**.** Let G be a connected Feynman graph with loop number L, external momenta p_i obeying physical d-dimensional momentum conservation, and propagator powers ν_e. Put $D = d - \epsilon$. A dimensional regularization datum first defines the scalar integral

$$I_G(D, \nu, p, m) = \int \prod_{\ell=1}^{L} \frac{\mathrm{d}^D q_\ell}{(2\pi)^D} \prod_{e\in E(G)} \frac{1}{(Q_e(q,p)^2 + m_e^2 - \mathrm{i}0)^{\nu_e}}$$

by Schwinger or Feynman parameters in a convergence domain and by meromorphic continuation in D and ν_e. The notation $\mathrm{d}^D q$ in this formula denotes this analytic rule, not a Borel measure on a literal vector space of nonintegral dimension. Tensor integrals are then defined by adjoining a continued metric-contraction algebra. Thus the D-dimensional metric $\hat{\eta}^{\mu\nu}$ and identity $\hat{\delta}^{\mu}{}_{\nu}$ satisfy

$$\hat{\delta}^{\mu}{}_{\mu} = D, \qquad \hat{\eta}^{\mu\rho}\hat{\eta}_{\rho\nu} = \hat{\delta}^{\mu}{}_{\nu},$$

and rotational covariance in this formal algebra fixes, for example,

$$\int \mathrm{d}^D q\, q^\mu q^\nu F(q^2) = \frac{\hat{\eta}^{\mu\nu}}{D} \int \mathrm{d}^D q\, q^2 F(q^2),$$

whenever the scalar integrals on the right are defined by the same meromorphic continuation.

The continuation in D enters in three distinct places.

1. **Loop integration.** Momentum integrals, phase-space integrals in unresolved sectors, and tensor averages use the D-dimensional metric $\hat{\eta}$.
2. **Algebra.** The contractions of Lorentz indices, gauge-field polarization sums, Dirac matrices, and Levi-Civita tensors require an additional prescription. This prescription is independent data beyond the scalar analytic continuation.
3. **External kinematics.** External observed momenta and polarizations may be kept in the physical d-dimensional subspace or continued together with the loops. This choice changes finite terms and evanescent operators, hence it is part of the renormalization convention.

The principal variants used in perturbative gauge theory differ precisely in these algebraic choices.[4]

Definition 47.14 (CDR, HV, DRED, and FDH data)**.** Let $d = 4$ for definiteness.

1. Conventional dimensional regularization, CDR, continues loop momenta, unobserved momenta, gauge polarizations, and Dirac gamma matrices to D dimensions.
2. The HV prescription keeps observed external states in the physical four-dimensional subspace. Loop momenta and unresolved internal polarizations are D-dimensional.
3. Dimensional reduction, DRED, keeps a four-dimensional index algebra η_4 and equips it with formal projectors
$$\eta_4 = \hat{\eta} + \tilde{\eta}, \qquad \hat{\eta}^{\mu}{}_{\mu} = D, \qquad \tilde{\eta}^{\mu}{}_{\mu} = 4 - D,$$
where loop momenta live in the $\hat{\eta}$-sector while the gauge and spin algebra remain four-dimensional. The $\tilde{\eta}$-components of a four-dimensional gauge field behave as evanescent scalar fields and require their own local counterterm coordinates when they are generated.
4. The four-dimensional helicity prescription, FDH, is a scattering amplitude variant in which external observed helicities are four-dimensional and unresolved loop momenta are dimensionally continued. Its finite conversion to CDR or HV is a scheme transformation only after the evanescent couplings have been specified.

The distinction matters in gauge theory. In vectorlike gauge theories without chiral γ_5 insertions, CDR and HV preserve the tensor algebra needed for Ward and Slavnov–Taylor identities at the regulated level, modulo local subtractions fixed by the chosen renormalization conditions. In supersymmetric theories, DRED has the specific advantage that the spin algebra remains four-dimensional. Its consistency beyond the lowest orders requires the evanescent scalar sector and its couplings to be included as part of the local action. A calculation that drops these evanescent coordinates has changed the regularization datum.

Definition 47.15 (γ_5 and Levi-Civita data)**.** A chiral dimensional regulator must specify the algebra generated by γ_5, the physical four-dimensional Levi-Civita tensor $\epsilon^{\mu\nu\rho\sigma}$, and the split between physical and evanescent subspaces. In the Breitenlohner–Maison/'t Hooft–Veltman prescription,
$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$$

[4] The original gauge-theory construction is G. 't Hooft and M. Veltman, "Regularization and renormalization of gauge fields," *Nuclear Physics B* **44** (1972), 189–213. For the Breitenlohner–Maison/'t Hooft–Veltman treatment of γ_5, see P. Breitenlohner and D. Maison, *Communications in Mathematical Physics* **52** (1977), 11–38, 39–54, 55–75. For dimensional reduction, see W. Siegel, "Supersymmetric dimensional regularization via dimensional reduction," *Physics Letters B* **84** (1979), 193–196, and D. Stockinger, "Regularization by dimensional reduction: consistency, quantum action principle, and supersymmetry," arXiv:hep-ph/0503129.

is four-dimensional in the mostly-plus convention fixed in Section 40.16: it anticommutes with physical gamma matrices and commutes with evanescent gamma matrices. With $\epsilon^{0123} = +1$, this is the same convention for which

$$\operatorname{tr}\left(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\right) = 4\mathrm{i}\epsilon^{\mu\nu\rho\sigma}.$$

In dimensional-reduction computations of the anomaly, γ_5 and $\epsilon^{\mu\nu\rho\sigma}$ remain four-dimensional objects while loop-momentum contractions are performed in the continued $\hat{\eta}$-sector and the evanescent $\tilde{\eta}$-sector is kept as an explicit local algebraic component.

There is no prescription in which γ_5 anticommutes with every D-dimensional gamma matrix, has the four-dimensional trace $\operatorname{tr}(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma)$, and preserves cyclic finite-dimensional trace manipulations for all divergent chiral graphs. The finite anomaly is precisely the remnant left after the regulated Ward identities, local counterterms, and evanescent algebra have been handled consistently. Chapter 51 uses this logic to keep the vector Ward identity and compute the axial anomaly.

Locality and Slavnov–Taylor control in dimensional schemes. The dimensional schemes used below are perturbative subtraction schemes for graph distributions, not measures on a noninteger-dimensional field space. In a power-counting renormalizable gauge theory whose regulated coordinate system includes every evanescent local field generated by the algebraic prescription, the forest formula subtracts Taylor polynomials in external momenta for each superficially divergent subgraph. These Taylor polynomials are local in position space, and the same locality statement applies to evanescent coordinates because they enter only through local tensor contractions in the continued algebra. The nontrivial input needed for gauge identities is the quantum action principle: at fixed loop order, a Slavnov–Taylor breaking is an integrated local functional of ghost number one. Nilpotency of the linearized Slavnov operator then makes the breaking a cocycle. An exact cocycle is removed by subtracting the corresponding local functional; a nonzero local cohomology class is an anomaly obstruction. The next theorem states the order-by-order restoration result with these hypotheses made explicit, so the cohomological mechanism is not presented as a separate proof detached from the quantum action principle.

Theorem 47.16 (All-order Slavnov–Taylor restoration)**.** *Let G be a compact semisimple gauge group and let S_0 be the gauge-fixed Yang–Mills action with matter in finite-dimensional unitary representations, Nakanishi–Lautrup fields, ghosts, antighosts, and external sources K, L for the nonlinear BRST variations. Assume that:*

1. *the classical BRST differential s_0 is off-shell nilpotent and S_0 satisfies $\mathcal{S}(S_0) = 0$;*
2. *the theory is power-counting renormalizable in dimension D, after including all evanescent local coordinates generated by the chosen dimensional scheme;*
3. *the regularization and subtraction prescription obey the quantum action principle: at a fixed loop order, the breaking of a local functional identity is an integrated local D-form whose ghost number and power-counting degree are the ones dictated by the identity;*
4. *the local gauge-anomaly class of the matter representation vanishes in*

$$H^{1,D}(s_0 \mid d),$$

with the same evanescent convention and source coordinates used to define the regularized graphs.

Then local counterterms can be chosen recursively so that the renormalized 1PI effective action

$$\Gamma^R = S_0 + \sum_{\ell \geq 1} \hbar^\ell \Gamma_\ell^R$$

satisfies the Slavnov–Taylor identity

$$\mathcal{S}(\Gamma^R) = 0$$

as an identity of formal power series in $\hbar$*. At each finite order* N*, this means*

$$\mathcal{S}\left(S_0 + \sum_{\ell=1}^{N} \hbar^\ell \Gamma_\ell^R \right) = O(\hbar^{N+1}).$$

The remaining finite freedom is the addition of ghost-number-zero local cocycles in $H^{0,D}(s_0 \mid d)$*, together with* s_0*-exact local terms that implement field, source, gauge-parameter, and coupling-coordinate redefinitions.*

Proof. Write $\mathcal{B}_X$ for the linearization of $\mathcal{S}$ at a functional X. In the variables of (47.44),

$$\mathcal{B}_X Y = \int_M \left[\frac{\delta_R X}{\delta A_\mu^a} \frac{\delta_L Y}{\delta K^{a\mu}} + \frac{\delta_R Y}{\delta A_\mu^a} \frac{\delta_L X}{\delta K^{a\mu}} \right. \\ \left. + \frac{\delta_R X}{\delta c^a} \frac{\delta_L Y}{\delta L^a} + \frac{\delta_R Y}{\delta c^a} \frac{\delta_L X}{\delta L^a} + B^a \frac{\delta_L Y}{\delta \bar{c}^a} \right] \mathrm{d}^D x.$$

For $X = S_0$, $\mathcal{B}_{S_0}$ is the integrated form of the classical BRST differential s_0. The identity $\mathcal{S}(S_0) = 0$, together with the graded Jacobi identity behind the Slavnov bracket, gives

$$\mathcal{B}_{S_0}^2 = 0$$

on integrated local functionals modulo total derivatives.

The proof is by induction on the loop order. Suppose that all counterterms through order $N - 1$ have been chosen and set

$$\Gamma_{<N} = S_0 + \sum_{\ell=1}^{N-1} \hbar^\ell \Gamma_\ell^R, \qquad \mathcal{S}(\Gamma_{<N}) = O(\hbar^N).$$

After all subdivergences have been subtracted, the quantum action principle applied to the N-loop functional gives

$$\mathcal{S}(\Gamma_{<N} + \hbar^N \Gamma_N^{\mathrm{reg}}) = \hbar^N \Delta_N + O(\hbar^{N+1}),$$

where $\Delta_N = \int_M a_N$ is an integrated local D-form of ghost number $+1$ and power-counting degree at most D. The consistency identity for the Slavnov operator,

$$\mathcal{B}_X \mathcal{S}(X) = 0,$$

is obtained by differentiating the quadratic expression $\mathcal{S}(X)$ and using the nilpotency encoded by the antibracket form. Taking the coefficient of $\hbar^N$ gives

$$\mathcal{B}_{S_0} \Delta_N = 0$$

modulo total derivatives. Thus a_N represents a class in $H^{1,D}(s_0 \mid d)$.

By the anomaly hypothesis, this class is zero for the theory under consideration. Therefore there are local forms b_N and r_N with ghost numbers 0 and 1 such that

$$a_N = s_0 b_N + dr_N.$$

Let $B_N = \int_M b_N$. Replacing the N-loop counterterm by

$$\Gamma_N^R = \Gamma_N^{\mathrm{reg}} - B_N$$

changes the order-N Slavnov breaking by

$$-\hbar^N \mathcal{B}_{S_0} B_N = -\hbar^N \Delta_N,$$

because the total derivative integrates to zero in the local functional cohomology used for counterterms. Hence

$$\mathcal{S}\big(\Gamma_{<N} + \hbar^N \Gamma_N^R\big) = O(\hbar^{N+1}).$$

This completes the induction and constructs the formal renormalized functional Γ^R.

If $C_N = \int_M c_N$ has ghost number zero and $\mathcal{B}_{S_0} C_N = 0$ modulo total derivatives, adding C_N does not spoil the identity at order N. If $C_N = \mathcal{B}_{S_0} R_N$, the change is a local canonical or field/source redefinition in the BRST variables. This identifies the finite ambiguity stated above. □

The theorem is a perturbative theorem about formal renormalized 1PI functionals. It does not construct a positive nonperturbative Hilbert space at $D \neq d$, and it does not replace a lattice or other nonperturbative regulator. Physical unitarity is recovered after renormalization and after taking the physical $D \to d$ limit of stable-channel amplitudes or infrared-safe observables. Cut identities at intermediate D are bookkeeping identities for the analytically continued integrands; the physical optical theorem is a statement about the resulting renormalized amplitudes in d dimensions.

For four-dimensional chiral Yang–Mills theories, the vanishing of the local gauge-anomaly class includes the cancellation of the cubic invariant entering the consistent nonabelian anomaly. Global gauge anomalies are separate obstructions: they are not detected by the local cohomology group $H^{1,D}(s_0 \mid d)$ and are treated in the finite-anomaly chapter.

Finally, dimensional regularization is separate from renormalization and from operator-insertion regularization. The regulator is the meromorphic assignment of graph distributions. Renormalization is the choice of local coordinate map and finite subtraction convention used to take the physical limit. A composite operator insertion requires its own source coordinate and contact-term prescription, even when the same dimensionally regularized graph integrals are used to compute its correlators.

47.11 Supersymmetric Ward Identities and Regulator Data

Supersymmetric gauge theories require one more layer of bookkeeping beyond the BRST data above. The additional symmetry generators are odd, their algebra contains translations and often gauge transformations, and in many multiplet descriptions their closure uses auxiliary fields or the equations of motion. For this reason the phrase that a regulator preserves supersymmetry has a precise meaning only after the fields, sources, evanescent variables, and operator insertions have been specified.

Definition 47.17 (Supersymmetry datum on a gauge-fixed local theory)**.** Let Φ^A denote the complete list of fields in a gauge-fixed perturbative theory, including ghosts, antighosts, Nakanishi–Lautrup fields, matter fields, and any auxiliary fields used to close the transformation law off shell. A supersymmetry datum consists of:

1. a finite-dimensional spinor space S of constant supersymmetry parameters;
2. for every $\varepsilon \in \mathsf{S}$, an odd derivation
$$q_\varepsilon : \mathcal{F}_{\text{loc}} \longrightarrow \mathcal{F}_{\text{loc}}$$
of the local jet algebra;
3. a local gauge-fixed action with external sources for the nonlinear BRST and supersymmetry variations;
4. a closure formula of the form
$$\{q_\varepsilon, q_\eta\} = a^\mu(\varepsilon, \eta)\partial_\mu + \delta_{\alpha(\varepsilon,\eta;\Phi)} + s\, r(\varepsilon, \eta; \Phi) + \mathcal{E}_i\, R^i_{\varepsilon,\eta}, \tag{47.41}$$
where $a^\mu(\varepsilon, \eta)$ is the translation parameter, δ_α is a gauge transformation with possibly field-dependent parameter, s is the BRST differential, $\mathcal{E}_i$ are the Euler–Lagrange expressions, and $R^i_{\varepsilon,\eta}$ are local differential operators.

If the last term in (47.41) is absent after auxiliary fields have been included, the supersymmetry datum is off-shell closed in the chosen field coordinates. If it is present, the closure is on shell and the correct off-shell object is the corresponding BV extended action rather than the transformation law on fields alone.

The BV formulation removes the ambiguity in the on-shell case. The Euler–Lagrange term in (47.41) is then encoded by antifield terms in the extended action. The operator combining BRST and supersymmetry is a nilpotent vector field on the field-antifield space. In algebraic renormalization this is expressed by adjoining constant ghosts: commuting spinor ghosts ϵ for the odd supersymmetry generators and an anticommuting vector ghost v^μ for translations. In a flat four-dimensional $\mathcal{N} = 1$ example the algebraic form begins as

$$s_{\text{ext}} = s_{\text{BRST}} + \epsilon^\alpha Q_\alpha + \bar{\epsilon}_{\dot\alpha}\bar{Q}^{\dot\alpha} + v^\mu\partial_\mu - 2\mathrm{i}\, \epsilon\sigma^\mu\bar{\epsilon}\, \frac{\partial}{\partial v^\mu} + \cdots, \tag{47.42}$$

where Q_α and $\bar{Q}_{\dot\alpha}$ act as the superspace derivations of Chapter 86. With the convention $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ and $[P_\mu, \Phi(x)] = \mathrm{i}\partial_\mu\Phi(x)$, the derivation represented by P_μ on coordinate-labelled fields is $\mathrm{i}\partial_\mu$. Hence
$$\{\epsilon Q, \bar{\epsilon}\bar{Q}\} = 2\mathrm{i}\, \epsilon\sigma^\mu\bar{\epsilon}\, \partial_\mu.$$

The term $-2\mathrm{i}\epsilon\sigma^\mu\bar{\epsilon}\, \partial/\partial v^\mu$ then cancels this square against the anticommutator with $v^\mu\partial_\mu$. The omitted terms are the gauge and antifield contributions required by the closure formula. The extended ghost number is the $\mathbb{Z}$-grading for which

$$\mathrm{gh}_{\text{ext}}(c) = \mathrm{gh}_{\text{ext}}(\epsilon) = \mathrm{gh}_{\text{ext}}(\bar{\epsilon}) = \mathrm{gh}_{\text{ext}}(v) = 1, \qquad \mathrm{gh}_{\text{ext}}(\text{ordinary fields and couplings}) = 0,$$

and antifields or external sources have the complementary degrees that make the extended action have total extended ghost number 0. The differential s_{ext} raises this grading by 1. The defining property is

$$s_{\text{ext}}^2 = 0 \quad \text{on integrated local functionals modulo total derivatives.}$$

This nilpotent differential, not the transformation of a single component field in isolation, is the object tested by renormalization.

Definition 47.18 (Separated regularization and scheme data)**.** A regularized supersymmetric gauge calculation contains four distinct kinds of data.

1. The *path-integral regulator* $\mathfrak{R}$: a finite cutoff, lattice, higher-derivative covariance, dimensional analytic continuation, or other rule that assigns regulated Green functions or regulated graph distributions to the field variables.
2. The *gauge-fixing and BV data*: the gauge-fixing fermion, ghosts, antifields or external sources for nonlinear variations, the extended differential s_{ext}, and the local action including all evanescent fields produced by the regulator.
3. The *operator-insertion regulator*: for every composite operator or source multiplet, a local source coordinate and contact-term prescription that define insertions before the regulator is removed.
4. The *renormalized coordinate scheme*: the finite choice of couplings, fields, gauge parameters, source coordinates, and evanescent coordinates after local subtractions have been made.

The regulator is compatible with a chosen supersymmetry datum through order N in formal perturbation theory if the source-extended renormalized effective action $\Gamma^R_{\leq N}$ satisfies

$$\mathcal{S}_{\text{ext}}(\Gamma^R_{\leq N}) = O(\hbar^{N+1}), \tag{47.43}$$

where $\mathcal{S}_{\text{ext}}$ is the Slavnov functional for the combined BRST, supersymmetry, and translation ghosts. Exact compatibility means (47.43) to all orders in the formal expansion under consideration.

This definition separates several phenomena that otherwise get conflated. A regulator may preserve the BRST identity while breaking a supersymmetry Ward identity, because the gauge orbit and the supermultiplet structure are different parts of the field-space data. Conversely, a regulator can preserve a nilpotent scalar supersymmetry of a twisted formulation while leaving the full Lorentzian supersymmetry algebra to be recovered only after taking a continuum limit and tuning the allowed local counterterms.

Proposition 47.19 (Cohomological restoration of supersymmetry Ward identities)**.** *Assume a power-counting renormalizable supersymmetric gauge theory has been written with the source and BV data of Definition 47.18. Suppose that:*

1. *the classical extended action S_{ext} satisfies the combined identity*

$$\mathcal{S}_{\text{ext}}(S_{\text{ext}}) = 0;$$

2. *the chosen regulator and subtraction procedure obey the quantum action principle for the combined identities: after lower-order subtractions, the order-N breaking of $\mathcal{S}_{\text{ext}}$ is an integrated local D-form of extended ghost number 1;*

3. *the local field-coordinate list includes every evanescent coordinate generated by the regulator, including epsilon-scalars and their independent couplings in dimensional reduction;*
4. *the class of the order-N breaking vanishes in*

$$H^{1,D}(s_{\text{ext}} \mid d)$$

computed in the same local algebra of fields, antifields, sources, constant ghosts, and evanescent variables.

Then there is a local counterterm at order N for which the renormalized effective action satisfies

$$\mathcal{S}_{\text{ext}}(\Gamma^R_{\leq N}) = O(\hbar^{N+1}).$$

If the cohomology class is nonzero, the breaking is an anomaly or a regulator obstruction in the specified symmetry problem; it cannot be removed by a local finite redefinition inside that coordinate system.

Proof. Suppose the identity has been restored through order $N-1$. The quantum action principle gives

$$\mathcal{S}_{\text{ext}}\big(\Gamma^R_{<N} + \hbar^N \Gamma^{\text{reg}}_N\big) = \hbar^N \Delta_N + O(\hbar^{N+1}), \qquad \Delta_N = \int a_N,$$

with a_N local of extended ghost number 1. Linearizing the extended Slavnov functional at the classical action gives the nilpotent operator $\mathcal{B}_{S_{\text{ext}}}$, whose action on local functionals is s_{ext} modulo total derivatives. The consistency identity

$$\mathcal{B}_X \mathcal{S}_{\text{ext}}(X) = 0$$

therefore implies

$$s_{\text{ext}} a_N + d r_N = 0$$

for a local $(D-1)$-form r_N. The vanishing of the cohomology class means

$$a_N = s_{\text{ext}} b_N + d c_N$$

with b_N local of extended ghost number 0. Adding the counterterm $-\hbar^N \int b_N$ changes the order-N breaking by $-\hbar^N \Delta_N$, while the total derivative integrates to zero in the local-functional quotient. This restores the identity through order N. The nonzero-class case follows because a local counterterm changes Δ_N only by an s_{ext}-exact term modulo d. □

Several regulators used for supersymmetric theories can now be described by their data.

1. **Dimensional reduction.** DRED keeps the four-dimensional spin and gauge index algebra used by the supersymmetry transformations while loop momenta are analytically continued in the $\hat{\eta}$-sector, where $\hat{\eta}$ is the continued $D = 4 - \epsilon$ metric in the dimensional-regularization conventions above. Its local coordinate list includes the $\tilde{\eta}$-sector epsilon-scalars, namely the evanescent $(4-D)$-dimensional components in the splitting $\eta_4 = \hat{\eta} + \tilde{\eta}$, and all couplings generated by their interactions. Within perturbation theory the question is whether the extended Slavnov identity can be restored in the local algebra containing these variables. Dropping the epsilon-scalar coordinates changes the regulator datum and invalidates the cohomology test.

2. **Conventional dimensional regularization.** CDR and HV provide BRST-compatible regulators for many vectorlike gauge calculations. For four-dimensional supersymmetry their continued tensor and spinor algebras do not carry the original component-field representation without extra evanescent data. The supersymmetry Ward identity must therefore be tested through $\mathcal{S}_{\text{ext}}$; any local breaking is either removed by the restoration criterion above or recorded as an obstruction for that scheme.

3. **Superspace and higher-derivative regulators.** In a superspace formulation, a regulator is compatible with the manifest supersymmetry when it is written as a local functional of superfields and supercovariant derivatives, with the Berezin integration and source supermultiplets specified. Gauge theories additionally require a gauge-covariant or background-covariant higher-derivative kernel and a BRST/BV treatment of the remaining gauge fixing. Residual divergences, when present, still require a local subtraction scheme whose Ward identities are checked by the same cohomological criterion.

4. **Pauli–Villars-type auxiliary determinants.** A Pauli–Villars-type regulator is specified by the auxiliary field content, statistics, mass matrix, gauge representation, and determinant prescription. Compatibility with supersymmetry requires regulator fields to be organized with the same supersymmetry datum and source identity, or else the resulting breaking must be local and cohomologically removable. The presence of heavy auxiliary fields by itself supplies no symmetry statement.

5. **Lattice and twisted regulators.** A lattice regulator gives an ordinary finite-dimensional integral before the continuum limit, but it replaces continuous translations and rotations by lattice symmetries. Full Poincare supersymmetry is therefore expressed, at finite lattice spacing, only through those subalgebras that survive the discretization. Twisted formulations may preserve a nilpotent scalar charge Q with

$$Q^2 = \delta_{\text{gauge}}(\varphi)$$

   or a lattice translation plus gauge transformation. The continuum claim is then a statement about the local counterterms allowed by the exact lattice symmetries and by the Q-Ward identity.

6. **Localization-compatible regulators.** A localization argument uses a chosen odd operator Q satisfying

$$Q^2 = \mathcal{L}_v + \delta_{\text{gauge}} + \delta_{\text{flavor}}$$

   on the fields and sources of the regulated theory. The deformation $t\,QV$ preserves a Q-closed expectation value only when the regulator, integration cycle, boundary conditions, and determinant phases are Q-compatible. The derivative of a regulated expectation value is then

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle \mathcal{O}\rangle_t = -\langle Q(V\mathcal{O})\rangle_t + \text{local source/contact contributions},$$

   and it vanishes for Q-closed observables only after those contact terms and possible Q-anomalies have been controlled.

Holomorphy and nonrenormalization arguments also belong to the same scheme language. A Wilsonian superpotential statement is a statement in a renormalized superspace source-coordinate system: chiral couplings are represented by background chiral superfields, the Wilsonian action is expanded in local superspace integrals, and the allowed finite counterterms are constrained by chirality, locality, gauge invariance, global charges, and the chosen regularity domain in coupling space. The conclusion concerns the F-term coordinate in that Wilsonian chart. The Kähler potential, 1PI effective action, real D-terms, thresholds, and contact terms obey their own source identities and require separate definitions.

47.12 Slavnov–Taylor Identities and Counterterms

BRST symmetry gives functional identities for the generating functional and for the 1PI effective action. In a compact notation, introduce sources $K^{a\mu}$ and L^a coupled to sA^a_μ and sc^a. We use left and right functional derivatives defined by

$$\delta F = \int_M \delta\Phi^A \frac{\delta_L F}{\delta\Phi^A} = \int_M \frac{\delta_R F}{\delta\Phi^A}\delta\Phi^A,$$

for each homogeneous field or source Φ^A. The parities are

$$\epsilon(A_\mu) = \epsilon(B) = \epsilon(L) = 0, \qquad \epsilon(c) = \epsilon(\bar{c}) = \epsilon(K) = 1.$$

The 1PI effective action $\Gamma[A, c, \bar{c}, B; K, L]$ obeys the Slavnov–Taylor identity

$$\mathcal{S}(\Gamma) := \int_M \left[\frac{\delta_R\Gamma}{\delta A^a_\mu}\frac{\delta_L\Gamma}{\delta K^{a\mu}} + \frac{\delta_R\Gamma}{\delta c^a}\frac{\delta_L\Gamma}{\delta L^a} + B^a\frac{\delta_L\Gamma}{\delta\bar{c}^a}\right] \mathrm{d}^D x = 0. \tag{47.44}$$

There are two separate functional identities in the gauge theories developed so far. In Abelian QED, after the gauge-fixing term has been separated, the gauge-invariant part of the 1PI functional is annihilated by a fixed first-order Ward–Takahashi differential operator on field space:

$$\mathcal{W}_\alpha \Gamma_{\text{inv}} = 0.$$

The operator $\mathcal{W}_\alpha$ contains the infinitesimal field variations, but it does not contain Γ_{inv}. The equation is therefore linear in the unknown functional. Differentiating it gives the Ward–Takahashi relations, including photon self-energy transversality and the equality between the Abelian vertex and spinor residue counterterms in Chapter 43.

The nonabelian gauge-fixed identity above has a different origin and a different algebraic form. The BRST variations $sA^a_\mu = (D_\mu c)^a$ and $sc^a = -\frac{1}{2}f^a{}_{bc}c^b c^c$ are composite local fields. To express their insertions in the quantum theory one introduces the sources K, L. Let $W[J, K, L]$ be the connected generating functional with ordinary sources J_A for the fields $\Phi^A = (A, c, \bar{c}, B)$ and with K, L coupled to the nonlinear BRST variations. The BRST change of variables gives the connected identity, before Legendre transformation in the J_A variables,

$$\int \left[J_{A^a_\mu}\frac{\delta_L W}{\delta K^{a\mu}} + J_{c^a}\frac{\delta_L W}{\delta L^a} + J_{\bar{c}^a}\frac{\delta_L W}{\delta J_{B^a}}\right] \mathrm{d}^D x = 0$$

with the source signs chosen to match (47.44). Passing to the 1PI functional replaces the ordinary sources by

$$J_{\Phi^A} = -\frac{\delta_R\Gamma}{\delta\Phi^A}$$

while leaving the BRST-variation sources K, L as external coordinates. Moreover

$$\frac{\delta_L W}{\delta K^{a\mu}} = \frac{\delta_L\Gamma}{\delta K^{a\mu}}, \qquad \frac{\delta_L W}{\delta L^a} = \frac{\delta_L\Gamma}{\delta L^a}, \qquad \frac{\delta_L W}{\delta J_{B^a}} = B^a.$$

Consequently the Legendre transform converts the connected BRST identity into a product of derivatives of the same functional Γ. In the Yang–Mills coordinates displayed in (47.44), this product is precisely the quadratic Slavnov–Taylor operator $\mathcal{S}(\Gamma)$:

$$\int_M \left[\frac{\delta_R\Gamma}{\delta A^a_\mu}\frac{\delta_L\Gamma}{\delta K^{a\mu}} + \frac{\delta_R\Gamma}{\delta c^a}\frac{\delta_L\Gamma}{\delta L^a} + B^a\frac{\delta_L\Gamma}{\delta \bar{c}^a}\right] \mathrm{d}^D x.$$

The quadratic form is the 1PI shadow of the homological statement $s^2 = 0$ and is the reason antifield/BV coordinates are the natural language for renormalized nonabelian gauge theory. The sources $K^{a\mu}$ and L^a have ghost numbers -1 and -2, respectively, so that the source terms $K^{a\mu} sA^a_\mu$ and $L^a sc^a$ have ghost number zero. They are introduced because the BRST transformations of A_μ and c are nonlinear composite fields. The Batalin–Vilkovisky formulation replaces this case-by-case source assignment: for every field Φ^A, one introduces an antifield Φ^*_A of opposite Grassmann parity and ghost number

$$\mathrm{gh}(\Phi^*_A) = -1 - \mathrm{gh}(\Phi^A),$$

and encodes gauge symmetry by an odd Poisson bracket, the antibracket, and a master equation. The present Slavnov–Taylor identity is the gauge-fixed Yang–Mills specialization of that homological structure.

The signs in (47.44) follow directly from these left/right conventions. At the classical source-coupled level write

$$S_{\text{ext}} = S_{\text{gf}} + \int_M \left(K^{a\mu} sA^a_\mu + L^a sc^a\right) \mathrm{d}^D x.$$

Since K is odd and L is even,

$$\frac{\delta_L S_{\text{ext}}}{\delta K^{a\mu}} = sA^a_\mu, \qquad \frac{\delta_L S_{\text{ext}}}{\delta L^a} = sc^a.$$

Applying the odd derivation s from the left gives

$$0 = sS_{\text{ext}} = \int_M \left[(sA^a_\mu)\frac{\delta_L S_{\text{ext}}}{\delta A^a_\mu} + (sc^a)\frac{\delta_L S_{\text{ext}}}{\delta c^a} + B^a\frac{\delta_L S_{\text{ext}}}{\delta \bar{c}^a}\right] \mathrm{d}^D x.$$

For the effective action, the Legendre transform is taken in the elementary fields but not in K, L. With the derivative convention above,

$$\frac{\delta_L\Gamma}{\delta K^{a\mu}} = \left\langle sA^a_\mu\right\rangle_{\text{1PI}}, \qquad \frac{\delta_L\Gamma}{\delta L^a} = \left\langle sc^a\right\rangle_{\text{1PI}},$$

and the elementary source terms are replaced by the right derivatives $\delta_R\Gamma/\delta A^a_\mu$ and $\delta_R\Gamma/\delta c^a$. Substitution gives (47.44) with no additional hidden sign; the c-term is written with $\delta_R\Gamma/\delta c$ precisely because c is odd. Chapter 48 develops the BV formalism as the natural framework for gauge-theory 1PI effective actions, Wilsonian effective actions, and renormalization compatible with gauge symmetry.

Renormalization is compatible with gauge theory when counterterms can be chosen so that (47.44) remains valid order by order. Algebraically, the possible invariant counterterms are classified by ghost-number-zero local BRST cohomology. A gauge anomaly is an obstruction at ghost number $+1$: it is a local functional $\mathcal{A}$ satisfying the linearized consistency condition

$$\mathcal{B}_\Gamma \mathcal{A} = 0$$

that cannot be written as $\mathcal{A} = \mathcal{B}_\Gamma X$ for a local functional X. The axial anomaly and the nonabelian gauge-anomaly cancellation conditions are developed in the anomaly chapters below.

Chapter 48

The BV Master Formalism for Gauge Effective Actions

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

48.1 Why Antifields Are Introduced

The BRST chapter introduced sources $K^{a\mu}$ and L^a for the nonlinear variations sA^a_μ and sc^a. Their role is to serve as coordinates dual to the BRST variations, thereby making the Slavnov–Taylor identity a functional equation for the 1PI effective action.

The Batalin–Vilkovisky formalism is the intrinsic version of this construction. It assigns a dual coordinate, called an antifield, to every field in the gauge-fixed or ungauge-fixed complex. The antibracket pairs a field with its antifield, and the master equation is the single equation that encodes gauge invariance, BRST nilpotency, gauge fixing, and the compatible renormalization identities.

The framework in this chapter is perturbative and local. We work with a regulated field theory or, equivalently for algebraic purposes, with the graded algebra of local functionals in finitely many jets of fields. Infinite dimensional functional derivatives are therefore shorthand for the corresponding regulated or local-jet operation. When an identity involves the BV Laplacian, the regulator and measure are part of the data.

This chapter supplies the continuum gauge-theory framework for effective actions. A Wilsonian or

1PI effective action for a gauge theory is a gauge-compatible object only after the gauge symmetry has been encoded in a BRST/BV complex, or after a lattice regulator has supplied a finite gauge-invariant integral over link variables. In the BV route the finite cutoff data are the odd symplectic field-antifield space, a compatible half-density, the regulated BV Laplacian, the master action, and the coarse-graining cycle. In the lattice route the finite cutoff data are the compact link-variable space, Haar measure, gauge action, gauge-invariant observables, and blocking or scaling map. Later gauge-theory Wilsonian claims use one of these two data types and state the comparison map between them when both appear.

48.2 Fields, Antifields, and Gradings

Let $\{\Phi^A\}$ denote the full set of fields in the gauge-theory complex. The index A includes discrete labels, spacetime indices, Lie-algebra indices, and the spacetime point in condensed notation. Examples are

$$A^a_\mu, \qquad c^a, \qquad \bar{c}^a, \qquad B^a, \qquad \psi, \qquad \bar{\psi}.$$

Each field has a Grassmann parity

$$\epsilon_A \in \mathbb{Z}/2\mathbb{Z}$$

and a ghost number $\mathrm{gh}(\Phi^A)$. The antifield paired with Φ^A is denoted by Φ^*_A and is assigned

$$\epsilon(\Phi^*_A) = \epsilon_A + 1 \pmod 2, \qquad \mathrm{gh}(\Phi^*_A) = -1 - \mathrm{gh}(\Phi^A).$$

Thus antifields have opposite parity and complementary ghost number. For the Yang–Mills non-minimal sector,

Φ^A	A_μ	c	$\bar{c}$	B
$\mathrm{gh}(\Phi^A)$	0	1	-1	0
$\mathrm{gh}(\Phi^*_A)$	-1	-2	0	-1

and the parities are reversed in the antifield row.

Let $\mathcal{F}_{\mathrm{BV}}$ be the graded-commutative algebra of local functionals in Φ^A, Φ^*_A and finitely many of their spacetime derivatives, modulo integration by parts when integrated local functionals are being compared. A functional $F \in \mathcal{F}_{\mathrm{BV}}$ has parity $|F|$ and ghost number $\mathrm{gh}(F)$ when it is homogeneous. Left and right variational derivatives are defined by

$$\delta F = \int \delta\Phi^A \, \frac{\delta^L F}{\delta\Phi^A} = \int \frac{\delta^R F}{\delta\Phi^A} \, \delta\Phi^A,$$

and similarly for antifields. The distinction is necessary because odd variables do not commute with the variation symbols.

For a local functional

$$F[\Phi] = \int_M f(x, \Phi, \partial\Phi, \dots, \partial^r\Phi) \, \mathrm{d}^D x,$$

the left Euler–Lagrange derivative is the coefficient of $\delta\Phi^A$ after moving derivatives off the variation:

$$\frac{\delta^L F}{\delta\Phi^A} = \sum_{|\alpha|\le r} (-\partial)_\alpha \frac{\partial^L f}{\partial(\partial_\alpha \Phi^A)}. \tag{48.1}$$

Here α is a multi-index and $(-\partial)_\alpha = (-1)^{|\alpha|}\partial_\alpha$. Boundary conditions or compact support are part of the definition whenever the integration by parts is used. In a finite regulator $\partial_\alpha \Phi^A$ is replaced by the corresponding finite set of regulated coordinates, and (48.1) becomes the ordinary graded partial derivative. The ghost number and parity of the variational derivative are

$$\mathrm{gh}\left(\frac{\delta^L F}{\delta \Phi^A}\right) = \mathrm{gh}(F) - \mathrm{gh}(\Phi^A), \qquad \left|\frac{\delta^L F}{\delta \Phi^A}\right| = |F| + \epsilon_A.$$

These bookkeeping rules are what make the BV bracket below homogeneous of parity one and ghost number one.

48.3 The Antibracket

Definition 48.1 (BV antibracket)**.** For homogeneous functionals $F, G \in \mathcal{F}_{\mathrm{BV}}$, the BV antibracket is

$$(F, G) = \int \left[\frac{\delta^R F}{\delta \Phi^A}\frac{\delta^L G}{\delta \Phi^*_A} - \frac{\delta^R F}{\delta \Phi^*_A}\frac{\delta^L G}{\delta \Phi^A}\right] \mathrm{d}^D x, \tag{48.2}$$

with summation over all field labels A. The spacetime integral is absent when the same formula is applied to a finite-dimensional regulator.

The bracket has parity and ghost number

$$|(F, G)| = |F| + |G| + 1, \qquad \mathrm{gh}(F, G) = \mathrm{gh}(F) + \mathrm{gh}(G) + 1.$$

It satisfies

$$(F, G) = -(-1)^{(|F|+1)(|G|+1)}(G, F)$$

and the odd Jacobi identity

$$(F, (G, H)) = ((F, G), H) + (-1)^{(|F|+1)(|G|+1)}(G, (F, H)).$$

It is an odd biderivation. Explicitly,

$$(F, GH) = (F, G)H + (-1)^{(|F|+1)|G|}G(F, H),$$

and

$$(FG, H) = F(G, H) + (-1)^{|G|(|H|+1)}(F, H)G.$$

The elementary brackets are

$$(\Phi^A(x), \Phi^*_B(y)) = \delta^A{}_B\, \delta^{(D)}(x - y), \qquad (\Phi^A, \Phi^B) = 0, \qquad (\Phi^*_A, \Phi^*_B) = 0,$$

with the delta distribution understood in the same regulated or distributional sense as the fields themselves.

Lemma 48.2 (Odd symplectic origin of the antibracket)**.** *At finite regulator, let*

$$\omega = \delta \Phi^*_A\, \delta \Phi^A$$

be the odd symplectic form on the graded vector space with coordinates (Φ^A, Φ^*_A)*. For a homogeneous function F, define its Hamiltonian vector field X_F by*

$$\iota_{X_F}\omega = \delta F.$$

Then the bracket $(F, G) := X_F G$ is exactly (48.2)*. It satisfies the elementary brackets, graded antisymmetry, the odd Jacobi identity, and the two biderivation identities displayed above.*

Proof. In Darboux coordinates the equation $\iota_{X_F}\omega = \delta F$ gives

$$X_F = \frac{\delta^R F}{\delta\Phi^A}\frac{\delta^L}{\delta\Phi^*_A} - \frac{\delta^R F}{\delta\Phi^*_A}\frac{\delta^L}{\delta\Phi^A}.$$

Applying this vector field to G gives (48.2). The elementary brackets follow by applying the formula to the coordinate functions. The biderivation identities follow because X_F is a graded derivation of parity $|F| + 1$.

For the Jacobi identity, use the defining relation and the closedness of the constant Darboux form:

$$\iota_{[X_F,X_G]}\omega = \delta(X_F G) = \delta(F, G).$$

Thus $[X_F, X_G] = X_{(F,G)}$, with the graded commutator of vector fields. The graded Jacobi identity for vector-field commutators gives the displayed odd Jacobi identity for $(\,\cdot\,,\,\cdot\,)$. For continuum local functionals, first smear the fields or impose a finite regulator so that the Darboux coordinate calculation is finite-dimensional. The variational derivatives in (48.2) are then the limits of the regulated coordinate derivatives, and the bracket identities pass to the declared local-functional limit on the common domain where those variational derivatives exist. □

48.4 The Classical Master Equation

Definition 48.3 (Classical BV action)**.** A classical BV action is an even local functional $S_{\mathrm{BV}} \in \mathcal{F}_{\mathrm{BV}}$ of ghost number zero satisfying the classical master equation

$$\frac{1}{2}(S_{\mathrm{BV}}, S_{\mathrm{BV}}) = 0. \tag{48.3}$$

It is required to reduce to the classical gauge-invariant action when all ghosts and antifields are set to zero.

The associated BV differential is

$$s_{\mathrm{BV}}F = (F, S_{\mathrm{BV}}).$$

If S_{BV} satisfies (48.3), then

$$s_{\mathrm{BV}}^2 = 0.$$

Using the odd Jacobi identity and the evenness of S_{BV},

$$((H, S_{\mathrm{BV}}), S_{\mathrm{BV}}) = \frac{1}{2}(H, (S_{\mathrm{BV}}, S_{\mathrm{BV}}))$$

for every functional H. The right hand side vanishes by (48.3). Hence

$$s_{\mathrm{BV}}^2 H = ((H, S_{\mathrm{BV}}), S_{\mathrm{BV}}) = 0.$$

Since this holds for every functional H in the BV algebra, the Hamiltonian vector field generated by S_{BV} is a differential. Thus the classical master equation is precisely the condition that the BRST/BV variation squares to zero off shell, before choosing a gauge-fixing Lagrangian submanifold.

This algebraic implication is the reason the master equation is stronger than a compact rewriting of a Ward identity. It constructs a differential on the space of fields, ghosts, antifields, and local functionals.

48.5 Noether Identities and the Minimal BV Complex

The master equation is constructed from the gauge identities of the classical action. Let $S_0[\phi]$ be a classical action for fields ϕ^i, and set

$$E_i(\phi) := \frac{\delta S_0}{\delta \phi^i}.$$

An infinitesimal gauge transformation is a collection of local differential operators $R^i{}_\alpha(\phi, \partial)$ acting on gauge parameters ϵ^α:

$$\delta_\epsilon \phi^i = R^i{}_\alpha \epsilon^\alpha.$$

Gauge invariance of S_0 is the Noether identity

$$E_i R^i{}_\alpha = 0 \tag{48.4}$$

after moving derivatives off ϵ^α. Condensed notation includes the spacetime integration and the signs from integration by parts.

The first BV variables are the ghosts c^α, the field antifields ϕ^*_i, and the ghost antifields c^*_α. Their ghost numbers are

$$\mathrm{gh}(\phi^i) = 0, \quad \mathrm{gh}(c^\alpha) = 1, \quad \mathrm{gh}(\phi^*_i) = -1, \quad \mathrm{gh}(c^*_\alpha) = -2.$$

The Koszul–Tate part of the BV differential resolves the equations of motion:

$$\delta_{\mathrm{KT}}\phi^i = 0, \qquad \delta_{\mathrm{KT}} c^\alpha = 0, \qquad \delta_{\mathrm{KT}}\phi^*_i = E_i, \qquad \delta_{\mathrm{KT}} c^*_\alpha = R^i{}_\alpha \phi^*_i.$$

Its square on c^*_α is

$$\delta^2_{\mathrm{KT}} c^*_\alpha = R^i{}_\alpha E_i,$$

which vanishes by (48.4). Thus the Noether identity is the first exactness condition in the antifield direction.

For an irreducible off-shell closed gauge algebra,

$$[R_\alpha, R_\beta]^i = R^i{}_\gamma C^\gamma{}_{\alpha\beta},$$

with the usual graded signs in the general case, the beginning of the minimal BV action is

$$S_{\min} = S_0 + \phi^*_i R^i{}_\alpha c^\alpha - \frac{1}{2} c^*_\gamma C^\gamma{}_{\alpha\beta} c^\alpha c^\beta + \cdots . \tag{48.5}$$

For field-independent structure constants and off-shell closure this displayed expression is complete. Field-dependent, open, or reducible gauge systems require higher antifield-number terms. Expanding $\frac{1}{2}(S_{\min}, S_{\min})$ by antifield number gives, in order, the Noether identity (48.4), the closure relation of the gauge generators, and the Jacobi relations or their higher homotopy replacements. Solving the master equation is therefore the construction of a single nilpotent differential whose antifield expansion records the complete gauge identity complex.

48.6 Minimal Yang–Mills BV Action

For a gauge theory whose BRST transformations close off shell, the minimal BV action is obtained by coupling antifields to the BRST variations. With the Hermitian Yang–Mills conventions of Chapter 45, $[t^a, t^b] = \mathrm{i}f^c{}_{ab}t^c$, so the output Lie-algebra index of $f^c{}_{ab}$ is written first. In this convention

$$sA^a_\mu = (D_\mu c)^a, \qquad sc^a = -\frac{1}{2}f^a{}_{bc}c^b c^c.$$

The minimal BV action for the gauge and ghost sector is

$$S_{\min} = S_{\mathrm{YM}}[A] + \int_M \left[A^{*\mu}_a (D_\mu c)^a - \frac{1}{2}c^*_a f^a{}_{bc}c^b c^c\right] \mathrm{d}^D x. \tag{48.6}$$

Matter fields are included by adding their classical action and antifield couplings

$$\int_M \left[\psi^* \left(\mathrm{i}c^a t^a_R \psi\right) + \left(-\mathrm{i}\bar{\psi}\, c^a t^a_R\right) \bar{\psi}^*\right] \mathrm{d}^D x,$$

with the order of odd factors fixed by the left/right derivative convention.

The master equation for (48.6) is the combined statement that S_{YM} is gauge invariant and that the BRST transformations are nilpotent. Let

$$R^a_\mu(A, c) := (D_\mu c)^a, \qquad R^a_c(c) := -\frac{1}{2}f^a{}_{bc}c^b c^c,$$

and write

$$S_{\min} = S_{\mathrm{YM}} + S_1, \qquad S_1 = \int_M \left(A^{*\mu}_a R^a_\mu + c^*_a R^a_c\right) \mathrm{d}^D x.$$

Give each antifield antifield number 1 and each field antifield number 0. Since S_{YM} is independent of antifields and S_1 is linear in antifields,

$$\frac{1}{2}(S_{\min}, S_{\min}) = (S_{\mathrm{YM}}, S_1) + \frac{1}{2}(S_1, S_1),$$

and the two displayed terms have antifield numbers 0 and 1, respectively. The antifield-number-zero component is

$$(S_{\mathrm{YM}}, S_1) = \int_M \frac{\delta^R S_{\mathrm{YM}}}{\delta A^a_\mu} R^a_\mu \, \mathrm{d}^D x = \int_M \frac{\delta S_{\mathrm{YM}}}{\delta A^a_\mu} (D_\mu c)^a \, \mathrm{d}^D x.$$

Gauge invariance of S_{YM} means that this expression vanishes when the odd ghost c is replaced by an arbitrary even infinitesimal gauge parameter ζ. Because the identity is algebraic in the parameter and its derivatives, the same coefficient identity gives the vanishing for c.

For the antifield-number-one component, the antibracket calculation gives

$$\frac{1}{2}(S_1, S_1) = \int_M \left[A^{*\mu}_a \, sR^a_\mu + c^*_a \, sR^a_c\right] \mathrm{d}^D x,$$

where s acts on functions of A, c by

$$sX = \int_M \left[R^a_\mu \frac{\delta_L X}{\delta A^a_\mu} + R^a_c \frac{\delta_L X}{\delta c^a}\right] \mathrm{d}^D x.$$

The two coefficients are explicitly

$$\begin{aligned}sR^a_\mu &= D_\mu R^a_c + f^a{}_{bc} R^b_\mu c^c \\ &= -\frac{1}{2} f^a{}_{bc} D_\mu (c^b c^c) + f^a{}_{bc} (D_\mu c)^b c^c = 0,\end{aligned}$$

where D_μ is an even derivation and the two terms in $D_\mu(c^b c^c)$ are equal after antisymmetry of $f^a{}_{bc}$ and the odd commutation of c with $D_\mu c$. Similarly,

$$\begin{aligned}sR^a_c &= -\frac{1}{2} f^a{}_{bc} \left(R^b_c c^c - c^b R^c_c \right) \\ &= -\frac{1}{12} \left(f^a{}_{be} f^e{}_{cd} + f^a{}_{ce} f^e{}_{db} + f^a{}_{de} f^e{}_{bc} \right) c^b c^c c^d = 0\end{aligned}$$

by the Jacobi identity. There are no higher antifield-number components for this off-shell closed Yang–Mills algebra. Thus $\frac{1}{2}(S_{\min}, S_{\min}) = 0$ is exactly the pair of statements $sS_{\mathrm{YM}} = 0$ and $s^2 A = s^2 c = 0$.

Remark 48.4 (Off-shell closed and open gauge algebras). The preceding construction used a special property of Yang–Mills theory. Let Φ^i denote the classical fields, let

$$E_i(\Phi) := \frac{\delta S_0}{\delta \Phi^i}$$

be the Euler–Lagrange derivative of the classical gauge-invariant action, and write an infinitesimal gauge variation as

$$\delta_\epsilon \Phi^i = R^i{}_\alpha(\Phi) \epsilon^\alpha.$$

Here i and α are condensed indices, including spacetime position and possible derivatives acting on the gauge parameter. The algebra is off-shell closed when the commutator of gauge vector fields satisfies an identity on field space,

$$R^j{}_\beta \frac{\delta R^i{}_\alpha}{\delta \Phi^j} - R^j{}_\alpha \frac{\delta R^i{}_\beta}{\delta \Phi^j} = R^i{}_\gamma C^\gamma{}_{\alpha\beta}(\Phi), \tag{48.7}$$

with no use of $E_i = 0$. Yang–Mills theory has $C^\gamma{}_{\alpha\beta} = f^\gamma{}_{\alpha\beta}$, in the local Lie-algebra notation of the BRST chapter. Then the minimal action is linear in antifields, apart from the ghost antifield term encoding (48.7), and the master equation is precisely the gauge-invariance and Jacobi-identity calculation displayed above.

An open algebra closes only modulo the equations of motion. For bosonic gauge parameters and bosonic fields, the corresponding commutator identity is

$$R^j{}_\beta \frac{\delta R^i{}_\alpha}{\delta \Phi^j} - R^j{}_\alpha \frac{\delta R^i{}_\beta}{\delta \Phi^j} = R^i{}_\gamma C^\gamma{}_{\alpha\beta}(\Phi) + M^{ij}{}_{\alpha\beta}(\Phi) E_j(\Phi), \tag{48.8}$$

with the standard Koszul signs inserted in theories with fermionic fields or fermionic gauge parameters. The coefficient $M^{ij}{}_{\alpha\beta}$ is graded antisymmetric in the pair (i, j) in the sense required by the Noether identities. If one couples antifields only linearly to the naive BRST variations, the antibracket $\frac{1}{2}(S, S)$ contains a term proportional to $\Phi^*_i M^{ij}{}_{\alpha\beta} E_j c^\alpha c^\beta$. This is zero after imposing the classical equations of motion, but it is not zero as an identity on the field algebra. The BV solution cancels it by adding higher antifield-number terms. In the same ungraded sign convention, the first such term is a quadratic antifield term of the form

$$\frac{1}{4} \int \Phi^*_i \Phi^*_j M^{ij}{}_{\alpha\beta}(\Phi) c^\alpha c^\beta,$$

with signs fixed by the parity convention. Further terms are then fixed recursively by the single equation $\frac{1}{2}(S_{\mathrm{BV}}, S_{\mathrm{BV}}) = 0$. Thus BV constructs, in open algebras, an off-shell nilpotent differential on the extended field-antifield algebra.

Reducible symmetries require additional ghosts. If

$$R^i{}_\alpha Z^\alpha{}_{a_1} = 0$$

identically, or modulo the equations of motion, then the gauge parameters themselves have gauge redundancies, and one introduces ghosts-for-ghosts together with their antifields. Standard examples where the BV framework is structural rather than optional include supergravity theories without a complete off-shell auxiliary-field formulation, type-II superstring field theory, and the Poisson sigma model. The elementary Faddeev–Popov/BRST construction in the preceding chapter concerns the off-shell closed Yang–Mills case.

48.7 Nonminimal Sector and Gauge Fixing

Gauge fixing is implemented by adding a contractible nonminimal pair and then choosing a Lagrangian submanifold in the BV field-antifield space. The cohomological content is carried by the same BV differential.

For Yang–Mills theory the nonminimal pair is $(\bar{c}^a, B^a)$, with

$$s\bar{c}^a = B^a, \qquad sB^a = 0.$$

The nonminimal BV term is

$$S_{\mathrm{nm}} = \int_M \bar{c}^*_a B^a \, \mathrm{d}^D x.$$

The total classical BV action is

$$S_{\mathrm{BV}} = S_{\mathrm{min}} + S_{\mathrm{nm}}.$$

In a gauge-fixed BV functional integral the variables $\bar{c}^a$ and B^a belong to the nonminimal integration sector. The field B^a is an even auxiliary integration variable, not an external source. Its purpose is to make the nonminimal BRST pair off-shell contractible and to write the gauge-fixing term before completing the square.

Definition 48.5 (Gauge-fixing fermion)**.** A gauge-fixing fermion is an odd functional $\Psi[\Phi]$ of ghost number -1 depending only on the fields. It determines the Lagrangian submanifold

$$\Phi^*_A = \frac{\delta^L \Psi}{\delta \Phi^A}. \tag{48.9}$$

The gauge-fixed action is the restriction

$$S_\Psi[\Phi] = S_{\mathrm{BV}} \left[\Phi, \Phi^* = \frac{\delta^L \Psi}{\delta \Phi} \right].$$

For covariant Yang–Mills gauges,

$$\Psi = \int_M \bar{c}^a \left(\partial^\mu A^a_\mu + \frac{g^2_{\mathrm{YM}} \xi}{2} B^a \right) \mathrm{d}^D x.$$

Substituting (48.9) into S_{BV}, and integrating by parts with the same boundary convention as in the BRST chapter, gives

$$S_\Psi = S_{\mathrm{YM}} + \int_M \left[B^a \partial^\mu A^a_\mu + \frac{g^2_{\mathrm{YM}}\xi}{2} B^a B^a - \bar{c}^a \partial^\mu D^{ab}_\mu(A) c^b \right] \mathrm{d}^D x.$$

Thus the Faddeev–Popov action is the restriction of the BV action to a gauge-fixing Lagrangian submanifold. At fixed regulator, the subsequent integration over B is Gaussian:

$$\int [DB] \, \exp\left\{ \mathrm{i} \int_M \left[B^a \partial^\mu A^a_\mu + \frac{g^2_{\mathrm{YM}}\xi}{2} B^a B^a \right] \mathrm{d}^D x \right\} = \mathcal{N}_B(\xi) \, \exp\left\{ -\frac{\mathrm{i}}{2 g^2_{\mathrm{YM}}\xi} \int_M (\partial^\mu A^a_\mu)^2 \, \mathrm{d}^D x \right\}.$$

After this auxiliary integral is performed, B is no longer a remaining field variable in the gauge-fixed path integral; retaining it instead is an equivalent first-order presentation of the same regularized Gaussian factor. Different gauge choices correspond to different Lagrangian submanifolds. They define equivalent physical cohomology when the BV integral has no boundary contribution and the quantum master equation is preserved.

Figure 48.1 displays the geometric content of these formulae. The BV space is an odd symplectic supermanifold with Darboux coordinates (Φ^A, Φ^*_A). A gauge-fixing fermion does not add a new dynamical variable; it chooses a Lagrangian submanifold on which the antifields are functions of the fields.

BV field–antifield geometry and gauge fixing

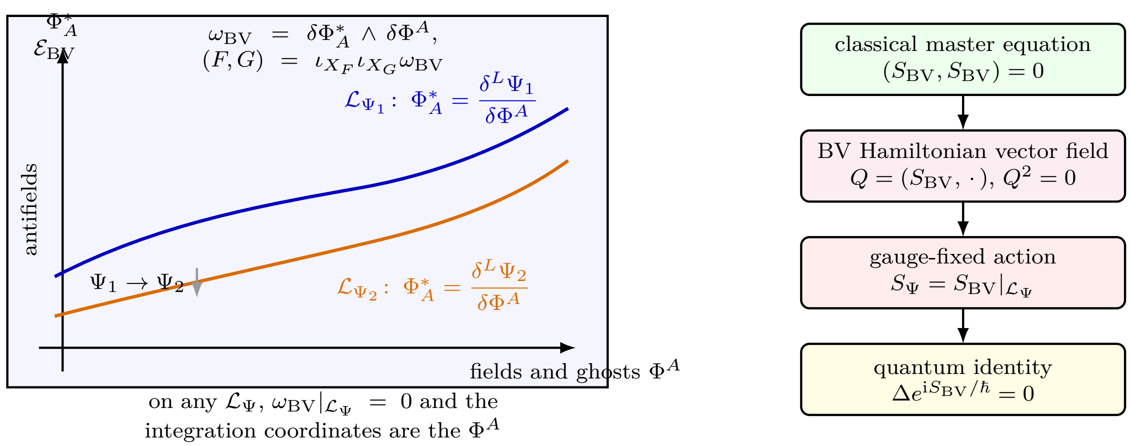

Figure 48.1: The BV antibracket is the Poisson bracket associated with the odd symplectic form on field–antifield space. A gauge-fixing fermion Ψ specifies the Lagrangian submanifold $\Phi^*_A = \delta^L \Psi / \delta \Phi^A$; restricting S_{BV} to this submanifold gives the gauge-fixed action.

48.8 Half-Densities and the BV Integration Measure

The phrase "the BV measure" has a precise finite-dimensional meaning. Let $\mathcal{E}$ be the finite-dimensional supermanifold of fields and antifields at a fixed regulator, equipped with the odd symplectic form

$$\omega = \delta\Phi^*_A \, \delta\Phi^A$$

in Darboux coordinates. A density on a supermanifold is a section of the Berezinian line $\mathrm{Ber}(\mathcal{E})$. A half-density is a section of $\mathrm{Ber}(\mathcal{E})^{1/2}$. In a coordinate system $z^I = (\Phi^A, \Phi^*_A)$, a half-density is written

$$\sigma = f(z)\,|Dz|^{1/2},$$

where f transforms by the square root of the Berezinian of the coordinate change. This transformation law is exactly what makes the restriction of σ to a Lagrangian submanifold into an ordinary Berezin density on that submanifold.

Definition 48.6 (Canonical BV operator on half-densities)**.** On an odd symplectic supermanifold $(\mathcal{E}, \omega)$, the canonical BV operator on half-densities is the odd second-order operator $\Delta_{1/2}$ defined in every Darboux chart by

$$\Delta_{1/2}\Big(f\,|D\Phi\,D\Phi^*|^{1/2}\Big) = \left[\sum_A (-1)^{\epsilon_A} \frac{\partial^R}{\partial \Phi^A} \frac{\partial^R f}{\partial \Phi^*_A}\right] |D\Phi\,D\Phi^*|^{1/2}. \tag{48.10}$$

The expression is invariant under odd-symplectic coordinate changes and $\Delta_{1/2}^2 = 0$. This is the finite-dimensional Khudaverdian semidensity operator; the displayed Darboux formula is the local expression used by perturbative regulators.

Definition 48.7 (Normal BV half-density data)**.** A finite-dimensional quantum BV regulator contains, in addition to $(\mathcal{E}, \omega)$, an even nowhere-vanishing reference half-density σ_0. It is called normal when

$$\Delta_{1/2}\sigma_0 = 0.$$

For normal half-density data, the BV Laplacian on functions is the divergence operator

$$\Delta_{\sigma_0} F := \sigma_0^{-1} \Delta_{1/2}(F\sigma_0). \tag{48.11}$$

In a Darboux chart in which $\sigma_0 = |D\Phi\,D\Phi^*|^{1/2}$, this becomes

$$\Delta_{\sigma_0} = \sum_A (-1)^{\epsilon_A} \frac{\partial^R}{\partial \Phi^A} \frac{\partial^R}{\partial \Phi^*_A}. \tag{48.12}$$

The square σ_0^2 is the corresponding Berezinian density. If a chosen regulator supplies a reference half-density with $\Delta_{1/2}\sigma_0 \neq 0$, its logarithmic defect is an additional local measure term; the symbol Δ_{BV} in this chapter denotes the function operator Δ_{σ_0} only after normal half-density data have been chosen. In Schwarz's geometric terminology, the pair consisting of the odd symplectic structure and these compatible volume/half-density data forms the finite-dimensional measure structure behind BV quantization.

Proposition 48.8 (Restriction to Lagrangians and BV Stokes)**.** *Let $L \subset \mathcal{E}$ be a Lagrangian submanifold with embedding ι_L. Every half-density σ on $\mathcal{E}$ determines a Berezin density $\iota_L^*\sigma$ on L. In a Darboux chart adapted to L, so that L is given by $\Phi^*_A = 0$,*

$$\iota_L^*\Big(f(\Phi, \Phi^*)\,|D\Phi\,D\Phi^*|^{1/2}\Big) = f(\Phi, 0)\,|D\Phi|.$$

If η is a compactly supported half-density, or if the chosen integration cycle has boundary behavior that kills total derivatives, then

$$\int_L \iota_L^*(\Delta_{1/2}\eta) = 0. \tag{48.13}$$

Proof. In an adapted Darboux chart the coordinates on the Lagrangian are the Φ^A's, and setting $\Phi^*_A = 0$ leaves the Berezin density

$$f(\Phi, 0)|D\Phi|.$$

Consider another adapted Darboux chart $(\widehat{\Phi}, \widehat{\Phi}^*)$. On L, the transformation has the block form

$$\widehat{\Phi} = \widehat{\Phi}(\Phi), \qquad \widehat{\Phi}^* = \left(\frac{\partial \Phi}{\partial \widehat{\Phi}}\right) \Phi^* + O((\Phi^*)^2),$$

with the displayed linear term forced by preservation of the odd symplectic form. Therefore the Berezinian of the full adapted transformation restricts to the square of the Berezinian of the induced transformation on L. The half-density transformation law on $\mathcal{E}$ consequently becomes exactly the Berezin-density transformation law on L. The local prescription thus glues to an intrinsic density $\iota_L^* \sigma$.

For the Stokes statement, write $\eta = h(\Phi, \Phi^*)|D\Phi\, D\Phi^*|^{1/2}$ in an adapted chart. Restricting $\Delta_{1/2}\eta$ to L gives

$$\sum_A (-1)^{\epsilon_A} \frac{\partial^R}{\partial \Phi^A} \left.\frac{\partial^R h}{\partial \Phi^*_A}\right|_{\Phi^*=0} |D\Phi|,$$

because the Darboux expression for $\Delta_{1/2}$ differentiates once in a field direction and once in its antifield partner. The displayed density is the divergence, on L, of the compactly supported Berezin vector-density whose A-component is

$$(-1)^{\epsilon_A} \left.\frac{\partial^R h}{\partial \Phi^*_A}\right|_{\Phi^*=0} |D\Phi|.$$

Its integral vanishes by the ordinary Berezin-Stokes theorem under the stated compact-support or boundary-decay hypothesis. A finite partition of unity by adapted Darboux charts gives the finite-dimensional statement for an arbitrary Lagrangian. □

48.9 The Quantum Master Equation

The classical master equation controls the algebra of gauge symmetry. The quantum functional integral also depends on the half-density data just defined. In field theory the operator Δ_{σ_0} requires a regulator because the two functional derivatives act at the same point. A quantum BV problem therefore specifies the regularized odd symplectic space, the normal reference half-density σ_0, and the action.

Definition 48.9 (Quantum master equation)**.** For Lorentzian weight $\exp(\mathrm{i}S/\hbar)$, the BV integrand is the half-density

$$\sigma_S := \exp(\mathrm{i}S/\hbar)\, \sigma_0.$$

The quantum master equation is the intrinsic condition

$$\Delta_{1/2}\sigma_S = 0. \tag{48.14}$$

When σ_0 is normal, (48.14) is equivalent to

$$\frac{1}{2}(S, S) - \mathrm{i}\hbar\, \Delta_{\sigma_0} S = 0. \tag{48.15}$$

Equivalently,

$$\Delta_{\sigma_0} \exp(\mathrm{i}S/\hbar) = 0.$$

Component form of the quantum master equation. For normal BV half-density data and an even action S,

$$\Delta_{\sigma_0} \exp(\mathrm{i}S/\hbar) = 0$$

is equivalent to

$$\frac{1}{2}(S, S) - \mathrm{i}\hbar\, \Delta_{\sigma_0} S = 0.$$

In Darboux coordinates with normal reference half-density, the BV Laplacian is an odd second-order operator. For homogeneous functions F, G, its failure to be a derivation is the antibracket:

$$\Delta_{\sigma_0}(FG) = (\Delta_{\sigma_0} F)G + (-1)^{|F|} F \Delta_{\sigma_0} G + (-1)^{|F|}(F, G). \tag{48.16}$$

This identity follows by applying (48.12) to the product FG and collecting the two terms in which one derivative hits each factor. Since S is even, induction using (48.16) gives

$$\Delta_{\sigma_0} S^n = nS^{n-1}\Delta_{\sigma_0} S + \frac{n(n-1)}{2} S^{n-2}(S, S). \tag{48.17}$$

Expanding the exponential and summing the power series yields

$$\Delta_{\sigma_0} \mathrm{e}^{\mathrm{i}S/\hbar} = \left[\frac{\mathrm{i}}{\hbar}\Delta_{\sigma_0} S - \frac{1}{2\hbar^2}(S, S)\right] \mathrm{e}^{\mathrm{i}S/\hbar}.$$

The exponential factor is invertible as a formal power series, so the vanishing of the left hand side is equivalent to the displayed component equation.

The half-density form is the coordinate-free statement. Gauge independence is then a version of Proposition 48.8: changing the gauge-fixing Lagrangian submanifold changes the integral by the integral of a $\Delta_{1/2}$-exact half-density, provided no boundary contribution is present.

Definition 48.10 (Gauge-fixed Wilsonian BV consistency)**.** At cutoff Λ, a gauge-fixed Wilsonian path integral is BV-consistent when it is obtained by restricting a BV half-density

$$\sigma_\Lambda = \exp(\mathrm{i}S_\Lambda/\hbar)\sigma_{0,\Lambda}$$

to a gauge-fixing Lagrangian submanifold $\mathcal{L}_{\Psi,\Lambda} \subset \mathcal{E}_\Lambda$, with

$$\Delta_{1/2,\Lambda}\sigma_\Lambda = 0.$$

Equivalently, for normal $\sigma_{0,\Lambda}$, the cutoff action satisfies

$$\frac{1}{2}(S_\Lambda, S_\Lambda)_\Lambda - \mathrm{i}\hbar\, \Delta_{\sigma_{0,\Lambda}} S_\Lambda = 0.$$

The gauge-fixed source functional is the restriction

$$Z_{\Lambda,\Psi}[J] = \int_{\mathcal{L}_{\Psi,\Lambda}} \iota^*_{\Psi,\Lambda} \left[\exp\left\{\frac{\mathrm{i}}{\hbar}\left(S_\Lambda + \langle J, \Phi\rangle\right)\right\}\sigma_{0,\Lambda}\right].$$

The definition identifies the master equation as the gauge-consistency condition for the gauge-fixed Wilsonian integral. The gauge condition Ψ selects a Lagrangian submanifold for computation; the equation lives on the field-antifield space before this restriction. Differentiating the restricted integral and applying BV Stokes gives the cutoff Slavnov–Taylor identities. Changing Ψ changes the representative of the same BV half-density integral when the boundary term in (48.13) vanishes. A failure of the displayed master equation is a ghost-number-one anomaly functional, and (48.19) is its Wess–Zumino consistency condition.

If the regulated theory fails to satisfy (48.15), the failure has ghost number +1. To first order in $\hbar$, write

$$\mathcal{M}(S) := \frac{1}{2}(S,S) - \mathrm{i}\hbar\,\Delta_{\sigma_0}S = \hbar\,\mathcal{A} + O(\hbar^2). \tag{48.18}$$

The BV Jacobi identity, the second-order identity for Δ_{σ_0}, and $\Delta_{\sigma_0}^2 = 0$ give the quantum consistency identity

$$(S, \mathcal{M}(S)) - \mathrm{i}\hbar\,\Delta_{\sigma_0}\mathcal{M}(S) = 0. \tag{48.19}$$

Indeed, for even S, $(S, \frac{1}{2}(S,S)) = 0$ and $\Delta_{\sigma_0}(S,S) = 2(\Delta_{\sigma_0}S, S)$, so the two order-$\hbar$ terms in (48.19) cancel. Substituting (48.18) and $S = S_0 + O(\hbar)$ into (48.19) gives

$$0 = \hbar\,(S_0, \mathcal{A}) + O(\hbar^2).$$

Equivalently, with $s_{\mathrm{BV}} := (\cdot, S_0)$,

$$s_{\mathrm{BV}}\mathcal{A} = (\mathcal{A}, S_0) = 0.$$

Changing the local counterterm by $\hbar B$ changes the anomaly by

$$\mathcal{A} \longmapsto \mathcal{A} + s_{\mathrm{BV}}B = \mathcal{A} + (B, S_0). \tag{48.20}$$

Thus the obstruction class lies in ghost-number-one local BV cohomology. This is the antifield version of the anomaly classification by $H^{1,D}(s \mid d)$. In the chiral gauge example of Chapter 51, the representative is the descent cocycle whose bottom component gives the consistent anomaly (51.30); adding a local counterterm changes the representative by an s_{BV}-exact cocycle, matching (48.20).

48.10 The 1PI Master Equation

The antifields are also the natural sources for nonlinear BRST variations in the 1PI formalism. With a gauge-fixing Lagrangian submanifold chosen for the fields, let $\iota_\Psi : \mathcal{L}_\Psi \hookrightarrow \mathcal{E}$ be its embedding and let Φ^*_{ext} denote the antifield coordinates left as external sources after the gauge-fixing canonical transformation. Define

$$Z[J, \Phi^*_{\mathrm{ext}}] = \int_{\mathcal{L}_\Psi} \iota^*_\Psi \left[\exp\left\{ \frac{\mathrm{i}}{\hbar} \left(S_{\mathrm{BV}}[\Phi, \Phi^*_{\mathrm{ext}}] + \int J_A \Phi^A \right) \right\} \sigma_0 \right].$$

In an adapted finite-regulator chart this is the compact formula with

$$D_{\sigma_0,\Psi}\Phi := \iota^*_\Psi \sigma_0$$

in place of the undefined symbol $[D\Phi]$. The external antifields are not integrated; they record the response to BRST variations. Let $W[J, \Phi^*_{\mathrm{ext}}]$ be the connected generator and let

$$\varphi^A = \frac{\delta W}{\delta J_A}, \qquad \Gamma[\varphi, \Phi^*_{\mathrm{ext}}] = W[J, \Phi^*_{\mathrm{ext}}] - \int J_A \varphi^A$$

be the 1PI effective action in the Lorentzian convention used earlier.

Assume that the regularized half-density integrand obeys the quantum master equation at $J = 0$ and that the Legendre transform is well defined on the field directions under consideration. The Ward identity obtained by applying $\Delta_{1/2}$ to the source-dependent integrand and then using BV Stokes gives

$$\int \frac{\delta^R \Gamma}{\delta \varphi^A} \frac{\delta^L \Gamma}{\delta \Phi^*_{\text{ext,A}}} \mathrm{d}^D x = 0.$$

Equivalently,

$$\frac{1}{2}(\Gamma, \Gamma) = 0, \tag{48.21}$$

where the bracket now pairs the mean field φ^A with the antifield $\Phi^*_{\text{ext,A}}$. In the Yang–Mills variables of the preceding chapter, (48.21) is the Slavnov–Taylor identity (47.44), with A^* and c^* replacing the special sources K and L, and with the nonminimal term producing $B\, \delta\Gamma/\delta\bar{c}$. The all-order restoration theorem 47.16 is therefore the gauge-fixed Yang–Mills form of the perturbative BV statement: when the local ghost-number-one obstruction class vanishes, counterterms may be chosen so that the renormalized 1PI functional satisfies (48.21) as a formal power series in $\hbar$. The ghost-number-zero BV cohomology records the remaining finite coordinate freedom.

48.11 Wilsonian BV Pushforward

The Wilsonian effective action is obtained by integrating out degrees of freedom above a scale. BV gives the condition under which this operation is compatible with gauge symmetry.

The input is more than a momentum cutoff. A gauge-compatible Wilsonian step contains a finite-dimensional or regularized BV phase space $(\mathcal{E}_\Lambda, \omega_\Lambda)$, a normal half-density $\sigma_{0,\Lambda}$, a solution S_Λ of the quantum master equation, a split into low and high BV variables, and a Lagrangian cycle for the high variables. Equivalently, in a lattice formulation it contains a finite lattice gauge integral and a gauge-invariant blocking map for observables or actions. These data are what make the phrase "integrating out gauge-field modes" a defined operation.

For a gauge-fixed Wilsonian path integral, the flow between cutoffs preserves Definition 48.10. In BV terms this means that the high-variable integration is a BV pushforward of the cutoff half-density. The resulting low-cutoff half-density again satisfies the quantum master equation, and every gauge-fixed representative obtained from it satisfies the corresponding cutoff Slavnov–Taylor identities.

Consider first a finite-dimensional odd symplectic vector space split as

$$\mathcal{E} = \mathcal{E}_{\text{low}} \oplus \mathcal{E}_{\text{high}}, \qquad \Delta_{1/2,\mathcal{E}} = \Delta_{1/2,\text{low}} + \Delta_{1/2,\text{high}}.$$

Assume the normal half-density factorizes compatibly as

$$\sigma_0 = \sigma_{0,\text{low}} \otimes \sigma_{0,\text{high}}.$$

Let $\mathcal{L}_{\text{high}} \subset \mathcal{E}_{\text{high}}$ be a Lagrangian subspace used to integrate out the high variables. Define the effective low-energy half-density by

$$\exp(\mathrm{i}S_{\text{eff}}/\hbar)\, \sigma_{0,\text{low}} = \int_{\mathcal{L}_{\text{high}}} \iota^*_{\text{high}} \left[\exp(\mathrm{i}S/\hbar)\, \sigma_0\right]. \tag{48.22}$$

Proposition 48.11 (BV pushforward)**.** *Assume*

$$\Delta_{1/2,\mathcal{E}}\left(\exp(\mathrm{i}S/\hbar)\sigma_0\right) = 0$$

and assume the integral over $\mathcal{L}_{\mathrm{high}}$ *has no boundary contribution for* $\Delta_{1/2,\mathrm{high}}$. *Then*

$$\Delta_{1/2,\mathrm{low}}\left(\exp(\mathrm{i}S_{\mathrm{eff}}/\hbar)\sigma_{0,\mathrm{low}}\right) = 0.$$

Proof. The split of the odd symplectic vector space and the compatible factorization of the reference half-density identify a full semidensity with a family of high-variable semidensities parametrized by the low fields. Since $\Delta_{1/2,\mathrm{low}}$ differentiates only the low coordinates and the fiber integral is assumed convergent, it may be passed through the high integration:

$$\begin{aligned}\Delta_{1/2,\mathrm{low}}\left(\exp(\mathrm{i}S_{\mathrm{eff}}/\hbar)\sigma_{0,\mathrm{low}}\right) &= \int_{\mathcal{L}_{\mathrm{high}}} \iota^*_{\mathrm{high}}\left[\Delta_{1/2,\mathrm{low}}\left(\exp(\mathrm{i}S/\hbar)\sigma_0\right)\right] \\ &= -\int_{\mathcal{L}_{\mathrm{high}}} \iota^*_{\mathrm{high}}\left[\Delta_{1/2,\mathrm{high}}\left(\exp(\mathrm{i}S/\hbar)\sigma_0\right)\right] = 0.\end{aligned}$$

The second equality uses the full QME and the compatible split $\Delta_{1/2,\mathcal{E}} = \Delta_{1/2,\mathrm{low}} + \Delta_{1/2,\mathrm{high}}$. The last equality is Proposition 48.8 applied to the high Lagrangian integration cycle, together with the explicit no-boundary hypothesis. Thus QME preservation is a chain-map statement for the BV pushforward; if the high cycle has a boundary contribution, the pushforward satisfies the anomalous boundary formula developed later rather than the homogeneous QME. □

This proposition is the regulated mathematical core of the Wilsonian BV identity. In a field theory with cutoff Λ, the Wilsonian action S_Λ is a scale-dependent local or quasi-local representative of the BV pushforward. Its master equation has the form

$$\frac{1}{2}(S_\Lambda, S_\Lambda)_\Lambda - \mathrm{i}\hbar\,\Delta_\Lambda S_\Lambda = 0,$$

where the bracket and Laplacian include the cutoff covariance and the remaining low-mode half-density. Exact RG flow is compatible with gauge symmetry when it preserves this equation. Changes of cutoff scheme are then BV canonical transformations together with possible local counterterm changes, with the gauge symmetry encoded by the transformed master action.

The lattice route gives a second gauge-compatible Wilsonian construction. A finite blocking map sends link variables on a fine lattice to link variables or gauge-invariant observables on a coarser lattice, and the pushforward of the compact Haar integral defines the coarse action or coarse observable law. The continuum Wilsonian statement then concerns a scaling limit of these finite lattice pushforwards. A comparison between the lattice and BV descriptions must identify the gauge-invariant observables, the local BV cohomology classes, and the limiting topology for correlation functions or effective-action coordinates.

48.12 Infinitesimal Exact RG in BV Form

The finite pushforward above is the primary definition. A differential renormalization-group equation is obtained from a differentiable family of finite pushforwards or from an infinitesimal change of regulator. The following finite-regulator statement records exactly what must be preserved.

Definition 48.12 (BV-compatible infinitesimal RG step)**.** Let $(\mathcal{E}, \omega, \sigma_0)$ be a finite-dimensional odd symplectic space with normal half-density data and let

$$\rho_t = \exp(\mathrm{i}S_t/\hbar)\sigma_0$$

be an even family of half-densities. An infinitesimal RG step is BV-compatible if there is an odd ghost-number -1 function R_t such that

$$\partial_t \rho_t = \Delta_{1/2}(R_t \rho_t). \tag{48.23}$$

The function R_t is part of the scheme data. It encodes the infinitesimal change of covariance, splitting, or gauge-fixing cycle after the regulator has made these words finite.

Infinitesimal BV-compatible RG identity. The condition in Definition 48.12 is the substantive hypothesis: it says that the velocity of the regulated half-density is $\Delta_{1/2}$-exact. Once this has been established by a finite cutoff construction, preservation of the quantum master equation is the cohomological tangent identity

$$\partial_t(\Delta_{1/2}\rho_t) = \Delta_{1/2}^2(R_t \rho_t) = 0.$$

Hence, if $\Delta_{1/2}\rho_{t_0} = 0$ at one value t_0, then $\Delta_{1/2}\rho_t = 0$ throughout the same interval, provided the same normal half-density data are used.

The action-coordinate form is a bookkeeping consequence of the same finite-regulator identity. Write $\rho_t = \mathrm{e}^{\mathrm{i}S_t/\hbar}\sigma_0$, use the function Laplacian induced by the normal half-density, and use that R_t is odd. The second-order identity gives

$$\Delta_{\sigma_0}(R_t \mathrm{e}^{\mathrm{i}S_t/\hbar}) = (\Delta_{\sigma_0} R_t)\mathrm{e}^{\mathrm{i}S_t/\hbar} - (R_t, \mathrm{e}^{\mathrm{i}S_t/\hbar}).$$

The bracket term is

$$(R_t, \mathrm{e}^{\mathrm{i}S_t/\hbar}) = \frac{\mathrm{i}}{\hbar}(R_t, S_t)\mathrm{e}^{\mathrm{i}S_t/\hbar} = -\frac{\mathrm{i}}{\hbar}(S_t, R_t)\mathrm{e}^{\mathrm{i}S_t/\hbar},$$

because S_t is even. Dividing

$$\partial_t \mathrm{e}^{\mathrm{i}S_t/\hbar} = \Delta_{\sigma_0}(R_t \mathrm{e}^{\mathrm{i}S_t/\hbar})$$

by $\mathrm{e}^{\mathrm{i}S_t/\hbar}$ and multiplying by $\hbar/\mathrm{i}$ gives

$$\partial_t S_t = (S_t, R_t) - \mathrm{i}\hbar\, \Delta_{\sigma_0} R_t. \tag{48.24}$$

The equation is a quantum canonical flow, not an arbitrary beta-function ansatz. It is the differential version of BV pushforward: the right hand side is $\Delta_{1/2}$-exact on half-densities, so it cannot create a master equation defect. A cutoff flow proposed for a gauge theory is therefore gauge-compatible only after its regulator supplies R_t, the odd symplectic structure, the half-density data, and the boundary condition making the finite pushforward or the differential equation legitimate.

48.13 Counterterms, Anomalies, and Physical Operators

Let S_{BV} be a classical solution of the master equation and let

$$s_{\mathrm{BV}} = (\cdot, S_{\mathrm{BV}}).$$

A first-order local deformation

$$S_{\mathrm{BV}} \longmapsto S_{\mathrm{BV}} + \epsilon C$$

preserves the classical master equation to order ϵ precisely when

$$s_{\mathrm{BV}} C = 0, \qquad \mathrm{gh}(C) = 0.$$

If $C = s_{\mathrm{BV}} B$, then the deformation is generated by a BV canonical transformation and does not change the physical theory. Thus invariant counterterms are classified by ghost-number-zero BV cohomology of local functionals, modulo total derivatives and canonical redefinitions.

An anomaly candidate is a ghost-number-one functional $\mathcal{A}$ satisfying

$$s_{\mathrm{BV}} \mathcal{A} = 0.$$

It is removable by a local counterterm exactly when

$$\mathcal{A} = s_{\mathrm{BV}} B.$$

This gives the precise cohomological meaning of anomaly cancellation in the perturbative BV framework: the obstruction class must vanish in the relevant local BV cohomology.

Physical local operators are treated in the same language. An insertion $\mathcal{O}$ is compatible with the gauge symmetry when

$$s_{\mathrm{BV}} \mathcal{O} = 0, \qquad \mathrm{gh}(\mathcal{O}) = 0,$$

and two insertions differing by $s_{\mathrm{BV}} \mathcal{X}$ define the same cohomology class. After gauge fixing, this statement reduces to the BRST cohomology of local observables described in the preceding chapter. Before gauge fixing, it is expressed without choosing a particular gauge slice.

48.14 BV–BRST Equivalence for Gauge-Fixed Yang–Mills

The gauge-fixed BRST complex used in the preceding chapter is obtained from the BV complex by two homological operations: a BV canonical transformation generated by the gauge-fixing fermion, and deletion of contractible nonminimal pairs. The next theorem states the equivalence in the form needed for perturbative Yang–Mills with matter.

Theorem 48.13 (Local BV–BRST comparison for Yang–Mills)**.** *Let G be compact and reductive, and let the classical Yang–Mills–matter action use the trace and coupling convention of Chapter 45,*

$$S_{\mathrm{YM}} = \frac{1}{4g_{\mathrm{YM}}^2} \int \mathrm{tr}(F_{\mu\nu} F^{\mu\nu}) + S_{\mathrm{matter}}.$$

Assume the perturbative local jet algebra is taken near a background for which the Koszul–Tate differential is acyclic in positive antifield number for the fields under consideration, and assume boundary conditions that make local functionals modulo total derivatives the correct cochain space. Then:

1. *The canonical BV transformation generated by a gauge-fixing fermion Ψ preserves the antibracket and the classical master equation.*

2. *Restriction to the Lagrangian submanifold $\Phi^* = \delta^L\Psi/\delta\Phi$ gives the gauge-fixed BRST differential on fields, with the nonminimal pair $s\bar{c} = B$, $sB = 0$.*

3. *The inclusion of antifield-independent representatives induces an isomorphism, for nonnegative ghost number, between local BV cohomology modulo* d *and gauge-fixed BRST cohomology modulo* d, *after quotienting the contractible pair $(\bar{c}, B)$:*

$$H^{g,D}(s_{\mathrm{BV}} \mid \mathrm{d}) \cong H^{g,D}(s_\Psi \mid \mathrm{d}), \qquad g \geq 0.$$

The isomorphism identifies counterterm classes, anomaly classes, and gauge-invariant local operator classes.

Proof. The finite-regulator BV phase space has Darboux coordinates (Φ^A, Φ^*_A). The gauge-fixing fermion generates the canonical change of variables

$$\Phi^A_\Psi = \Phi^A, \qquad \Phi^*_{\Psi,A} = \Phi^*_A - \frac{\delta^L\Psi}{\delta\Phi^A}.$$

It is canonical because

$$\delta\Phi^*_{\Psi,A}\,\delta\Phi^A_\Psi = \delta\Phi^*_A\,\delta\Phi^A - \delta\left(\frac{\delta^L\Psi}{\delta\Phi^A}\right)\delta\Phi^A,$$

and the second term is the odd-symplectic differential of the exact one-form generated by Ψ; its antisymmetrized second variation vanishes. Hence the antibracket is unchanged, and $(S_{\mathrm{BV}}, S_{\mathrm{BV}}) = 0$ is equivalent to the same equation in the transformed coordinates. Setting $\Phi^*_\Psi = 0$ is precisely the Lagrangian restriction $\Phi^* = \delta^L\Psi/\delta\Phi$.

On antifield-independent functions of the fields, the Hamiltonian vector field $(\,\cdot\,, S_{\mathrm{BV}})$ restricted to this Lagrangian is the gauge-fixed BRST variation. For Yang–Mills the displayed minimal action gives $sA = Dc$, $sc = -\frac{1}{2}[c, c]$, and the nonminimal term gives $s\bar{c} = B$, $sB = 0$. The proof of the classical master equation above therefore gives $s_\Psi^2 = 0$ before eliminating B.

It remains to compare cohomology. Filter the BV local functional complex by antifield number. The antifield-number -1 piece of s_{BV} is the Koszul–Tate differential δ_{KT}, with $\delta_{\mathrm{KT}}\Phi^*_i = E_i$ and $\delta_{\mathrm{KT}} c^*_\alpha = R^i{}_\alpha \Phi^*_i$. By the stated regularity hypothesis, δ_{KT} has no cohomology in positive antifield number. Therefore the spectral sequence of the antifield-number filtration collapses to representatives of antifield number zero for $g \geq 0$, modulo the gauge variation induced by the longitudinal BRST part.

The nonminimal pair is contractible. Let N_{nm} count the number of $\bar{c}$, B, and their derivatives in a local monomial, and let

$$h_{\mathrm{nm}} = \sum_{|\alpha| \geq 0} \partial_\alpha \bar{c}^a \frac{\partial^L}{\partial(\partial_\alpha B^a)}.$$

On the subalgebra generated by the nonminimal pair and its derivatives,

$$s h_{\mathrm{nm}} + h_{\mathrm{nm}} s = N_{\mathrm{nm}}.$$

If a cocycle has $N_{\mathrm{nm}} > 0$, division by this positive integer writes that component as an s-exact term. Hence the nonminimal sector contributes no cohomology. Combining this doublet contraction with the Koszul–Tate acyclicity gives the displayed isomorphism. $\square$

48.15 Local Cohomology Classification for Yang–Mills With Matter

The comparison theorem turns the abstract statement "a BV class" into a computable local object. In four-dimensional power-counting-renormalizable Yang–Mills with scalars and spinors in finite-dimensional unitary representations, the local classes used by perturbation theory have the following concrete representatives.

Proposition 48.14 (Renormalizable ghost-number-zero representatives)**.** *Under the hypotheses of Theorem 48.13, every ghost-number-zero counterterm density of engineering dimension at most four is cohomologous, modulo total derivatives and field redefinitions, to a gauge invariant density built from covariant fields:*

$$F_{\mu\nu}, \qquad D_\mu, \qquad \psi, \bar{\psi}, \qquad \phi,$$

with all gauge indices contracted by invariant tensors of the representation. For the pure gauge sector this gives

$$\frac{1}{4}\operatorname{tr}(F_{\mu\nu}F^{\mu\nu}), \qquad \frac{1}{4}\operatorname{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu})$$

in the monograph trace convention $\operatorname{tr}_\square(t^a t^b) = \delta^{ab}$*. With matter, the same list includes covariant kinetic terms, mass terms allowed by the global symmetries, Yukawa couplings, and scalar potential terms whose gauge indices are contracted invariantly. Antifield-dependent ghost-number-zero representatives encode field redefinitions, coupling-coordinate changes, and global-symmetry currents rather than new gauge-invariant interaction densities.*

Proof. Filter the local BV complex by antifield number. The Koszul–Tate differential is the first differential in the associated spectral sequence. By the acyclicity hypothesis in Theorem 48.13, positive antifield number classes in ghost number zero are either killed or represented by the standard Noether-current and field-redefinition classes. The nonminimal pair is a contractible BRST doublet, as shown in the proof of the comparison theorem, so $(\bar{c}, B)$ and their derivatives do not contribute to the cohomology. Thus the interaction-density part of a ghost-number-zero class can be represented by an antifield-independent local polynomial in

$$A_\mu, \quad \psi, \bar{\psi}, \quad \phi$$

and finitely many ordinary derivatives, modulo total derivatives.

On this antifield-independent representative the remaining differential is the longitudinal gauge differential

$$s_{\text{gauge}} A = Dc, \qquad s_{\text{gauge}} X = \mathrm{i} c^a t^a_R X$$

for every matter field X in representation R. Expanding the condition $s_{\text{gauge}} a + \mathrm{d}b = 0$ in powers of the ghost c says that the local density a is invariant under infinitesimal gauge transformations, up to the already-quotiented total derivative. Expand the local polynomial in monomials of covariant jets. Each monomial carries a finite tensor product of gauge representations, and infinitesimal invariance is exactly the statement that the coefficient tensor is fixed by the Lie-algebra action on that finite tensor product. Since G is compact reductive, Lie-algebra invariance integrates to G-invariance on these finite-dimensional representation spaces. Thus the allowed coefficients are precisely invariant tensors of the matter representations and traces of the adjoint curvature representation. Ordinary derivatives of matter fields are replaced recursively by covariant derivatives, and commutators of covariant derivatives give curvature insertions

$$[D_\mu, D_\nu]X = \mathrm{i}F^a_{\mu\nu}t^a_R X.$$

In the pure gauge sector the invariant tensors are traces in representations of G; in the monograph normalization $\mathrm{tr}_\square(t^a t^b) = \delta^{ab}$, the two independent dimension-four Lorentz-scalar densities without matter are the parity-even and parity-odd contractions

$$\mathrm{tr}(F_{\mu\nu}F^{\mu\nu}), \qquad \mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu}).$$

Finally impose the engineering-dimension bound in $D = 4$:

$$[F_{\mu\nu}] = 2, \qquad [D_\mu] = 1, \qquad [\phi] = 1, \qquad [\psi] = [\bar{\psi}] = \frac{3}{2}.$$

The possible covariant monomials of dimension at most four are therefore: gauge kinetic and topological densities; scalar kinetic terms $(D\phi)^2$; Dirac/Weyl kinetic terms; fermion and scalar mass terms allowed by gauge and global symmetries; Yukawa contractions $\phi\psi\psi$ or their complex-conjugate representation-theoretic variants; and invariant scalar polynomials of degree at most four, including possible singlet tadpoles or cubic terms when the representation permits them. All gauge indices must be contracted by invariant tensors. Total derivatives vanish in the relative cohomology $H^{0,4}(s \mid \mathrm{d})$, while BRST-exact ghost-number-zero terms are generated by BV canonical transformations and hence are precisely local field redefinitions or coupling-coordinate changes. This proves the stated list and separates genuine interaction-density coordinates from antifield representatives of redefinitions and currents. □

Proposition 48.15 (Ghost-number-one anomaly calculation)**.** *For a four-dimensional chiral Yang–Mills theory in the same perturbative local setting, a perturbative local gauge-anomaly candidate is represented in*

$$H^{1,4}(s_{\mathrm{BV}} \mid \mathrm{d})$$

by the descent of the six-form invariant polynomial

$$I_6 = \frac{\mathrm{i}}{24\pi^2}\,\mathrm{Tr}_R(\mathsf{F}^3)$$

in the anti-Hermitian background-connection convention of Chapter 51. Its component coefficient is proportional to the symmetric invariant tensor

$$d_R^{abc} := \mathrm{Tr}_R(t^{(a}t^b t^{c)}).$$

If the sum of d_R^{abc} over all left-handed Weyl fermions vanishes for every triple of gauge generators, then the perturbative local gauge anomaly class vanishes. If it does not vanish, no local counterterm restores the quantum master equation in this perturbative local cohomology.

Proof from the QME and descent. Let the loop expansion of the regulated 1PI effective action be

$$\Gamma_\Lambda = S_\Lambda + \sum_{\ell \geq 1} \hbar^\ell \Gamma_{\Lambda,\ell}.$$

Set $\Gamma_{\Lambda,0} = S_\Lambda$. The quantum master defect at the first loop order ℓ_0 where it is nonzero has the local form

$$\mathcal{B}_{\ell_0} = \frac{1}{2}\sum_{\ell_1+\ell_2=\ell_0}(\Gamma_{\Lambda,\ell_1},\Gamma_{\Lambda,\ell_2}) - \mathrm{i}\Delta_\Lambda\Gamma_{\Lambda,\ell_0-1} = \int_M a_4^{(1)},$$

where the BV antibracket has ghost number 1 and the density $a_4^{(1)}$ is a local four-form of ghost number 1. Applying the linearized classical BV differential $s_{\mathrm{BV}} = (S_\Lambda, -)$ to the QME and using the Jacobi identity gives

$$s_{\mathrm{BV}}a_4^{(1)} = \mathrm{d}a_3^{(2)}.$$

Adding a local counterterm $B_4^{(0)}$ to Γ_{Λ,ℓ_0} changes the density by

$$a_4^{(1)} \longmapsto a_4^{(1)} + s_{\mathrm{BV}}B_4^{(0)} + \mathrm{d}B_3^{(1)},$$

so the obstruction to restoring the QME at this order is a class of $H^{1,4}(s_{\mathrm{BV}} \mid \mathrm{d})$.

For the chiral Yang–Mills field content, the BV–BRST comparison map sends this class to the ordinary consistent gauge-anomaly class described in Chapter 51. In the anti-Hermitian descent convention that chapter uses,

$$I_6 = \frac{\mathrm{i}}{24\pi^2}\sum_i \mathrm{Tr}_{R_i}(\mathsf{F}^3)$$

is closed and gauge invariant, and

$$I_6 = \mathrm{d}I_5^{(0)}, \qquad sI_5^{(0)} = \mathrm{d}I_4^{(1)}$$

produces the representative $I_4^{(1)}$. Since F^a are two-forms, their products commute, and the coefficient multiplying $\mathsf{F}^a\mathsf{F}^b\mathsf{F}^c$ is exactly the symmetric invariant tensor

$$\sum_i d_{R_i}^{abc} = \sum_i \mathrm{Tr}_{R_i}(t^{(a}t^b t^{c)}).$$

The local cohomology theorem identifies these degree-three invariant polynomials with the cubic gauge part of the relative group $H^{1,4}(s_{\mathrm{BV}} \mid \mathrm{d})$. Hence a vanishing total tensor gives the zero class in this sector, while a nonzero total tensor gives a QME defect whose class is invariant under local counterterm changes.

Equation (48.18) and the consistency identity (48.19) show that the first nonzero QME defect is a ghost-number-one s_{BV}-cocycle modulo total derivatives. The BV–BRST comparison theorem identifies this group with the gauge-fixed relative BRST cohomology. The descent construction of Chapter 51 starts from the closed invariant polynomial $\mathrm{Tr}_R(\mathsf{F}^3)$, writes it locally as $\mathrm{d}I_5^{(0)}$, and then applies s to obtain

$$sI_5^{(0)} + \mathrm{d}I_4^{(1)} = 0.$$

The integrated four-form $I_4^{(1)}$ is the consistent anomaly representative. Its cubic group factor is $\mathrm{Tr}_R(t^a\{t^b,t^c\})$, equivalently the symmetric tensor d_R^{abc} after symmetrization over external gauge fields. Adding a local counterterm changes $I_4^{(1)}$ by an s-exact term plus a total derivative, as in (48.20). Therefore the class vanishes exactly when the total symmetric invariant coefficient vanishes in the chosen representation content. □

Remark 48.16 (Scope of the obstruction). The word "anomaly" in Proposition 48.15 refers to the perturbative local obstruction detected by $H^{1,4}(s_{\mathrm{BV}} \mid \mathrm{d})$. Global gauge anomalies, determinant-line topology, and finite background-anomaly phases are different objects; they are treated in Chapter 55 and in the later chapters on invertible field theories and eta invariants.

48.16 Local Quantum Observables as a BV Factorization Algebra

The BV effective-action formalism has a local-observable counterpart. This is the perturbative factorization-algebra language. It is useful here because it states locality at the level of observables rather than only at the level of a single action functional.

Definition 48.17 (Prefactorization algebra of BV observables)**.** Let M be spacetime and let $\mathrm{Open}(M)$ be the category of open subsets. A BV prefactorization algebra assigns to each open $U \subset M$ a cochain complex

$$\mathrm{Obs}_\Lambda(U)$$

of regulated quantum observables supported in U. If $U_1, \ldots, U_n \subset V$ are pairwise disjoint opens, it assigns a cochain map

$$m_{U_1,\ldots,U_n;V} : \mathrm{Obs}_\Lambda(U_1) \otimes \cdots \otimes \mathrm{Obs}_\Lambda(U_n) \longrightarrow \mathrm{Obs}_\Lambda(V),$$

compatible with permutation of the U_i's and with iterated inclusions. It is a factorization algebra when these maps satisfy descent for Weiss covers: observables on V are recovered, up to quasi-isomorphism, from observables on covers by opens that contain every finite subset of V.

For a finite BV regulator at scale Λ, the cochain differential on observables is

$$Q_\Lambda \mathcal{O} := (S_\Lambda, \mathcal{O})_\Lambda - \mathrm{i}\hbar\, \Delta_\Lambda \mathcal{O}. \tag{48.25}$$

The bracket and Laplacian are the regulated ones associated with the same half-density data used in the quantum master equation. The support condition in $\mathrm{Obs}_\Lambda(U)$ means that the kernels of $\mathcal{O}$ are supported in U, with the regulator determining what class of kernels or jets is allowed.

Proposition 48.18 (QME implies the observable differential)**.** *If S_Λ satisfies*

$$\frac{1}{2}(S_\Lambda, S_\Lambda)_\Lambda - \mathrm{i}\hbar\, \Delta_\Lambda S_\Lambda = 0,$$

then $Q_\Lambda^2 = 0$. Moreover the disjoint-support product maps in Definition 48.17 are cochain maps.

Proof. Let $\mathrm{ad}_{S_\Lambda}(\mathcal{O}) = (S_\Lambda, \mathcal{O})_\Lambda$. The regulated odd Laplacian is assumed to be square-zero on the finite regulator algebra, and it generates the regulated antibracket:

$$\Delta_\Lambda (F, G)_\Lambda = (\Delta_\Lambda F, G)_\Lambda - (-1)^{|F|}(F, \Delta_\Lambda G)_\Lambda.$$

Since S_Λ is even, this identity gives

$$\Delta_\Lambda (S_\Lambda, \mathcal{O})_\Lambda + (S_\Lambda, \Delta_\Lambda \mathcal{O})_\Lambda = (\Delta_\Lambda S_\Lambda, \mathcal{O})_\Lambda.$$

The odd Jacobi identity gives

$$\mathrm{ad}_{S_\Lambda}^2 \mathcal{O} = \frac{1}{2}\big((S_\Lambda, S_\Lambda)_\Lambda, \mathcal{O}\big)_\Lambda.$$

Therefore, using $\Delta_\Lambda^2 = 0$,

$$\begin{aligned} Q_\Lambda^2 \mathcal{O} &= \mathrm{ad}_{S_\Lambda}^2 \mathcal{O} - \mathrm{i}\hbar \left[\Delta_\Lambda (S_\Lambda, \mathcal{O})_\Lambda + (S_\Lambda, \Delta_\Lambda \mathcal{O})_\Lambda\right] \\ &= \left(\frac{1}{2}(S_\Lambda, S_\Lambda)_\Lambda - \mathrm{i}\hbar\, \Delta_\Lambda S_\Lambda, \mathcal{O}\right)_\Lambda. \end{aligned}$$

The quantum master equation sets the Hamiltonian in the final bracket to zero, so $Q_\Lambda^2 = 0$.

For disjoint supports, the regulated bracket and Laplacian have no coincident-point contraction between two different factors except the contractions included in the product map. Therefore Q_Λ obeys the graded Leibniz rule with respect to the product of disjoint observables, and the maps $m_{U_1,\dots,U_n;V}$ commute with Q_Λ. □

Changing the cutoff from Λ to Λ' gives a cochain map

$$W_{\Lambda\Lambda'} : \mathrm{Obs}_\Lambda(U) \longrightarrow \mathrm{Obs}_{\Lambda'}(U)$$

when it is produced by BV pushforward with the same boundary and locality data as in Section 48.12. The homotopy-RG content is the statement

$$Q_{\Lambda'} W_{\Lambda\Lambda'} = W_{\Lambda\Lambda'} Q_\Lambda$$

and compatibility of $W_{\Lambda\Lambda'}$ with the disjoint-support products. Thus the factorization-algebra form is the observable-side record of the same BV renormalization problem: local counterterms repair failures of the cochain and product identities precisely when the relevant local BV cohomology class is trivial.

48.17 Logical Output

The output of this chapter is the following framework.

1. A gauge theory is represented on an enlarged graded field space with fields, ghosts, nonminimal variables, and antifields.
2. The antibracket is the odd symplectic pairing between fields and antifields.
3. The classical master equation constructs a nilpotent differential.
4. Gauge fixing is restriction to a Lagrangian submanifold determined by a gauge-fixing fermion.
5. The quantum master equation is the regulated half-density statement of measure-compatible gauge symmetry.
6. The 1PI and Wilsonian effective actions in continuum gauge theory are defined as BV objects satisfying the corresponding master identities; a lattice gauge formulation supplies the alternative finite-cutoff route by compact group integrals and gauge-invariant blocking maps.
7. Counterterms, anomalies, and physical operators are local BV cohomology classes at the appropriate ghost numbers.

This is the framework used below whenever gauge-theory effective actions are discussed beyond elementary Faddeev–Popov perturbation theory.

49.1 QCD as a Renormalized Gauge Theory

Quantum chromodynamics in four dimensions is Yang–Mills theory with gauge group $SU(N_c)$ coupled to N_f Dirac fermions in the fundamental representation. Write the quark fields as

$$q^i_{I\alpha}(x), \qquad i = 1, \ldots, N_c, \quad I = 1, \ldots, N_f,$$

where i is color, I is flavor, and α is a spinor index. We use the Hermitian-generator normalization fixed in Chapter 45, specifically (45.1), (45.12), and (45.16),

$$\mathrm{tr}_\square(t^a t^b) = \delta^{ab}.$$

The group-theoretic constants used in renormalization are defined by

$$f^a{}_{cd} f^b{}_{cd} = C_A \delta^{ab}, \qquad \mathrm{tr}_R(t^a_R t^b_R) = T_R \delta^{ab}, \qquad t^a_R t^a_R = C_R \mathbf{1}_R. \tag{49.1}$$

For $SU(N_c)$,

$$C_A = 2N_c, \qquad T_F = 1, \qquad C_F = \frac{N_c^2 - 1}{N_c}.$$

These are twice the values often quoted with generators T^a normalized by $\mathrm{tr}_\square(T^aT^b) = \frac{1}{2}\delta^{ab}$. The physical matrix-valued connection is unchanged; only the component coordinates and the coupling coordinate are rescaled. In the present convention the gauge action is $-\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$.

The renormalized coupling $g(\mu)$ depends on a scale μ and on the renormalization scheme. The beta function is

$$\beta(g) := \mu\frac{\mathrm{d}g}{\mathrm{d}\mu}.$$

The first coefficient is obtained below from the background-field 1PI effective action. For N_f Dirac fermions in a representation R, in a mass-independent scheme the result is

$$\beta(g) = -\frac{g^3}{16\pi^2}\left(\frac{11}{3}C_A - \frac{4}{3}T_RN_f\right) + O(g^5). \tag{49.2}$$

Equivalently,

$$\beta(g) = -\frac{g^3}{24\pi^2}\,(11N_c - 2N_f) + O(g^5) \tag{49.3}$$

for fundamental quarks in this trace normalization.

49.2 Ordinary Covariant-Gauge Green-Function Rules

The covariant gauge-fixed rules used in ordinary Yang–Mills perturbation theory are rules for time-ordered Green functions of the local variables $A^a_\mu, c^a, \bar{c}^a, q, \bar{q}$. Their physical interpretation is supplied by the BRST cohomology and by gauge-invariant operators, but the local rules themselves are needed for renormalization and for comparing different gauges.

In this section write g for g_{YM}, and use the normalization (45.16),

$$\mathcal{L}_{\mathrm{YM}} = -\frac{1}{4g^2}F^a_{\mu\nu}F^{a\mu\nu}, \qquad F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^a{}_{bc}A^b_\mu A^c_\nu.$$

This is the coupling-absorbed normalization of Chapter 45: $D_\mu = \partial_\mu - \mathrm{i}A_\mu$, and the coupling is the coefficient in front of the curvature term. In the Abelian specialization it is related to the explicit-coupling QED convention by (45.6). Thus the beta function extracted below from the coefficient of $F^a_{\mu\nu}F^{a\mu\nu}/g^2$ is written in Yang–Mills field coordinates; QED wavefunction renormalization constants in Chapter 43 use the explicit-coupling field coordinate and must first be translated by the same rescaling before being compared term by term. The Lorenz gauge condition is

$$F^a(A) = \partial^\mu A^a_\mu.$$

Under the infinitesimal gauge transformation

$$\delta_\zeta A^{a\mu} = \partial^\mu\zeta^a + f^a{}_{bc}A^{b\mu}\zeta^c,$$

the variation of $F^a(A)$ is

$$\delta_\zeta F^a(A) = \partial_\mu\left(\partial^\mu\zeta^a + f^a{}_{bc}A^{b\mu}\zeta^c\right).$$

Replacing the gauge parameter by the ghost c^a, and pairing the gauge condition with the antighost $\bar{c}^a$, gives the Faddeev–Popov action

$$S_{\mathrm{gh}} = -\int \mathrm{d}^4x\,\bar{c}^a\partial_\mu\left(\partial^\mu c^a + f^a{}_{bc}A^{b\mu}c^c\right). \tag{49.4}$$

Equivalently, after integrating by parts and discarding the boundary term,

$$S_{\text{gh}} = \int \mathrm{d}^4x\, \partial_\mu \bar{c}^a \left(\partial^\mu c^a + f^a{}_{bc} A^{b\mu} c^c \right).$$

The operator is the massless scalar kinetic operator, while the fields are Grassmann odd. With the momentum convention displayed in the figure below,

$$\langle \Omega | \, \mathrm{T}\, \widehat{\bar{c}}^a(x) \widehat{c}_b(y) | \Omega \rangle = \delta^a{}_b \int \frac{\mathrm{d}^4k}{(2\pi)^4} \mathrm{e}^{\mathrm{i}k\cdot(x-y)} \frac{-\mathrm{i}}{k^2 - \mathrm{i}\epsilon}. \tag{49.5}$$

The extra sign of a closed ghost loop is a Berezin-Gaussian fact, not an independent rule. Let K denote the free ghost kinetic operator and let V denote any matrix of background insertions carrying the ghost-gluon vertices. In a finite-dimensional regulator, with the ordered Berezin convention used for Grassmann Gaussians in the spinor path-integral chapter,

$$\frac{Z_{\text{gh}}[V]}{Z_{\text{gh}}[0]} = \frac{\int [\mathrm{d}\bar{c}\, \mathrm{d}c]\, \exp[-\bar{c}(K+V)c]}{\int [\mathrm{d}\bar{c}\, \mathrm{d}c]\, \exp[-\bar{c}Kc]} = \det(1 + K^{-1}V).$$

Hence the connected n-insertion ghost cycle is the term

$$\operatorname{Tr} \log(1 + K^{-1}V) = \sum_{n\geq 1} \frac{(-1)^{n+1}}{n} \operatorname{Tr}\big((K^{-1}V)^n\big).$$

A commuting complex scalar with the same quadratic operator would instead produce $\det(1 + K^{-1}V)^{-1}$, and therefore the opposite sign for the same closed cycle after the local vertex factors are held fixed. Equivalently, in the Wick-contraction expansion, closing a ghost cycle requires a cyclic permutation of Grassmann-odd variables before the c's and $\bar{c}$'s are paired; this cyclic parity is the same closed-loop sign as for fermions. The Feynman rules below implement this determinant sign by assigning a factor -1 to each closed ghost loop.

The ghost-gluon vertex is read from the term

$$\int \mathrm{d}^4x\, \partial_\mu \bar{c}^a\, f^a{}_{bc} A^{b\mu} c^c.$$

If the momentum k is assigned to the antighost line as in figure 49.1, the displayed local vertex factor is

$$V_{\bar{c}^a c^c A^{b\mu}}(k) = -k_\mu f^a{}_{bc}. \tag{49.6}$$

Changing the direction of the ghost arrow or the sign convention for incoming momenta changes the displayed sign in the corresponding way; the invariant object is the action (49.4). There is no local $\bar{c}\, c\, A\, A$ vertex in this Lorenz gauge, because $\partial^\mu D_\mu(A)$ is only linear in A_μ.

The B-field form of the gauge-fixing term is

$$\int \mathrm{d}^4x \left(B^a \partial^\mu A^a_\mu + \frac{g^2\xi}{2} B^a B^a \right).$$

Eliminating B^a gives

$$S_{\text{gf}} = -\frac{1}{2g^2\xi} \int \mathrm{d}^4x\, (\partial^\mu A^a_\mu)(\partial^\nu A^a_\nu). \tag{49.7}$$

The quadratic gauge-field action is then inverted by

$$\langle\Omega|\,\mathrm{T}\;\widehat{A}_{a\mu}(x)\widehat{A}_{b\nu}(y)|\Omega\rangle = \int \frac{\mathrm{d}^4k}{(2\pi)^4}\mathrm{e}^{\mathrm{i}k\cdot(x-y)}g^2\frac{-\mathrm{i}\delta_{ab}}{k^2-\mathrm{i}\epsilon}\left[\eta_{\mu\nu}+(\xi-1)\frac{k_\mu k_\nu}{k^2}\right]. \tag{49.8}$$

The factor g^2 is a consequence of the $1/g^2$ multiplying the Yang–Mills kinetic term in the connection normalization used here.

Expanding $F^a_{\mu\nu}F^{a\mu\nu}$ gives the cubic and quartic gluon self-interactions:

$$\begin{aligned} S_{AAA} &= -\frac{1}{2g^2}\int \mathrm{d}^4x\, f^a{}_{bc}\big(\partial_\mu A^a_\nu - \partial_\nu A^a_\mu\big)A^{b\mu}A^{c\nu}, \\ S_{AAAA} &= -\frac{1}{4g^2}\int \mathrm{d}^4x\, f^a{}_{bc}f^a{}_{de}A^{b\mu}A^{c\nu}A^d_\mu A^e_\nu. \end{aligned} \tag{49.9}$$

These displayed action terms specify the convention before any momentum-flow choice is made for a vertex tensor. Figure 49.1 records the corresponding propagator and vertex conventions in a notation that distinguishes quark, ghost, and gauge lines, and also distinguishes present from absent local vertices; the visual distinction is used below when the ghost-loop sign and the absent four-ghost vertex are discussed.

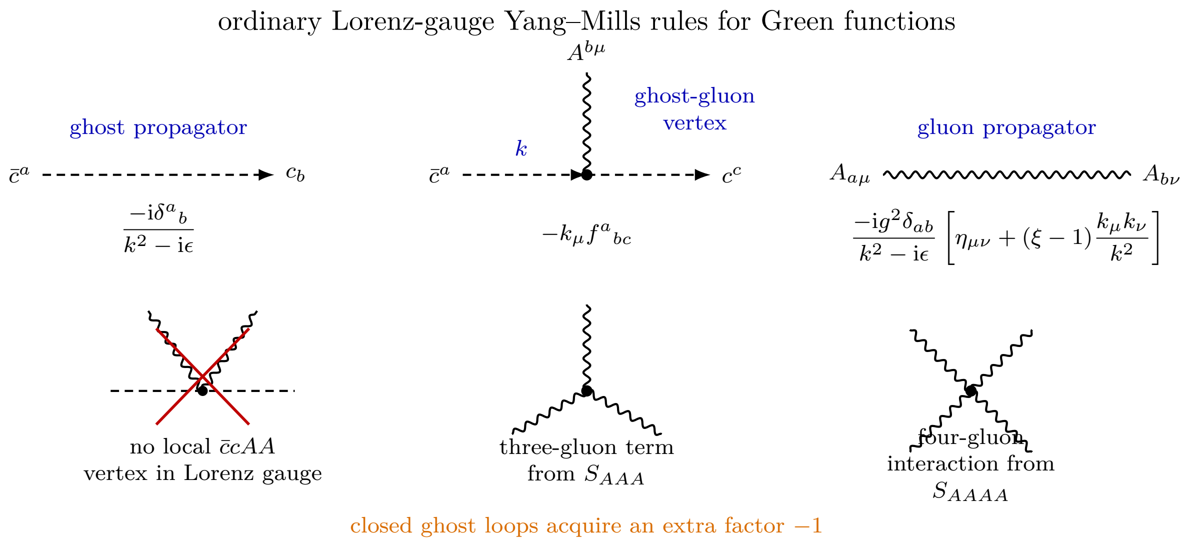

Figure 49.1: The ordinary covariant-gauge rules following from the Lorenz Faddeev–Popov action. Dashed arrows denote the ghost-number flow from antighost to ghost; wavy lines denote gauge fields. The rules organize gauge-fixed Green functions, while physical state spaces are described by BRST cohomology.

49.3 Background-Field Derivation of the One-Loop Beta Function

49.3.1 Background Gauge Datum and Effective Coupling Coordinate

The coupling in a nonabelian gauge theory is most cleanly extracted from the coefficient of the background curvature term in the 1PI effective action. Let $A_\mu = \widetilde{A}_\mu + a_\mu$, where $\widetilde{A}_\mu$ is a background connection and a_μ is the quantum fluctuation. The background covariant derivative in a representation R is denoted

$$\widetilde{D}_\mu = \partial_\mu - \mathrm{i}\widetilde{A}^a_\mu t^a_R, \qquad \widetilde{F}_{\mu\nu} = \partial_\mu \widetilde{A}_\nu - \partial_\nu \widetilde{A}_\mu - \mathrm{i}[\widetilde{A}_\mu, \widetilde{A}_\nu].$$

In the adjoint representation,

$$(\widetilde{D}_\mu X)^a = \partial_\mu X^a + f^a{}_{bc}\widetilde{A}^b_\mu X^c.$$

The structure constants and trace invariants in this calculation are those of (49.1); in particular, for fundamental quarks of $SU(N_c)$ in the monograph's trace normalization,

$$C_A = 2N_c, \qquad T_F = 1, \qquad C_F = \frac{N_c^2 - 1}{N_c}.$$

Choose the background-field gauge condition

$$\widetilde{D}^\mu a_\mu = 0.$$

Under a background gauge transformation with parameter $\zeta = \zeta^a t^a$,

$$\delta\widetilde{A}_\mu = \widetilde{D}_\mu \zeta, \qquad \delta a_\mu = -\mathrm{i}[a_\mu, \zeta],$$

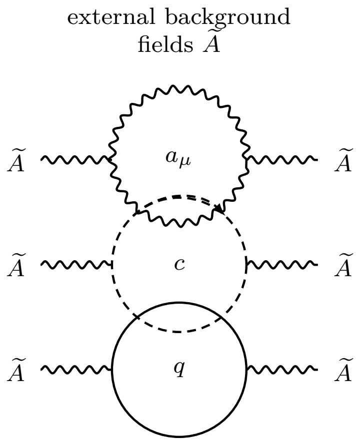
and the ghosts and quarks transform in the adjoint and R representations, respectively. Since this transformation acts linearly on the variables integrated over in the path integral and as a connection transformation on $\widetilde{A}$, the resulting 1PI functional $\Gamma[\widetilde{A}]$ is invariant under background gauge transformations. Its dimension-four term therefore has the form

$$\Gamma[\widetilde{A}] \supset -\frac{1}{4g^2(\mu)} \int \mathrm{d}^4x\, \widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu} \tag{49.10}$$

in Lorentzian signature, up to terms with more powers of $\widetilde{F}$, covariant derivatives, or quark fields. The problem is therefore reduced to computing one coefficient in a gauge-invariant functional, rather than separately renormalizing gauge-fixed vertices.

Figure 49.2 displays the actual coefficient extraction used below. The useful object is not a separate renormalization of each gauge-fixed vertex, but the determinant-weighted coefficient of $\int \widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}$ in the background effective action.

background-field one-loop coefficients



determinant weight	**coefficient in** b	**contribution to** $\beta_0 = 4b$
$-\frac{1}{2}\operatorname{Tr}\log D_A$ vector fluctuation	$+\dfrac{5}{6}C_A$	$+\dfrac{10}{3}C_A$
$+\operatorname{Tr}\log D_{\rm gh}$ Faddeev–Popov ghosts	$+\dfrac{1}{12}C_A$	$+\dfrac{1}{3}C_A$
$+N_f \operatorname{Tr}\log D_\psi$ Dirac quarks in R	$-\dfrac{1}{3}T_R N_f$	$-\dfrac{4}{3}T_R N_f$
sum	$b = \dfrac{11}{12}C_A - \dfrac{1}{3}T_R N_f$	$\beta_0 = \dfrac{11}{3}C_A - \dfrac{4}{3}T_R N_f$

$$\Gamma^{(1)}[\widetilde{A}] \supset \frac{b}{8\pi^2}\frac{\mu^{-\epsilon}}{\epsilon}\int \mathrm{d}^D x\, \widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}, \text{ hence } \mu\frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{g^3}{16\pi^2}\beta_0 + O(g^5).$$

Figure 49.2: The background-field method keeps the effective action invariant under gauge transformations of $\widetilde{A}$, so the one-loop running is read from the coefficient of $\widetilde{F}^2$. The table records the determinant weights and the coefficient b used in (49.23); the usual one-loop coefficient is $\beta_0 = 4b$.

Set the background quark and ghost fields to zero and use background Feynman gauge. The part of the action quadratic in $a_\mu, q, \bar{q}, c, \bar{c}$ has the form

$$S^{(2)} = \int \mathrm{d}^4 x \left[-\frac{1}{4g_0^2} a^\mu_a (D_A)_{a\mu,b\nu} a^\nu_b + \bar{q} D_\psi q + \bar{c}^a D^{ab}_{\rm gh} c^b \right], \tag{49.11}$$

where g_0 is the bare coupling. The operators are differential operators whose coefficients are built from $\widetilde{D}_\mu$ and $\widetilde{F}_{\mu\nu}$. In background Feynman gauge their principal pieces are

$$D_\psi = -\gamma^\mu \widetilde{D}_\mu, \qquad D_{\rm gh} = \widetilde{D}_\mu \widetilde{D}^\mu,$$

and D_A is the adjoint vector operator obtained from the quadratic part of $(\widetilde{F} + \widetilde{D}a - \widetilde{D}a + [a,a])^2$ together with the gauge-fixing term. The Gaussian integral gives

$$\mathrm{i}\Gamma^{(1)}[\widetilde{A}] = \log\left[\frac{(\det D_\psi)^{N_f}\det D_{\rm gh}}{(\det D_A)^{1/2}}\right]. \tag{49.12}$$

The numerator reflects Grassmann integration for quarks and ghosts; the denominator is the square root from the bosonic gauge-field Gaussian.

49.3.2 Constant-Background Extraction of the Logarithmic Coefficient

To extract the logarithmic coefficient, take $\widetilde{A}_\mu$ to be approximately constant inside a large box and to vanish smoothly outside. The box size supplies an infrared scale $L \sim \mu^{-1}$. In the constant region, the functional trace of a function of a differential operator reduces to an ordinary momentum integral. Figure 49.3 separates the position-space infrared regulator from the momentum-space large-$|k|$ tail whose logarithm gives the ultraviolet pole:

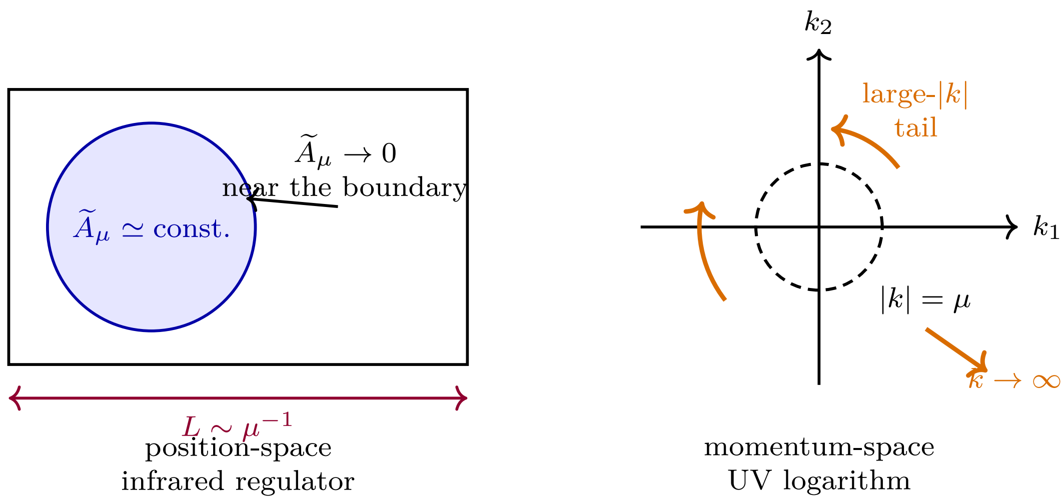


Figure 49.3: The constant-background computation is a local extraction of the logarithmic coefficient. The background is chosen nearly constant in a region of size L, and the scale $\mu \sim L^{-1}$ is used as the infrared cutoff in the momentum integral; the ultraviolet pole is the large-momentum tail of the same local trace.

$$\operatorname{Tr} f(D) = \int \mathrm{d}^D x \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, \operatorname{tr} f(M(k)). \tag{49.13}$$

Here Tr includes integration over spacetime and trace over all indices, while tr is the finite-dimensional trace over spin, Lorentz, and color indices of the symbol $M(k)$.

The coefficient can be extracted either by expanding the finite-dimensional symbols in (49.13) or, equivalently, by computing the logarithmic heat-kernel coefficient of the same local operators. The equivalence follows because both calculations isolate the parity-even curvature-squared functional that renormalizes $1/g^2$. In the symbol expansion, the only tensor average needed at fourth order is

$$\frac{k^{\nu_1}k^{\nu_2}k^{\nu_3}k^{\nu_4}}{(k^2)^4} \longrightarrow \frac{1}{(k^2)^2 D(D+2)}\left(\delta^{\nu_1\nu_2}\delta^{\nu_3\nu_4} + \delta^{\nu_1\nu_3}\delta^{\nu_2\nu_4} + \delta^{\nu_1\nu_4}\delta^{\nu_2\nu_3}\right). \tag{49.14}$$

The scalar integral carrying the logarithmic divergence is

$$I_\epsilon(\mu) := \int_{|k|>\mu} \frac{\mathrm{d}^{4-\epsilon}k}{(2\pi)^{4-\epsilon}} \frac{1}{(k^2)^2} = \frac{1}{8\pi^2}\frac{\mu^{-\epsilon}}{\epsilon} + \text{finite}. \tag{49.15}$$

49.3.3 Heat-Kernel Determinant Calculation

For a self-contained evaluation, use the Euclidean logarithmic coefficient of a Laplace-type operator

$$\mathcal{L} = -\nabla^2 + E$$

on a vector bundle $\mathcal{E}$. Let $\Omega_{\mu\nu} := [\nabla_\mu, \nabla_\nu]$. In flat space,

$$\operatorname{Tr}\log\mathcal{L} \supset -I_\epsilon(\mu)\int \mathrm{d}^D x\ \operatorname{tr}_{\mathcal{E}}\left(\frac{1}{2}E^2 + \frac{1}{12}\Omega_{\mu\nu}\Omega^{\mu\nu}\right). \tag{49.16}$$

This is obtained from $\operatorname{Tr}\log\mathcal{L} = -\int_0^\infty \frac{\mathrm{d}t}{t}\operatorname{Tr}\mathrm{e}^{-t\mathcal{L}}$ and the flat-space heat kernel

$$\operatorname{Tr}\mathrm{e}^{-t\mathcal{L}} \sim (4\pi t)^{-D/2}\int \mathrm{d}^D x\ \operatorname{tr}_{\mathcal{E}}\left[1 + tE + t^2\left(\frac{1}{2}E^2 + \frac{1}{12}\Omega_{\mu\nu}\Omega^{\mu\nu}\right) + \cdots\right].$$

The pole in dimensional regularization is the same pole as (49.15).

Let t^a_{ad} denote the Hermitian adjoint-representation generators, defined by

$$(t^a_{\mathrm{ad}})^b{}_c = \mathrm{i}f^b{}_{ac}, \qquad \operatorname{tr}_{\mathrm{ad}}(t^a_{\mathrm{ad}}t^b_{\mathrm{ad}}) = C_A\delta^{ab}.$$

The curvature endomorphism of the adjoint covariant derivative is the anti-Hermitian operator

$$\operatorname{ad}\widetilde{F}_{\mu\nu} := -\mathrm{i}\widetilde{F}^a_{\mu\nu}t^a_{\mathrm{ad}}.$$

Thus the adjoint trace used in the heat-kernel coefficient satisfies

$$\operatorname{tr}_{\mathrm{ad}}\big(\operatorname{ad}\widetilde{F}_{\mu\nu}\ \operatorname{ad}\widetilde{F}^{\mu\nu}\big) = (-\mathrm{i})^2\widetilde{F}^a_{\mu\nu}\widetilde{F}^{b\mu\nu}\operatorname{tr}_{\mathrm{ad}}(t^a_{\mathrm{ad}}t^b_{\mathrm{ad}}) = -C_A\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}, \tag{49.17}$$

where the sign comes from the two explicit factors of $-\mathrm{i}$. For a matter representation R with Hermitian generators t^a_R,

$$\operatorname{tr}_R\big((-\mathrm{i}\widetilde{F}^a_{\mu\nu}t^a_R)(-\mathrm{i}\widetilde{F}^{b\mu\nu}t^b_R)\big) = -T_R\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}.$$

First consider one Dirac quark in R. The first-order operator is $\mathcal{D}_\psi := \gamma^\mu\widetilde{D}_\mu$, and the logarithmic part of $\operatorname{Tr}\log\mathcal{D}_\psi$ is one half of that of the Laplace-type operator $-\mathcal{D}_\psi^2$. With

$$-\mathcal{D}_\psi^2 = -\widetilde{D}^2 - \frac{1}{2}\gamma^{\mu\nu}\Omega_{\mu\nu}, \qquad \gamma^{\mu\nu} := \frac{1}{2}[\gamma^\mu, \gamma^\nu],$$

one has

$$E_\psi = -\frac{1}{2}\gamma^{\mu\nu}\Omega_{\mu\nu}.$$

Using

$$\operatorname{tr}_{\mathrm{spin}}\gamma^{\mu\nu}\gamma^{\rho\sigma} = 4\left(\delta^{\mu\sigma}\delta^{\nu\rho} - \delta^{\mu\rho}\delta^{\nu\sigma}\right),$$

the heat-kernel density is

$$\operatorname{tr}_{\mathrm{spin}\otimes\mathrm{R}}\left(\frac{1}{2}E_\psi^2 + \frac{1}{12}\Omega_{\mu\nu}\Omega^{\mu\nu}\right) = \frac{2}{3}T_R\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}.$$

The extra factor $1/2$ relating $\operatorname{Tr}\log\mathcal{D}_\psi$ to $\operatorname{Tr}\log(-\mathcal{D}_\psi^2)$ gives

$$\operatorname{Tr}\log D_\psi \supset -\frac{1}{3}T_R I_\epsilon(\mu)\int \mathrm{d}^D x\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu} \tag{49.18}$$

for one Dirac flavor.

For the Faddeev–Popov ghosts in background gauge, the relevant Laplace-type operator is the scalar adjoint operator $\mathcal{L}_{\rm gh} = -\widetilde{D}^2$. Hence $E_{\rm gh} = 0$, and (49.16) gives

$$\operatorname{Tr}\log D_{\rm gh} \supset \frac{1}{12} C_A I_\epsilon(\mu) \int \mathrm{d}^D x\, \widetilde{F}^a_{\mu\nu} \widetilde{F}^{a\mu\nu}. \tag{49.19}$$

For the gauge fluctuation in background Feynman gauge, the Euclidean vector operator has the form

$$(\mathcal{L}_A)_\mu{}^\nu = -\widetilde{D}^2 \delta_\mu{}^\nu - 2\,\operatorname{ad}(\widetilde{F}_\mu{}^\nu).$$

It is a Laplace-type operator on one-forms valued in the adjoint bundle with

$$(E_A)_\mu{}^\nu = -2\,\operatorname{ad}(\widetilde{F}_\mu{}^\nu), \qquad (\Omega_{\rho\sigma})_\mu{}^\nu = \delta_\mu{}^\nu\,\operatorname{ad}(\widetilde{F}_{\rho\sigma}).$$

The finite-dimensional trace is taken in $D = 4 - \epsilon$ one-form components and in the adjoint representation. Using (49.17) and the antisymmetry of $\widetilde{F}_{\mu\nu}$,

$$\operatorname{tr}\frac{1}{2}E_A^2 = \frac{1}{2}\operatorname{tr}_{\rm ad}\left[(-2\,\operatorname{ad}\widetilde{F}_\mu{}^\nu)(-2\,\operatorname{ad}\widetilde{F}_\nu{}^\mu)\right] = 2C_A\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}, \tag{49.20}$$

$$\operatorname{tr}\frac{1}{12}\Omega_{\rho\sigma}\Omega^{\rho\sigma} = \frac{D}{12}\operatorname{tr}_{\rm ad}\big(\operatorname{ad}\widetilde{F}_{\rho\sigma}\,\operatorname{ad}\widetilde{F}^{\rho\sigma}\big) = -\frac{D}{12}C_A\,\widetilde{F}^a_{\rho\sigma}\widetilde{F}^{a\rho\sigma}. \tag{49.21}$$

The D-dependence in (49.21) has an evanescent part. Write

$$\mu^{-\epsilon} = 1 - \epsilon L_\mu + O(\epsilon^2),$$

where L_μ is the finite logarithm determined by the subtraction convention in (49.15). Then

$$(2-D)\frac{\mu^{-\epsilon}}{\epsilon} = (-2+\epsilon)\frac{\mu^{-\epsilon}}{\epsilon} = -\frac{2}{\epsilon} + 1 + 2L_\mu + O(\epsilon), \qquad D\frac{\mu^{-\epsilon}}{\epsilon} = \frac{4}{\epsilon} - 1 - 4L_\mu + O(\epsilon).$$

Consequently, replacing D by 4 is legitimate for the pole coefficient; the omitted $(D-4)I_\epsilon(\mu)$ part is a finite local contribution. Equations (49.20) and (49.21) therefore give the pole density

$$\left(2 - \frac{4}{12}\right) C_A\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu} = \frac{5}{3}C_A\,\widetilde{F}^a_{\mu\nu}\widetilde{F}^{a\mu\nu}.$$

The vector determinant contribution is therefore

$$\operatorname{Tr}\log D_A \supset -\frac{5}{3} C_A I_\epsilon(\mu) \int \mathrm{d}^D x\, \widetilde{F}^a_{\mu\nu} \widetilde{F}^{a\mu\nu}. \tag{49.22}$$

49.3.4 One-Loop Coupling Flow

Combining (49.18), (49.19), and (49.22) with the determinant weights in (49.12) gives the coefficient

$$b = -\frac{N_f}{3}T_R + \left[-\frac{1}{2}\left(-\frac{5}{3}\right) + \frac{1}{12}\right] C_A = \frac{11}{12}C_A - \frac{N_f}{3}T_R. \tag{49.23}$$

The term $5C_A/6$ comes from the vector determinant after the bosonic factor $-1/2$, the term $C_A/12$ from the Faddeev–Popov determinant, and the term $-N_f T_R/3$ from the N_f quark determinants.

Comparing the logarithmic part of $\Gamma[\widetilde{A}]$ with (49.10) gives

$$-\frac{1}{4g^2(\mu)} = -\frac{1}{4g_0^2} + \frac{b}{8\pi^2}\frac{\mu^{-\epsilon}}{\epsilon} + \text{finite}. \tag{49.24}$$

In $D = 4 - \epsilon$, write the dimensionless coupling as

$$\lambda^2(\mu) = \mu^\epsilon g^2(\mu).$$

This is the gauge-theory analogue of the scalar convention $g^\epsilon = \mu^\epsilon[\lambda + \cdots]$: the square appears because the Yang–Mills kinetic term is parameterized by $1/g^2$. Thus λ is the dimensionless D-dimensional coupling coordinate, while $g(\mu)$ retains the engineering dimension $-\epsilon/2$. Equivalently,

$$\frac{1}{g_0^2} = \mu^\epsilon \left[\frac{1}{\lambda^2(\mu)} + \frac{b}{2\pi^2}\frac{1}{\epsilon} + \text{finite} + O(\lambda^2)\right]. \tag{49.25}$$

The bare coupling g_0 is independent of the auxiliary scale μ. Differentiating (49.25) at fixed g_0 and then taking $\epsilon \to 0$ gives

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu}\frac{1}{\lambda^2(\mu)} = \frac{b}{2\pi^2} + O(\lambda^2), \qquad \beta(\lambda) = -\frac{b}{4\pi^2}\lambda^3 + O(\lambda^5). \tag{49.26}$$

Setting $\epsilon = 0$ and writing g for the four-dimensional dimensionless coupling,

$$\frac{b}{4\pi^2} = \frac{1}{16\pi^2}\left(\frac{11}{3}C_A - \frac{4}{3}T_R N_f\right),$$

which is (49.2). For fundamental quarks of $SU(N_c)$, $T_R = T_F = 1$ and $C_A = 2N_c$, giving (49.3).

49.4 Dimensional Transmutation

Assume

$$b_0 := 11N_c - 2N_f > 0.$$

At one loop,

$$\mu\frac{\mathrm{d}g}{\mathrm{d}\mu} = -\frac{b_0}{24\pi^2}g^3.$$

Integrating between μ_0 and μ gives

$$\frac{1}{g^2(\mu)} = \frac{1}{g^2(\mu_0)} + \frac{b_0}{12\pi^2}\log\frac{\mu}{\mu_0}. \tag{49.27}$$

Thus $g(\mu)$ decreases at large μ. This property is asymptotic freedom.

The integration constant may be traded for a scale. At one-loop accuracy,

$$\Lambda = \mu\,\exp\left\{-\frac{12\pi^2}{b_0 g^2(\mu)}\right\}. \tag{49.28}$$

Higher-loop definitions multiply the right side by powers and series in $g(\mu)$, and the numerical value depends on the renormalization scheme. The scheme-independent statement is that a dimensionless renormalized coupling has been replaced, after a renormalization condition is chosen, by a dimensionful RG-invariant scale, together with the quark masses. This is dimensional transmutation.

Perturbative predictions at external momentum scale Q are organized by the small parameter $g(Q)$ when $Q \gg \Lambda$. At scales comparable to Λ, the perturbative expansion is no longer a controlled expansion in small coupling. Statements about the spectrum, confinement, and the mass gap then require nonperturbative input.

Remark 49.1 (Mass-gap problem and the status of continuum Yang–Mills)*.* For pure compact $SU(N_c)$ Yang–Mills theory in four dimensions, the existence of the continuum quantum field theory on $\mathbb{R}^4$ and the existence of a positive mass gap form the Yang–Mills Millennium problem; see Remark 45.2. The issue is not the formal writing of the action or the perturbative construction of renormalized Green functions. It is the construction of a nonperturbative continuum measure, or equivalently a Hilbert-space or algebraic quantum theory, whose correlation functions satisfy the required structural properties and whose physical spectrum above the vacuum has a strictly positive lower bound.

The finite-lattice theory at nonzero lattice spacing is a well-defined statistical-mechanical system, and numerical as well as analytic evidence strongly supports a gapped pure Yang–Mills continuum limit. The proof of that continuum limit and its gap in $D = 4$ remains a separate mathematical problem. The QCD discussion below therefore treats confinement, flux tubes, and hadronic spectral statements as nonperturbative physical inputs or as properties of regulated/lattice formulations, not as consequences of the one-loop beta function.

49.5 Regulated Gauge-Invariant Matrix Elements

The basic nonperturbative quantities of QCD are not matrix elements of isolated colored fields. They are limits, when such limits exist, of regulated gauge-invariant matrix elements. A calculation may use gauge-fixed quark and gluon variables internally, but the object being defined must be a color-singlet operator, a line operator, or a BRST-cohomology class with a specified regulator and renormalization prescription.

Definition 49.2 (Regulated gauge-invariant QCD matrix-element specification)**.** A regulated gauge-invariant QCD matrix-element specification consists of:

1. a regulator family $\mathcal{R}_\epsilon$, such as a finite lattice, a gauge-covariant heat-kernel cutoff, or a gauge-fixed BV regulator together with its quantum master equation;
2. a regulated operator $\mathcal{O}_\epsilon$ built from local gauge-invariant fields, closed Wilson loops, or colored fields whose exposed color indices are joined by Wilson transporters along specified paths;
3. the external states or density matrix in which the operator is evaluated, for example hadron states, the vacuum, a thermal state, or a finite-volume transfer-matrix state;
4. ultraviolet, endpoint, cusp, and rapidity subtractions whenever the operator contains coincident fields, cusped Wilson lines, infinite Wilson lines, or lightlike separations;
5. a topology in which the renormalized matrix elements are required to converge as $\epsilon \to 0$, usually a distribution topology in spacetime, momentum fraction, or detector angle.

Only after these data have been supplied does a symbol such as a Wilson loop, PDF, fragmentation function, soft function, quasi-PDF, static potential, or energy-flow correlator denote a nonperturbative QCD quantity. If the continuum limit or lightcone limit is not known to exist, the same formula is a regulated definition plus a continuum-existence hypothesis, not a theorem.

The Wilson transporter is the mechanism by which separated colored insertions become gauge-covariant before their endpoint indices are contracted. For example,

$$\bar{q}(x)W_{\square}(x,y)q(y), \qquad F^a_{\mu\nu}(x)W^{ab}_{\mathrm{ad}}(x,y)F^b_{\rho\sigma}(y),$$

are gauge-invariant bilocals after the spinor and Lorentz indices are contracted as specified. Closed Wilson loops are obtained by taking the color trace of a transporter around a closed curve. Baryonic static-source operators join N_c fundamental Wilson lines at a color-antisymmetric junction. Soft functions and parton distributions use Wilson lines whose directions are fixed by the high-energy kinematics; their lightlike or cusped nature is a source of additional renormalization, not an optional convention.

This rule is not limited to perturbation theory. On a lattice, the transporter is the ordered product of link variables and gauge invariance is exact at nonzero lattice spacing. In a continuum path-integral or Hilbert-space construction, the same Wilson-line operator must be obtained as a renormalized composite. Perturbative Feynman graphs then compute short-distance coefficients, anomalous dimensions, and matching kernels for these nonperturbative matrix elements. They do not replace the matrix elements by colored asymptotic particles. Energy correlators are a useful complementary case: the detector operator is built from the gauge-invariant stress tensor, so no Wilson line is needed in the operator definition, although perturbative representatives of the same observable still involve colored internal coordinates after factorization.

49.6 Infrared Possibilities and Wilson Loop Diagnostics

The one-loop beta function determines the ultraviolet direction of the flow when $B_0 > 0$. It does not by itself determine the infrared theory. The first controlled alternative to strong infrared coupling is visible only after the two-loop term is kept. Put

$$a(\mu) := \frac{g(\mu)^2}{16\pi^2}.$$

In a mass-independent gauge-invariant renormalization scheme, the two-loop beta function has the form

$$\beta_a(a) := \mu\frac{\mathrm{d}a}{\mathrm{d}\mu} = -2B_0a^2 - 2B_1a^3 + O(a^4), \tag{49.29}$$

where the one-loop coefficient is the one derived above,

$$B_0 = \frac{11}{3}C_A - \frac{4}{3}T_RN_f,$$

and the two-loop coefficient is

$$B_1 = \frac{34}{3}C_A^2 - \left(\frac{20}{3}C_AT_R + 4C_RT_R\right)N_f. \tag{49.30}$$

The constants C_A, T_R, C_R are those of (49.1); in particular no hidden $\mathrm{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ convention is being used. The coefficient B_1 is the universal two-loop coefficient of the mass-independent gauge beta function. The one-loop derivation in the preceding section fixes B_0 in the present normalization; the present subsection uses the two-loop coefficient to derive the fixed point and its domain of validity.

The universality of B_0 and B_1 is elementary at the level of coupling coordinates. Let a' be another dimensionless coupling coordinate with

$$a' = a + r_1 a^2 + r_2 a^3 + O(a^4).$$

Then

$$\beta_{a'}(a') = \frac{\mathrm{d}a'}{\mathrm{d}a}\,\beta_a(a) = -2B_0 a'^2 - 2B_1 a'^3 + O(a'^4).$$

Thus a small two-loop zero is not an artifact of a quadratic coordinate change. Its precise location beyond the first nontrivial order is scheme-dependent, because $O(a^4)$ terms affect the next coefficient in the small-B_0 expansion.

For fundamental quarks in the trace convention of this monograph,

$$C_A = 2N_c, \qquad T_F = 1, \qquad C_F = \frac{N_c^2 - 1}{N_c}.$$

Hence

$$B_0 = \frac{2}{3}(11N_c - 2N_f), \qquad B_1 = \frac{136}{3}N_c^2 - \left(\frac{52}{3}N_c - \frac{4}{N_c}\right)N_f. \tag{49.31}$$

Asymptotic freedom requires $B_0 > 0$, while a perturbative infrared zero requires $B_1 < 0$. These inequalities give the weakly coupled Banks–Zaks window

$$\frac{34N_c^3}{13N_c^2 - 3} < N_f < \frac{11}{2}N_c. \tag{49.32}$$

inside the larger asymptotically free range $N_f < 11N_c/2$. More precisely, define the distance from the upper edge by

$$\epsilon_{\mathrm{BZ}} := \frac{11N_c - 2N_f}{3}, \qquad N_f = \frac{11}{2}N_c - \frac{3}{2}\epsilon_{\mathrm{BZ}}. \tag{49.33}$$

Then $B_0 = 2\epsilon_{\mathrm{BZ}}$, and

$$B_1 = -2(25N_c^2 - 11) + \left(26N_c - \frac{6}{N_c}\right)\epsilon_{\mathrm{BZ}}.$$

The two-loop zero is

$$a_*^{(2)} = -\frac{B_0}{B_1} = \frac{2\epsilon_{\mathrm{BZ}}}{2(25N_c^2 - 11) - (26N_c - 6/N_c)\epsilon_{\mathrm{BZ}}}, \tag{49.34}$$

and the fixed-point coordinate of the full perturbative beta function is

$$a_* = \frac{\epsilon_{\mathrm{BZ}}}{25N_c^2 - 11} + O(\epsilon_{\mathrm{BZ}}^2). \tag{49.35}$$

The $O(\epsilon_{\mathrm{BZ}}^2)$ coefficient is not determined by (49.29) alone, because it receives a contribution from the three-loop coefficient. The leading coefficient in (49.35), by contrast, is scheme-independent.

The linearized exponent of the coupling perturbation is obtained without an extra assumption:

$$\omega_{\mathrm{BZ}} := \left.\frac{\partial \beta_a}{\partial a}\right|_{a=a_*} = -\frac{2B_0^2}{B_1} + O(B_0^3) = \frac{4\epsilon_{\mathrm{BZ}}^2}{25N_c^2 - 11} + O(\epsilon_{\mathrm{BZ}}^3). \tag{49.36}$$

With the convention $\beta_a = \mathrm{d}a/\mathrm{d}\log\mu$, the positive sign means that the perturbation $a - a_*$ decays when the flow is followed toward the infrared. The massless theory is essential: quark mass terms are relevant deformations of the fixed point and must be tuned to zero. At fixed finite N_c, N_f is an integer, so ϵ_{BZ} is not continuously adjustable in the literal theory. The perturbative expansion may be viewed as an analytic expansion in the fermion-determinant power N_f, or more physically in the Veneziano regime with N_f/N_c just below $11/2$, where the 't Hooft coupling $N_c a_*$ is small.

The fixed points obtained in this way are the Banks–Zaks fixed points. The statement is perturbative: it constructs a weak-coupling zero of the renormalized massless beta function and gives perturbative scaling data for gauge-invariant local operators. It is not a derivation of confinement or of the low-flavor infrared behavior of QCD.

Controlled Approximation 49.3 (Banks–Zaks perturbative fixed point versus a conformal-window theorem)**.** The Banks–Zaks construction used here is the following perturbative construction, not a theorem that every theory with flavor number in (49.32) is a nonperturbative conformal field theory. One fixes a mass-independent gauge-invariant renormalization scheme, restricts to the massless theory, treats N_f near the upper edge of asymptotic freedom so that $a_* = O(\epsilon_{\mathrm{BZ}})$, and computes renormalized correlators of gauge-invariant local or light-ray operators as formal asymptotic series in the small fixed-point coordinate. The first two beta coefficients determine the leading location (49.35) and the leading irrelevant exponent (49.36); higher coefficients and finite operator normalizations are scheme coordinates. If a nonperturbative regulator and scaling limit are supplied and the RG trajectory remains in the same small-coupling neighborhood, these perturbative data are the local coordinates of the resulting infrared theory. Without that extra construction they are a controlled perturbative fixed-point expansion. The lower edge of the nonperturbative conformal window, if it exists for the chosen gauge group and matter content, is not determined by (49.29).

Figure 49.4 compares the two beta-function shapes relevant here: asymptotic freedom without a weak infrared zero and the Banks–Zaks case with a perturbative infrared fixed point.

two infrared possibilities visible in a two-loop beta function

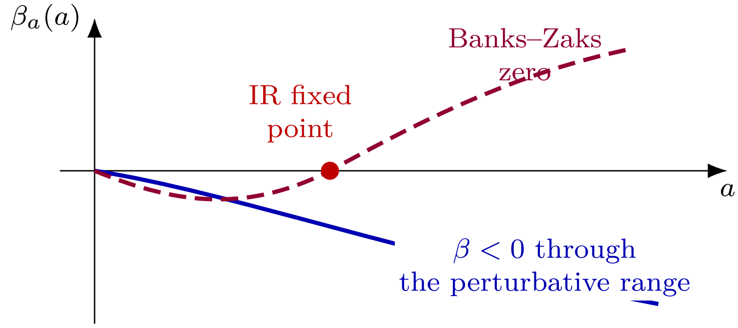

Figure 49.4: A negative one-loop coefficient implies ultraviolet asymptotic freedom. The infrared behavior depends on the subsequent terms. The solid curve has no weak infrared zero, while the dashed curve has a small two-loop zero giving a controlled perturbative fixed point; absence of such a zero leaves the flow outside perturbative control in the infrared.

For smaller N_f, perturbation theory around the ultraviolet fixed point no longer determines the infrared limit. The confining regime discussed below is therefore a conditional infrared scenario, not a conclusion derived from the one-loop beta function alone. The condition called confinement here is a spectral and observable hypothesis: isolated finite-energy asymptotic particles carry no color, and physical states are created from the vacuum by gauge-invariant operators. Deriving this spectral statement from the four-dimensional continuum QCD Lagrangian is an open nonperturbative problem. Quark and gluon fields remain part of the short-distance gauge-fixed description; the confinement statement concerns the gauge-invariant Hilbert-space spectrum and the algebra of physical observables.

The basic nonlocal observable for this confinement diagnostic is the Wilson line. For an oriented path C from x_1 to x_2, define

$$W_R(C) = P \exp\left\{ \mathrm{i} \int_C A^a_\mu(x) t^a_R \, \mathrm{d}x^\mu \right\}, \tag{49.37}$$

where R is a representation of the gauge group, t^a_R are its generators, and P denotes ordering along the path. The nonlocal operator

$$\bar{q}(x_2)\, W_R(C)\, q(x_1)$$

is gauge invariant when the endpoints transform in conjugate representations. It creates a color-neutral state containing a quark, an antiquark, and the gauge flux connecting them.

Figure 49.5 fixes the Wilson-line convention used for gauge-invariant quark bilinears and for closed Wilson-loop observables: path ordering is along the chosen curve, and endpoint representations are conjugate.

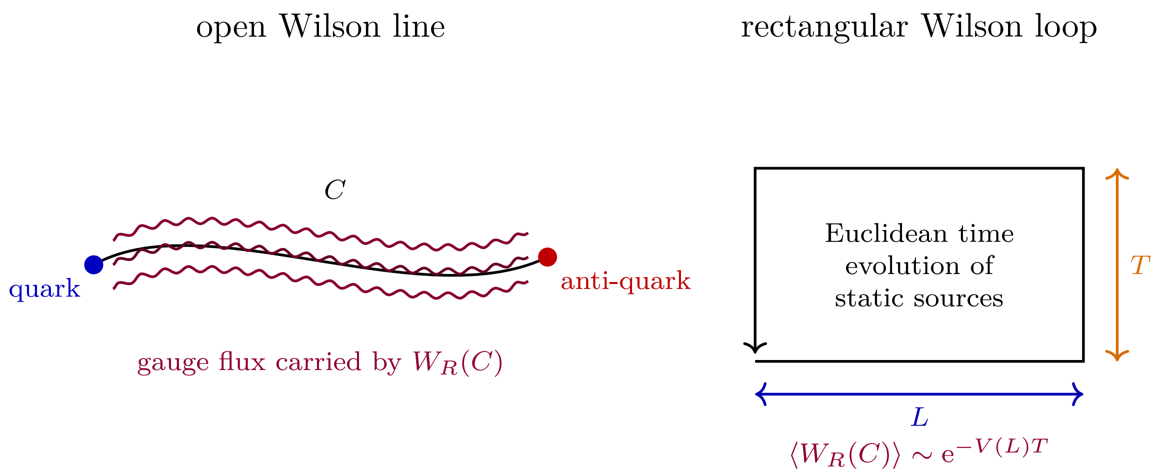

Figure 49.5: An open Wilson line attached to endpoint fields gives a gauge-invariant operator with color flux between the endpoints. A large Euclidean rectangular Wilson loop extracts the static potential between external color sources.

In pure Yang–Mills theory, where there are no dynamical fundamental quarks, a fundamental flux string cannot break by pair creation of fundamental matter. It carries a charge under the center one-form symmetry. For a large Euclidean rectangle $C_{L,T}$ of spatial width L and time height T,

$$\langle W_R(C_{L,T})\rangle \sim \mathrm{e}^{-V_R(L)T} \qquad (T\to\infty). \tag{49.38}$$

An area law

$$\langle W_R(C_{L,T})\rangle \sim \mathrm{e}^{-\gamma LT}$$

is equivalent, in this static-source setup, to a linearly growing potential

$$V_R(L) \sim \gamma L.$$

Chapter 46 gives the finite-cutoff version of this statement: at sufficiently small lattice β, the character expansion of the Wilson action converges and gives an area bound for fundamental Wilson loops. That theorem belongs to the strong-coupling lattice regime. A proof of the corresponding continuum four-dimensional pure Yang–Mills area law would require control of the $\beta\to\infty$ scaling trajectory and is part of the same nonperturbative construction problem as the mass gap. In QCD with dynamical fundamental quarks, the same Wilson loop is no longer a sharp order parameter for confinement because the flux tube can break by quark-antiquark pair creation. The physical spectral statement remains that asymptotic particles are color singlets.

49.7 The ’t Hooft Large-N_c Expansion

49.7.1 Planar Counting and Factorization

The large-N_c expansion is a statement about a sequence of gauge theories, not about a single theory at $N_c = 3$. The sequence used here is $SU(N_c)$ Yang–Mills theory with the same trace convention as above,

$$\mathrm{tr}_{\Box}(t^a t^b) = \delta^{ab}, \qquad C_A = 2N_c, \qquad T_F = 1,$$

and with

$$\lambda := g^2 N_c \tag{49.39}$$

held fixed as $N_c \to \infty$. In the common half-trace convention $\operatorname{tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$, the corresponding coupling is $g_{\mathrm{ht}}^2 = 2g^2$ and the conventional 't Hooft coupling is $\lambda_{\mathrm{ht}} = g_{\mathrm{ht}}^2 N_c = 2\lambda$. The constant factor 2 has no effect on the N_c-power counting, but it matters when comparing formulae across conventions.

For the color-counting argument it is useful to write the gauge field as a traceless matrix,

$$A_\mu = A_\mu^a t^a, \qquad (A_\mu)^i{}_i = 0,$$

and to separate the color-index contractions from the spacetime integrals, spin tensors, gauge-fixing tensors, and momentum denominators. The fundamental finite-dimensional identity in the present trace normalization is

$$\sum_{a=1}^{N_c^2-1} (t^a)^i{}_j (t^a)^k{}_\ell = \delta^i{}_\ell \delta^k{}_j - \frac{1}{N_c}\delta^i{}_j \delta^k{}_\ell. \tag{49.40}$$

Here is the derivation, since this is where convention errors most often enter. On $\operatorname{End}(\mathbb{C}^{N_c})$ use the bilinear pairing $(X, Y) = \operatorname{tr}_\square(XY)$. The matrix units have completeness kernel $\delta^i{}_\ell \delta^k{}_j$, which is the identity operator on all matrices. The one-dimensional scalar subspace is spanned by $\mathbf{1}$, whose squared norm is N_c, so the projector onto the scalar subspace has kernel $N_c^{-1}\delta^i{}_j\delta^k{}_\ell$. Since $\{t^a\}$ is an orthonormal basis of the traceless subspace, summing $(t^a)^i{}_j(t^a)^k{}_\ell$ gives the identity projector minus the scalar projector, which is exactly (49.40). The first term is the $U(N_c)$ double-line propagator: one color line carries the fundamental index and the other carries the antifundamental index. The second term subtracts the trace part and is explicitly lower order in $1/N_c$. It is therefore included in the expansion as a subleading insertion; it cannot increase the leading power of N_c. Ghost fields in covariant gauges are adjoint-valued and have the same double-line color structure, with the Grassmann sign already accounted for by the determinant argument above. Quark propagators carry one fundamental color line.

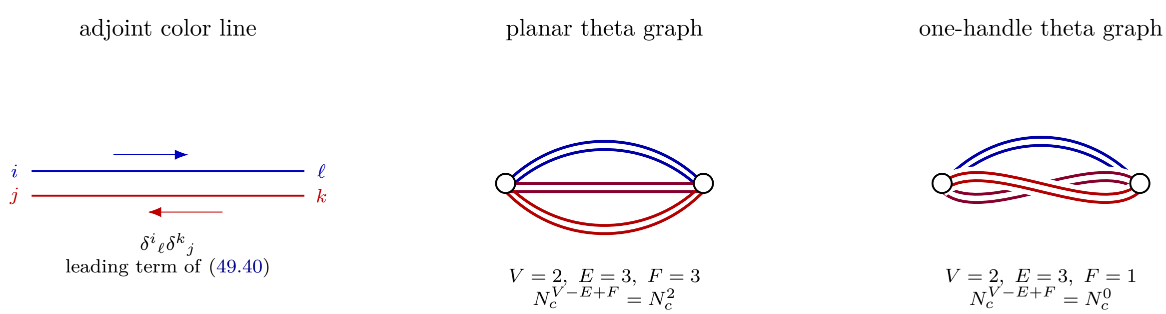

Figure 49.6: The adjoint propagator is represented by two oriented color lines. Thickening a double-line graph gives an oriented surface. The planar and one-handle theta graphs have the same number of vertices and propagators; the nonplanar routing has two fewer closed color faces and is therefore suppressed by N_c^{-2} at fixed $\lambda = g^2 N_c$.

The power counting is most transparent after the gauge-fixed adjoint quadratic form and all adjoint interaction monomials are written in the single-trace form

$$S_{\rm adj} = \frac{N_c}{\lambda} \int \mathrm{d}^4x \ \mathrm{tr}_\Box \left(\frac{1}{2}\Phi K \Phi + \sum_\alpha c_\alpha \, \Phi_{\alpha_1} \cdots \Phi_{\alpha_{r_\alpha}} \right), \tag{49.41}$$

where Φ denotes adjoint gauge, ghost, or auxiliary fields, K is the appropriate kinetic operator including spacetime and Lorentz indices, and the c_α are N_c-independent tensors once λ is held fixed. This rewriting is only a normalization of perturbative variables; it is not a new definition of QCD. It records the same fact already visible from

$$\frac{1}{4g^2}\,\mathrm{tr}_\Box\, F_{\mu\nu}F^{\mu\nu} = \frac{N_c}{4\lambda}\,\mathrm{tr}_\Box\, F_{\mu\nu}F^{\mu\nu}.$$

With the normalization (49.41), each adjoint propagator contributes a factor λ/N_c, each single-trace adjoint vertex contributes a factor N_c/λ, and each closed color face contributes a factor N_c from summing an index from 1 to N_c. Spacetime loop integrals and Lorentz numerators multiply this color factor but do not alter the topological exponent.

Let Γ be a connected adjoint ribbon graph with V single-trace vertices, E adjoint propagators, and F closed color faces. Thickening the ribbons and vertices produces a compact oriented surface Σ_Γ possibly with boundaries. If the surface has genus h and b boundaries, then

$$\chi(\Sigma_\Gamma) = V - E + F = 2 - 2h - b. \tag{49.42}$$

Therefore a fixed ribbon graph contributes

$$\mathcal{A}_\Gamma = N_c^{V-E+F}\lambda^{E-V}\,\mathcal{I}_\Gamma(\lambda,\mu,\{p\}) = N_c^{2-2h-b}\lambda^{E-V}\,\mathcal{I}_\Gamma(\lambda,\mu,\{p\}), \tag{49.43}$$

up to the explicitly subleading terms generated by the $-N_c^{-1}\delta^i{}_j\delta^k{}_\ell$ part of (49.40). The factor $\mathcal{I}_\Gamma$ contains the regulated momentum integrals, tensor contractions, signs, and scheme-dependent finite parts. Equation (49.43) is the topological content of the 't Hooft expansion: at fixed λ, changing the genus by one suppresses a connected contribution by N_c^{-2}.

The theta graph in figure 49.6 gives the elementary computation. Both routings have $V = 2$ cubic vertices and $E = 3$ propagators, hence both carry the same power $\lambda^{E-V} = \lambda$. The planar routing has $F = 3$, so

$$\mathcal{A}_{\rm planar} \sim N_c^2 \lambda\, \mathcal{I}_{\rm planar}.$$

The crossed routing thickens to a torus with $F = 1$, so

$$\mathcal{A}_{\text{one handle}} \sim N_c^0 \lambda\, \mathcal{I}_{\text{one handle}}.$$

For comparable regulated integrals at the same external data, the color topology alone gives

$$\frac{\mathcal{A}_{\text{one handle}}}{\mathcal{A}_{\rm planar}} = O(N_c^{-2}) \qquad (\lambda \text{ fixed}). \tag{49.44}$$

This is a finite color-index statement at each fixed ribbon graph. It does not by itself prove convergence of the perturbation series, nor does it define the four-dimensional continuum gauge theory nonperturbatively.

Single-trace operator insertions are counted as boundaries. For adjoint words

$$\mathcal{O}_r(x) = \mathrm{tr}_\Box\big(\Phi_{r_1}(x)\cdots\Phi_{r_{\ell_r}}(x)\big),$$

the connected genus-h contribution to an m-point function of unnormalized single traces scales as

$$\left\langle \mathcal{O}_1(x_1)\cdots\mathcal{O}_m(x_m)\right\rangle_{c,h} = O\left(N_c^{2-2h-m}\right), \tag{49.45}$$

again at fixed λ and fixed operator words. If $\widehat{\mathcal{O}}_r = N_c^{-1}\mathcal{O}_r$, then

$$\left\langle \widehat{\mathcal{O}}_1\cdots\widehat{\mathcal{O}}_m\right\rangle_{c,h} = O\left(N_c^{2-2h-2m}\right).$$

In particular,

$$\left\langle \widehat{\mathcal{O}}_1\widehat{\mathcal{O}}_2\right\rangle_c = O(N_c^{-2}), \qquad \langle\widehat{\mathcal{O}}_1\widehat{\mathcal{O}}_2\rangle = \langle\widehat{\mathcal{O}}_1\rangle\langle\widehat{\mathcal{O}}_2\rangle + O(N_c^{-2}). \tag{49.46}$$

This large-N_c factorization is often the most useful nonperturbative consequence of the counting: it says that fluctuations of normalized single-trace observables are suppressed in the planar limit, provided the large-N_c limit of the regulated theory exists.

49.7.2 Eguchi–Kawai Volume Reduction

Large-N_c factorization suggests a further possibility: in some center-symmetric large-N_c regimes, single-trace Wilson-loop expectation values on a large lattice may be obtained from a reduced matrix model with fewer sites. Double-line counting supplies factorization of normalized single traces; volume reduction additionally requires matching the finite-regulator loop equations in a center-symmetric sector.

Let $\Lambda_L = (\mathbb{Z}/L\mathbb{Z})^d$ be a periodic hypercubic lattice, and let $U_\mu(x) \in SU(N_c)$ be the link from x to $x+\hat{\mu}$. The pure-gauge Wilson measure is

$$\mathrm{d}\nu_L(U) = Z_L^{-1}\exp\left\{bN_c\sum_{x\in\Lambda_L}\sum_{\mu<\nu}\operatorname{Re}\operatorname{Tr}_\Box U_{\mu\nu}(x)\right\}\prod_{x,\mu}\mathrm{d}U_\mu(x),$$

where

$$U_{\mu\nu}(x) = U_\mu(x)U_\nu(x+\hat{\mu})U_\mu(x+\hat{\nu})^{-1}U_\nu(x)^{-1}.$$

The one-site Eguchi–Kawai reduced model has d matrices $V_\mu \in SU(N_c)$ and measure

$$\mathrm{d}\nu_{\mathrm{EK}}(V) = Z_{\mathrm{EK}}^{-1}\exp\left\{bN_c\sum_{\mu<\nu}\operatorname{Re}\operatorname{Tr}_\Box V_\mu V_\nu V_\mu^{-1}V_\nu^{-1}\right\}\prod_\mu \mathrm{d}V_\mu. \tag{49.47}$$

The parameter b is a lattice coupling coordinate. The present discussion uses it at fixed regulator; continuum statements require a separate scaling limit.

A path word in the reduced model is a sequence

$$p = ((\mu_1,\epsilon_1),\ldots,(\mu_\ell,\epsilon_\ell)), \qquad \epsilon_r = \pm 1,$$

with associated matrix

$$V(p) = V_{\mu_1}^{\epsilon_1}\cdots V_{\mu_\ell}^{\epsilon_\ell}$$

and displacement vector

$$n_\rho(p) = \sum_{r=1}^{\ell}\epsilon_r\,\delta_{\rho\mu_r}. \tag{49.48}$$

The normalized trace

$$W_{\mathrm{red}}(p) = \frac{1}{N_c}\,\mathrm{Tr}_{\Box}\,V(p)$$

is gauge invariant under simultaneous conjugation $V_\mu \mapsto \Omega V_\mu \Omega^{-1}$ even when $n(p) \neq 0$. This is precisely why the reduced model needs an additional center-selection rule: in the extended lattice theory, an open path is not a Wilson-loop observable, whereas its reduced trace would otherwise be an allowed matrix observable.

The reduced action is invariant under the independent center transformations

$$V_\mu \longmapsto z_\mu V_\mu, \qquad z_\mu \in Z(SU(N_c)) \simeq \mathbb{Z}_{N_c}. \tag{49.49}$$

Under this transformation,

$$W_{\mathrm{red}}(p) \longmapsto \left(\prod_{\rho=1}^{d} z_\rho^{\,n_\rho(p)}\right) W_{\mathrm{red}}(p). \tag{49.50}$$

Center selection for reduced open words. Assume the reduced finite-N_c state is invariant under (49.49). If the center charge of a word is nontrivial, namely if $n_\rho(p) \not\equiv 0 \pmod{N_c}$ for at least one ρ, then

$$\big\langle W_{\mathrm{red}}(p)\big\rangle_{\mathrm{EK}} = 0.$$

Consequently, if a charged reduced word has a nonzero expectation value in a chosen large-N_c state, that state cannot implement ordinary Eguchi–Kawai volume reduction for Wilson loops. Choose a direction ρ for which $n_\rho(p) \not\equiv 0 \pmod{N_c}$. There exists $z_\rho \in \mathbb{Z}_{N_c}$ such that $z_\rho^{\,n_\rho(p)} \neq 1$. Invariance of the state gives

$$\langle W_{\mathrm{red}}(p)\rangle_{\mathrm{EK}} = z_\rho^{n_\rho(p)} \langle W_{\mathrm{red}}(p)\rangle_{\mathrm{EK}},$$

where all other z_σ's are set to 1. The prefactor differs from one, hence the expectation value is zero. If a charged expectation is nonzero, the assumed center invariance is false. Such an expectation is an extra reduced-model observable with no counterpart as a closed Wilson loop in the unreduced lattice theory, so the reduced loop equations cannot be identified with the unreduced Wilson-loop equations without further modification.

The loop-equation form of volume reduction can now be stated cleanly.

Definition 49.4 (Volume-reduction structure for Wilson loops)**.** A volume-reduction structure for pure large-N_c lattice Yang–Mills Wilson loops consists of the following assumptions and regulator objects:

1. a sequence of finite-volume Wilson lattice measures with fixed lattice coupling coordinate b, and a sequence of reduced measures such as (49.47) or a twisted/quenched variant;

2. a class $\mathcal{C}$ of closed lattice paths whose normalized Wilson-loop expectations have large-N_c limits;

3. translation invariance of the large-volume loop expectations and large-N_c factorization of normalized single-trace loop observables;

4. unbroken reduced center symmetry strong enough to enforce the vanishing of all reduced open words that appear in the loop equations for $\mathcal{C}$;

5. uniqueness, in the selected center-symmetric sector, of the solution to the limiting Schwinger–Dyson loop equations with the specified boundary and reflection-positivity data.

When these assumptions and regulator objects are supplied, volume reduction means

$$\lim_{N_c\to\infty}\lim_{L\to\infty}\left\langle \frac{1}{N_c}\operatorname{Tr}U(C)\right\rangle_L = \lim_{N_c\to\infty}\left\langle \frac{1}{N_c}\operatorname{Tr}V(C)\right\rangle_{\text{red}} \tag{49.51}$$

for every $C \in \mathcal{C}$, where $V(C)$ is obtained from the sequence of directions in the lattice path C. The equality concerns single-trace Wilson-loop coordinates at fixed regulator. Colored local fields, baryons, finite-N_c spectra, and continuum limits require additional definitions and additional limiting statements.

The content of this structure is not decorative. In a Schwinger–Dyson equation for a Wilson loop, varying a link on the loop produces terms in which the loop splits at repeated visits to the varied link. In the unreduced theory these split loops may be based at different lattice sites; translation invariance and large-N_c factorization replace their joint expectation by the product of one-loop expectations. In the reduced model the corresponding matrix words are all based at the single site, and open words can appear algebraically. The center-selection rule above is what removes the charged open words. The uniqueness clause in Definition 49.4 is also load-bearing: two different center-symmetric solutions of the same limiting loop equations would not be distinguished by the formal loop-equation matching alone.

Controlled Approximation 49.5 (Status of Eguchi–Kawai reduction)**.** The original one-site Eguchi–Kawai model is a valid reduced candidate only in regimes where its center symmetry is not spontaneously broken in the large-N_c limit. At weak lattice coupling in dimensions larger than two, the center of the original one-site model breaks; the naive model then produces a reduced large-N_c state with charged reduced-word expectation values rather than the desired large-volume Wilson-loop theory. Quenched Eguchi–Kawai, twisted Eguchi–Kawai, partial reduction, and adjoint matter with periodic boundary conditions are different attempts to stabilize the needed center realization. Each changes the finite-regulator construction and therefore requires its own loop-equation and symmetry analysis. This monograph uses volume reduction only when the relevant center, factorization, and uniqueness hypotheses are explicitly part of the statement.

Fundamental quarks introduce boundaries rather than handles. A closed quark loop carries one fundamental color sum and one flavor sum. In the fixed-flavor 't Hooft limit N_f is held fixed, and a graph with b_q quark-loop boundaries scales as

$$N_f^{b_q} N_c^{2-2h-b_q}. \tag{49.52}$$

Thus each additional closed quark loop is suppressed by one power of N_c^{-1} relative to a gluonic planar vacuum contribution. In the Veneziano limit, by contrast, N_f/N_c is held fixed; the factor

$$N_f^{b_q} N_c^{2-2h-b_q} = \left(\frac{N_f}{N_c}\right)^{b_q} N_c^{2-2h}$$

shows that quark-loop boundaries are no longer suppressed. The Banks–Zaks discussion above naturally belongs to this Veneziano scaling when N_f/N_c is tuned close to 11/2.

The same counting explains the leading N_c-dependence of hadronic interactions in a confining large-N_c theory, subject to the separate spectral assumptions stated below. A mesonic color-singlet operator $M_{IJ} = \bar{q}_I q_J$ has a connected m-point function of order N_c when all insertions lie on one quark boundary. The canonically normalized meson source is therefore $N_c^{-1/2} M_{IJ}$, and connected m-meson amplitudes scale as $N_c^{1-m/2}$. Glueball operators normalized to have order-one connected two-point functions have connected m-point couplings of order N_c^{2-m}.

49.7.3 Large-N_c Baryons and Spin-Flavor Coordinates

Baryons require a separate order of limits and a separate normalization. In an $SU(N_c)$ theory with N_f fundamental quark flavors, a local baryon operator in a chosen spin-flavor channel has the color-antisymmetric local form

$$B_{\mathcal{A}}(x) = \epsilon_{i_1 \cdots i_{N_c}} \, \mathcal{A}^{I_1\alpha_1, \dots, I_{N_c}\alpha_{N_c}} \, q^{i_1}_{I_1\alpha_1}(x) \cdots q^{i_{N_c}}_{I_{N_c}\alpha_{N_c}}(x), \tag{49.53}$$

where i_r are color indices, I_r are flavor indices, α_r are spinor indices, and $\mathcal{A}$ is a tensor selecting the spin-flavor channel. The color tensor is totally antisymmetric. Therefore, for baryons built from quarks in the same spatial orbital, the remaining spin-flavor wavefunction is symmetric under exchange of the N_c quarks. This is a kinematic consequence of Fermi statistics and the ϵ-contraction, not a dynamical theorem about the spectrum.

Take the large-N_c limit with N_f fixed, quark masses fixed in N_c-independent units, and the spatial volume sent to infinity in the usual order needed to define particle states. If a baryon state created by (49.53) exists and has a Hartree description in which each quark moves in an N_c-independent mean field, then its leading mass is $O(N_c)$. Indeed there are N_c one-body contributions, while the two-body estimate gives

$$\binom{N_c}{2} g^2 = \frac{N_c(N_c-1)}{2} \, \frac{\lambda}{N_c} = \frac{\lambda}{2}(N_c - 1), \tag{49.54}$$

which is also $O(N_c)$ at fixed λ. The Hartree statement is a controlled large-N_c organization only after the existence of such color-singlet baryon states has been assumed or established in a regulator. It is not a derivation of baryons from the continuum Yang–Mills path integral.

Spin and flavor splittings are subleading in the same limit. If the baryon is described at low energy by a slowly rotating spin-flavor collective coordinate with moment of inertia $I_{\mathrm{rot}} = O(N_c)$, then the rotor contribution has the form

$$\Delta M_J = \frac{J(J+1)}{2 I_{\mathrm{rot}}}, \tag{49.55}$$

so fixed-spin splittings are $O(N_c^{-1})$. In theories with chiral symmetry breaking, the same scaling is compatible with a soliton description in the mesonic effective theory: $F_\pi^2 = O(N_c)$, meson interaction vertices have the large-N_c scaling $g_m = O(N_c^{1-m/2})$, and a soliton mass built from the mesonic action is $O(N_c)$. The spin-flavor multiplet structure often called contracted $SU(2N_f)$ is the algebraic form of the large-N_c consistency conditions on baryon matrix elements, for example on pion-baryon scattering. In this monograph it is used only with the displayed hypotheses: fixed N_f, a confining theory with baryon states, and a low-energy regime where the collective-coordinate description is valid. In the Veneziano limit with N_f/N_c fixed, the spin-flavor representation theory and baryon entropy grow differently and must be analyzed as a distinct limit.

For two light flavors the contracted spin-flavor algebra can be written without appealing to a quark-model Hamiltonian. It is the large-N_c limit of the exact one-body spin-flavor algebra acting on the symmetric spin-flavor part of a color-singlet baryon source.

Definition 49.6 (Two-flavor spin-flavor one-body generators)**.** On the spin-flavor space

$$\left(\mathbb{C}^2_{\text{spin}} \otimes \mathbb{C}^2_{\text{isospin}}\right)^{\otimes N_c}$$

write σ_r^i and τ_r^a for Pauli matrices acting on the spin and isospin factors of the r-th quark slot. Define

$$J^i = \sum_{r=1}^{N_c} \frac{\sigma_r^i}{2}, \qquad I^a = \sum_{r=1}^{N_c} \frac{\tau_r^a}{2}, \qquad G^{ia} = \sum_{r=1}^{N_c} \frac{\sigma_r^i \tau_r^a}{4}. \tag{49.56}$$

Here J^i generates spatial spin, I^a generates isospin, and G^{ia} is the mixed spin-isospin one-body generator. The normalization is fixed by the displayed Pauli matrices; it is independent of the gauge-group trace convention used in the Yang–Mills action.

Contraction of the two-flavor baryon spin-flavor algebra. The generators of Definition 49.6 satisfy the exact finite-N_c commutation relations

$$[J^i, J^j] = \mathrm{i}\varepsilon^{ijk} J^k, \qquad [I^a, I^b] = \mathrm{i}\varepsilon^{abc} I^c, \qquad [J^i, I^a] = 0, \tag{49.57}$$

$$[J^i, G^{ja}] = \mathrm{i}\varepsilon^{ijk} G^{ka}, \qquad [I^a, G^{ib}] = \mathrm{i}\varepsilon^{abc} G^{ic}, \tag{49.58}$$

$$[G^{ia}, G^{jb}] = \frac{\mathrm{i}}{4}\delta^{ij}\varepsilon^{abc} I^c + \frac{\mathrm{i}}{4}\delta^{ab}\varepsilon^{ijk} J^k. \tag{49.59}$$

Set $X^{ia} = G^{ia}/N_c$. On any sequence of baryon states whose matrix elements of J^i and I^a grow no faster than $O(N_c)$, the commutator of the rescaled mixed generators obeys

$$[X^{ia}, X^{jb}] = \frac{\mathrm{i}}{4N_c^2}\delta^{ij}\varepsilon^{abc} I^c + \frac{\mathrm{i}}{4N_c^2}\delta^{ab}\varepsilon^{ijk} J^k = O(N_c^{-1}) \tag{49.60}$$

in matrix elements, and it is $O(N_c^{-2})$ on fixed-spin and fixed-isospin families. The limiting algebra has X^{ia}'s transforming as vectors under spin and isospin but commuting among themselves. This is the two-flavor contracted $SU(4)$ algebra. Operators acting on different quark slots commute, so it is enough to compute the one-slot algebra. Let $s^i = \sigma^i/2$ and $t^a = \tau^a/2$. The Pauli relations give

$$[s^i, s^j] = \mathrm{i}\varepsilon^{ijk} s^k, \qquad \{s^i, s^j\} = \frac{1}{2}\delta^{ij},$$

and the same formulae with s, i, j, k replaced by t, a, b, c. Since spin and isospin matrices commute with each other,

$$[s^i t^a, s^j t^b] = \frac{1}{2}\{s^i, s^j\}[t^a, t^b] + \frac{1}{2}[s^i, s^j]\{t^a, t^b\}.$$

Substituting the Pauli relations gives

$$[s^i t^a, s^j t^b] = \frac{\mathrm{i}}{4}\delta^{ij}\varepsilon^{abc} t^c + \frac{\mathrm{i}}{4}\delta^{ab}\varepsilon^{ijk} s^k. \tag{49.61}$$

Summing (49.61) over the N_c quark slots gives (49.59). The remaining commutators follow in the same way from the facts that s^i transforms as a spin vector and t^a transforms as an isospin vector.

Dividing G^{ia} by N_c gives

$$[X^{ia}, X^{jb}] = \frac{1}{N_c^2}[G^{ia}, G^{jb}],$$

which is (49.60). If matrix elements of J and I are at most order N_c, the right-hand side is at most order N_c^{-1}. If the spin and isospin labels are held fixed as $N_c \to \infty$, it is order N_c^{-2}. The commutators with J and I in (49.58) survive the rescaling because $[J, X] = [J, G]/N_c$ and $[I, X] = [I, G]/N_c$. Thus the limiting algebra is a semidirect product of spin and isospin rotations with commuting generators X^{ia}.

The expansion also gives the perturbative origin of the string language used in the next section. Ribbon graphs are organized by the genus of an oriented surface, while the connected vacuum functional has the form

$$\log Z = \sum_{h \geq 0} N_c^{2-2h}\, F_h(\lambda)$$

as a formal expansion in $1/N_c^2$ at fixed λ. A confining flux tube, when it exists, is a different and more infrared object: it is defined by line operators and static-source sectors. The large-N_c topological expansion is therefore compatible with a genus expansion for a string description of gauge dynamics, but it is not itself a proof of the continuum QCD string or of confinement.

49.8 QCD Strings and Flux-Tube Effective Theory

The QCD string is the long-distance effective dynamics of a chromoelectric flux tube, defined by gauge-invariant line observables and by the spectrum in sectors with external color sources. In pure $SU(N_c)$ Yang–Mills theory there is a center one-form symmetry with charge in $\mathbb{Z}_{N_c}$. A Wilson line in a representation R has center charge equal to its N-ality $k_R \in \mathbb{Z}_{N_c}$. A static pair of external sources with nonzero k_R lies in a superselection sector that cannot relax to the vacuum by local gluonic excitations alone. The flux tube connecting the sources is the lowest-energy state in this sector at fixed separation.

For a Euclidean rectangle $C_{L,T}$, the transfer-matrix interpretation of $\langle W_R(C_{L,T})\rangle$ gives the spectral expansion

$$\langle W_R(C_{L,T})\rangle = \sum_\alpha |\langle \alpha; L, R|\mathcal{O}_R(L)\Omega\rangle|^2 \mathrm{e}^{-E_\alpha(L)T}, \qquad T > 0, \tag{49.62}$$

where $\mathcal{O}_R(L)$ is a gauge-invariant operator that creates the two static sources separated by L, and $|\alpha; L, R\rangle$ are eigenstates of the Hamiltonian in the corresponding static-source sector. If the lowest energy is isolated and the overlap in (49.62) is nonzero, then

$$V_R(L) = E_0(L) = -\lim_{T\to\infty} \frac{1}{T} \log\langle W_R(C_{L,T})\rangle.$$

The string tension in this sector is the asymptotic slope, when the limit exists,

$$\sigma_R := \lim_{L\to\infty} \frac{E_0(L)}{L}. \tag{49.63}$$

For representations with the same N-ality, gluon screening can change the short-distance representation carried by the flux, so the asymptotic tension depends on the center charge k_R, not on the full microscopic representation R, after all lower-energy screening channels are included.

49.8.1 Center Sectors and k-String Tensions

The preceding definition becomes sharper when the gauge theory has no dynamical fields of nonzero center charge. Let the microscopic gauge group be the simply connected group $SU(N_c)$, and let the only dynamical fields be adjoint fields. The electric one-form symmetry is then $\mathbb{Z}_{N_c}$. An external source in a representation R has center charge

$$k_R \equiv \text{number of fundamental boxes of } R \pmod{N_c}.$$

The static-source Hilbert space decomposes into sectors labelled by this charge. If dynamical matter of center charge q is present, the label is only the quotient charge left unscreened by such matter; if the global form of the gauge group is changed, the allowed Wilson lines and the one-form symmetry are changed as in the line-operator classification of Chapter 113. Thus a k-string is a spectral sector of a specified gauge theory, including its global form and its dynamical matter content, rather than an intrinsic label of a Lie algebra.

Definition 49.7 (Center-sector string tension)**.** In pure $SU(N_c)$ Yang–Mills theory, fix $k \in \{1, \dots, N_c - 1\}$. A k-string tension is the number

$$\sigma_k = \lim_{L\to\infty} \frac{E_k(L) - E_{\text{vac}}}{L}, \tag{49.64}$$

when the following objects and limits exist: a regulator with a positive transfer matrix, a static-source or winding-flux sector of electric center charge k, the lowest energy $E_k(L)$ in that sector for flux length L, the vacuum energy subtraction E_{vac} in the same finite box, and the thermodynamic and continuum limits in which the dimensionless ratio σ_k/σ_1 stabilizes. Charge conjugation identifies the sectors k and $N_c - k$, hence

$$\sigma_k = \sigma_{N_c-k}. \tag{49.65}$$

A sector is elementary at the level of tensions only if

$$\sigma_k < \min_{\substack{k_1+\cdots+k_m \equiv k \pmod{N_c} \\ m\geq 2}} (\sigma_{k_1} + \cdots + \sigma_{k_m}) \tag{49.66}$$

for all nontrivial decompositions into allowed unscreened center charges. If the inequality is saturated, the lowest state may be a multi-string threshold rather than a single stable flux tube.

The normalized ratios

$$R_k(N_c) = \frac{\sigma_k}{\sigma_1}$$

are nonperturbative observables. Two closed formulas are often useful as comparison coordinates, but neither is a theorem of nonsupersymmetric four-dimensional Yang–Mills theory:

$$R_k^{\text{Casimir}}(N_c) = \frac{k(N_c - k)}{N_c - 1}, \tag{49.67}$$

$$R_k^{\text{sine}}(N_c) = \frac{\sin(\pi k/N_c)}{\sin(\pi/N_c)}. \tag{49.68}$$

The first is the ratio of quadratic Casimirs of the rank-k antisymmetric representation and the fundamental representation. The second is the sine profile that appears in particular Abelianized supersymmetric BPS-vortex regimes, and is derived in that setting in Volume VII. In the present Yang–Mills discussion, both formulas are comparison functions for lattice or other nonperturbative determinations of σ_k.

Trace-delta Casimir comparison. Let t^a be $SU(N_c)$ fundamental generators normalized by

$$\mathrm{tr}_\square(t^a t^b) = \delta^{ab}.$$

Let $A_k = \Lambda^k \mathbb{C}^{N_c}$ be the rank-k antisymmetric representation, $1 \le k \le N_c - 1$. The comparison function (49.67) comes from the following representation-theory calculation in the same trace convention as the Yang–Mills action. The quadratic Casimir eigenvalues are

$$C_2(A_k) = \frac{k(N_c - k)(N_c + 1)}{N_c}, \qquad C_2(\square) = \frac{N_c^2 - 1}{N_c}, \tag{49.69}$$

and hence

$$\frac{C_2(A_k)}{C_2(\square)} = \frac{k(N_c - k)}{N_c - 1}.$$

The trace-delta Fierz identity in the fundamental representation is

$$\sum_a (t^a)^i{}_j (t^a)^m{}_n = \delta^i{}_n \delta^m{}_j - \frac{1}{N_c} \delta^i{}_j \delta^m{}_n. \tag{49.70}$$

Contracting $j = n$ and summing over j gives

$$\sum_a (t^a t^a)^i{}_m = \left(N_c - \frac{1}{N_c}\right) \delta^i{}_m,$$

so $C_2(\square) = (N_c^2 - 1)/N_c$.

On $V^{\otimes k}$, with $V = \mathbb{C}^{N_c}$, the total generator is

$$T^a_{\mathrm{tot}} = \sum_{r=1}^{k} t^a_{(r)},$$

where $t^a_{(r)}$ acts on the r-th tensor factor. Its quadratic Casimir is

$$\sum_a T^a_{\mathrm{tot}} T^a_{\mathrm{tot}} = \sum_{r=1}^{k} \sum_a t^a_{(r)} t^a_{(r)} + 2 \sum_{1 \le r < s \le k} \sum_a t^a_{(r)} t^a_{(s)}.$$

By (49.70), the two-site operator is

$$\sum_a t^a_{(r)} t^a_{(s)} = P_{rs} - \frac{1}{N_c},$$

where P_{rs} exchanges the two tensor factors. On $\Lambda^k V$, $P_{rs} = -1$. Therefore

$$C_2(A_k) = k\, \frac{N_c^2 - 1}{N_c} + 2\binom{k}{2}\left(-1 - \frac{1}{N_c}\right) = \frac{k(N_c - k)(N_c + 1)}{N_c}.$$

Dividing by the fundamental value gives (49.67). The factor-of-two convention in the generator trace cancels in the ratio, but it is displayed because this chapter uses the trace-delta normalization throughout.

For $1 \leq k \leq N_c - 1$, the sine comparison function (49.68) has the charge-conjugation symmetry

$$R_k^{\text{sine}}(N_c) = R_{N_c-k}^{\text{sine}}(N_c),$$

the strict subadditivity property

$$R_{k+\ell}^{\text{sine}}(N_c) < R_k^{\text{sine}}(N_c) + R_\ell^{\text{sine}}(N_c), \qquad k, \ell \geq 1, \quad k + \ell \leq N_c - 1, \tag{49.71}$$

and the fixed-k, large-N_c expansion

$$R_k^{\text{sine}}(N_c) = k - \frac{\pi^2}{6} \frac{k(k^2-1)}{N_c^2} + O(N_c^{-4}). \tag{49.72}$$

The first identity is $\sin(\pi(N_c - k)/N_c) = \sin(\pi k/N_c)$. The inequality follows from

$$\sin a + \sin b - \sin(a+b) = 4 \sin \frac{a}{2} \sin \frac{b}{2} \sin \frac{a+b}{2} > 0, \qquad a = \frac{\pi k}{N_c}, \quad b = \frac{\pi \ell}{N_c},$$

in the range $0 < a, b$ and $a + b < \pi$. The expansion is the quotient of the Taylor series for $\sin(\pi k/N_c)$ and $\sin(\pi/N_c)$. These identities are finite comparison algebra; the dynamical question is whether a continuum gauge theory has flux-sector transfer-matrix eigenvalues whose ratios approach one of these comparison functions.

The Casimir comparison function obeys the same charge-conjugation symmetry, and its fixed-k expansion begins as

$$R_k^{\text{Casimir}}(N_c) = k - \frac{k(k-1)}{N_c} + O(N_c^{-2}). \tag{49.73}$$

This is the expansion of

$$\frac{k(N_c - k)}{N_c - 1} = k \frac{1 - k/N_c}{1 - 1/N_c}.$$

The different $1/N_c$ behavior in (49.72) and (49.73) is one reason that k-strings are useful probes of large-N_c confinement dynamics. For the low ranks often used in lattice comparisons, the two functions give

N_c	k	R_k^{Casimir}	R_k^{sine}
4	2	4/3	$\sqrt{2}$
5	2	3/2	$(1+\sqrt{5})/2$
6	2	8/5	$\sqrt{3}$
6	3	9/5	2
8	2	12/7	$\sqrt{2+\sqrt{2}}$
8	3	15/7	$1+\sqrt{2}$
8	4	16/7	$\sqrt{4+2\sqrt{2}}$

Published lattice determinations for $SU(4)$, $SU(5)$, $SU(6)$, and $SU(8)$ determine the transfer-matrix quantity σ_k/σ_1 after continuum extrapolation, with operator-overlap, finite-volume, and lattice-spacing errors stated. A derivation of either comparison formula would require an independent spectral argument inside the gauge theory. The improved pure-gauge computations generally place the measured ratios between the two comparison curves; the support supplied by those measurements is for that interpolation pattern rather than for exact Casimir scaling in four-dimensional nonsupersymmetric Yang–Mills theory.

Controlled Approximation 49.8 (k-string comparison formulas)**.** When this monograph compares lattice k-string data to (49.67) or (49.68), the comparison means precisely this: the lattice calculation supplies a nonperturbative estimate of σ_k/σ_1, while the two displayed functions are finite comparison coordinates with distinct group-theoretic or supersymmetric origins. No conclusion about the microscopic mechanism of confinement follows from numerical closeness alone. A mechanism claim would require an operator-level derivation of the relevant transfer-matrix sector and its large-L spectrum.

49.8.2 Effective String Action and the Luscher Term

Figure 49.7 records the static-source flux tube as the object whose ground-state energy $E_0(L)$ defines the string tension σ_R in (49.63).

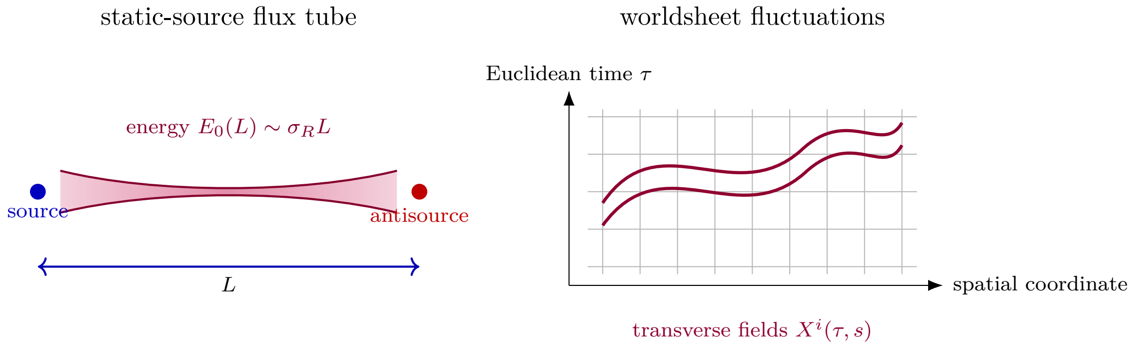

Figure 49.7: The QCD string is the long-distance flux-tube sector selected by gauge-invariant line operators. At large separation the lowest energy is extensive in the source separation, while the low-energy excitations are transverse fluctuations of the flux-tube worldsheet.

The effective string description uses QCD as its microscopic definition and expands the flux-tube energies and matrix elements at large L. Choose worldsheet coordinates (τ, s), with $0 \le s \le L$, and fix static gauge so that the embedding of the worldsheet in D-dimensional spacetime is

$$X^0(\tau, s) = \tau, \qquad X^1(\tau, s) = s, \qquad X^i(\tau, s) \;\; (i = 2, \dots, D-1)$$

for the transverse fluctuations. The leading local action compatible with worldsheet locality, Euclidean time translation, spatial rotations transverse to the string, and the nonlinear realization of target-space Poincare symmetry is the area action

$$S_{\text{eff}} = \sigma_R \int \mathrm{d}\tau\, \mathrm{d}s \sqrt{\det(\delta_{ab} + \partial_a X^i \partial_b X^i)} + \mu_R \int \mathrm{d}\tau + S_{\text{higher}}, \tag{49.74}$$

where $a, b \in \{\tau, s\}$, repeated transverse indices i are summed, and μ_R is an endpoint energy for an open string ending on external sources. The term S_{higher} contains local operators with more derivatives and possible boundary terms. Expanding the square root gives

$$S_{\text{eff}} = \sigma_R L T + \frac{\sigma_R}{2} \int \mathrm{d}\tau\, \mathrm{d}s\, \partial_a X^i \partial_a X^i + \cdots .$$

The first quantum correction to the flux-tube energy is therefore a worldsheet determinant. The determinant must be renormalized as an effective field-theory determinant: local divergent terms are absorbed into the worldsheet area coefficient, endpoint energies, and higher local operators, while the nonlocal finite term is a prediction.

Lemma 49.9 (Free transverse determinant and the Luscher term)**.** *Assume that, at distances $L\sqrt{\sigma_R} \gg 1$, the only gapless worldsheet fields of the open static-source flux tube are the $c_\perp = D-2$ transverse displacement fields X^i, and that the static sources impose Dirichlet boundary conditions on these displacements at $s = 0, L$. After subtracting local counterterms proportional to the worldsheet area and to the length of the two boundaries, the Gaussian fluctuation determinant contributes*

$$\Delta E_0^{\mathrm{open}}(L) = -\frac{\pi c_\perp}{24L}$$

to the long-time energy extracted from the rectangular Wilson loop. For a closed flux tube winding a spatial circle of length L, with periodic transverse fields and with the transverse zero mode treated as the center-of-mass coordinate rather than as an oscillator, the corresponding finite part is

$$\Delta E_0^{\mathrm{closed}}(L) = -\frac{\pi c_\perp}{6L}.$$

Proof. The coefficient σ_R in the quadratic action is removed from the oscillator frequencies by the canonical rescaling $Y^i = \sqrt{\sigma_R} X^i$. For one open transverse scalar with Dirichlet boundary conditions,

$$Y(\tau, s) = \sum_{n\geq 1} q_n(\tau) \sin\frac{\pi n s}{L}, \qquad \omega_n = \frac{\pi n}{L}.$$

The formal zero-point energy is $\frac{1}{2}\sum_{n\geq 1}\omega_n$. A spectral regulator gives

$$E_\alpha^{\mathrm{open}}(L) = \frac{1}{2}\sum_{n\geq 1}\frac{\pi n}{L}\, n^{-\alpha} = \frac{\pi}{2L}\zeta_{\mathrm{R}}(\alpha - 1).$$

The heat-kernel expansion of this regulated determinant contains local divergences proportional to L and to the endpoints. These renormalize σ_R and μ_R in (49.74). The nonlocal finite part is the analytic continuation at $\alpha = 0$:

$$E_{\mathrm{fin}}^{\mathrm{open}}(L) = \frac{\pi}{2L}\zeta_{\mathrm{R}}(-1) = -\frac{\pi}{24L}.$$

Multiplication by $c_\perp$ gives the open-string coefficient.

For one periodic transverse scalar on a circle, the nonzero modes are labelled by $n \in \mathbb{Z}\setminus\{0\}$ and have $\omega_n = 2\pi|n|/L$. Equivalently, for each $n \geq 1$ there are sine and cosine oscillators of frequency $2\pi n/L$. The zero-point contribution is therefore

$$E_\alpha^{\mathrm{closed}}(L) = \sum_{n\geq 1}\frac{2\pi n}{L}\, n^{-\alpha} = \frac{2\pi}{L}\zeta_{\mathrm{R}}(\alpha - 1),$$

whose finite part at $\alpha = 0$ is $-\pi/(6L)$. The omitted zero mode is the transverse center-of-mass coordinate of the closed string; it produces the ordinary volume normalization of the state rather than an L^{-1} Casimir energy. This proves the closed coefficient. □

Consequently, under the hypotheses of Lemma 49.9, the open-string ground-state energy has the universal large-L form

$$E_0(L) = \sigma_R L + \mu_R - \frac{\pi(D-2)}{24L} + O(L^{-3}) \tag{49.75}$$

for a long open flux tube. For a closed flux tube winding a spatial circle, the corresponding leading form is

$$E_0^{\text{closed}}(L) = \sigma_k L - \frac{\pi(D-2)}{6L} + O(L^{-3}), \tag{49.76}$$

again under the assumption that the only gapless worldsheet fields are the transverse displacement modes. The coefficients of the displayed $1/L$ terms are universal because they depend only on the central charge $D-2$ of these free transverse modes. The higher powers in $1/L$, the spectrum of massive worldsheet excitations, and the validity range of the expansion are dynamical properties of the particular gauge theory.

The Nambu–Goto square-root spectrum is a useful reference point, not the definition of the QCD string. If all higher-derivative and boundary coefficients in S_{higher} are set to their Nambu–Goto values, the open and closed ground-state energies expand as

$$\begin{aligned}
E_0^{\text{NG,open}}(L) &= \sigma_R L\sqrt{1 - \frac{\pi(D-2)}{12\sigma_R L^2}} \\
&= \sigma_R L - \frac{\pi(D-2)}{24L} - \frac{\pi^2(D-2)^2}{1152\,\sigma_R L^3} + O(L^{-5}), \qquad (49.77)\\
E_0^{\text{NG,closed}}(L) &= \sigma_R L\sqrt{1 - \frac{\pi(D-2)}{3\sigma_R L^2}} \\
&= \sigma_R L - \frac{\pi(D-2)}{6L} - \frac{\pi^2(D-2)^2}{72\,\sigma_R L^3} + O(L^{-5}). \qquad (49.78)
\end{aligned}$$

The equality of the $1/L$ term with (49.75) and (49.76) is forced by the free transverse massless fields. Agreement at later orders is a statement about the effective-string matching coefficients and the nonlinearly realized target-space Lorentz symmetry, and must be checked or imposed in the particular effective theory being used.

Controlled Approximation 49.10 (Effective string expansion of a confining flux tube)**.** An effective-string prediction for a flux-tube level consists of a static source sector or closed-string winding sector, a renormalized string tension, boundary counterterms when endpoints are present, a list of gapless and massive worldsheet fields, a local derivative expansion for S_{higher}, and a declared large-distance regime

$$L\sqrt{\sigma_R} \gg 1, \qquad E_{\text{gap}}^{\text{ws}} L \gg 1$$

for every massive worldsheet excitation not retained explicitly. The universal Luscher term is the first finite prediction under these hypotheses. Every later coefficient is either fixed by the worldsheet symmetry constraints within the chosen effective theory or is a matching parameter to be determined from the microscopic gauge theory, for example from lattice static-potential or flux-tube spectrum data.

49.8.3 Excited Flux-Tube Levels

The same quadratic worldsheet theory gives the first approximation to the excited flux-tube spectrum. For an open string with fixed endpoints, the transverse oscillator modes are labelled by

$$n \in \mathbb{Z}_{>0}, \qquad i = 1, \ldots, c_\perp, \qquad c_\perp = D-2.$$

Let $N_{n,i} \in \mathbb{Z}_{\geq 0}$ be the occupation number of the oscillator of frequency $\pi n/L$. The total oscillator level is

$$N = \sum_{i=1}^{c_\perp} \sum_{n\geq 1} n\, N_{n,i}. \tag{49.79}$$

The Gaussian effective string therefore predicts

$$E_N^{\text{open}}(L) = \sigma_R L + \mu_R + \frac{\pi}{L}\left(N - \frac{c_\perp}{24}\right) + O(L^{-3}) \tag{49.80}$$

before the L^{-3} corrections from the nonlinear action and boundary operators are included. The number of oscillator states at level N, prior to resolving the finite symmetry group of the particular flux-tube channel, is the coefficient of q^N in

$$Z_{\text{open,osc}}(q) = \prod_{n=1}^{\infty} (1-q^n)^{-c_\perp}. \tag{49.81}$$

For $D = 4$, where $c_\perp = 2$, the first coefficients are

$$1,\ 2,\ 5,\ 10, \ldots.$$

These are not yet a complete list of lattice quantum numbers. A flux tube between static sources also carries parity, charge conjugation when defined, and angular momentum around the source axis; those labels are obtained by decomposing the oscillator states under the residual spacetime symmetries of the static-source sector.

In four spacetime dimensions, place a static fundamental source and static antifundamental source on the z-axis at $z = \pm L/2$. The continuum symmetry group preserving this source pair is the usual cylindrical group $D_{\infty h}$. Its labels are:

$$\Lambda = 0, 1, 2, \ldots \quad \Longleftrightarrow \quad \Sigma, \Pi, \Delta, \Phi, \ldots,$$

where Λ is the absolute value of the angular momentum about the source axis; a sign $\eta = \pm 1$, denoted g/u, for the combined operation which exchanges the source and antisource and inverts about the midpoint; and, only for $\Lambda = 0$, a reflection sign $\epsilon = \pm$ for reflection through a plane containing the source axis. At finite lattice spacing with the axis chosen along a lattice direction, $D_{\infty h}$ is reduced to the corresponding lattice subgroup. The continuum labels are therefore continuum and large-distance assignments obtained after subduction and extrapolation, not exact labels of a single finite lattice calculation.

Open flux-tube oscillator labels. Assume the Gaussian open-string sector in $D = 4$, with circular transverse oscillators $a^\dagger_{n,+}$ and $a^\dagger_{n,-}$ of frequency $\pi n/L$, where $n \geq 1$ and the signs denote angular momentum ± 1 about the source axis. For a Fock monomial

$$\prod_{n\geq 1} \left(a^\dagger_{n,+}\right)^{N_{n,+}} \left(a^\dagger_{n,-}\right)^{N_{n,-}} \Omega_{\text{str}},$$

the oscillator level, axial angular-momentum label, and g/u sign are

$$N = \sum_{n\geq 1} n(N_{n,+} + N_{n,-}), \tag{49.82}$$

$$\Lambda = \left| \sum_{n\geq 1} (N_{n,+} - N_{n,-}) \right|, \tag{49.83}$$

$$\eta = (-1)^{\sum_{n\geq 1} n(N_{n,+}+N_{n,-})}. \tag{49.84}$$

For $\Lambda = 0$, reflection through a plane containing the source axis exchanges $+$ and $-$ oscillators, so reflection eigenstates are the even and odd combinations of each reflection orbit; if the monomial is pointwise fixed by this exchange, only the even Σ^+ state is obtained.

This is bookkeeping in the Gaussian reference Hilbert space. The level formula is the definition of the open-string oscillator level in (49.79). A circular transverse oscillator is built from

$$X^+ = X^2 + iX^3, \qquad X^- = X^2 - iX^3.$$

Under a rotation by angle α about the source axis, $X^\pm \mapsto e^{\pm i\alpha} X^\pm$. A monomial with occupations $N_{n,\pm}$ therefore has axial angular momentum $\sum_n (N_{n,+} - N_{n,-})$, and the irreducible cylindrical label records its absolute value Λ.

The operation defining g/u exchanges the endpoints and sends $(z, X^2, X^3) \mapsto (-z, -X^2, -X^3)$ in the static-source coordinate system. The mode function transforms as

$$\sin \frac{\pi n(L-s)}{L} = (-1)^{n+1} \sin \frac{\pi n s}{L},$$

while the transverse vector itself contributes the additional sign -1. Thus a single n-th transverse oscillator has eigenvalue $(-1)^n$ under the combined operation, and multiplication over all occupied oscillators gives the sign η in (49.84). Reflection through a plane containing the axis complex-conjugates X^+ and X^-, hence exchanges the two circular polarizations. For $\Lambda > 0$ this reflection relates the two helicity components of the same two-dimensional real representation. For $\Lambda = 0$ it can be diagonalized, giving $\epsilon = \pm$ when the reflection orbit has two monomials and only the even state when the monomial is fixed.

For the first oscillator levels in $D = 4$ this gives

level N	$D_{\infty h}$ content of the Gaussian reference sector	total oscillator degeneracy
0	Σ_g^+	1
1	Π_u	2
2	$\Sigma_g^+ \oplus \Pi_g \oplus \Delta_g$	5
3	$\Sigma_u^+ \oplus \Sigma_u^- \oplus 2\Pi_u \oplus \Delta_u \oplus \Phi_u$	10

At the next level the decomposition contains

$$3\Sigma_g^+ \oplus \Sigma_g^- \oplus 3\Pi_g \oplus 3\Delta_g \oplus \Phi_g \oplus (\Lambda = 4)_g,$$

with total oscillator degeneracy 20. Thus Σ_g^- is an allowed cylindrical channel, but it is not present in the first three free transverse-oscillator levels. This distinction matters when one compares the long-string reference spectrum with hybrid static-potential data.

The table is a long-string reference decomposition. A measured hybrid static potential in the same Λ_η^ϵ channel may contain massive surface excitations, endpoint-local excitations, or short-distance gluelump physics that are not present in the free transverse oscillator Hilbert space. Conversely, the free oscillator labels become useful at large L only after a transfer-matrix calculation has isolated the corresponding static sector and after the effective-string expansion is within its declared regime.

In the lattice program initiated by Juge, Kuti, and Morningstar, the objects called Π_u, Σ_g^-, $\Sigma_u^\pm$, Π_g, and so on are channel-resolved static energies extracted from correlation matrices of gauge-invariant source operators subduced to the finite lattice subgroup of $D_{\infty h}$. The label is therefore assigned before an effective-string fit is made. At small separation the same channel can be governed by a gluelump-like excitation of the gauge field bound to a compact static color-octet source pair; at large separation, if no lower massive worldsheet or endpoint excitation intervenes, the channel may approach one of the long-string oscillator towers above. The observed L-dependence of a hybrid static potential is the interpolation between these two spectral descriptions, with the Nambu–Goto reference formula supplying only the asymptotic massless-transverse-oscillator comparison. The channels Π_u and Σ_g^- are especially useful diagnostics: Π_u is the first transverse oscillator tower in the Gaussian long-string limit, whereas a low-lying Σ_g^- level indicates additional channel dynamics until the higher-level long-string asymptotics are actually reached.

For a closed flux tube winding a spatial circle, the quadratic theory has left- and right-moving oscillators. Define

$$N_L = \sum_{i=1}^{c_\perp} \sum_{n\geq 1} n\, N_{n,i}^L, \qquad N_R = \sum_{i=1}^{c_\perp} \sum_{n\geq 1} n\, N_{n,i}^R.$$

Translation along the winding circle gives a quantized longitudinal momentum

$$p_\parallel = \frac{2\pi q}{L}, \qquad q \in \mathbb{Z},$$

and the residual worldsheet translation constraint imposes the level-matching condition

$$N_L - N_R = q. \tag{49.85}$$

At Gaussian order the closed-string energy is

$$E_{N_L,N_R,q}^{\text{closed}}(L) = \sigma_k L + \frac{2\pi}{L}\left(N_L + N_R - \frac{c_\perp}{12}\right) + O(L^{-3}), \tag{49.86}$$

with the q-dependent kinetic contribution first entering at order L^{-3} in the large-L expansion. The $N_L = N_R = 0$ case recovers (49.76).

In the Nambu–Goto reference theory these oscillator levels are packaged into the square-root formulas

$$E_N^{\text{NG,open}}(L) = \sigma_R L \sqrt{1 + \frac{2\pi}{\sigma_R L^2}\left(N - \frac{c_\perp}{24}\right)}, \tag{49.87}$$

$$E_{N_L,N_R,q}^{\text{NG,closed}}(L) = \sigma_k L \sqrt{1 + \frac{4\pi}{\sigma_k L^2}\left(N_L + N_R - \frac{c_\perp}{12}\right) + \left(\frac{2\pi q}{\sigma_k L^2}\right)^2}, \tag{49.88}$$

with (49.85) imposed in the closed case. Expanding these formulas gives

$$E_N^{\mathrm{NG,open}}(L) = \sigma_R L + \frac{\pi}{L}\left(N - \frac{c_\perp}{24}\right) - \frac{\pi^2}{2\sigma_R L^3}\left(N - \frac{c_\perp}{24}\right)^2 + O(L^{-5}), \tag{49.89}$$

$$\begin{aligned} E_{N_L,N_R,q}^{\mathrm{NG,closed}}(L) = \sigma_k L &+ \frac{2\pi}{L}\left(N_L + N_R - \frac{c_\perp}{12}\right) \\ &+ \frac{2\pi^2}{\sigma_k L^3}\left[q^2 - \left(N_L + N_R - \frac{c_\perp}{12}\right)^2\right] + O(L^{-5}). \end{aligned} \tag{49.90}$$

The square-root formulas are useful because they organize a large set of levels with the same conventions, but the QCD statement is weaker and more precise: the Gaussian $1/L$ structure follows from the assumed gapless transverse modes, while the $1/L^3$ and later terms are effective-string matching data unless a universality theorem for the relevant order and boundary condition has been established.

49.8.4 Oscillator Growth and the Flux-String Hagedorn Scale

The degeneracy of the oscillator levels in (49.81) grows exponentially. This growth is a statement about the effective long-string Hilbert space. The deconfinement transition of the four-dimensional gauge theory is a property of the thermal gauge-theory transfer matrix and is discussed in Volume X. The calculation here gives the scale at which a gas of arbitrarily long effective-string states ceases to have a finite canonical partition function inside the regime where the long-string description is used.

Colored-partition growth and the string Hagedorn scale. Let $p_c(N)$ be the coefficient of q^N in

$$\prod_{n=1}^{\infty}(1-q^n)^{-c}, \qquad c \in \mathbb{Z}_{>0}.$$

Then

$$\log p_c(N) = 2\pi\sqrt{\frac{cN}{6}} + O(\log N) \qquad (N \to \infty). \tag{49.91}$$

For the Nambu–Goto reference spectrum of a long confining flux string with $c_\perp = D-2$ transverse massless fields and tension σ, the oscillator density has the exponential scale

$$\rho(E) \sim \exp(\beta_{\mathrm{H}}^{\mathrm{ws}} E), \qquad \beta_{\mathrm{H}}^{\mathrm{ws}} = \sqrt{\frac{\pi c_\perp}{3\sigma}}. \tag{49.92}$$

Set $q = \mathrm{e}^{-\varepsilon}$, with $\varepsilon > 0$. The logarithm of the oscillator generating function is

$$-c\sum_{n\geq 1}\log(1-\mathrm{e}^{-n\varepsilon}) = c\sum_{m\geq 1}\frac{1}{m}\frac{\mathrm{e}^{-m\varepsilon}}{1-\mathrm{e}^{-m\varepsilon}}.$$

As $\varepsilon \downarrow 0$, comparison with the corresponding Riemann sum, or equivalently the modular transformation of the Dedekind eta function, gives

$$\log\prod_{n=1}^{\infty}(1-\mathrm{e}^{-n\varepsilon})^{-c} = \frac{\pi^2 c}{6\varepsilon} + O(\log\varepsilon). \tag{49.93}$$

Cauchy's coefficient formula writes $p_c(N)$ as the contour integral of $q^{-N-1}\prod_n(1-q^n)^{-c}$. The exponential part of the integrand on the positive saddle is

$$N\varepsilon + \frac{\pi^2 c}{6\varepsilon}.$$

The stationary point is

$$\varepsilon_* = \pi\sqrt{\frac{c}{6N}},$$

and the saddle exponent is

$$N\varepsilon_* + \frac{\pi^2 c}{6\varepsilon_*} = 2\pi\sqrt{\frac{cN}{6}}.$$

Gaussian fluctuations and the $O(\log\varepsilon)$ term in (49.93) contribute only logarithmic corrections to $\log p_c(N)$, proving (49.91).

For an open Nambu–Goto reference string at large excitation number, (49.87) gives

$$E^2 = 2\pi\sigma N + O(N^0)$$

in the oscillator-dominated regime. Substituting $N = E^2/(2\pi\sigma) + O(1)$ into (49.91) gives

$$\log\rho(E) = 2\pi\sqrt{\frac{c_\perp}{6}\frac{E^2}{2\pi\sigma}} + O(\log E) = E\sqrt{\frac{\pi c_\perp}{3\sigma}} + O(\log E).$$

For a closed string with level matching at zero longitudinal momentum, $N_L = N_R = N$. The degeneracy is $p_{c_\perp}(N)^2$, while (49.88) gives

$$E^2 = 8\pi\sigma N + O(N^0).$$

The doubled entropy and the doubled energy coefficient combine to the same $\beta_{\mathrm{H}}^{\mathrm{ws}}$. This proves (49.92).

Controlled Approximation 49.11 (Flux-tube Hagedorn scale)**.** Equation (49.92) is a consequence of three declared inputs: a stable long flux-tube sector, $c_\perp$ massless transverse fields with the oscillator generating function above, and the Nambu–Goto high-level relation between excitation level and energy. It is a worldsheet-density statement. A four-dimensional deconfinement temperature requires the thermal gauge-theory path integral, center symmetry and matter-content data, and the infinite-volume limit. Equality between a thermal transition scale and the worldsheet Hagedorn scale is an additional dynamical statement whose proof would have to relate the thermal transfer matrix to the long-string density (49.92).

49.8.5 Static Observables, Lattice Extraction, and the Meaning of String Tension

The static potential and the effective string are nonperturbative objects. Their definition does not use perturbative gluon states. It uses the Hilbert space obtained from the gauge theory with external static sources, or equivalently the transfer matrix acting on gauge-invariant line-operator states. On a Euclidean lattice with spacing a_{lat}, a rectangular Wilson loop is the trace of the ordered product of link variables around the rectangle. In the continuum notation used in this chapter it is written

$$W_R(C) = \mathrm{tr}_R\ \mathcal{P}\exp\left(i\oint_C A_\mu\,\mathrm{d}x^\mu\right),$$

where R is a representation of the gauge group and $\mathcal{P}$ denotes ordering along the contour. The continuum expression is a compact notation for the renormalized line operator obtained from a chosen regulator; a Wilson loop with cusps or corners has additional local renormalizations at those singular points.

The area-law statement relevant for the static flux tube is therefore a statement after local perimeter and corner terms have been separated. For large rectangles $C_{L,T}$, a pure gauge theory in a confining center sector has

$$-\log\langle W_R(C_{L,T})\rangle = \sigma_k LT + \rho_R(L+T) + \kappa_R + o(LT) \tag{49.94}$$

when both L and T are large in a regime where the lowest flux-tube channel of N-ality $k = k_R$ dominates. The perimeter coefficient ρ_R and the corner coefficient κ_R are not the string tension. They depend on the definition of the line operator and on its ultraviolet renormalization. The coefficient σ_k is the asymptotic energy per unit length of the lowest flux tube in the corresponding center-charge sector.

Rectangular area coefficient and static-potential slope. The equality between the rectangular area coefficient and the large-distance static-potential slope is a transfer-matrix extraction, not an independent proof of confinement. Assume the static-source spectral expansion (49.62), assume a nonzero overlap with the lowest state for all sufficiently large L, and assume that the gap above $E_0(L)$ is bounded below by a positive function whose large-T suppression is uniform in the large-L window under consideration. If

$$E_0(L) = \sigma_k L + \mu_R + o(L) \qquad (L\to\infty),$$

then the coefficient of LT in $-\log\langle W_R(C_{L,T})\rangle$, with $T\to\infty$ taken before the large-L slope, is σ_k. Conversely, if the rectangular Wilson loop has the form (49.94) with a controlled transfer-matrix limit at each fixed L, then

$$\lim_{L\to\infty}\frac{E_0(L)}{L} = \sigma_k.$$

Indeed, writing the spectral expansion in the form

$$\langle W_R(C_{L,T})\rangle = c_0(L)\mathrm{e}^{-E_0(L)T}\left[1+\sum_{\alpha>0}\frac{c_\alpha(L)}{c_0(L)}\mathrm{e}^{-(E_\alpha(L)-E_0(L))T}\right],$$

where $c_0(L)\neq 0$ by hypothesis. The uniform gap assumption implies that the logarithm of the bracket divided by T vanishes as $T\to\infty$, so

$$-\lim_{T\to\infty}\frac{1}{T}\log\langle W_R(C_{L,T})\rangle = E_0(L).$$

If $E_0(L) = \sigma_k L + \mu_R + o(L)$, the coefficient multiplying LT in the large-rectangle logarithm is σ_k; the L-independent endpoint energy μ_R, the overlap $c_0(L)$, perimeter terms, and corner terms do not contribute to the double slope $\lim_{L\to\infty} L^{-1}\lim_{T\to\infty} T^{-1}(-\log\langle W\rangle)$. The converse is the same identity read in the opposite direction: the transfer-matrix limit extracts $E_0(L)$, and the assumed rectangular area coefficient fixes the large-L slope of this extracted energy.

On a Euclidean time circle of circumference β, the corresponding static observable is the Polyakov loop

$$P_R(\mathbf{x}) = \mathrm{tr}_R\, \mathcal{P} \exp\left(i \int_0^\beta A_0(\tau, \mathbf{x})\, \mathrm{d}\tau\right).$$

The two-source free energy is defined by

$$F_R(L; \beta) = -\frac{1}{\beta} \log\langle P_R(\mathbf{0})^\dagger P_R(\mathbf{L})\rangle_\beta.$$

When the zero-temperature transfer-matrix limit is taken by sending $\beta \to \infty$, $F_R(L; \beta)$ approaches the same static energy extracted from a long rectangular Wilson loop, up to the vacuum-energy and line-renormalization conventions used in defining the loop. At finite temperature in pure Yang–Mills theory, the expectation value of a single fundamental Polyakov loop is charged under the temporal center symmetry and is therefore an order parameter for that finite-temperature symmetry after the infinite-volume limit is specified. This is related to, but not identical with, the zero-temperature string tension σ_k. The latter is a property of the large-distance static-source spectrum.

In practical lattice calculations one does not measure σ_k by fitting a bare Wilson loop alone. One constructs a family of gauge-invariant operators in the same static-source sector, computes their Euclidean correlation matrix, and uses a variational transfer-matrix problem to isolate the lowest and excited energies. The effective string expansion then describes the large-L behavior of these extracted energies. This is the operational reason that the QCD string is a nonperturbative observable: it is a statement about the spectrum selected by gauge-invariant line operators, not about perturbative gluons propagating between color charges.

49.8.6 Baryonic Flux Networks

Baryonic confinement is not a copy of the mesonic static potential with one more endpoint. In an $SU(N_c)$ gauge theory a gauge-invariant static baryon operator is made by joining N_c fundamental Wilson lines to a common color junction and contracting their color indices with $\epsilon_{i_1\cdots i_{N_c}}$. For paths Γ_r running from a junction point y to source positions $\mathbf{x}_r$,

$$\mathcal{B}_{\Gamma_1,\ldots,\Gamma_{N_c}} = \epsilon_{i_1\cdots i_{N_c}} U(\Gamma_1)^{i_1}{}_{j_1} \cdots U(\Gamma_{N_c})^{i_{N_c}}{}_{j_{N_c}} Q^{j_1}(\mathbf{x}_1) \cdots Q^{j_{N_c}}(\mathbf{x}_{N_c}).$$

Here $Q^j(\mathbf{x}_r)$ denotes a static fundamental source insertion; it is not a dynamical asymptotic quark state. The determinant-one property of $SU(N_c)$ makes the contraction at the junction gauge invariant. For $N_c = 3$, and for source separations large compared with the inverse mass gap, the leading string model predicts an energy proportional to the length of the minimal three-pronged network, not to a unique pairwise potential. Endpoint and junction energies are local terms and must be separated from the coefficient of the large lengths:

$$V_{3Q}(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3) = \sigma\, L_Y(\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3) + \mu_1 + \mu_2 + \mu_3 + \mu_J + o(L_Y). \tag{49.95}$$

Proposition 49.12 (Steiner length for a three-source baryonic string)**.** *Let $a = |\mathbf{x}_2 - \mathbf{x}_3|$, $b = |\mathbf{x}_3 - \mathbf{x}_1|$, and $c = |\mathbf{x}_1 - \mathbf{x}_2|$ be the side lengths of a Euclidean triangle, and let Δ be its area. If* *every angle of the triangle is less than $2\pi/3$, the length minimizing $\sum_{r=1}^{3} |\mathbf{y} - \mathbf{x}_r|$ is realized by a point $\mathbf{y}_F$ from which the three segments meet at angles $2\pi/3$, and*

$$L_Y^2 = \frac{1}{2}\left(a^2 + b^2 + c^2 + 4\sqrt{3}\,\Delta\right). \tag{49.96}$$

If one angle is at least $2\pi/3$, the minimizing network collapses to the two sides adjacent to that angle.

Proof. For an interior minimizer $\mathbf{y}_F$, vary $\mathbf{y} \mapsto \mathbf{y} + \delta\mathbf{y}$. The first variation of $\sum_r |\mathbf{y} - \mathbf{x}_r|$ is

$$\delta\mathbf{y} \cdot \sum_{r=1}^{3} \frac{\mathbf{y}_F - \mathbf{x}_r}{|\mathbf{y}_F - \mathbf{x}_r|}.$$

It vanishes for all $\delta\mathbf{y}$ precisely when the three unit vectors from the sources to the junction sum to zero. Three unit vectors sum to zero only when their pairwise angles are $2\pi/3$.

Set $r_i = |\mathbf{y}_F - \mathbf{x}_i|$. Because the angles at the junction are $2\pi/3$,

$$a^2 = r_2^2 + r_3^2 + r_2 r_3, \qquad b^2 = r_3^2 + r_1^2 + r_3 r_1, \qquad c^2 = r_1^2 + r_2^2 + r_1 r_2.$$

Also the total area is the sum of the three triangles with common vertex $\mathbf{y}_F$:

$$\Delta = \frac{\sqrt{3}}{4}(r_1 r_2 + r_2 r_3 + r_3 r_1).$$

Therefore

$$\frac{1}{2}(a^2 + b^2 + c^2 + 4\sqrt{3}\,\Delta) = r_1^2 + r_2^2 + r_3^2 + 2(r_1 r_2 + r_2 r_3 + r_3 r_1) = (r_1 + r_2 + r_3)^2,$$

which proves (49.96). If an angle is at least $2\pi/3$, the stationarity condition cannot be realized by a point inside the triangle with all three meeting angles $2\pi/3$. The convexity of the sum of distances then places the minimum on the boundary; reducing the same one-dimensional problem along the boundary gives the vertex at the large angle, and the network is the union of the two adjacent sides. $\square$

Figure 49.8 illustrates the Steiner-network length entering the baryonic flux-string model: three strings meet at $2\pi/3$ when the Fermat point lies inside the source triangle, and otherwise the minimum lies on the boundary.

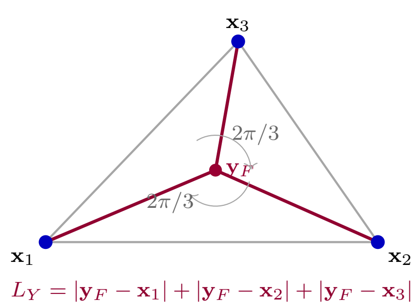

Figure 49.8: For three static fundamental sources in pure $SU(3)$ Yang–Mills theory, the long-distance baryonic string model uses a gauge-invariant color junction. When all triangle angles are below $2\pi/3$, the leading network is the Steiner tree whose three segments meet at $2\pi/3$.

For an equilateral triangle of side a, (49.96) gives

$$L_Y = \sqrt{3}\,a.$$

The frequently used pairwise comparison length

$$L_\Delta = \frac{1}{2}(a+b+c)$$

would give $L_\Delta = 3a/2$ in the same equilateral geometry. These are different large-distance hypotheses for the static baryon sector, not two forms of the same formula. The gauge-invariant object in the baryonic Wilson-line construction contains a junction, and the effective string description must decide, by matching to the gauge theory, whether the long-distance energy is governed by a junction network, by an approximately pairwise regime over the available distances, or by a crossover between the two.

49.8.7 Closed Flux Tubes, Glueball Channels, and Large-N String Coupling

A closed flux tube is cleanly defined on a spatial torus by a spatial Polyakov loop winding a noncontractible cycle,

$$\mathcal{P}_R(\tau) = \mathrm{tr}_R\, \mathcal{P} \exp\left(i \oint_{S^1_L} A_i(\tau,\mathbf{x})\,\mathrm{d}x^i\right).$$

Its Euclidean time correlator has a transfer-matrix expansion

$$\langle \mathcal{P}_R(\tau)^\dagger \mathcal{P}_R(0)\rangle = \sum_n |\langle n;k,L|\mathcal{P}_R(0)\Omega\rangle|^2 \mathrm{e}^{-E_n^{(k)}(L)\tau},$$

where k is the center charge of R. The closed-string formulas (49.76), (49.86), and (49.88) apply to this winding sector under the large-L effective-string hypotheses stated above.

This winding-sector statement is sharper than the phrase "glueballs are closed strings." A glueball is a state in the vacuum sector created by local gauge-invariant operators such as $\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$ and $\mathrm{tr}(F_{\mu\nu}\widetilde{F}^{\mu\nu})$. A noncontractible winding flux tube belongs to a different finite-volume sector. A contractible closed flux loop, by contrast, can shrink to a size of order $\sigma^{-1/2}$, where the long-string derivative expansion is no longer controlled. Thus the closed-string picture of glueball spectra and Regge trajectories is a dynamical large-N_c and effective-string hypothesis, not a consequence of the Gaussian Luscher calculation. What is nonperturbatively well defined are the gauge-invariant correlators and their spectral decomposition; the string interpretation is an additional infrared organization whose range must be tested or derived.

Large N_c supplies the natural weak-coupling parameter for such a string interpretation once a confining flux-tube spectrum exists. The ribbon-graph counting in the preceding section gives a connected contribution of order

$$N_c^{2-2h-b}$$

for a surface of genus h with b color-trace boundaries before any chosen normalization of the external loop operators. A handle is therefore suppressed by N_c^{-2}. Identifying the closed-string genus expansion as g_s^{2h-2} gives the parametric relation

$$g_s \sim \frac{1}{N_c}.$$

The same counting implies that splitting and joining processes of normalized closed-string states carry the corresponding factors of N_c^{-1} fixed by the number of topology-changing vertices. This statement is a consequence of color topology; it is not a derivation of the worldsheet action. The microscopic input still required is the existence of a confining large-N_c gauge theory with isolated flux-tube and glueball states in the relevant channels.

Three-dimensional confining gauge theories are especially clean testbeds for the same logic. In $D = 3$ there is a single transverse displacement field, so the universal terms become

$$\Delta E_0^{\text{open}}(L) = -\frac{\pi}{24L}, \qquad \Delta E_0^{\text{closed}}(L) = -\frac{\pi}{6L}.$$

The reduced transverse symmetry makes the lattice spectral assignments less crowded than in four dimensions, while the effective-string expansion has the same conceptual structure: line operators define the sector, the transfer matrix extracts energies, the free transverse field gives the universal Casimir term, and later coefficients encode symmetry constraints and microscopic matching.

With dynamical fundamental quarks the fundamental one-form symmetry is explicitly broken. The static-source Hilbert space then contains states made from two color-singlet static-light mesons, and the ground-state energy at very large L approaches the two-meson threshold rather than growing without bound. A flux tube can still be a well-defined long-lived state over a range of L, and its worldsheet effective theory can describe the corresponding resonant or metastable channel, but the limiting string tension (49.63) is no longer an order parameter in the same sense as in pure Yang–Mills theory. This distinction is essential when using string language in QCD: line operators, static-source sectors, and calorimetric observables are physical, and asymptotic final states are color-singlet hadrons.

49.9 Heavy-Quark Effective Theory and the Wilson-Line Limit

The static-source sector just described is also the first term in a controlled expansion for a dynamical quark whose mass is much larger than the hadronic scale. This expansion is called heavy-quark effective theory (HQET). Its mathematical content is the regulator-dependent comparison of gauge-invariant QCD matrix elements with gauge-invariant matrix elements of a local expansion in inverse powers of the heavy mass. The heavy quark is still a colored field variable, so physical matrix elements are made gauge invariant by the same Wilson-line and color-singlet constructions used elsewhere in this chapter.

Throughout this section the spacetime metric is mostly plus, $\eta_{\mu\nu} = \mathrm{diag}(-,+,+,+)$. A heavy-quark velocity is a future-directed timelike unit vector v^μ satisfying $v^2 = -1$. The orthogonal projector onto the three-plane transverse to v is

$$\Pi_v{}^\mu{}_\nu = \delta^\mu{}_\nu + v^\mu v_\nu, \qquad D_\perp^\mu = \Pi_v{}^\mu{}_\nu D^\nu. \tag{49.97}$$

The identity $v_\mu D_\perp^\mu = 0$ follows immediately from $v^2 = -1$. A near-mass-shell heavy momentum is written

$$p^\mu = m_Q v^\mu + k^\mu, \tag{49.98}$$

where m_Q is the heavy-quark mass coordinate in the chosen regulated QCD Lagrangian and the residual momentum k^μ is required to be small compared with m_Q on the states or test functions under consideration. The split is not unique: replacing v by $v + \delta v$, with $v \cdot \delta v = 0$ to first order, and replacing k by $k - m_Q \delta v$ leaves p fixed. This elementary redundancy is the kinematic origin of reparametrization constraints on the effective action.

Let $\gamma_v = \gamma_\mu v^\mu$. Since $\gamma_v^2 = -1$, the operator $\mathrm{i}\gamma_v$ has eigenvalues ± 1, and

$$P_v^\pm = \frac{1}{2}(1 \pm \mathrm{i}\gamma_v) \tag{49.99}$$

are complementary spinor projections. The sign in (49.99) is tied to the phase convention below. Define $\tau_v(x) = -v \cdot x$; in the rest frame $v = (1, 0, 0, 0)$, this is the ordinary time coordinate. A heavy Dirac field Q is decomposed at fixed velocity by

$$Q(x) = \mathrm{e}^{-\mathrm{i}m_Q \tau_v(x)}\big(h_v(x) + H_v(x)\big), \qquad P_v^+ h_v = h_v, \qquad P_v^- H_v = H_v. \tag{49.100}$$

The phase removes the rest-energy oscillation associated with $m_Q v^\mu$. The field H_v carries the complementary Dirac components and is separated from h_v by a gap of order m_Q in the free theory.

Definition 49.13 (HQET regulator specification)**.** A finite-cutoff HQET regulator specification at velocity v consists of:

1. A gauge-covariant ultraviolet regulator for QCD with the heavy field Q and mass coordinate m_Q, together with an infrared domain of states or test functions whose residual momenta obey $|k|/m_Q \le \varepsilon \ll 1$.
2. The projected field $h_v = P_v^+ h_v$, transforming in the fundamental representation of the gauge group, and a Wilsonian procedure which integrates out H_v and modes whose virtuality is of order m_Q.
3. A local gauge-covariant action

$$S^{(N)}_{\mathrm{HQET}}[h_v, A] = \int \bar{h}_v\, \mathrm{i}v \cdot D\, h_v \,\mathrm{d}^4x + \sum_{r=1}^{N} \frac{1}{(2m_Q)^r} \sum_a C_{r,a}(\mu, m_Q) \int \mathcal{O}_{r,a}(x)\,\mathrm{d}^4x, \tag{49.101}$$

   where each $\mathcal{O}_{r,a}$ is a local gauge-invariant density built from $h_v, \bar{h}_v, F_{\mu\nu}$, and transverse covariant derivatives $D_\perp$, modulo equations of motion and integration by parts in the chosen coordinate system on local functionals.
4. Renormalized composite operators, for example

$$\bar{q}\,\Gamma Q \longmapsto \sum_{r,a} \frac{1}{(2m_Q)^r} C_{\Gamma,r,a}(\mu, m_Q)\, \mathcal{J}^{\mathrm{HQET}}_{\Gamma,r,a}[q, h_v, A],$$

   with the same regulator and subtraction data. A current matching statement is a statement about matrix elements of these renormalized operators, not an identity between classical monomials.

The leading action is normalized so that the coefficient of $\bar{h}_v \mathrm{i}v \cdot D h_v$ is one. The first dimension-five operators may be represented by

$$\mathcal{O}_{\mathrm{kin}} = \bar{h}_v D_{\perp\mu} D_\perp^\mu h_v, \qquad \mathcal{O}_{\mathrm{mag}} = \bar{h}_v \sigma_{\mu\nu} F^{\mu\nu} h_v, \tag{49.102}$$

with coefficients fixed by the chosen matching convention. In a reparametrization-compatible scheme the coefficient of the kinetic operator is fixed relative to the leading term; the chromomagnetic coefficient is a genuine short-distance matching coefficient.

The leading HQET equation is the equation for parallel transport along the heavy-quark worldline. This is the precise sense in which an infinitely heavy quark becomes a Wilson line.

Static propagator as a Wilson line. Let $x(s) = x_0 + sv$, and let

$$W_v(s_2, s_1) = \mathcal{P} \exp \left\{ \mathrm{i} \int_{s_1}^{s_2} v^\mu A_\mu^a(x(s)) t_\square^a \, \mathrm{d}s \right\} \tag{49.103}$$

be the fundamental Wilson transporter along the heavy trajectory. At finite regulator and with background A_μ smooth on the scale of the regulator, the retarded Green kernel of the leading HQET operator on this trajectory is

$$G_v(s_2, s_1) = \theta(s_2 - s_1) \, W_v(s_2, s_1) \, P_v^+, \tag{49.104}$$

up to the conventional overall factor fixed by the normalization of the first-order inverse. In particular, every gauge-invariant heavy-light or heavy-heavy correlator at leading power contains the Wilson line carried by the heavy source. The calculation is the Green-kernel inversion of the first-order covariant derivative. The transporter satisfies the initial-value problem

$$\frac{\mathrm{d}}{\mathrm{d}s_2} W_v(s_2, s_1) = \mathrm{i} v^\mu A_\mu^a(x(s_2)) t_\square^a W_v(s_2, s_1), \qquad W_v(s_1, s_1) = \mathbf{1}.$$

Equivalently $v \cdot D_{x(s_2)} W_v(s_2, s_1) = 0$, using the chapter convention $D_\mu = \partial_\mu - \mathrm{i} A_\mu$. Applying the first-order operator to $\theta(s_2 - s_1) W_v(s_2, s_1) P_v^+$ gives only the derivative of the step function, because the covariant derivative annihilates the transporter for $s_2 \neq s_1$. This is the delta distribution on the oriented line. The projector P_v^+ records the spinor components retained in the heavy field. Gauge covariance follows from the same Wilson-transporter endpoint transformation law displayed in (49.292).

Consider N_h heavy flavors whose masses have been removed by separate phases and whose residual dynamics are described by the leading HQET action at the same velocity v. The leading action

$$S_0 = \sum_{A=1}^{N_h} \int \bar{h}_{v,A} \, \mathrm{i} v \cdot D \, h_{v,A} \, \mathrm{d}^4 x$$

is invariant under unitary rotations of the heavy-flavor labels and under unitary rotations of the projected spin components commuting with P_v^+. These symmetries act on the heavy variables alone and leave the gauge and light-quark fields fixed. The operator $\mathrm{i} v \cdot D$ is scalar in the heavy-flavor labels and contains no gamma matrix acting inside the projected spin space. If $h_{v,A} \mapsto U_A{}^B S h_{v,B}$, where U is a unitary matrix on flavor labels and S is unitary on the image of P_v^+, then $\bar{h}_{v,A} \mathrm{i} v \cdot D h_{v,A}$ is unchanged after summing over A. The Wilson-line form of the propagator makes the same statement in correlator language: at leading power the heavy source transports color, while its spin and heavy-flavor labels are parallel spectators.

For a free heavy particle with $p^\mu = m_Q v^\mu + k^\mu$ and $p^2 + m_Q^2 = 0$, the residual momentum obeys

$$2 m_Q \, v \cdot k + k^2 = 0. \tag{49.105}$$

In the rest frame, writing $k^\mu = (E_{\mathrm{res}}, \mathbf{k})$, this gives

$$E_{\mathrm{res}} = \sqrt{m_Q^2 + |\mathbf{k}|^2} - m_Q = \frac{|\mathbf{k}|^2}{2 m_Q} - \frac{|\mathbf{k}|^4}{8 m_Q^3} + O\left(\frac{|\mathbf{k}|^6}{m_Q^5} \right). \tag{49.106}$$

Thus the first correction to the static theory is the transverse kinetic energy. Gauge covariance promotes the transverse momentum to $D_\perp$, giving the operator $\mathcal{O}_{\rm kin}$ in (49.102). Indeed, substituting $p = m_Q v + k$ and $v^2 = -1$ into $p^2 + m_Q^2 = 0$ gives (49.105). In the rest frame, $p = (m_Q + E_{\rm res}, \mathbf{k})$, so the positive-energy solution is $m_Q + E_{\rm res} = \sqrt{m_Q^2 + |\mathbf{k}|^2}$. Expanding the square root in $|\mathbf{k}|^2/m_Q^2$ gives (49.106). The covariant operator statement follows from replacing the residual transverse momentum by the transverse covariant derivative in the local Wilsonian expansion; the coefficient is fixed by matching the free dispersion and, in an interacting reparametrization-compatible scheme, by the invariance of the momentum split (49.98).

Controlled Approximation 49.14 (Meaning of the heavy-mass expansion)**.** Fix a regulator, a velocity v, a renormalization scale $\mu \ll m_Q$, and a class of gauge-invariant external states and operator insertions whose residual momenta and invariant hadronic scales are bounded by $\Lambda_{\rm had}$. A truncation of HQET at order N asserts an estimate of the form

$$\left| \langle \mathcal{O} \rangle_{\rm QCD} - \langle \mathcal{O}^{(N)}_{\rm HQET} \rangle_{\rm HQET} \right| \le C_{\mathcal{O},N} \left(\frac{\Lambda_{\rm had}}{m_Q} \right)^{N+1}$$

for the chosen smeared matrix elements, after the QCD operator and the HQET operator have been matched in the same renormalization scheme. The constant $C_{\mathcal{O},N}$, the topology in which the estimate is meant, and the range of μ are part of the assertion. The Wilson-line limit derived above supplies the leading operator structure; the existence of a uniform heavy-mass expansion for a specified family of hadronic matrix elements is additional dynamical and renormalization information.

49.10 Heavy-Light Currents and Heavy-Quark Symmetry

The static Wilson-line limit becomes predictive only after composite currents and hadron states are matched. Let q be a light quark field and let Q be a heavy quark field. The mostly-plus spinor convention of Definition 40.19 fixes the Hermitian vector and axial currents with an explicit factor of i. Thus in this section

$$A^\mu_{qQ} = \mathrm{i}[\bar{q}\gamma^\mu\gamma_5 Q]_{\rm R}, \qquad V^\mu_{qQ} = \mathrm{i}[\bar{q}\gamma^\mu Q]_{\rm R}.$$

More generally a renormalized heavy-light QCD current is a renormalized gauge-invariant local operator

$$J^{\rm QCD}_\Gamma(x) = [\kappa_\Gamma \bar{q}(x)\Gamma Q(x)]_{\rm R},$$

where Γ is a fixed spinor matrix, $\kappa_\Gamma \in \{1, \mathrm{i}\}$ is part of the current convention, and the subscript records the regulator and subtraction convention. In HQET this current is represented by an expansion

$$J^{\rm QCD}_\Gamma = C_\Gamma(m_Q,\mu)\,[\kappa_\Gamma \bar{q}\Gamma h_v]_{\rm R} + \sum_a \frac{B_{\Gamma,a}(m_Q,\mu)}{2m_Q}\,\mathcal{J}^{(1)}_{\Gamma,a} + O(m_Q^{-2}) \tag{49.107}$$

inside the chosen class of matrix elements. The operators $\mathcal{J}^{(1)}_{\Gamma,a}$ are local gauge-invariant HQET currents with one additional transverse derivative, chromomagnetic insertion, or light-quark mass insertion, modulo the leading equations of motion in the chosen operator basis. Equation (49.107) is a matching statement for renormalized operator-valued distributions tested on low-residual-momentum states.

Assume that for a heavy flavor Q there is an isolated stable pseudoscalar meson P_Q and an isolated stable vector meson V_Q in the same light-cloud channel. Their decay constants are defined by

$$\langle 0|\, A^{\mu}_{qQ}\, |P_Q(p)\rangle = f_{P_Q}\, p^{\mu}, \tag{49.108}$$

$$\langle 0|\, V^{\mu}_{qQ}\, |V_Q(p,\varepsilon)\rangle = f_{V_Q}\, M_{V_Q}\, \varepsilon^{\mu}, \tag{49.109}$$

where $p^2 = -M^2$, $p^0 > 0$, and the vector polarization satisfies $p \cdot \varepsilon = 0$. Momentum eigenstates in QCD are normalized by

$$\langle H(p')|H(p)\rangle = 2p^0(2\pi)^3\delta^3(\mathbf{p} - \mathbf{p}').$$

The corresponding HQET residual-momentum state is normalized by

$${}_{\mathrm{HQET}}\langle H_v(k')|H_v(k)\rangle_{\mathrm{HQET}} = 2v^0(2\pi)^3\delta^3(\mathbf{k} - \mathbf{k}'),$$

with $p^{\mu} = M_H v^{\mu} + k^{\mu}$, and the leading state matching is

$$|H_Q(p = M_H v + k)\rangle_{\mathrm{QCD}} = \sqrt{M_H}\, |H_v(k)\rangle_{\mathrm{HQET}} + O(\Lambda_{\mathrm{had}}/m_Q) \tag{49.110}$$

for matrix elements in the stated residual-momentum domain.

Heavy-light decay-constant scaling. Let

$${}_{\mathrm{HQET}}\langle 0|\, \mathrm{i}[\bar{q}\gamma^{\mu}\gamma_5 h_v]_{\mathrm{R}}|P_v(0)\rangle_{\mathrm{HQET}} = F_P(\mu)\, v^{\mu}.$$

Then the leading HQET matching of the axial current gives

$$f_{P_Q}\sqrt{M_{P_Q}} = C_A(m_Q,\mu)F_P(\mu) + O(\Lambda_{\mathrm{had}}/m_Q). \tag{49.111}$$

The analogous vector-meson relation has the same static reduced matrix element up to the spin rotation dictated by the leading static symmetry described above. At $p^{\mu} = M_{P_Q} v^{\mu}$, the QCD definition (49.108) gives

$$\langle 0|A^{\mu}_{qQ}|P_Q(p)\rangle_{\mathrm{QCD}} = f_{P_Q} M_{P_Q} v^{\mu}.$$

Using the leading current matching

$$A^{\mu}_{qQ} = C_A(m_Q,\mu)\, \mathrm{i}[\bar{q}\gamma^{\mu}\gamma_5 h_v]_{\mathrm{R}} + O(m_Q^{-1})$$

and the state relation (49.110) gives

$$\langle 0|A^{\mu}_{qQ}|P_Q(p)\rangle_{\mathrm{QCD}} = C_A\sqrt{M_{P_Q}}\, F_P(\mu)v^{\mu} + O(\Lambda_{\mathrm{had}}/m_Q).$$

Equating the coefficients of v^{μ} gives (49.111). The vector statement follows because the leading static action transports color but contains no operator acting on the projected heavy spin; pseudoscalar and vector states in the same light cloud are related by the heavy-spin symmetry of the leading theory.

Heavy-to-heavy currents compare two static sectors with velocities v and v'. Define the recoil variable

$$w = -v \cdot v' \geq 1. \tag{49.112}$$

For pseudoscalar ground-state mesons in the same light-cloud channel, the leading HQET vector-current matrix element has the form

$$_{\mathrm{HQET}}\langle H_{v'}|\, \mathcal{V}^{\mu}_{Q'Q}(v', v)\, |H_v\rangle_{\mathrm{HQET}} = \xi(w)(v + v')^{\mu}, \tag{49.113}$$

where

$$\mathcal{V}^{\mu}_{Q'Q}(v', v) = \mathrm{i}[\bar{h}^{(Q')}_{v'} \gamma^{\mu} h^{(Q)}_{v}]_{\mathrm{R}}$$

with the coefficient fixed by coupling the leading HQET action to a background heavy-flavor gauge field. The scalar function ξ is the leading heavy-quark symmetry form factor. For the full QCD states this corresponds to

$$\begin{aligned} &\langle H_{Q'}(M_{Q'}v')|\, \mathrm{i}[\bar{Q}'\gamma^{\mu}Q]_{\mathrm{R}}\, |H_Q(M_Q v)\rangle \\ &\quad = \sqrt{M_{Q'}M_Q}\, C_{Q'Q}(m_{Q'}, m_Q, \mu)\, \xi(w)(v + v')^{\mu} + O(\Lambda_{\mathrm{had}}/m_Q, \Lambda_{\mathrm{had}}/m_{Q'}). \end{aligned} \tag{49.114}$$

More general spin states are obtained from the same light-cloud overlap by inserting the appropriate heavy-spin trace factors.

Lemma 49.15 (Zero-recoil normalization)**.** *At zero recoil, $v' = v$, the leading heavy-quark symmetry form factor obeys*

$$\xi(1) = 1 \tag{49.115}$$

when the current is normalized as the generator of the heavy-flavor symmetry of the leading HQET action.

Proof. At $v' = v$, the leading HQET action has a unitary flavor symmetry rotating the heavy labels Q and Q' while leaving the light fields and gauge field fixed. This statement is made inside the leading static theory, before the short-distance matching coefficient $C_{Q'Q}$ and before $1/m_Q$ corrections are restored. Couple this symmetry to a smooth background matrix-valued connection ${B_{\mu}}^{A}{}_{B}$ by replacing $D_{\mu}h_{v,A}$ with $(D_{\mu}{\delta_A}^{B} - \mathrm{i}{B_{\mu}}^{B}{}_{A})h_{v,B}$. Differentiation of the action with respect to ${B_{\mu}}^{Q}{}_{Q'}$ defines the current $\mathcal{V}^{\mu}_{Q'Q}(v, v)$, and the associated charge

$$Q_{Q'Q} = \int_{\Sigma_t} \mathrm{d}^3x\, n_{\mu}\, \mathcal{V}^{\mu}_{Q'Q}(v, v)$$

is the generator of the heavy-flavor rotation on the one-heavy-particle sector. Here n_{μ} is the future unit normal covector to the quantization slice. Choose the isolated ground states in the same light-cloud channel with the same Hilbert-space norm and with phases fixed so that the flavor rotation maps one state to the other. The Ward identity for the background flavor source then gives

$$Q_{Q'Q}|H^{(Q)}_v\rangle = |H^{(Q')}_v\rangle.$$

Translation covariance in the fixed-velocity sector and the absence of any other vector built from a single velocity imply that the local current matrix element has the form $A\, v^{\mu}$. Integrating $n_{\mu}Av^{\mu}$ over the normalization volume and using the preceding charge action fixes $A = 2$ in the velocity-state normalization used in (49.113). Equivalently,

$$_{\mathrm{HQET}}\langle H^{(Q')}_v|\mathcal{V}^{\mu}_{Q'Q}(v, v)|H^{(Q)}_v\rangle_{\mathrm{HQET}} = 2v^{\mu}.$$

Comparing with (49.113) at $v' = v$ gives $\xi(1) = 1$. ∎

Controlled Approximation 49.16 (Heavy-light current expansion)**.** A heavy-light or heavy-to-heavy form-factor prediction must specify the renormalized QCD current, the HQET current basis, the state normalization, the matching coefficients, and the spectral assumption that the meson states used in the matrix element are isolated in the relevant channel. The leading relations (49.111) and (49.113) are symmetry consequences of the static theory after these data are fixed. Corrections of order $1/m_Q$ are matrix elements of the subleading current operators and of insertions from the subleading HQET action; their absence or suppression at special kinematic points is an additional theorem only when the corresponding operator basis and symmetry argument are displayed.

49.11 Nonrelativistic Heavy Pairs and Potential Matching

Quarkonium requires a heavy-mass expansion with two heavy fields and a specified time foliation. Choose the rest frame of the heavy pair and write t for its time coordinate. A nonrelativistic heavy quark is represented by a two-component Pauli field $\psi(t, \mathbf{x})$ in the fundamental representation. The corresponding antiquark is represented, after charge conjugation, by another Pauli field $\chi(t, \mathbf{x})$ which also transforms in the fundamental representation; its adjoint $\chi^\dagger$ creates an antiquark and transforms as a row antifundamental. With

$$D_t = \partial_t - \mathrm{i}A_0, \qquad \mathbf{D} = \nabla - \mathrm{i}\mathbf{A},$$

the leading nonrelativistic action is

$$S^{(0)}_{\mathrm{NR}} = \int \mathrm{d}t\,\mathrm{d}^3\mathbf{x}\,\left[\psi^\dagger\left(\mathrm{i}D_t + \frac{\mathbf{D}^2}{2m_Q}\right)\psi + \chi^\dagger\left(\mathrm{i}D_t + \frac{\mathbf{D}^2}{2m_Q}\right)\chi\right]. \tag{49.116}$$

The sign of the spatial Laplacian in (49.116) is fixed by the convention $D_i e^{\mathrm{i}\mathbf{p}\cdot\mathbf{x}} = \mathrm{i}p_i e^{\mathrm{i}\mathbf{p}\cdot\mathbf{x}}$ in the free theory.

Definition 49.17 (NRQCD regulator and operator specification)**.** An NRQCD regulator and operator specification for a heavy flavor of mass m_Q consists of: items.

1. A gauge-covariant regulator for QCD and a matching scale below m_Q, together with a class of states whose heavy-quark three-momenta obey $|\mathbf{p}|/m_Q \ll 1$.
2. Pauli fields ψ, χ, the gauge fields, and a local action of the form

   $$S^{(N)}_{\mathrm{NRQCD}} = S^{(0)}_{\mathrm{NR}} + \sum_a \frac{c_a(\mu, m_Q)}{m_Q^{d_a-4}} \int \mathcal{O}^{\mathrm{NR}}_a(t, \mathbf{x})\,\mathrm{d}t\,\mathrm{d}^3\mathbf{x},$$

   where $\mathcal{O}^{\mathrm{NR}}_a$ ranges over gauge-invariant local operators built from $\psi, \chi, F_{\mu\nu}$, covariant derivatives, Pauli matrices, and local four-heavy-field annihilation operators, ordered by the chosen velocity and $1/m_Q$ power counting.
3. Renormalized heavy-pair composite operators. A quarkonium interpolator or current is part of the specification only after its Wilson-line dressing, regulator, and subtraction convention have been specified.

The Pauli magnetic term

$$\frac{c_F}{2m_Q}\,\psi^\dagger\sigma^i B_i\psi-\frac{c_F}{2m_Q}\,\chi^\dagger\sigma^i B_i\chi,\qquad B_i=\frac{1}{2}\epsilon_{ijk}F_{jk},$$

is the first spin-dependent single-particle correction in a parity-invariant coordinate system. Its coefficient is a matching coefficient; it is not deduced from the leading Schrödinger action alone.

Free NRQCD dispersion. The free equation following from the leading quark term in (49.116) has plane-wave solutions

$$\psi(t,\mathbf{x})=u\,\mathrm{e}^{-\mathrm{i}Et+\mathrm{i}\mathbf{p}\cdot\mathbf{x}}$$

with

$$E=\frac{|\mathbf{p}|^2}{2m_Q}.$$

Thus (49.116) realizes the leading term of the relativistic residual-energy expansion (49.106). Substitution of the plane wave gives

$$\left(E-\frac{|\mathbf{p}|^2}{2m_Q}\right)u=0,$$

because $\nabla^2\mathrm{e}^{\mathrm{i}\mathbf{p}\cdot\mathbf{x}}=-|\mathbf{p}|^2\mathrm{e}^{\mathrm{i}\mathbf{p}\cdot\mathbf{x}}$. A nonzero spinor amplitude u therefore requires the displayed dispersion relation.

Gauge-invariant quarkonium operators are bilocal at nonzero separation. Let

$$\mathbf{x}_1=\mathbf{R}+\frac{\mathbf{r}}{2},\qquad \mathbf{x}_2=\mathbf{R}-\frac{\mathbf{r}}{2},$$

and let $W(\mathbf{x}_2,\mathbf{x}_1;t)$ be the equal-time fundamental Wilson transporter from $\mathbf{x}_1$ to $\mathbf{x}_2$. Define the singlet bilocal

$$S(t,\mathbf{R},\mathbf{r})=\frac{1}{\sqrt{N_c}}\,\chi^\dagger(t,\mathbf{x}_2)W(\mathbf{x}_2,\mathbf{x}_1;t)\psi(t,\mathbf{x}_1). \tag{49.117}$$

An octet bilocal with a color label based at $\mathbf{R}$ is represented by

$$O^a(t,\mathbf{R},\mathbf{r})=\chi^\dagger(t,\mathbf{x}_2)W(\mathbf{x}_2,\mathbf{R};t)\,t^a\,W(\mathbf{R},\mathbf{x}_1;t)\psi(t,\mathbf{x}_1). \tag{49.118}$$

The octet transforms in the adjoint representation at $\mathbf{R}$; the singlet is gauge invariant.

Gauge covariance of the bilocals. Under a gauge transformation $U(t,\mathbf{x})$,

$$\psi(\mathbf{x}_1)\mapsto U(\mathbf{x}_1)\psi(\mathbf{x}_1),\qquad \chi^\dagger(\mathbf{x}_2)\mapsto\chi^\dagger(\mathbf{x}_2)U(\mathbf{x}_2)^{-1},$$

and

$$W(\mathbf{x}_2,\mathbf{x}_1)\mapsto U(\mathbf{x}_2)W(\mathbf{x}_2,\mathbf{x}_1)U(\mathbf{x}_1)^{-1}.$$

The endpoint matrices cancel in (49.117). In (49.118) the endpoint matrices again cancel, while the generator at $\mathbf{R}$ transforms by conjugation, $t^a\mapsto U(\mathbf{R})t^aU(\mathbf{R})^{-1}$, which is the adjoint action.

Potential NRQCD is obtained by integrating out the relative-momentum scale $m_Q v_{\rm rel}$ while retaining the lower energy scale $m_Q v_{\rm rel}^2$. The singlet part of the resulting bilocal action has the form

$$S^S_{\rm pNRQCD} = \int {\rm d}t\, {\rm d}^3\mathbf{R}\, {\rm d}^3\mathbf{r}\, S^\dagger \left[{\rm i}\partial_t + \frac{\nabla_{\mathbf{r}}^2}{m_Q} - V_S(r;\mu) + \cdots \right] S, \tag{49.119}$$

where $r = |\mathbf{r}|$. The potential $V_S(r;\mu)$ is a matching coefficient for the bilocal singlet operator. In a weak-coupling matching regime, the tree-level Coulomb exchange gives

$$V_S^{(0)}(r) = -\frac{g^2 C_F}{4\pi r}, \tag{49.120}$$

with $C_F = (N_c^2 - 1)/N_c$ and the same trace-delta coupling used throughout this chapter. This formula is invariant under conversion to the common half-trace convention because $g_{\rm ht}^2 = 2g^2$ and $C_F^{\rm ht} = C_F/2$.

Tree-level singlet color factor. In the trace convention of (49.1), the color factor for one-gluon exchange in a normalized quark-antiquark singlet is $-C_F$. Hence the attractive Coulomb potential is (49.120).

The normalized singlet color tensor is $\delta^i{}_j/\sqrt{N_c}$. The antiquark generator is the negative transpose of the quark generator. Acting with $t^a \otimes (-t^{aT})$ on the singlet gives

$$-\frac{1}{\sqrt{N_c}}(t^a t^a)^i{}_j = -C_F \frac{\delta^i{}_j}{\sqrt{N_c}}.$$

The spatial Fourier transform of the Coulomb kernel is

$$\int \frac{{\rm d}^3\mathbf{q}}{(2\pi)^3} \frac{{\rm e}^{{\rm i}\mathbf{q}\cdot\mathbf{r}}}{|\mathbf{q}|^2} = \frac{1}{4\pi r},$$

so the product of the exchange kernel $g^2/|\mathbf{q}|^2$ with the singlet color eigenvalue gives (49.120).

Leading Coulombic $1S$ quarkonium level. Assume a weak-coupling pNRQCD chart in which the spin-independent singlet Hamiltonian is truncated to

$$H_C = -\frac{\nabla_{\mathbf{r}}^2}{m_Q} - \frac{\alpha_C}{r}, \qquad \alpha_C := \frac{g^2 C_F}{4\pi}, \qquad r = |\mathbf{r}|. \tag{49.121}$$

Here m_Q is the heavy-quark mass coordinate in the same short-distance scheme as the potential coordinate. The normalized $1S$ eigenfunction

$$\psi_{1S}(\mathbf{r}) = \left(\frac{\kappa^3}{\pi}\right)^{1/2} {\rm e}^{-\kappa r}, \qquad \kappa := \frac{m_Q \alpha_C}{2}, \tag{49.122}$$

has energy

$$E_{1S}^{(0)} = -\frac{m_Q \alpha_C^2}{4}, \qquad |\psi_{1S}(0)|^2 = \frac{(m_Q\alpha_C)^3}{8\pi}. \tag{49.123}$$

The corresponding leading spin-averaged quarkonium mass coordinate is

$$M_{1S}^{(0)} = 2m_Q + E_{1S}^{(0)}$$

before the additive mass–potential rearrangements of Section 49.12 and before ultrasoft, relativistic, and spin-dependent corrections are included.

For $r > 0$,

$$\nabla^2 \mathrm{e}^{-\kappa r} = \left(\kappa^2 - \frac{2\kappa}{r}\right) \mathrm{e}^{-\kappa r}.$$

Thus

$$H_C \mathrm{e}^{-\kappa r} = \left[-\frac{\kappa^2}{m_Q} + \left(\frac{2\kappa}{m_Q} - \alpha_C\right)\frac{1}{r}\right] \mathrm{e}^{-\kappa r}.$$

With $\kappa = m_Q\alpha_C/2$ the $1/r$ term cancels and the eigenvalue is $-\kappa^2/m_Q = -m_Q\alpha_C^2/4$. The normalization follows from

$$4\pi \left(\frac{\kappa^3}{\pi}\right) \int_0^\infty r^2 \mathrm{e}^{-2\kappa r}\, \mathrm{d}r = 4\kappa^3 \frac{2}{(2\kappa)^3} = 1,$$

and the value at the origin is the square of the normalization constant. The mass formula is then the definition of the spin-averaged singlet energy coordinate in this leading Hamiltonian. This calculation does not define the physical charmonium or bottomonium spectrum by itself: it computes the first term in a declared pNRQCD expansion whose mass scheme, matching scale, and omitted operators must be specified.

Quarkonium fine and hyperfine spin algebra. Fix a quarkonium radial level and orbital angular momentum L in a pNRQCD specification. Let

$$\mathbf{S}_Q = \frac{1}{2}\boldsymbol{\sigma}_Q, \qquad \mathbf{S}_{\bar{Q}} = \frac{1}{2}\boldsymbol{\sigma}_{\bar{Q}}, \qquad \mathbf{S} = \mathbf{S}_Q + \mathbf{S}_{\bar{Q}}, \qquad \mathbf{J} = \mathbf{L} + \mathbf{S}.$$

Assume that, to first order in the spin-dependent part of the matched Hamiltonian, the restriction to this radial-orbital subspace has the form

$$H_{nL}^{\mathrm{sd}} = A_{nL}\, \mathbf{S}_Q \cdot \mathbf{S}_{\bar{Q}} + B_{nL}\, \mathbf{L} \cdot \mathbf{S} + C_{nL}\, \mathcal{T}_{LS}, \tag{49.124}$$

where A_{nL}, B_{nL}, C_{nL} are radial matrix elements or matching coefficients in the chosen scheme, and $\mathcal{T}_{LS}$ is the rotational scalar obtained by coupling a traceless rank-two orbital tensor to a traceless rank-two spin tensor. Then

$$\mathbf{S}_Q \cdot \mathbf{S}_{\bar{Q}} = \begin{cases} -\frac{3}{4}, & S = 0, \\ \frac{1}{4}, & S = 1, \end{cases} \tag{49.125}$$

and, on the triplet $S = 1$ states,

$$\mathbf{L} \cdot \mathbf{S} = \frac{1}{2}\big(J(J+1) - L(L+1) - 2\big) = \begin{cases} -(L+1), & J = L - 1, \\ -1, & J = L, \\ L, & J = L + 1. \end{cases} \tag{49.126}$$

If $M(^1L_L)$ denotes the singlet mass and $M(^3L_J)$ the triplet masses computed to this first order from a common spin-independent radial level $E_{nL}^{(0)}$, then the triplet centroid obeys

$$\overline{M}(^3L) := \frac{\sum_{J=L-1}^{L+1}(2J+1)M(^3L_J)}{3(2L+1)} = E_{nL}^{(0)} + \frac{1}{4}A_{nL}, \tag{49.127}$$

with the obvious omission of the nonexistent $J = L - 1$ term when $L = 0$. The centroid hyperfine difference is therefore

$$\overline{M}(^3L) - M(^1L_L) = A_{nL}. \tag{49.128}$$

The two heavy spins are spin-$\frac{1}{2}$ representations. Since

$$\mathbf{S}^2 = \mathbf{S}_Q^2 + \mathbf{S}_{\bar{Q}}^2 + 2\mathbf{S}_Q \cdot \mathbf{S}_{\bar{Q}}, \qquad \mathbf{S}_Q^2 = \mathbf{S}_{\bar{Q}}^2 = \frac{3}{4},$$

one has

$$\mathbf{S}_Q \cdot \mathbf{S}_{\bar{Q}} = \frac{1}{2}\left(S(S+1) - \frac{3}{2}\right),$$

which gives (49.125) for $S = 0, 1$. Similarly

$$\mathbf{J}^2 = \mathbf{L}^2 + \mathbf{S}^2 + 2\mathbf{L} \cdot \mathbf{S}$$

gives the first equality in (49.126); substituting $S = 1$ and $J = L - 1, L, L + 1$ gives the displayed three values.

It remains to check the centroid. The trace of $\mathbf{L} \cdot \mathbf{S}$ on the tensor product of the orbital L space and the triplet spin space vanishes:

$$\mathrm{Tr}_{L \otimes S=1}(\mathbf{L} \cdot \mathbf{S}) = \sum_i \mathrm{Tr}_L(L_i)\, \mathrm{Tr}_{S=1}(S_i) = 0,$$

because every generator of an irreducible $SU(2)$ representation is traceless. The operator $\mathcal{T}_{LS}$ is a contraction of traceless rank-two tensors, so its trace on the same tensor product also vanishes. The weighted sum $\sum_J (2J+1) M(^3L_J)$ is precisely this trace after decomposition into irreducible J summands. Therefore only the spin-independent energy and the triplet spin-spin eigenvalue $\frac{1}{4}A_{nL}$ survive in the centroid, proving (49.127). The singlet has $\mathbf{L} \cdot \mathbf{S} = 0$, no rank-two spin tensor, and spin-spin eigenvalue $-\frac{3}{4}$; subtracting its first-order mass from the triplet centroid gives (49.128). The spin algebra above is the part of quarkonium spectroscopy that follows from angular momentum and the matched operator form alone. The numerical values of A_{nL}, B_{nL}, C_{nL} are QCD matching data. In weak-coupling pNRQCD they are computed from perturbative potentials and wavefunctions in a stated mass scheme; in strong-coupling pNRQCD they are Wilson-loop and chromofield insertion matrix elements. In either case the symbols "hyperfine splitting" and "fine structure" refer to the spectral differences defined by (49.126)–(49.128), rather than to a freestanding constituent-potential model.

Leading weak-coupling $1S$ hyperfine coordinate. In the weak-coupling $1S$ chart above, retain the leading chromomagnetic contact operator

$$H_{\mathrm{ss}}^{1S} = \frac{8\pi\alpha_C\, c_F(\mu)^2}{3m_Q^2}\, \mathbf{S}_Q \cdot \mathbf{S}_{\bar{Q}}\, \delta^{(3)}(\mathbf{r}), \tag{49.129}$$

where $c_F(\mu)$ is the chromomagnetic matching coefficient in the same short-distance mass and coupling scheme as m_Q and α_C. To first order in this operator,

$$M(^3S_1) - M(^1S_0) = \frac{8\pi\alpha_C\, c_F(\mu)^2}{3m_Q^2}|\psi_{1S}(0)|^2 = \frac{m_Q\, c_F(\mu)^2\, \alpha_C^4}{3}. \tag{49.130}$$

The displayed number is a leading coordinate in the declared weak-coupling pNRQCD scheme. It is not by itself a precision prediction for charmonium or bottomonium until the mass scheme, higher-order potentials, ultrasoft terms, nonperturbative corrections, and continuum-limit uncertainties have been specified. First-order perturbation theory in the normalized Coulombic $1S$ state gives

$$\langle H_{\rm ss}^{1S}\rangle_S = \frac{8\pi\alpha_C\, c_F(\mu)^2}{3m_Q^2}|\psi_{1S}(0)|^2\,\langle \mathbf{S}_Q\cdot\mathbf{S}_{\bar Q}\rangle_S.$$

For the triplet $S=1$ the spin expectation value is $1/4$, and for the singlet $S=0$ it is $-3/4$, as shown in (49.125). Their difference is one, so the triplet-singlet mass splitting is exactly the contact coefficient times $|\psi_{1S}(0)|^2$. Substituting (49.123),

$$|\psi_{1S}(0)|^2 = \frac{(m_Q\alpha_C)^3}{8\pi},$$

gives the second equality in (49.130). The proof uses only the declared pNRQCD contact operator and the Coulombic $1S$ wavefunction; all other terms belong to the stated remainder of the weak-coupling chart.

Controlled Approximation 49.18 (Quarkonium scale separation)**.** Let $v_{\rm rel}$ be the velocity coordinate assigned to a family of quarkonium states. The weak-coupling potential expansion assumes

$$m_Q \gg m_Q v_{\rm rel} \gg m_Q v_{\rm rel}^2, \qquad m_Q v_{\rm rel} \gg \Lambda_{\rm QCD},$$

so that the soft relative-momentum scale can be integrated out perturbatively. Strong-coupling pNRQCD instead treats the potential as a nonperturbative matching coefficient defined by static Wilson-loop and chromofield-insertion matrix elements. In both regimes a claim of accuracy requires a norm or class of smeared matrix elements and an explicit remainder estimate in powers of $v_{\rm rel}$, $1/m_Q$, and $\Lambda_{\rm QCD}/(m_Q v_{\rm rel})$ when that ratio is used.

49.12 Heavy-Quark Mass Coordinates and Static Energies

The mass m_Q appearing in HQET, NRQCD, and pNRQCD is a coordinate in a regulated Lagrangian and in its matched effective descriptions. In a confining four-dimensional QCD theory an isolated colored quark is not an asymptotic particle, so a quark pole mass is not a gauge-invariant spectral observable. Perturbation theory in a fixed gauge nevertheless defines formal mass coordinates, including an on-shell coordinate order by order. Such coordinates are useful only after their infrared sensitivity and their relation to gauge-invariant quantities have been stated.

The gauge-invariant static quark-antiquark energy is extracted from Wilson loops. With a specified line-renormalization prescription, define

$$E_{\rm stat}(r;\mu) = -\lim_{T\to\infty}\frac{1}{T}\log\langle W_\Box(r,T)\rangle_{\text{ren},\mu}, \tag{49.131}$$

where $W_\Box(r,T)$ is the rectangular fundamental Wilson loop of spatial size r and time extent T. The subscript records the ultraviolet and line-renormalization convention. Additive constants in $E_{\rm stat}$ are not absolute observables; energy differences and matched hadron masses are.

At distances r in a weak-coupling matching range, the pNRQCD singlet potential is a coordinate in the decomposition

$$E_{\mathrm{stat}}(r;\mu) = 2m_{\mathrm{sd}}(\mu_f) + V_{\mathrm{sd}}(r;\mu,\mu_f) + \Delta_{\mathrm{us}}(r;\mu,\mu_f), \tag{49.132}$$

where m_{sd} is a short-distance heavy-quark mass coordinate, V_{sd} is the corresponding singlet potential coordinate, and Δ_{us} denotes lower-energy contributions retained in pNRQCD. The auxiliary scale μ_f separates contributions assigned to the mass coordinate from contributions assigned to the potential coordinate.

Remark 49.19 (Constant mass-coordinate transformations). Let δm be a finite scheme change independent of r. The coordinate transformation

$$m'_{\mathrm{sd}} = m_{\mathrm{sd}} + \delta m, \qquad V'_{\mathrm{sd}}(r) = V_{\mathrm{sd}}(r) - 2\delta m \tag{49.133}$$

leaves the static energy (49.132) unchanged when Δ_{us} is held fixed. If a pNRQCD Hamiltonian is shifted by $V_{\mathrm{sd}} \mapsto V_{\mathrm{sd}} - 2\delta m$, every singlet eigenvalue E_n is shifted by $-2\delta m$, and $2m_{\mathrm{sd}} + E_n$ is unchanged.

Substitution into (49.132) gives

$$2(m_{\mathrm{sd}} + \delta m) + (V_{\mathrm{sd}} - 2\delta m) + \Delta_{\mathrm{us}} = 2m_{\mathrm{sd}} + V_{\mathrm{sd}} + \Delta_{\mathrm{us}}.$$

For a Hamiltonian $H_{\mathrm{sd}} = T + V_{\mathrm{sd}}$, the transformed Hamiltonian is $H'_{\mathrm{sd}} = H_{\mathrm{sd}} - 2\delta m$. If $H_{\mathrm{sd}}\psi_n = E_n\psi_n$, then $H'_{\mathrm{sd}}\psi_n = (E_n - 2\delta m)\psi_n$. Therefore

$$2(m_{\mathrm{sd}} + \delta m) + (E_n - 2\delta m) = 2m_{\mathrm{sd}} + E_n.$$

The statement is finite-dimensional spectral algebra applied to the regularized Hamiltonian, and then to any limit in which the relevant eigenvalue exists.

One useful short-distance coordinate is the potential-subtracted mass. Start from a formal perturbative pole coordinate m_{pole} and define

$$m_{\mathrm{PS}}(\mu_f) = m_{\mathrm{pole}} - \delta m_{\mathrm{PS}}(\mu_f), \qquad \delta m_{\mathrm{PS}}(\mu_f) = -\frac{1}{2}\int_{|\mathbf{q}|<\mu_f} \frac{\mathrm{d}^3\mathbf{q}}{(2\pi)^3}\,\widetilde{V}(\mathbf{q}), \tag{49.134}$$

where $\widetilde{V}(\mathbf{q})$ is the perturbative momentum-space singlet potential in the same convention. At tree level

$$\widetilde{V}^{(0)}(\mathbf{q}) = -\frac{g^2 C_F}{|\mathbf{q}|^2}.$$

Consequently

$$\delta m^{(0)}_{\mathrm{PS}}(\mu_f) = \frac{g^2 C_F}{4\pi^2}\,\mu_f. \tag{49.135}$$

In the common half-trace convention this is the same expression because $g^2_{\mathrm{ht}} C_F^{\mathrm{ht}} = g^2 C_F$.

Using spherical coordinates in momentum space,

$$\int_{|\mathbf{q}|<\mu_f} \frac{\mathrm{d}^3\mathbf{q}}{(2\pi)^3}\,\frac{1}{|\mathbf{q}|^2} = \frac{4\pi}{(2\pi)^3}\int_0^{\mu_f} \mathrm{d}q = \frac{\mu_f}{2\pi^2}.$$

Multiplying by $g^2 C_F/2$, as dictated by (49.134) and $\widetilde{V}^{(0)} = -g^2 C_F/|\mathbf{q}|^2$, gives (49.135).

Remark 49.20 (Renormalon language in the heavy-quark sector). The leading infrared sensitivity of the formal perturbative pole coordinate and the additive constant in the perturbative static potential are tied to the same long-distance momentum region. In perturbative large-order language this is described as a cancellation of the leading static-energy renormalon between $2m_{\text{pole}}$ and $V_{\text{pole}}(r)$. The mathematically precise statement used here is the finite coordinate transformation (49.133) and the definition of short-distance coordinates such as (49.134). A claim about a Borel singularity, its residue, or its cancellation is a claim about a specified perturbative expansion and summation prescription, not a nonperturbative definition of the quark mass.

Controlled Approximation 49.21 (Mass schemes in quarkonium predictions)**.** A quarkonium prediction based on pNRQCD must state the mass coordinate, the potential coordinate, the subtraction scale μ_f when one is used, and the class of matrix elements or energy levels being approximated. Replacing (m, V) by a short-distance pair (m', V') is exact at the level of the matched Hamiltonian if (49.133) is imposed. Truncating perturbative series introduces residual μ_f- and scheme-dependence; the size of that dependence is an error diagnostic only after the truncation order, velocity counting, and ultrasoft treatment have been fixed.

49.13 Color and Physical External States

The gauge-fixed quark and gluon fields are useful local variables in perturbation theory. Physical states are BRST cohomology classes, and local physical operators are represented by gauge-invariant or BRST-closed operators. This has an immediate consequence for scattering: LSZ reduction applied to the elementary quark or gluon fields does not by itself define a physical hadron S-matrix. Physical external states in QCD are created by color-singlet operators, such as

$$\bar{q}_I q_J, \qquad \bar{q}_I \gamma^\mu q_J, \qquad \epsilon_{i_1 \cdots i_{N_c}} q^{i_1}_{I_1} \cdots q^{i_{N_c}}_{I_{N_c}}, \qquad \operatorname{tr}(F_{\mu\nu} F^{\mu\nu}).$$

The first three are mesonic current, vector-current, and baryonic examples; the last is a gluonic example.

Confinement, in the spectral sense used here, is the assertion that isolated finite-energy asymptotic particles carry no color. In four-dimensional QCD this assertion is a nonperturbative physical input, supported by the observed hadron spectrum and by lattice evidence, rather than a theorem presently derived from the continuum Lagrangian. The monograph uses this precise spectral hypothesis when discussing QCD phenomenology: the asymptotic states are hadrons, while the short-distance operator expansion is expressed in terms of quark and gluon fields because those are the local variables of the renormalized gauge theory.

Open Problem 49.22 (Asymptotic completeness of physical QCD). Starting from a nonperturbative four-dimensional QCD Hilbert space $\mathcal{H}_{\text{phys}}$, its unitary translation representation, and its gauge-invariant local observable algebra, construct the physical incoming and outgoing scattering theory. The required asymptotic space

$$\mathcal{H}_{\text{as}}^{\text{QCD}}$$

should be built from stable color-singlet Wigner particles in the relevant superselection sectors: mesons, baryons, glueballs in pure Yang–Mills subsectors, and, in chiral limits, the massless Goldstone modes with their long-distance scattering structure. Unstable hadronic resonances should enter through the analytic structure of the color-singlet scattering operator rather than as ordinary external vectors. The wave operators

$$\Omega^{\mathrm{QCD}}_{\mathrm{in/out}} : \mathcal{H}^{\mathrm{QCD}}_{\mathrm{as}} \longrightarrow \mathcal{H}_{\mathrm{phys}}$$

should be isometric, should intertwine translations, and should have common closed range equal to the finite-energy physical sector under consideration:

$$\overline{\operatorname{Ran}\Omega^{\mathrm{QCD}}_{\mathrm{in}}} = \overline{\operatorname{Ran}\Omega^{\mathrm{QCD}}_{\mathrm{out}}} = \mathcal{H}^{\mathrm{sector}}_{\mathrm{phys}}.$$

One must also construct the detector limits, such as the energy-flow operators below, on the same scattering domain and prove that the inclusive calorimetric observables used in high-energy QCD are obtained from this Hilbert-space scattering theory.

This problem is logically stronger than asymptotic freedom, factorization, a mass gap in pure Yang–Mills theory, or the spectral confinement hypothesis used above. Asymptotic freedom controls short-distance operator products and partonic coefficient functions. Factorization gives a perturbative expansion for selected inclusive observables after the relevant operator matrix elements have been defined. Asymptotic completeness is a large-time statement about the range of physical wave operators in the gauge-invariant Hilbert space.

49.14 Hadron Spectroscopy as Ab Initio QCD

49.14.1 Spectral Sources and Finite-Volume Data

Hadron spectroscopy is not a list of model names assigned to observed peaks. It is a collection of spectral and scattering statements about the gauge-invariant Hilbert space of QCD. A spectroscopic claim must therefore state which Hilbert-space object is being computed. Stable hadrons are isolated eigenvalues of the mass operator $M^2 = P_\mu P^\mu$ in color-singlet superselection sectors. Resonances are poles of color-singlet scattering amplitudes on specified nonphysical sheets, as in Chapter 26; they are not additional vectors in the asymptotic Hilbert space. Finite-volume energy levels are regulator observables whose infinite-volume interpretation requires a quantization map, not a direct equality between a box eigenvalue and a resonance mass.

Let I, J denote flavor labels and let i, j be color labels. Typical local color-singlet sources are

$$M_{\Gamma,IJ}(x) = \bar{q}_I(x)\Gamma q_J(x), \tag{49.136}$$

$$B_{\alpha_1\cdots\alpha_{N_c};I_1\cdots I_{N_c}}(x) = \epsilon_{i_1\cdots i_{N_c}}\, q^{i_1}_{\alpha_1 I_1}(x)\cdots q^{i_{N_c}}_{\alpha_{N_c} I_{N_c}}(x), \tag{49.137}$$

$$G_{\mathcal{P}}(x) = \operatorname{tr}\mathcal{P}(F_{\mu\nu}, D_\rho)(x). \tag{49.138}$$

Here Γ is a Dirac matrix, possibly with covariant derivatives inserted and with Lorentz indices projected to a definite spin channel, and $\mathcal{P}$ is a gauge-covariant polynomial whose color indices are traced using the convention fixed in (49.1). Nonlocal sources are allowed, but their Wilson lines, smearing kernels, and endpoint renormalizations are part of the operator definition. For example, a hybrid meson source may be represented by

$$\bar{q}_I(x)\Gamma^{\mu\nu}F_{\mu\nu}(x)q_J(x),$$

or by a point-split bilinear with a Wilson-line path and a field-strength insertion on that path. These are different regulator coordinates unless a continuum matching relation has been supplied.

Definition 49.23 (Hadron spectral extraction setup)**.** A QCD hadron spectral extraction setup consists of:

1. the quark masses, gauge group, global form, spacetime volume, boundary conditions, and regulator action;
2. a list of gauge-invariant interpolating operators, including their flavor, parity, charge conjugation, spin or cubic-group channel, smearing, and renormalization prescriptions;
3. the Euclidean correlation matrix
$$C_{AB}(t) = \langle \mathcal{O}_A(t)\mathcal{O}_B^\dagger(0)\rangle - \langle \mathcal{O}_A\rangle\langle \mathcal{O}_B^\dagger\rangle;$$
4. a declared estimator of finite-volume color-singlet energies from the transfer matrix or Euclidean correlators, including its source basis, fit window, covariance treatment, and stability diagnostics;
5. a map from finite-volume energies to infinite-volume observables: isolated stable masses for one-particle states, and scattering amplitudes or pole positions for resonances;
6. continuum, chiral, heavy-quark, and infinite-volume extrapolations, with the systematics stated separately.

The setup is called *ab initio* only when the matrix elements are defined from the QCD path integral or Hilbert space itself. A constituent model may be useful as a coordinate chart or mnemonic, but it is not an ab initio definition of the spectrum.

Definition 49.24 (Operator-sector spectroscopy chart)**.** Fix a finite-volume regulator and a symmetry channel Γ. Let $\mathcal{V}_\Gamma$ be a finite-dimensional vector space of renormalized gauge-invariant interpolating operators in that channel, modulo operators whose matrix elements vanish on the finite-volume Hilbert subspace being sampled. A spectroscopy chart is a choice of ordered basis $(\mathcal{O}_1, \ldots, \mathcal{O}_m)$ of $\mathcal{V}_\Gamma$, together with any declared decomposition

$$\mathcal{V}_\Gamma = \mathcal{V}_{\mathrm{loc}} \oplus \mathcal{V}_{\text{two-hadron}} \oplus \mathcal{V}_{\mathrm{flux}} \oplus \cdots . \tag{49.139}$$

The summands in (49.139) are source subspaces, not Hilbert-space superselection sectors. For example, $\mathcal{V}_{\mathrm{loc}}$ may contain local $q\bar{q}$, baryon, or pure-glue operators, $\mathcal{V}_{\text{two-hadron}}$ may contain products of separately projected hadron operators, and $\mathcal{V}_{\mathrm{flux}}$ may contain point-split bilinears with field-strength insertions or extended Wilson-line paths. The decomposition is part of the chart; it is not an invariant classification of states unless a regulator, renormalization scheme, and continuum matching prescription have also been supplied.

For a finite spatial torus and a reflection-positive lattice regulator, the spectral decomposition has the same form as (140.66):

$$C_{AB}(t) = \sum_{n\geq 0} Z_A^{(n)}\overline{Z_B^{(n)}}\mathrm{e}^{-E_n t}, \qquad Z_A^{(n)} = \langle \Omega|\mathcal{O}_A|n, L\rangle.$$

The vectors $|n, L\rangle$ are finite-volume color-singlet eigenvectors. If an eigenvalue converges, after removing the center-of-mass motion and taking the regulator limits, to an isolated one-particle mass below all relevant thresholds, the resulting number is a stable-hadron mass. Above threshold the finite-volume levels instead sample the scattering operator. In a single elastic two-particle channel with total momentum zero, particle masses m_1, m_2, relative momentum k, and energy

$$E = \sqrt{m_1^2 + k^2} + \sqrt{m_2^2 + k^2},$$

the simplest unmixed partial-wave quantization condition is

$$\delta_\ell(k) + \phi_\ell(q) = n\pi, \qquad q = \frac{kL}{2\pi}, \tag{49.140}$$

where δ_ℓ is the infinite-volume elastic phase shift and ϕ_ℓ is a known geometric function built from the finite-volume zeta function. Equation (49.140) is not a model of a resonance. It is a finite-volume reconstruction theorem under elasticity, locality, and regulator hypotheses. In realistic QCD channels one must use the coupled-channel determinant version, because cubic symmetry mixes partial waves and inelastic thresholds are often nearby.

Source coordinates and invariant output. The QCD output of the preceding construction is not a preferred source basis. At finite regulator the invariant spectral data are the color-singlet transfer-matrix energies and their symmetry labels; after the continuum and infinite-volume limits they become stable masses, scattering amplitudes, or sheet-labeled pole data according to the channel. Source-overlap phrases such as "mostly two-hadron", "mostly hybrid", or "mostly glueball" are coordinate statements about the chosen operator family. They acquire unambiguous meaning only after the source subspaces in (49.139), their renormalization and smearing prescriptions, and the positive form used to compare overlap covectors have all been declared. Changing these source coordinates can change the quoted overlap fractions without changing the finite-volume energy or the reconstructed pole. This chapter therefore records the QCD-specific operators and the spectral or scattering quantity being extracted, while the finite-regulator estimator itself is part of the numerical methodology.

Remark 49.25 (Spectroscopic names as derived coordinates)*.* In the finite-volume QCD framework above, the invariant output of a stable sector is an energy level and its quantum numbers, while the invariant output of a resonance sector is a sheet-labeled pole and residue data after a finite-volume-to-infinite-volume reconstruction. Names such as conventional meson, glueball, hybrid, molecule, tetraquark, or flux-tube excitation are therefore derived coordinates on source overlaps, pole residues, large-N_c scaling, and deformation behavior. They are not additional definitions of QCD states.

49.14.2 Elastic Finite-Volume Reconstruction

Definition 49.26 (Periodic Green function and S-wave zeta coordinate)**.** For a cubic spatial torus of side L, let

$$\mathbf{p_n} := \frac{2\pi}{L}\mathbf{n}, \qquad \mathbf{n} \in \mathbb{Z}^3,$$

and let $k > 0$ be such that $k^2 \neq \mathbf{p_n}^2$ for all $\mathbf{n}$. The periodic Helmholtz Green function is the distribution

$$G_L(\mathbf{r}; k) := \frac{1}{L^3} \sum_{\mathbf{n} \in \mathbb{Z}^3} \frac{\mathrm{e}^{\mathrm{i}\mathbf{p_n}\cdot\mathbf{r}}}{\mathbf{p_n}^2 - k^2}, \qquad (\Delta + k^2) G_L(\mathbf{r}; k) = -\delta_L(\mathbf{r}), \tag{49.141}$$

where δ_L is the periodic delta distribution. Its singular expansion at the origin is written

$$G_L(\mathbf{r};k) = \frac{1}{4\pi|\mathbf{r}|} + c_L(k) + O(|\mathbf{r}|), \qquad \mathbf{r} \to 0. \tag{49.142}$$

Equivalently, with $q = kL/(2\pi)$, define the analytically continued Luescher zeta coordinate $\mathcal{Z}_{00}(1;q^2)$ by

$$4\pi c_L(k) = \frac{2}{\sqrt{\pi}\,L}\,\mathcal{Z}_{00}(1;q^2), \qquad \mathcal{Z}_{00}(s;q^2) := \frac{1}{\sqrt{4\pi}}\sum_{\mathbf{n}\in\mathbb{Z}^3}\frac{1}{(\mathbf{n}^2-q^2)^s} \quad (\operatorname{Re} s > \tfrac{3}{2}), \tag{49.143}$$

continued meromorphically to $s = 1$. The singular summands at $\mathbf{n}^2 = q^2$ are absent from the elastic interval under discussion; when a free two-particle level is crossed, the condition is read by the usual limiting prescription from adjacent q^2.

Proposition 49.27 (S-wave finite-volume quantization from wave matching)**.** *Consider a single elastic two-particle channel in the center-of-mass frame. Assume the two stable particles have masses m_1, m_2, the interaction range in the relative coordinate is contained in $|\mathbf{r}| < R$, the box obeys $L > 2R$, and the finite-volume corrections from virtual particles wrapping around the torus are bounded by $C\mathrm{e}^{-m_{\mathrm{gap}}L}$ for some positive mass scale m_{gap} in the omitted exchange channel. In an exact finite-range model this exponential remainder is absent. Assume also that the cubic irrep isolates the S-wave, so higher partial waves are not retained in the truncation. Let k be the relative momentum determined by*

$$E = \sqrt{m_1^2 + k^2} + \sqrt{m_2^2 + k^2}.$$

Then the finite-volume energy is allowed precisely when

$$k\cot\delta_0(k) = 4\pi c_L(k) = \frac{2}{\sqrt{\pi}\,L}\mathcal{Z}_{00}(1;q^2), \qquad q = \frac{kL}{2\pi}. \tag{49.144}$$

Equivalently,

$$q\cot\delta_0(k) = \frac{1}{\pi^{3/2}}\mathcal{Z}_{00}(1;q^2), \qquad \delta_0(k) + \phi_0(q) = n\pi, \qquad \cot\phi_0(q) = -\frac{\mathcal{Z}_{00}(1;q^2)}{\pi^{3/2}q}. \tag{49.145}$$

Proof. Outside the interaction region the relative wave function $\psi(\mathbf{r})$ satisfies the free Helmholtz equation $(\Delta + k^2)\psi = 0$ and periodic boundary conditions. In the S-wave truncation any such finite-volume solution with a source at the origin is proportional, in the exterior region $R < |\mathbf{r}| < L/2$, to the periodic Green function $G_L(\mathbf{r};k)$. The proportionality constant is irrelevant; the quantization condition is obtained by comparing the ratio of the regular and singular terms in the short-distance expansion.

The infinite-volume elastic S-wave outside the interaction range has the standard real form

$$\psi_\infty(r) = A\,\frac{\sin(kr + \delta_0(k))}{kr}, \qquad r > R.$$

Expanding this expression at small r gives

$$\psi_\infty(r) = A\left[\frac{\sin\delta_0(k)}{kr} + \cos\delta_0(k) + O(r)\right].$$

Thus the ratio of the regular coefficient to the $1/r$ coefficient is

$$\frac{A\cos\delta_0(k)}{A\sin\delta_0(k)/k} = k\cot\delta_0(k). \tag{49.146}$$

On the other hand, the finite-volume exterior solution proportional to (49.141) has expansion

$$B\,G_L(\mathbf{r};k) = B\left[\frac{1}{4\pi r} + c_L(k) + O(r)\right], \qquad r = |\mathbf{r}|.$$

Its regular-to-singular ratio is $4\pi c_L(k)$. Matching the exterior finite-volume solution to the infinite-volume scattering boundary condition therefore gives the first equality in (49.144). The second equality is the zeta coordinate definition (49.143).

Multiplying the first form by $L/(2\pi)$ and using $q = kL/(2\pi)$ gives the first equation in (49.145). The phase form follows by defining ϕ_0 through $\cot\phi_0 = -\mathcal{Z}_{00}(1;q^2)/(\pi^{3/2}q)$:

$$\cot\delta_0(k) = -\cot\phi_0(q) = \cot\bigl(n\pi - \phi_0(q)\bigr),$$

which is equivalent to $\delta_0(k) + \phi_0(q) = n\pi$ modulo π. The only physics input beyond the spectral existence of the two-particle level is the replacement of the interacting QFT outside the range by the elastic scattering boundary condition, with exponential finite-volume corrections controlled by the lightest omitted exchange. Thus the formula is a reconstruction statement with explicit hypotheses, not a model of the resonance. □

49.14.3 Single- and Coupled-Channel Pole Coordinates

For the single-channel finite-volume pole reconstruction target, assume that, on an open real energy interval I, a QCD channel is elastic, has two stable color-singlet particles of masses m_1, m_2, and has been reduced, by a stated cubic-irrep analysis, to a single partial wave ℓ. Put $J = \{E^2 : E \in I\}$ and

$$\rho_{12}(s) = \frac{2k(s)}{\sqrt{s}}, \qquad E = \sqrt{m_1^2 + k(s)^2} + \sqrt{m_2^2 + k(s)^2},$$

for $s = E^2 \in J$, and use the partial-wave normalization

$$S_\ell(s) = 1 + 2\mathrm{i}\rho_{12}(s)t_\ell^{(I)}(s) = \mathrm{e}^{2\mathrm{i}\delta_\ell(s)}.$$

Then the physical-sheet elastic amplitude is equivalently written

$$t_\ell^{(I)}(s) = \frac{1}{K_\ell^{-1}(s) - \mathrm{i}\rho_{12}(s)}, \qquad K_\ell^{-1}(s) = \rho_{12}(s)\cot\delta_\ell(s), \tag{49.147}$$

where $K_\ell^{-1}(s)$ is real on J. Each finite-volume energy $E_n \in I$ satisfying (49.140) determines the real-axis coordinate

$$K_\ell^{-1}(E_n^2) = -\rho_{12}(E_n^2)\cot\phi_\ell(q_n), \qquad q_n = \frac{k(E_n)L}{2\pi}. \tag{49.148}$$

If K_ℓ^{-1} and ρ_{12} have the chosen analytic continuations to a simply connected neighborhood of a candidate resonance pole and no additional channel threshold crosses that neighborhood, the corresponding second-sheet pole s_* is a zero of

$$K_\ell^{-1}(s_*) + \mathrm{i}\rho_{12}(s_*) = 0. \tag{49.149}$$

This is the algebraic target of a one-channel finite-volume resonance extraction, not by itself a proof that the required analytic continuation has been controlled. Elastic unitarity in the normalization above says $S_\ell^* S_\ell = 1$ on I. Hence

$$t_\ell^{(I)}(s) = \frac{\mathrm{e}^{2\mathrm{i}\delta_\ell(s)} - 1}{2\mathrm{i}\rho_{12}(s)} = \frac{\mathrm{e}^{\mathrm{i}\delta_\ell(s)}\sin\delta_\ell(s)}{\rho_{12}(s)}$$

and therefore

$$\big(t_\ell^{(I)}(s)\big)^{-1} = \rho_{12}(s)\big(\cot\delta_\ell(s) - \mathrm{i}\big).$$

This proves (49.147) and identifies the real coordinate $K_\ell^{-1} = \rho_{12}\cot\delta_\ell$. At a finite-volume level satisfying $\delta_\ell(k_n) + \phi_\ell(q_n) = n\pi$,

$$\cot\delta_\ell(k_n) = \cot\big(n\pi - \phi_\ell(q_n)\big) = -\cot\phi_\ell(q_n),$$

which gives (49.148). Across the elastic unitarity cut the chosen branch of the two-body momentum changes sign, so ρ_{12} changes sign while K_ℓ^{-1}, being the real analytic coordinate fixed on the cut, continues through the same germ. Thus the amplitude on the adjacent sheet is

$$t_\ell^{(II)}(s) = \frac{1}{K_\ell^{-1}(s) + \mathrm{i}\rho_{12}(s)},$$

and its isolated poles are precisely the zeros of the denominator, giving (49.149).

A concrete determination of s_* also contains an analytic representation or parametrization of K_ℓ^{-1}, regulator and volume limits for the input energies, and separate bounds for neglected partial waves and inelastic channels.

Lemma 49.28 (Coupled-channel K-matrix determinant and sheet continuation)**.** *Let $a, b = 1, \dots, N$ label finitely many stable two-particle color-singlet channels in a fixed set of conserved quantum numbers, and let α, β label the partial waves and cubic-irrep components retained in a finite-volume analysis. On a real interval below the next omitted threshold, let $\rho(s)$ be the positive diagonal matrix with entries $\rho_a(s) = 2k_a(s)/\sqrt{s}$, repeated on the retained angular-momentum indices. With the normalization*

$$S = 1 + 2\mathrm{i}\,\rho^{1/2} t^{(I)} \rho^{1/2},$$

elastic coupled-channel unitarity is equivalent, on the interval, to

$$t^{(I)}(s) = \big(K^{-1}(s) - \mathrm{i}\rho(s)\big)^{-1}, \qquad K^{-1}(s)^\dagger = K^{-1}(s). \tag{49.150}$$

Suppose, in addition, that the coupled-channel finite-volume reconstruction theorem has been established for this channel and written in the same normalization, so that the finite-volume energies in a cubic irrep Γ obey

$$\det\big(K^{-1}(E^2) + F^\Gamma(E, L)\big) = 0, \tag{49.151}$$

where $F^\Gamma(E, L)$ is the real geometric matrix determined by the box, total momentum, masses, and irrep projection. In the one-channel unmixed limit $F^\Gamma = \rho_{12}\cot\phi_\ell$, so (49.151) reduces to (49.148). If Σ is the diagonal matrix whose entry is $+1$ on a channel kept on the physical branch and -1 on a channel analytically continued through its unitary cut, the corresponding sheet amplitude is

$$t^{(\Sigma)}(s) = \big(K^{-1}(s) - \mathrm{i}\,\Sigma\rho(s)\big)^{-1}, \qquad \det\big(K^{-1}(s_*) - \mathrm{i}\,\Sigma\rho(s_*)\big) = 0. \tag{49.152}$$

Proof. From $S^\dagger S = 1$ and $S = 1 + 2\mathrm{i}\rho^{1/2} t^{(I)} \rho^{1/2}$, one obtains

$$t^{(I)} - t^{(I)\dagger} = 2\mathrm{i}\, t^{(I)\dagger} \rho\, t^{(I)}.$$

Multiplying by $\left(t^{(I)\dagger}\right)^{-1}$ on the left and by $\left(t^{(I)}\right)^{-1}$ on the right gives

$$\left(t^{(I)\dagger}\right)^{-1} - \left(t^{(I)}\right)^{-1} = 2\mathrm{i}\rho, \qquad \left(t^{(I)}\right)^{-1} - \left(t^{(I)\dagger}\right)^{-1} = -2\mathrm{i}\rho.$$

Thus $K^{-1} := \left(t^{(I)}\right)^{-1} + \mathrm{i}\rho$ is Hermitian on the physical interval, and (49.150) follows. The finite-volume determinant relation is the stated reconstruction input expressed in this K-matrix coordinate. In the one-channel unmixed reduction, its zero condition is

$$K_\ell^{-1}(E^2) + \rho_{12}(E^2) \cot \phi_\ell(q) = 0, \qquad K_\ell^{-1}(E^2) = -\rho_{12}(E^2) \cot \phi_\ell(q),$$

which is exactly (49.148). Finally, analytic continuation through a chosen channel cut changes the sign of that channel's two-body momentum, hence of the corresponding diagonal entry of ρ, while the K^{-1} germ is held fixed. Repeating this sign choice for all channels gives the matrix Σ, the sheet amplitude in (49.152), and the determinant pole condition. □

Definition 49.29 (QCD resonance pole data)**.** The resonance pole data in a hadronic channel consist of a channel space of stable color-singlet asymptotic states, a physical-region scattering matrix $S_{ab}(s)$, a specified analytic continuation across specified unitary cuts, and an isolated pole s_* of the continued matrix or of an equivalent partial-wave amplitude. The mass and width coordinates

$$\sqrt{s_*} = M_* - \frac{\mathrm{i}}{2}\Gamma_*$$

are pole coordinates after a branch of the square root has been declared. For a broad or overlapping resonance, line-shape parameters on the real axis are not invariant substitutes for s_*.

This definition is the correct language for the ρ, the light scalar isoscalar pole usually denoted $f_0(500)$, many excited baryons, and near-threshold exotic candidates. The notation "tetraquark", "molecule", "hybrid", or "glueball component" is then a statement about operator overlaps, pole motion under controlled deformations, large-N_c scaling, or residue factorization. It is not a separate definition of the state.

Definition 49.30 (Controlled pole-motion chart)**.** Let η be a real coordinate on a family of QCD-like theories or regulators whose action, operator definitions, stable-channel spectrum, and renormalization prescription have been specified for η in an open interval I. Examples include a quark-mass coordinate, $1/N_c$ in a large-N_c family, a finite-volume boundary condition used as an auxiliary probe before the infinite-volume limit, or a coupling to a source that is set to zero after differentiating. A pole-motion chart in a fixed set of conserved quantum numbers consists of:

1. a channel space $\mathcal{C}_\eta$ of stable color-singlet asymptotic states for each η, with an identification of these channel spaces over the interval where no threshold crossing changes the channel list;
2. an analytic family of continued partial-wave amplitudes $t_{ab}^{(\Sigma)}(s;\eta)$ on a declared sheet Σ;
3. an isolated simple pole $s_*(\eta)$ and residue vectors $g_a(\eta)$ satisfying

$$t_{ab}^{(\Sigma)}(s;\eta) = \frac{g_a(\eta) g_b(\eta)}{s_*(\eta) - s} + h_{ab}(s;\eta),$$

with h_{ab} holomorphic near $s_*(\eta)$.

The derivative $\mathrm{d}s_*/\mathrm{d}\eta$, the projective residue vector $[g_a(\eta)]$, and their behavior near thresholds are coordinates on the declared chart. They are not intrinsic labels unless the family, channel identification, and sheet have been included in the statement.

49.14.4 Near-Threshold Effective-Range Coordinates

For a shallow S-wave bound-state effective-range chart, consider one stable two-hadron channel with reduced mass μ, threshold energy set to $E = 0$, and center-of-mass momentum $k = \sqrt{2\mu E}$, where the physical branch has $k > 0$ for $E > 0$ and $\operatorname{Im} k > 0$ below threshold. Suppose that in an energy disk whose radius is large compared with the binding energy but small compared with the first omitted left-hand or inelastic singularity, the elastic S-wave amplitude is represented by the effective-range form

$$f(k) = \frac{1}{-a^{-1} + \frac{1}{2} r_e k^2 - \mathrm{i}k}, \tag{49.153}$$

where a is the scattering length and r_e is the effective range in this normalization. If f has a bound-state pole at $E = -B = -\kappa^2/(2\mu)$, with $\kappa > 0$, then

$$\frac{1}{a} = \kappa - \frac{1}{2} r_e \kappa^2. \tag{49.154}$$

Moreover, near $E = -B$,

$$f(E) = -\frac{g_{\text{eff}}^2}{E+B} + O(1), \qquad g_{\text{eff}}^2 = \frac{\kappa}{\mu(1 - r_e\kappa)}. \tag{49.155}$$

When $1 - r_e\kappa \neq 0$, the dimensionless coordinate

$$X_{\text{ERE}} := \frac{a\kappa}{2 - a\kappa} = \frac{1}{1 - r_e\kappa} \tag{49.156}$$

is determined by the low-energy pole and the first two effective-range parameters. It is a compositeness coordinate in this one-channel effective-range chart, not a regulator-independent probability attached to a QCD eigenstate without the hypotheses above.

The bound-state pole lies on the physical sheet at $k = \mathrm{i}\kappa$. The denominator of (49.153) therefore vanishes:

$$-a^{-1} + \frac{1}{2} r_e (\mathrm{i}\kappa)^2 - \mathrm{i}(\mathrm{i}\kappa) = -a^{-1} - \frac{1}{2} r_e \kappa^2 + \kappa = 0,$$

which gives (49.154).

Let

$$D(k) = -a^{-1} + \frac{1}{2} r_e k^2 - \mathrm{i}k.$$

Since $E = k^2/(2\mu)$, one has

$$\frac{\mathrm{d}D}{\mathrm{d}E} = (r_e k - \mathrm{i})\frac{\mu}{k}.$$

Evaluating at $k = \mathrm{i}\kappa$ gives

$$\left.\frac{\mathrm{d}D}{\mathrm{d}E}\right|_{E=-B} = \frac{\mu(r_e\kappa - 1)}{\kappa}.$$

Thus

$$D(E) = \frac{\mu(r_e\kappa - 1)}{\kappa}(E + B) + O((E + B)^2),$$

and

$$f(E) = \frac{\kappa}{\mu(r_e\kappa - 1)} \frac{1}{E + B} + O(1) = -\frac{\kappa}{\mu(1 - r_e\kappa)} \frac{1}{E + B} + O(1),$$

which is (49.155). Finally, (49.154) gives

$$a\kappa = \frac{1}{1 - \frac{1}{2}r_e\kappa}.$$

Substituting this expression into $a\kappa/(2 - a\kappa)$ yields

$$\frac{a\kappa}{2 - a\kappa} = \frac{1}{1 - r_e\kappa},$$

proving (49.156).

The calculation is deliberately local. It does not classify every near-threshold QCD pole. In coupled channels, or when the omitted range scale is not separated from κ^{-1}, the residue vector and pole motion of Definition 49.30 are the appropriate coordinates. A statement that a pole is molecular, compact, hybrid, or predominantly glueball-like must then be translated into source overlaps, residues, large-N_c behavior, or a specified deformation path.

The light pseudoscalar sector has additional structure because chiral symmetry and the anomaly constrain the low-energy coordinates. Chapter 55 derives the pion effective theory, the Gell-Mann–Oakes–Renner relation, and the Witten–Veneziano large-N_c formula for the singlet mass. The vector and scalar resonances require the scattering-amplitude language above.

49.14.5 Light-Meson Scattering and Roy Coordinates

Definition 49.31 ($\pi\pi$ isospin amplitudes)**.** For equal pion masses let $s + t + u = 4m_\pi^2$ and write the $SU(2)_V$-invariant four-pion amplitude as in (55.58),

$$\mathcal{A}_{ab\to cd} = \delta_{ab}\delta_{cd}A(s, t, u) + \delta_{ac}\delta_{bd}A(t, s, u) + \delta_{ad}\delta_{bc}A(u, t, s).$$

The scalar function A is symmetric in its last two arguments; this is the Bose symmetry obtained by interchanging the two pions in an equal-mass initial or final pair while keeping the tensor decomposition above fixed. The s-channel isospin amplitudes are

$$\begin{pmatrix} T^0 \\ T^1 \\ T^2 \end{pmatrix} = \begin{pmatrix} 3 & 1 & 1 \\ 0 & 1 & -1 \\ 0 & 1 & 1 \end{pmatrix} \begin{pmatrix} A(s, t, u) \\ A(t, s, u) \\ A(u, t, s) \end{pmatrix}. \tag{49.157}$$

Equivalently,

$$T^0 = 3A(s, t, u) + A(t, s, u) + A(u, t, s), \quad T^1 = A(t, s, u) - A(u, t, s), \quad T^2 = A(t, s, u) + A(u, t, s).$$

Crossing matrices in the $\pi\pi$ isospin basis. With $\mathbf{T} := (T^0, T^1, T^2)^T$, crossing $s \leftrightarrow t$ and $s \leftrightarrow u$ is

$$\mathbf{T}(t,s,u) = C_{st}\mathbf{T}(s,t,u), \qquad \mathbf{T}(u,t,s) = C_{su}\mathbf{T}(s,t,u), \tag{49.158}$$

where

$$C_{st} = \begin{pmatrix} \frac{1}{3} & 1 & \frac{5}{3} \\ \frac{1}{3} & \frac{1}{2} & -\frac{5}{6} \\ \frac{1}{3} & -\frac{1}{2} & \frac{1}{6} \end{pmatrix}, \qquad C_{su} = \begin{pmatrix} \frac{1}{3} & -1 & \frac{5}{3} \\ -\frac{1}{3} & \frac{1}{2} & \frac{5}{6} \\ \frac{1}{3} & \frac{1}{2} & \frac{1}{6} \end{pmatrix}. \tag{49.159}$$

The matrices in (49.159) are part of the normalization of the Roy coordinates used below. Let

$$\mathbf{A} := \begin{pmatrix} A(s,t,u) \\ A(t,s,u) \\ A(u,t,s) \end{pmatrix}, \qquad M := \begin{pmatrix} 3 & 1 & 1 \\ 0 & 1 & -1 \\ 0 & 1 & 1 \end{pmatrix}.$$

Equation (49.157) is $\mathbf{T} = M\mathbf{A}$, and

$$M^{-1} = \begin{pmatrix} \frac{1}{3} & 0 & -\frac{1}{3} \\ 0 & \frac{1}{2} & \frac{1}{2} \\ 0 & -\frac{1}{2} & \frac{1}{2} \end{pmatrix}.$$

The exchange $s \leftrightarrow t$ sends $\mathbf{A}$ to $P_{st}\mathbf{A}$, where P_{st} interchanges the first two components, and $s \leftrightarrow u$ sends $\mathbf{A}$ to $P_{su}\mathbf{A}$, where P_{su} interchanges the first and third components. Therefore $C_{st} = MP_{st}M^{-1}$ and $C_{su} = MP_{su}M^{-1}$, which gives (49.159). In particular $C_{st}^2 = C_{su}^2 = 1$, as required by applying the same crossing operation twice.

For $\pi\pi$ scattering, write the isospin partial waves as $t_\ell^I(s)$ by

$$T^I(s,t(s,z),u(s,z)) = 32\pi \sum_{\ell=0}^{\infty} (2\ell+1) P_\ell(z)\, t_\ell^I(s), \qquad t(s,z) = -\frac{s-4m_\pi^2}{2}(1-z), \tag{49.160}$$

with projection

$$t_\ell^I(s) = \frac{1}{64\pi} \int_{-1}^{1} P_\ell(z) T^I(s,t(s,z),u(s,z))\, \mathrm{d}z.$$

In this normalization physical-region elastic unitarity is

$$\operatorname{Im} t_\ell^I(s) = \rho_{\pi\pi}(s) |t_\ell^I(s)|^2, \qquad \rho_{\pi\pi}(s) = \sqrt{1 - \frac{4m_\pi^2}{s}},$$

below the first inelastic threshold. The S-wave scattering-length coordinates used in this section are

$$a_0^0 := t_0^0(4m_\pi^2), \qquad a_0^2 := t_0^2(4m_\pi^2).$$

Definition 49.32 (Roy input for $\pi\pi$ scattering)**.** Roy input on a real interval $J \subset [4m_\pi^2, s_{\max})$ consists of:

1. the pion mass, the isospin amplitudes $\mathbf{T}$, and the partial wave normalization (49.160);
2. a domain of fixed-t analyticity in which twice-subtracted Cauchy representations are valid and the boundary values on the right- and left-hand cuts exist as tempered distributions;
3. the crossing matrices (49.159);

4. subtraction constants a_0^0, a_0^2;
5. high-energy and high-partial-wave absorptive input sufficient for the two subtractions and for the convergence of the partial-wave projections.

The subtraction polynomial projected to partial waves is

$$k_0^0(s; a_0^0, a_0^2) = a_0^0 + \frac{s - 4m_\pi^2}{12m_\pi^2}\,(2a_0^0 - 5a_0^2), \tag{49.161}$$

$$k_1^1(s; a_0^0, a_0^2) = \frac{s - 4m_\pi^2}{72m_\pi^2}\,(2a_0^0 - 5a_0^2), \tag{49.162}$$

$$k_0^2(s; a_0^0, a_0^2) = a_0^2 - \frac{s - 4m_\pi^2}{24m_\pi^2}\,(2a_0^0 - 5a_0^2), \tag{49.163}$$

and $k_\ell^I = 0$ for the other partial waves in the twice-subtracted polynomial. This normalization fixes what is meant below by the Roy kernels $K_{\ell\ell'}^{II'}$.

Proposition 49.33 (Roy projection from fixed-t analyticity and crossing)**.** *Assume the Roy input of Definition 49.32. Then, for $s \in J$, the real part of each retained partial wave obeys*

$$\operatorname{Re} t_\ell^I(s) = k_\ell^I(s; a_0^0, a_0^2) + \sum_{I',\ell'} \int_{4m_\pi^2}^{\infty} \mathrm{d}s'\, K_{\ell\ell'}^{II'}(s, s')\, \operatorname{Im} t_{\ell'}^{I'}(s'). \tag{49.164}$$

More explicitly, if the twice-subtracted fixed-t representation is written after crossing the left-hand cut into the form

$$\operatorname{Re} T^I(s, t(s, z)) = P^I(s, z; a_0^0, a_0^2) + 32\pi \sum_{I',\ell'} (2\ell' + 1) \int_{4m_\pi^2}^{\infty} \mathrm{d}s'\, R_{\ell'}^{II'}(s, z; s')\, \operatorname{Im} t_{\ell'}^{I'}(s'), \tag{49.165}$$

then

$$k_\ell^I(s) = \frac{1}{64\pi} \int_{-1}^{1} P_\ell(z) P^I(s, z)\, \mathrm{d}z, \qquad K_{\ell\ell'}^{II'}(s, s') = \frac{2\ell' + 1}{2} \int_{-1}^{1} P_\ell(z) R_{\ell'}^{II'}(s, z; s')\, \mathrm{d}z. \tag{49.166}$$

The functions $R_{\ell'}^{II'}$, hence the kernels $K_{\ell\ell'}^{II'}$, are determined by the Cauchy denominators, the two subtractions, the crossing matrices C_{st}, C_{su}, and the Legendre projection of the absorptive parts.

Proof. Fix t in the declared fixed-t analyticity domain. The twice-subtracted Cauchy representation expresses the boundary value of $\mathbf{T}(s, t)$ as a subtraction polynomial plus integrals over the discontinuities on the right-hand and left-hand cuts. By crossing, the left-hand discontinuity is rewritten as a right-hand discontinuity of the crossed isospin vector, multiplied by C_{st} or C_{su} according to which crossed channel has become physical. This is the step where (49.158) enters; without it the left-hand cut is not a QCD input in the same isospin coordinates.

For $s' \geq 4m_\pi^2$, expand the absorptive part in partial waves,

$$\operatorname{Im} T^{I'}(s', t(s', z')) = 32\pi \sum_{\ell'=0}^{\infty} (2\ell' + 1) P_{\ell'}(z')\, \operatorname{Im} t_{\ell'}^{I'}(s').$$

Performing the z'-projection contained in the crossed-channel Cauchy terms gives the functions $R_{\ell'}^{II'}(s, z; s')$ in (49.165). The convergence assumptions in the Roy input justify interchanging this partial-wave expansion with the subtracted dispersion integrals on J.

Finally project the resulting fixed-t formula in the s-channel:

$$\operatorname{Re} t_\ell^I(s) = \frac{1}{64\pi} \int_{-1}^{1} P_\ell(z) \operatorname{Re} T^I(s, t(s,z))\, \mathrm{d}z.$$

Substituting (49.165) and using the orthogonality normalization already built into (49.160) gives exactly (49.164) with the projected polynomial and kernel in (49.166). The explicit polynomials (49.161)–(49.163) are the projection of the two independent isospin-even subtraction constants; the $I = 1$, $\ell = 1$ subtraction is proportional to the same combination $2a_0^0 - 5a_0^2$ because crossing fixes the first $s - 4m_\pi^2$ derivative of the odd isospin amplitude at threshold. □

Remark 49.34 (Status of a Roy pole extraction). A pole extraction from (49.164) is controlled only after the high-energy absorptive input, inelastic channels, matching point, subtraction constants, and error correlations have been specified. For the ρ, the relevant pole is obtained by continuing the $I = 1$, $\ell = 1$ partial wave through the elastic cut. For the light scalar isoscalar pole $f_0(500)$, the corresponding continuation is in the $I = 0$, $\ell = 0$ wave and is especially sensitive to the subtraction constants and low-energy crossing constraints. The same logic governs Roy–Steiner equations for πK, πN, and related channels, with unequal masses and additional crossed-channel partial waves changing the kernel construction but not the Cauchy-crossing-projection logic.

49.14.6 Light-Meson Pole Charts

Definition 49.35 (Concrete light-meson pole chart)**.** A concrete light-meson pole statement in this chapter consists of a color-singlet channel, a partial wave, a reconstruction method, and a sheet-labeled pole or stable mass. The minimal chart used for the examples below is:

(i) π, K, η, η'. The QCD channel is the pseudoscalar flavor sector. The amplitude coordinate is a stable mass, together with mixing coordinates where appropriate. The controlled route uses chiral effective theory matched to QCD, lattice masses, and the anomaly constraints of Chapter 51.

(ii) ρ. The QCD channel is $I = 1$, $\ell = 1$ $\pi\pi$. The amplitude coordinate is the second-sheet pole of $t_1^1(s)$. The controlled route is Roy input or finite-volume P-wave $\pi\pi$ quantization followed by analytic continuation.

(iii) $f_0(500)$. The QCD channel is $I = 0$, $\ell = 0$ $\pi\pi$. The amplitude coordinate is a broad second-sheet pole of $t_0^0(s)$. The controlled route is Roy input with subtraction constants and correlated high-energy input.

(iv) K^*. The QCD channel is $I = \frac{1}{2}$, P-wave πK. The amplitude coordinate is the second-sheet pole of the unequal-mass partial wave. The controlled route is Roy–Steiner input or finite-volume πK quantization.

(v) K_0^* channel. The QCD channel is $I = \frac{1}{2}$, S-wave πK. The amplitude coordinate is nearby pole data, often broad. The controlled route is Roy–Steiner input with explicit treatment of inelastic and left-hand input.

(vi) Hybrid or exotic 1^{-+} channels. The QCD channel is specified by a finite operator-source family containing $q\bar{q}F$ or Wilson-line operators. The amplitude coordinate is pole data plus source-overlap and pole-motion coordinates. The controlled route supplies color-singlet finite-volume energies from the declared source family and then performs finite-volume scattering reconstruction.

The entries are not model assignments. They are instructions for which QCD operator sector, partial wave, analytic sheet, and reconstruction theorem must be supplied before the label denotes a spectroscopic output.

Linear elastic pole coordinate near a narrow vector resonance. Consider a one-channel elastic partial wave in the normalization

$$t^{(I)}(s) = \frac{1}{K^{-1}(s) - \mathrm{i}\rho(s)}, \qquad t^{(II)}(s) = \frac{1}{K^{-1}(s) + \mathrm{i}\rho(s)}.$$

Let M_0^2 be a real point in the elastic interval such that

$$K^{-1}(M_0^2) = 0, \qquad A := \left.\frac{\mathrm{d}K^{-1}}{\mathrm{d}s}\right|_{M_0^2} > 0, \qquad \rho_0 := \rho(M_0^2) > 0,$$

and suppose that, in a neighborhood whose size is small compared with the nearest omitted singularity,

$$K^{-1}(s) = A(s - M_0^2) + O((s - M_0^2)^2), \qquad \rho(s) = \rho_0 + O(s - M_0^2).$$

Then the adjacent-sheet pole in this linearized chart is

$$s_* = M_0^2 - \mathrm{i}\,\frac{\rho_0}{A} + O\!\left(\frac{\rho_0^2}{A^2}\,\sup|(K^{-1})''| + \frac{\rho_0}{A}\sup|\rho'|\right), \tag{49.167}$$

where the suprema are taken on the same neighborhood. If the pole is parametrized by

$$\sqrt{s_*} = M_* - \frac{\mathrm{i}}{2}\Gamma_*$$

and the pole is narrow enough that $|s_* - M_0^2| \ll M_0^2$, then

$$M_* = M_0 + O(\Gamma_*^2/M_0), \qquad \Gamma_* = \frac{\rho_0}{AM_0} + O(\rho_0^2/A^2M_0^3). \tag{49.168}$$

In the exactly linear and constant approximation the second-sheet pole condition is

$$K^{-1}(s_*) + \mathrm{i}\rho(s_*) = 0 \quad\Longrightarrow\quad A(s_* - M_0^2) + \mathrm{i}\rho_0 = 0,$$

which gives $s_* = M_0^2 - \mathrm{i}\rho_0/A$. The displayed remainder follows by substituting

$$s_* = M_0^2 - \mathrm{i}\rho_0/A + \Delta$$

into the full denominator and solving once for Δ by Taylor's theorem on the neighborhood where the derivative of $K^{-1} + \mathrm{i}\rho$ remains bounded away from zero. This is an ordinary one-complex-variable implicit-function estimate; its small parameters are the quadratic variation of K^{-1} and the variation of the phase-space factor across the pole displacement.

Finally,

$$(M_* - \mathrm{i}\Gamma_*/2)^2 = M_*^2 - \frac{\Gamma_*^2}{4} - \mathrm{i}M_*\Gamma_*.$$

Comparing the imaginary part with $\operatorname{Im} s_* = -\rho_0/A + O(\rho_0^2/A^2M_0^2)$ gives (49.168); the real part then gives the stated correction to M_*. The calculation supplies a coordinate linearization of the pole equation. It is appropriate for a narrow ρ-type vector pole in an elastic window. For a broad scalar such as the $f_0(500)$, the pole coordinate itself is the invariant output and a real-axis mass-width pair is a secondary chart, if it is used at all.

Remark 49.36 (How the chart is used). For the ρ, one may use the $I = 1$, $\ell = 1$ entry of Definition 49.35 and, when the elastic window and narrowness assumptions are adequate, the linear pole coordinate above. For $f_0(500)$, the same one-channel formula is not the correct primary language: the broad pole is obtained by solving the analytically continued Roy equations for $t_0^0(s)$. For πK resonances the unequal-mass Roy–Steiner construction above fixes the kinematics and the crossing input. For near-threshold exotic candidates, the effective-range and pole-motion charts of Definition 49.30 and the shallow effective-range calculation above specify what is meant by a molecular or compact coordinate. In every case the QCD statement is a pole or a stable mass extracted from a declared operator and regulator setup.

49.14.7 Unequal-Mass and Baryon-Meson Channels

Definition 49.37 (Unequal-mass elastic kinematics). Let $A(m_1) + B(m_2) \to A(m_1) + B(m_2)$ be elastic scattering of two stable color-singlet hadrons, and set

$$s_\pm := (m_1 \pm m_2)^2, \qquad \lambda(s, m_1^2, m_2^2) := (s - s_+)(s - s_-).$$

For $s > s_+$, define the center-of-mass momentum

$$k_s(s) := \frac{\lambda(s, m_1^2, m_2^2)^{1/2}}{2\sqrt{s}}.$$

If z_s is the cosine of the s-channel scattering angle, the Mandelstam variables in the physical elastic region are

$$t(s, z_s) = -2k_s(s)^2(1 - z_s), \qquad u(s, z_s) = 2(m_1^2 + m_2^2) - s - t(s, z_s). \tag{49.169}$$

The identity

$$s + t + u = 2(m_1^2 + m_2^2) \tag{49.170}$$

is part of the kinematic convention. For πK scattering one takes $(m_1, m_2) = (m_\pi, m_K)$.

Elastic unequal-mass projection. In the kinematics of Definition 49.37, a scalar amplitude $T(s, t, u)$ with fixed internal quantum numbers has the s-channel partial-wave expansion

$$T(s, t(s, z_s), u(s, z_s)) = 16\pi \sum_{\ell=0}^{\infty} (2\ell + 1) P_\ell(z_s) f_\ell(s), \tag{49.171}$$

with inverse

$$f_\ell(s) = \frac{1}{32\pi} \int_{-1}^{1} P_\ell(z_s) T(s, t(s, z_s), u(s, z_s)) \, \mathrm{d}z_s. \tag{49.172}$$

With

$$\rho_{12}(s) := \frac{2k_s(s)}{\sqrt{s}} = \frac{\lambda(s, m_1^2, m_2^2)^{1/2}}{s},$$

elastic unitarity in this normalization is

$$\operatorname{Im} f_\ell(s) = \rho_{12}(s) |f_\ell(s)|^2 \tag{49.173}$$

below the first inelastic threshold. In the center-of-mass frame the incoming and outgoing spatial momenta have magnitude $k_s(s)$. The energy of each species is the same before and after scattering, hence the momentum transfer has zero energy component and spatial magnitude squared

$$|\mathbf{k} - \mathbf{k}'|^2 = 2k_s(s)^2(1 - z_s).$$

With the Mandelstam convention used in this chapter this gives $t = -|\mathbf{k} - \mathbf{k}'|^2$, proving (49.169). The sum rule (49.170) follows directly from the definitions of s, t, u and the four on-shell conditions.

The partial-wave inversion is the Legendre orthogonality identity

$$\int_{-1}^{1} P_\ell(z) P_{\ell'}(z)\, \mathrm{d}z = \frac{2}{2\ell + 1}\delta_{\ell\ell'}$$

applied to (49.171). Finally the two-body phase-space density in these conventions is $\rho_{12}(s) = 2k_s(s)/\sqrt{s}$. Applying $S_\ell^* S_\ell = 1$ to

$$S_\ell(s) = 1 + 2\mathrm{i}\rho_{12}(s) f_\ell(s)$$

gives (49.173).

Definition 49.38 (Roy–Steiner input)**.** Roy–Steiner input for an unequal-mass two-hadron problem consists of:

1. the masses, exact internal quantum numbers, and invariant amplitudes $\mathbf{T}(s, t, u)$ in a declared basis of isospin or charge channels;
2. the crossing matrices relating the chosen s-channel basis to the u- and t-channel bases;
3. s-channel partial waves $f_\ell^a(s)$ and crossed-channel partial waves $g_\ell^c(t)$, each with an explicit normalization such as (49.171);
4. a fixed-t, fixed-u, or hyperbolic dispersion domain in which the required subtracted Cauchy representations are valid as boundary values of holomorphic functions;
5. subtraction constants, matching points, and high-energy/high-partial wave input sufficient to make all projected integrals converge.

This input is a reconstruction coordinate for amplitudes. It includes the analyticity, crossing, subtraction, and asymptotic assumptions; QCD supplies the channel Hilbert spaces and current or hadron matrix elements to which those assumptions are applied.

Proposition 49.39 (Roy–Steiner projection construction)**.** *Assume Roy–Steiner input in the sense of Definition 49.38. Let J_s and J_t be real intervals below the first omitted inelastic thresholds in the s- and crossed t-channels. Then the retained s-channel partial waves have the form*

$$\begin{aligned}\operatorname{Re} f_\ell^a(s) = k_\ell^a(s; \mathbf{a}) &+ \sum_{b,\ell'} \int_{s_+}^{\infty} \mathrm{d}s'\, K_{\ell\ell'}^{ab}(s, s')\, \operatorname{Im} f_{\ell'}^b(s') \\ &+ \sum_{c,\ell'} \int_{t_{\mathrm{th}}}^{\infty} \mathrm{d}t'\, G_{\ell\ell'}^{ac}(s, t')\, \operatorname{Im} g_{\ell'}^c(t'), \qquad s \in J_s, \end{aligned} \tag{49.174}$$

and the crossed-channel partial waves have analogous equations

$$\operatorname{Re} g_\ell^c(t) = \widetilde{k}_\ell^c(t;\mathbf{a}) + \sum_{b,\ell'} \int_{s_+}^{\infty} \mathrm{d}s'\, \widetilde{G}_{\ell\ell'}^{cb}(t,s')\ \operatorname{Im} f_{\ell'}^b(s') + \sum_{d,\ell'} \int_{t_{\mathrm{th}}}^{\infty} \mathrm{d}t'\, \widetilde{K}_{\ell\ell'}^{cd}(t,t')\ \operatorname{Im} g_{\ell'}^d(t'), \qquad t \in J_t. \tag{49.175}$$

Here $\mathbf{a}$ *denotes the declared subtraction constants. The kernels* $K, G, \widetilde{G}, \widetilde{K}$ *are the Legendre projections of the subtracted Cauchy denominators after the crossed-channel discontinuities have been rewritten with the declared crossing matrices.*

Proof. Begin with the subtracted Cauchy representation in the chosen Roy–Steiner domain. Its discontinuity terms are located on the physical cuts of the s, u, and t variables. The right-hand s-channel cut is already expressed in the basis whose partial waves are f_ℓ^a. The u- and t-channel cuts are first moved into their physical variables and then rewritten in the chosen s-channel basis using the crossing matrices included in the input. This produces a fixed-angle representation

$$\begin{aligned}
&\operatorname{Re} T^a(s, t(s,z_s), u(s,z_s)) \\
&= P^a(s,z_s;\mathbf{a}) + \sum_{b,\ell'} \int_{s_+}^{\infty} \mathrm{d}s'\, R_{\ell'}^{ab}(s,z_s;s')\ \operatorname{Im} f_{\ell'}^b(s') \\
&\quad + \sum_{c,\ell'} \int_{t_{\mathrm{th}}}^{\infty} \mathrm{d}t'\, H_{\ell'}^{ac}(s,z_s;t')\ \operatorname{Im} g_{\ell'}^c(t').
\end{aligned}$$

The convergence part of the input justifies the interchange of the partial-wave sums, dispersion integrals, and z_s-projection on J_s. Projecting with

$$\frac{1}{32\pi} \int_{-1}^{1} P_\ell(z_s)(\,\cdot\,)\,\mathrm{d}z_s$$

defines

$$k_\ell^a(s) = \frac{1}{32\pi} \int_{-1}^{1} P_\ell(z_s) P^a(s,z_s)\,\mathrm{d}z_s,$$

and similarly defines $K_{\ell\ell'}^{ab}$ and $G_{\ell\ell'}^{ac}$ as the same projection of $R_{\ell'}^{ab}$ and $H_{\ell'}^{ac}$. This gives (49.174). For the t-channel, use the crossed-channel angle z_t, the t-channel partial-wave normalization, and the crossed basis of amplitudes before projection. The same subtracted Cauchy denominators then project to $\widetilde{G}_{\ell\ell'}^{cd}$ and $\widetilde{K}_{\ell\ell'}^{cd}$, while the polynomial part projects to $\widetilde{k}_\ell^c(t)$. This gives (49.175). No additional dynamical assumption enters at the projection stage; all dynamical input is already contained in the analytic domain, crossing matrices, absorptive parts, and subtraction constants of the input. □

49.14.8 Quarkonium, Baryon, and Hybrid Source Charts

Definition 49.40 (Quarkonium spectroscopy chart)**.** A neutral heavy quarkonium entry is a color-singlet $Q\bar{Q}$ spectral coordinate with flavor $Q = c$ or $Q = b$, radial label n, orbital angular momentum $L = 0, 1, 2, \ldots$, total heavy-quark spin $S = 0, 1$, and total angular momentum J. The spectroscopic notation is

$$n\,^{2S+1}L_J, \qquad L = S, P, D, F, \ldots \quad \text{for} \quad L = 0, 1, 2, 3, \ldots. \tag{49.176}$$

For hidden flavor, charge conjugation is an exact quantum number in the isospin-symmetric QCD-plus-QED-decoupled convention. The low-lying chart is:

state type	$n\,^{2S+1}L_J$	J^{PC}	standard entries
pseudoscalar	$n\,^1S_0$	0^{-+}	$\eta_c(nS),\ \eta_b(nS)$
vector	$n\,^3S_1$	1^{--}	$J/\psi,\ \psi(nS),\ \Upsilon(nS)$
scalar triplet	$n\,^3P_0$	0^{++}	$\chi_{c0}(nP),\ \chi_{b0}(nP)$
axial triplet	$n\,^3P_1$	1^{++}	$\chi_{c1}(nP),\ \chi_{b1}(nP)$
tensor triplet	$n\,^3P_2$	2^{++}	$\chi_{c2}(nP),\ \chi_{b2}(nP)$
singlet P-wave	$n\,^1P_1$	1^{+-}	$h_c(nP),\ h_b(nP)$

The entries in the last column are names for QCD spectral levels or sheet-labeled poles in the corresponding channels. The chart by itself is not a potential model. A prediction of the level $M_{n\,^{2S+1}L_J}$ requires a regulator or an effective Hamiltonian with a stated heavy-quark mass scheme, matching coefficients, ultrasoft treatment, and error estimate.

Quarkonium J^{PC} rule. For a neutral $Q\bar{Q}$ color-singlet state in the chart of Definition 49.40, the allowed angular momenta are

$$J \in \{|L - S|, |L - S| + 1, \ldots, L + S\},$$

and the parity and charge-conjugation quantum numbers are

$$P = (-1)^{L+1}, \qquad C = (-1)^{L+S}. \tag{49.177}$$

The angular-momentum statement is the Clebsch–Gordan decomposition of the orbital representation L with the total spin representation S. For a fermion-antifermion pair, intrinsic parities multiply to -1. The orbital wavefunction contributes $(-1)^L$ under spatial inversion, giving

$$P = (-1)(-1)^L = (-1)^{L+1}.$$

Charge conjugation exchanges the quark and antiquark. In the center-of-mass frame this exchange reverses the relative coordinate, contributing $(-1)^L$. The spin wavefunction contributes $+1$ on the spin-singlet state and -1 on the spin-triplet state after the fermion exchange convention is included; this factor is $(-1)^S$ relative to the orbital factor in the standard $Q\bar{Q}$ convention. Therefore

$$C = (-1)^L(-1)^S = (-1)^{L+S}.$$

Substitution gives the entries in Definition 49.40: for example $^1S_0$ has 0^{-+}, $^3S_1$ has 1^{--}, ^3P_J has J^{++}, and $^1P_1$ has 1^{+-}.

Heavy quarkonium uses a different controlled coordinate system. If

$$m_Q \gg m_Q v \gg m_Q v^2$$

is a useful hierarchy, the pNRQCD Hamiltonian of the preceding sections predicts the charmonium and bottomonium level spacings through a potential coordinate, spin-dependent $1/m_Q$ operators, and ultrasoft corrections. The spin-averaged levels, hyperfine splittings, and fine structure are then matrix elements in a stated effective Hamiltonian. They are not predictions of a nonrelativistic potential unless the matching coefficients, mass scheme, and ultrasoft treatment have been fixed as part of the input. The angular momentum algebra that turns these matched operators into centroid, fine, and hyperfine coordinates is the finite-dimensional content of the J^{PC} rule above and the spin algebra paragraph.

Baryon spectroscopy is likewise a QCD spectral problem, not a three-body mechanics problem imposed from outside. For $N_f = 3$ light flavors, the lowest baryons organize approximately into flavor $SU(3)$ octet and decuplet representations when the quark masses are close. To first order in an octet symmetry-breaking Hamiltonian, the octet masses may be written as

$$M(Y, I) = M_0 + aY + b\left(I(I+1) - \frac{Y^2}{4}\right), \tag{49.178}$$

where Y is hypercharge and I is isospin. This coordinate chart gives the Gell-Mann–Okubo relation

$$2(M_N + M_\Xi) = 3M_\Lambda + M_\Sigma. \tag{49.179}$$

For the decuplet, first-order octet breaking gives equal spacing along the hypercharge ladder. These relations are symmetry consequences of a stated approximation; the actual QCD masses require lattice, dispersive, and chiral extrapolation inputs.

Assume that first-order $SU(3)$-breaking baryon masses are described by (49.178) in the octet and by $M_{10}(Y) = M_{10,0} + cY$ in the decuplet. Then (49.179) holds and

$$M_{\Sigma^*} - M_\Delta = M_{\Xi^*} - M_{\Sigma^*} = M_\Omega - M_{\Xi^*}. \tag{49.180}$$

For the octet,

$$(Y, I)_N = (1, \tfrac{1}{2}), \quad (Y, I)_\Lambda = (0, 0), \quad (Y, I)_\Sigma = (0, 1), \quad (Y, I)_\Xi = (-1, \tfrac{1}{2}).$$

Substitution in (49.178) gives

$$M_N = M_0 + a + \frac{b}{2}, \quad M_\Xi = M_0 - a + \frac{b}{2}, \quad M_\Lambda = M_0, \quad M_\Sigma = M_0 + 2b,$$

which implies (49.179). For the decuplet the hypercharges are $1, 0, -1, -2$. A linear function of Y has equal successive differences, giving (49.180).

In the large-N_c limit with N_f fixed, the baryon operator (49.137) contains N_c quark fields. The pair-counting argument around (49.54) gives a mass of order N_c, while collective spin-flavor splittings are typically $O(1/N_c)$ in the rotor regime. This is a controlled limit of QCD under its own hypotheses, and it explains why baryons require a separate large-N_c analysis from mesons. It does not license importing constituent-quark spectra as QCD predictions.

Definition 49.41 (Baryon-meson resonance reconstruction data)**.** Fix conserved quantum numbers: baryon number one, total isospin I, total strangeness S, total angular momentum and parity J^P, and any other exact charges in the chosen QCD mass convention. A two-body baryon-meson resonance reconstruction data consist of:

1. a finite list of stable color-singlet two-body channels $a = (B_a, M_a)$ in the chosen energy window, with baryon mass M_{B_a}, meson mass m_{M_a}, spin s_{B_a}, meson spin s_{M_a}, and intrinsic parities P_{B_a}, P_{M_a};

2. a list of retained orbital angular momenta L_a and spin couplings producing the declared J^P;
3. the infinite-volume partial-wave matrix $t_{ab}^{J^P}(s)$, with phase-space matrix

$$\rho_a(s) = \frac{2k_a(s)}{\sqrt{s}}, \qquad \sqrt{s} = \sqrt{M_{B_a}^2 + k_a(s)^2} + \sqrt{m_{M_a}^2 + k_a(s)^2};$$

4. a reconstruction method for t^{J^P}, for example a coupled-channel finite-volume determinant or a Roy–Steiner representation;
5. a sheet label $\Sigma = \mathrm{diag}(\sigma_a)$, with $\sigma_a = \pm 1$, specifying which channel momenta have been continued through their unitarity cuts;
6. pole positions s_* and residue vectors g_a defined by

$$t_{ab}^{(\Sigma),J^P}(s) = \frac{g_a g_b}{s_* - s} + h_{ab}(s), \tag{49.181}$$

   where h_{ab} is holomorphic at s_* on the same sheet.

The invariant content is the pole position, the sheet, and the residue projective vector g_a, together with the operator and regulator data by which the amplitude was obtained. Names such as radial excitation, molecule, compact multiquark configuration, or meson-baryon bound state are interpretive coordinates on these data.

Pseudoscalar-meson–baryon partial-wave quantum numbers. Let a positive-parity spin-$\frac{1}{2}$ baryon B scatter with a pseudoscalar meson M of spin 0 and parity -1. In a two-body partial wave of orbital angular momentum L, the allowed total angular momenta and parity are

$$J \in \begin{cases} \{\frac{1}{2}\}, & L = 0, \\ \{L - \frac{1}{2}, L + \frac{1}{2}\}, & L \geq 1, \end{cases} \qquad P = (-1)^{L+1}. \tag{49.182}$$

Consequently an S-wave channel has $J^P = \frac{1}{2}^-$, while a P-wave channel has $J^P = \frac{1}{2}^+$ or $J^P = \frac{3}{2}^+$. The two-body Hilbert space at fixed center-of-mass momentum decomposes under spatial rotations as the tensor product of the orbital representation of spin L, the baryon spin representation $\frac{1}{2}$, and the meson spin representation 0. Therefore the total spin content is

$$L \otimes \frac{1}{2} = \begin{cases} \frac{1}{2}, & L = 0, \\ (L - \frac{1}{2}) \oplus (L + \frac{1}{2}), & L \geq 1, \end{cases}$$

which gives the allowed J's. Parity multiplies the intrinsic parities by the orbital factor $(-1)^L$:

$$P = P_B P_M (-1)^L = (+1)(-1)(-1)^L = (-1)^{L+1}.$$

The S- and P-wave cases are the first two values of L.

This elementary representation-theoretic step is often where baryon resonance nomenclature enters the analysis. The $\Delta(1232)$ channel is the $I = \frac{3}{2}$, $J^P = \frac{3}{2}^+$ P-wave πN amplitude. A Roper-type nucleon resonance is a pole in the $I = \frac{1}{2}$, $J^P = \frac{1}{2}^+$ channel, with residues into the retained πN, ηN, and multi-hadron channels determined by the chosen coupled-channel amplitude. The $\Lambda(1405)$-type channel has $I = 0$, $S = -1$, $J^P = \frac{1}{2}^-$, and its minimal two-body description couples the $\bar{K}N$ and $\pi\Sigma$ S-wave channels. In each case the QCD statement is the sheet-labeled pole of Definition 49.41. A finite-volume calculation supplies color-singlet energy levels through finite source-family correlators; the pole information is then reconstructed only after a coupled-channel quantization condition and analytic continuation have been specified. A dispersive calculation supplies it through the corresponding analyticity and crossing assumptions.

Proposition 49.42 (Two-channel sheet continuation and residue vector)**.** *Fix a partial wave and an energy neighborhood in which two stable color-singlet two-body channels are the only open channels retained in the analysis. Suppose that, in this neighborhood, the coupled-channel amplitude admits a K-matrix representation*

$$t^{\text{phys}}(s) = \left[K(s)^{-1} - \mathrm{i}\ \mathrm{diag}\big(\rho_1(s), \rho_2(s)\big)\right]^{-1}, \tag{49.183}$$

where $K(s)^{-1}$ is a complex-analytic symmetric matrix that is real symmetric on the physical real interval, and each $\rho_a(s)$ is the chosen square-root phase-space branch for channel a. For a sheet label $\sigma = (\sigma_1, \sigma_2)$, $\sigma_a = \pm 1$, define

$$D_\sigma(s) := K(s)^{-1} - \mathrm{i}\ \mathrm{diag}\big(\sigma_1\rho_1(s), \sigma_2\rho_2(s)\big), \qquad t^{(\sigma)}(s) := D_\sigma(s)^{-1}. \tag{49.184}$$

Then a resonance pole on this sheet is a zero of

$$\Delta_\sigma(s) := \det D_\sigma(s). \tag{49.185}$$

If s_* is a simple zero of Δ_σ and $\operatorname{rank} D_\sigma(s_*) = 1$, *then*

$$t^{(\sigma)}(s) = -\frac{\operatorname{adj} D_\sigma(s_*)}{\Delta'_\sigma(s_*)}\,\frac{1}{s_* - s} + O(1). \tag{49.186}$$

Because $D_\sigma(s_*)$ is complex symmetric, the adjugate in (49.186) *has rank one and can be written as $c\, v_a v_b$, where v spans* $\ker D_\sigma(s_*)$. *Thus the projective residue vector in Definition 49.41 is the null direction of the analytically continued denominator, with the overall complex phase fixed only after choosing a residue normalization.*

In the constant local coordinate chart

$$K^{-1} = \begin{pmatrix} a & b \\ b & c \end{pmatrix}, \qquad \rho_a(s) = \rho_a,$$

the pole equation on sheet σ is

$$(a - \mathrm{i}\sigma_1\rho_1)(c - \mathrm{i}\sigma_2\rho_2) - b^2 = 0. \tag{49.187}$$

Proof. Equation (49.183) is the representation assumed in the proposition. On the physical interval it is equivalent to the two-channel elastic-unitarity identity

$$\mathrm{Im}\big(t^{\text{phys}}(s)^{-1}\big) = -\,\mathrm{diag}(\rho_1(s), \rho_2(s))$$

on the physical interval. Analytic continuation through the unitarity cut of channel a changes the sign of the square root $k_a(s)$, hence of $\rho_a(s)$, and leaves the other channel branches unchanged. This gives (49.184). Since the matrix inverse is meromorphic wherever the entries are analytic, its poles are precisely the zeros of $\det D_\sigma$, unless the adjugate vanishes to sufficient order to cancel the zero. Under the stated rank-one and simple-zero hypotheses, the adjugate does not vanish, and

$$D_\sigma(s)^{-1} = \frac{\operatorname{adj} D_\sigma(s)}{\Delta_\sigma(s)} = \frac{\operatorname{adj} D_\sigma(s_*)}{(s-s_*)\Delta'_\sigma(s_*)} + O(1),$$

which is (49.186) after rewriting $(s-s_*)^{-1} = -(s_*-s)^{-1}$. A 2×2 matrix of rank one has rank-one adjugate; for a complex symmetric matrix the left and right null directions agree, so this rank-one matrix is proportional to vv^T. The constant formula (49.187) is the determinant of the displayed 2×2 denominator. □

This proposition is the minimal algebra behind statements about the $\Lambda(1405)$-type $\bar{K}N$-$\pi\Sigma$ sector, hidden-charm pentaquark channels, and near-threshold heavy-meson channels. The number of poles, their locations, and their residues are outputs of a finite-volume or dispersive reconstruction. The phrase "molecular" can be used only after a specific residue, pole-motion, or source-overlap coordinate has been declared; it is not an independent QCD definition.

Definition 49.43 (Light-baryon spectroscopy charts)**.** Work with baryon number $B = 1$ and three light flavors (u, d, s). Let strangeness be denoted by $S_{\rm str}$, so the hypercharge used in (49.178) is $Y = B + S_{\rm str} = 1 + S_{\rm str}$. The ground-state flavor multiplet charts used below are:

multiplet	**entry**	**I**	**Y**	$\mathbf{J}^P$
8	$N = (p, n)$	$\frac{1}{2}$	1	$\frac{1}{2}^+$
8	Λ	0	0	$\frac{1}{2}^+$
8	$\Sigma = (\Sigma^+, \Sigma^0, \Sigma^-)$	1	0	$\frac{1}{2}^+$
8	$\Xi = (\Xi^0, \Xi^-)$	$\frac{1}{2}$	-1	$\frac{1}{2}^+$
10	Δ	$\frac{3}{2}$	1	$\frac{3}{2}^+$
10	Σ^*	1	0	$\frac{3}{2}^+$
10	Ξ^*	$\frac{1}{2}$	-1	$\frac{3}{2}^+$
10	Ω^-	0	-2	$\frac{3}{2}^+$

The table is a chart of exact conserved quantum numbers and approximate flavor-$SU(3)$ organization. The masses are QCD spectral values obtained from the color-singlet Hamiltonian or from a regulator converging to it. Equation (49.179) and (49.180) are first-order coordinates on these spectral values; they are not definitions of the baryons.

Definition 49.44 (Excited light-baryon channel chart)**.** An excited light-baryon entry in this monograph is specified by:

(i) exact charges $B = 1$, I, $S_{\rm str}$, J^P, and any additional exact discrete quantum numbers of the chosen mass convention;

(ii) a finite list of two-body and effective multi-hadron channels retained in the reconstruction of Definition 49.41;

(iii) a sheet-labeled pole s_* of the corresponding color-singlet amplitude, or an isolated stable level if the state lies below every open channel in the stated volume and mass regime;

(iv) the residue projective vector into the retained channels, when the interpretation of the pole requires an overlap or composition coordinate.

The following entries are the minimal light-baryon examples that must be carried through any concrete coupled-channel analysis:

(a) $\Delta(1232)$: charges $(I, S_{\text{str}}, J^P) = (\frac{3}{2}, 0, \frac{3}{2}^+)$; retained channel πN in the P-wave; QCD output a nearby second-sheet pole of $t^{3/2^+}_{\pi N,\pi N}$.

(b) $N(1440)$-type channel: charges $(\frac{1}{2}, 0, \frac{1}{2}^+)$; retained channels $\pi N, \eta N, \pi\pi N$; QCD output a coupled-channel pole whose radial-label interpretation comes from pole motion and source overlaps.

(c) $N(1535)$-type channel: charges $(\frac{1}{2}, 0, \frac{1}{2}^-)$; retained channels $\pi N, \eta N, K\Lambda, K\Sigma$; QCD output an S-wave pole with residue data.

(d) $\Sigma(1385)$: charges $(1, -1, \frac{3}{2}^+)$; retained channels $\pi\Lambda, \pi\Sigma, \bar{K}N$; QCD output a strange P-wave pole.

(e) $\Lambda(1405)$-type channel: charges $(0, -1, \frac{1}{2}^-)$; retained channels $\bar{K}N, \pi\Sigma$; QCD output one or more sheet-labeled S-wave poles.

(f) $\Lambda(1520)$: charges $(0, -1, \frac{3}{2}^-)$; retained channels $\bar{K}N, \pi\Sigma$; QCD output a D-wave dominated pole coordinate.

The words "Roper", "$\Lambda(1405)$", and similar labels are therefore shorthand for entries in this chart. A lattice calculation supplies the finite-volume spectrum and operator overlaps; a dispersive or Hamiltonian-scattering analysis supplies an analytic continuation. Without that continuation there is no invariant resonance mass or width.

Definition 49.45 (Heavy-baryon QCD/HQET chart)**.** Let $Q = c$ or b, and consider one-heavy-quark baryons Qqq. After the heavy-quark velocity v^μ and mass scheme for m_Q are fixed, the color-singlet Hilbert-space sector admits an HQET expansion in which the light degrees of freedom carry angular momentum j_ℓ and flavor quantum numbers. The basic entries are:

family	**light flavor**	$\mathbf{j}_\ell$	J^P **at leading order**
Λ_Q, Ξ_Q	$\bar{\mathbf{3}}$ of light flavor	0	$\frac{1}{2}^+$
$\Sigma_Q, \Xi'_Q, \Omega_Q$	$\mathbf{6}$ of light flavor	1	$\frac{1}{2}^+, \frac{3}{2}^+$

The leading HQET statement is a spectral degeneracy at fixed j_ℓ and light-flavor representation, before $1/m_Q$ chromomagnetic terms are included. Doubly heavy baryons such as Ξ_{cc}, Ξ_{bc}, and Ω_{cc} are QCD sectors with two heavy fields and one light field. They may be organized by heavy-diquark variables only after a scale separation and color-$\bar{\mathbf{3}}$ matching calculation has been specified.

Definition 49.46 (Near-threshold heavy spectroscopy chart)**.** Heavy-flavor spectroscopy contains stable baryon sectors and resonance or near-threshold pole sectors. The following chart fixes the QCD object before any model language is introduced:

(a) Ξ_{cc}, Ω_{cc}: exact charges $B = 1,\ C = 2$; minimal sources ccq; QCD output isolated color-singlet masses when the levels lie below the relevant strong thresholds.

(b) $\Lambda_b, \Sigma_b, \Xi_b, \Omega_b$: exact charges $B = 1$ with bottom flavor -1; minimal sources bqq; QCD output stable or narrow levels organized by the HQET chart above.

(c) P_c-type hidden-charm baryon sector: exact charges $B = 1,\ C = 0$ with hidden $c\bar{c}$; retained channels $J/\psi\, p, \Sigma_c\bar{D}, \Sigma_c\bar{D}^*, \ldots$; QCD output a sheet-labeled baryon-meson pole.

(d) T_{cc}-type sector: exact charges $B = 0,\ C = 2$; retained channels $DD^*, D^*D^*, \ldots$; QCD output a near-threshold meson-meson pole or bound-state pole.

(e) $X(6900)$-type sector: exact charges $B = 0$, $C = 0$ with hidden $c\bar{c}c\bar{c}$; retained channels $J/\psi\, J/\psi, \eta_c\eta_c, \ldots$; QCD output a coupled heavy-quarkonium pole.

The entries with $B = 0$ are included because they use the same pole-motion and effective-range machinery as the baryon-number-one pentaquark channels. Labels such as compact tetraquark, hadronic molecule, or diquark-antidiquark are then coordinates on residues, pole motion under quark-mass variation, large-N_c behavior, and source-overlap coordinates. They are not primitive spectral definitions.

Definition 49.47 (Glueball and hybrid spectroscopy source families)**.** Fix J^{PC}, flavor quantum numbers, and a finite-volume regulator with a transfer matrix. A glueball source family is a finite-dimensional subspace $\mathcal{V}_G$ spanned by gauge-invariant pure-glue operators, such as traces of small Wilson loops or local curvature polynomials after operator renormalization. A flavor-singlet meson source family is a subspace $\mathcal{V}_M$ spanned by color-singlet quark bilinears and multi-hadron operators with the same exact quantum numbers. A hybrid source family is a subspace $\mathcal{V}_H$ spanned by gauge-invariant sources in which quark fields are connected by Wilson lines and one or more local curvature insertions, for example representative operator families of the form $\bar{q}(x)\Gamma\, U(x,y)F_{\mu\nu}(y)U(y,z)q(z)$ after the endpoint and composite-operator renormalizations are specified.

The QCD spectrum is the spectrum extracted from the full correlation matrix on the span of these source spaces and their multi-hadron completions. The labels glueball, hybrid, and flavor-singlet meson are source-family coordinates on eigenvectors and pole residues. They become invariant only after a supplementary limit or comparison is stated, for example the pure Yang–Mills limit, the large-N_c limit, or a declared quark-mass deformation path.

Controlled Approximation 49.48 (Two-state mixing coordinate)**.** A two-state mixing matrix is a coordinate on a controlled finite-dimensional projection of the transfer-matrix problem, not a definition of the QCD spectrum. It is admissible only after the source subspaces, the inner product, the fitting window, and the error made by omitting other levels have been stated. Within such a projection, suppose two normalized basis vectors $|G\rangle \in \mathcal{V}_G$ and $|M\rangle \in \mathcal{V}_M \oplus \mathcal{V}_H$ give the self-adjoint matrix

$$H_{\text{eff}}(x) = \begin{pmatrix} M_G(x) & h(x) \\ h(x) & M_M(x) \end{pmatrix}, \tag{49.188}$$

where x is a declared deformation coordinate, such as a quark mass or $1/N_c$.

Remark 49.49 (Avoided crossing in a two-state spectroscopy chart). In the controlled approximation 49.48, the two projected energies are

$$E_\pm(x) = \frac{M_G(x) + M_M(x)}{2} \pm \sqrt{\left(\frac{M_M(x) - M_G(x)}{2}\right)^2 + h(x)^2}. \tag{49.189}$$

If $M_G(x_0) = M_M(x_0)$ and $h(x_0) \neq 0$, the projected levels are separated by $2|h(x_0)|$. Away from degeneracy, a real orthogonal diagonalization angle $\theta(x)$ may be chosen so that

$$\tan 2\theta(x) = \frac{2h(x)}{M_M(x) - M_G(x)}. \tag{49.190}$$

The characteristic polynomial of (49.188) is

$$E^2 - (M_G + M_M)E + M_G M_M - h^2.$$

Solving this quadratic gives (49.189). At $M_G = M_M$, the square root is $|h|$, so the separation is $2|h|$. For the angle, write the rotated off-diagonal entry as

$$\frac{1}{2}(M_G - M_M)\sin 2\theta + h\cos 2\theta.$$

Setting it to zero gives $(M_M - M_G)\sin 2\theta = 2h\cos 2\theta$, which is (49.190) when the denominator is nonzero. At degeneracy the diagonalizing angle is $\theta = \pi/4$ modulo basis signs.

The proposition explains why an eigenstate cannot be assigned an invariant glueball or hybrid percentage from a two-by-two table alone. The invariant quantities are the QCD energies or pole positions and the declared matrix elements. The percentages are coordinates depending on the finite source space, normalization, and deformation path.

Heavy-baryon spin average removes the chromomagnetic coordinate. Fix a one-heavy-quark baryon family with $j_\ell > 0$. Suppose that, through order $1/m_Q$, the only spin-dependent term in the effective Hamiltonian on the two-state multiplet $J = j_\ell \pm \frac{1}{2}$ is

$$H_{\mathrm{mag}} = \frac{2\kappa_{j_\ell}}{m_Q}\,\mathbf{S}_Q\cdot\mathbf{j}_\ell, \tag{49.191}$$

where $\mathbf{S}_Q^2 = \frac{3}{4}$ and $\mathbf{j}_\ell^2 = j_\ell(j_\ell+1)$. Then the degeneracy-weighted spin average

$$\overline{M}_{j_\ell} := \frac{(2j_\ell)M_{j_\ell-\frac{1}{2}} + (2j_\ell+2)M_{j_\ell+\frac{1}{2}}}{4j_\ell+2} \tag{49.192}$$

is independent of κ_{j_ℓ} at this order. In particular, for the Σ_Q, Σ_Q^*-type doublet, $j_\ell = 1$ and

$$\overline{M}_{\Sigma_Q} = \frac{M_{\Sigma_Q} + 2M_{\Sigma_Q^*}}{3} \tag{49.193}$$

has no chromomagnetic $1/m_Q$ contribution in the stated scheme.

On a state with total spin J,

$$\mathbf{S}_Q\cdot\mathbf{j}_\ell = \frac{1}{2}\left[J(J+1) - j_\ell(j_\ell+1) - \frac{3}{4}\right].$$

For $J_- = j_\ell - \frac{1}{2}$, this eigenvalue is

$$\frac{1}{2}\left[(j_\ell - \tfrac{1}{2})(j_\ell + \tfrac{1}{2}) - j_\ell(j_\ell+1) - \frac{3}{4}\right] = -\frac{j_\ell+1}{2}.$$

For $J_+ = j_\ell + \frac{1}{2}$, it is

$$\frac{1}{2}\left[(j_\ell + \tfrac{1}{2})(j_\ell + \tfrac{3}{2}) - j_\ell(j_\ell+1) - \frac{3}{4}\right] = \frac{j_\ell}{2}.$$

The degeneracies are $2J_- + 1 = 2j_\ell$ and $2J_+ + 1 = 2j_\ell + 2$. Hence

$$(2j_\ell)\left(-\frac{j_\ell+1}{2}\right) + (2j_\ell+2)\left(\frac{j_\ell}{2}\right) = 0.$$

The spin-average (49.192) therefore cancels the coefficient κ_{j_ℓ} independently of its value. The remaining terms are the heavy-quark mass coordinate, the spin-independent light-sector energy, the kinetic $1/m_Q$ coordinate, and higher-order corrections.

Remark 49.50 (Large-N_c baryon catalog coordinate). The large-N_c baryon discussion preceding (49.54) gives a second controlled organization of baryon spectra. Its invariant inputs are the QCD Hamiltonian, baryon number one, fixed N_f, and the large-N_c scaling limit. Under the Hartree and rotor hypotheses stated there, baryon masses have an $O(N_c)$ common part and $O(1/N_c)$ spin-flavor splittings. The contracted $SU(2N_f)$ algebra is a leading-order relation among baryon matrix elements in this limit. It complements the finite-N_c spectral and coupled-channel charts above; it does not replace the QCD pole or eigenvalue definitions.

49.14.9 Current Matrix Elements and Forward Sum Rules

Definition 49.51 (Nucleon current matrix elements)**.** Let $|N(p,s)\rangle$ be an isolated one-nucleon state in the color-singlet QCD Hilbert space, with $p^2 = -M_N^2$, $p^0 > 0$, and spin label s. In the mostly-plus spinor convention of Section 40.16, use the same Dirac–Pauli basis as in Definition 43.4. For the Hermitian electromagnetic current J^μ_{em}, normalized by the flavor charges of the quarks, define the nucleon Dirac and Pauli form factors by

$$\langle N(p',s')|J^\mu_{\text{em}}(0)|N(p,s)\rangle = \frac{\mathrm{i}e}{(2\pi)^3}\,\bar u_{s'}(p')\left[\gamma^\mu F_1^N(k^2) + \frac{1}{M_N}S^{\mu\nu}k_\nu F_2^N(k^2)\right]u_s(p), \qquad k := p - p', \tag{49.194}$$

where $e > 0$ is the elementary charge and $S^{\mu\nu} = -\mathrm{i}[\gamma^\mu,\gamma^\nu]/4$. The charge normalization is

$$F_1^p(0) = 1, \qquad F_1^n(0) = 0.$$

The anomalous magnetic moment coordinate is $F_2^N(0)$, and the magnetic moment in nuclear magnetons is $F_1^N(0) + F_2^N(0)$ after the conventional normalization by $e/(2M_N)$.

For spacelike transfer set

$$Q^2 := -k^2 > 0, \qquad \tau := \frac{Q^2}{4M_N^2}.$$

The Sachs coordinates are the linear combinations

$$G_E^N(Q^2) = F_1^N(-Q^2) - \tau F_2^N(-Q^2), \qquad G_M^N(Q^2) = F_1^N(-Q^2) + F_2^N(-Q^2). \tag{49.195}$$

They are useful Breit-frame coordinates for elastic electron–nucleon scattering, but the nonperturbative definition is the current matrix element (49.194). A lattice, dispersive, or experimental extraction must state the current renormalization, finite-volume matrix-element method, excited-state removal, and analytic continuation or fit ansatz used to obtain the functions of Q^2.

Remark 49.52 (Sachs and Dirac–Pauli coordinates). For $\tau \neq -1$, the coordinate change (49.195) is invertible:

$$F_1^N(-Q^2) = \frac{G_E^N(Q^2) + \tau G_M^N(Q^2)}{1+\tau}, \qquad F_2^N(-Q^2) = \frac{G_M^N(Q^2) - G_E^N(Q^2)}{1+\tau}. \tag{49.196}$$

At $Q^2 = 0$,

$$G_E^N(0) = F_1^N(0), \qquad G_M^N(0) = F_1^N(0) + F_2^N(0).$$

The two equations in (49.195) form the linear system

$$\begin{pmatrix} G_E \\ G_M \end{pmatrix} = \begin{pmatrix} 1 & -\tau \\ 1 & 1 \end{pmatrix}\begin{pmatrix} F_1 \\ F_2 \end{pmatrix}.$$

The determinant is $1+\tau$. Inverting the matrix gives (49.196). Setting $Q^2=0$, hence $\tau=0$, gives the stated zero-transfer normalizations. No model of nucleon substructure enters this argument; it is only a change of coordinates on the same current matrix element.

Definition 49.53 (Isovector axial form factors)**.** Let A_a^μ be the renormalized isovector axial current, with $a=1,2,3$ and flavor generator $\tau_a/2$. Between one-nucleon states, parity, Lorentz covariance, and isospin give the decomposition

$$\langle N(p',s')|A_a^\mu(0)|N(p,s)\rangle = \frac{\mathrm{i}}{(2\pi)^3}\,\bar u_{s'}(p')\left[\gamma^\mu\gamma_5\,G_A(Q^2)+\frac{k^\mu}{2M_N}\gamma_5\,G_P(Q^2)\right]\frac{\tau_a}{2}\,u_s(p), \quad (49.197)$$

again with $Q^2=-k^2$. The number $g_A := G_A(0)$ is the axial charge in this current normalization. The induced pseudoscalar form factor G_P contains the pion-pole contribution dictated by the chiral Ward identity and the pion effective theory of Chapter 55; beyond that pole, its regular part is another QCD matrix element. Thus nucleon axial data are part of the same ab initio program as the mass spectrum: they are not defined by a quark-model wave function but by renormalized current insertions between color-singlet Hilbert-space states.

Proposition 49.54 (Stable-current three-point extraction)**.** *Let a reflection-positive finite-volume regulator of QCD on a spatial torus $\mathbb{T}_L^3$ be fixed, with Hilbert space $\mathcal{H}_L$, vacuum Ω_L, self-adjoint Hamiltonian $H_L \geq 0$, and momentum operators $\mathbf{P}_L$. Let $J_{\mathcal{R}}$ be a renormalized, gauge-invariant current in a specified operator-renormalization scheme $\mathcal{R}$, and let $J_{\mathcal{R},\mathbf{q}}$ denote its spatial Fourier component carrying momentum $\mathbf{q}$. Choose momenta $\mathbf{p},\mathbf{p}'\in(2\pi/L)\mathbb{Z}^3$ with $\mathbf{p}'=\mathbf{p}+\mathbf{q}$. Suppose that in the two relevant baryon-number-one momentum sectors there are normalized one-nucleon eigenvectors*

$$H_L|N,L;\mathbf{p},r\rangle = E_L(\mathbf{p})|N,L;\mathbf{p},r\rangle, \qquad H_L|N,L;\mathbf{p}',r'\rangle = E_L(\mathbf{p}')|N,L;\mathbf{p}',r'\rangle,$$

isolated from the rest of the spectrum in the same quantum-number channels by positive gaps $\Delta_L(\mathbf{p})$ and $\Delta_L(\mathbf{p}')$. Here r,r' label chosen rows in the relevant finite-volume symmetry irreducible representations; after the $L\to\infty$ limit these rows are matched to the usual spin labels. Let $\mathcal{O}^\dagger_{\mathbf{p},r}$ and $\mathcal{O}^\dagger_{\mathbf{p}',r'}$ be gauge-invariant baryon sources, projected to the indicated momentum and row, and set

$$\psi_{\mathbf{p},r} := \mathcal{O}^\dagger_{\mathbf{p},r}\Omega_L, \qquad \psi_{\mathbf{p}',r'} := \mathcal{O}^\dagger_{\mathbf{p}',r'}\Omega_L.$$

Assume their one-particle overlaps

$$Z_{\mathbf{p},r} := \langle N,L;\mathbf{p},r|\psi_{\mathbf{p},r}\rangle, \qquad Z_{\mathbf{p}',r'} := \langle N,L;\mathbf{p}',r'|\psi_{\mathbf{p}',r'}\rangle$$

are nonzero. At fixed regulator, assume $J_{\mathcal{R},\mathbf{q}}$ is bounded on the finite-energy subspace generated by these sources; on a lattice with compact gauge variables and local fermion bilinears this is the ordinary boundedness statement for the regulated local insertion.

Define the Euclidean two- and three-point functions

$$C_2(t;\mathbf{p},r) := \langle\psi_{\mathbf{p},r}, e^{-H_L t}\psi_{\mathbf{p},r}\rangle, \quad (49.198)$$

$$C_3^{J_{\mathcal{R}}}(t,\tau;\mathbf{p}',r';\mathbf{p},r) := \langle\psi_{\mathbf{p}',r'}, e^{-H_L(t-\tau)}J_{\mathcal{R},\mathbf{q}}e^{-H_L\tau}\psi_{\mathbf{p},r}\rangle, \qquad 0<\tau<t. \quad (49.199)$$

Then

$$C_2(t;\mathbf{p},r) = |Z_{\mathbf{p},r}|^2 e^{-E_L(\mathbf{p})t} + R_2(t;\mathbf{p},r), \qquad |R_2(t;\mathbf{p},r)| \leq \|\eta_{\mathbf{p},r}\|^2 e^{-(E_L(\mathbf{p})+\Delta_L(\mathbf{p}))t}, \quad (49.200)$$

where $\eta_{\mathbf{p},r} := (1 - P_{\mathbf{p},r})\psi_{\mathbf{p},r}$ *and* $P_{\mathbf{p},r}$ *is the spectral projection onto* $|N, L; \mathbf{p}, r\rangle$*. Moreover*

$$\begin{aligned} C_3^{J_{\mathcal{R}}}(t, \tau; \mathbf{p}', r'; \mathbf{p}, r) = \overline{Z_{\mathbf{p}',r'}} Z_{\mathbf{p},r}\, e^{-E_L(\mathbf{p}')(t-\tau)} e^{-E_L(\mathbf{p})\tau} \langle N, L; \mathbf{p}', r' | J_{\mathcal{R},\mathbf{q}} | N, L; \mathbf{p}, r\rangle \\ + R_3(t, \tau; \mathbf{p}', r'; \mathbf{p}, r), \end{aligned} \tag{49.201}$$

with the explicit bound

$$\begin{aligned} |R_3| \le \|J_{\mathcal{R},\mathbf{q}}\| \Big(&\|\eta_{\mathbf{p}',r'}\|\, |Z_{\mathbf{p},r}|\, e^{-(E_L(\mathbf{p}')+\Delta_L(\mathbf{p}'))(t-\tau)} e^{-E_L(\mathbf{p})\tau} \\ &+ |Z_{\mathbf{p}',r'}|\, \|\eta_{\mathbf{p},r}\|\, e^{-E_L(\mathbf{p}')(t-\tau)} e^{-(E_L(\mathbf{p})+\Delta_L(\mathbf{p}))\tau} \\ &+ \|\eta_{\mathbf{p}',r'}\|\, \|\eta_{\mathbf{p},r}\|\, e^{-(E_L(\mathbf{p}')+\Delta_L(\mathbf{p}'))(t-\tau)} e^{-(E_L(\mathbf{p})+\Delta_L(\mathbf{p}))\tau} \Big). \end{aligned} \tag{49.202}$$

Consequently the ratio

$$\mathcal{R}_{J_{\mathcal{R}}}(t, \tau) := \frac{C_3^{J_{\mathcal{R}}}(t, \tau; \mathbf{p}', r'; \mathbf{p}, r)}{\overline{Z_{\mathbf{p}',r'}} Z_{\mathbf{p},r}\, e^{-E_L(\mathbf{p}')(t-\tau)} e^{-E_L(\mathbf{p})\tau}} \tag{49.203}$$

satisfies

$$\mathcal{R}_{J_{\mathcal{R}}}(t, \tau) = \langle N, L; \mathbf{p}', r' | J_{\mathcal{R},\mathbf{q}} | N, L; \mathbf{p}, r\rangle + O(e^{-\Delta_L(\mathbf{p}')(t-\tau)}) + O(e^{-\Delta_L(\mathbf{p})\tau})$$

as $\tau \to \infty$ *and* $t - \tau \to \infty$*, with constants fixed by the source norms, overlaps, and regulated-current norm above.*

Proof. The proof is the spectral theorem for the finite-volume transfer-matrix Hamiltonian. We give the details because this is the mathematical content behind the phrase "extracting a form factor". Decompose the source vectors into their one-particle components and orthogonal remainders,

$$\psi_{\mathbf{p},r} = Z_{\mathbf{p},r} |N, L; \mathbf{p}, r\rangle + \eta_{\mathbf{p},r}, \qquad \psi_{\mathbf{p}',r'} = Z_{\mathbf{p}',r'} |N, L; \mathbf{p}', r'\rangle + \eta_{\mathbf{p}',r'}.$$

By the assumed spectral gaps, the spectral support of $\eta_{\mathbf{p},r}$ lies in $[E_L(\mathbf{p}) + \Delta_L(\mathbf{p}), \infty)$, and similarly for $\eta_{\mathbf{p}',r'}$. Hence

$$\|e^{-H_L s} \eta_{\mathbf{p},r}\| \le e^{-(E_L(\mathbf{p})+\Delta_L(\mathbf{p}))s} \|\eta_{\mathbf{p},r}\|, \qquad s \ge 0,$$

and the corresponding estimate holds in the primed channel. Substituting the decomposition of $\psi_{\mathbf{p},r}$ into (49.198) gives the leading term $|Z_{\mathbf{p},r}|^2 e^{-E_L(\mathbf{p})t}$. The cross terms vanish because $\eta_{\mathbf{p},r}$ is orthogonal to the one-particle eigenspace and $e^{-H_L t}$ preserves the spectral decomposition. The remaining η-term is bounded by the preceding estimate, proving (49.200).

For the three-point function, insert the same decompositions on the sink and source sides of (49.199). The term in which both spectral projections are one-particle projections is exactly the first line of (49.201). The three remaining terms contain an excited component on the sink side, on the source side, or on both sides. Applying the gap estimate to the side on which the excited component propagates, and applying Cauchy's inequality together with the regulated operator norm of $J_{\mathcal{R},\mathbf{q}}$, gives the three terms in (49.202). Division by the nonzero leading overlap factor gives (49.203) and the stated asymptotic error. Nothing in the argument assumes a constituent description of the nucleon; the only inputs are reflection positivity, spectral isolation, a renormalized gauge-invariant current insertion, and nonzero overlap of the chosen source with the state. □

The continuum nucleon form factors of Definition 49.51 are obtained from the finite-volume matrix element in Proposition 49.54 only after the current-renormalization scheme has been fixed and the regulator and volume limits have been taken with the chosen state normalization. A plateau in a ratio of Euclidean correlators is therefore evidence for the hypotheses of the proposition in a numerical calculation; it is not itself the definition of the form factor.

Definition 49.55 (Forward Compton amplitude and polarizabilities)**.** Let N be a stable proton or neutron state of mass M_N and spin $\frac{1}{2}$. Work in the nucleon rest frame and let a real photon have energy $\omega > 0$, direction $\mathbf{n} \in S^2$, and transverse polarization representatives $\boldsymbol{\epsilon}, \boldsymbol{\epsilon}'$ satisfying $\mathbf{n} \cdot \boldsymbol{\epsilon} = \mathbf{n} \cdot \boldsymbol{\epsilon}' = 0$. The forward real-Compton amplitude is the on-shell, connected, LSZ-reduced matrix element of two insertions of the renormalized electromagnetic current J^{μ}_{em}, with the photon coupling and the one-nucleon state normalization fixed by the scattering chapters. For a spin state with unit spin vector $\mathbf{s}$, define the scalar forward amplitudes $f_N(\omega)$ and $g_N(\omega)$ by

$$\mathcal{A}^{\mathrm{fwd}}_{\gamma N \to \gamma N} = \boldsymbol{\epsilon}'^{*} \cdot \boldsymbol{\epsilon}\, f_N(\omega) + \mathrm{i}\, \mathbf{s} \cdot \big(\boldsymbol{\epsilon}'^{*} \times \boldsymbol{\epsilon}\big)\, g_N(\omega). \tag{49.204}$$

This equation is a definition of the normalization of f_N, g_N. Let

$$f_N^{\mathrm{nb}}(\omega) := f_N(\omega) - f_N^{\mathrm{Born}}(\omega)$$

denote the non-Born amplitude after subtracting the one-nucleon pole contribution, whose normalization is specified in the low-energy expansion below. With this normalization the optical-theorem convention for the absorptive non-Born amplitude is

$$\operatorname{Im} f_N^{\mathrm{nb}}(\omega + \mathrm{i}0) = \frac{\omega}{4\pi}\, \sigma^{\mathrm{abs}}_{\gamma N}(\omega), \qquad \omega \geq \omega_{\mathrm{th}}, \tag{49.205}$$

where ω_{th} is the first inelastic threshold and $\sigma^{\mathrm{abs}}_{\gamma N}$ is the total real-photon absorption cross section in the same convention, not the elastic Compton cross section. The spin-dependent optical theorem similarly uses the helicity-difference absorption cross section $\Delta\sigma_{\gamma N} := \sigma_{1/2} - \sigma_{3/2}$:

$$\operatorname{Im} g_N(\omega + \mathrm{i}0) = \frac{\omega}{8\pi}\, \Delta\sigma_{\gamma N}(\omega). \tag{49.206}$$

The spin-independent electric-plus-magnetic polarizability is the coefficient of the first non-Born term in the low-energy expansion

$$f_N(\omega) = f_N^{\mathrm{Born}}(\omega) + \big(\alpha_E^N + \beta_M^N\big)\omega^2 + O(\omega^4). \tag{49.207}$$

The Born amplitude is the one-nucleon pole contribution determined by the charge $F_1^N(0)$, magnetic moment $F_1^N(0) + F_2^N(0)$, and the same Compton Ward identity used in the QED external-state chapter. Equation (49.207) defines only the sum $\alpha_E^N + \beta_M^N$. Separating α_E^N from β_M^N requires either non-forward Compton amplitudes or a background-field definition with separately specified electric and magnetic external fields.

Proposition 49.56 (Baldin sum rule as a forward-dispersion theorem)**.** *Assume that the spin-independent forward Compton amplitude $f_N^{\mathrm{nb}}(\omega)$ is an even function of ω analytic in the complex ω-plane cut along $(-\infty, -\omega_{\mathrm{th}}] \cup [\omega_{\mathrm{th}}, \infty)$, real on the real interval $|\omega| < \omega_{\mathrm{th}}$, and sufficiently bounded at infinity so that the once-subtracted Cauchy formula below has no boundary term. Then*

$$f_N^{\mathrm{nb}}(\omega) - f_N^{\mathrm{nb}}(0) = \frac{2\omega^2}{\pi} \int_{\omega_{\mathrm{th}}}^{\infty} \frac{\operatorname{Im} f_N^{\mathrm{nb}}(\omega' + \mathrm{i}0)}{\omega'(\omega'^2 - \omega^2)}\, \mathrm{d}\omega', \qquad |\omega| < \omega_{\mathrm{th}}. \tag{49.208}$$

If the small-ω expansion (49.207) exists and the integral may be expanded at $\omega = 0$, then

$$\alpha_E^N + \beta_M^N = \frac{1}{2\pi^2} \int_{\omega_{\rm th}}^{\infty} \frac{\sigma_{\gamma N}^{\rm abs}(\omega')}{\omega'^2} \, {\rm d}\omega'. \tag{49.209}$$

Proof. Set $F(\omega) := f_N^{\rm nb}(\omega) - f_N^{\rm nb}(0)$. By crossing in the forward channel F is even. Apply Cauchy's theorem to $F(z)/(z^2 - \omega^2)$ on a contour surrounding the two cuts and use the assumed large-$|z|$ bound to drop the circle at infinity. The discontinuity on the positive cut is

$$F(\omega' + {\rm i}0) - F(\omega' - {\rm i}0) = 2{\rm i} \ {\rm Im} \, f_N^{\rm nb}(\omega' + {\rm i}0).$$

The negative cut gives the same contribution after the change $\omega' \mapsto -\omega'$, because F is even. The residues at $z = \pm\omega$ then give (49.208). For $|\omega| < \omega_{\rm th}$,

$$\frac{1}{\omega'^2 - \omega^2} = \frac{1}{\omega'^2} + O(\omega^2),$$

under the stated integrability assumption. Therefore the coefficient of ω^2 in $F(\omega)$ is

$$\frac{2}{\pi} \int_{\omega_{\rm th}}^{\infty} \frac{{\rm Im} \, f_N^{\rm nb}(\omega' + {\rm i}0)}{\omega'^3} \, {\rm d}\omega'.$$

Using the optical theorem (49.205) gives (49.209). The proof shows precisely where the analytic and high-energy hypotheses enter; QCD supplies the current matrix elements, while the dispersion relation is an additional analyticity statement about the real-photon forward amplitude. □

Definition 49.57 (Forward spin polarizabilities)**.** Keep the normalization of the spin-dependent forward Compton amplitude g_N in (49.204) and the helicity difference

$$\Delta\sigma_{\gamma N}(\omega) := \sigma_{1/2}(\omega) - \sigma_{3/2}(\omega),$$

where the subscript is the total γN helicity in the rest frame of the target. Let $F_1^N(q^2)$ and $F_2^N(q^2)$ be the Dirac and Pauli form factors in the current matrix element (49.194), and set

$$Q_N := F_1^N(0), \qquad \kappa_N := F_2^N(0).$$

Thus $Q_p = 1$, $Q_n = 0$, and κ_N is the anomalous magnetic moment in units $e/(2M_N)$ in the conventions of this chapter. The spin-dependent low-energy theorem fixes the term linear in ω:

$$g_N(\omega) = -\frac{e^2\kappa_N^2}{8\pi M_N^2} \, \omega + \gamma_0^N \, \omega^3 + O(\omega^5). \tag{49.210}$$

Equation (49.210) defines the forward spin polarizability γ_0^N once the one-nucleon Born normalization has been fixed by $F_1^N(0)$ and $F_2^N(0)$. The absence of a Q_N^2 term in the coefficient of ω is part of the low-energy Ward-identity statement: the point-charge contribution is spin independent in the forward limit, while the anomalous magnetic moment controls the leading spin-dependent Born amplitude.

Proposition 49.58 (Gerasimov–Drell–Hearn and forward spin-polarizability sum rules)**.** *Assume that $g_N(\omega)$, after the Compton Ward identity has combined the s-channel, u-channel, and local Born pieces into a function regular at $\omega = 0$, is an odd function of ω analytic in the complex ω-plane cut along $(-\infty, -\omega_{\text{th}}] \cup [\omega_{\text{th}}, \infty)$, real on $|\omega| < \omega_{\text{th}}$, and sufficiently bounded at infinity that the unsubtracted odd dispersion relation below has no boundary term. Assume also that the threshold and high-energy behavior allow the first two terms of the small-ω expansion of the dispersion integral. Then, in the normalization of (49.206),*

$$g_N(\omega) = \frac{2\omega}{\pi} \int_{\omega_{\text{th}}}^{\infty} \frac{\operatorname{Im} g_N(\omega' + \mathrm{i}0)}{\omega'^2 - \omega^2} \, \mathrm{d}\omega', \qquad |\omega| < \omega_{\text{th}}, \tag{49.211}$$

and therefore

$$\int_{\omega_{\text{th}}}^{\infty} \frac{\Delta\sigma_{\gamma N}(\omega')}{\omega'} \, \mathrm{d}\omega' = -\frac{\pi e^2}{2M_N^2} \, \kappa_N^2 = -\frac{2\pi^2 \alpha_{\text{em}}}{M_N^2} \, \kappa_N^2, \tag{49.212}$$

$$\gamma_0^N = \frac{1}{4\pi^2} \int_{\omega_{\text{th}}}^{\infty} \frac{\Delta\sigma_{\gamma N}(\omega')}{\omega'^3} \, \mathrm{d}\omega'. \tag{49.213}$$

Here $\alpha_{\text{em}} := e^2/(4\pi)$. The sign in (49.212) follows from the convention $\Delta\sigma_{\gamma N} = \sigma_{1/2} - \sigma_{3/2}$.

Proof. Let ω lie in the cut plane with $|\omega| < \omega_{\text{th}}$. Apply Cauchy's theorem to $g_N(z)/(z^2 - \omega^2)$ on a contour encircling the two cuts and small circles around $z = \pm\omega$. The residue contribution is

$$\frac{g_N(\omega)}{2\omega} + \frac{g_N(-\omega)}{-2\omega} = \frac{g_N(\omega)}{\omega},$$

because g_N is odd. The large circle gives no contribution by hypothesis. On the positive cut the discontinuity is

$$g_N(\omega' + \mathrm{i}0) - g_N(\omega' - \mathrm{i}0) = 2\mathrm{i} \operatorname{Im} g_N(\omega' + \mathrm{i}0).$$

On the negative cut, the change of variable $\omega' \mapsto -\omega'$ gives the same contribution, because oddness of g_N makes $\operatorname{Im} g_N(-\omega' + \mathrm{i}0) = \operatorname{Im} g_N(\omega' + \mathrm{i}0)$ with the opposite orientation of the cut. Combining the two cuts gives (49.211).

For $|\omega| < \omega_{\text{th}}$,

$$\frac{1}{\omega'^2 - \omega^2} = \frac{1}{\omega'^2} + \frac{\omega^2}{\omega'^4} + O(\omega^4)$$

under the stated integrability assumption. Hence

$$g_N(\omega) = \omega \, \frac{2}{\pi} \int_{\omega_{\text{th}}}^{\infty} \frac{\operatorname{Im} g_N(\omega' + \mathrm{i}0)}{\omega'^2} \, \mathrm{d}\omega' + \omega^3 \, \frac{2}{\pi} \int_{\omega_{\text{th}}}^{\infty} \frac{\operatorname{Im} g_N(\omega' + \mathrm{i}0)}{\omega'^4} \, \mathrm{d}\omega' + O(\omega^5).$$

Substitution of (49.206) turns the coefficient of ω into

$$\frac{1}{4\pi^2} \int_{\omega_{\text{th}}}^{\infty} \frac{\Delta\sigma_{\gamma N}(\omega')}{\omega'} \, \mathrm{d}\omega',$$

and the coefficient of ω^3 into the right side of (49.213). Comparing the linear coefficient with the low-energy theorem (49.210) gives

$$\int_{\omega_{\text{th}}}^{\infty} \frac{\Delta\sigma_{\gamma N}(\omega')}{\omega'} \, \mathrm{d}\omega' = 4\pi^2 \left(-\frac{e^2 \kappa_N^2}{8\pi M_N^2} \right),$$

which is (49.212). Thus the sum rule is not an independent model assumption about nucleon structure; it is the equality of two definitions of the same coefficient, one from the low-energy current Ward identity and one from the absorptive spectral representation, under the stated analyticity and boundedness hypotheses. □

The practical hierarchy of spectroscopic control is therefore:

- Stable mesons and baryons are isolated color-singlet mass eigenvalues; their controlled extraction uses the finite-volume transfer matrix and continuum extrapolation.
- Elastic resonances are second-sheet poles of partial waves; their controlled extraction uses Luscher, Roy, or Roy–Steiner reconstruction.
- Heavy quarkonium is a color-singlet $Q\bar{Q}$ spectrum; its controlled extraction uses a matched NRQCD or pNRQCD Hamiltonian and lattice checks.
- Hybrids and glueballs are operator-overlap sectors and pole data; their controlled extraction uses declared color-singlet source families, finite-volume energies or scattering amplitudes, large-N_c scaling, and mixing analysis.
- Exotic near-threshold states are poles plus residues in coupled channels; their controlled extraction uses finite-volume coupled-channel amplitudes.

Every entry in this list is a statement about QCD observables. The words “quark model”, “molecule”, “diquark”, and “flux-tube excitation” may summarize patterns in a chosen coordinate system, but the monograph treats them as derived interpretations only after the corresponding spectral or pole input has been defined.

49.15 Euclidean Current Sum Rules and Borel Windows

QCD current sum rules are linear identities for gauge-invariant current correlators. Their mathematical core consists of a spectral representation, a spacelike OPE, and a chosen linear functional that suppresses subtraction constants and weights different parts of the spectrum. A finite-parameter spectral ansatz is an additional approximation layer, whose status is fixed by the error estimates stated below.

Let $J(x)$ be a renormalized local color-singlet operator with fixed quantum numbers, for example $J = \bar{q}\Gamma q$, $\operatorname{tr} F_{\mu\nu}F^{\mu\nu}$, or a baryonic color singlet. In Euclidean momentum notation $Q^2 > 0$, define the connected two-point function

$$\Pi_J(Q^2;\mu) := \int_{\mathbb{R}^4} \mathrm{d}^4x\, \mathrm{e}^{\mathrm{i}Q\cdot x} \langle J(x)J^\dagger(0)\rangle_{\mathrm{conn},\mu}, \qquad Q^2 := Q_\mu Q_\mu. \tag{49.214}$$

When J carries Lorentz indices, Π_J denotes one scalar invariant after projecting onto a specified tensor structure. Positivity of the Euclidean correlator for $J^\dagger J$ gives a positive spectral measure in channels where reflection positivity applies. With enough subtractions, the spacelike correlator has the form

$$\Pi_J(Q^2;\mu) = P_N(Q^2;\mu) + \int_{s_{\mathrm{th}}}^{\infty} \frac{\rho_J(s;\mu)}{s+Q^2}\, \mathrm{d}s, \tag{49.215}$$

where P_N is a polynomial fixed by the subtraction convention, s_{th} is the lowest physical threshold in the channel, and ρ_J is the spectral density associated with the same current normalization. Equation (49.215) is a dispersion representation of a color-singlet Wightman distribution.

At large spacelike Q^2, the current product has an operator-product expansion

$$\Pi_J(Q^2;\mu) \sim \sum_a C_{J,a}(Q^2,\mu)\,\langle \mathcal{O}_a(0;\mu)\rangle, \qquad Q^2 \to +\infty, \tag{49.216}$$

with local gauge-invariant operators $\mathcal{O}_a$ of increasing dimension and Wilson coefficients $C_{J,a}$. The symbol $\sim$ means an asymptotic expansion in a specified sector of the spacelike Q^2-plane, after the renormalization scheme and operator basis have been fixed. Vacuum expectation values such as $\langle \bar{q}q\rangle_\mu$ or $\langle \operatorname{tr} F^2\rangle_\mu$ are scheme-dependent coordinates of the vacuum state. They become physical only through the full renormalized combination in a specified observable.

Definition 49.59 (Borel–Laplace sum-rule functional)**.** For a function $F(Q^2)$ whose large-Q^2 behavior permits the limit, set

$$\mathcal{B}_{M^2}[F] := \lim_{\substack{n,Q^2\to\infty\\ Q^2/n=M^2}} \frac{(Q^2)^n}{(n-1)!}\left(-\frac{\mathrm{d}}{\mathrm{d}Q^2}\right)^n F(Q^2), \qquad M^2>0. \tag{49.217}$$

The positive parameter M^2 is the Borel or Laplace scale. The associated sum-rule coordinate is

$$\mathcal{S}_J(M^2;\mu) := \mathcal{B}_{M^2}\Pi_J = \frac{1}{M^2}\int_{s_{\text{th}}}^{\infty} \mathrm{e}^{-s/M^2}\rho_J(s;\mu)\,\mathrm{d}s, \tag{49.218}$$

provided the Borel transform can be interchanged with the spectral integral.

Borel transform of the subtracted dispersion kernel. The functional in Definition 49.59 annihilates every polynomial in Q^2. For $s \ge 0$,

$$\mathcal{B}_{M^2}\left[\frac{1}{s+Q^2}\right] = \frac{1}{M^2}\mathrm{e}^{-s/M^2}. \tag{49.219}$$

For an integer $m \ge 1$,

$$\mathcal{B}_{M^2}\left[(Q^2)^{-m}\right] = \frac{1}{(m-1)!\,(M^2)^m}. \tag{49.220}$$

If $F(Q^2)$ is a polynomial of degree d, then $(-\partial_{Q^2})^n F = 0$ for $n > d$, so $\mathcal{B}_{M^2}F = 0$. For the dispersion kernel,

$$\left(-\frac{\mathrm{d}}{\mathrm{d}Q^2}\right)^n \frac{1}{s+Q^2} = \frac{n!}{(s+Q^2)^{n+1}}.$$

Putting $Q^2 = nM^2$ gives

$$\frac{(Q^2)^n}{(n-1)!}\frac{n!}{(s+Q^2)^{n+1}} = \frac{1}{M^2}\left(1+\frac{s}{nM^2}\right)^{-n-1} \longrightarrow \frac{1}{M^2}\mathrm{e}^{-s/M^2}.$$

For $(Q^2)^{-m}$,

$$\left(-\frac{\mathrm{d}}{\mathrm{d}Q^2}\right)^n (Q^2)^{-m} = \frac{\Gamma(m+n)}{\Gamma(m)}(Q^2)^{-m-n}.$$

The Borel expression is therefore

$$\frac{\Gamma(m+n)}{\Gamma(m)\Gamma(n)}(nM^2)^{-m}.$$

Since $\Gamma(n+m)/\Gamma(n) = n^m(1+O(n^{-1}))$ for fixed integer m, the limit is (49.220).

Controlled Approximation 49.60 (QCD Borel sum-rule window)**.** A Borel sum-rule analysis in a channel J consists of:

1. a renormalized current J, tensor projection, and scheme at scale μ;
2. a truncated OPE $\Pi_J^{(D_{\max})}(Q^2;\mu)$ with a stated estimate for the omitted operator dimensions and perturbative orders after applying $\mathcal{B}_{M^2}$;
3. a spectral ansatz for ρ_J, often a low-energy part with finitely many parameters plus a perturbative continuum above a threshold s_0;
4. a nonempty interval $M^2 \in [M^2_{\min}, M^2_{\max}]$ on which the omitted-OPE estimate and the spectral-tail estimate are both controlled.

Only the equality (49.218) with the exact ρ_J is a consequence of the dispersion representation and the Borel transform. The finite-parameter extraction of a mass, residue, or coupling is a controlled approximation only after the spectral ansatz and the two error estimates above have been supplied.

For a single isolated stable state in the channel, the spectral measure has an atom $Z_R\delta(s-m_R^2)$. If the remaining spectral weight is represented by a continuum model $\rho_{\text{cont}}(s)$, then (49.218) becomes

$$\mathcal{S}_J(M^2) = \frac{Z_R}{M^2}\mathrm{e}^{-m_R^2/M^2} + \frac{1}{M^2}\int_{s_{\text{cont}}}^{\infty} \mathrm{e}^{-s/M^2}\rho_{\text{cont}}(s)\,\mathrm{d}s. \tag{49.221}$$

The common pole-plus-continuum model sets $\rho_{\text{cont}}(s)$ equal to a perturbative spectral density above a fit threshold s_0. Its validity is an empirical and analytic control question about the exact spectral measure, judged by stability under M^2, s_0, current choice, OPE truncation, and comparison with regulator observables such as lattice spectra.

For a finite retained spectral model

$$\mathcal{S}(\tau) = \sum_{r=1}^{N} Z_r e^{-\tau m_r^2}, \qquad Z_r > 0, \quad \tau := 1/M^2.$$

the logarithmic derivative used as a mass estimator is

$$-\frac{\mathrm{d}}{\mathrm{d}\tau}\log\mathcal{S}(\tau) = \frac{\sum_r Z_r m_r^2 e^{-\tau m_r^2}}{\sum_r Z_r e^{-\tau m_r^2}}. \tag{49.222}$$

because the numerator is $-\mathcal{S}'(\tau)$. The right side is a normalized average with positive weights $Z_r e^{-\tau m_r^2}$. It equals m_R^2 for a single retained atom and otherwise averages the squared masses present in the retained spectral model.

Thus a Borel plateau diagnoses the weighted average in (49.222) changes slowly over the chosen interval after the declared continuum subtraction and OPE truncation. Single-state dominance is a further spectral statement about the retained model. The object being computed remains the current correlator (49.214); the extracted spectral parameters inherit all assumptions of the Borel window.

49.16 Detector Observables and Energy Correlators

A nonperturbative formulation of high-energy QCD final states begins with detector measurements in the physical Hilbert space. The calorimetric observable is built from the renormalized, gauge-invariant stress tensor $T^{\mu\nu}$, whose normalization is fixed by the translation generators:

$$P^{\nu} = \int_{\mathbb{R}^3} \mathrm{d}^3x\, T^{0\nu}(t, \mathbf{x})$$

on the common domain of finite-energy states where the integral is defined as a quadratic form.

Construction 49.61 (Energy-flow detector from the stress tensor)**.** For a real test function $f \in C^{\infty}(S^2)$, define the formal null-infinity flux quadratic form by

$$\widehat{\mathcal{E}}(f) = \mathrm{w-}\lim_{R\to\infty} R^2 \int_{-\infty}^{\infty} \mathrm{d}t \int_{S^2} \mathrm{d}\Omega(\mathbf{n})\, f(\mathbf{n})\, n_i\, \widehat{T}^{0i}(t, R\mathbf{n}). \tag{49.223}$$

The notation means that the limit is first tested between finite-energy physical states. The operation is part of the detector definition only after the domain and closure properties below have been supplied.

Hypothesis 49.62 (Detector existence and self-adjointness)**.** There is a dense scattering domain $\mathcal{D}_{\mathrm{det}} \subset \mathcal{H}_{\mathrm{phys}}$, stable under finite products of the smeared detector forms used below, such that for every real $f \in C^{\infty}(S^2)$ the weak limit (49.223) exists on $\mathcal{D}_{\mathrm{det}}$, is symmetric there, and has a unique self-adjoint closure. For each pair $\Psi, \Phi \in \mathcal{D}_{\mathrm{det}}$, the map

$$f \longmapsto \langle \Psi | \widehat{\mathcal{E}}(f) | \Phi \rangle$$

is a distribution of finite order on S^2. The constant test function satisfies

$$\widehat{\mathcal{E}}(1) = H_{\mathrm{out}}$$

on outgoing scattering states, where H_{out} is the outgoing Hamiltonian restricted to the physical scattering Hilbert space. Finally, for every angular patch $U \subset S^2$, the quadratic form obtained by testing $\widehat{\mathcal{E}}(f)$ with $\operatorname{supp} f \subset U$ is the $R \to \infty$ limit of a family of complete null-generator energy integrals with nonnegative transverse smearings whenever $f \geq 0$. This last clause is the geometric detector/ANEC bridge; without it, ANEC and calorimetric positivity are statements about different limiting operators.

Detector positivity from ANEC. Assume Hypothesis 49.62. Assume in addition that the stress tensor satisfies the averaged null energy condition as a quadratic-form statement on the same scattering domain: for every future null direction n^{μ}, every nonnegative transverse smearing φ, and every $\Psi \in \mathcal{D}_{\mathrm{det}}$,

$$\int \mathrm{d}^2x_{\perp}\, \varphi(x_{\perp}) \int_{-\infty}^{\infty} \mathrm{d}\lambda\, \langle \Psi | T_{\mu\nu}(x_{\perp} + \lambda n) n^{\mu} n^{\nu} | \Psi \rangle \geq 0.$$

Then the self-adjoint closure of $\widehat{\mathcal{E}}(f)$ is positive for every $f \geq 0$.

Write a nonnegative smooth angular test function as a finite sum of functions supported in coordinate patches on S^2, using a partition of unity. In each patch, the large-R detector limit is the conformal or asymptotic image of a null-energy integral along the complete generator labelled by $\mathbf{n}$, with transverse smearing determined by the angular support of f. The Jacobian relating the angular measure to transverse measure is positive. The ANEC inequality therefore gives nonnegative quadratic form values for each patch. Summing the patch contributions gives

$$\langle\Psi|\widehat{\mathcal{E}}(f)|\Psi\rangle \geq 0 \qquad (\Psi \in \mathcal{D}_{\mathrm{det}},\ f \geq 0).$$

Since the operator has a unique self-adjoint closure by Hypothesis 49.62, positivity of the quadratic form on a core implies positivity of the closure by the spectral theorem.

Remark 49.63 (Status in QCD and in conformal theories). For free massless fields, the limit in (49.223) is obtained by inserting the mode expansion and applying stationary phase at null infinity. For conformal field theories satisfying the light-transform hypotheses of Chapter 65, the detector is the stress-tensor light-ray operator and positivity is supplied by the ANEC theorem stated there. In four-dimensional QCD, the detector is the expected physical calorimeter observable, but its nonperturbative construction depends on the existence of the continuum theory, the physical scattering space, and the hadronic asymptotic completeness problem stated in Open Problem 49.22. Perturbative KLN cancellation proves finiteness of regulator-expanded coefficients for IRC-continuous measurements after the relevant sums over degenerate states and the required factorization steps have been made; it does not construct the self-adjoint detector operator on the exact physical Hilbert space.

Open Problem 49.64 (Energy-flow operators in four-dimensional QCD). Construct the operators $\widehat{\mathcal{E}}(f)$ of Construction 49.61 in continuum four-dimensional QCD. The construction should start from a nonperturbative definition of the physical Hilbert space, identify a dense finite-energy scattering domain, prove the null-infinity weak limits, prove essential self-adjointness or specify the self-adjoint extension selected by detector physics, prove positivity from an ANEC theorem in the same framework, and show that $\widehat{\mathcal{E}}(1)$ agrees with the outgoing Hamiltonian on the hadronic scattering subspace.

Here $\mathbf{n} \in S^2$ is a unit spatial direction and $\mathrm{d}\Omega$ is the rotation-invariant measure on S^2. The distribution $\widehat{\mathcal{E}}(\mathbf{n})$ is defined by $\widehat{\mathcal{E}}(f) = \int_{S^2} \mathrm{d}\Omega(\mathbf{n}) f(\mathbf{n}) \widehat{\mathcal{E}}(\mathbf{n})$. On an outgoing state of stable hadrons with momenta p_r, species labels a_r, and the normalization conventions of scattering theory,

$$\widehat{\mathcal{E}}(f)|p_1, a_1; \ldots; p_N, a_N\rangle_{\mathrm{out}} = \left(\sum_{r=1}^{N} p_r^0\, f(\widehat{\mathbf{p}}_r)\right)|p_1, a_1; \ldots; p_N, a_N\rangle_{\mathrm{out}}, \qquad \widehat{\mathbf{p}}_r := \frac{\mathbf{p}_r}{|\mathbf{p}_r|}. \tag{49.224}$$

Equation (49.224) is the spectral action of the detector limit on physical hadronic asymptotic states.

Asymptotic multiplication model. The preceding formula has a precise operator-theoretic meaning once an outgoing scattering representation has been chosen. Let $\mathcal{H}_{\mathrm{out}}$ be the physical outgoing scattering subspace and write it as a direct integral over hadronic scattering configurations,

$$\mathcal{H}_{\mathrm{out}} \simeq \int_{\mathcal{X}_{\mathrm{out}}}^{\oplus} \mathcal{K}_Y \,\mathrm{d}\nu(Y).$$

Here Y specifies the number of stable hadrons, their species labels, on-shell momenta, and the discrete or continuous degeneracy labels left after the standard Bose–Fermi symmetrizations;

$\mathcal{K}_Y$ is the corresponding finite or countable multiplicity space. The outgoing Hamiltonian is multiplication by

$$E_{\mathrm{tot}}(Y) = \sum_{r\in Y} p_r^0.$$

For a bounded Borel function $f : S^2 \to \mathbb{C}$, define

$$m_f(Y) := \sum_{r\in Y} p_r^0 f(\widehat{\mathbf{p}}_r), \qquad \mathcal{E}_{\mathrm{mult}}(f) := M_{m_f}, \tag{49.225}$$

where M_{m_f} is the direct-integral multiplication operator with maximal domain

$$\mathrm{Dom}\, M_{m_f} = \left\{ \Psi : \int_{\mathcal{X}_{\mathrm{out}}} |m_f(Y)|^2 \|\Psi(Y)\|^2_{\mathcal{K}_Y}\, \mathrm{d}\nu(Y) < \infty \right\}.$$

If f is real, M_{m_f} is self-adjoint; if $f \geq 0$, it is positive; and

$$|m_f(Y)| \leq \|f\|_\infty E_{\mathrm{tot}}(Y), \qquad \mathrm{Dom}\, H_{\mathrm{out}} \subset \mathrm{Dom}\, \mathcal{E}_{\mathrm{mult}}(f). \tag{49.226}$$

Moreover the family is strongly commuting, because all members are multiplication operators on the same direct-integral space. For bounded $f_1, \dots, f_k$,

$$\mathcal{E}_{\mathrm{mult}}(f_1)\cdots\mathcal{E}_{\mathrm{mult}}(f_k) = M_{\prod_{j=1}^k m_{f_j}}, \qquad \mathrm{Dom}\, H^k_{\mathrm{out}} \subset \mathrm{Dom}\big(\mathcal{E}_{\mathrm{mult}}(f_1)\cdots\mathcal{E}_{\mathrm{mult}}(f_k)\big). \tag{49.227}$$

Indeed

$$\left|\prod_{j=1}^k m_{f_j}(Y)\right| \leq \left(\prod_{j=1}^k \|f_j\|_\infty\right) E_{\mathrm{tot}}(Y)^k,$$

which gives the displayed domain inclusion. The stress-tensor flux operator $\widehat{\mathcal{E}}(f)$ of Construction 49.61, when it exists, is required to agree with $\mathcal{E}_{\mathrm{mult}}(f)$ after the outgoing wave operator identifies finite-energy scattering states with their asymptotic configurations. This agreement is part of the nonperturbative detector construction problem; perturbation theory may test its matrix elements after the detector operator has been defined.

The corresponding eventwise calorimetric measure of the final state X is

$$\mu_X = \sum_{r\in X} p_r^0\, \delta_{\widehat{\mathbf{p}}_r}, \qquad \widehat{\mathcal{E}}_X(f) = \int_{S^2} f\, \mathrm{d}\mu_X.$$

The detector observable depends on X only through the positive measure μ_X. The multiplication model also fixes the meaning of coincident detectors. For a finite configuration X,

$$\prod_{j=1}^k \widehat{\mathcal{E}}_X(f_j) = \int_{(S^2)^k} f_1(\mathbf{n}_1)\cdots f_k(\mathbf{n}_k)\, \mathrm{d}\mu_X(\mathbf{n}_1)\cdots \mathrm{d}\mu_X(\mathbf{n}_k). \tag{49.228}$$

Thus the product measure includes the diagonal strata $\mathbf{n}_i = \mathbf{n}_j$. A separated-angle correlator is the restriction of the resulting distribution away from these diagonals; deleting the diagonal weight defines a different observable and must be declared as an additional measurement prescription.

Given a normalized incoming physical state Ψ_{in}, or a state prepared by a local color-singlet current and then evolved to future infinity, the k-point energy correlator is the distribution on $(S^2)^k$

$$\mathcal{G}_k(f_1, \dots, f_k; \Psi) = {}_{\mathrm{out}}\langle \Psi | \widehat{\mathcal{E}}(f_1)\cdots\widehat{\mathcal{E}}(f_k) | \Psi \rangle_{\mathrm{out}}. \tag{49.229}$$

After inserting a complete set of physical hadronic out-states, this becomes

$$\mathcal{G}_k(f_1,\ldots,f_k;\Psi) = \sum_X |\langle X,\mathrm{out} \mid \Psi,\mathrm{out}\rangle|^2 \prod_{\ell=1}^{k} \left(\sum_{r\in X} p_r^0\, f_\ell(\widehat{\mathbf{p}}_r) \right), \tag{49.230}$$

with the usual replacement of the displayed sum by direct integrals over continuous multiparticle phase space. This formula is nonperturbative: all states in X are physical hadronic states, and the operator being measured is built from $T^{\mu\nu}$.

Connected cumulants and contact strata. Let $\mathbb{P}_\Psi$ denote the probability measure on outgoing configurations induced by the normalized state Ψ in the multiplication model. For bounded detector tests $f_1,\ldots,f_k$, put

$$X_j(Y) := \mathcal{E}_Y(f_j) = \int_{S^2} f_j \, \mathrm{d}\mu_Y.$$

Then $\mathcal{G}_k(f_1,\ldots,f_k;\Psi)$ is the raw moment

$$\mathbb{E}_{\mathbb{P}_\Psi}[X_1\cdots X_k].$$

The connected energy correlator in this event-ensemble sense is the cumulant

$$\mathcal{G}_k^{\mathrm{conn}}(f_1,\ldots,f_k;\Psi) = \sum_{\pi\in\Pi_k} (-1)^{|\pi|-1}(|\pi|-1)! \prod_{B\in\pi} \mathcal{G}_{|B|}\big((f_i)_{i\in B};\Psi\big), \tag{49.231}$$

where Π_k is the set of set partitions of $\{1,\ldots,k\}$. Thus, for example,

$$\mathcal{G}_2^{\mathrm{conn}}(f,g) = \mathcal{G}_2(f,g) - \mathcal{G}_1(f)\mathcal{G}_1(g),$$

and $\mathcal{G}_3^{\mathrm{conn}}$ is obtained by subtracting the three one-block–two-block products and adding twice the product of the three one-point functions. This is a subtraction of event-to-event factorization in the probability distribution of final states.

It is a different operation from removing coincident-detector contacts. For a fixed event Y, the product measure $\mu_Y^{\otimes k}$ decomposes into strata labeled by coincidences among detector labels. Already for three detectors,

$$\begin{aligned}\mathcal{E}_Y(f)\mathcal{E}_Y(g)\mathcal{E}_Y(h) = &\sum_{\substack{r,s,t\in Y\\ r,s,t \text{ distinct}}} E_rE_sE_t f_r g_s h_t \\ &+ \sum_{\substack{r,t\in Y\\ r\neq t}} E_r^2E_t f_r g_r h_t + \sum_{\substack{r,s\in Y\\ r\neq s}} E_r^2E_s f_r g_s h_r \\ &+ \sum_{\substack{r,s\in Y\\ r\neq s}} E_rE_s^2 f_r g_s h_s + \sum_{r\in Y} E_r^3 f_r g_r h_r,\end{aligned} \tag{49.232}$$

where $E_r = p_r^0$ and $f_r = f(\widehat{\mathbf{p}}_r)$, etc. The last four terms are diagonal contact strata of the detector product; they are present before the average over events is taken. If $\mathbb{P}_\Psi$ is concentrated on a single event, all ensemble cumulants of order $k\geq 2$ vanish, but the diagonal terms in (49.232) remain in the raw detector product. Conversely, deleting diagonal strata produces a separated-detector measurement prescription, not an ensemble-connected correlator. A calculation that quotes a "connected" or "contact-subtracted" energy correlator must therefore state which of these two operations is being performed.

Soft and collinear continuity of smeared energy flow. Let $f \in C^1(S^2)$. Suppose a final-state calorimetric measure μ_X is changed either by adding one particle of energy ε at direction $\mathbf{m}$, or by replacing two particles of energies E_a, E_b and directions $\mathbf{n}_a, \mathbf{n}_b$ by one particle of energy $E_a + E_b$ in the direction

$$\mathbf{n}_{ab} = \frac{E_a \mathbf{n}_a + E_b \mathbf{n}_b}{|E_a \mathbf{n}_a + E_b \mathbf{n}_b|}.$$

The resulting detector change obeys

$$\left| \Delta \widehat{\mathcal{E}}_X(f) \right| \leq \varepsilon \|f\|_\infty$$

in the soft case, and

$$\left| \Delta \widehat{\mathcal{E}}_X(f) \right| \leq (E_a + E_b) \operatorname{Lip}(f) \, \operatorname{diam}\{\mathbf{n}_a, \mathbf{n}_b, \mathbf{n}_{ab}\}$$

in the collinear case. For a soft particle, the measure changes by $\varepsilon \delta_{\mathbf{m}}$, so the change of the detector value is $\varepsilon f(\mathbf{m})$, whose absolute value is bounded by $\varepsilon \|f\|_\infty$. For a collinear recombination, the change is

$$E_a f(\mathbf{n}_a) + E_b f(\mathbf{n}_b) - (E_a + E_b) f(\mathbf{n}_{ab}).$$

Writing this as

$$E_a \big(f(\mathbf{n}_a) - f(\mathbf{n}_{ab}) \big) + E_b \big(f(\mathbf{n}_b) - f(\mathbf{n}_{ab}) \big)$$

and using the Lipschitz constant of f on the round sphere gives

$$|\Delta \widehat{\mathcal{E}}_X(f)| \leq E_a \operatorname{Lip}(f) d(\mathbf{n}_a, \mathbf{n}_{ab}) + E_b \operatorname{Lip}(f) d(\mathbf{n}_b, \mathbf{n}_{ab}),$$

which is bounded by the displayed diameter estimate. Thus the smeared detector is continuous for the weak calorimetric topology generated by finite-energy measures tested against $C^1(S^2)$ functions: soft additions vanish with their energy, and collinear recombinations vanish uniformly on bounded-energy sectors as the angular diameter tends to zero.

The same estimate applies to products $\prod_{\ell=1}^k \widehat{\mathcal{E}}_X(f_\ell)$ on any fixed finite-energy sector by the elementary telescoping identity

$$\prod_{\ell=1}^k A_\ell - \prod_{\ell=1}^k B_\ell = \sum_{j=1}^k \left(\prod_{\ell<j} A_\ell \right) (A_j - B_j) \left(\prod_{\ell>j} B_\ell \right),$$

with $A_\ell = \widehat{\mathcal{E}}_{X'}(f_\ell)$ and $B_\ell = \widehat{\mathcal{E}}_X(f_\ell)$. Thus smeared energy correlators are continuous functions of the calorimetric measure for soft and collinear degenerations. Perturbative finiteness then has a precise theorem boundary: at each fixed order in a regulator for which the Kinoshita–Lee–Nauenberg cancellation and QCD factorization hold for the chosen inclusive channel, measurement functions with the above continuity produce finite coefficients after summing over degenerate final states and virtual corrections. The operator definition (49.229) is the nonperturbative observable; perturbation theory computes its short-distance expansion in the regime where asymptotic freedom supplies a controlled small coupling.

The unsmeared product $\widehat{\mathcal{E}}(\mathbf{n}_1) \cdots \widehat{\mathcal{E}}(\mathbf{n}_k)$ is a distribution. Coincident directions carry contact singularities because several detector insertions can act on the same hadron. The separated-angle correlator is obtained by testing against functions supported away from the coincidence diagonals in $(S^2)^k$; fully smeared correlators include the contact terms determined by the detector operator product itself.

49.16.1 Energy-Energy Correlation in Electron-Positron Annihilation

Let a color-singlet current create a state of total center-of-mass energy Q. For each physical hadronic final state X, write

$$z_r = \frac{p_r^0}{Q}, \qquad \cos\chi_{rs} = \widehat{\mathbf{p}}_r \cdot \widehat{\mathbf{p}}_s.$$

The normalized two-point energy-energy correlator is the distribution

$$\mathrm{EEC}(\chi) = \frac{1}{\sigma_{\text{tot}}} \sum_X \int \mathrm{d}\sigma_X \sum_{r,s\in X} z_r z_s\, \delta(\cos\chi - \cos\chi_{rs}), \tag{49.233}$$

where $\mathrm{d}\sigma_X$ is the differential cross-section measure for the exclusive hadronic channel X, and the sum is a direct integral over continuous phase space. The terms $r = s$ are the coincident-detector contact part at $\chi = 0$. A convention that removes this contact part defines a different distribution at $\chi = 0$ and the same separated-angle function for $0 < \chi < \pi$.

Equation (49.233) is the detector form of the Basham–Brown–Ellis–Love observable. Its perturbative expansion in asymptotically free QCD is a calculation of the current-created state and of the detector insertions in the short-distance region. The back-to-back limit $\chi \to \pi$ is controlled by soft and collinear radiation constrained by transverse momentum conservation; the small-angle limit is controlled by a collinear operator product of energy-flow insertions. Both limits require resummation because the separated-angle distribution contains large logarithms of $1 + \cos\chi$ or $1 - \cos\chi$, respectively.

EEC moment sum rules and the contact term. Let X be a physical final state in the center-of-mass frame of a color-singlet source, with total energy Q and total spatial momentum zero. Set

$$z_r = \frac{p_r^0}{Q}, \qquad \mathbf{n}_r = \frac{\mathbf{p}_r}{|\mathbf{p}_r|}, \qquad \zeta_{rs} = \mathbf{n}_r \cdot \mathbf{n}_s.$$

Define the eventwise two-point calorimetric distribution in $\zeta = \cos\chi$ by

$$E_{2,X}(\zeta) = \sum_{r,s\in X} z_r z_s\, \delta(\zeta - \zeta_{rs}). \tag{49.234}$$

Then, as distributional moments on $[-1, 1]$,

$$\int_{-1}^{1} E_{2,X}(\zeta)\, \mathrm{d}\zeta = 1, \qquad \int_{-1}^{1} \zeta\, E_{2,X}(\zeta)\, \mathrm{d}\zeta = 0. \tag{49.235}$$

The coincident-detector contact part at $\zeta = 1$ has weight

$$E_{2,X}^{\text{contact}}(\zeta) = \left(\sum_{r\in X} z_r^2\right) \delta(\zeta - 1). \tag{49.236}$$

Consequently the cross-section averaged EEC of (49.233), including the $r = s$ terms, satisfies the same zeroth and first moment sum rules after division by σ_{tot}.

The total-energy condition gives

$$\sum_{r\in X} z_r = 1.$$

Testing (49.234) against the constant function 1 gives

$$\sum_{r,s} z_r z_s = \left(\sum_r z_r\right)^2 = 1.$$

Testing against ζ gives

$$\sum_{r,s} z_r z_s \, \mathbf{n}_r \cdot \mathbf{n}_s = \left|\sum_r z_r \mathbf{n}_r\right|^2 .$$

Since the source is in its center-of-mass frame,

$$\sum_r p_r^0 \mathbf{n}_r = \sum_r \mathbf{p}_r = 0,$$

and the first moment vanishes. The contact contribution is exactly the subsum with $r = s$, for which $\zeta_{rr} = 1$. Averaging the eventwise identities with the positive cross-section measure and dividing by σ_{tot} preserves the two moment identities.

Remark 49.65 (Use of the sum rules). The eventwise sum rules above are statements about the nonperturbative detector observable, not about partons. A fixed-order calculation, a resummed endpoint formula, a lattice-inspired approximation, or a parton shower that claims to represent the normalized EEC must specify how the $\zeta = 1$ contact term is treated and must satisfy the moment identities after the same convention is applied. If the contact term is removed, the remaining separated-angle distribution no longer has unit integral by itself; the missing weight is $\langle \sum_r z_r^2 \rangle$.

Legendre moments and calorimetric multipoles. The contact-inclusive two-detector distribution has stronger eventwise constraints than the first two moments alone. For every $\ell \geq 0$ define

$$M_{\ell,X} := \int_{-1}^{1} P_\ell(\zeta) E_{2,X}(\zeta) \, \mathrm{d}\zeta = \sum_{r,s \in X} z_r z_s P_\ell(\mathbf{n}_r \cdot \mathbf{n}_s).$$

With the usual orthonormal complex spherical harmonics on S^2, the addition theorem gives

$$P_\ell(\mathbf{n} \cdot \mathbf{m}) = \frac{4\pi}{2\ell + 1} \sum_{a=-\ell}^{\ell} Y_{\ell a}(\mathbf{n}) \overline{Y_{\ell a}(\mathbf{m})}.$$

Hence

$$M_{\ell,X} = \frac{4\pi}{2\ell + 1} \sum_{a=-\ell}^{\ell} \left| \sum_{r \in X} z_r Y_{\ell a}(\mathbf{n}_r) \right|^2 \geq 0. \tag{49.237}$$

This positivity is a property of the positive calorimetric measure $\sum_r z_r \delta_{\mathbf{n}_r}$. It is not a property of the separated-angle density after the coincident-detector atom has been removed. Indeed, for $\ell = 1$,

$$M_{1,X} = \sum_{r,s} z_r z_s \, \mathbf{n}_r \cdot \mathbf{n}_s = \left|\sum_r z_r \mathbf{n}_r\right|^2 ,$$

so the color-singlet center-of-mass condition sets the full moment to zero; the separated part alone then has first Legendre moment $-\sum_r z_r^2$. The contact atom is therefore forced by positivity and momentum conservation, not by a cosmetic endpoint convention.

The next moment displays the quadrupole coordinate. Put

$$Q_{ij}(X) := \sum_{r\in X} z_r \left(n_r^i n_r^j - \frac{1}{3}\delta_{ij} \right).$$

Then

$$\operatorname{tr} Q(X)^2 = \sum_{r,s} z_r z_s \left((\mathbf{n}_r \cdot \mathbf{n}_s)^2 - \frac{1}{3} \right), \qquad M_{2,X} = \frac{3}{2} \operatorname{tr} Q(X)^2 \geq 0.$$

Cross-section averaging preserves (49.237). Thus any perturbative, resummed, shower, or finite-resolution representation of the normalized EEC must say which endpoint/contact convention realizes these multipole positivity constraints. A separated-angle approximation that fits the bulk shape but gives a negative contact-inclusive M_ℓ is not a positive detector measure.

Three-detector moment and contact ledger. The same detector definition gives a genuinely higher-point distribution before any partonic approximation is made. For the same event X, define the ordered three-detector distribution on the three angular invariants $\zeta_{12}, \zeta_{13}, \zeta_{23}$ by

$$\begin{aligned} E_{3,X}(\zeta_{12}, \zeta_{13}, \zeta_{23}) := \sum_{r,s,t\in X} & z_r z_s z_t \, \delta(\zeta_{12} - \mathbf{n}_r \cdot \mathbf{n}_s) \, \delta(\zeta_{13} - \mathbf{n}_r \cdot \mathbf{n}_t) \\ & \times \delta(\zeta_{23} - \mathbf{n}_s \cdot \mathbf{n}_t). \end{aligned} \tag{49.238}$$

Its support is not the whole cube $[-1, 1]^3$, but the Gram-positive region of triples of unit directions, plus the diagonal strata. As moments of this distribution,

$$\int E_{3,X} = 1, \qquad \int \zeta_{12} E_{3,X} = \int \zeta_{13} E_{3,X} = \int \zeta_{23} E_{3,X} = 0 \tag{49.239}$$

in a color-singlet center-of-mass event. The proof is the same detector algebra as above: the constant test gives $(\sum_r z_r)^3 = 1$, while, for example,

$$\sum_{r,s,t} z_r z_s z_t \, \mathbf{n}_r \cdot \mathbf{n}_s = \left| \sum_r z_r \mathbf{n}_r \right|^2 \left(\sum_t z_t \right) = 0.$$

The other two pair moments are identical after relabeling the ordered detectors.

The diagonal contact strata are now richer than in the EEC. The completely coincident stratum is

$$\left(\sum_{r\in X} z_r^3 \right) \delta(\zeta_{12} - 1)\delta(\zeta_{13} - 1)\delta(\zeta_{23} - 1). \tag{49.240}$$

There are also three pair-coincidence strata. For instance, the stratum where detectors 1 and 2 hit the same hadron but detector 3 hits a different hadron is

$$\sum_{\substack{r,t\in X \\ r\neq t}} z_r^2 z_t \, \delta(\zeta_{12} - 1)\delta(\zeta_{13} - \zeta_{rt})\delta(\zeta_{23} - \zeta_{rt}), \qquad \zeta_{rt} = \mathbf{n}_r \cdot \mathbf{n}_t, \tag{49.241}$$

with two analogous terms for $1 = 3$ and $2 = 3$. Removing all these diagonal strata defines a separated three-detector observable. It does not by itself obey (49.239); the missing weights are precisely the contact coordinates above. Thus higher-point energy correlators inherit the same lesson as the EEC: endpoint/contact coordinates are part of the detector observable, not optional decorations added after a partonic calculation.

49.16.2 Light-Ray Interpretation and Endpoint Regimes

The detector density $\widehat{\mathcal{E}}(\mathbf{n})$ is the QCD analogue of the stress-tensor light transform developed in Chapter 65. In a conformal theory the light transform is an operator-valued distribution controlled by Lorentzian conformal representation theory. In QCD the coupling runs, so the same formula is not a conformal operator identity. It remains an asymptotic detector definition in the physical Hilbert space, and the short-distance limits are computed by matching the detector product onto operators whose renormalization group evolution is controlled by QCD anomalous dimensions.

Proof-status architecture for the EEC program. The exact detector identities above and the endpoint formulae below live at different levels of the argument. First, the physical detector layer starts from the stress-tensor flux limit or, on the outgoing scattering representation, from multiplication by the calorimetric measure. This layer fixes positivity, total-energy moments, diagonal contact strata, multipole positivity, and the distinction between ensemble cumulants and eventwise contacts. Second, the conformal fixed-point layer is the light-ray operator framework of Chapter 65: it supplies representation-theoretic homogeneity, finite light-ray charts, diagonal-contact extensions, and endpoint pushforwards only under the Lorentzian analyticity and growth hypotheses stated there. Third, the QCD small-angle layer replaces fixed-point light-ray data by renormalized Wilson-line/light-ray operator coordinates with ultraviolet and rapidity subtractions, protected moment rows, finite chart changes, and projected curvature or omitted-channel remainders. Fourth, the perturbative endpoint layer computes coefficients, anomalous dimensions, contact counterterms, and matching functions in one declared scheme; the tree-level collinear coefficients and cusp-log flatness check are tests of this layer, not the full all-order light-ray OPE/mixing theorem. Finally, the observable prediction layer glues the separated bulk, small-angle endpoint, back-to-back endpoint, and explicit endpoint atoms so that the detector moment identities remain true.

Thus the dependency chain is

$$\begin{aligned}\text{detector measure and contacts} &\Longrightarrow \text{CFT or QCD light-ray endpoint chart}\\ &\Longrightarrow \text{renormalized mixing/factorization calculation}\\ &\Longrightarrow \text{endpoint gluing and observable prediction.}\end{aligned}$$

Skipping any arrow changes the mathematical claim. A separated-angle fixed-order distribution without contact data is not the normalized detector observable; a finite retained light-ray block without a curvature or omitted-channel estimate is not an endpoint theorem; and a resummed endpoint formula without the gluing and moment ledger is not yet a prediction for the full normalized EEC on $[-1, 1]$.

For $0 < \chi < \pi$, the EEC is a separated-angle distribution. Two endpoint regions have different expansions. In the small-angle region set

$$\theta^2 := 2(1 - \cos\chi) \ll 1.$$

The product of two nearby detector insertions is matched onto a sum of collinear light-ray operators:

$$\widehat{\mathcal{E}}(\mathbf{n}_1)\widehat{\mathcal{E}}(\mathbf{n}_2) \sim \sum_A C_A(\theta, Q, \mu)\, \mathbb{O}_A(\mathbf{n}, \mu), \qquad \mathbf{n}_1, \mathbf{n}_2 \to \mathbf{n}. \tag{49.242}$$

Here $\mathbb{O}_A$ are light-ray operators in the collinear direction, including twist-two energy-flow moments and their descendants in the appropriate channel. The symbol $\sim$ denotes an asymptotic expansion after smearing against angular test functions supported at $\theta \ll 1$. The coefficient functions C_A are perturbatively computable at large transverse scale $Q\theta$, and the evolution of $\mathbb{O}_A$ resums logarithms of θ.

In the back-to-back region set

$$q_T^2 := Q^2(1+\cos\chi) \ll Q^2.$$

Momentum conservation forces the two measured energy deposits to recoil against soft and collinear radiation of small total transverse momentum. The factorized form is the transverse-momentum resummation analogue

$$\frac{\mathrm{d}\sigma}{\mathrm{d}q_T^2} = H(Q,\mu) \int \frac{\mathrm{d}^2 b}{(2\pi)^2}\, \mathrm{e}^{\mathrm{i}b\cdot q_T}\, J_n(b,\mu,\nu)\, J_{\bar{n}}(b,\mu,\nu)\, S(b,\mu,\nu) + O(q_T/Q), \tag{49.243}$$

for a color-singlet source and in a rapidity-renormalization scheme with rapidity scale ν. The hard, jet, and soft functions have coupled μ- and ν-evolution equations; solving them resums Sudakov logarithms of q_T/Q. The power remainder and the absence or treatment of Glauber exchanges are part of the factorization hypothesis.

Here and below $\alpha_s(\mu) := g^2(\mu)/(4\pi)$ in the trace-delta gauge coordinate of this chapter. Whenever a coefficient is proportional to $\alpha_s C_F$, it is invariant under conversion to the common half-trace generator convention because $g_{\mathrm{ht}}^2 C_F^{\mathrm{ht}} = g^2 C_F$, as in (49.120).

The leading double logarithm is fixed already by the lightlike cusp anomalous dimension. Let $b = |b|$ in (49.243), set

$$b_{\mathrm{F}} := 2\mathrm{e}^{-\gamma_E}, \qquad \mu_b := \frac{b_{\mathrm{F}}}{b}, \qquad L_b := \log\frac{Q^2}{\mu_b^2} = \log\frac{Q^2 b^2}{b_{\mathrm{F}}^2}.$$

The constant b_{F} is a Fourier-convention constant, not a new physical scale. In the trace-delta convention of this chapter the one-loop quark cusp anomalous dimension is

$$\Gamma_{\mathrm{cusp}}^q(g) = \frac{g^2 C_F}{4\pi^2} + O(g^4) = \frac{\alpha_s C_F}{\pi} + O(\alpha_s^2), \tag{49.244}$$

where $C_F = (N_c^2-1)/N_c$.

Assume the back-to-back factorization datum (49.243) for a color-singlet quark-current event shape, with the hard scale Q, the impact-parameter scale $\mu_b = b_{\mathrm{F}}/b$, and a subtraction scheme in which the leading large logarithms are generated by the quark cusp anomalous dimension (49.244). If running of g and all non-cusp anomalous dimensions are omitted, the leading-logarithmic impact-parameter kernel has the form

$$W_{\mathrm{LL}}(b,Q) = W(b,\mu_b)\, \exp\left[-\frac{1}{2}\,\Gamma_{\mathrm{cusp}}^q(g)\, L_b^2\right]. \tag{49.245}$$

Equivalently, at one loop,

$$W_{\mathrm{LL}}(b,Q) = W(b,\mu_b)\, \exp\left[-\frac{\alpha_s C_F}{2\pi} L_b^2 + O(\alpha_s^2 L_b^2)\right].$$

Its content is the fixed-coupling leading-logarithmic component of the factorization formula. The factorized expression is an impact-parameter representation of the recoil constraint. The hard matching is naturally made at scale Q, while the transverse-distance functions are naturally evaluated at scale μ_b. Cusp evolution between these two scales gives the logarithmic exponent

$$S_{\mathrm{LL}}(Q,b) = \int_{\mu_b^2}^{Q^2} \frac{\mathrm{d}\kappa^2}{\kappa^2}\, \Gamma^q_{\mathrm{cusp}}(g)\, \log\frac{Q^2}{\kappa^2}$$

when g is held fixed and non-cusp anomalous dimensions are discarded. Changing variables to

$$u = \log\frac{Q^2}{\kappa^2}$$

turns the integral into

$$S_{\mathrm{LL}}(Q,b) = \Gamma^q_{\mathrm{cusp}}(g) \int_0^{L_b} u\,\mathrm{d}u = \frac{1}{2}\,\Gamma^q_{\mathrm{cusp}}(g) L_b^2.$$

The kernel in (49.243) is suppressed by the Sudakov no-resolved-recoil factor between the two scales; this fixes the minus sign in $\exp[-S_{\mathrm{LL}}]$ in the chosen evolution convention. Substituting (49.244) gives the displayed one-loop form.

Remark 49.66 (Scope of the Sudakov formula). The fixed-coupling display above supplies only the cusp-controlled double logarithm inside a full back-to-back EEC theorem. A complete perturbative prediction must specify the rapidity regulator, the hard, jet, and soft functions, their finite scheme constants, matching to the fixed separated-angle distribution, running-coupling improvement, and the leading power corrections in q_T/Q. The calculation isolates the universal cusp-controlled double logarithm that any such consistent factorization scheme must reproduce.

Lemma 49.67 (Tree-level collinear coefficient for the separated EEC)**.** *Use the standard four-dimensional, azimuth-integrated, final-state collinear splitting convention*

$$\mathrm{d}P_{a\to bc} = \frac{\alpha_s}{2\pi}\, P_{a\to bc}(x)\,\mathrm{d}x\,\frac{\mathrm{d}\theta^2}{\theta^2}, \qquad 0 < x < 1, \tag{49.246}$$

where x and $1-x$ are the daughter energy fractions and θ is their small opening angle. The real-emission contribution of this resolved splitting to the ordered separated-angle EEC is weighted by

$$w_{\mathrm{EEC}}(x) = 2x(1-x). \tag{49.247}$$

Consequently, for $\zeta = \cos\chi$ and $\theta^2 = 2(1-\zeta) + O((1-\zeta)^2)$, the leading-power separated-angle collinear density generated by a parent of type a has the form

$$\frac{\mathrm{d}P_a^{\mathrm{EEC}}}{\mathrm{d}\zeta} = \frac{\alpha_s}{2\pi}\,\frac{\Gamma_a^{\mathrm{EEC}}}{1-\zeta} + \textit{terms less singular as } \zeta\to 1, \tag{49.248}$$

with resolved real-kernel coefficients

$$\begin{aligned}
\Gamma_q^{\mathrm{EEC}} &= \int_0^1 2x(1-x)\, C_F\frac{1+x^2}{1-x}\,\mathrm{d}x = \frac{3}{2}\,C_F,\\
\Gamma_{g\to gg}^{\mathrm{EEC}} &= \int_0^1 2x(1-x)\,2C_A\left[\frac{x}{1-x} + \frac{1-x}{x} + x(1-x)\right]\mathrm{d}x = \frac{14}{5}\,C_A,\\
\Gamma_{g\to q\bar q}^{\mathrm{EEC}} &= \int_0^1 2x(1-x)\,T_F\big(x^2 + (1-x)^2\big)\mathrm{d}x = \frac{1}{5}\,T_F
\end{aligned} \tag{49.249}$$

per quark flavor in the last line. The endpoint singularities of the real splitting kernels are integrable in these coefficients because the detector weight $2x(1-x)$ vanishes when either daughter carries zero energy.

Proof. For one parent of energy E splitting into two collinear daughters of energies xE and $(1-x)E$, the ordered two-detector contribution at the nonzero opening angle consists of the two ordered pairs (b,c) and (c,b). Its energy weight divided by E^2 is therefore

$$x(1-x) + (1-x)x = 2x(1-x),$$

which proves (49.247). The coincident daughter terms have contact weight

$$x^2 + (1-x)^2,$$

and the identity

$$x^2 + (1-x)^2 + 2x(1-x) = 1$$

is the local version of the zeroth-moment sum rule in the eventwise EEC moment identities above: a collinear splitting redistributes the parent's detector weight between the contact point and the separated small angle without changing the total two-detector weight.

At leading collinear power the probability measure for the resolved splitting is (49.246). Since

$$1 - \zeta = 1 - \cos\theta = \frac{\theta^2}{2} + O(\theta^4),$$

the positive measure $\mathrm{d}\theta^2/\theta^2$, pulled back to the ζ-line near $\zeta = 1$, is

$$\frac{\mathrm{d}\theta^2}{\theta^2} = \frac{\mathrm{d}\zeta}{1-\zeta} + O(1)\,\mathrm{d}\zeta,$$

where the equality is an equality of positive densities on intervals $\zeta < 1$, not an oriented one-form identity. Multiplying the splitting probability by the ordered EEC weight and retaining only the leading distribution as $\zeta \to 1$ gives (49.248) with

$$\Gamma_a^{\mathrm{EEC}} = \sum_{a\to bc} \int_0^1 2x(1-x) P_{a\to bc}(x)\,\mathrm{d}x.$$

Substituting the real tree-level kernels displayed in (49.249) reduces the three coefficients to elementary polynomial integrals:

$$2C_F \int_0^1 x(1+x^2)\,\mathrm{d}x = \frac{3}{2} C_F,$$

$$4C_A \int_0^1 \left[x^2 + (1-x)^2 + x^2(1-x)^2\right]\mathrm{d}x = \frac{14}{5} C_A,$$

and

$$2T_F \int_0^1 x(1-x)\big(x^2 + (1-x)^2\big)\mathrm{d}x = \frac{1}{5} T_F.$$

This proves (49.249). $\square$

Remark 49.68 (What the tree coefficient does and does not prove). Lemma 49.67 is a derivation of the first resolved real-emission coefficient in the small-angle expansion under the stated collinear splitting convention. It is not the full small-angle EEC theorem. Beyond this leading coefficient, one must define the renormalized light-ray operator basis, include virtual terms and contact conventions, solve the mixing problem, and match the endpoint expansion to the separated-angle distribution in a fixed regulator and subtraction scheme. The exact observable remains the detector distribution (49.233).

Small-angle light-ray OPE structure. The symbolic matching formula (49.242) becomes a mathematical statement only after the operator coordinates, endpoint variable, regulator, and contact convention have been declared. Let

$$\rho := 1 - \zeta = 1 - \cos\chi, \qquad \rho \simeq \frac{\theta^2}{2}$$

in the small-angle region. A renormalized QCD light-ray OPE structure for this endpoint consists of the following ingredients:

$$\mathcal{D}^{\mathrm{coll}}_{\mathrm{EEC}} = \big(\mathfrak{L}_{\mathbf{n}}, \{\mathbb{O}_A\}, \mathcal{S}_{\mathrm{UV}}, \mathcal{S}_{\mathrm{rap}}, \gamma_{AB}, \eta_{AB}, C_A\big).$$

Here $\mathfrak{L}_{\mathbf{n}}$ is a linear space of gauge-invariant renormalized light-ray operator-valued distributions in the null direction specified by $\mathbf{n}$. The indexed family $\{\mathbb{O}_A(\mathbf{n};\mu,\nu)\}$ is a chosen coordinate basis of this space, including the leading twist energy-flow moments and any operators that mix with them under the declared symmetries. The symbols $\mathcal{S}_{\mathrm{UV}}$ and $\mathcal{S}_{\mathrm{rap}}$ denote, respectively, the ultraviolet subtraction scheme and, when a lightlike Wilson-line or rapidity singularity is present, the rapidity subtraction scheme. The scale μ is the ultraviolet renormalization scale and ν is the rapidity scale; if a scheme has no separate rapidity regulator, all ν-dependent objects below are omitted. The kernels γ_{AB} and η_{AB} are distributional mixing kernels in whatever momentum-fraction, Mellin, or angular variables label the basis. The coefficient $C_A(\rho, Q, \mu, \nu)$ acts on smooth endpoint test functions in ρ, with its separated-angle density, endpoint subtractions, and $\delta(\rho)$ contact coefficient all specified by the same subtraction scheme.

With column-vector operator convention, the renormalization equations are

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\mathbb{O}_A = -\sum_B \gamma_{AB}\otimes\mathbb{O}_B, \qquad \nu\frac{\mathrm{d}}{\mathrm{d}\nu}\mathbb{O}_A = -\sum_B \eta_{AB}\otimes\mathbb{O}_B, \tag{49.250}$$

where $\otimes$ denotes the convolution product in the operator labels and matrix multiplication in the discrete labels. Since the product of detectors is a physical operator-valued distribution after the detector observable is normalized, the endpoint expansion

$$\widehat{\mathcal{E}}(\mathbf{n}_1)\widehat{\mathcal{E}}(\mathbf{n}_2) \simeq \sum_A C_A\otimes\mathbb{O}_A$$

must be independent of μ and of ν. Differentiating this identity and using (49.250) gives the coefficient equations

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}C_A = \sum_B C_B\otimes\gamma_{BA}, \qquad \nu\frac{\mathrm{d}}{\mathrm{d}\nu}C_A = \sum_B C_B\otimes\eta_{BA}. \tag{49.251}$$

This sign and transpose convention fixes the cancellation between the anomalous dimension of the coefficient row and the anomalous dimension of the operator column. In a Mellin basis where the convolution diagonalizes, (49.251) reduces to ordinary matrix multiplication in the remaining operator indices.

The separated-angle real-emission coefficient in Lemma 49.67 supplies the positive density on $\rho > 0$. The renormalized endpoint coefficient also contains endpoint subtractions and coincident-detector contact data. To state this coefficient, fix a small but finite endpoint interval $0 < \rho < \rho_0$. The plus distribution on this interval is defined by

$$\int_0^{\rho_0} \left[\frac{1}{\rho}\right]_{\rho_0,+} \varphi(\rho)\,\mathrm{d}\rho := \int_0^{\rho_0} \frac{\varphi(\rho) - \varphi(0)}{\rho}\,\mathrm{d}\rho \tag{49.252}$$

for every smooth test function φ on $[0, \rho_0]$. Therefore the first singular real coefficient

$$\frac{\alpha_s}{2\pi}\,\frac{\Gamma_a^{\mathrm{EEC}}}{\rho}$$

is promoted, in a renormalized endpoint coefficient, to the distributional form

$$C_a^{(1)}(\rho) = \frac{\alpha_s}{2\pi}\,\Gamma_a^{\mathrm{EEC}}\left[\frac{1}{\rho}\right]_{\rho_0,+} + K_a^{(1)}(\rho_0, \mu, \nu)\,\delta(\rho) + C_{a,\mathrm{reg}}^{(1)}(\rho). \tag{49.253}$$

The constant $K_a^{(1)}$ and the regular distribution $C_{a,\mathrm{reg}}^{(1)}$ are scheme- and matching-dependent. The plus prescription carries the coincident-detector subtraction that makes the endpoint distribution act on test functions with finite endpoint limits. The remaining finite $\delta(\rho)$ coefficient is fixed after the virtual terms, operator renormalization, and matching convention are specified in the same scheme. Thus the real coefficient Γ_a^{EEC} is a necessary local input to the small-angle OPE; the anomalous dimensions and the full coefficient of a renormalized light-ray operator are determined by the complete scheme-dependent endpoint datum.

The dependence on the endpoint resolution boundary is also distributional, not verbal. For $0 < \rho_a < \rho_b$, define

$$D_{\rho_*}(\rho) := \left[\frac{\Theta(\rho_* - \rho)}{\rho}\right]_+$$

by

$$\langle D_{\rho_*}, \varphi\rangle = \int_0^{\rho_*} \frac{\varphi(\rho) - \varphi(0)}{\rho}\,\mathrm{d}\rho$$

for smooth endpoint tests. Then, as distributions on $[0, \rho_b]$,

$$D_{\rho_b} = D_{\rho_a} + \frac{\mathbf{1}_{\rho_a<\rho<\rho_b}}{\rho} - \log\frac{\rho_b}{\rho_a}\,\delta(\rho). \tag{49.254}$$

Testing the right-hand side against φ gives

$$\int_0^{\rho_a} \frac{\varphi - \varphi(0)}{\rho}\,\mathrm{d}\rho + \int_{\rho_a}^{\rho_b} \frac{\varphi(\rho)}{\rho}\,\mathrm{d}\rho - \log\frac{\rho_b}{\rho_a}\varphi(0) = \int_0^{\rho_b} \frac{\varphi - \varphi(0)}{\rho}\,\mathrm{d}\rho.$$

Thus enlarging the endpoint chart by the annulus $\rho_a < \rho < \rho_b$ adds the ordinary separated-angle integral over that annulus and simultaneously shifts the coincident-detector contact coordinate by the logarithmic amount required to keep constant tests unchanged. This is the finite-resolution form of the endpoint contact convention: a statement such as "drop the contact term" is incomplete until the endpoint resolution boundary and the compensating $\delta(\rho)$ coordinate have both been declared.

The eventwise moment identity (49.235) imposes a useful check on this bookkeeping. Let M_A be the energy-sum functional on the chosen light-ray operator basis, so that $M_A \mathbb{O}_A$ extracts the component that contributes to the zeroth EEC moment. Conservation of total energy says that this functional has zero anomalous dimension:

$$\sum_A M_A \, \gamma_{AB} = 0, \qquad \sum_A M_A \, \eta_{AB} = 0 \tag{49.255}$$

in any scheme that preserves the detector normalization. Combining (49.251) with (49.255) shows that the RG evolution cannot change the zeroth moment; only the declared redistribution between separated-angle weight and the $\delta(\rho)$ contact term can change the displayed representative. This is why every perturbative EEC formula must specify whether it includes the coincident-detector contact term. Without that convention, even a formally correct endpoint singularity does not define the same distribution as the nonperturbative observable (49.233).

Finite renormalized light-ray mixing chart. The preceding equations describe the continuum endpoint expansion, whose full operator basis is infinite and distributional. In an actual calculation one uses a finite coordinate chart on this space. The following finite chart is the algebraic core that every higher-order small-angle EEC calculation must instantiate before its anomalous dimensions and matching coefficients can be compared across schemes.

Fix a finite set of light-ray operator labels $\mathcal{I}_L$, for example a spin, twist, flavor, and derivative truncation, and let $\mathbb{O}_I^{\mathrm{reg}}(\Lambda, \nu_0)$, $I \in \mathcal{I}_L$, be regulated gauge-invariant light-ray composites with the endpoint and rapidity regulator specified. A finite renormalized chart consists of an invertible matrix $Z_{IA}(\Lambda, \mu, \nu; \mathcal{R})$ and renormalized operator coordinates defined by

$$\mathbb{O}_A(\mu, \nu; \mathcal{R}) = \sum_{I \in \mathcal{I}_L} (Z^{-1})_{AI}(\Lambda, \mu, \nu; \mathcal{R}) \, \mathbb{O}_I^{\mathrm{reg}}(\Lambda, \nu_0), \tag{49.256}$$

after the regulator limit is taken in matrix elements in the declared test space. If the regulated coordinates are independent of μ after the regulator and bare parameters are held fixed, then differentiating (49.256) gives

$$\gamma = Z^{-1} \mu \frac{\mathrm{d}Z}{\mathrm{d}\mu}, \qquad \mu \frac{\mathrm{d}}{\mathrm{d}\mu} \mathbb{O} = -\gamma \, \mathbb{O}, \tag{49.257}$$

with column-vector notation. A regulated coefficient row C^{reg} that pairs with the regulated operators as $C^{\mathrm{reg}} \mathbb{O}^{\mathrm{reg}}$ therefore gives the renormalized coefficient row

$$C(\rho, Q, \mu, \nu; \mathcal{R}) = C^{\mathrm{reg}}(\rho, Q, \Lambda, \nu_0) \, Z(\Lambda, \mu, \nu; \mathcal{R}), \tag{49.258}$$

and hence

$$\mu \frac{\mathrm{d}C}{\mathrm{d}\mu} = C \, \gamma. \tag{49.259}$$

This is the finite-matrix derivation of the sign and transpose convention in (49.250)–(49.251). No physical statement is attached to Z or C separately: only the paired distribution $C\mathbb{O}$, together with its endpoint contact coordinate, represents the detector product.

Finite scheme changes are coordinate changes on the same renormalized light-ray space. Let $R(\mu,\nu)$ be an invertible finite matrix and set

$$\mathbb{O}' = R^{-1}\mathbb{O}, \qquad C' = CR.$$

Then $C'\mathbb{O}' = C\mathbb{O}$, while the anomalous-dimension matrix becomes

$$\gamma' = R^{-1}\gamma R + R^{-1}\mu\frac{\mathrm{d}R}{\mathrm{d}\mu}, \tag{49.260}$$

and C' obeys $\mu \mathrm{d}C'/\mathrm{d}\mu = C'\gamma'$. Thus a quoted "light-ray anomalous dimension" is incomplete until its operator coordinate chart is specified. If $M\mathbb{O}$ is the protected total-energy moment, then $M\gamma = 0$. In the changed coordinates $M' = MR$ and

$$\mu\frac{\mathrm{d}M'}{\mathrm{d}\mu} = M'\gamma'.$$

The stronger condition that the displayed row M is unchanged is therefore not automatic; it is a restriction on admissible schemes, $MR = M$. This is the finite-coordinate version of the normalization convention behind (49.255).

Finite transport and two-scale consistency. The finite chart also makes precise what is meant by solving the light-ray mixing problem. Write

$$t = \log\mu, \qquad r = \log\nu.$$

For a single ultraviolet scale, let $U(t,t_0)$ be the matrix solution of

$$\partial_t U(t,t_0) = U(t,t_0)\gamma(t), \qquad U(t_0,t_0) = \mathbf{1}. \tag{49.261}$$

When $\gamma(t)$ at different scales does not commute, (49.261) is the definition of the path-ordered product; no choice of ordered exponential is meaningful without the side on which γ acts. With the row/column convention of (49.257)–(49.259), the transported coordinates are

$$C(t) = C(t_0)U(t,t_0), \qquad \mathbb{O}(t) = U(t,t_0)^{-1}\mathbb{O}(t_0), \tag{49.262}$$

and the paired endpoint distribution is independent of t:

$$C(t)\mathbb{O}(t) = C(t_0)\mathbb{O}(t_0).$$

Indeed, differentiating $U^{-1}U = \mathbf{1}$ gives

$$\partial_t U^{-1} = -\gamma(t)U^{-1},$$

because $\partial_t U = U\gamma$. Thus

$$\partial_t\mathbb{O}(t) = -\gamma(t)\mathbb{O}(t), \qquad \partial_t C(t) = C(t)\gamma(t),$$

and the two terms in $\partial_t(C\mathbb{O})$ cancel. If $M(t)$ is the coordinate row representing the protected total-energy moment, its transport law in a moving chart is

$$\partial_t M(t) = M(t)\gamma(t). \tag{49.263}$$

The convention $M(t) = M(t_0)$ for all t is therefore equivalent to $M\gamma(t) = 0$ in that fixed chart. This is the all-order version of the finite left-null-vector check in (49.255).

If both ultraviolet and rapidity scales are present, the operator column is declared to obey

$$\partial_t \mathbb{O} = -\gamma(t,r)\mathbb{O}, \qquad \partial_r \mathbb{O} = -\eta(t,r)\mathbb{O}.$$

The two scale evolutions define a path-independent endpoint coordinate only if the connection is flat on the chart:

$$\partial_t \eta - \partial_r \gamma + [\gamma, \eta] = 0. \tag{49.264}$$

This equation is not an optional aesthetic condition. It is the equality of mixed derivatives of the same renormalized operator coordinate. To see the sign, compute

$$\partial_r \partial_t \mathbb{O} = -(\partial_r \gamma)\mathbb{O} + \gamma\eta\,\mathbb{O}, \qquad \partial_t \partial_r \mathbb{O} = -(\partial_t \eta)\mathbb{O} + \eta\gamma\,\mathbb{O}.$$

Equating the two expressions gives (49.264). In a finite chart with nonzero curvature

$$\mathcal{F}_{tr} := \partial_t \eta - \partial_r \gamma + [\gamma, \eta],$$

transporting C and $\mathbb{O}$ along two different paths in (μ, ν)-space produces different coordinate representatives unless the curvature action is compensated by additional operators or by a prescribed scheme-change wall. A calculation that quotes separate μ- and ν-anomalous dimensions for the EEC endpoint has therefore supplied a consistent renormalized light-ray chart only after (49.264), the protected moment row, and the endpoint contact convention have been checked in the same scheme.

This paragraph gives the structural consistency condition. It is not itself a small-angle EEC loop calculation. In a concrete rapidity-factorized scheme one must display the regulated endpoint operator basis, compute the two matrices $\gamma(t,r)$ and $\eta(t,r)$ with the same subtraction and contact-term convention, and then verify $\partial_t \eta - \partial_r \gamma + [\gamma, \eta] = 0$ on that basis. If the finite basis is a truncation of an infinite operator space, the check must also state the projected curvature $P_L(\partial_t \eta - \partial_r \gamma + [\gamma, \eta])P_L$, the curvature components that leave the retained subspace, and the contact-coordinate terms that compensate endpoint scheme changes. Vanishing only after discarding an omitted operator is not flatness of the retained chart; it is an approximation statement requiring an omitted-operator remainder. The finite matrix check recorded in the companion script verifies the sign and row/column convention of the flatness equation, including the derivative terms, but it does not replace this scheme-specific QCD calculation.

Projected curvature and omitted light-ray coordinates. The most common failure mode in a finite light-ray calculation is not an incorrect commutator sign, but an omitted operator channel. Let P_L be the projection onto the retained light-ray labels and $Q_L = 1 - P_L$. In a fixed chart write

$$\gamma_{LL} = P_L \gamma P_L, \qquad \gamma_{LQ} = P_L \gamma Q_L, \qquad \gamma_{QL} = Q_L \gamma P_L,$$

and similarly for η. If the full connection is flat on the enlarged operator space and P_L is scale-independent, then the curvature computed from the retained block alone is

$$\partial_t \eta_{LL} - \partial_r \gamma_{LL} + [\gamma_{LL}, \eta_{LL}] = \eta_{LQ}\gamma_{QL} - \gamma_{LQ}\eta_{QL}. \tag{49.265}$$

Indeed, insert $P_L + Q_L = 1$ between the two factors in the commutator part of (49.264). Thus a nonzero retained curvature is not automatically an inconsistency of the full endpoint construction;

it is an explicit omitted-channel term. A finite small-angle EEC calculation that keeps only P_L must therefore either include the right-hand side of (49.265) in its remainder estimate or enlarge the light-ray/contact-coordinate chart until the flatness check is performed on the enlarged block.

This statement is coordinate covariant. For a finite change of retained coordinates $R_L(t,r)$,

$$\mathbb{O}'_L = R_L^{-1}\mathbb{O}_L, \qquad C'_L = C_L R_L,$$

one has

$$\gamma'_{LL} = R_L^{-1}\gamma_{LL}R_L + R_L^{-1}\partial_t R_L, \qquad \eta'_{LL} = R_L^{-1}\eta_{LL}R_L + R_L^{-1}\partial_r R_L,$$

and the retained curvature transforms by conjugation,

$$\mathcal{F}'_{LL} = R_L^{-1}\mathcal{F}_{LL}R_L.$$

Consequently a retained curvature cannot be removed by changing finite coordinates inside the same retained space. What can change is the split between an operator block and endpoint contact coordinates, in which case the flatness equation must be checked in the enlarged chart and the induced change of contact distribution must be recorded in the endpoint convention.

Endpoint observable transport budget. The last step in a finite endpoint calculation is not the display of γ, η, or a coefficient row. It is the statement that the retained chart gives a stable distribution when paired with endpoint detector tests. The following finite proposition is the algebraic budget behind that statement.

Proposition 49.69 (Finite endpoint observable transport budget)**.** *Fix a finite retained light-ray label set L, an endpoint test φ, and one logarithmic scale $t = \log\mu$. Suppose the retained small-angle endpoint contribution in a fixed state is represented by*

$$V_L(\varphi;t) = C_L(\varphi;t)\,O_L(t) + K_L(\varphi;t), \tag{49.266}$$

where $C_L(\varphi;t)$ is a row of coefficient distributions evaluated on φ, $O_L(t)$ is the column of retained light-ray matrix elements, and $K_L(\varphi;t)$ is the explicit endpoint contact coordinate. Let $\gamma_{LL}(t)$ be the retained anomalous-dimension matrix, and let $D_L(\varphi;t)$ be the row produced by a scale-dependent change of endpoint extension convention, such as moving an annulus into a plus-chart. Assume

$$\partial_t O_L = -\gamma_{LL}O_L + E_O, \tag{49.267}$$

$$\partial_t C_L(\varphi) = C_L(\varphi)\gamma_{LL} + D_L(\varphi) + E_C(\varphi), \tag{49.268}$$

$$\partial_t K_L(\varphi) = -D_L(\varphi)O_L + E_K(\varphi). \tag{49.269}$$

Then

$$\partial_t V_L(\varphi;t) = E_C(\varphi;t)O_L(t) + C_L(\varphi;t)E_O(t) + E_K(\varphi;t). \tag{49.270}$$

Consequently, for any interval $[t_0,t_1]$,

$$\big|V_L(\varphi;t_1) - V_L(\varphi;t_0)\big| \le \int_{t_0}^{t_1} \left(\|E_C(\varphi;t)\|\,\|O_L(t)\| + \|C_L(\varphi;t)\|\,\|E_O(t)\| + |E_K(\varphi;t)|\right)\mathrm{d}t \tag{49.271}$$

for any dual pair of finite vector norms. In particular, exact operator transport, exact coefficient transport, and the matching contact shift make the retained endpoint observable independent of t.

Proof. Differentiate (49.266) and insert (49.267)–(49.269):

$$\partial_t V_L = (C_L\gamma_{LL} + D_L + E_C)O_L + C_L(-\gamma_{LL}O_L + E_O) - D_L O_L + E_K.$$

The anomalous-dimension terms cancel because the coefficient is a row and the operator is a column. The endpoint-extension row D_L cancels only because the contact coordinate in (49.269) carries the compensating sign. This gives (49.270). Integrating in t and applying the finite norm inequality for a row-column pairing gives (49.271). □

The rows D_L are not new anomalous dimensions. They record changes of distributional representative at $\rho = 0$, such as the shift in (49.254). The residuals E_O, E_C, E_K are where an actual finite-basis endpoint calculation must place its omitted operator channels, projected curvature, approximate loop-order truncation, and endpoint matching defects. A claimed all-order renormalized light-ray OPE for the EEC must drive the right side of (49.271) to zero in the declared detector-test topology, or must state the resulting approximation error. Thus a mixing matrix and a list of endpoint plus distributions become an observable theorem only after this transport budget is supplied.

Minimal cusp-log flatness check. A useful first check is the part of a rapidity-factorized endpoint chart that is forced by a cusp logarithm. Work in a finite block in which the cusp endomorphism A is fixed and commutes with itself at different scales. Let $\Gamma_{\mathrm{cusp}}(t)$ denote the cusp coefficient in the same trace and coupling convention as the endpoint calculation, and suppose the rapidity dependence of the ultraviolet anomalous dimension contains

$$\gamma_{\mathrm{cusp}}(t, r) = \Gamma_{\mathrm{cusp}}(t)\, r\, A. \tag{49.272}$$

Then the rapidity anomalous dimension in the same chart must contain a term

$$\eta_{\mathrm{cusp}}(t, r) = G_{\mathrm{cusp}}(t)\, A, \qquad \frac{\mathrm{d}G_{\mathrm{cusp}}}{\mathrm{d}t} = \Gamma_{\mathrm{cusp}}(t), \tag{49.273}$$

up to pieces whose t-derivative is zero in this block. Indeed,

$$\partial_t \eta_{\mathrm{cusp}} = \Gamma_{\mathrm{cusp}}(t) A = \partial_r \gamma_{\mathrm{cusp}}, \qquad [\gamma_{\mathrm{cusp}}, \eta_{\mathrm{cusp}}] = 0.$$

Thus the cusp-logarithmic part of (49.264) is satisfied. With the opposite sign in (49.273), the curvature would be $-2\Gamma_{\mathrm{cusp}}(t)A$. The sign statement belongs to the declared operator convention $\partial_t \mathbb{O} = -\gamma\mathbb{O}$, $\partial_r \mathbb{O} = -\eta\mathbb{O}$. A full small-angle EEC calculation must still compute the non-cusp matrices, endpoint contact counterterms, and operator components beyond this cusp block in one declared rapidity scheme.

Controlled Approximation 49.70 (Finite light-ray mixing truncation)**.** A finite small-angle EEC calculation based on a label set $\mathcal{I}_L$ is a controlled approximation only after it supplies:

1. the regulated light-ray composites $\mathbb{O}_I^{\mathrm{reg}}$ and the subtraction matrix Z;
2. the endpoint test-function space on which the coefficient distributions $C_A(\rho)$, including plus distributions and contact coordinates, act;
3. the matrices γ and, when present, η, with the protected energy-moment row and its scheme convention;

4. the transport matrices or path-ordered products solving (49.261), and, in a two-scale scheme, the flatness condition (49.264);
5. a remainder functional $R_L(\varphi, \Psi)$ for the omitted operators, stated in the topology of the matrix elements or cross-section distributions being computed.

Without the last item, a finite light-ray basis is a useful coordinate truncation but not an approximation theorem for the EEC distribution.

Controlled Approximation 49.71 (Perturbative EEC endpoint calculations)**.** A perturbative endpoint calculation of the EEC consists of a declared endpoint variable, a factorization or light-ray OPE formula such as (49.242) or (49.243), anomalous dimensions and matching coefficients through specified orders, a prescription for matching the endpoint expansion to the separated-angle fixed-order distribution, and a power correction estimate in θ or q_T/Q. The exact observable remains the hadronic detector distribution (49.233).

Endpoint matching as distributional gluing. The endpoint formulae above live in different distribution charts. A prediction for the full normalized EEC on $[-1, 1]$ requires a gluing prescription, because the contact coefficient at $\zeta = 1$, the perturbative back-to-back delta coordinate at $\zeta = -1$, and the separated-angle density contribute to the same moment sum rules.

Let $\mathcal{R}(\zeta)$ be the distribution on the open interval $(-1, 1)$ obtained from the declared bulk expression and the overlap-subtracted small-angle and back-to-back endpoint formulae, all tested against smooth functions whose support avoids the two endpoints. Suppose its first two moments exist after the declared endpoint subtractions:

$$I_0[\mathcal{R}] = \langle \mathcal{R}, 1 \rangle, \qquad I_1[\mathcal{R}] = \langle \mathcal{R}, \zeta \rangle. \tag{49.274}$$

If the two endpoint atoms are retained as explicit scheme coordinates, write

$$\mathcal{E}_{\text{match}}(\zeta) = \mathcal{R}(\zeta) + K_+\,\delta(1-\zeta) + K_-\,\delta(1+\zeta). \tag{49.275}$$

Here K_+ is the coincident-detector contact coordinate and K_- is the back-to-back endpoint coordinate generated by the perturbative source and recoil expansion. Only K_+ has the direct eventwise interpretation (49.236). The two exact detector moment identities (49.235) impose

$$I_0[\mathcal{R}] + K_+ + K_- = 1, \qquad I_1[\mathcal{R}] + K_+ - K_- = 0. \tag{49.276}$$

When both endpoint atoms are left as matching coordinates, the solution is

$$K_+ = \frac{1 - I_0[\mathcal{R}] - I_1[\mathcal{R}]}{2}, \qquad K_- = \frac{1 - I_0[\mathcal{R}] + I_1[\mathcal{R}]}{2}. \tag{49.277}$$

If K_+ is instead fixed independently by the detector contact definition, then (49.276) becomes a consistency test on the bulk, small-angle, and back-to-back calculations in the chosen subtraction scheme. A mismatch is a statement about truncation, missing power corrections, or incompatible endpoint conventions, rather than a new observable. This is the minimal matching structure required before a perturbative endpoint formula can be compared with the nonperturbative distribution (49.233).

49.16.3 Multipoint Correlators and Energy-Flow Polynomials

For a jet or event with a chosen positive energy scale E_{ref}, define $z_i = E_i/E_{\mathrm{ref}}$ and θ_{ij} to be the angular distance between directions i and j. For $\beta > 0$, the N-point energy correlation function used in jet substructure has the form

$$e_N^{(\beta)} = \sum_{i_1 < \cdots < i_N} z_{i_1} \cdots z_{i_N} \prod_{a<b} \theta_{i_a i_b}^{\beta}. \tag{49.278}$$

The strict positivity of β makes the observable collinear continuous: when two labels become collinear, every factor distinguishing the split vanishes or recombines into the total energy weight. The soft behavior is linear in the soft energy weight. Thus (49.278) is infrared and collinear safe in the sense of the soft/collinear continuity estimate for smeared energy flow above.

More generally, a finite graph G with vertices $\{1, \ldots, N\}$ defines an energy-flow polynomial

$$\mathrm{EFP}_G^{(\beta)} = \sum_{i_1,\ldots,i_N} z_{i_1} \cdots z_{i_N} \prod_{(a,b)\in E(G)} \theta_{i_a i_b}^{\beta}. \tag{49.279}$$

This is again a polynomial functional of the calorimetric measure and angular kernel. It is a useful coordinate system on infrared-collinear safe event information because it is built from the same positive detector measure μ_X rather than from colored partonic labels. In an exact QCD calculation the final states are hadrons; in a short-distance approximation, quark and gluon variables enter through factorized coefficient functions, evolution kernels, and power corrections for this color-singlet observable.

49.16.4 Track Selectors and Charged-Energy Correlators

Collider detectors often measure a selected part of the calorimetric final state, for example the energy carried by long-lived charged hadrons. The nonperturbative definition again begins with physical hadronic final states. Let $\mathfrak{A}_{\mathrm{st}}$ be the label set of stable hadron species in the scattering representation, and fix a selector

$$\tau : \mathfrak{A}_{\mathrm{st}} \longrightarrow [0, 1].$$

For an ideal charged-track selector, $\tau(a) = 1$ for the species whose charged tracks are included in the measurement and $\tau(a) = 0$ for the species omitted by the tracking system. A detector with efficiencies or acceptance weights is represented by intermediate values of τ, once those weights have been calibrated independently of the QCD short-distance calculation.

For a hadronic final state

$$X = \{(p_r, a_r)\}_{r=1}^{N_X}, \qquad \mathbf{n}_r = \mathbf{p}_r/|\mathbf{p}_r|,$$

define the selected calorimetric measure

$$\mu_X^{\tau} = \sum_{r\in X} \tau(a_r) p_r^0 \, \delta_{\mathbf{n}_r}. \tag{49.280}$$

It satisfies $0 \le \mu_X^{\tau} \le \mu_X$ as positive measures. The smeared track detector on the outgoing multiplication representation is therefore

$$\widehat{\mathcal{E}}_X^{\tau}(f) = \int_{S^2} f \, \mathrm{d}\mu_X^{\tau} = \sum_{r\in X} \tau(a_r) p_r^0 f(\mathbf{n}_r).$$

Products of track detectors are products of this selected measure:

$$\prod_{j=1}^{k} \widehat{\mathcal{E}}_X^{\tau}(f_j) = \int_{(S^2)^k} f_1(\mathbf{n}_1)\cdots f_k(\mathbf{n}_k)\,\mathrm{d}\mu_X^{\tau}(\mathbf{n}_1)\cdots \mathrm{d}\mu_X^{\tau}(\mathbf{n}_k). \tag{49.281}$$

Thus track energy correlators are physical detector observables once the selector τ and the detector calibration have been specified.

The exact moment identities are selected-energy identities. In a center-of-mass event with $z_r = p_r^0/Q$, set

$$e_\tau(X) = \sum_r \tau(a_r) z_r, \qquad \mathbf{p}_\tau(X) = \sum_r \tau(a_r) z_r \mathbf{n}_r.$$

The eventwise two-point selected-energy distribution

$$E_{2,X}^{\tau}(\zeta) = \sum_{r,s\in X} \tau(a_r)\tau(a_s) z_r z_s\, \delta(\zeta - \mathbf{n}_r\cdot\mathbf{n}_s)$$

obeys

$$\int_{-1}^{1} E_{2,X}^{\tau}(\zeta)\,\mathrm{d}\zeta = e_\tau(X)^2, \qquad \int_{-1}^{1} \zeta E_{2,X}^{\tau}(\zeta)\,\mathrm{d}\zeta = |\mathbf{p}_\tau(X)|^2. \tag{49.282}$$

For $\tau \equiv 1$ these reduce to (49.235). For a proper track selector they are additional nonperturbative event variables: the selected charged energy and selected charged three-momentum fluctuate from event to event even when the total energy and total three-momentum are fixed.

Perturbative calculations of selected-energy correlators require nonperturbative track functions. In a factorization scheme, a track function for a parton label i is a positive distribution $T_i(x,\mu)$ on $[0,1]$, normalized by

$$\int_0^1 T_i(x,\mu)\,\mathrm{d}x = 1,$$

whose moment

$$M_i^{(n)}(\mu) = \int_0^1 x^n T_i(x,\mu)\,\mathrm{d}x$$

is the n-th moment of the selected-energy fraction carried by hadrons in a collinear jet initiated by i, in the chosen scheme. The functions T_i are nonperturbative light-ray/fragmentation data; perturbation theory controls their evolution and their convolution with hard and jet coefficients.

The local collinear bookkeeping is fixed by energy partition. If a parent parton i splits into daughters j,k with energy fractions $z, 1-z$, and the selected fractions in the daughter collinear sectors are x_j, x_k, then the selected fraction of the parent sector is

$$x = z x_j + (1-z) x_k.$$

Therefore the real-splitting contribution to the n-th selected-fraction moment has the binomial form

$$M_{i\to jk}^{(n)}(z) = \sum_{a=0}^{n} \binom{n}{a} z^a (1-z)^{n-a} M_j^{(a)} M_k^{(n-a)}. \tag{49.283}$$

In particular,

$$M_{i\to jk}^{(1)}(z) = z M_j^{(1)} + (1-z) M_k^{(1)}$$

and

$$M^{(2)}_{i\to jk}(z) = z^2 M^{(2)}_j + (1-z)^2 M^{(2)}_k + 2z(1-z) M^{(1)}_j M^{(1)}_k.$$

The last line separates the contact and resolved two-detector weights in a track EEC calculation:

$$w_{\tau,\mathrm{contact}}(z;j,k) = z^2 M^{(2)}_j + (1-z)^2 M^{(2)}_k, \qquad w_{\tau,\mathrm{sep}}(z;j,k) = 2z(1-z) M^{(1)}_j M^{(1)}_k. \quad (49.284)$$

For the full calorimeter, $M^{(n)}_i = 1$ for every parton label and every n, and the separated weight reduces to the ordinary EEC weight $2z(1-z)$ in (49.247).

A controlled track-energy calculation must specify the selector τ, the operator or fragmentation definition of the track functions T_i, the factorization scheme and scale μ, the evolution equation for T_i in that scheme, the endpoint/contact convention for the selected detector products, and the power remainder that compares the selected hadronic observable (49.281) with the finite partonic factorization formula. The selected-energy observable is defined at the hadron level; the partonic track functions are the bridge used for its short-distance expansion.

49.17 Current Correlators and the Hadronic Tensor

Deep inelastic scattering probes a hadron by a local current. The process is inclusive:

$$e^-(k,\sigma) + N(P,s) \longrightarrow e^-(k',\sigma') + X, \qquad q := k - k',$$

where N is the target hadron and X runs over all hadronic final states with total momentum $P_X = P + q$. The exchange momentum is spacelike,

$$Q^2 := -q^2 > 0, \qquad x_B := \frac{Q^2}{2P\cdot q}.$$

The variable x_B is the Bjorken scaling variable.

Figure 49.9 fixes the inclusive DIS kinematics used below: the current transfers spacelike momentum q, the hadronic final state is summed over X, and $x_B = Q^2/(2P\cdot q)$.

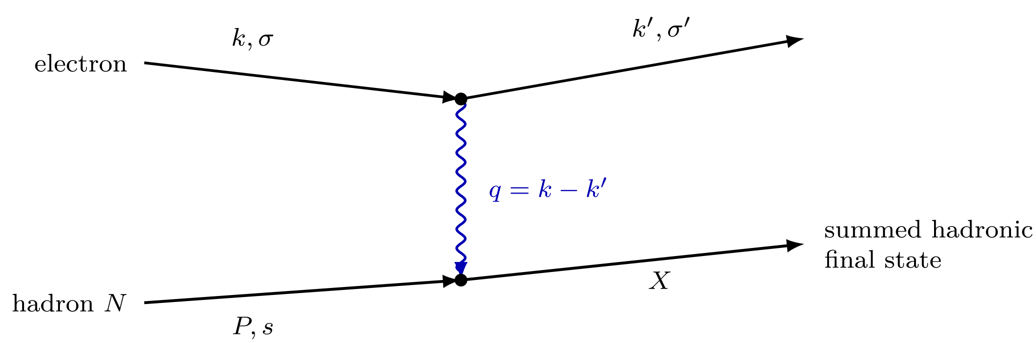

Figure 49.9: Inclusive deep inelastic scattering. The lepton line is treated perturbatively in the electromagnetic coupling, while the hadronic part is the current-current matrix element in QCD.

Let the electromagnetic current be

$$J^\mu(x) = \sum_I e_I\, \bar q_I(x)\gamma^\mu q_I(x),$$

where e_I is the electric charge of flavor I. At leading order in the electromagnetic coupling, the amplitude for a fixed hadronic final state has the form

$$\mathcal{A}_{\sigma',X;\sigma,s} = \bar{u}_{\sigma'}(k')\, e\gamma_\mu\, u_\sigma(k)\, \frac{-\mathrm{i}}{q^2 - \mathrm{i}\epsilon}\, \langle X|J^\mu(0)|P,s\rangle. \tag{49.285}$$

After summing over all hadronic final states X with the fixed transferred momentum q, the QCD part of the differential cross section is the spin-averaged positive tensor

$$W^{\mu\nu}(P,q) = \frac{1}{2}\sum_s \sum_X (2\pi)^4 \delta^{(4)}(P_X - P - q)\, \langle P,s|J^\nu(0)|X\rangle\langle X|J^\mu(0)|P,s\rangle. \tag{49.286}$$

where $\sum_X$ denotes the sum over species and the invariant phase-space integrals for a complete set of hadronic states, using the same state normalization as in the scattering chapters. Completeness and translation covariance give the equivalent form

$$W^{\mu\nu}(P,q) = \frac{1}{2}\sum_s \int \mathrm{d}^4x\, \mathrm{e}^{-\mathrm{i}q\cdot x} \langle P,s|J^\nu(x)J^\mu(0)|P,s\rangle, \tag{49.287}$$

in those conventions. Thus $W^{\mu\nu}$ is a Wightman matrix element between hadron states. Its positivity follows directly from the sum over X in (49.286).

Current conservation gives

$$q_\mu W^{\mu\nu} = q_\nu W^{\mu\nu} = 0.$$

For an unpolarized target, Lorentz covariance, current conservation, and parity give two scalar structure functions. Define

$$\Pi^\mu(P,q) := P^\mu - \frac{P\cdot q}{q^2} q^\mu.$$

Then

$$W^{\mu\nu}(P,q) = \left(\eta^{\mu\nu} - \frac{q^\mu q^\nu}{q^2}\right) W_1(\nu,Q^2) + \Pi^\mu(P,q)\Pi^\nu(P,q)\, W_2(\nu,Q^2), \qquad \nu := \frac{P\cdot q}{M}, \tag{49.288}$$

where $M^2 = P^2$. Other common normalizations absorb powers of M and $P\cdot q$ into W_1, W_2.

The support condition is kinematic. If N is the lightest hadron with the chosen conserved quantum numbers, then

$$(P+q)^2 = P_X^2 \geq M^2.$$

Since $q^2 = -Q^2$, this implies

$$2P\cdot q \geq Q^2, \qquad 0 < x_B \leq 1$$

for the physical inclusive region.

The time-ordered forward Compton amplitude is

$$T^{\mu\nu}(P,q) = \frac{\mathrm{i}}{2}\sum_s \int \mathrm{d}^4x\, \mathrm{e}^{-\mathrm{i}q\cdot x} \langle P,s|\,\mathrm{T}\ J^\nu(x)J^\mu(0)|P,s\rangle. \tag{49.289}$$

Its discontinuity in the energy variable is determined by the same Wightman matrix elements:

$$\mathrm{Disc}\ T^{\mu\nu}(P,q) = 2\pi\left[W^{\mu\nu}(P,q) + W^{\nu\mu}(P,-q)\right], \tag{49.290}$$

with the second term absent in the physical region $P \cdot q > 0$ for the spacelike process. Thus the inclusive cross section is controlled by the absorptive part of a time-ordered current-current amplitude, and the observable tensor is the Wightman object (49.286).

The Bjorken limit is

$$Q^2 \to \infty, \qquad x_B \text{ fixed.}$$

The short-distance region $x \to 0$ in (49.289) is then controlled by the operator product expansion of the two currents:

$$\mathrm{T}\ J^\mu(x) J^\nu(0) \sim \sum_a C_a^{\mu\nu}(x,\mu)\, \mathcal{O}_a(0,\mu). \tag{49.291}$$

The Wilson coefficients $C_a^{\mu\nu}$ are determined by short-distance renormalization and can be computed in perturbation theory at large Q. The matrix elements $\langle P|\mathcal{O}_a(0,\mu)|P\rangle$ are long-distance hadronic data.

49.18 Twist, Parton Distributions, and Factorization

49.18.1 Twist and Light-Ray Operator Definitions

For a local symmetric traceless operator of Lorentz spin s and scaling dimension Δ, its twist is

$$\tau := \Delta - s.$$

In an interacting theory Δ is a renormalized scaling exponent of the chosen operator basis. The word "twist" in this section is therefore a statement about the renormalized leading-power expansion, not only about the engineering dimension of a classical monomial. In the Bjorken limit, the leading terms in the OPE are the smallest-twist operators compatible with the quantum numbers of the currents. A convenient way to collect the tower of leading-twist matrix elements is by light-ray operators.

Let n^μ be a future-directed lightlike vector, $n^2 = 0$, and choose the normalization $P \cdot n > 0$ for the target momentum. For a representation R of the gauge group, define the straight Wilson transporter

$$W_R(\lambda n, 0) = \mathcal{P} \exp \left\{ \mathrm{i} \int_0^\lambda n^\mu A_\mu^a(sn) t_R^a \, \mathrm{d}s \right\}.$$

Here $A_\mu = A_\mu^a t^a$ is the same connection coordinate used throughout the chapter, with $D_\mu = \partial_\mu - \mathrm{i} A_\mu$ and $-\frac{1}{4g^2} \operatorname{tr} F_{\mu\nu} F^{\mu\nu}$. The symbol $\mathcal{P}$ orders factors with larger parameter s to the left.

Gauge covariance of the open light-ray operator. Let $U(x)$ be a smooth gauge transformation in the fundamental representation, and let $U_R(x)$ be its image in a representation R. With the transformation law

$$A_\mu \longmapsto U A_\mu U^{-1} - \mathrm{i}(\partial_\mu U) U^{-1}, \qquad q(x) \longmapsto U(x) q(x),$$

the transporter satisfies

$$W_R(\lambda n, 0) \longmapsto U_R(\lambda n) W_R(\lambda n, 0) U_R(0)^{-1}. \tag{49.292}$$

Consequently

$$\bar{q}(\lambda n)W_{\Box}(\lambda n,0)\gamma\cdot n\,q(0)$$

is a color-singlet bilocal operator before renormalization, and its renormalized descendants remain gauge invariant if the regularization and subtraction scheme preserve background gauge covariance.

Let $W_R(s,0)$ denote the partial transporter from 0 to sn. It is the solution of

$$\frac{\mathrm{d}}{\mathrm{d}s}W_R(s,0)=\mathrm{i}n^\mu A^a_\mu(sn)t^a_R W_R(s,0),\qquad W_R(0,0)=\mathbf{1}.$$

After the gauge transformation, the product $U_R(sn)W_R(s,0)U_R(0)^{-1}$ obeys the same differential equation with the transformed connection and has the same initial value at $s=0$. Uniqueness of solutions to this finite-dimensional linear ordinary differential equation gives the stated transformation law. The endpoint factors cancel against the transformations of $\bar{q}(\lambda n)$ and $q(0)$, because the gamma matrix acts on spinor indices and is the identity in color space.

For an unpolarized target, write

$$\langle\mathcal{X}\rangle_{P,H}:=\frac{1}{2}\sum_s\langle P,s|\mathcal{X}|P,s\rangle,$$

with the one-particle normalization fixed in the scattering chapters. The renormalized quark light-ray operator and its parton distribution are

$$\mathbb{O}_q(\lambda n;\mu):=\left[\bar{q}(\lambda n)W_{\Box}(\lambda n,0)\gamma\cdot n\,q(0)\right]_\mu, \tag{49.293}$$

$$f_{q/H}(x,\mu):=\frac{1}{2P\cdot n}\int\frac{\mathrm{d}\lambda}{2\pi}\,\mathrm{e}^{-\mathrm{i}x\lambda P\cdot n}\langle\mathbb{O}_q(\lambda n;\mu)\rangle_{P,H}. \tag{49.294}$$

The factor $2P\cdot n$ fixes the convention so that a free quark target has $f_{q/q}(x)=\delta(1-x)$. The antiquark distribution is defined by the charge-conjugate bilocal with the fields interchanged and the transporter running between the same endpoints. The gluon distribution is defined from the adjoint light-ray operator

$$\mathbb{O}_g(\lambda n;\mu):=\Big[F^a_{n\rho}(\lambda n)W^{ab}_{\mathrm{ad}}(\lambda n,0)F^{b\rho}_n(0)\Big]_\mu,\qquad F_{n\rho}:=n^\mu F_{\mu\rho}, \tag{49.295}$$

$$f_{g/H}(x,\mu):=\frac{1}{2x(P\cdot n)^2}\int\frac{\mathrm{d}\lambda}{2\pi}\,\mathrm{e}^{-\mathrm{i}x\lambda P\cdot n}\langle\mathbb{O}_g(\lambda n;\mu)\rangle_{P,H},\qquad 0<x<1. \tag{49.296}$$

The factor $1/x$ is part of the conventional normalization of the gluon light-ray distribution; it is what makes the N-th Mellin moment correspond to the spin-N local gluon operator below. Possible singular behavior at $x=0$ belongs to the small-x problem and is not hidden inside the definition.

Definition 49.72 (Renormalized integrated PDF coordinate)**.** For a hadron species H, a renormalized integrated PDF coordinate consists of the following objects.

1. A nonperturbative QCD presentation, or a finite-regulator approximation to one, which supplies normalized color-singlet hadron states $|P,s\rangle$ with $P^2=M_H^2$ and $P\cdot n>0$.
2. A lightlike direction n^μ, an orientation of the straight segment from 0 to λn, and the representation labels of the Wilson transporters appearing in (49.293) and (49.295).

3. A finite ultraviolet regulator Λ and regulated gauge-invariant bilocal composites $\mathbb{O}_a^\Lambda(\lambda n)$, smeared in λ before any distributional limit is taken.
4. A subtraction and factorization scheme at scale μ, encoded by a convolutional coordinate map Z_{ab} from $\mathbb{O}_a^\Lambda$ to renormalized light-ray coordinates $\mathbb{O}_b(\mu)$ in the sense of (49.299).
5. A declared distribution space in the light-cone fraction variable x, including the endpoint contact convention at $x = 0, 1$, on which the Fourier transform in $\lambda P \cdot n$ is paired with test functions.

The integrated PDF $f_{a/H}(x, \mu)$ is the resulting matrix-element distribution. In the conventions of (49.294) and (49.296),

$$f_{q/H}(\,\cdot\,, \mu) = \frac{1}{2P \cdot n}\, \mathcal{F}_{\lambda P \cdot n \to x}\big[\langle \mathbb{O}_q(\lambda n; \mu)\rangle_{P,H}\big], \tag{49.297}$$

$$f_{g/H}(\,\cdot\,, \mu) = \frac{1}{2x(P \cdot n)^2}\, \mathcal{F}_{\lambda P \cdot n \to x}\big[\langle \mathbb{O}_g(\lambda n; \mu)\rangle_{P,H}\big], \tag{49.298}$$

where the second equality is an equality in the declared distribution space on which multiplication by $1/x$ has been specified. The symbol $\mathcal{F}_{\lambda P \cdot n \to x}$ denotes the Fourier transform with the phases displayed in the defining formulae above. Equations (49.297) and (49.298) define renormalized operator coordinates. Support in $0 \le x \le 1$, positivity properties, probability language, and the appearance of the same distribution in a measured structure function are additional spectral, scheme, and factorization statements; they are not part of the definition of the renormalized light-ray matrix element.

The preceding equations are nonperturbative operator definitions once the underlying quantum field theory supplies the renormalized light-ray operators $\mathbb{O}_a(\lambda n; \mu)$ as operator-valued distributions, or at least as matrix-element distributions between the hadron states under consideration. They are not definitions in terms of on-shell quarks or gluons, and they do not presuppose a colored particle interpretation. In four-dimensional continuum QCD this existence statement is tied to the still-open problem of constructing the theory and to the additional ultraviolet problem of renormalizing lightlike Wilson-line composites. A gauge-invariant regulator can define finite approximants, but the continuum lightcone limit, the operator-renormalization limit, and the factorization theorem are separate assertions. Equal-time Euclidean bilocals used in lattice quasi-PDF or pseudo-PDF methods are therefore matching observables for the light-ray definition, not the definition itself.

The subscript μ in (49.293)–(49.296) means that the singular lightlike bilocal has been defined in a specified regularization and factorization scheme. Let $\mathbb{O}_a^\Lambda(x)$ denote the Fourier-coordinate operator obtained from the same gauge-invariant light-ray composite in a finite ultraviolet regulator Λ, after the path geometry, endpoint prescription, and finite regulator have been fixed. This cutoff-regulated operator is not a new physical observable; it is the finite-regulator coordinate from which the renormalized light-ray coordinate is obtained. For integrated collinear PDFs, the coordinate change is a convolution in the light-cone momentum fraction:

$$\mathbb{O}_a^\Lambda(x) = \sum_b \int_x^1 \frac{\mathrm{d}z}{z}\, Z_{ab}\Big(\frac{x}{z}, \mu, \Lambda\Big)\, \mathbb{O}_b(z; \mu), \tag{49.299}$$

where a, b range over quarks, antiquarks, and gluons, and the convolution is understood after pairing with test functions in a distribution space whose endpoint contact conventions have been declared. This equation is a definition of the renormalized light-ray coordinates. It separates regularization, the introduction of the finite object $\mathbb{O}_a^\Lambda$, from renormalization, the choice of the finite coordinate map Z and of the operator coordinate $\mathbb{O}_b(\mu)$. For TMDs or other observables with unresolved transverse momentum, an additional rapidity renormalization is required; it is not part of the integrated PDF definition used in inclusive DIS.

The DGLAP kernel is the infinitesimal form of this operator-coordinate map, not a transition probability for physical colored asymptotic states. Let Z^{-1} be the convolution inverse in the chosen finite channel basis. Differentiating (49.299) at fixed $\mathbb{O}^\Lambda$ gives

$$0 = \sum_b (\mu\partial_\mu Z_{ab}) \otimes \mathbb{O}_b(\mu) + \sum_b Z_{ab} \otimes \mu\partial_\mu \mathbb{O}_b(\mu),$$

where $\otimes$ denotes the same light-cone fraction convolution. Hence

$$\mu\partial_\mu \mathbb{O}_c(x;\mu) = \sum_b \int_x^1 \frac{\mathrm{d}z}{z}\, P_{cb}\Big(\frac{x}{z}, g(\mu)\Big)\, \mathbb{O}_b(z;\mu), \qquad P_{cb} := -\sum_a Z_{ca}^{-1} \otimes \mu\partial_\mu Z_{ab}. \tag{49.300}$$

Taking hadron matrix elements of (49.300) gives (49.314) below. The finite perturbative calculation of P is a calculation of the ultraviolet coordinate change of the light-ray operator. The subsequent use of P in a measured DIS observable still requires the leading-power factorization statement.

Local moments of the light-ray definition. The light-ray definition contains the local twist-two tower as its Taylor coefficients at zero separation. This statement is often quoted as a formal identity between PDFs and partons; here it is only a statement about the renormalized Wilson-line operator in (49.293). Define the left covariant derivative on the transported antiquark endpoint by

$$\bar{q}\overleftarrow{D}_n := n^\mu \partial_\mu \bar{q} + \mathrm{i}\,\bar{q}\, n^\mu A_\mu, \qquad n^2 = 0.$$

The sign is fixed by the same convention $D_\mu q = (\partial_\mu - \mathrm{i}A_\mu)q$ used in the Wilson transporter above. Since

$$\frac{\mathrm{d}}{\mathrm{d}\lambda}\big(\bar{q}(\lambda n) W_\Box(\lambda n, 0)\big) = \big(\bar{q}\overleftarrow{D}_n\big)(\lambda n) W_\Box(\lambda n, 0),$$

iteration gives the short-distance expansion

$$\bar{q}(\lambda n) W_\Box(\lambda n, 0)\gamma\cdot n\, q(0) = \sum_{N\geq 0} \frac{\lambda^N}{N!}\, \bar{q}(0)(\overleftarrow{D}_n)^N \gamma\cdot n\, q(0) \tag{49.301}$$

as a formal operator identity before subtraction, and as a renormalized operator-coordinate identity after the corresponding local and bilocal subtractions have been matched. It is useful to absorb the endpoint sign into the moment operator

$$\mathcal{O}^{\leftarrow}_{q,N}(n;\mu) := \Big[\bar{q}(0)(-\mathrm{i}\overleftarrow{D}_n)^N \gamma\cdot n\, q(0)\Big]_\mu. \tag{49.302}$$

The minus sign is not optional: a free one-quark matrix element of $\bar{q}(\lambda n)\gamma\cdot n q(0)$ is proportional to $\exp(\mathrm{i}\lambda P\cdot n)$, so $-\mathrm{i}\overleftarrow{D}_n$ has eigenvalue $P\cdot n$ on the left endpoint. With the Fourier convention in (49.294), the inverse distributional relation is

$$\frac{1}{2P\cdot n}\langle \mathbb{O}_q(\lambda n;\mu)\rangle_{P,H} = \int_{\mathbb{R}} \mathrm{d}x\, \mathrm{e}^{\mathrm{i}x\lambda P\cdot n} f_{q/H}(x,\mu),$$

whenever the pairing with test functions justifies inversion. Differentiating at $\lambda = 0$ therefore gives, for $N \geq 0$,

$$\int_0^1 \mathrm{d}x\, x^N f_{q/H}(x,\mu) = \frac{\langle \mathcal{O}^{\leftarrow}_{q,N}(n;\mu)\rangle_{P,H}}{2(P\cdot n)^{N+1}}. \tag{49.303}$$

The familiar symmetric traceless tensor $\bar{q}\gamma^{(\mu_0}\mathrm{i}D^{\mu_1}\cdots\mathrm{i}D^{\mu_N)}q$ is obtained by polarizing in the null vector n and changing from the left-endpoint representative to a symmetric representative. In forward matrix elements the difference is a sum of total-derivative representatives with fixed momentum transfer zero; in off-forward matrix elements those total derivatives are precisely the terms that produce GPD polynomiality in Section 49.21. Thus (49.303) is the convention-clean moment statement for the present forward PDF definition, while the symmetric local tensor is a different coordinate on the same leading-twist operator tower.

For the gluon definition the extra factor $1/x$ in (49.296) shifts the moment index. Let $\overleftarrow{D}_{n,\mathrm{ad}}$ be the left covariant derivative acting on the adjoint field at λn, including the adjoint connection in the same Wilson-transporter convention. For $N \geq 1$, define

$$\mathcal{O}^{\leftarrow}_{g,N}(n;\mu) := \Big[F^a_{n\rho}(0)(-\mathrm{i}\overleftarrow{D}_{n,\mathrm{ad}})^{N-1}F^{a\rho}_{n}(0)\Big]_\mu, \tag{49.304}$$

with the color contraction written after transporting the left endpoint to zero. The inverse relation following from (49.296) is

$$\frac{1}{2(P\cdot n)^2}\langle \mathbb{O}_g(\lambda n;\mu)\rangle_{P,H} = \int_{\mathbb{R}} \mathrm{d}x\, \mathrm{e}^{\mathrm{i}x\lambda P\cdot n}\, x f_{g/H}(x,\mu),$$

and therefore

$$\int_0^1 \mathrm{d}x\, x^N f_{g/H}(x,\mu) = \frac{\langle \mathcal{O}^{\leftarrow}_{g,N}(n;\mu)\rangle_{P,H}}{2(P\cdot n)^{N+1}}, \qquad N \geq 1. \tag{49.305}$$

Equations (49.303) and (49.305) are moment identities inside a specified renormalized operator scheme. They do not assert positivity, support, or factorization. Positivity and support require the spectral interpretation of the hadron matrix element in the relevant scattering representation; factorization requires the separate leading-power hypothesis stated below.

49.18.2 Euclidean Spatial Bilocals and Large-Momentum Matching

Lattice access to the light-ray definitions (49.294)–(49.296) uses different operator coordinates. The basic object is a spacelike equal-time bilocal, not a lightlike bilocal. Let e_3 be a fixed unit spatial vector and let $P^\mu = (E_P, 0, 0, P_3)$, $P_3 > 0$, be a one-hadron momentum in a finite-volume regulator with a transfer matrix and a gauge-invariant Hilbert space. For a Dirac matrix Γ and a real spatial separation z, define the regulated spatial Wilson-line operator

$$\mathcal{Q}_\Gamma(z;\Lambda) := [\bar{q}(ze_3)\, W_\square(ze_3, 0)\, \Gamma\, q(0)]_\Lambda\,. \tag{49.306}$$

Here Λ denotes the complete ultraviolet and finite-volume regulator data, including the lattice spacing and box when the operator is realized on a lattice. The Wilson transporter is along the straight spatial segment. Its linear length divergence, endpoint divergences, and finite subtraction are part of the operator-renormalization datum; they are not part of the definition of the light-ray PDF.

At finite gauge-covariant regulator, the operator $\mathcal{Q}_\Gamma(z;\Lambda)$ is gauge invariant as a color-singlet bilocal. A background-gauge-covariant finite-part prescription therefore produces a gauge-invariant renormalized spatial-bilocal matrix element. This is the endpoint-cancellation argument of the Wilson-transporter covariance calculation above, with the lightlike path sn replaced by the spatial path sze_3, $0 \le s \le 1$. The parallel transporter transforms as

$$W_\square(ze_3, 0) \longmapsto U(ze_3) W_\square(ze_3, 0) U(0)^{-1}.$$

The factor $U(0)^{-1}$ cancels the transformation of $q(0)$, the factor $U(ze_3)$ cancels the transformation of $\bar{q}(ze_3)$, and Γ acts only on spinor indices. The finite-part map changes regulator coordinates and operator coordinates but carries no free color index when it is background gauge covariant.

Let

$$\mathcal{M}^{\mathcal{R}}_{\Gamma/H}(z, P_3) := \frac{1}{2P_3} \langle P, H | \mathcal{Q}^{\mathcal{R}}_\Gamma(z) | P, H \rangle, \qquad \nu := P_3 z, \tag{49.307}$$

where $\mathcal{R}$ denotes a specified finite-part prescription. A quasi-PDF coordinate is the Fourier transform

$$\widetilde{f}^{\mathcal{R}}_{\Gamma/H}(x, P_3) := P_3 \int_{\mathbb{R}} \frac{\mathrm{d}z}{2\pi} \, \mathrm{e}^{\mathrm{i}xP_3 z} \, \mathcal{M}^{\mathcal{R}}_{\Gamma/H}(z, P_3), \tag{49.308}$$

understood as a tempered distribution in x after smearing. The prefactor P_3 fixes the inverse convention

$$\mathcal{M}^{\mathcal{R}}_{\Gamma/H}(z, P_3) = \int_{\mathbb{R}} \mathrm{d}x \, \mathrm{e}^{-\mathrm{i}xP_3 z} \, \widetilde{f}^{\mathcal{R}}_{\Gamma/H}(x, P_3)$$

for distributions for which the Fourier inversion is valid. A pseudo-PDF or Ioffe-time coordinate instead regards the same matrix element as a function, or distribution, of the Ioffe time $\nu = P_3 z$ and spacelike length $z^2 > 0$ in Euclidean notation:

$$\mathfrak{M}^{\mathcal{R}}_{\Gamma/H}(\nu, z^2) := \mathcal{M}^{\mathcal{R}}_{\Gamma/H}(z, P_3). \tag{49.309}$$

When $\mathfrak{M}^{\mathcal{R}}_{\Gamma/H}(0, z^2) \neq 0$, the reduced Ioffe-time coordinate

$$\mathfrak{M}_{\mathrm{red}}(\nu, z^2) := \frac{\mathfrak{M}^{\mathcal{R}}_{\Gamma/H}(\nu, z^2)}{\mathfrak{M}^{\mathcal{R}}_{\Gamma/H}(0, z^2)}$$

cancels any multiplicative Wilson-line factor depending only on z^2 in that scheme. It does not remove matching coefficients, target-mass effects, or higher-twist matrix elements.

Controlled Approximation 49.73 (Large-momentum matching statement)**.** Fix a renormalized spatial-bilocal scheme $\mathcal{R}$, a light-ray factorization scheme at scale μ, and a test function $h \in C_c^\infty(\mathbb{R})$. A large-momentum matching statement for (49.308) consists of kernels $C^{\mathcal{R}}_{\Gamma a}$, with a running over the light-ray operator basis, such that

$$\begin{aligned}\left\langle \widetilde{f}^{\mathcal{R}}_{\Gamma/H}(\,\cdot\,, P_3), h \right\rangle = \sum_a \int_0^1 \mathrm{d}y \, f_{a/H}(y, \mu) \int_{\mathbb{R}} \mathrm{d}x \, h(x) \, \frac{1}{y} C^{\mathcal{R}}_{\Gamma a}\left(\frac{x}{y}, \frac{\mu}{P_3}\right) \\ + R^{\mathcal{R}}_{\Gamma,H}[h; P_3, \mu].\end{aligned} \tag{49.310}$$

The statement is controlled only after the topology of the remainder has been specified. A typical leading-power version requires, for fixed compact support of h,

$$|R^{\mathcal{R}}_{\Gamma,H}[h; P_3, \mu]| \le C_h \left(\frac{M_H^2}{P_3^2} + \frac{\Lambda_{\mathrm{had}}^2}{P_3^2} \right) + R_{\mathrm{reg}}[h; a, L, P_3], \tag{49.311}$$

where M_H is the hadron mass, $\Lambda_{\rm had}$ is a hadronic scale attached to higher-twist matrix elements, and $R_{\rm reg}$ records finite lattice-spacing, finite-volume, and finite-operator-length errors before the continuum and infinite-volume limits are taken. Endpoint regions, small x, and threshold $x \to 1$ require additional test-function restrictions or separate factorization data.

The kernels in Controlled Approximation 49.73 are short-distance coordinates. In perturbation theory they are determined by matching matrix elements of the spatial bilocal and the light-ray operator in the same infrared state, so the infrared dependence cancels in the difference. That perturbative statement is not, by itself, a nonperturbative theorem about the large-P_3 limit of QCD. A theorem-level version would need a renormalized construction of the spatial Wilson-line operator, a spacelike short-distance OPE with remainder estimates uniform after hadron matrix elements, and a proof that the large-momentum limit converts the spacelike operator coordinates to the light-ray coordinates in the stated distributional topology.

Scheme covariance of finite matching kernels. Let f denote the column vector of light-ray PDFs in a convolution algebra, and suppose a quasi-PDF coordinate satisfies $\widetilde{f} = C \otimes f$ at leading power. If a finite light-ray scheme change is $f' = R \otimes f$, where R has a convolution inverse, then the same quasi-PDF coordinate is written in the primed scheme as

$$\widetilde{f} = C' \otimes f', \qquad C' = C \otimes R^{-1}.$$

If a linear charge functional $N(f) = \sum_a n_a \int_0^1 f_a(y)\,\mathrm{d}y$ is preserved by R and the matching kernel satisfies

$$\sum_i m_i \int_{\mathbb{R}} C_{ia}(\xi)\,\mathrm{d}\xi = n_a$$

for the corresponding quasi-PDF charge weights m_i, then the matched quasi-PDF has the same charge N at leading power.

Associativity of convolution gives

$$(C \otimes R^{-1}) \otimes (R \otimes f) = C \otimes (R^{-1} \otimes R) \otimes f = C \otimes f.$$

For the charge statement, integrate the matching formula over x with weights m_i. The change of variables $x = y\xi$, $y > 0$, gives

$$\sum_i m_i \int_{\mathbb{R}} \mathrm{d}x\, \frac{1}{y} C_{ia}(x/y) = \sum_i m_i \int_{\mathbb{R}} \mathrm{d}\xi\, C_{ia}(\xi) = n_a.$$

The remaining y-integral is exactly $N(f)$. The assumed preservation of N by R says that the same value is obtained in the primed light-ray coordinates.

49.18.3 DIS Factorization and DGLAP Evolution

Figure 49.10 records the operator factorization used for inclusive DIS: the short-distance current product is matched to renormalized light-ray operators whose convolutional renormalization gives DGLAP evolution.

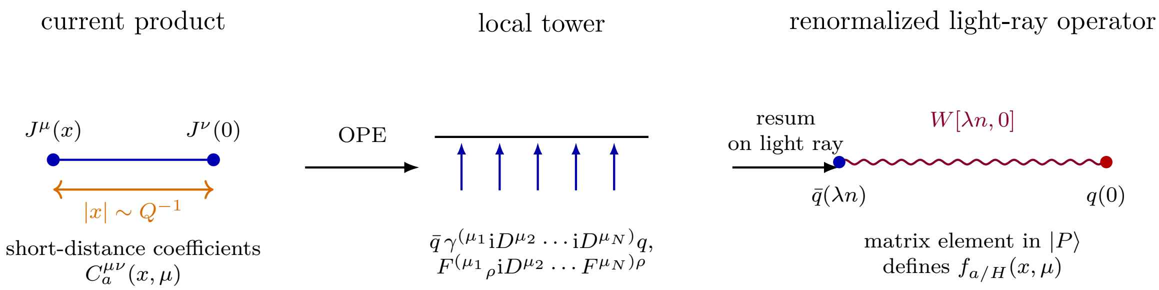

Figure 49.10: The short-distance current product is first expanded into local renormalized operators. The leading-twist tower can then be packaged into gauge-invariant light-ray operators whose hadron matrix elements define parton distributions. The Wilson segment $W[\lambda n, 0]$ is the open transporter connecting the colored fields in the bilocal operator.

The factorization assertion has two logically separate parts. The first is the exact definition of the hadronic tensor as the current-current Wightman matrix element (49.287). The second is the leading-power short-distance statement that, after the current OPE and light-ray renormalization have been performed, the same observable can be coordinatized by universal hadronic light-ray matrix elements and perturbative coefficient functions.

Common dependency ladder for QCD factorization. The local definitions above and the boundary sections below are used through a single comparison architecture. For a process family $\mathfrak{P}$, a theorem-level factorization statement has to provide:

1. the exact color-singlet observable $W_{\mathfrak{P}}$, usually a Wightman current tensor or a finite-regulator Euclidean matrix element;
2. the gauge-invariant operator coordinates, including Wilson-line geometry and the ultraviolet, cusp, endpoint, or rapidity subtractions required by that geometry;
3. the short-distance coefficient, impact-factor, or matching map in a stated distribution topology;
4. the scale-transport equations and finite-scheme covariance making the auxiliary factorization coordinates cancel in the paired observable;
5. the leading-region or boundary mechanism, including threshold, small-x, soft, rapidity, Y-term, or Glauber items whenever the process probes them;
6. a power-remainder estimate uniform on the declared test-function window;
7. the continuum, infinite-volume, large-momentum, or rapidity-regulator limit when the preceding objects are first constructed at finite regulator.

Equivalently, after pairing with a test function φ in the declared topology, the comparison between the exact observable and the factorized coordinate must be bounded by a sum of named errors,

$$
\begin{aligned}
&|\langle W_{\mathfrak{P},Q} - \mathcal{F}_{\mathfrak{P},Q}, \varphi\rangle| \le \mathcal{E}^{\mathrm{fact}}_{\mathfrak{P},Q}(\varphi),\\
&\mathcal{E}^{\mathrm{fact}}_{\mathfrak{P},Q} := \epsilon^{\mathrm{obs}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{op}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{sub}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{coeff}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{evol}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{bdry}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{rem}}_{\mathfrak{P},Q} + \epsilon^{\mathrm{lim}}_{\mathfrak{P},Q}.
\end{aligned}
\tag{49.312}
$$

Here $\mathcal{F}_{\mathfrak{P},Q}$ denotes the claimed factorized coordinate. For compact-x inclusive DIS, the boundary term records the exclusion of threshold and small-x regions. For Drell–Yan and other TMD observables it contains the rapidity subtraction, the Y-term, and the Glauber status. For small-x observables it contains the Wilson-line rapidity state, the projective generator limit, and the impact-factor map to a measured process. The finite calculations retained in this chapter check individual entries in this ladder; they are not substitutes for a proof that every required entry can be made small on a common directed window.

Hypothesis 49.74 (Leading-twist DIS factorization hypothesis)**.** Fix a factorization scheme and a compact interval $K \Subset (0,1)$ of Bjorken x. A leading-twist factorization hypothesis for an inclusive structure function F_i consists of coefficient distributions $C_{i,a}$, renormalized integrated PDFs $f_{a/H}$, and constants $C_{K,\varphi}$, Λ_{HT}, and $p > 0$, such that for every test function $\varphi \in C_c^\infty(K)$ the difference between the exact structure function and the factorized expression obeys

$$\left| \left\langle F_i - \sum_a C_{i,a} \otimes f_{a/H}, \varphi \right\rangle \right| \leq C_{K,\varphi} \left(\frac{\Lambda_{\mathrm{HT}}}{Q} \right)^p$$

for all sufficiently large Q. The convolution is the one displayed in (49.313). The compact-x restriction excludes the separate threshold $x \to 1$ and small-x limits, whose large logarithms require additional factorization data.

Under this hypothesis, factorization expresses a structure function F_i in the form

$$F_i(x_B, Q) = \sum_a \int_{x_B}^1 \frac{\mathrm{d}z}{z}\, C_{i,a}\bigg(\frac{x_B}{z}, \frac{Q}{\mu}, g(\mu) \bigg)\, f_{a/H}(z,\mu) + R_i(x_B, Q), \tag{49.313}$$

where a runs over quark, antiquark, and gluon parton species, and the remainder R_i satisfies the distributional power bound in Hypothesis 49.74. The coefficients $C_{i,a}$ are short-distance kernels; the distributions $f_{a/H}$ are universal hadronic matrix elements for the chosen factorization scheme. This paragraph is not a statement about colored asymptotic particles. The “parton” label a is a label in the light-ray operator basis and in the coefficient algebra.

The role of the parton distributions in (49.313) is also the point at which the nonabelian theory departs from the abelian Bloch–Nordsieck construction of Remark 44.8. A quark or gluon entering a short-distance hard subprocess is a colored partonic variable, not a physical asymptotic state. Its collinear gluon cloud is tied to a color generator and to the Wilson line in (49.294). Summing over unresolved final-state gluons gives the final-state part of an infrared-collinear safe observable, but the singularities associated with a massless incoming colored parton are absorbed into the renormalized light-ray operator defining $f_{a/H}$. Equivalently, the collinear subtraction that renormalizes the PDF is part of the definition of the factorized hadronic observable. The residual μ-dependence of this subtraction is the DGLAP evolution below.

The operator-coordinate RG equation (49.300) gives the evolution equation

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu} f_{a/H}(x,\mu) = \sum_b \int_x^1 \frac{\mathrm{d}z}{z}\, P_{ab}\Big(\frac{x}{z}, g(\mu) \Big)\, f_{b/H}(z,\mu), \tag{49.314}$$

where P_{ab} are splitting kernels, equivalently the anomalous-dimension kernels of the renormalized light-ray operator coordinates in the sign convention of (49.300). This is the precise sense in which short-distance quark and gluon variables control high-energy hadronic observables while physical asymptotic states remain color singlets. The factorized observable is independent of the auxiliary scale only when the coefficient functions obey the dual equation

$$\mu\partial_\mu C_{i,b} = -\sum_a C_{i,a} \otimes P_{ab}. \tag{49.315}$$

Then

$$\mu\partial_\mu \sum_a C_{i,a} \otimes f_{a/H} = \sum_b \left(\mu\partial_\mu C_{i,b} + \sum_a C_{i,a} \otimes P_{ab} \right) \otimes f_{b/H} = 0$$

inside the declared convolution algebra. Any residual scale dependence in a finite-order calculation is therefore a truncation or power-remainder effect, not a change in the nonperturbative definition of the PDF.

49.18.4 One-Loop Splitting Kernels and Sum-Rule Checks

At leading order, in the same convention as (49.314),

$$P_{ab}(x, g) = \frac{g^2}{8\pi^2} P_{ab}^{(0)}(x) + O(g^4).$$

For unpolarized distributions in the $\overline{\mathrm{MS}}$ scheme,

$$C_F = \frac{N_c^2 - 1}{N_c}, \qquad C_A = 2N_c, \qquad T_R = 1,$$

in the trace normalization of (49.1). These are twice the standard half-trace numbers, while the overall perturbative coefficient in (49.314) is written in the corresponding coupling coordinate. Let

$$D_0(x) := \left(\frac{1}{1-x} \right)_+ \tag{49.316}$$

be the plus distribution defined by

$$\int_0^1 \mathrm{d}x\, D_0(x)\, \varphi(x) = \int_0^1 \mathrm{d}x\, \frac{\varphi(x) - \varphi(1)}{1-x}$$

for every smooth test function φ. Products such as $xD_0(x)$ are defined by multiplication of this distribution by the smooth function x. With this unambiguous convention, the nonzero leading kernels are

$$\begin{aligned}
P_{q_i q_j}^{(0)}(x) &= \delta_{ij}\, C_F \left[2D_0(x) - 1 - x + \frac{3}{2}\delta(1-x) \right], \\
P_{\bar{q}_i \bar{q}_j}^{(0)}(x) &= P_{q_i q_j}^{(0)}(x), \\
P_{q_i g}^{(0)}(x) &= P_{\bar{q}_i g}^{(0)}(x) = T_R \big[x^2 + (1-x)^2 \big], \\
P_{g q_i}^{(0)}(x) &= P_{g \bar{q}_i}^{(0)}(x) = C_F\, \frac{1 + (1-x)^2}{x}, \\
P_{gg}^{(0)}(x) &= 2C_A \left[xD_0(x) + \frac{1-x}{x} + x(1-x) \right] + \frac{11C_A - 4T_R N_f}{6} \delta(1-x).
\end{aligned} \tag{49.317}$$

This notation avoids the common ambiguity between plus-prescribing the whole rational function and plus-prescribing only the pole at $x = 1$. For example, $2D_0 - 1 - x$ is the distribution often abbreviated as $(1 + x^2)/(1 - x)_+$ in particle-physics notation. Equivalently, for the flavor singlet quark distribution $\Sigma = \sum_{i=1}^{N_f}(q_i + \bar{q}_i)$,

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\begin{pmatrix}\Sigma\\ f_g\end{pmatrix} = \frac{g^2}{8\pi^2}\begin{pmatrix}P_{qq}^{(0)} & 2N_f P_{qg}^{(0)}\\ P_{gq}^{(0)} & P_{gg}^{(0)}\end{pmatrix} \otimes \begin{pmatrix}\Sigma\\ f_g\end{pmatrix} + O(g^4),$$

where $\otimes$ denotes the convolution appearing in (49.314). Nonsinglet quark combinations evolve with the same $P_{qq}^{(0)}$ and do not mix with the gluon at this order.

The kernels in (49.317) obey the following one-loop distributional sum-rule checks:

$$\int_0^1 \mathrm{d}x\, P_{qq}^{(0)}(x) = 0,$$

and the two momentum-column identities

$$\int_0^1 \mathrm{d}x\, x\big(P_{qq}^{(0)}(x) + P_{gq}^{(0)}(x)\big) = 0, \qquad \int_0^1 \mathrm{d}x\, x\big(2N_f P_{qg}^{(0)}(x) + P_{gg}^{(0)}(x)\big) = 0.$$

Thus nonsinglet quark number and the total light-cone momentum fraction are preserved by the leading-order evolution. For $m \geq 0$,

$$\int_0^1 \mathrm{d}x\, x^m D_0(x) = \int_0^1 \mathrm{d}x\, \frac{x^m - 1}{1 - x} = -H_m, \qquad H_m := \sum_{r=1}^{m} \frac{1}{r},$$

with $H_0 = 0$. The number sum rule is

$$C_F\left(2H_0 - \int_0^1 (1 + x)\,\mathrm{d}x + \frac{3}{2}\right) = 0.$$

For a quark parent,

$$\int_0^1 \mathrm{d}x\, xP_{qq}^{(0)}(x) = C_F\left(-2 - \frac{1}{2} - \frac{1}{3} + \frac{3}{2}\right) = -\frac{4}{3}C_F,$$

while

$$\int_0^1 \mathrm{d}x\, xP_{gq}^{(0)}(x) = C_F\int_0^1 \mathrm{d}x\,\left[1 + (1 - x)^2\right] = \frac{4}{3}C_F.$$

For a gluon parent,

$$\int_0^1 \mathrm{d}x\, xP_{qg}^{(0)}(x) = T_R\int_0^1 \mathrm{d}x\, x\big[x^2 + (1 - x)^2\big] = \frac{1}{3}T_R,$$

and

$$\int_0^1 \mathrm{d}x\, xP_{gg}^{(0)}(x) = 2C_A\left(-H_2 + \frac{1}{2} + \frac{1}{12}\right) + \frac{11C_A - 4T_R N_f}{6} = -\frac{2}{3}T_R N_f.$$

The two column sums therefore vanish.

49.19 Transverse-Momentum Dependent Distributions and Rapidity Renormalization

Integrated PDFs are obtained after summing over all transverse momentum in the collinear sector. Observables differential in a transverse momentum, for example color-singlet production with $q_\perp^2 \ll Q^2$, require a different operator coordinate. The relevant nonperturbative input is not the integrated light-ray operator (49.293); it is a transverse-separated light-ray matrix element with Wilson lines whose geometry creates rapidity divergences. Rapidity subtraction is therefore part of the definition, in the same sense that ultraviolet subtraction is part of the definition of a renormalized local operator.

Let $n, \bar{n}$ be future-directed lightlike vectors with $n \cdot \bar{n} = 2$, and let $b_\perp$ be transverse:

$$b_\perp \cdot n = b_\perp \cdot \bar{n} = 0.$$

For a real parameter λ, set

$$z^\mu = \lambda n^\mu + b_\perp^\mu.$$

A finite rapidity regulator may be implemented by replacing lightlike Wilson lines by Wilson lines along non-lightlike directions $v, \bar{v}$, by an analytic rapidity regulator, by a delta regulator, or by an equivalent gauge-covariant subtraction. The monograph denotes the regulator data collectively by ρ. At finite ρ and finite ultraviolet cutoff Λ, let $\mathcal{U}_v^{[\eta]}(z, 0; \rho, \Lambda)$ be a staple transporter from 0 to z, with longitudinal direction v, transverse bridge $b_\perp$, and orientation $\eta = +1$ for future-pointing and $\eta = -1$ for past-pointing staples.

Definition 49.75 (TMD operator definition)**.** A quark TMD operator definition for a hadron H with momentum P consists of:

1. the vectors $n, \bar{n}$, a transverse separation $b_\perp$, and an orientation η of the staple Wilson line;
2. a finite rapidity regulator ρ and ultraviolet regulator Λ, both chosen in a gauge-covariant way;
3. the unsubtracted beam matrix element
$$B_{q/H}^{\mathrm{unsub}}(x, b_\perp; \rho, \Lambda, \eta) = \frac{1}{2P \cdot n} \int \frac{\mathrm{d}\lambda}{2\pi}\, \mathrm{e}^{-\mathrm{i}x\lambda P\cdot n} \Big\langle \bar{q}(z)\, \mathcal{U}_v^{[\eta]}(z, 0; \rho, \Lambda)\, \gamma \cdot n\, q(0) \Big\rangle_{P,H};$$
4. the vacuum soft factor $S(b_\perp; \rho, \Lambda, \eta)$, defined by the trace of the closed Wilson geometry obtained by multiplying the corresponding v- and $\bar{v}$-staples in the vacuum;
5. a finite-part prescription, denoted $\mathrm{FP}_{\rho,\Lambda}$, which removes ultraviolet and rapidity regulator dependence and introduces the scales μ and ζ.

The renormalized TMD in this scheme is

$$F_{q/H}^{[\eta]}(x, b_\perp; \mu, \zeta) = \mathrm{FP}_{\rho,\Lambda} \left[Z_q(\mu, \zeta; \rho, \Lambda)\, \frac{B_{q/H}^{\mathrm{unsub}}(x, b_\perp; \rho, \Lambda, \eta)}{S(b_\perp; \rho, \Lambda, \eta)^{1/2}} \right]. \tag{49.318}$$

The square root is a convention for assigning half of the soft subtraction to each collinear sector. A different finite assignment is a different TMD scheme, related by a finite multiplicative transformation. The variables μ and ζ record, respectively, ultraviolet and rapidity renormalization. The orientation η is part of the operator definition; time-reversal odd TMDs may change sign between future- and past-pointing staples, as in semi-inclusive DIS versus Drell–Yan kinematics.

At finite regulator, the numerator and soft factor in (49.318) are gauge invariant after taking the color trace and endpoint fields into account. Hence a background gauge-covariant finite-part prescription produces a gauge-invariant renormalized TMD matrix element. Every Wilson segment transforms by multiplication with the gauge transformation at its endpoints, as in (49.292). Along a staple, the factors at internal junctions cancel between adjacent segments. The remaining endpoint factors at 0 and z cancel the gauge transformations of $q(0)$ and $\bar{q}(z)$. In the soft factor all Wilson lines are multiplied inside a trace, so the residual base-point factor is removed by cyclicity of the trace. The finite-part map changes only regulator and scale coordinates; if it is background gauge covariant, it cannot introduce an uncanceled color index.

Rapidity evolution is the statement that changing the auxiliary rapidity scale changes the coordinate description of the same physical transverse momentum distribution. It is most transparent in impact-parameter space, where convolutions in transverse momentum become products. Put

$$\ell_\mu := \log \mu, \qquad \ell_\zeta := \log \sqrt{\zeta}.$$

For a fixed x-test function and fixed $b_\perp$, suppose the paired TMD matrix element is nonzero and obeys

$$\frac{\partial}{\partial \ell_\zeta} \log F^{[\eta]}_{q/H}(x, b_\perp; \mu, \zeta) = \mathcal{D}_q(b_\perp; \mu), \tag{49.319}$$

$$\frac{\partial}{\partial \ell_\mu} \log F^{[\eta]}_{q/H}(x, b_\perp; \mu, \zeta) = \gamma^q_F(g(\mu), \ell_\zeta - \ell_\mu). \tag{49.320}$$

The first equation defines the Collins–Soper kernel $\mathcal{D}_q$ in the chosen convention.

Collins–Soper consistency condition. The two scale variables ℓ_μ and ℓ_ζ are coordinates on the renormalized TMD scheme, so a differentiable TMD whose mixed scale derivatives commute obeys the corresponding integrability condition. Explicitly, if the derivatives in (49.319)–(49.320) commute on the renormalized TMD distribution, then

$$\frac{\partial}{\partial \ell_\mu} \mathcal{D}_q(b_\perp; \mu) = \frac{\partial}{\partial \ell_\zeta} \gamma^q_F(g(\mu), \ell_\zeta - \ell_\mu). \tag{49.321}$$

In the convention

$$\gamma^q_F(g, \ell_\zeta - \ell_\mu) = \gamma^{q,0}_F(g) - 2\Gamma^q_{\mathrm{cusp}}(g)(\ell_\zeta - \ell_\mu),$$

this gives

$$\frac{\partial}{\partial \log \mu} \mathcal{D}_q(b_\perp; \mu) = -2\Gamma^q_{\mathrm{cusp}}(g(\mu)). \tag{49.322}$$

At small $b_\perp$, the one-loop kernel compatible with the cusp normalization of (49.369) is

$$\mathcal{D}_q(b_\perp; \mu) = -\frac{g^2(\mu) C_F}{4\pi^2} \log \frac{\mu^2 b_\perp^2 \mathrm{e}^{2\gamma_{\mathrm{E}}}}{4} + O(g^4), \tag{49.323}$$

up to a finite $b_\perp$-dependent scheme term independent of μ. The last display is a normalization check on the one-loop result: $\partial_{\log \mu} \log(\mu^2 b_\perp^2 \mathrm{e}^{2\gamma_{\mathrm{E}}}/4) = 2$, so differentiating (49.323) gives $-g^2 C_F/(2\pi^2) + O(g^4)$, which is $-2\Gamma^q_{\mathrm{cusp}}(g) + O(g^4)$ with $\Gamma^q_{\mathrm{cusp}}(g) = g^2 C_F/(4\pi^2) + O(g^4)$ in the trace-delta normalization. The substantive QCD input is the regulated Wilson-line operator definition, the existence and scheme dependence of rapidity renormalization, and the perturbative or nonperturbative determination of Γ^q_{cusp} and $\mathcal{D}_q$; the displayed consistency relation only records the integrability of the chosen scale coordinates.

Remark 49.76 (Finite TMD scheme changes). Let $R(b_\perp;\mu,\zeta)$ be a finite scalar function and set $F' = \mathrm{e}^R F$. Then

$$\mathcal{D}' = \mathcal{D} + \frac{\partial R}{\partial \ell_\zeta}, \qquad \gamma'_F = \gamma_F + \frac{\partial R}{\partial \ell_\mu}.$$

The consistency relation (49.321) is preserved. Therefore the separation of a rapidity-sensitive cross section into hard, TMD, and soft coordinates is scheme dependent, whereas the final cross section is not.

Take logarithms of $F' = \mathrm{e}^R F$ and differentiate with respect to ℓ_ζ and ℓ_μ. The displayed transformations follow. Taking ∂_{ℓ_μ} of the first transformation and ∂_{ℓ_ζ} of the second gives the same extra term $\partial_{\ell_\mu}\partial_{\ell_\zeta} R$. Hence the difference between the two sides of (49.321) is unchanged.

Hypothesis 49.77 (Small-$q_\perp$ color-singlet TMD factorization hypothesis)**.** For a color-singlet final state of invariant mass Q produced in hadron–hadron scattering, a leading-power small-$q_\perp$ TMD factorization hypothesis consists of TMD schemes for the two incoming hadrons, a hard function $H_{ij}(Q,\mu)$, rapidity scales satisfying $\zeta_A\zeta_B = Q^4$, a Y-term that matches the region $|q_\perp| \sim Q$, a statement about Glauber exchange, and a distributional remainder estimate. In the region $\Lambda_{\mathrm{QCD}} \lesssim |q_\perp| \ll Q$ the singular part has the impact-parameter form

$$\frac{\mathrm{d}\sigma_{\mathrm{sing}}}{\mathrm{d}Q^2\mathrm{d}^2q_\perp} = \sum_{i,j} H_{ij}(Q,\mu) \int \frac{\mathrm{d}^2 b_\perp}{(2\pi)^2}\, \mathrm{e}^{\mathrm{i}b_\perp\cdot q_\perp} F_{i/A}(x_A, b_\perp;\mu,\zeta_A) F_{j/B}(x_B, b_\perp;\mu,\zeta_B). \tag{49.324}$$

The formula is a theorem only when the regulator construction, cancellation or operator representation of Glauber exchange, and the topology of the power-remainder estimate have all been supplied.

49.20 Drell–Yan Factorization and Glauber Status

Drell–Yan production is the timelike current analogue of DIS:

$$h_A(P_A) + h_B(P_B) \longrightarrow \ell^+\ell^- + X, \qquad q = p_{\ell^+} + p_{\ell^-}, \qquad q^2 = Q^2 > 0.$$

The QCD object is again a Wightman current matrix element, now between a two-hadron incoming state. For unpolarized hadrons define

$$W^{\mu\nu}_{AB}(P_A,P_B,q) = \frac{1}{N_{\mathrm{spin}}} \sum_{\sigma_A,\sigma_B} \sum_X (2\pi)^4 \delta^{(4)}(P_A+P_B-q-P_X) \langle P_A,P_B|J^\mu(0)|X\rangle\langle X|J^\nu(0)|P_A,P_B\rangle. \tag{49.325}$$

Equivalently, by translation covariance and completeness,

$$W^{\mu\nu}_{AB}(P_A,P_B,q) = \frac{1}{N_{\mathrm{spin}}} \sum_{\sigma_A,\sigma_B} \int \mathrm{d}^4x\, \mathrm{e}^{\mathrm{i}q\cdot x} \langle P_A,P_B|J^\mu(x)J^\nu(0)|P_A,P_B\rangle, \tag{49.326}$$

with the same state-normalization convention as in the scattering chapters. The partonic formulae below are short-distance coordinates for this tensor; they are not definitions of a cross section with colored asymptotic states.

Drell–Yan leading-power kinematics. Let

$$s := (P_A + P_B)^2, \qquad \tau := \frac{Q^2}{s},$$

and choose the hadron center-of-mass frame with the A-hadron moving in the positive longitudinal direction. At leading power in hadron masses and transverse momentum, the longitudinal momentum fractions entering the short-distance hard collision are

$$x_A = \sqrt{\tau}\, \mathrm{e}^{y}, \qquad x_B = \sqrt{\tau}\, \mathrm{e}^{-y}, \tag{49.327}$$

where

$$y := \frac{1}{2} \log \frac{q^0 + q^3}{q^0 - q^3}$$

is the lepton-pair rapidity. Hence

$$x_A x_B = \tau, \qquad y = \frac{1}{2} \log \frac{x_A}{x_B}.$$

In light-cone coordinates adapted to the beam directions, write the leading hadron momenta as

$$P_A^+ = \sqrt{s}, \quad P_A^- = 0, \qquad P_B^- = \sqrt{s}, \quad P_B^+ = 0,$$

and neglect transverse components in the leading-power kinematic identity. The active partons carry

$$q^+ = x_A P_A^+, \qquad q^- = x_B P_B^-.$$

Therefore $Q^2 = q^+ q^- + O(q_\perp^2, M_{A,B}^2) = x_A x_B s + O(q_\perp^2, M_{A,B}^2)$, which gives $x_A x_B = \tau$ at leading power. The rapidity satisfies

$$y = \frac{1}{2} \log \frac{q^+}{q^-} = \frac{1}{2} \log \frac{x_A}{x_B}.$$

Solving the two equations gives (49.327).

Integrated collinear factorization coordinate. If the lepton-pair transverse momentum is not kept differential, the appropriate leading-power coordinate is the integrated collinear factorization formula, not the TMD formula below. Fix a compact rapidity and invariant-mass window in which $x_A, x_B \in K \Subset (0,1)$ and the threshold and small-x boundaries are excluded. A leading-power integrated Drell–Yan factorization hypothesis consists of renormalized integrated PDF coordinates $f_{i/A}, f_{j/B}$, a short-distance coefficient distribution C_{ij}^{DY}, and a distributional remainder bound such that

$$\frac{\mathrm{d}\sigma_{\mathrm{DY}}}{\mathrm{d}Q^2 \mathrm{d}y} = \sum_{i,j} \int_{x_A}^1 \frac{\mathrm{d}\xi_A}{\xi_A} \int_{x_B}^1 \frac{\mathrm{d}\xi_B}{\xi_B}\, f_{i/A}(\xi_A, \mu)\, f_{j/B}(\xi_B, \mu)\, C_{ij}^{\mathrm{DY}}\left(\frac{x_A}{\xi_A}, \frac{x_B}{\xi_B}; Q, \mu\right) + R_{\mathrm{DY}}. \tag{49.328}$$

The PDFs in (49.328) are the Wilson-line light-ray matrix elements of Definition 49.72. The coefficient C_{ij}^{DY} is a hard matching distribution in the same factorization scheme; it includes the chosen flux, electroweak-current, and Jacobian normalization. The remainder R_{DY} contains the declared power corrections, threshold and small-x exclusions, perturbative truncation remainder, and the Glauber item discussed below. Thus the formula is not an identity between colored partonic cross sections. It is a comparison between the exact color-singlet Wightman tensor (49.326) and a factorized coordinate built from two incoming light-ray operator matrix elements.

The scale cancellation is the two-incoming-leg analogue of (49.315). In a Mellin or Laplace chart where the two convolutions become products, let $f_A(N_A, \mu)$ and $f_B(N_B, \mu)$ be column vectors in parton species, and write the factorized coordinate as

$$\widetilde{\Sigma}_{\mathrm{DY}}(N_A, N_B; \mu) = f_A(N_A, \mu)^T \widetilde{C}_{\mathrm{DY}}(N_A, N_B; Q, \mu) f_B(N_B, \mu). \tag{49.329}$$

If

$$\mu \frac{\mathrm{d} f_A}{\mathrm{d}\mu} = P_A f_A, \qquad \mu \frac{\mathrm{d} f_B}{\mathrm{d}\mu} = P_B f_B,$$

then auxiliary-scale independence of (49.329) requires

$$\mu \frac{\mathrm{d}\widetilde{C}_{\mathrm{DY}}}{\mathrm{d}\mu} = -P_A^T \widetilde{C}_{\mathrm{DY}} - \widetilde{C}_{\mathrm{DY}} P_B. \tag{49.330}$$

Indeed,

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu}\big(f_A^T \widetilde{C}_{\mathrm{DY}} f_B\big) = f_A^T \big(P_A^T \widetilde{C}_{\mathrm{DY}} + \mu\partial_\mu \widetilde{C}_{\mathrm{DY}} + \widetilde{C}_{\mathrm{DY}} P_B\big) f_B,$$

which vanishes by (49.330). A finite factorization-scheme change $f'_A = R_A f_A$, $f'_B = R_B f_B$ preserves the same physical coordinate only if

$$\widetilde{C}'_{\mathrm{DY}} = (R_A^{-1})^T \widetilde{C}_{\mathrm{DY}} R_B^{-1}.$$

This matrix identity is the clean bookkeeping behind statements that the two incoming collinear singularities have been absorbed into the PDFs. A factorization proof must still supply the leading-region analysis, soft cancellation or soft factor, Glauber status, and the remainder topology; the algebra above only fixes the paired RG structure once those objects exist.

Controlled Approximation 49.78 (Integrated Drell–Yan theorem boundary)**.** The exact object in integrated Drell–Yan is a tested distribution obtained from the color-singlet Wightman tensor (49.326), not the partonic coordinate (49.328). Fix a compact (Q^2, y)-window K, away from threshold and small-x boundaries, and let $\mathcal{D}_K$ be the corresponding test-function space. A leading-power integrated factorization theorem for this window must supply:

1. a finite-regulator definition of the exact tested functional $\mathfrak{T}_{\mathrm{DY}}[\varphi]$, $\varphi \in \mathcal{D}_K$, from (49.326);
2. the renormalized light-ray PDF coordinates and the hard coefficient in the same subtraction scheme;
3. a leading-region map from the exact current product to the two incoming collinear sectors, with its error measured in $\mathcal{D}_K^*$;
4. a soft-cancellation or soft-factor construction in the same regulator;
5. a Glauber statement strong enough for the chosen measurement topology, such as a commutator or inclusive-projection bound of the form described below;
6. a power-remainder topology, including hadron-mass, threshold, small-x, and perturbative-truncation qualifications;
7. a regulator-limit statement identifying which residuals vanish and which remain as declared approximation errors.

Thus the formula (49.328) becomes a theorem only after the residuals in this list are bounded for the exact tested Wightman functional. The paired RG equation (49.330) is one coordinate-transport check inside this boundary; it is not the boundary itself.

Proposition 49.79 (Tested Drell–Yan factorization residual budget)**.** *In the setting of Controlled Approximation 49.78, suppose the subtraction analysis represents the exact tested functional as*

$$\mathfrak{T}_{\rm DY}[\varphi] = f_A^T C_\varphi f_B + \Delta_{\rm lead}[\varphi] + \Delta_{\rm soft}[\varphi] + \Delta_{\rm G}[\varphi] + \Delta_{\rm pwr}[\varphi] + \Delta_{\rm reg}[\varphi], \tag{49.331}$$

where $f_A^T C_\varphi f_B$ is the tested version of (49.328). Assume that, on a window $Q \geq Q_0$,

$$|\Delta_a[\varphi]| \leq \epsilon_a(Q_0)\, \|\varphi\|_{\mathcal{D}_K}, \qquad a \in \{\mathrm{lead}, \mathrm{soft}, \mathrm{G}, \mathrm{pwr}, \mathrm{reg}\}. \tag{49.332}$$

Then

$$\left|\mathfrak{T}_{\rm DY}[\varphi] - f_A^T C_\varphi f_B\right| \leq (\epsilon_{\rm lead} + \epsilon_{\rm soft} + \epsilon_{\rm G} + \epsilon_{\rm pwr} + \epsilon_{\rm reg})\, \|\varphi\|_{\mathcal{D}_K}. \tag{49.333}$$

If the paired PDF/coefficient transport (49.330) is exact, then $f_A^T C_\varphi f_B$ is independent of the auxiliary factorization scale, but the physical mismatch in (49.333) is controlled only by the five residual norms above. Scale covariance of the factorized coordinate does not make any nonzero residual disappear.

Proof. Subtract the factorized coordinate from (49.331) and apply the triangle inequality together with (49.332). The final statement is the scale derivative calculation already displayed in (49.330): the derivative of $f_A^T C_\varphi f_B$ cancels between the two PDF legs and the dual hard coefficient. This cancellation concerns only the retained coordinate. The exact Wightman functional can agree with it in the declared topology only when the listed residual functionals are separately bounded, or vanish in the regulator and large-Q limits being claimed. □

Hypothesis 49.80 (Drell–Yan small-$q_\perp$ TMD factorization hypothesis)**.** A leading-power Drell–Yan TMD factorization hypothesis consists of:

1. the renormalized current hard function $H_{ij}(Q,\mu)$;
2. past-pointing TMD operator data $F^{[-]}_{i/A}(x_A, b_\perp; \mu, \zeta_A)$ and $F^{[-]}_{j/B}(x_B, b_\perp; \mu, \zeta_B)$, in the notation of Definition 49.75;
3. rapidity scales constrained by $\zeta_A \zeta_B = Q^4$;
4. a Y-term matching to the region $|q_\perp| \sim Q$;
5. a proof or controlled hypothesis for Glauber exchange;
6. a distributional power-remainder estimate in $q_\perp/Q$ and in the hadron-mass corrections.

The singular small-$q_\perp$ term is then represented as

$$\frac{\mathrm{d}\sigma_{\rm sing}}{\mathrm{d}Q^2 \mathrm{d}y\, \mathrm{d}^2 q_\perp} = \sum_{i,j} H_{ij}(Q,\mu) \int \frac{\mathrm{d}^2 b_\perp}{(2\pi)^2}\, \mathrm{e}^{\mathrm{i} b_\perp \cdot q_\perp} F^{[-]}_{i/A}(x_A, b_\perp; \mu, \zeta_A) F^{[-]}_{j/B}(x_B, b_\perp; \mu, \zeta_B), \tag{49.334}$$

plus the stated Y-term and power remainder. The past-pointing staple orientation is part of the operator definition. It is the operator-level source of the sign reversal of time-reversal-odd TMD coordinates between semi-inclusive DIS and Drell–Yan, once the relevant antiunitary transformation and spin conventions are specified.

Finite unitarity model for Glauber cancellation. Let $\mathcal{H}_{\rm obs}$ be a finite-dimensional observed Hilbert space, let $\mathcal{H}_{\rm un}$ be an unobserved Hilbert space, let ρ be a trace-class density matrix on $\mathcal{H}_{\rm obs} \otimes \mathcal{H}_{\rm un}$, and let M be an observable acting only on $\mathcal{H}_{\rm obs}$. If the effect of a Glauber exchange on the unobserved degrees of freedom is represented by a unitary U_G acting only on $\mathcal{H}_{\rm un}$, then

$$\mathrm{Tr}_{\rm obs,un}\left[(M \otimes \mathbf{1})(\mathbf{1} \otimes U_G)\rho(\mathbf{1} \otimes U_G^\dagger)\right] = \mathrm{Tr}_{\rm obs,un}\left[(M \otimes \mathbf{1})\rho\right]. \tag{49.335}$$

Use cyclicity of the full trace and $(\mathbf{1} \otimes U_G^\dagger)(M \otimes \mathbf{1})(\mathbf{1} \otimes U_G) = M \otimes \mathbf{1}$. The result is

$$\mathrm{Tr}\left[\rho(\mathbf{1} \otimes U_G^\dagger)(M \otimes \mathbf{1})(\mathbf{1} \otimes U_G)\right] = \mathrm{Tr}\left[\rho(M \otimes \mathbf{1})\right],$$

which is (49.335). Equivalently, the partial trace over the unobserved Hilbert space is invariant under unitary conjugation on that same unobserved factor. The finite model therefore isolates the algebraic input used in inclusive Glauber-cancellation arguments: the observed measurement must be insensitive to the unitary acting on the summed-over sector.

The same finite model also gives the residual which must be bounded when the measurement is not fully inclusive. For a general tested measurement M_φ on $\mathcal{H}_{\rm obs} \otimes \mathcal{H}_{\rm un}$, define

$$\Delta_{\rm G}^{\rm fin}[\varphi] = \mathrm{Tr}\left[\rho\big((\mathbf{1} \otimes U_G^\dagger)M_\varphi(\mathbf{1} \otimes U_G) - M_\varphi\big)\right]. \tag{49.336}$$

Then

$$\Delta_{\rm G}^{\rm fin}[\varphi] = 0 \quad \text{if} \quad [M_\varphi, \mathbf{1} \otimes U_G] = 0,$$

and in finite dimension

$$|\Delta_{\rm G}^{\rm fin}[\varphi]| \le \|\rho\|_1 \left\|(\mathbf{1} \otimes U_G^\dagger)M_\varphi(\mathbf{1} \otimes U_G) - M_\varphi\right\|_{\rm op}. \tag{49.337}$$

Thus the integrated Drell–Yan Glauber residual $\Delta_{\rm G}[\varphi]$ in (49.331) is not a ceremonial slot. It asks whether, after the leading-region and contour-deformation analysis has identified the regulated eikonal Glauber action, the tested color-singlet observable is inclusive enough for the commutator to vanish, or whether the remaining commutator is quantitatively small in the declared measurement topology.

Controlled Approximation 49.81 (What the finite Glauber calculation proves)**.** The finite unitarity calculation above is the algebraic identity that a Drell–Yan factorization proof must realize after the leading regions, color flow, rapidity regulator, and measurement topology have been fixed. It does not prove by itself that QCD Glauber exchanges act only on an unobserved tensor factor, nor that the contour deformations needed to isolate the leading regions are valid. Those statements are part of the Glauber item in Hypothesis 49.80. If the observable measures hadronic radiation in a way that resolves the spectator sector, or if a color exchange remains entangled with the measured hard sector, the finite identity above no longer supplies the required cancellation.

49.21 Off-Forward Light-Ray Matrix Elements and GPDs

Generalized parton distributions are light-ray matrix elements between different hadron momenta. They do not require a rapidity subtraction in the same way as TMDs, because the operator remains integrated over transverse momentum. Their new feature is off-forwardness.

Let p' and p be on-shell spin-$\frac{1}{2}$ hadron momenta, and define

$$P = \frac{p' + p}{2}, \qquad \Delta = p' - p, \qquad t = \Delta^2, \qquad \xi = -\frac{\Delta \cdot n}{2P \cdot n}.$$

For the symmetric light-ray separation

$$z^\mu = \lambda n^\mu,$$

define the quark vector GPDs H^q and E^q by

$$\begin{aligned} &\int \frac{\mathrm{d}\lambda}{2\pi}\, \mathrm{e}^{-\mathrm{i}x\lambda P\cdot n} \langle p', s'| \left[\bar{q}\left(\frac{\lambda n}{2}\right) W_\square\left(\frac{\lambda n}{2}, -\frac{\lambda n}{2}\right) \gamma \cdot n\, q\left(-\frac{\lambda n}{2}\right)\right]_\mu |p, s\rangle \\ &\quad = \bar{u}_{s'}(p') \left[\gamma \cdot n\, H^q(x, \xi, t; \mu) + \frac{\mathrm{i}\sigma^{n\alpha}\Delta_\alpha}{2M}\, E^q(x, \xi, t; \mu)\right] u_s(p), \end{aligned} \tag{49.338}$$

where $\sigma^{n\alpha} := n_\mu \sigma^{\mu\alpha}$, and M is the hadron mass. The support and endpoint behavior of the distributions are properties of the renormalized light-ray matrix elements and of the chosen hadronic state; they are not imposed by a parton model.

Lemma 49.82 (Polynomiality of GPD moments)**.** *Assume the renormalized twist-two local operators obtained from the light-ray operator in* (49.338) *exist as local operator-valued distributions between the hadron states under consideration. Then the N-th Mellin moments*

$$\int_{-1}^{1} \mathrm{d}x\, x^{N-1} H^q(x, \xi, t; \mu), \qquad \int_{-1}^{1} \mathrm{d}x\, x^{N-1} E^q(x, \xi, t; \mu)$$

are polynomials in ξ of degree at most N, with coefficients that are Lorentz-scalar form factors depending on t and μ.

Proof. Expanding the symmetric light-ray operator in λ gives the local twist-two tower

$$\bar{q}\, \gamma^{(\mu_1} \mathrm{i}D^{\mu_2} \cdots \mathrm{i}D^{\mu_N)} q - \text{traces},$$

contracted with $n_{\mu_1} \cdots n_{\mu_N}$. Since $n^2 = 0$, all trace terms vanish after contraction with these n's. Lorentz covariance of the off-forward matrix element gives a finite decomposition into symmetric tensors made from P, Δ, the metric, and the spinor bilinears $\bar{u}(p')\gamma^\alpha u(p)$ and $\bar{u}(p')\mathrm{i}\sigma^{\alpha\beta}\Delta_\beta u(p)$. After contraction with $n_{\mu_1} \cdots n_{\mu_N}$, each term contains

$$(P \cdot n)^{N-k} (\Delta \cdot n)^k = (P \cdot n)^N (-2\xi)^k$$

for some $0 \le k \le N$, multiplied by a scalar form factor depending only on t and μ. Dividing by the overall powers of $P \cdot n$ in the GPD decomposition therefore gives a polynomial in ξ of degree no larger than N. This argument uses only locality, Lorentz covariance, and the existence of the renormalized local twist-two tower; it does not use a probability interpretation. □

Deeply virtual Compton scattering and related exclusive processes use these GPDs in coefficient-function convolutions. As in inclusive DIS and TMD factorization, the GPD itself is the renormalized hadronic light-ray matrix element. The factorization theorem connecting it to a measured exclusive amplitude is an additional leading-power assertion with its own endpoint, Glauber, and power-remainder data.

49.22 Asymptotic Freedom and Exclusive Pion Amplitudes

49.22.1 Pion Light-Ray Data and Factorization Scheme

Inclusive DIS uses forward light-ray matrix elements. Exclusive pion amplitudes use light-ray matrix elements between the vacuum and a one-pion state. This is the part of the pion S-matrix where asymptotic freedom gives a direct large-momentum prediction: the short-distance subgraph is a perturbatively renormalized quark-gluon amplitude, while the pion appears only through a renormalized gauge-invariant light-ray matrix element. The statement is not that a pion is a weakly bound pair of on-shell quarks. The pion input is the same hadronic state defined by the nonperturbative QCD sector; only the coefficient multiplying its light-ray matrix element is perturbative.

Let P^μ be the momentum of a charged pion and let n^μ be a future-directed lightlike vector with $P \cdot n > 0$. In the isospin-symmetric two-flavor theory, define the charged-pion light-cone distribution amplitude by the renormalized bilocal matrix element

$$\langle \Omega | \left[\bar{d}(\lambda n) \, W_\square(\lambda n, 0) \, \gamma \cdot n \, \gamma_5 \, u(0) \right]_\mu | \pi^+(P) \rangle = \mathrm{i} f_\pi \, P \cdot n \int_0^1 \mathrm{d}x \, \mathrm{e}^{-\mathrm{i}x\lambda P\cdot n} \, \varphi_\pi(x, \mu). \tag{49.339}$$

The Wilson transporter is the same path-ordered fundamental transporter used in (49.293). The normalization of f_π is the axial-current normalization of Chapter 55,

$$\langle \Omega | A_a^\mu(0) | \pi^b(P) \rangle = \mathrm{i} f_\pi P^\mu \delta_a{}^b.$$

Setting $\lambda = 0$ in (49.339) therefore fixes

$$\int_0^1 \mathrm{d}x \, \varphi_\pi(x, \mu) = 1. \tag{49.340}$$

The support interval $[0, 1]$ is a property of the leading-twist light-ray operator between the vacuum and the one-pion state. It is not a probability postulate. The function φ_π is a renormalized distribution in x, depending on the factorization scheme and scale.

Definition 49.83 (Exclusive pion factorization scheme)**.** An exclusive large-Q pion factorization statement consists of:

1. a renormalized QCD matrix element whose external hadrons and currents are gauge-invariant;
2. a light-ray operator basis, here represented at leading twist by $\varphi_\pi(x, \mu)$;
3. a hard coefficient T_H, computed with external collinear partons and subtracted in the same scheme as the light-ray operator;
4. a convolution prescription in the momentum fractions;
5. a topology for the remainder, for example $O(\Lambda_{\mathrm{QCD}}^2/Q^2)$ after excluding endpoint regions by the stated hypotheses, together with the order in α_s to which T_H is known.

The scheme is part of the definition of the controlled approximation. Without it, a formula involving a pion distribution amplitude is only notation.

49.22.2 ERBL Evolution and Gegenbauer Coordinates

The one-loop renormalization of the light-ray operator in (49.339) gives the Efremov–Radyushkin–Brodsky– Lepage evolution equation

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\varphi_\pi(x,\mu)=\frac{\alpha_s(\mu)}{2\pi}\int_0^1\mathrm{d}y\,V(x,y)\varphi_\pi(y,\mu)+O(\alpha_s^2),\tag{49.341}$$

where, in the trace-delta convention,

$$V(x,y)=C_F\left[\theta(y-x)\frac{x}{y}\left(1+\frac{1}{y-x}\right)+\theta(x-y)\frac{1-x}{1-y}\left(1+\frac{1}{x-y}\right)\right]_+.\tag{49.342}$$

The plus prescription acts on the x-variable:

$$\int_0^1\mathrm{d}x\,[K(x,y)]_+f(x):=\int_0^1\mathrm{d}x\,K(x,y)\big(f(x)-f(y)\big),\tag{49.343}$$

for test functions smooth near $x=y$. Equation (49.343) makes the conservation of the axial current normalization manifest:

$$\int_0^1\mathrm{d}x\,V(x,y)=0.$$

Proposition 49.84 (Diagonalization of the leading ERBL kernel)**.** *For $n\geq 0$, let $C_n^{3/2}$ be the Gegenbauer polynomial orthogonal on $[-1,1]$ with weight $(1-z^2)$. The leading ERBL kernel preserves the basis*

$$\varphi_n(x):=6x(1-x)C_n^{3/2}(2x-1),$$

and

$$\int_0^1\mathrm{d}y\,V(x,y)\varphi_n(y)=-\frac{1}{2}\gamma_n^{(0)}\,\varphi_n(x),\tag{49.344}$$

with

$$\gamma_n^{(0)}=C_F\left[1-\frac{2}{(n+1)(n+2)}+4\sum_{k=2}^{n+1}\frac{1}{k}\right].\tag{49.345}$$

In particular $\gamma_0^{(0)}=0$ and $\gamma_n^{(0)}>0$ for every $n\geq 1$.

Proof. Write

$$P_n(x):=C_n^{3/2}(2x-1),\qquad \varphi_n(x)=6x(1-x)P_n(x).$$

The plus prescription in (49.343) subtracts the same raw kernel with the first argument integrated. Therefore, for any polynomial P, the singular action of (49.342) on $\varphi_P(y):=6y(1-y)P(y)$ is the following finite polynomial:

$$\begin{aligned}\frac{1}{C_F}\int_0^1\mathrm{d}y\,V(x,y)\varphi_P(y)&=6(1-x)\int_0^x\mathrm{d}y\,y\big(P(y)-P(x)\big)\left(1+\frac{1}{x-y}\right)\\&\quad+6x\int_x^1\mathrm{d}y\,(1-y)\big(P(y)-P(x)\big)\left(1+\frac{1}{y-x}\right).\end{aligned}\tag{49.346}$$

This identity is only the definition of the plus distribution written at fixed x: the factors $y(1-x)$ and $x(1-y)$ come from $(1-x)\varphi_P(y)/(1-y)$ and $x\varphi_P(y)/y$, while the delta subtraction supplies the terms with $P(x)$. The apparent poles are removable because $P(y)-P(x)$ is divisible by $y-x$.

Let $P(x) = \sum_{m=0}^{N} p_m x^m$, and put $H_m = \sum_{r=1}^{m} r^{-1}$, $H_0 = 0$. Evaluating the beta integrals in (49.346) gives the explicit coefficient operator

$$
\begin{aligned}
\mathcal{E}[P](x) &:= \frac{1}{C_F}\int_0^1 \mathrm{d}y\, V(x,y)\varphi_P(y) \\
&= 6(1-x)\left[\sum_{m=0}^{N} p_m \frac{x^{m+2}}{m+2} - \frac{x^2}{2}P(x) - \sum_{m=1}^{N} p_m x^{m+1}(H_{m+1}-1)\right] \\
&\quad + 6x\left[\sum_{m=0}^{N} p_m\left(\frac{1}{(m+1)(m+2)} - \frac{x^{m+1}}{m+1} + \frac{x^{m+2}}{m+2}\right) - \frac{(1-x)^2}{2}P(x)\right. \\
&\qquad\left. + \sum_{m=1}^{N} p_m \sum_{j=0}^{m-1} x^j\left(\frac{1}{(m-j)(m-j+1)} - \frac{x^{m-j}}{m-j} + \frac{x^{m-j+1}}{m-j+1}\right)\right].
\end{aligned}
\tag{49.347}
$$

For $P = P_n$, the coefficients are fixed by

$$
P_0(x) = 1, \qquad P_1(x) = 3(2x-1),
$$

and by the Gegenbauer recurrence

$$
(n+1)P_{n+1}(x) = (2n+3)(2x-1)P_n(x) - (n+2)P_{n-1}(x). \tag{49.348}
$$

Substitution of this recurrence into the coefficient operator (49.347) gives, by induction on n,

$$
\mathcal{E}[P_n](x) = -\frac{1}{2}\left[1 - \frac{2}{(n+1)(n+2)} + 4\sum_{k=2}^{n+1}\frac{1}{k}\right] 6x(1-x)P_n(x). \tag{49.349}
$$

The induction is finite algebra in the polynomial ring $\mathbb{Q}[x]$: (49.347) gives the action on each monomial, (49.348) gives the next P_n, and the new harmonic term changes by $H_{n+2} - H_{n+1} = 1/(n+2)$. The cases $n = 0, 1$ start the induction; $n = 0$ is the axial-current normalization already expressed by $\int_0^1 \mathrm{d}x\, V(x,y) = 0$. Restoring the overall factor C_F proves (49.344). The factor $1/2$ in (49.344) is tied to the convention that the evolution equation was written with $\alpha_s/(2\pi)$ in (49.341); in the common convention in which the moment equation is written with $\alpha_s/(4\pi)$, the same $\gamma_n^{(0)}$ appears without this extra displayed factor. □

The diagonal basis has a representation-theoretic origin: the collinear conformal group acting on two light-ray quark fields has $SL(2,\mathbb{R})$ quadratic Casimir diagonalized by $x(1-x)C_n^{3/2}(2x-1)$, and the one-loop kernel (49.342) is compatible with this action after the plus subtraction. The proof above keeps the normalization independent of that interpretation by reducing the statement to the finite polynomial identity (49.349).

Therefore a pion LCDA may be expanded as

$$
\varphi_\pi(x,\mu) = 6x(1-x)\left[1 + \sum_{n=1}^{\infty} a_n(\mu) C_n^{3/2}(2x-1)\right], \tag{49.350}
$$

with odd a_n vanishing in the isospin-symmetric charge-conjugation channel. At leading order

$$
\mu\frac{\mathrm{d}}{\mathrm{d}\mu}a_n(\mu) = -\frac{\alpha_s(\mu)}{4\pi}\gamma_n^{(0)} a_n(\mu) + O(\alpha_s^2), \tag{49.351}
$$

and asymptotic freedom drives all $n \geq 1$ moments to zero. The ultraviolet fixed shape is consequently

$$\varphi_\pi^{\mathrm{as}}(x) = 6x(1-x). \tag{49.352}$$

The approach to this shape is logarithmic and scheme dependent at finite scale. The statement (49.352) is therefore an asymptotic consequence of the light-ray anomalous dimensions, not an empirical model for the pion at moderate momentum transfer.

49.22.3 Hard Exclusive Form Factors and Boundary Regimes

The spacelike charged-pion electromagnetic form factor is defined by

$$\langle \pi^+(P')|J^\mu_{\mathrm{em}}(0)|\pi^+(P)\rangle = (P+P')^\mu F_\pi(Q^2), \qquad Q^2 := -(P'-P)^2 > 0. \tag{49.353}$$

At leading twist and leading order in the hard coefficient,

$$F_\pi(Q^2) = \frac{4\pi\alpha_s(\mu)C_F}{N_c}\,\frac{f_\pi^2}{Q^2}\left[\int_0^1 \mathrm{d}x\,\frac{\varphi_\pi(x,\mu)}{x}\right]\left[\int_0^1 \mathrm{d}y\,\frac{\varphi_\pi(y,\mu)}{y}\right] + O(\alpha_s^2, Q^{-4})_{\mathrm{fac}}. \tag{49.354}$$

The subscript "fac" means that the power remainder belongs to the factorization scheme of Definition 49.83; endpoint sensitivity can modify the practical convergence at accessible Q^2 unless controlled by an additional Sudakov or nonperturbative input.

Derivation of the leading hard coefficient. Project each pion onto the color-singlet leading-twist collinear pair defined by (49.339). A single hard gluon must transfer large transverse momentum between the two collinear quark lines; without this exchange the electromagnetic current cannot convert the initial collinear color-singlet into the final one at fixed large Q^2. The tree hard subgraph contains one gluon propagator of virtuality $O(Q^2)$ and one internal quark propagator of virtuality $O(Q^2)$. Contracting the spin projectors fixed by the axial matrix element gives the numerator proportional to $P \cdot P'$, and the color-singlet projection gives

$$\frac{1}{N_c}\,t^a_{ij}t^a_{ji} = \frac{C_F}{N_c}.$$

The two endpoint denominators are the light-cone momentum fractions carried by the active quarks. With the LCDA normalization (49.340), the sum of the two photon attachments to the charged pion gives (49.354). No on-shell colored external state appears in the final formula; colored partons were only projectors used to compute the short-distance coefficient in the chosen factorization scheme.

Substituting $\varphi_\pi^{\mathrm{as}}$ gives

$$Q^2F_\pi(Q^2) \sim \frac{36\pi\alpha_s(Q)C_F}{N_c}\,f_\pi^2. \tag{49.355}$$

For $N_c = 3$, this is

$$Q^2F_\pi(Q^2) \sim 16\pi\alpha_{\mathrm{ht}}(Q)f_\pi^2$$

in the common half-trace convention. Equivalently, if one uses the phenomenological convention $f_\pi^{(130)} = \sqrt{2}\,f_\pi$, the same statement is often written as $Q^2F_\pi \sim 8\pi\alpha_{\mathrm{ht}}(f_\pi^{(130)})^2$. The monograph keeps the Chapter 55 convention f_π fixed, so (49.355) is the convention-safe formula.

The neutral-pion transition form factor is defined by

$$\mathrm{i}\int \mathrm{d}^4x\, \mathrm{e}^{\mathrm{i}q\cdot x}\langle \pi^0(P)|\,\mathrm{T}\; J^\mu_{\mathrm{em}}(x)J^\nu_{\mathrm{em}}(0)|\Omega\rangle = \epsilon^{\mu\nu\rho\sigma}q_\rho k_\sigma\, F_{\pi^0\gamma\gamma^*}(Q^2), \tag{49.356}$$

with $k^2 = 0$, $q^2 = -Q^2$, and $P = q + k$. The low-energy endpoint is fixed by the anomaly calculation of Chapters 51 and 55:

$$F_{\pi^0\gamma\gamma^*}(0) = \frac{1}{4\pi^2 f_\pi} \tag{49.357}$$

in the present f_π convention. At large spacelike Q^2, leading twist factorization gives

$$F_{\pi^0\gamma\gamma^*}(Q^2) = \frac{f_\pi}{3Q^2}\int_0^1 \mathrm{d}x\,\varphi_\pi(x,\mu)\left(\frac{1}{x}+\frac{1}{1-x}\right) + O(\alpha_s, Q^{-4})_{\mathrm{fac}}. \tag{49.358}$$

For the asymptotic LCDA,

$$Q^2F_{\pi^0\gamma\gamma^*}(Q^2) \longrightarrow 2f_\pi. \tag{49.359}$$

In the $f_\pi^{(130)} = \sqrt{2}f_\pi$ convention this is $\sqrt{2}f_\pi^{(130)}$. The anomaly value (49.357) and the asymptotic value (49.359) constrain two different boundary regimes of the same form factor. They do not imply a unique interpolation. Published high-Q^2 measurements are therefore tests of the approach to the factorized regime and of LCDA shape assumptions, not independent definitions of the anomaly or of asymptotic freedom.

The BaBar/Belle tension in the neutral-pion transition form factor is best formulated in exactly these terms. A reported finite-Q^2 trend can challenge a chosen LCDA model, a treatment of endpoint regions, or an estimate of power corrections. It cannot by itself refute (49.357) or (49.359), because those two equations live at opposite ends of the form factor and rest on different controlled arguments: the first on the axial anomaly and the second on leading-twist factorization plus ERBL evolution. Any quantitative comparison to data must therefore state the factorization scale, perturbative order, LCDA input, and power-correction model before it is a QCD statement.

Controlled Approximation 49.85 (Brodsky–Farrar scaling)**.** Consider a fixed-angle exclusive process

$$H_1 + H_2 \longrightarrow H_3 + H_4$$

whose leading Fock components contain n_i collinear elementary fields in the corresponding leading-twist light-ray operator, and set $n = \sum_i n_i$. If a leading-power exclusive factorization theorem holds, if endpoint configurations are power suppressed in the specified scheme, and if the hard coefficient is evaluated at momentum transfer of order $\sqrt{s}$, then

$$\mathcal{M}(s,t) \sim s^{\,2-n/2} \quad \text{at fixed } t/s, \qquad \frac{\mathrm{d}\sigma}{\mathrm{d}t} \sim s^{\,2-n}. \tag{49.360}$$

The derivation is the power counting of the hard coefficient after all external hadrons have been replaced by their normalized leading-twist distribution amplitudes. It is not a dimensional-analysis argument applied to hadron fields. For example, a pion electromagnetic form factor has $n = 4$ across the two pion light-ray operators and therefore scales as $F_\pi(Q^2) \sim Q^{-2}$, while fixed-angle $\pi\pi \to \pi\pi$ has $n = 8$ and gives $\mathrm{d}\sigma/\mathrm{d}t \sim s^{-6}$, up to logarithmic evolution and controlled power corrections.

The pion S-matrix is thus accessed by different controlled descriptions in different regions. Chapter 55 derives the chiral low-energy amplitudes and anomaly couplings; Chapter 29 develops the analytic and dispersive language needed for the resonance region; the present section gives the asymptotic exclusive regime governed by light-ray factorization and asymptotic freedom. These are not three theories. They are three coordinate systems on matrix elements of the same QCD operators, with different hypotheses controlling their errors. A complete nonperturbative construction of QCD would define the relevant matrix elements first; chiral perturbation theory, dispersive methods, lattice calculations, and hard exclusive factorization are then approximation or reconstruction methods applied to that common object.

49.23 Local Twist-Two Operators and Integer Moments

The light-ray definition packages an infinite family of local operators. For quarks, the symmetric traceless spin-N operators have the form

$$\mathcal{O}_q^{\mu_1\cdots\mu_N} = \bar{q}\,\gamma^{(\mu_1}\mathrm{i}D^{\mu_2}\cdots\mathrm{i}D^{\mu_N)}q - \text{traces}, \qquad N \geq 1,$$

with gauge-covariant derivatives in the appropriate representation. The parentheses denote symmetrization over Lorentz indices. The gluon operators are

$$\mathcal{O}_g^{\mu_1\cdots\mu_N} = F^{(\mu_1}{}_{\rho}\,\mathrm{i}D^{\mu_2}\cdots\mathrm{i}D^{\mu_{N-1}}F^{\mu_N)\rho} - \text{traces}, \qquad N \geq 2.$$

Both have twist two after subtracting traces. Their hadron matrix elements are fixed by Lorentz covariance up to scalar reduced matrix elements:

$$\langle P|\mathcal{O}_a^{\mu_1\cdots\mu_N}(\mu)|P\rangle = 2\,a_{a,N}(\mu)\big(P^{\mu_1}\cdots P^{\mu_N} - \text{traces}\big), \qquad a = q, g.$$

The normalization of $a_{a,N}$ is fixed already at tree level by replacing the hadron with a single parton state. Let $|p,i,s\rangle$ be a massless quark of flavor i and spin s, and use $\bar{u}_s(p)\gamma^\mu u_s(p) = 2p^\mu$. Since each covariant derivative in $\mathcal{O}_{q_j}$ acts on the external plane wave as multiplication by p^μ at tree level,

$$\langle p,i,s|\mathcal{O}_{q_j}^{\mu_1\cdots\mu_N}|p,i,s\rangle_{\text{tree}} = 2\delta_{ij}\big(p^{\mu_1}\cdots p^{\mu_N} - \text{traces}\big).$$

Thus a quark target has

$$a_{q_j,N}^{q_i,\text{tree}} = \delta_{ij}, \qquad a_{g,N}^{q_i,\text{tree}} = 0.$$

For a single gluon state $|p,A,\lambda\rangle$, the linearized field strength is

$$F^{\mu\nu,A}(x) = \mathrm{i}\big(p^\mu\varepsilon_\lambda^\nu - p^\nu\varepsilon_\lambda^\mu\big)\mathrm{e}^{-\mathrm{i}p\cdot x}, \qquad p\cdot\varepsilon_\lambda = 0.$$

The color- and spin-averaged partonic matrix element is

$$\frac{1}{2(N_c^2-1)}\sum_{A,\lambda}\langle p,A,\lambda|\mathcal{O}_g^{\mu_1\cdots\mu_N}|p,A,\lambda\rangle_{\text{tree}} = 2\big(p^{\mu_1}\cdots p^{\mu_N} - \text{traces}\big),$$

so

$$a_{g,N}^{g,\text{tree}} = 1, \qquad a_{q_j,N}^{g,\text{tree}} = 0.$$

Equivalently, the tree-level parton distributions are $f_{q_j/q_i}(x) = \delta_{ij}\delta(1-x)$, $f_{g/g}(x) = \delta(1-x)$, and the mixed quark-gluon distributions vanish.

Expanding the light-ray operator near zero separation gives these local operators contracted with the lightlike vector n^μ. Consequently the integer moments of the parton distributions are the same reduced matrix elements, with the precise flavor and charge-conjugation combination fixed by the current channel:

$$a_{a,N}(\mu) = \int_0^1 \mathrm{d}x\, x^{N-1} f_{a/H}(x,\mu)$$

for the corresponding parton combination. The local OPE and the nonlocal light-ray factorization are therefore two presentations of the same short-distance data.

Renormalization mixes operators with the same spin, twist, and quantum numbers. Taking integer moments of (49.314) gives

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu} a_{a,N}(\mu) = \sum_b P_{ab,N}(g(\mu))\, a_{b,N}(\mu), \qquad P_{ab,N}(g) = \int_0^1 \mathrm{d}x\, x^{N-1} P_{ab}(x,g).$$

The coefficient functions in the current OPE obey the dual evolution so that the physical structure functions are independent of the auxiliary factorization scale. This is the local-operator form of perturbative scaling violation in deep inelastic scattering.

For a spin-N leading-twist operator whose scaling dimension near the ultraviolet is

$$\Delta_N(g) = N + 2 + \tau_{1,N} g^2 + O(g^4),$$

the one-loop running

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu} \frac{1}{g^2(\mu)} = \frac{b}{2\pi^2} + O(g^2)$$

implies logarithmic scaling of its matrix element and Wilson coefficient. Equivalently, with

$$\omega := \frac{2P\cdot q}{Q^2} = \frac{1}{x_B},$$

the leading large-Q term in the N-th moment contribution has the form

$$W_N(Q,\omega) \propto \omega^N \left(\log\frac{Q}{\Lambda}\right)^{-2\pi^2\tau_{1,N}/b} \left[1 + O\!\left(\frac{1}{\log(Q/\Lambda)}\right)\right], \qquad (49.361)$$

up to the matrix of anomalous dimensions when several operators mix. The power ω^N is the Bjorken-scaling kinematic dependence of a spin-N operator; asymptotic freedom turns exact scaling into logarithmic scaling violation.

49.24 Cusped Wilson Lines, Large Spin, and the DIS Endpoint

The compact-x factorization statement in Hypothesis 49.74 deliberately does not claim uniform control as $x_B \to 1$. In that endpoint region the invariant mass of the hadronic final state,

$$W_X^2 = (P+q)^2 = M^2 + Q^2\left(\frac{1}{x_B} - 1\right),$$

is much smaller than Q^2. The short-distance coefficient functions then contain distributions supported near $x = 1$, such as $[\log^k(1-x)/(1-x)]_+$, and the perturbative expansion must be reorganized. The universal coefficient controlling the leading endpoint singularity is most cleanly defined by a cusped Wilson-line operator. This definition is an operator statement, not a parton-model picture.

Let R be a finite-dimensional unitary representation of $SU(N_c)$, with quadratic Casimir C_R in the trace-delta convention (49.1). In Euclidean signature choose two unit vectors e_1, e_2 with $e_1 \cdot e_2 = \cos\phi$, $0 < \phi < \pi$, and let $\Gamma_{\phi,L,\epsilon}$ be the two-segment path

$$x(s) = -se_1, \quad \epsilon \le s \le L, \qquad x(t) = te_2, \quad \epsilon \le t \le L,$$

joined at the origin after removing a ball of radius ϵ. The regulated cusped line is the path-ordered transporter

$$W_R(\Gamma_{\phi,L,\epsilon}) = \mathcal{P}\exp\left\{\mathrm{i}\int_{\Gamma_{\phi,L,\epsilon}} A^a_\mu(x) t^a_R \,\mathrm{d}x^\mu\right\}.$$

The straight-line endpoint and perimeter renormalizations are fixed by the same regulator applied to a smooth line. After these local smooth-line renormalizations are divided out, the remaining logarithmic singularity at the corner defines the Euclidean cusp coefficient $K_R(\phi, g)$ by

$$-\log\langle W_R(\Gamma_{\phi,L,\epsilon})\rangle_{\text{smooth}-\text{subtracted}} = K_R(\phi, g)\log\frac{L}{\epsilon} + O(1). \tag{49.362}$$

The minus sign in this definition is part of the convention: it combines with the i^2 from expanding the Wilson transporter, so that the one-loop coefficient below is read directly from the positive Euclidean propagator. For timelike Wilson lines in Lorentzian signature we instead use the positive lightlike cusp anomalous dimension

$$\Gamma^R_{\text{cusp}}(g) := \lim_{\chi\to\infty}\frac{\Gamma^R_{\text{cusp}}(\chi, g)}{\chi}, \qquad -v_1\cdot v_2 = \cosh\chi, \quad v_1^2 = v_2^2 = -1,$$

where $\Gamma^R_{\text{cusp}}(\chi, g)$ is obtained from the same local renormalization problem by the analytic continuation $\phi = \mathrm{i}\chi$. This convention is the one used in (49.244).

At one loop the angular dependence follows from a single eikonal exchange. In Feynman gauge, with the connection normalization of this chapter, the Euclidean short-distance propagator is

$$\langle A^a_\mu(x)A^b_\nu(0)\rangle = \frac{g^2\delta^{ab}\delta_{\mu\nu}}{4\pi^2 x^2} + O(g^4).$$

The exchange between the two rays contributes, up to cutoff-independent finite terms, the following scale-invariant part of $-\log\langle W_R\rangle$:

$$\frac{g^2 C_R}{4\pi^2}\int_\epsilon^L \mathrm{d}s\int_\epsilon^L \mathrm{d}t\,\frac{e_1\cdot e_2}{s^2 + t^2 + 2st\,e_1\cdot e_2}.$$

The coefficient of $\log(L/\epsilon)$ is local at the cusp, so set $t = sr$ in the scale-invariant part. The angular integral is

$$J(\phi) := \int_0^\infty \frac{\cos\phi\,\mathrm{d}r}{r^2 + 2r\cos\phi + 1} = \phi\cot\phi. \tag{49.363}$$

Indeed,

$$r^2 + 2r\cos\phi + 1 = (r + \cos\phi)^2 + \sin^2\phi,$$

and the antiderivative is

$$\cot\phi\,\arctan\frac{r+\cos\phi}{\sin\phi}.$$

Taking r from 0 to ∞ gives $\cot\phi(\pi/2-\arctan(\cot\phi))=\phi\cot\phi$, with the principal branch of arctan for $0<\phi<\pi$. A smooth straight line corresponds to $\phi=0$, for which $J(0)=1$. Therefore the corner-specific logarithm is

$$K_R^{(1)}(\phi,g)=\frac{g^2C_R}{4\pi^2}\big(\phi\cot\phi-1\big). \tag{49.364}$$

Continuing $\phi=\mathrm{i}\chi$ gives the Lorentzian timelike cusp coefficient

$$\Gamma^R_{\text{cusp}}(\chi,g)=\frac{g^2C_R}{4\pi^2}\big(\chi\coth\chi-1\big)+O(g^4),\qquad \Gamma^R_{\text{cusp}}(g)=\frac{g^2C_R}{4\pi^2}+O(g^4). \tag{49.365}$$

For $R=\Box$, this is exactly the quark coefficient in (49.244).

The same coefficient appears in the endpoint renormalization of light-ray operators. Near $x=1$, the emitted radiation is soft compared with the parent quark momentum, and the Wilson transporter in the light-ray operator is approximated by eikonal propagation along the two nearly lightlike directions selected by the incoming hadron and the hard current. The local renormalization of the resulting lightlike cusp supplies the coefficient of the plus distribution $D_0=(1-x)_+^{-1}$ in the nonsinglet kernel:

$$P_{\text{ns}}(x,g)=\Gamma^q_{\text{cusp}}(g)\,D_0(x)+\text{terms with less singular Mellin growth as } x\to 1. \tag{49.366}$$

Equation (49.366) is meant as a perturbative renormalization statement for the specified light-ray operator and subtraction scheme. It is not a nonperturbative theorem about the full endpoint region of every DIS observable; threshold factorization also requires a hard coefficient, a jet function, a soft matrix element, a rapidity prescription when appropriate, and a controlled power remainder.

The Mellin transform turns this endpoint problem into a large-spin problem. For a distribution $K(x)$, define

$$K_N:=\int_0^1 \mathrm{d}x\,x^{N-1}K(x).$$

Using the D_0 convention above, the nonsinglet one-loop kernel has the exact moment

$$P^{(0)}_{\text{ns},N}=C_F\left[-2H_{N-1}-\frac{1}{N}-\frac{1}{N+1}+\frac{3}{2}\right],\qquad N\geq 1. \tag{49.367}$$

The harmonic number appears because

$$\int_0^1\mathrm{d}x\,x^{N-1}D_0(x)=\int_0^1\mathrm{d}x\,\frac{x^{N-1}-1}{1-x}=-H_{N-1}. \tag{49.368}$$

The last equality follows by writing $(1-x^{N-1})/(1-x)=1+x+\cdots+x^{N-2}$ before integration. Thus (49.367) gives quark-number conservation at $N=1$, and at large N

$$P^{(0)}_{\text{ns},N}=-2C_F\log N+C_F\left(\frac{3}{2}-2\gamma_{\mathrm{E}}\right)+O(N^{-1}). \tag{49.369}$$

Therefore, with $P = (g^2/8\pi^2)P^{(0)} + O(g^4)$,

$$P_{\mathrm{ns},N}(g) = -\Gamma^q_{\mathrm{cusp}}(g)\log N + O(N^0), \qquad \Gamma^q_{\mathrm{cusp}}(g) = \frac{g^2 C_F}{4\pi^2} + O(g^4). \tag{49.370}$$

This is the evolution eigenvalue for matrix elements in the convention $\mu\,\mathrm{d}a_N/\mathrm{d}\mu = P_N a_N$. If instead one writes the anomalous dimension of the local twist-two operator itself by $\mu\,\mathrm{d}\mathcal{O}_N/\mathrm{d}\mu = -\gamma^{\mathcal{O}}_N\mathcal{O}_N + \cdots$, then

$$\gamma^{\mathcal{O}}_N(g) = \Gamma^q_{\mathrm{cusp}}(g)\log N + O(N^0).$$

The sign difference is bookkeeping: coefficient functions and operator matrix elements obey dual renormalization-group equations so that the physical hadronic tensor is independent of the factorization scale.

The product $g^2 C_R$ in (49.365) is invariant under generator-coordinate changes. If T^a denotes the common half-trace generator and $g_{\mathrm{ht}} = \sqrt{2}\,g$, then

$$g^2 C_F = g^2_{\mathrm{ht}} C^{\mathrm{ht}}_F.$$

The cusp coefficient is thus independent of the choice of generator coordinates once the coupling coordinate is transformed with the action.

Endpoint resummation is not a new definition of the PDF. It is an additional factorization of the coefficient function in a region where the compact-x remainder estimate is not uniform. A precise threshold factorization theorem must specify the hard current coefficient, the jet function for the nearly collinear final-state radiation, the soft Wilson-line matrix element, the contour prescription for Mellin or Laplace inversion, and a remainder estimate in the joint limit $Q \to \infty$, $N \to \infty$. The large-spin logarithm in (49.370) is the operator-renormalization side of that structure. The same Wilson-line cusp observable is the QCD analogue of the large-spin cusp scaling function studied in Chapter 98, but the logical status is different: in QCD it is a perturbative Wilson-line anomalous dimension tied to factorization hypotheses, while in planar $\mathcal{N} = 4$ super Yang–Mills the BES equation gives an integrability construction of the planar large-spin function in a special conformal theory. The small-x limit is a different boundary of the same DIS observable and is not obtained by continuing the threshold expansion.

49.25 Small-x Boundary, Dipoles, and the BFKL Kernel

The compact-x_B factorization hypothesis in Hypothesis 49.74 also does not claim uniform control as $x_B \to 0$. Put

$$Y := \log\frac{1}{x_B},$$

up to a process-dependent finite shift fixed by the chosen rapidity factorization scheme. In the high-energy boundary $Y \gg 1$, powers of $g^2 Y$ may compete with powers of g^2. The leading-logarithmic small-x expansion is therefore not a new definition of QCD and not a replacement for the hadronic tensor (49.286). It is a rapidity factorization of regulated Wilson-line matrix elements in a kinematic region where the ordinary twist-two evolution at fixed x_B is not uniform.

Let $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathbb{R}^2$ denote transverse coordinates, and set

$$r_{xy} := |\mathbf{x} - \mathbf{y}|.$$

The leading transverse kernel is

$$M_{\mathbf{xyz}} := \frac{r_{xy}^2}{r_{xz}^2 r_{zy}^2}. \tag{49.371}$$

The singularities at $\mathbf{z} = \mathbf{x}$ and $\mathbf{z} = \mathbf{y}$ are not meaningful as separate real-emission probabilities. They are defined only after the virtual subtraction in the evolution equation, or after an equivalent rapidity regulator and finite-part map have been specified.

Definition 49.86 (Regulated small-x dipole setup)**.** A small-x dipole setup for a color-singlet probe consists of:

1. a QCD regulator $\mathcal{R}_\epsilon$ preserving background gauge covariance, or a gauge-fixed BV regulator with the quantum master equation;
2. two nearly lightlike Wilson-line directions, a rapidity regulator ρ, and a finite rapidity separation Y;
3. fundamental Wilson transporters $U_{\rho,Y}(\mathbf{x})$ and $U_{\rho,Y}(\mathbf{y})$, with transverse closures or boundary conditions that make the residual endpoint gauge transformations explicit;
4. the renormalized color dipole matrix element
$$S_Y(\mathbf{x},\mathbf{y}) := \frac{1}{N_c}\Big\langle \mathrm{tr}_\square\big[U_{\rho,Y}(\mathbf{x})U_{\rho,Y}(\mathbf{y})^\dagger\big]\Big\rangle^{\mathrm{ren}}_{\epsilon,\rho,Y}, \qquad N_Y(\mathbf{x},\mathbf{y}) := 1 - S_Y(\mathbf{x},\mathbf{y}); \tag{49.372}$$
5. a finite-part prescription for ultraviolet endpoint divergences, lightlike or near-lightlike rapidity divergences, and possible cusp divergences introduced by the chosen closures.

The quantity S_Y is a Wilson-line matrix element. Its connection to a measured small-x structure function is an additional high-energy factorization statement with its own impact factor, rapidity subtraction, and power-remainder data.

At finite regulator, the trace in (49.372) is gauge invariant after the endpoint closures or boundary conditions of Definition 49.86 are included. A background gauge-covariant finite-part prescription therefore gives a gauge-invariant renormalized dipole matrix element. Each Wilson transporter transforms by multiplication with the gauge transformation at its two endpoints. Along a closed contour the adjacent endpoint factors cancel and the residual base-point factor is removed by the cyclicity of $\mathrm{tr}_\square$. If the regulated Wilson lines are represented instead as open lines ending at a rapidity boundary, the boundary condition is part of the setup and supplies the same endpoint cancellation. The finite-part map changes only regulator and scale coordinates and is assumed background gauge covariant; hence it cannot introduce an uncanceled color index.

Hypothesis 49.87 (Leading-logarithmic dipole/BFKL evolution setup)**.** In a fixed-coupling leading-logarithmic rapidity scheme, the linearized color-singlet dipole amplitude obeys

$$\partial_Y N_Y(\mathbf{x},\mathbf{y}) = \frac{g^2 C_A}{8\pi^3}\int_{\mathbb{R}^2} \mathrm{d}^2\mathbf{z}\, M_{\mathbf{xyz}}\big[N_Y(\mathbf{x},\mathbf{z}) + N_Y(\mathbf{z},\mathbf{y}) - N_Y(\mathbf{x},\mathbf{y})\big], \tag{49.373}$$

where $C_A = 2N_c$ in the trace convention of (49.1). Equivalently, with

$$\bar{\alpha}_{\mathrm{s}} := \frac{g^2 C_A}{4\pi^2} = \frac{g^2 N_c}{2\pi^2},$$

the right-hand side is

$$\bar{\alpha}_{\mathrm{s}} \frac{1}{2\pi} \int \mathrm{d}^2\mathbf{z}\, M_{\mathbf{xyz}}[\cdots].$$

In the common half-trace convention, $g_{\mathrm{ht}}^2 = 2g^2$ and $C_A^{\mathrm{ht}} = N_c$, so the product $g^2 C_A = g_{\mathrm{ht}}^2 C_A^{\mathrm{ht}}$ and the kernel coefficient are unchanged.

For a large-N_c dipole-factorization truncation of the Balitsky hierarchy, the corresponding non-linear equation for $N_Y = 1 - S_Y$ has the additional term

$$-\frac{g^2 C_A}{8\pi^3} \int \mathrm{d}^2\mathbf{z}\, M_{\mathbf{xyz}}\, N_Y(\mathbf{x},\mathbf{z}) N_Y(\mathbf{z},\mathbf{y}). \tag{49.374}$$

At finite N_c, the exact Wilson-line rapidity hierarchy contains higher multi-trace operators; replacing them by the product in (49.374) is an additional closure assumption, not a theorem about continuum QCD.

49.25.1 Finite Wilson-Line Evolution and the JIMWLK Theorem Boundary

The preceding dipole equation is a closed equation only after a truncation has been chosen. The more invariant small-x object is the rapidity evolution of the whole algebra generated by Wilson lines. To state the mathematical content without importing the usual folklore terminology, first put the Wilson-line variables on a finite transverse regulator.

Definition 49.88 (Finite Wilson-line rapidity-evolution generator)**.** Let $\Lambda_\perp$ be a finite set of transverse sites and let

$$\mathcal{C}_{\Lambda_\perp} := SU(N_c)^{\Lambda_\perp} \tag{49.375}$$

with product Haar measure $\mathrm{d}h(U)$. For $\mathbf{x} \in \Lambda_\perp$ and Lie-algebra index a, let $L_{\mathbf{x}}^a$ be the left-invariant vector field

$$(L_{\mathbf{x}}^a F)(U) := \frac{\mathrm{d}}{\mathrm{d}t} F(\ldots, \mathrm{e}^{\mathrm{i}tt^a} U_{\mathbf{x}}, \ldots)\Big|_{t=0}, \tag{49.376}$$

where the generators obey the trace convention of (49.1). A finite Wilson-line rapidity-evolution structure consists of a family of smooth coefficients

$$\mathcal{A}_{\mathbf{xy}}^{ab}(U;Y) = \mathcal{A}_{\mathbf{yx}}^{ba}(U;Y)$$

whose finite matrix $(\mathcal{A}_{\mathbf{xy}}^{ab})$ is nonnegative at each (U,Y), is equivariant under residual global color conjugation, and is defined in the same rapidity and ultraviolet regulator scheme as the Wilson lines. The corresponding finite Wilson-line generator is the second-order operator

$$(\mathcal{H}_Y F)(U) := \frac{1}{2} \sum_{\mathbf{x},\mathbf{y} \in \Lambda_\perp} \sum_{a,b} L_{\mathbf{x}}^a \left[\mathcal{A}_{\mathbf{xy}}^{ab}(U;Y) L_{\mathbf{y}}^b F(U) \right]. \tag{49.377}$$

This finite generator is a finite-regulator replacement for the JIMWLK Hamiltonian only after the coefficient $\mathcal{A}$ has been derived from a specified QCD rapidity factorization scheme.

The finite object has two equivalent presentations. In the weak, or observable, presentation a rapidity-dependent state $W_Y \mathrm{d}h$ on $\mathcal{C}_{\Lambda_\perp}$ obeys

$$\frac{\mathrm{d}}{\mathrm{d}Y} \int_{\mathcal{C}_{\Lambda_\perp}} F(U)\, W_Y(U)\, \mathrm{d}h(U) = \int_{\mathcal{C}_{\Lambda_\perp}} (\mathcal{H}_Y F)(U)\, W_Y(U)\, \mathrm{d}h(U) \tag{49.378}$$

for every smooth gauge-invariant Wilson-line observable F. In the strong, or density, presentation

$$\partial_Y W_Y = \mathcal{H}_Y^* W_Y, \qquad \mathcal{H}_Y^* w = \frac{1}{2} \sum_{\mathbf{x},\mathbf{y},a,b} L_{\mathbf{y}}^b \left[\mathcal{A}_{\mathbf{xy}}^{ab}(U;Y) L_{\mathbf{x}}^a w \right], \tag{49.379}$$

where the adjoint is taken with respect to product Haar measure. The two forms are identical by integration by parts on the compact Lie group:

$$\int (L_{\mathbf{x}}^a F) G \, \mathrm{d}h = - \int F (L_{\mathbf{x}}^a G) \, \mathrm{d}h.$$

Applying this identity twice to (49.377) gives (49.379). Since $\mathcal{H}_Y 1 = 0$, the total mass $\int W_Y \mathrm{d}h$ is conserved. Since the coefficient matrix is nonnegative, the principal symbol is that of a diffusion on the compact manifold. When the closure of $\mathcal{H}_Y$ on continuous functions satisfies the positive maximum principle, the Hille–Yosida theorem gives the corresponding Markov semigroup. This semigroup assertion belongs to ordinary finite-dimensional diffusion analysis; the QCD-specific work is the derivation and limiting control of $\mathcal{A}$. These are finite statements about $\mathcal{C}_{\Lambda_\perp}$, not continuum QCD theorems.

For the dipole observable

$$F_{\mathbf{xy}}(U) := \frac{1}{N_c} \operatorname{tr}_\square (U_{\mathbf{x}} U_{\mathbf{y}}^\dagger), \tag{49.380}$$

the weak equation (49.378) generates the first equation of the Balitsky hierarchy. The right-hand side contains Wilson-line observables with more transverse labels. A closed BK equation is obtained only after large-N_c, mean-field, or other factorization input has replaced those higher observables by products of dipoles. Thus the logical chain is

$$\text{finite Wilson-line diffusion} \longrightarrow \text{Balitsky hierarchy} \longrightarrow \text{BK closure under extra hypotheses,}$$

not a direct theorem from the BFKL eigenvalue calculation.

Dipole projection and the BK closure boundary. The first arrow in the preceding display is an operator statement on the finite Wilson-line algebra; the second arrow is a closure operation on a subsystem of expectation values. It is useful to write this subsystem before passing to the continuum transverse plane. Fix a finite transverse set $\Lambda_\perp$ and nonnegative cell weights $\omega_{\mathbf{xy};\mathbf{z}}(Y)$, symmetric under $\mathbf{x} \leftrightarrow \mathbf{y}$, which represent the regulated cell-integrals of the leading dipole kernel in the same rapidity scheme as $\mathcal{H}_Y$. For distinct transverse labels set

$$S_{\mathbf{xy}}^{(1)}(Y) := \langle F_{\mathbf{xy}} \rangle_Y, \qquad S_{\mathbf{xz};\mathbf{zy}}^{(2)}(Y) := \langle F_{\mathbf{xz}} F_{\mathbf{zy}} \rangle_Y,$$

where the expectation is the weak Wilson-line state in (49.378). A finite leading-logarithmic dipole projection is the assertion that

$$\partial_Y S_{\mathbf{xy}}^{(1)} = \sum_{\mathbf{z} \in \Lambda_\perp \setminus \{\mathbf{x},\mathbf{y}\}} \omega_{\mathbf{xy};\mathbf{z}} \left(S_{\mathbf{xz};\mathbf{zy}}^{(2)} - S_{\mathbf{xy}}^{(1)} \right). \tag{49.381}$$

Equation (49.381) is not a closed equation for $S^{(1)}$. Its new variable is the double-dipole expectation $S^{(2)}$, whose rapidity derivative involves still higher Wilson-line observables. This is the finite-regulator form of the Balitsky hierarchy.

The BK reduction is a controlled approximation only if one supplies a decorrelation estimate for the connected double-dipole coordinate

$$C_{\mathbf{xz};\mathbf{zy}}(Y) := S^{(2)}_{\mathbf{xz};\mathbf{zy}}(Y) - S^{(1)}_{\mathbf{xz}}(Y)S^{(1)}_{\mathbf{zy}}(Y).$$

With

$$E^{\mathrm{BK}}_{\mathbf{xy}}(Y) := \sum_{\mathbf{z}\neq\mathbf{x},\mathbf{y}} \omega_{\mathbf{xy};\mathbf{z}}(Y)\, C_{\mathbf{xz};\mathbf{zy}}(Y), \tag{49.382}$$

the exact first dipole equation is

$$\partial_Y S^{(1)}_{\mathbf{xy}} = \sum_{\mathbf{z}\neq\mathbf{x},\mathbf{y}} \omega_{\mathbf{xy};\mathbf{z}} \left(S^{(1)}_{\mathbf{xz}}S^{(1)}_{\mathbf{zy}} - S^{(1)}_{\mathbf{xy}}\right) + E^{\mathrm{BK}}_{\mathbf{xy}}.$$

Thus the phrase "large-N_c BK equation" means that a separate argument has made E^{BK} negligible in the norm and rapidity interval under discussion. In the amplitude variable $N^{(1)}_{\mathbf{xy}} = 1 - S^{(1)}_{\mathbf{xy}}$, the closed finite BK equation obtained by setting $E^{\mathrm{BK}} = 0$ is

$$\partial_Y N_{\mathbf{xy}} = \sum_{\mathbf{z}\neq\mathbf{x},\mathbf{y}} \omega_{\mathbf{xy};\mathbf{z}} \left(N_{\mathbf{xz}} + N_{\mathbf{zy}} - N_{\mathbf{xy}} - N_{\mathbf{xz}}N_{\mathbf{zy}}\right). \tag{49.383}$$

This is the finite-cell version of (49.373) plus (49.374).

The finite error estimate is elementary but important. Suppose a real mean-field solution $\widetilde{S}_{\mathbf{xy}}$ and the exact first coordinates $S^{(1)}_{\mathbf{xy}}$ both take values in $[0,1]$ on a rapidity interval $0 \le Y \le Y_*$, share the same initial data, and have

$$L := \sup_{Y\le Y_*}\sup_{\mathbf{x}\neq\mathbf{y}} \sum_{\mathbf{z}\neq\mathbf{x},\mathbf{y}} \omega_{\mathbf{xy};\mathbf{z}}(Y) < \infty, \qquad \varepsilon(Y) := \sup_{\mathbf{x}\neq\mathbf{y}} |E^{\mathrm{BK}}_{\mathbf{xy}}(Y)|.$$

Writing

$$d(Y) := \sup_{\mathbf{x}\neq\mathbf{y}} |S^{(1)}_{\mathbf{xy}}(Y) - \widetilde{S}_{\mathbf{xy}}(Y)|,$$

one obtains

$$d(Y) \le \int_0^Y \mathrm{e}^{3L(Y-s)}\varepsilon(s)\,\mathrm{d}s. \tag{49.384}$$

Indeed, on the unit interval $|ab - a'b'| \le |a-a'| + |b-b'|$, so the product term contributes at most $2Ld(Y)$, the virtual term at most $Ld(Y)$, and the connected covariance term contributes $\varepsilon(Y)$; Gronwall gives (49.384). The closed BK vector field also points into the unit cube: at $S_{\mathbf{xy}} = 0$ its right-hand side is nonnegative, while at $S_{\mathbf{xy}} = 1$ it is nonpositive. This finite ODE fact explains the black-disk and transparent fixed points of the closed approximation. It does not replace the missing QCD estimate on E^{BK}, nor the continuum limit of the cell weights.

The continuum JIMWLK problem is the removal of the finite transverse regulator and rapidity regulator from this finite compact-manifold construction while keeping the Wilson-line observables, the coefficient kernel, and the factorization map to the measured process in a topology strong enough to pass to the limit in (49.378). The monograph therefore treats the color-glass weight functional as a renormalized Wilson-line state, not as a literal probability measure on classical gluon fields unless such a measure has been constructed in the chosen regulator.

Projective continuum limit for Wilson-line states. A continuum statement of JIMWLK must be stronger than a sequence of finite Balitsky equations. Let $\{\Lambda_\perp^{(m)}\}_{m\in I}$ be a directed family of finite transverse regulators and let $\mathcal{A}_m = C^\infty(SU(N_c)^{\Lambda_\perp^{(m)}})^{G_{\mathrm{diag}}}$ be the gauge-invariant Wilson-line algebra on the m-th regulator. A cylinder observable F depends on a fixed finite list of transverse labels; for all sufficiently fine regulators it has a representative $F_m \in \mathcal{A}_m$. A projective Wilson-line state limit on $[0, Y_*]$ consists of

$$\big(\omega_{m,Y}, \mathcal{H}_{m,Y}, F \mapsto F_m, \omega_Y, \mathcal{H}_Y^{\mathrm{cyl}}, \mathcal{I}_Y\big)$$

with the following data. First, the finite states are compatible on cylinder observables:

$$\sup_{0\le Y\le Y_*} |\omega_{m,Y}(F_m) - \omega_Y(F)| \le \delta_{m,F}, \qquad \delta_{m,F} \longrightarrow 0. \tag{49.385}$$

Second, the finite generators converge on the same cylinder test:

$$\sup_{0\le Y\le Y_*} \|\mathcal{H}_{m,Y} F_m - (\mathcal{H}_Y^{\mathrm{cyl}} F)_m\|_\infty \le \varepsilon_{m,F}, \qquad \varepsilon_{m,F} \longrightarrow 0. \tag{49.386}$$

Third, the rapidity dependence is uniformly controlled on cylinder tests, so the finite weak equations are equicontinuous in Y and limits may be passed through rapidity integrals. Fourth, positivity, normalization, and the positive-maximum-principle/Markov property hold at finite m and are closed under the cylinder limit. Fifth, $\mathcal{I}_Y$ is the process map: it turns the Wilson-line state into the measured small-x observable with the chosen impact factors, subtractions, and power-remainder topology.

Under these hypotheses the finite weak equation has a genuine cylinder limit. Indeed, for $Y_0 < Y_1$,

$$\omega_{m,Y_1}(F_m) - \omega_{m,Y_0}(F_m) = \int_{Y_0}^{Y_1} \omega_{m,s}(\mathcal{H}_{m,s} F_m)\, \mathrm{d}s.$$

After adding and subtracting the limiting terms one obtains the error ledger

$$\begin{aligned} &\left|\omega_{Y_1}(F) - \omega_{Y_0}(F) - \int_{Y_0}^{Y_1} \omega_s(\mathcal{H}_s^{\mathrm{cyl}} F)\, \mathrm{d}s\right| \\ &\qquad \le 2\delta_{m,F} + \int_{Y_0}^{Y_1} \big(\delta_{m,\mathcal{H}^{\mathrm{cyl}} F}(s) + \varepsilon_{m,F}(s)\big)\, \mathrm{d}s, \end{aligned} \tag{49.387}$$

where the right-hand side is written with the corresponding uniform or integrable bound on the state error for the generator observable when the errors depend on s. Letting $m \to \infty$ gives the continuum weak equation on the cylinder algebra,

$$\omega_{Y_1}(F) - \omega_{Y_0}(F) = \int_{Y_0}^{Y_1} \omega_s(\mathcal{H}_s^{\mathrm{cyl}} F)\, \mathrm{d}s.$$

If $Y \mapsto \omega_Y(F)$ is absolutely continuous, this is the differential weak JIMWLK equation for cylinder observables. The BK closure estimate above controls one projected dipole subsystem and one connected covariance coordinate; it does not supply (49.385), (49.386), or the process map. Thus continuum JIMWLK is a projective theorem about Wilson-line states and QCD factorization; the formal functional Hamiltonian names only the candidate cylinder generator.

Conformal covariance of the transverse kernel. The measure

$$\mathrm{d}^2\mathbf{z}\, M_{\mathbf{xyz}}$$

is invariant under translations, rotations, uniform scalings, and inversion $\mathbf{u} \mapsto \mathbf{u}/|\mathbf{u}|^2$, whenever the transformed points avoid the inversion center. Thus the leading fixed-coupling transverse kernel is covariant under the real Mobius transformations generated by these maps.

Translations and rotations preserve all distances and $\mathrm{d}^2\mathbf{z}$. Under the scaling $\mathbf{u} \mapsto \lambda\mathbf{u}$, the kernel $M_{\mathbf{xyz}}$ scales as λ^{-2}, while $\mathrm{d}^2\mathbf{z}$ scales as λ^2.

For inversion, write $\mathbf{u}' = \mathbf{u}/|\mathbf{u}|^2$. The Euclidean distance and area element transform as

$$|\mathbf{u}' - \mathbf{v}'|^2 = \frac{|\mathbf{u} - \mathbf{v}|^2}{|\mathbf{u}|^2|\mathbf{v}|^2}, \qquad \mathrm{d}^2\mathbf{z}' = \frac{\mathrm{d}^2\mathbf{z}}{|\mathbf{z}|^4}.$$

Substituting these identities gives

$$M_{\mathbf{x}'\mathbf{y}'\mathbf{z}'}\,\mathrm{d}^2\mathbf{z}' = \frac{r_{xy}^2/(|\mathbf{x}|^2|\mathbf{y}|^2)}{r_{xz}^2/(|\mathbf{x}|^2|\mathbf{z}|^2)\, r_{zy}^2/(|\mathbf{z}|^2|\mathbf{y}|^2)} \frac{\mathrm{d}^2\mathbf{z}}{|\mathbf{z}|^4} = M_{\mathbf{xyz}}\,\mathrm{d}^2\mathbf{z}.$$

This proves the stated covariance.

Proposition 49.89 (Mellin eigenvalue of the leading BFKL kernel)**.** *Let* $0 < \operatorname{Re}\gamma < 1$. *For the power*

$$f_\gamma(\mathbf{x}, \mathbf{y}) = \left(\mu_\perp^2 r_{xy}^2\right)^\gamma,$$

define the subtracted transverse integral by analytic regularization as in the proof below. Then

$$\frac{1}{2\pi}\int_{\mathbb{R}^2} \mathrm{d}^2\mathbf{z}\, M_{\mathbf{xyz}}\big[f_\gamma(\mathbf{x}, \mathbf{z}) + f_\gamma(\mathbf{z}, \mathbf{y}) - f_\gamma(\mathbf{x}, \mathbf{y})\big] = \chi(\gamma) f_\gamma(\mathbf{x}, \mathbf{y}), \tag{49.388}$$

where

$$\chi(\gamma) = 2\psi(1) - \psi(\gamma) - \psi(1-\gamma), \qquad \psi(u) := \frac{\mathrm{d}}{\mathrm{d}u}\log\Gamma(u). \tag{49.389}$$

Proof. By translation and scaling it suffices to set $\mathbf{y} = 0$, $r_{xy} = 1$, and $\mu_\perp = 1$. The singular terms in the three brackets are regulated in $d = 2 - 2\epsilon$ transverse dimensions. The Euclidean beta integral

$$\int \mathrm{d}^d\mathbf{z}\, \frac{1}{(\mathbf{z}^2)^a((\mathbf{z} - \mathbf{x})^2)^b} = \pi^{d/2} \frac{\Gamma(d/2 - a)\Gamma(d/2 - b)\Gamma(a + b - d/2)}{\Gamma(a)\Gamma(b)\Gamma(d - a - b)} (\mathbf{x}^2)^{d/2 - a - b} \tag{49.390}$$

is first valid in its convergence domain and then analytically continued. Applying (49.390) to the three pieces gives

$$J_\epsilon(\gamma) = \pi^{1-\epsilon} \frac{\Gamma(\gamma - \epsilon)\Gamma(-\epsilon)\Gamma(1 - \gamma + \epsilon)}{\Gamma(1-\gamma)\Gamma(\gamma - 2\epsilon)},$$

$$J_\epsilon(1-\gamma) = \pi^{1-\epsilon} \frac{\Gamma(1 - \gamma - \epsilon)\Gamma(-\epsilon)\Gamma(\gamma + \epsilon)}{\Gamma(\gamma)\Gamma(1 - \gamma - 2\epsilon)},$$

$$J_\epsilon(0) = \pi^{1-\epsilon} \frac{\Gamma(-\epsilon)^2\Gamma(1+\epsilon)}{\Gamma(-2\epsilon)}.$$

The regulated subtracted integral is

$$J_\epsilon(\gamma) + J_\epsilon(1-\gamma) - J_\epsilon(0).$$

Using

$$\Gamma(u+\delta) = \Gamma(u)\big(1 + \delta\psi(u) + O(\delta^2)\big)$$

and the corresponding expansion at the pole $u = 0$, the $1/\epsilon$ terms cancel and the finite part is

$$2\pi\,[2\psi(1) - \psi(\gamma) - \psi(1-\gamma)].$$

Dividing by 2π proves (49.388). □

The leading fixed-coupling kernel in (49.373) has

$$\chi\left(\frac{1}{2}\right) = 4\log 2, \qquad \chi\left(\frac{1}{2} + \mathrm{i}\nu\right) = 4\log 2 - 14\zeta(3)\nu^2 + O(\nu^4).$$

These values follow from

$$\psi\left(\frac{1}{2}\right) = -\gamma_{\mathrm{E}} - 2\log 2, \qquad \psi''\left(\frac{1}{2}\right) = -14\zeta(3),$$

inserted into (49.389); in particular $\chi'(\frac{1}{2}) = 0$ and $\chi''(\frac{1}{2}) = 28\zeta(3)$. A Mellin component near $\gamma = \frac{1}{2}$ therefore evolves as

$$\exp\big[\bar{\alpha}_{\mathrm{s}}\,4\log 2\,Y - \bar{\alpha}_{\mathrm{s}}\,14\zeta(3)\nu^2 Y + O(\bar{\alpha}_{\mathrm{s}}\nu^4 Y)\big]$$

inside the fixed-coupling leading-logarithmic setup.

Controlled Approximation 49.90 (Status of small-x resummation)**.** A small-x resummation used for a QCD observable must state: the regulated Wilson-line operator being evolved; the rapidity variable and subtraction scheme; the impact factor connecting the Wilson-line matrix element to the measured process; whether running coupling, energy-scale, collinear-improvement, saturation, or finite-N_c hierarchy effects are included; and the topology of the remainder estimate. The BFKL kernel in Proposition 49.89 is a theorem about the leading transverse integral. Its physical use in high-energy hadron scattering additionally requires the Wilson-line operator definition, impact factor, rapidity-factorization scheme, and unitarization or saturation framework appropriate to the observable.

Chapter 50

Jets, Infrared-Safe Observables, and Hadronization

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Jets enter quantum field theory as observables built from the energy and momentum deposited by physical final states. The final states in QCD are hadronic states in the physical Hilbert space; quarks and gluons are short-distance variables used inside a gauge-fixed or factorized calculation. The mathematical question is therefore not how to assign reality to colored partons, but when a measurement on physical final states admits a controlled short-distance expansion in which partonic variables are legitimate internal coordinates.

50.1 Weighted Cross Sections and Measurement Functions

Let $|i\rangle$ be an incoming scattering state and let X range over a complete family of outgoing physical states. A detector observable is a measurable function $F(X)$ of the final state. Its weighted inclusive cross section has the form

$$\sigma[F] = \frac{1}{\mathcal{N}_i} \sum_X (2\pi)^D \delta^{(D)}(P_i - P_X) |\langle X|T|i\rangle|^2 \, F(X), \tag{50.1}$$

where $\mathcal{N}_i$ is the incoming flux normalization and T is the transition operator defined by $S = \mathbf{1} + \mathrm{i}T$. Equation (50.1) is stated in terms of physical states. A perturbative partonic formula is a further expansion of the same quantity, after an infrared regulator and an ultraviolet renormalization scheme have been chosen:

$$\sigma_{\text{part}}[F] = \sum_{n \geq 0} \int \mathrm{d}\Phi_n \, |\mathcal{M}_n(p_1, \ldots, p_n)|^2 \, F_n(p_1, \ldots, p_n). \tag{50.2}$$

Here $\mathrm{d}\Phi_n$ is the n-body Lorentz-invariant phase-space measure, $\mathcal{M}_n$ is a renormalized partonic matrix element, and F_n is the partonic representative of the detector measurement. The functions F_n must satisfy compatibility conditions at the boundaries of phase space where a parton becomes soft or two partons become collinear.

Definition 50.1 (Infrared and collinear safety)**.** A family of measurement functions $F = \{F_n\}_{n \geq 0}$ is infrared and collinear safe, abbreviated IRC safe, if the following limits hold on the phase-space regions relevant to the observable:

$$\lim_{\lambda \downarrow 0} F_{n+1}(p_1, \ldots, p_n, \lambda q) = F_n(p_1, \ldots, p_n), \tag{50.3}$$

$$\lim_{\theta \downarrow 0} F_{n+1}(p_1, \ldots, zp, (1-z)p, \ldots, p_n) = F_n(p_1, \ldots, p, \ldots, p_n), \qquad 0 < z < 1. \tag{50.4}$$

The convergence is required with enough uniformity that the difference between the two sides is integrable against the soft and collinear factorization kernels of the theory at the perturbative order under consideration. Equivalently, near a single unresolved boundary and away from other unresolved boundaries, there must be constants $C, \alpha > 0$, depending on the compact set of resolved momenta but not on the unresolved scale, such that

$$|F_{n+1}(p_1, \ldots, p_n, \lambda q) - F_n(p_1, \ldots, p_n)| \leq C\lambda^\alpha, \tag{50.5}$$

$$|F_{n+1}(p_1, \ldots, zp, (1-z)p, \ldots, p_n) - F_n(p_1, \ldots, p, \ldots, p_n)| \leq C\theta^\alpha, \tag{50.6}$$

where θ is the splitting angle. On corners where several emissions are unresolved, the same estimate is required after replacing each unresolved cluster by its reduced soft or collinear configuration. These estimates make the products with $\mathrm{d}\lambda/\lambda$ and $\mathrm{d}\theta^2/\theta^2$ locally integrable after the real–virtual subtraction.

Controlled Approximation 50.2 (Fixed-order cancellation for IRC-safe measurements)**.** Consider an inclusive observable in a massless gauge theory for which the renormalized real and virtual matrix elements admit the soft and collinear boundary factorizations displayed below, with remainders locally integrable after subtracting the reduced lower-multiplicity channel. If the measurement family F is IRC safe in the sense of Definition 50.1, then real-emission singularities and virtual singularities cancel locally on the unresolved phase-space boundaries after the KLN sum over degenerate final states. With incoming hadrons, the remaining initial-state collinear singularities are absorbed into the renormalized parton distribution functions.

The derivation is a fixed-order perturbative one and uses the displayed factorization formulae as input. It is not a nonperturbative theorem about arbitrary jet measurements. In a soft region, with an extra gluon momentum $k = \lambda q$, the real matrix element factorizes as

$$|\mathcal{M}_{n+1}|^2 \, \mathrm{d}\Phi_{n+1} = |\mathcal{M}_n|^2 \, \mathrm{d}\Phi_n \left[\sum_{i,j} \mathcal{S}_{ij}(q) \right] \frac{\mathrm{d}\lambda}{\lambda} \mathrm{d}\Omega_q + R_{\text{soft}}.$$

The remainder R_{soft} is locally integrable by the hypothesis of the controlled approximation. The eikonal factor $\mathcal{S}_{ij}$ is the same factor that appears with opposite sign in the virtual soft correction to the n-parton channel. Equation (50.3) replaces the real measurement by F_n on the singular part of the integral, so the real and virtual soft integrals have the same weight and cancel.

In a final-state collinear region, two momenta approach

$$p_a = zp + r, \qquad p_b = (1-z)p - r, \qquad r_\perp^2 \to 0.$$

The real matrix element and phase space factorize as

$$|\mathcal{M}_{n+1}|^2 \, \mathrm{d}\Phi_{n+1} = |\mathcal{M}_n(\ldots, p, \ldots)|^2 \, \mathrm{d}\Phi_n \, \frac{\alpha_s}{2\pi} P_{ab\leftarrow c}(z) \frac{\mathrm{d}r_\perp^2}{r_\perp^2} \mathrm{d}z + R_{\text{coll}}.$$

The remainder R_{coll} is locally integrable by the hypothesis of the controlled approximation. Equation (50.4) gives the same measurement weight to the unresolved pair and to its parent momentum. The singular integral then cancels against the corresponding virtual collinear correction in the KLN sum. If the collinear parton is in the initial state of a hadron collision, the same factorization kernel multiplies the operator renormalization of the parton distribution function rather than canceling inside the hard partonic subprocess. The finite hard coefficient is obtained after this mass factorization step.

Examples of IRC-safe observables include the total e^+e^- hadronic cross section, thrust

$$T(X) = \max_{\widehat{n}} \frac{\sum_{h\in X} |\vec{p}_h \cdot \widehat{n}|}{\sum_{h\in X} |\vec{p}_h|},$$

the C-parameter, jet masses defined with an IRC-safe algorithm, and the energy correlators of Chapter 49. Observables that measure an identified hadron, a charged-particle multiplicity, or a single unsummed collinear fragment require additional nonperturbative input such as fragmentation functions or detector-specific response functions.

50.2 Sterman–Weinberg Jets

The original two-jet observable of Sterman and Weinberg is a clean example of the preceding definition. In e^+e^- annihilation at center-of-mass energy Q, choose two parameters

$$0 < \epsilon_{\text{out}} < 1, \qquad 0 < \delta_{\text{cone}} < \pi.$$

An event is counted as a two-jet event if there exist two cones of half-angle δ_{cone} such that the total energy outside the two cones is at most $\epsilon_{\text{out}} Q$. The corresponding measurement function is

$$F_{\text{SW}}(X) = \begin{cases} 1, & \text{if } X \text{ satisfies the two-cone energy condition,} \\ 0, & \text{otherwise.} \end{cases}$$

Soft safety follows because adding a particle of energy λQ changes the out-of-cone energy by at most λQ. Away from the boundary where the out-of-cone energy is exactly $\epsilon_{\text{out}} Q$, the classification is unchanged for sufficiently small λ. The boundary has zero measure in the phase-space integral, and the unresolved soft singularity is integrated with the same measurement weight as the event without the soft particle.

Collinear safety follows because a sufficiently collinear splitting of a momentum inside one of the cones remains inside the same cone, while a splitting outside the cones preserves the total out-of-cone energy in the collinear limit. The singular collinear phase-space integral therefore sees the parent momentum measurement.

For very small $\epsilon_{\rm out}$ and $\delta_{\rm cone}$, the fixed-order series contains logarithms such as

$$\alpha_s^m \log^r \epsilon_{\rm out} \log^s \delta_{\rm cone}, \qquad r+s \le 2m.$$

The two-jet cross section is then still an IRC-safe observable, but the useful short-distance expansion is a resummed expansion rather than a fixed-order polynomial in $\alpha_s(Q)$.

50.3 Sequential Recombination Jet Algorithms

Modern collider jet definitions are usually algorithmic. For a hadron collider, let p_{Ti} be transverse momentum, y_i rapidity, and ϕ_i azimuth. Define

$$\Delta R_{ij}^2 = (y_i - y_j)^2 + (\phi_i - \phi_j)^2.$$

The generalized k_T family with radius R and exponent p uses

$$d_{ij} = \min(p_{Ti}^{2p}, p_{Tj}^{2p}) \frac{\Delta R_{ij}^2}{R^2}, \qquad d_{iB} = p_{Ti}^{2p}. \tag{50.7}$$

At each step the smallest number among all d_{ij} and d_{iB} is selected. If it is d_{ij}, the two objects are recombined, usually by adding their four-momenta. If it is d_{iB}, object i is declared a jet and removed from the list. The cases

$$p = 1, \qquad p = 0, \qquad p = -1$$

give the k_T, Cambridge–Aachen, and anti-k_T algorithms, respectively.

Figure 50.1 shows the geometry behind (50.7). The same rapidity–azimuth event can produce a circular hard catchment region for anti-k_T, while the k_T metric permits soft constituents to precluster and therefore gives a catchment boundary controlled by soft radiation.

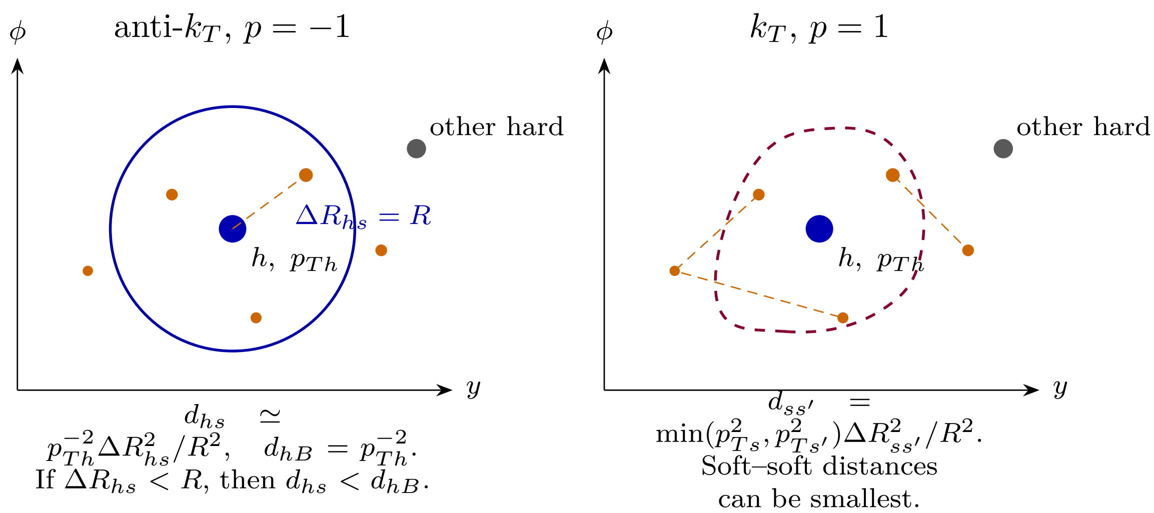

Figure 50.1: Generalized k_T clustering in the rapidity–azimuth plane. For anti-k_T, a soft constituent inside $\Delta R < R$ clusters with the hard particle before the hard particle reaches the beam distance, producing an approximately circular hard catchment region. For k_T, soft–soft distances may be smallest, so soft preclusters can control the eventual jet boundary even for the same event.

For $p = 1, 0, -1$, the generalized k_T clustering algorithm with four-momentum recombination defines IRC-safe jet momenta and IRC-safe cross sections after imposing a finite jet transverse-momentum threshold. For a collinear splitting $p \to zp, (1-z)p$, the angular distance satisfies $\Delta R_{ab} \to 0$, so $d_{ab} \to 0$. The two collinear objects are therefore recombined before they can affect finite-angle clustering, and four-momentum recombination restores the parent momentum.

For a soft momentum q, the effect of recombination with a hard object changes the hard jet momentum by $O(q)$. If the soft object is clustered among other soft objects or declared as a separate jet, a finite jet transverse-momentum threshold removes it in the soft limit. In the anti-k_T case, a soft object within radius R of a hard jet has pair distance controlled by the hard transverse momentum, so it is pulled into the hard jet without moving the hard boundary at leading power. The k_T and Cambridge–Aachen cases may cluster soft radiation differently, but the resulting change of any finite-energy jet momentum vanishes with the soft energy. Thus the measurement functions associated with the algorithm obey (50.3) and (50.4).

The anti-k_T algorithm is widely used because hard jets acquire stable, approximately circular catchment areas in the rapidity–azimuth plane while retaining IRC safety. Cone algorithms require more care. A seedless infrared-safe cone algorithm can be defined by searching over all stable cones. A seed-based cone algorithm with a transverse-momentum seed threshold can fail soft safety: adding an arbitrarily soft seed may create a stable cone that was absent before, changing the hard jets by a finite amount.

50.4 Factorization and Resummation

IRC safety makes fixed-order perturbation theory finite, but it does not make every region of the observable distribution well approximated by a few fixed orders. When an event shape $e(X)$

is small, the final state is constrained to contain narrow energetic jets plus soft radiation. A factorized description separates the scales, but the separation is not a statement that the exact QCD Hilbert space has literally split into independent colored subspaces. It is a statement about a controlled expansion of a gauge-invariant weighted cross section in which the short-distance coefficient and the long-distance matrix elements are separately defined after a regulator, an overlap-subtraction prescription, and a renormalization scheme are chosen.

For a two-jet event shape in e^+e^-, a leading singular factorized form has the convolution form

$$\frac{\mathrm{d}\sigma}{\mathrm{d}e} = H(Q,\mu)\int \mathrm{d}s_1\,\mathrm{d}s_2\,\mathrm{d}k\,J(s_1,\mu)J(s_2,\mu)S(k,\mu)\,\delta\!\left(e - \frac{s_1+s_2}{Q^2} - \frac{k}{Q}\right) + O(e^0). \tag{50.8}$$

The displayed $O(e^0)$ denotes terms that are nonsingular as distributions at the two-jet endpoint; it is not an error estimate until the observable, test function, and endpoint scaling region have been specified. The hard function H is the squared Wilson coefficient of the QCD current matched onto an effective current. The jet functions J are regulated collinear matrix elements of gauge-invariant collinear fields. The soft function S is a regulated vacuum matrix element of soft Wilson lines with the soft measurement operator inserted. Their renormalization-group equations resum logarithms of the separated scales.

Soft-collinear effective theory gives a systematic operator language for factorizations of the form (50.8). Its assumptions are visible in the operator definitions: mode scaling, Wilson-line decoupling at leading power, measurement factorization, and a power expansion in the small event-shape parameter. The same logic applies to hadron-collider observables, with the additional parton distribution functions needed for incoming hadrons and with factorization-breaking channels treated as separate hypotheses.

50.4.1 Mode Expansion and Logarithmic Accuracy

For a two-jet observable with small dimensionless event shape e, choose lightlike vectors $n, \bar{n}$ with $n \cdot \bar{n} = 2$ and write momenta as

$$p^\mu = \frac{n\cdot p}{2}\bar{n}^\mu + \frac{\bar{n}\cdot p}{2}n^\mu + p_\perp^\mu.$$

The SCET expansion parameter λ is fixed by the measured region. A mode is not an exact particle species; it is a coordinate chart on momentum regions, implemented in a regulator by smooth cutoffs or by an equivalent subtraction prescription. For thrust-like two-jet kinematics, $e \sim \lambda^2$, and the momentum scalings are

$$p_n^\mu \sim Q(\lambda^2, 1, \lambda), \qquad p_{\bar{n}}^\mu \sim Q(1, \lambda^2, \lambda), \qquad p_s^\mu \sim Q(\lambda^2, \lambda^2, \lambda^2),$$

where the three entries denote $(n\cdot p, \bar{n}\cdot p, p_\perp)$. A leading-power factorization theorem is a statement that, for $e \ll 1$ and away from additional measured hierarchies,

$$\frac{\mathrm{d}\sigma}{\mathrm{d}e} = H \otimes J_n \otimes J_{\bar{n}} \otimes S + O(\lambda) \quad \text{or} \quad O(e^{1/2}),$$

with the precise power depending on the measurement and recoil convention. The symbol $\otimes$ denotes the convolution variables in the displayed factorization formula, not an abstract tensor product. The hard function is a Wilson coefficient of the QCD current matched onto SCET operators; the jet functions are matrix elements of collinear fields with collinear Wilson lines; the soft function is a vacuum matrix element of soft Wilson lines with the measurement operator inserted.

Definition 50.3 (SCET operator specification for a two-jet endpoint)**.** A two-jet SCET operator specification for a color-singlet source consists of:

1. two lightlike directions $n, \bar{n}$ with $n \cdot \bar{n} = 2$, a small parameter λ, and momentum regions with the scaling displayed above;
2. gauge-covariant collinear fields in the n and $\bar{n}$ sectors, with collinear Wilson lines $W_n, W_{\bar{n}}$ along the conjugate lightlike directions, and gauge-invariant building blocks such as
$$\chi_n := W_n^\dagger \xi_n, \qquad \mathcal{B}^\mu_{n\perp} := W_n^\dagger \, \mathrm{i} D^\mu_{n\perp} W_n$$
where $D_{n\perp} = \partial_{n\perp} - \mathrm{i} A_{n\perp}$ uses the coupling-absorbed Yang–Mills connection of Chapter 45. Thus the normalization of $\mathcal{B}_{n\perp}$ is fixed by the same gauge-field coordinate that appears in $-\frac{1}{4g^2_{\mathrm{YM}}} \operatorname{tr}(F_{\mu\nu}F^{\mu\nu})$;
3. soft Wilson lines $Y_n, Y_{\bar{n}}$ in the representations carried by the energetic charges, with their future- or past-pointing orientation fixed by whether the corresponding charge is outgoing or incoming;
4. a matched current, for example
$$J_{\mathrm{QCD}}(0) = C(Q, \mu) \, \bar{\chi}_{\bar{n}}(0) \Gamma \chi_n(0) + O(\lambda),$$
before the soft Wilson-line decoupling is applied;
5. renormalized jet and soft matrix elements, with the two-jet soft matrix element having the Wilson-line form
$$S(k, \mu) = \frac{1}{N_c} \operatorname{tr} \langle \Omega | \overline{\mathrm{T}} \Big(Y_{\bar{n}}^\dagger Y_n \Big) \, \delta\Big(k - \widehat{k}_s\Big) \, \mathrm{T} \Big(Y_n^\dagger Y_{\bar{n}} \Big) \, |\Omega\rangle_\mu,$$
where $\widehat{k}_s$ is the soft measurement operator appropriate to the event shape;
6. an overlap-subtraction prescription, often called a zero-bin subtraction, preventing the same momentum region from being counted both as soft and as the soft limit of a collinear mode;
7. rapidity-regulator and rapidity-renormalization data whenever the Wilson-line geometry produces rapidity divergences not removed by ordinary ultraviolet renormalization;
8. a statement about Glauber exchange: cancellation, absorption into an additional operator, or failure of the proposed factorization.

All entries are part of the definition of the factorized approximation. The symbols H, J, S in (50.8) have no invariant meaning until these choices, including their renormalization scheme, have been specified.

Overlap subtraction as finite inclusion–exclusion. The zero-bin entry in Definition 50.3 is a mathematical subtraction, not a phrase meaning that an integral may be ignored. At finite regulator, let Λ be a finite set of momentum cells and let $\Lambda_n, \Lambda_s \subset \Lambda$ denote the cells represented by the leading n-collinear and soft approximations. Their common soft-collinear corner is

$$\Lambda_0 = \Lambda_n \cap \Lambda_s.$$

Let f_ℓ be the value of the measurement test function on cell ℓ, and let $I_n(\ell)$, $I_s(\ell)$, and $I_0(\ell)$ be the regulated leading collinear, leading soft, and common overlap densities on their domains. The finite overlap-subtracted singular coordinate is

$$I_{\mathrm{scet}}[f] = \sum_{\ell\in\Lambda_n} I_n(\ell)f_\ell + \sum_{\ell\in\Lambda_s} I_s(\ell)f_\ell - \sum_{\ell\in\Lambda_0} I_0(\ell)f_\ell. \tag{50.9}$$

If $I_n = I_s = I_0$ on Λ_0, the overlap contribution is counted once, not twice. This is the finite inclusion–exclusion content of the zero-bin subtraction. In dimensional regularization some overlap integrals are scaleless and vanish after analytic continuation; that is a feature of that regulator and subtraction scheme, not a regulator-independent proof that the overlap was absent.

A change of overlap convention is a finite scheme change only when it is paired across the collinear and soft coordinates. If δI_0 is moved from the collinear subtraction into the soft coordinate, the two displayed sums in (50.9) change separately, but their sum changes by

$$-\sum_{\ell\in\Lambda_0} \delta I_0(\ell)f_\ell + \sum_{\ell\in\Lambda_0} \delta I_0(\ell)f_\ell = 0.$$

This is the finite algebraic reason that overlap subtraction data belong in the definition of the factorized approximation. The continuum theorem still requires estimates showing that the regulated partition, the overlap approximants, and the measurement remainder converge in the topology in which the cross section is tested.

Leading soft Wilson-line decoupling identity. At finite regulator and at leading power in the n-collinear sector, the soft connection appearing through $n\cdot D_s = n\cdot\partial - \mathrm{i}n\cdot A_s$ can be removed from the collinear kinetic operator by multiplication by a soft Wilson line. More precisely, if Y_n satisfies

$$n\cdot D_s\, Y_n = 0,$$

and the original collinear field is written $\xi_n = Y_n\xi_n^{(0)}$, then

$$\mathrm{i}n\cdot D_s\, \xi_n = Y_n\, \mathrm{i}n\cdot\partial\, \xi_n^{(0)}.$$

Thus the leading soft interactions are transferred from the collinear Lagrangian to Wilson lines in the external operators and measurement matrix elements.

Using the Leibniz rule,

$$n\cdot D_s(Y_n\xi_n^{(0)}) = (n\cdot D_s Y_n)\xi_n^{(0)} + Y_n\, n\cdot\partial\, \xi_n^{(0)}.$$

The first term vanishes by the defining differential equation for Y_n. Multiplying by i gives the displayed identity. In a finite-dimensional regulated path integral, the change of variables is multiplication by an invertible color matrix at each regulated spacetime point. With a gauge-covariant regulator its Berezin or bosonic Jacobian is a local gauge-invariant factor; in the factorized construction that factor is included in the same renormalized soft and collinear operator specification rather than treated as an extra physical assumption. The identity itself is algebraic and does not assert that subleading soft interactions or Glauber exchanges decouple.

Finite Glauber unitarity diagnostic. Glauber exchange is a factorization boundary because its momentum scaling is not removed by the leading soft Wilson-line identity above. At finite regulator one useful diagnostic is purely operator-theoretic. Let $\mathcal{H}_{\text{spec}}$ be the finite Hilbert space carrying the spectator and exchanged color coordinates that are not resolved by a proposed inclusive measurement, let ρ_{spec} be the corresponding reduced density matrix, and let U_G be the finite unitary generated by the regulated Glauber operator on this space. If the measurement operator is inclusive over these coordinates, so that it is represented by $M_{\text{incl}} = \mathbf{1}_{\text{spec}}$ on this factor, then

$$\operatorname{Tr}_{\text{spec}}\Big(M_{\text{incl}} U_G \rho_{\text{spec}} U_G^{\dagger}\Big) = \operatorname{Tr}_{\text{spec}} \rho_{\text{spec}}. \tag{50.10}$$

More generally, the same finite cancellation holds whenever the measured operator M commutes with U_G:

$$\operatorname{Tr}_{\text{spec}}\Big(M U_G \rho_{\text{spec}} U_G^{\dagger}\Big) = \operatorname{Tr}_{\text{spec}}\Big(U_G^{\dagger} M U_G \rho_{\text{spec}}\Big) = \operatorname{Tr}_{\text{spec}}(M \rho_{\text{spec}}). \tag{50.11}$$

Thus an inclusive color-singlet measurement may be insensitive to a unitary Glauber rotation even though the rotation is present at amplitude level. The same algebra also shows where a factorization assertion can fail. If the measurement projects onto a spectator or color-flow coordinate that does not commute with U_G, then $U_G^{\dagger} M U_G \neq M$, and the trace need not equal the value without the Glauber exchange. In that case the exchanged Glauber coordinate must either be included as an additional operator in the factorization structure or the proposed factorization statement is false for that measurement.

There is also a quantitative finite version, useful because real factorization proofs rarely give exact commutation at an intermediate regulator. For any bounded finite measurement M, define the Glauber remainder

$$\Delta_G(M, \rho_{\text{spec}}) = \operatorname{Tr}_{\text{spec}}\Big(M U_G \rho_{\text{spec}} U_G^{\dagger}\Big) - \operatorname{Tr}_{\text{spec}}(M \rho_{\text{spec}}). \tag{50.12}$$

Cyclicity gives the exact identity

$$\Delta_G(M, \rho_{\text{spec}}) = \operatorname{Tr}_{\text{spec}}\Big((U_G^{\dagger} M U_G - M)\rho_{\text{spec}}\Big). \tag{50.13}$$

Consequently, with $\|\cdot\|$ the operator norm and $\|\cdot\|_1$ the trace norm,

$$|\Delta_G(M, \rho_{\text{spec}})| \leq \|U_G^{\dagger} M U_G - M\| \, \|\rho_{\text{spec}}\|_1. \tag{50.14}$$

If $U_G = \exp(\mathrm{i}K_G)$, the Duhamel formula refines the first factor to

$$U_G^{\dagger} M U_G - M = \mathrm{i} \int_0^1 e^{-\mathrm{i}sK_G} [M, K_G] e^{\mathrm{i}sK_G} \, \mathrm{d}s,$$

and hence

$$\|U_G^{\dagger} M U_G - M\| \leq \|[M, K_G]\|.$$

The finite diagnostic therefore has an honest error coordinate: exact factorization is recovered when the measured algebra is invariant under the Glauber unitary, and approximate factorization requires a small commutator in the measurement norm relevant to the smeared cross section. This is the operator-theoretic content behind phrases such as "Glauber cancellation"; the continuum theorem must still supply the limiting K_G, the topology, and the bound.

Equations (50.10)–(50.11) are only the finite unitarity mechanism. A continuum QCD factorization proof must also identify the regulated Glauber region, show how the eikonal approximations and contour deformations isolate it, prove the required inclusive sum or commutation property for the actual measurement, and bound the remainder in the topology of the smeared cross section. Without these extra analytic steps, saying that Glauber exchanges "cancel" is merely a claim about a missing part of the factorization structure.

Hypothesis 50.4 (Leading-power SCET factorization structure)**.** A leading-power SCET factorization statement for an observable F consists of a small parameter λ, a list of modes with momentum scaling, a mode-separated operator basis through the declared order in λ, a renormalized matrix-element definition of each hard, jet, beam, and soft function, an overlap-subtraction prescription, a measurement decomposition on those modes, a statement that Glauber or other factorization-breaking exchanges either cancel or are represented by additional operators, and a remainder estimate in powers of λ on the kinematic region where the formula is used. If the formula is asserted as a theorem, the estimate must be stated in a topology on smeared cross sections or cumulants; otherwise it is a controlled approximation hypothesis.

Controlled Approximation 50.5 (Distributional leading-power factorization estimate)**.** The content of a leading-power factorization formula is an estimate on smeared physical cross sections, not an equality of pointwise functions. Assume that, for the chosen hard scale Q, the physical QCD final-state observable e determines a positive cross-section measure $\mathrm{d}\mu_Q(e)$ on an endpoint window W_Q. Let $\mathcal{B}_{\text{end}}$ be a Banach space of endpoint test functions $\varphi\colon W_Q \to \mathbb{C}$, with norm $\|\varphi\|_{\mathcal{B}_{\text{end}}}$, strong enough to control the singular distributions under discussion. The physical smeared functional is

$$\Sigma_Q^{\text{phys}}(\varphi) = \int_{W_Q} \varphi(e)\,\mathrm{d}\mu_Q(e). \tag{50.15}$$

A two-jet operator specification $\mathcal{D}_{\text{SCET}}$ as in Definition 50.3 defines, after the specified regulator, overlap subtraction, rapidity subtraction when needed, and renormalization scheme, a singular distributional coordinate $\mathrm{d}\mu^{\text{SCET}}_{Q,\text{sing}}(e;\mathcal{D}_{\text{SCET}})$. Its smeared functional is

$$\Sigma^{\text{SCET}}_{Q,\text{sing}}(\varphi;\mathcal{D}_{\text{SCET}}) = \langle H \otimes J_n \otimes J_{\bar n} \otimes S, \varphi\rangle_{\mathcal{D}_{\text{SCET}}}\,, \tag{50.16}$$

where the pairing includes the measurement convolution, the endpoint transform convention if one is used, and the subtraction prescription.

A controlled leading-power factorization claim on W_Q is the assertion that there exist an exponent $p > 0$, a scale-dependent endpoint parameter λ_W, and a remainder bound R_Q such that

$$\left|\Sigma_Q^{\text{phys}}(\varphi) - \Sigma^{\text{SCET}}_{Q,\text{sing}}(\varphi;\mathcal{D}_{\text{SCET}})\right| \le R_Q\,\|\varphi\|_{\mathcal{B}_{\text{end}}}, \qquad R_Q \le C_Q\,\lambda_W^p \tag{50.17}$$

for every $\varphi \in \mathcal{B}_{\text{end}}$ in the declared kinematic range. If the hard, jet, soft, or anomalous-dimension entries are perturbatively truncated, the displayed R_Q must be enlarged by the declared perturbative truncation remainder in the same norm. The common phrases "leading power" and "factorization theorem" therefore have a definite meaning only after the physical functional, test space, factorization structure, endpoint parameter, and remainder topology have all been specified.

The same formulation also fixes the status of finite scheme changes. In a scalar transform-space chart, a finite multiplicative coordinate change

$$H' = HR_H, \qquad \widetilde{J}'_n = \widetilde{J}_n R_n, \qquad \widetilde{J}'_{\bar n} = \widetilde{J}_{\bar n} R_{\bar n}, \qquad \widetilde{S}' = \widetilde{S} R_S \tag{50.18}$$

represents the same singular distribution only if

$$R_H R_n R_{\bar{n}} R_S = 1 \tag{50.19}$$

as an identity in the transform variable and scale. The anomalous dimensions then transform as

$$\gamma_i' = \gamma_i + \mu \frac{\mathrm{d}}{\mathrm{d}\mu} \log R_i, \qquad i = H, J_n, J_{\bar{n}}, S, \tag{50.20}$$

and the sum of the transformed anomalous dimensions still vanishes because

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu} \log(R_H R_n R_{\bar{n}} R_S) = 0.$$

In a mixing problem the same statement is a similarity-covariant statement about matrix kernels and path-ordered products. It is part of the coordinate structure of the factorized approximation, not an optional convention added after the formula has been written.

Renormalization of the hard, jet, and soft functions gives evolution equations. The resummation structure is clearest after a Laplace transform, or any equivalent transform, has converted the measurement convolution into an ordinary product. Write the transformed singular coordinate as

$$\widetilde{C}(\nu, Q; \mu) = H(Q, \mu)\, \widetilde{J}_n(\nu, Q, \mu)\, \widetilde{J}_{\bar{n}}(\nu, Q, \mu)\, \widetilde{S}(\nu, Q, \mu),$$

where ν is conjugate to the event-shape measurement. A scalar renormalization-group transport structure consists of anomalous dimensions

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu} \log H = \gamma_H, \qquad \mu \frac{\mathrm{d}}{\mathrm{d}\mu} \log \widetilde{J}_a = \gamma_{J_a}, \qquad \mu \frac{\mathrm{d}}{\mathrm{d}\mu} \log \widetilde{S} = \gamma_S,$$

all in the same subtraction and rapidity scheme, satisfying the consistency condition

$$\gamma_H + \gamma_{J_n} + \gamma_{J_{\bar{n}}} + \gamma_S = 0. \tag{50.21}$$

In a distributional formulation the same equation is an identity of convolution kernels. If color or operator mixing is present, the scalar exponentials below are replaced by path-ordered evolution matrices and the consistency condition is the corresponding statement that the product observable has no residual common-scale dependence.

For a scalar transport structure, define

$$U_i(\mu, \mu_i) = \exp\left\{ \int_{\log \mu_i}^{\log \mu} \gamma_i(\nu, Q; \mu')\, \mathrm{d} \log \mu' \right\}, \qquad i = H, J_n, J_{\bar{n}}, S.$$

The resummed singular coordinate is then

$$\begin{aligned} \widetilde{C}_{\mathrm{sing}}(\nu, Q) = {} & H(Q, \mu_H) U_H(\mu, \mu_H)\, \widetilde{J}_n(\nu, Q, \mu_J) U_{J_n}(\mu, \mu_J) \\ & \times \widetilde{J}_{\bar{n}}(\nu, Q, \mu_J) U_{J_{\bar{n}}}(\mu, \mu_J)\, \widetilde{S}(\nu, Q, \mu_S) U_S(\mu, \mu_S). \end{aligned} \tag{50.22}$$

Differentiating $\log \widetilde{C}_{\mathrm{sing}}$ with respect to the common scale $\log \mu$ gives the left-hand side of (50.21); hence the expression is independent of μ inside the accuracy to which the anomalous dimensions and matching functions have been supplied. The natural choices $\mu_H \sim Q$, $\mu_J \sim Q\sqrt{e}$, and $\mu_S \sim Qe$, or their transform-space analogues, are not extra physics assumptions. They are coordinate choices that keep the boundary functions free of the large logarithms subsequently generated by the evolution kernels. Finite subtraction-scheme changes may redistribute terms between the anomalous dimensions and the boundary functions. Such a redistribution is a valid coordinate change only when the hard, jet, and soft entries are changed together so that (50.21) and the product coordinate $\widetilde{C}_{\rm sing}$ are preserved to the declared order.

If L denotes the large logarithm of the measured hierarchy, logarithmic accuracy is a statement about a definite truncation of (50.22). At LL one keeps the cusp anomalous dimension and beta-function data needed to generate the leading tower in the exponent, with tree-level boundary functions. NLL adds the next tower by including the next cusp data, the first non-cusp anomalous dimensions, and the corresponding running-coupling terms. NNLL adds the next tower and the matching constants required by the declared convention. Primed labels such as NLL$'$ or NNLL$'$ mean that fixed boundary functions are included one order higher than the unprimed logarithmic transport. The labels are therefore incomplete unless the observable, the factorization theorem, the transform convention, the natural scales, the anomalous-dimension orders, the matching orders, and the matching prescription to fixed order are all listed. They are formal perturbative-accuracy statements in a logarithmic hierarchy, not numerical error bounds once the hierarchy is lost, a Landau-pole region is approached, or an unproved factorization remainder dominates.

50.4.2 Massive-Vector Sudakov Boundaries

High-energy jet measurements in the Standard Model involve a second short-distance boundary in addition to the QCD soft and collinear boundaries: massive electroweak gauge bosons can be soft or collinear relative to an energetic charged line while their physical masses stop the logarithmic integration. The correct object is a massive-vector factorization coordinate for a specified observable and charge sector. The physical mass M_V and the hard scale Q are part of the electroweak perturbative datum, while the QCD hadronic measurement remains a physical final-state observable as above.

Let R be a representation of the gauge factor carried by an energetic line, and define its quadratic charge by

$$T^a_R T^a_R = C_R\,\mathbf{1}_R.$$

Here T^a_R are the canonical generators after the gauge field has been canonically normalized, so $\alpha_V = g_V^2/(4\pi)$ is the coupling that appears in the emission probability. The corresponding convention is tied to the Yang–Mills normalization of Chapter 45: the path-integral gauge field is written with kinetic term $-\frac{1}{4g^2_{\rm YM}}\operatorname{tr} F_{\mu\nu}F^{\mu\nu}$, and canonical perturbative fields carry the coupling in the vertices.

Controlled Approximation 50.6 (Single-line massive-vector Sudakov chart)**.** Fix an energetic external charge in representation R, a hard scale Q, a massive vector boson of mass M_V, and a hierarchy $Q \gg M_V$. In the strongly ordered soft-collinear chart, use the transverse momentum $k_\perp$ and energy fraction z of an unresolved virtual vector boson as coordinates. Put

$$L_V = \log\frac{Q^2}{M_V^2}, \qquad y = \log\frac{Q^2}{k_\perp^2}, \qquad x = \log\frac{1}{z}.$$

The massive vector permits the logarithmic range

$$0 < y < L_V, \qquad 0 < x < \frac{y}{2}, \tag{50.23}$$

where the second inequality is the soft-collinear energy ordering $z > k_\perp/Q$. Approximating the emission measure by $(\alpha_V C_R/\pi)\,\mathrm{d}x\,\mathrm{d}y$, the one-line virtual Sudakov coordinate is

$$\Delta_R^{(V)}(Q, M_V) = \exp\left[-\frac{\alpha_V C_R}{\pi}\, A_V(L_V)\right], \qquad A_V(L_V) = \int_0^{L_V} \mathrm{d}y \int_0^{y/2} \mathrm{d}x = \frac{1}{4} L_V^2. \tag{50.24}$$

The approximation consists precisely of the eikonal numerator, the soft-collinear phase-space chart, fixed coupling, one unresolved massive vector, and a scalar charge channel.

The derivation of (50.24) is the finite phase-space geometry. The lower transverse-momentum boundary $k_\perp = M_V$ gives $y = L_V$, the upper boundary $k_\perp = Q$ gives $y = 0$, and the condition that the emitted vector have energy larger than its transverse momentum gives $x < y/2$. The area is therefore the triangle of base L_V and height $L_V/2$. The exponent in (50.24) is the virtual no-emission coordinate in this chart. A real-emission calculation cancels the same logarithmic coordinate only for measurements that sum over the corresponding unresolved massive-vector final states and over the charge channels connected by those emissions. In electroweak applications the incoming beam and the measured final state often select weak charge. The factorized object is then a matrix in the external charge density space, with entries built from products of generators T_i^a on the participating energetic lines. A scalar exponential such as (50.24) is the one-line diagonal representative of this more general charge-transport structure.

This is the clean way to place boosted and electroweak jet statements inside the monograph. A boosted massive-particle substructure analysis is a measurement on stable hadronic and leptonic final states, together with a declared resonance-pole or narrow-width approximation when an unstable particle label such as W, Z, t, or H is used. The small parameters are then listed explicitly, for example

$$\frac{m_{\text{obj}}}{p_T}, \qquad \frac{\Gamma_{\text{obj}}}{m_{\text{obj}}}, \qquad \frac{M_W}{Q}, \qquad \lambda_{\text{jet}},$$

as applicable to the chosen observable. The perturbative electroweak Sudakov transport, the QCD jet and soft functions, the resonance approximation, and the nonperturbative hadronization or track coordinates are separate entries in the prediction. Their remainders have different meanings and must be stated separately before a numerical prediction can be assigned a claimed accuracy.

Controlled Approximation 50.7 (Perturbative prediction for an IRC-safe jet observable)**.** A perturbative prediction for a jet observable consists of: the renormalized fixed-order hard functions through a stated order in α_s; the logarithmic accuracy of any resummation, such as LL, NLL, NNLL, or beyond; the factorization theorem and its power corrections; the renormalized PDFs or fragmentation functions when they enter; and a prescription for matching resummed and fixed-order regions without double counting.

50.4.3 Global and Non-Global Soft Measurements

A factorization statement for a small event shape is much simpler when the measurement is global, meaning that every soft direction is measured with a weight compatible with the same soft function. Jet vetoes, gaps between jets, and many substructure cuts are not global. Then a soft gluon emitted into an unmeasured angular region is not vetoed, but it changes the color source that can radiate a later softer gluon into the measured region. This is the mathematical origin of non-global logarithms. The point is not the name; it is that the measurement algebra is no longer generated by a single linear Wilson-line soft function.

The following finite model records the part of the argument that can be made without invoking an unregulated continuum angular integral. Fix finitely many angular cells $\mathcal{C}$ away from the hard Wilson-line directions. Let $\mathcal{M} \subset \mathcal{C}$ be the measured, vetoed cells and $\mathcal{U} = \mathcal{C} \setminus \mathcal{M}$ the unmeasured cells. For every ordered dipole (i, j), let $K_{ij}^c \geq 0$ be the cell-integrated eikonal emission kernel into cell c. In a continuum soft-dipole approximation, one representative regulated coordinate for this rate is

$$K_{ij}^c = \int_{\Omega_c} \frac{\mathrm{d}\Omega_k}{4\pi} \frac{\alpha_s C_{\mathrm{dip}}}{\pi} \frac{1 - \widehat{n}_i \cdot \widehat{n}_j}{(1 - \widehat{n}_i \cdot \widehat{k})(1 - \widehat{k} \cdot \widehat{n}_j)}$$

after the collinear neighborhoods of i and j and the ultraviolet coupling convention have been specified. In the finite model the numbers K_{ij}^c are simply positive regulator coordinates.

Let $G_{ij}(L)$ denote the finite soft-dipole gap coordinate for the dipole (i, j), where L is the logarithm of the resolved soft-energy hierarchy, and impose the initial condition $G_{ij}(0) = 1$. The finite non-global evolution equation is

$$\frac{\mathrm{d}}{\mathrm{d}L} G_{ij}(L) = -A_{ij} G_{ij}(L) + \sum_{u \in \mathcal{U}} K_{ij}^u \big(G_{iu}(L) G_{uj}(L) - G_{ij}(L)\big), \qquad A_{ij} := \sum_{m \in \mathcal{M}} K_{ij}^m. \tag{50.25}$$

The first term is direct veto radiation into the measured cells. The second term is real–virtual balanced for radiation into an unmeasured cell: if every gap coordinate is identically one, it contributes zero. Its nonlinear product is the essential non-global structure: after an unmeasured emission at direction u, the original dipole is replaced by the two dipoles (i, u) and (u, j), each of which can subsequently radiate into $\mathcal{M}$.

Differentiating (50.25) at $L = 0$ gives a useful diagnostic. Since $G_{ij}(0) = 1$,

$$G'_{ij}(0) = -A_{ij}.$$

A second differentiation gives

$$G''_{ij}(0) = A_{ij}^2 - \sum_{u \in \mathcal{U}} K_{ij}^u \big(A_{iu} + A_{uj} - A_{ij}\big).$$

Therefore

$$G_{ij}(L) = 1 - A_{ij} L + \frac{L^2}{2} \left[A_{ij}^2 - \mathcal{N}_{ij}\right] + O(L^3), \qquad \mathcal{N}_{ij} := \sum_{u \in \mathcal{U}} K_{ij}^u \big(A_{iu} + A_{uj} - A_{ij}\big). \tag{50.26}$$

The $A_{ij}^2/2$ term is the square of the direct global Sudakov veto. The term $\mathcal{N}_{ij}$ is the first finite non-global coefficient. It vanishes when there is no unmeasured region, and it also vanishes in the special additive case $A_{iu} + A_{uj} = A_{ij}$ for every unmeasured cell u. A generic angular veto does not satisfy this identity. Thus the failure of globalness is not a cosmetic complication in logarithmic counting; it changes the evolution problem from a linear anomalous dimension to a nonlinear Wilson-line measurement problem.

Equation (50.25) is not a theorem about full QCD. It is a finite large-N_c, strongly energy-ordered, soft-dipole coordinate system for one obstruction to naive factorization. Beyond this finite model one must specify the color density matrix at finite N_c, the regulator for collinear neighborhoods of the hard lines, the matching to the hard and collinear functions, the treatment of recoil, and the status of Glauber exchanges. Super-leading logarithms, when present, are not explained by the finite non-global coefficient alone; they signal an additional factorization obstruction that must be stated in the operator structure of Hypothesis 50.4.

50.5 Jet Substructure Observables and Grooming

Jet substructure observables are measurements on the constituents of a previously identified jet. The jet definition, recombination scheme, grooming algorithm, and substructure measurement are all part of the observable. Their IRC behavior must therefore be checked as a combined map from the final-state calorimetric measure to a number or distribution.

Definition 50.8 (Soft drop)**.** Start with the constituents of a jet of radius R_0, recluster them with the Cambridge–Aachen metric, and recursively decluster the last clustering step into two branches i, j. Let

$$z_{ij} = \frac{\min(p_{Ti}, p_{Tj})}{p_{Ti} + p_{Tj}}, \qquad \theta_{ij} = \frac{\Delta R_{ij}}{R_0}.$$

For parameters $z_{\mathrm{cut}} > 0$ and $\beta_{\mathrm{SD}} \geq 0$, the soft-drop condition is

$$z_{ij} > z_{\mathrm{cut}}\, \theta_{ij}^{\beta_{\mathrm{SD}}}.$$

If the condition fails, the softer branch is removed and the recursion continues on the harder branch. If the condition holds, the remaining constituents define the groomed jet. The case $\beta_{\mathrm{SD}} = 0$ is the modified mass-drop tagger.

IRC classification of soft-drop outputs. With an IRC-safe input jet algorithm and a finite transverse-momentum threshold for the original jet, the following statements hold away from the boundary hypersurfaces of the measurement.

1. If $\beta_{\mathrm{SD}} > 0$, the soft-drop groomed four-momentum is IRC safe.
2. If $\beta_{\mathrm{SD}} = 0$, the groomed four-momentum is not collinear safe as a standalone observable.
3. For $\beta_{\mathrm{SD}} = 0$, any claimed IRC safety statement must name the measured functional of the groomed constituents, for example a groomed jet mass or an energy-correlation shape, and must check the collinear limit of that functional rather than the groomed four-vector itself.

Add a particle of transverse momentum λp_T with $\lambda \downarrow 0$. If it is tested against a hard branch at finite angle, then $z_{ij} = O(\lambda)$, while $z_{\mathrm{cut}}\theta_{ij}^{\beta_{\mathrm{SD}}}$ has a positive lower bound on compact subsets away from $\theta_{ij} = 0$. The soft branch is removed and cannot change the groomed four-momentum except on the codimension-one surface where the inequality is exactly saturated. If the soft particle is collinear to a hard branch, Cambridge–Aachen recombines or declusters it at small θ, and its contribution to the branch momentum vanishes with λ.

For a collinear splitting of a hard particle, the two branches have $\theta_{ij} \downarrow 0$. If $\beta_{\mathrm{SD}} > 0$, then

$$z_{\mathrm{cut}}\theta_{ij}^{\beta_{\mathrm{SD}}} \longrightarrow 0.$$

For every fixed splitting fraction $0 < z < 1$, the soft-drop condition is therefore eventually satisfied, and the collinear pair is retained as the parent four-momentum. This gives the collinear limit of the groomed four-vector.

If $\beta_{\rm SD} = 0$, the right-hand side of the soft-drop condition is the fixed number $z_{\rm cut}$. Consider a massless one-particle jet of four-momentum p, and replace it by a collinear pair zp and $(1-z)p$ with $0 < z < z_{\rm cut} < 1/2$. Cambridge–Aachen declustering sees the two branches, the soft-drop condition fails, and the softer branch is removed. The groomed four-vector is $(1-z)p$, not p, even in the exact collinear limit. Hence the groomed four-vector is not collinear safe for $\beta_{\rm SD} = 0$.

This counterexample does not by itself classify every functional of the groomed constituents. A groomed mass, energy-correlation ratio, or tagged substructure variable can still be IRC safe, but its safety is a statement about that functional and its normalization. The check must be made at the level of Definition 50.1.

Finite-tree formulation and decision margins. The preceding definition hides a useful finite mathematical structure: before one takes continuum, perturbative, or detector limits, soft drop is a deterministic map on a finite Cambridge–Aachen declustering tree. Let T be a rooted binary tree whose leaves are the constituents of a fixed input jet. For every internal vertex v, let v_L, v_R be the two branches obtained by undoing one Cambridge–Aachen recombination. Write

$$E_{v,a} = \sum_{\ell \in v_a} p_{T\ell}, \qquad z_v = \frac{\min(E_{v,L}, E_{v,R})}{E_{v,L} + E_{v,R}}, \qquad \theta_v = \frac{\Delta R(v_L, v_R)}{R_0},$$

where the branch direction entering $\Delta R(v_L, v_R)$ is the four-momentum recombination direction of that branch. A fixed-tree soft-drop specification consists of T, the leaf momenta, a declared tie-breaking rule when $E_{v,L} = E_{v,R}$, and the parameters $(z_{\rm cut}, \beta_{\rm SD})$. The recursion starts at the root. At a vertex v, if

$$z_v > z_{\rm cut}\theta_v^{\beta_{\rm SD}},$$

the algorithm stops and retains precisely the leaves below v. If the condition fails, it moves to the harder child and deletes the softer child.

This finite-tree specification is the object whose soft and collinear limits must be tested before it is inserted into a partonic phase-space integral. Define the soft-drop decision margin and, on failed vertices, the harder-branch margin by

$$m_v^{\rm SD} = \left| z_v - z_{\rm cut}\theta_v^{\beta_{\rm SD}} \right|, \qquad m_v^{\rm hard} = \frac{|E_{v,L} - E_{v,R}|}{E_{v,L} + E_{v,R}}. \tag{50.27}$$

For a finite event with no zero-energy branch, all quantities z_v and θ_v are continuous functions of the leaf momenta on any chart where the Cambridge–Aachen tree T itself is unchanged. Hence, if every vertex visited by the recursion has $m_v^{\rm SD} > 0$, and every failed vertex has $m_v^{\rm hard} > 0$, there is a neighborhood of the leaf momenta in which the same vertices are visited, the same branches are deleted, and the same leaf set is retained. If the tree T is generated from the momenta rather than supplied as part of the input, one must additionally require positive Cambridge–Aachen clustering margins: every pairwise angular distance comparison that determines the tree must remain separated from its nearest competitor. These margins are the precise finite-event meaning of the phrase "away from soft-drop and clustering boundaries." At such a point any groomed observable that is a smooth function of the retained momenta has the same local soft or collinear behavior as the retained-momentum map specified by the fixed recursion. The boundary hypersurfaces $m_v^{\mathrm{SD}} = 0$, $m_v^{\mathrm{hard}} = 0$, and the Cambridge–Aachen distance tie hypersurfaces require separate distributional analysis and cannot be silently discarded when a singular measurement or endpoint resummation is being defined.

Measured mMDT functionals. The $\beta_{\mathrm{SD}} = 0$ counterexample above is deliberately a counterexample to the groomed four-vector. It is not a license to classify every measured functional of the groomed set by the same sentence. A useful finite-event test is the following. For a retained finite leaf set S, define the homogeneous angular moment

$$G_\kappa(S) = \frac{1}{E_S^2 R_0^\kappa} \sum_{\ell,m\in S} E_\ell E_m \, \theta_{\ell m}^\kappa, \qquad E_S = \sum_{\ell\in S} E_\ell, \qquad \kappa > 0, \tag{50.28}$$

where $\theta_{\ell m}$ is the angular distance and the diagonal terms vanish. In the one-prong collinear split used in the mMDT counterexample, with energies $(1-z)E$ and zE, $0 < z < z_{\mathrm{cut}}$, the mMDT recursion retains only the harder daughter. Therefore

$$G_\kappa(\{(1-z)E\}) = 0 = G_\kappa(\{E\})$$

in the exact collinear limit. If $\beta_{\mathrm{SD}} > 0$, the same pair is retained for sufficiently small opening angle θ, and

$$G_\kappa(\{(1-z)E, zE\}) = 2z(1-z)\left(\frac{\theta}{R_0}\right)^\kappa,$$

which tends to zero as $\theta \downarrow 0$. Thus a positive-angular-power shape such as (50.28) passes this elementary collinear test even when the groomed four-vector does not.

By contrast, the retained-energy fraction

$$r_E(S) = \frac{E_S}{E_{\mathrm{input}}}$$

is not collinear safe for mMDT as a standalone observable: the same exact collinear split changes r_E from 1 to $1-z$. This is the measurement-level lesson. For $\beta_{\mathrm{SD}} = 0$, a groomed observable is acceptable only after its own collinear boundary behavior is checked. Angular weights with positive powers can kill the deleted one-prong collinear branch; energy-retention observables cannot. Endpoint distributions of G_κ, groomed masses, or ratios built from them still require their own factorization and resummation data, because IRC safety of the measurement is only the first finiteness condition.

Fixed-coupling soft-drop mass radiator. A useful measured-observable calibration is the groomed jet-mass cumulative distribution in the single-emission soft-collinear chart. The calculation below is the logarithmic phase-space geometry that a factorization theorem must reproduce in its leading coordinate.

Controlled Approximation 50.9 (Soft-drop mass at fixed-coupling soft-collinear accuracy)**.** Consider one energetic parton of color factor C_i and one unresolved emission with energy fraction $z \ll 1$, normalized angle $\theta = \Delta R/R_0 \ll 1$, and groomed mass coordinate

$$\rho = \frac{m_{J,\mathrm{gr}}^2}{p_T^2 R_0^2} = z\theta^2$$

in this chart. Approximate the real-emission measure by

$$\frac{\alpha_s C_i}{\pi}\frac{\mathrm{d}\theta^2}{\theta^2}\frac{\mathrm{d}z}{z},$$

hold α_s fixed, ignore finite terms in the splitting function, recoil, boundary corrections at $z \sim 1$, clustering logarithms, non-global correlations, and power corrections in ρ, z_{cut}. The soft-drop condition is $z > z_{\mathrm{cut}}\theta^{\beta_{\mathrm{SD}}}$. With

$$L_\rho = \log\frac{1}{\rho}, \qquad L_z = \log\frac{1}{z_{\mathrm{cut}}}, \qquad b = \frac{\beta_{\mathrm{SD}}}{2},$$

the leading radiator is the area

$$A_\beta(L_\rho, L_z) = \int_0^\infty \mathrm{d}t \int_0^\infty \mathrm{d}u\, \mathbf{1}_{\{u+t<L_\rho\}}\, \mathbf{1}_{\{u<L_z+bt\}}, \tag{50.29}$$

where $t = \log(1/\theta^2)$ and $u = \log(1/z)$. Hence

$$\Sigma_{\mathrm{SD}}^{\mathrm{LL}}(\rho) = \exp\left[-\frac{\alpha_s C_i}{\pi} A_\beta(L_\rho, L_z)\right] \tag{50.30}$$

inside this controlled approximation.

The area in (50.29) is elementary but instructive. If $L_\rho \le L_z$, the mass constraint is stronger than the grooming constraint throughout the triangular region $u + t < L_\rho$, so

$$A_\beta(L_\rho, L_z) = \frac{1}{2}L_\rho^2.$$

If $L_\rho > L_z$, the two boundary lines

$$u = L_\rho - t, \qquad u = L_z + bt$$

intersect at

$$t_* = \frac{L_\rho - L_z}{1+b}.$$

The area is therefore

$$A_\beta(L_\rho, L_z) = L_z t_* + \frac{b}{2}t_*^2 + \frac{1}{2}(L_\rho - t_*)^2, \qquad t_* = \frac{L_\rho - L_z}{1+b}, \qquad L_\rho > L_z. \tag{50.31}$$

For mMDT, $\beta_{\mathrm{SD}} = 0$, this reduces to

$$A_0(L_\rho, L_z) = L_\rho L_z - \frac{1}{2}L_z^2, \qquad L_\rho > L_z. \tag{50.32}$$

Thus mMDT removes the soft double logarithm below the grooming scale: the radiator grows linearly in L_ρ, with coefficient fixed by $L_z = \log(1/z_{\mathrm{cut}})$. For $\beta_{\mathrm{SD}} > 0$, the coefficient of the asymptotic L_ρ^2 term is nonzero and depends continuously on β_{SD}; the grooming boundary still removes part of the soft triangle, but no longer removes the double-logarithmic growth completely.

Equations (50.30)–(50.32) should be read as a calibration of logarithmic phase space. A physical prediction for a groomed jet-mass distribution must replace this chart by a renormalized factorization structure: the hard production process, the jet function for the initiating parton, the groomed soft or collinear-soft function, overlap subtractions, running coupling, finite splitting functions, matching to fixed order, non-global and clustering effects where present, and the hadronization coordinate appropriate to the measured mass region.

Renormalized soft-drop mass factorization structure. The preceding radiator becomes a QCD prediction only after the measured groomed-mass coordinate has been embedded in a renormalized operator definition. Let Q denote the hard energy scale of the measured jet, for instance $Q = p_T R_0$ in a small-radius hadron-collider chart, and let

$$\rho = \frac{m_{J,\mathrm{gr}}^2}{Q^2}.$$

In the soft-collinear coordinates of Controlled Approximation 50.9, the emission that lies simultaneously on the mass boundary and on the soft-drop boundary satisfies

$$z\theta^2 = \rho, \qquad z = z_{\mathrm{cut}}\theta^{\beta_{\mathrm{SD}}}.$$

Solving these two equations gives the boundary scales

$$\theta_* = \left(\frac{\rho}{z_{\mathrm{cut}}}\right)^{1/(2+\beta_{\mathrm{SD}})}, \qquad z_* = z_{\mathrm{cut}}^{2/(2+\beta_{\mathrm{SD}})}\rho^{\beta_{\mathrm{SD}}/(2+\beta_{\mathrm{SD}})}. \tag{50.33}$$

Thus $z_*\theta_*^2 = \rho$ and $z_* = z_{\mathrm{cut}}\theta_*^{\beta_{\mathrm{SD}}}$. These identities are not a factorization theorem, but they determine the scales that any such theorem must see: ordinary collinear radiation carrying the measured jet mass has virtuality of order $Q^2\rho$, while radiation near the grooming boundary has light-cone components of order

$$p_{\mathrm{cs}}^- \sim Qz_*, \qquad p_{\mathrm{cs}}^+ \sim Q\rho, \qquad |p_{\mathrm{cs}\perp}| \sim Q\sqrt{\rho z_*}.$$

Consequently its invariant transverse scale is

$$\mu_{\mathrm{cs}} \sim Q\sqrt{\rho z_*}, \qquad \mu_J \sim Q\sqrt{\rho}, \qquad \mu_G \sim Qz_{\mathrm{cut}}, \qquad \mu_H \sim Q. \tag{50.34}$$

For $\beta_{\mathrm{SD}} = 0$, $z_* = z_{\mathrm{cut}}$ and $\mu_{\mathrm{cs}} \sim Q\sqrt{\rho z_{\mathrm{cut}}}$; this is the scale separation behind the single-logarithmic mMDT radiator in (50.32).

Definition 50.10 (Soft-drop groomed-mass factorization structure)**.** Fix the jet algorithm, recoil convention, recombination scheme, hard process, partonic channel i, subtraction scheme, and soft-drop parameters $(z_{\mathrm{cut}}, \beta_{\mathrm{SD}})$. A leading singular soft-drop groomed-mass factorization structure consists of:

1. a hard coefficient $H_i(Q, \mu)$ for the short-distance production of the measured energetic parton or color representation;
2. a global-soft veto coordinate $S_i^G(z_{\mathrm{cut}}, R_0, \mu)$ describing wide-angle soft radiation that is removed by grooming but affects the probability that the event lies in the selected groomed-jet sample;
3. a renormalized collinear jet distribution $J_i(\rho_J, \mu)$ and a renormalized collinear-soft distribution $S_{i,\mathrm{SD}}^{\mathrm{cs}}(\rho_{\mathrm{cs}}; z_{\mathrm{cut}}, \beta_{\mathrm{SD}}, R_0, \mu)$, both understood as distributions paired with endpoint test functions;
4. the measurement decomposition $\rho = \rho_J + \rho_{\mathrm{cs}}$ in the leading singular chart, together with the overlap-subtraction and rapidity-renormalization data needed to avoid double counting the common soft-collinear boundary;

5. anomalous dimensions, in the same scheme, satisfying the common-scale consistency condition
$$\gamma_H + \gamma_G + \gamma_J + \gamma_{\rm cs} = 0 \tag{50.35}$$
as an identity of transform-space functions or, before transform, of convolution kernels;
6. a remainder functional $R_{\rm SD}$ on the stated test-function space, recording power corrections in $\rho, z_{\rm cut}, R_0$, finite splitting functions beyond the declared singular order, recoil and clustering effects, non-global correlations not included in S_i^G, Glauber obstructions if the measurement is not inclusive enough, and nonperturbative coordinates when one of the scales in (50.34) approaches $\Lambda_{\rm QCD}$.

The corresponding singular coordinate is
$$\begin{aligned}\left\langle \frac{{\rm d}\Sigma^{\rm SD}_{i,\rm sing}}{{\rm d}\rho}, \varphi \right\rangle &= H_i(Q,\mu)\, S_i^G(z_{\rm cut}, R_0, \mu) \int {\rm d}\rho_J\, {\rm d}\rho_{\rm cs}\, J_i(\rho_J,\mu) S^{\rm cs}_{i,\rm SD}(\rho_{\rm cs},\mu)\varphi(\rho_J+\rho_{\rm cs}) \\ &\quad + \langle R_{\rm SD}, \varphi\rangle\,,\end{aligned} \tag{50.36}$$
for every endpoint test function φ in the declared domain. The symbols S_i^G, J_i, and $S^{\rm cs}_{i,\rm SD}$ do not have standalone physical meaning outside this common structure; finite scheme changes may move terms among them only if (50.35) and the paired distribution (50.36) are preserved.

Controlled Approximation 50.11 (Perturbative soft-drop mass resummation)**.** A perturbative resummation based on Definition 50.10 is controlled on a region of endpoint tests only when the scales $\mu_H, \mu_G, \mu_J, \mu_{\rm cs}$ in (50.34) remain in the perturbative regime, the factorization remainder $R_{\rm SD}$ is bounded in the declared topology, and the logarithmic-accuracy label specifies the anomalous dimensions, boundary matching functions, fixed-order matching prescription, rapidity scheme if present, and scale-profile map used to avoid crossing nonperturbative regions. If $\mu_{\rm cs}$ is of order $\Lambda_{\rm QCD}$, the collinear-soft distribution in (50.36) must be replaced by a nonperturbative shape coordinate or by a regulator-level reconstruction observable with its own matching theorem. A Monte-Carlo tune or an empirical model may supply a useful phenomenological coordinate, but it is then an additional input, not a derivation of the soft-drop mass distribution from perturbative QCD.

Groomed momentum sharing and Sudakov-conditioned coordinates. A second soft-drop observable, often denoted z_g, records the momentum sharing at the first declustering step that passes the soft-drop condition. For a finite Cambridge–Aachen tree in the notation above, let v_* be the first vertex visited by the recursion for which
$$z_{v_*} > z_{\rm cut}\theta_{v_*}^{\beta_{\rm SD}}.$$
If such a vertex exists, define
$$z_g = z_{v_*}, \qquad \theta_g = \theta_{v_*}.$$
If no such vertex exists, the pair (z_g, θ_g) is not a number attached to the event; one must either work with the event-selection indicator or declare a separate null value outside the numerical range. This elementary point is already enough to show that z_g is not an ordinary IRC-safe measurement in the sense of Definition 50.1: in the one-particle collinear limit there is no accepted split, while a nearby two-particle configuration may have a finite accepted value. The useful short-distance statement about z_g is therefore not fixed-order IRC safety. It is an all-order, Sudakov-conditioned statement inside a specified strongly ordered soft-collinear approximation.

Controlled Approximation 50.12 (Sudakov-conditioned groomed sharing)**.** Fix an initiating parton channel i, a normalized angle $\vartheta = \theta/R_0 \in (0,1]$, a soft-collinear ordering in decreasing ϑ, and a positive symmetrized splitting kernel $\overline{P}_i(z)$ on $0 < z \le 1/2$ in the declared subtraction scheme. In the fixed-coupling, independent-emission, strongly ordered chart, the accepted-emission rate is

$$\mathrm{d}\Gamma_i = a_i\,\overline{P}_i(z)\,\frac{\mathrm{d}\vartheta}{\vartheta}\,\mathrm{d}z\,\mathbf{1}_{\{z>z_{\mathrm{cut}}\vartheta^{\beta_{\mathrm{SD}}}\}}, \qquad a_i = \frac{\alpha_s C_i}{\pi}. \tag{50.37}$$

Let

$$\mathcal{P}_i(\zeta) = \int_\zeta^{1/2} \overline{P}_i(z)\,\mathrm{d}z, \qquad \mathcal{R}_i(\vartheta) = a_i \int_\vartheta^1 \frac{\mathrm{d}\vartheta'}{\vartheta'}\,\mathcal{P}_i\Big(z_{\mathrm{cut}}\vartheta'^{\beta_{\mathrm{SD}}}\Big), \qquad \Delta_i(\vartheta) = e^{-\mathcal{R}_i(\vartheta)}. \tag{50.38}$$

Here $\Delta_i(\vartheta)$ is the probability, inside this chart, that no emission at an angle larger than ϑ has passed grooming. The joint density of the first accepted split is then

$$\mathrm{d}\mathbb{P}_i(z_g,\vartheta_g) = \Delta_i(\vartheta_g)\,a_i\,\overline{P}_i(z_g)\,\frac{\mathrm{d}\vartheta_g}{\vartheta_g}\,\mathrm{d}z_g\,\mathbf{1}_{\{z_g>z_{\mathrm{cut}}\vartheta_g^{\beta_{\mathrm{SD}}}\}}. \tag{50.39}$$

This is a controlled approximation only after the kernel, coupling prescription, ordering variable, recoil convention, endpoint regularization, and matching to the rest of the factorization structure have been specified.

The derivation of (50.39) is the stopping-time identity for the ordered emission process. The probability of no accepted split before angle ϑ_g is $\Delta_i(\vartheta_g)$. The probability of one accepted split in the infinitesimal cell $(\vartheta_g, \vartheta_g + \mathrm{d}\vartheta_g) \times (z_g, z_g + \mathrm{d}z_g)$ is the rate (50.37). Multiple emissions in the same infinitesimal ordered cell are higher order in the cell volume. Multiplying these two factors gives (50.39). This argument does not replace a QCD factorization theorem; it is the finite probabilistic core that such a theorem must reproduce in its leading logarithmic coordinate.

The special case $\beta_{\mathrm{SD}} = 0$ exposes the mechanism transparently. Then $\mathcal{P}_i(z_{\mathrm{cut}}\vartheta^{\beta_{\mathrm{SD}}}) = \mathcal{P}_i(z_{\mathrm{cut}})$ is independent of ϑ, so

$$\Delta_i(\vartheta) = \vartheta^{a_i\mathcal{P}_i(z_{\mathrm{cut}})}.$$

If the idealized chart is allowed to run to arbitrarily small angle, the probability of eventually finding an accepted split is one, and integrating (50.39) over ϑ_g gives

$$p_i^{\mathrm{mMDT}}(z_g) = \frac{\overline{P}_i(z_g)}{\displaystyle\int_{z_{\mathrm{cut}}}^{1/2} \overline{P}_i(z)\,\mathrm{d}z}\,\mathbf{1}_{\{z_{\mathrm{cut}}<z_g\le 1/2\}}. \tag{50.40}$$

Indeed,

$$a_i\overline{P}_i(z_g)\int_0^1 \vartheta^{a_i\mathcal{P}_i(z_{\mathrm{cut}})}\,\frac{\mathrm{d}\vartheta}{\vartheta} = \frac{\overline{P}_i(z_g)}{\mathcal{P}_i(z_{\mathrm{cut}})}.$$

With a finite angular cutoff $\vartheta_{\min}$, the same expression is the conditional density after dividing by the accepted-event probability $1 - \Delta_i(\vartheta_{\min})$. The cancellation of a_i in (50.40) is not a statement that the observable is nonperturbative-free; it is a consequence of conditioning on the first accepted splitting inside this leading ordered chart. Running coupling, finite splitting functions, flavor changes, hadron masses, detector thresholds, and nonperturbative collinear dynamics all belong to the factorization and remainder data, not to the stopping-time identity alone.

For $\beta_{\mathrm{SD}} > 0$, a value $z_g < z_{\mathrm{cut}}$ can occur only at an angle satisfying

$$\vartheta_g < \left(\frac{z_g}{z_{\mathrm{cut}}}\right)^{1/\beta_{\mathrm{SD}}}.$$

The fixed-order expansion of the z_g distribution is then singular at the collinear boundary, while the all-order expression (50.39) may still define a finite distribution because $\Delta_i(\vartheta)$ suppresses the small-angle region. This is the precise sense, within the stated approximation, in which the coordinate is Sudakov-conditioned. It is a useful perturbative object only together with the Sudakov factor, the conditioning convention, and the remainder estimate for the measured jet sample.

Definition 50.13 (N-subjettiness)**.** For a jet with constituents k, choose N axes $\{a_1, \ldots, a_N\}$ by a specified IRC-safe axis prescription. For $\beta_\tau > 0$,

$$\tau_N^{(\beta_\tau)} = \frac{1}{p_{TJ} R_0^{\beta_\tau}} \sum_{k \in J} p_{Tk} \min_{a=1,\ldots,N} (\Delta R_{ka})^{\beta_\tau}.$$

Ratios such as $\tau_{21} = \tau_2/\tau_1$ are substructure coordinates only on the domain where the denominator is separated from zero; near the denominator boundary their distribution requires the same factorization and resummation data as the underlying τ_N.

The axis prescription is part of the observable. One prescription with a clean nonperturbative formulation is global minimization over axes. Let (Y, d) be the compact angular patch of a jet, with $\operatorname{diam} Y \le R_0$, and let μ be the positive transverse energy measure of the jet constituents on Y. For $M = \mu(Y) > 0$, define

$$\tau_{N,\min}^{(\beta_\tau)}(\mu) = \frac{1}{M R_0^{\beta_\tau}} \inf_{(a_1,\ldots,a_N)\in Y^N} \int_Y \min_{1\le r\le N} d(\mathbf{n}, a_r)^{\beta_\tau}\, \mathrm{d}\mu(\mathbf{n}). \tag{50.41}$$

For an event consisting of finitely many hadrons this is the usual N-subjettiness value with axes chosen by global minimization. The set of minimizing axes can have several components at symmetric configurations; the observable in (50.41) is the minimized value, not a chosen point in the minimizer set.

Lemma 50.14 (Continuity of minimized N-subjettiness)**.** *Fix $N \ge 1$, $\beta_\tau > 0$, $0 < m_0 < E < \infty$, and restrict to positive measures μ on Y with $m_0 \le \mu(Y) \le E$. The functional $\tau_{N,\min}^{(\beta_\tau)}$ of (50.41) is weakly continuous. If a soft constituent of transverse energy ε is added, then*

$$\left|\tau_{N,\min}^{(\beta_\tau)}(\mu + \varepsilon\delta_{\mathbf{m}}) - \tau_{N,\min}^{(\beta_\tau)}(\mu)\right| \le \frac{2\varepsilon}{m_0}. \tag{50.42}$$

If two constituents of total transverse energy E_{ab} and angular separation θ are replaced by their transverse-energy parent direction $\mathbf{n}_{ab}$, and if

$$d(\mathbf{n}_a, \mathbf{n}_{ab}) + d(\mathbf{n}_b, \mathbf{n}_{ab}) \le c\,\theta,$$

then

$$\left|\Delta\tau_{N,\min}^{(\beta_\tau)}\right| \le \frac{E_{ab}}{m_0 R_0^{\beta_\tau}}\, C_{\beta_\tau, R_0}\,(c\theta)^{\alpha_\tau}, \qquad \alpha_\tau = \min(\beta_\tau, 1), \tag{50.43}$$

where one may take $C_{\beta,R_0} = 1$ for $0 < \beta \le 1$ and $C_{\beta,R_0} = \beta R_0^{\beta-1}$ for $\beta \ge 1$.

Proof. For $A = (a_1, \dots, a_N) \in Y^N$, set

$$\Phi_A(\mathbf{n}) = \min_{1 \le r \le N} d(\mathbf{n}, a_r)^{\beta_\tau}.$$

The space Y^N is compact, and $A \mapsto \Phi_A$ is continuous as a map from Y^N to $C(Y)$ with the uniform norm. Therefore the infimum in (50.41) is attained. The family $\{\Phi_A : A \in Y^N\}$ is compact in $C(Y)$. If $\mu_j \to \mu$ weakly with uniformly bounded total mass, then

$$\sup_{A \in Y^N} \left| \int \Phi_A \, \mathrm{d}\mu_j - \int \Phi_A \, \mathrm{d}\mu \right| \longrightarrow 0.$$

Indeed, approximate the compact family $\{\Phi_A\}$ by a finite η-net in $C(Y)$, use weak convergence on the finite net, and then let $\eta \downarrow 0$. Taking infima over A is continuous under this uniform convergence, and division by $M = \mu(Y)$, bounded away from zero, gives weak continuity of $\tau_{N,\min}^{(\beta_\tau)}$.

For a soft addition, write

$$I(\mu) = \inf_A \int \Phi_A \, \mathrm{d}\mu.$$

Since $0 \le \Phi_A \le R_0^{\beta_\tau}$, one has

$$|I(\mu + \varepsilon\delta_{\mathbf{m}}) - I(\mu)| \le \varepsilon R_0^{\beta_\tau}.$$

Also $I(\mu) \le M R_0^{\beta_\tau}$. With $M' = M + \varepsilon$,

$$\left| \frac{I(\mu + \varepsilon\delta_{\mathbf{m}})}{M' R_0^{\beta_\tau}} - \frac{I(\mu)}{M R_0^{\beta_\tau}} \right| \le \frac{\varepsilon}{M'} + \frac{\varepsilon}{M'} \le \frac{2\varepsilon}{m_0}.$$

For collinear recombination, the total mass M is unchanged. The function $t \mapsto t^{\beta_\tau}$ on $[0, R_0]$ is α_τ-Hölder with the displayed constant:

$$|u^{\beta_\tau} - v^{\beta_\tau}| \le C_{\beta_\tau, R_0} |u - v|^{\alpha_\tau}.$$

For every axis tuple A,

$$|\Phi_A(\mathbf{n}_a) - \Phi_A(\mathbf{n}_{ab})| + |\Phi_A(\mathbf{n}_b) - \Phi_A(\mathbf{n}_{ab})| \le C_{\beta_\tau, R_0} (c\theta)^{\alpha_\tau},$$

up to replacing c by a harmless larger constant if the parent-direction bound is stated separately for each daughter. Hence the change in $\int \Phi_A \, \mathrm{d}\mu$ is bounded by $E_{ab} C_{\beta_\tau, R_0} (c\theta)^{\alpha_\tau}$, uniformly in A. Taking infima before and after recombination and dividing by $M R_0^{\beta_\tau}$, with $M \ge m_0$, gives (50.43). $\square$

Thus minimizing-axis N-subjettiness is an IRC-continuous calorimetric observable as a value functional. An algorithm that returns one selected minimizing axis may jump at degenerate events, but the minimized value used in the weighted cross section is continuous in the soft and collinear senses above. Ratios such as τ_{21} inherit this control only on regions where the denominator is bounded away from zero; otherwise their endpoint distribution is a separate singular observable.

Energy-correlation functions, defined in Chapter 49, provide a detector-based substructure alternative. They depend only on the positive calorimetric measure and angular kernels, whereas N-subjettiness also depends on an axis-finding map. Both are useful, but their mathematical inputs differ.

50.6 Energy Correlators as Calorimetric Coordinates

The cleanest way to formulate jet substructure without assigning physical status to partons is to regard an event as a positive energy measure on the celestial sphere or on a jet patch. For a final state X, write

$$\mu_X = \sum_{r \in X} E_r \, \delta_{\mathbf{n}_r}, \qquad \mathbf{n}_r = \frac{\mathbf{p}_r}{|\mathbf{p}_r|},$$

or, inside a jet of reference energy $E_{\rm ref}$,

$$\bar{\mu}_X = \frac{1}{E_{\rm ref}} \mu_X.$$

The total mass of $\bar{\mu}_X$ is one for a fully normalized jet and is at most one if acceptance cuts or grooming remove energy. A calorimetric observable is a function, distribution, or positive functional of this measure. The energy-flow detector of Chapter 49 is the operator whose spectral value on a hadronic out-state is precisely μ_X.

Definition 50.15 (Smeared energy-correlator functional)**.** Let $K \in C((S^2)^k)$. The K-smeared k-point energy-correlator functional of a finite positive Borel measure μ on S^2 is

$$\mathcal{C}_K^{(k)}(\mu) = \int_{(S^2)^k} K(\mathbf{n}_1, \ldots, \mathbf{n}_k) \, \mathrm{d}\mu(\mathbf{n}_1) \cdots \mathrm{d}\mu(\mathbf{n}_k). \tag{50.44}$$

If K is supported away from coincidence diagonals, this is a separated-angle detector product. If K meets a diagonal, the functional includes the contact part in which two detector insertions act on the same hadron. Both are part of the detector observable; removing a contact term is a different distributional convention.

The usual EEC is obtained by choosing a sequence of kernels

$$K_\Delta(\mathbf{n}_1, \mathbf{n}_2; \chi) \longrightarrow \delta(\cos\chi - \mathbf{n}_1 \cdot \mathbf{n}_2)$$

as angular distributions. Energy-correlation functions used for substructure, such as (49.278), are special cases with kernels built from powers of pairwise angular distances and with diagonal terms omitted or killed by positive powers of the distance.

Lemma 50.16 (Continuity of smeared energy correlators)**.** *Let K be Lipschitz on $(S^2)^k$, and restrict to measures with total mass at most E. Then $\mathcal{C}_K^{(k)}$ is continuous in the weak topology of finite measures. Moreover, if a final state is changed by adding a soft particle of energy ε, then*

$$|\Delta \mathcal{C}_K^{(k)}| \leq k \, \|K\|_\infty \, E^{k-1} \varepsilon + O(\varepsilon^2). \tag{50.45}$$

If two particles with total energy E_{ab} and angular separation θ_{ab} are replaced by their energy-weighted parent direction, then

$$|\Delta \mathcal{C}_K^{(k)}| \leq k \; \mathrm{Lip}(K) \, E^{k-1} E_{ab} \, O(\theta_{ab}) \tag{50.46}$$

on compact regions where the parent direction is defined.

Proof. Weak continuity follows because K is continuous on the compact space $(S^2)^k$, and product measures $\mu_j^{\otimes k}$ converge weakly to $\mu^{\otimes k}$ when $\mu_j \to \mu$ weakly with uniformly bounded total mass. This can be checked first on factorized kernels $K = f_1 \otimes \cdots \otimes f_k$, where the statement is the product of $\int f_i \, \mathrm{d}\mu_j \to \int f_i \, \mathrm{d}\mu$, and then extended to all continuous K by the Stone–Weierstrass theorem on $(S^2)^k$.

For a soft addition, write $\mu' = \mu + \varepsilon\delta_{\mathbf{m}}$. Expanding $(\mu+\varepsilon\delta_{\mathbf{m}})^{\otimes k} - \mu^{\otimes k}$, the terms linear in ε insert the new point in one of k slots and integrate the other $k-1$ slots against μ. Their absolute value is bounded by $k\|K\|_\infty E^{k-1}\varepsilon$; the remaining terms have at least two factors of ε.

For a collinear recombination, the signed measure difference is

$$\delta\mu = E_a\delta_{\mathbf{n}_a} + E_b\delta_{\mathbf{n}_b} - E_{ab}\delta_{\mathbf{n}_{ab}}, \qquad E_{ab} = E_a + E_b.$$

It has total mass zero. In each tensor slot, pairing $\delta\mu$ with the Lipschitz function obtained by fixing the other $k-1$ angles gives a bound by $\mathrm{Lip}(K)E_{ab}O(\theta_{ab})$. Summing over the k possible slots and bounding the other integrations by E^{k-1} gives (50.46). In terms with two or more insertions of $\delta\mu$, choose one insertion and use its zero total mass against the Lipschitz dependence on that slot; the remaining $\delta\mu$-insertions are bounded by their total variation, at most $2E_{ab}$. Thus every such term still carries the same $O(\theta_{ab})$ factor, with a constant depending on k, E, E_{ab}, and $\|K\|_\infty + \mathrm{Lip}(K)$. This proves the displayed IRC-continuity estimates. □

Theorem 50.17 (Energy-correlator polynomials separate calorimetric observables)**.** *Let*

$$\mathcal{M}_E(S^2) = \{\mu \geq 0 : \mu(S^2) \leq E\}$$

be the compact space of finite positive Borel measures on S^2, equipped with the weak topology. Let $\mathcal{A}_E$ be the real algebra generated by the linear energy moments

$$\mu \longmapsto \int_{S^2} f(\mathbf{n}) \, \mathrm{d}\mu(\mathbf{n}), \qquad f \in C(S^2).$$

Equivalently, $\mathcal{A}_E$ is the algebra of finite linear combinations of smeared energy correlators $\mathcal{C}_K^{(k)}$ with factorized kernels $K = f_1 \otimes \cdots \otimes f_k$. Then $\mathcal{A}_E$ is uniformly dense in $C(\mathcal{M}_E(S^2))$.

Proof. The space $\mathcal{M}_E(S^2)$ is compact in the weak topology. Indeed, positive measures with total mass at most E are a weak-$*$ closed subset of the radius-E ball in the dual of $C(S^2)$, and that ball is weak-$*$ compact by Banach–Alaoglu; because $C(S^2)$ is separable, this compact topology is metrizable. The algebra $\mathcal{A}_E$ contains constants by taking the empty product, and it is closed under multiplication because products of linear moments are generated by the algebra definition.

It separates points. If $\mu \neq \nu$, the signed measure $\mu - \nu$ is a nonzero continuous linear functional on $C(S^2)$. By the Riesz representation theorem there is an $f \in C(S^2)$ such that

$$\int f \, \mathrm{d}\mu \neq \int f \, \mathrm{d}\nu.$$

Thus the linear moment $M_f(\mu) = \int f \, \mathrm{d}\mu$ distinguishes μ and ν. The real Stone–Weierstrass theorem applies to the compact Hausdorff space $\mathcal{M}_E(S^2)$: a real subalgebra of $C(\mathcal{M}_E(S^2))$ that contains constants and separates points is uniformly dense. Hence $\mathcal{A}_E$ is dense.

A monomial

$$M_{f_1}(\mu)\cdots M_{f_k}(\mu)=\int_{(S^2)^k} f_1(\mathbf{n}_1)\cdots f_k(\mathbf{n}_k)\,\mathrm{d}\mu(\mathbf{n}_1)\cdots \mathrm{d}\mu(\mathbf{n}_k)$$

is exactly $\mathcal{C}^{(k)}_K(\mu)$ for the factorized kernel $K = f_1\otimes\cdots\otimes f_k$, by the defining property of the product measure $\mu^{\otimes k}$. Finite linear combinations of such monomials are therefore exactly the finite factorized-kernel energy-correlator polynomials, so the dense algebra is an energy-correlator algebra. □

The theorem is a finite-resolution statement. It applies to continuous functions of the calorimetric measure on the compact energy ball $\mathcal{M}_E(S^2)$. Sharp step-function cuts, exact jet-counting boundaries, and distributional angular kernels are obtained as limits of continuous observables, and their boundary terms must be analyzed separately. Graph-indexed energy-flow polynomials used in jet physics choose a concrete family of angular kernels built from pairwise distances. Treating that smaller family as a practical basis requires an additional approximation statement for angular kernels on the detector resolution and symmetry class being used. The object-level reason for their robustness is the theorem above: energy correlators are coordinates on the positive energy measure itself, not on a partonic history.

50.7 Shape Functions and Track Functions

When a measured event shape is of order Λ_{QCD}/Q, the soft function in (50.8) contains nonperturbative matrix elements. The endpoint statement has two logically separate pieces. First one must define a soft operator coordinate. Then one may state a factorized approximation that convolves this coordinate with a short-distance coefficient in a specified endpoint topology.

Definition 50.18 (Leading shape-function operator definition)**.** Fix a two-jet SCET operator specification as in Definition 50.3, an event-shape soft measurement coordinate $\widehat{\ell}_e$, and a renormalization scheme $\mathcal{R}_\mu$ for the cusp and endpoint singularities of the Wilson-line operator. A leading shape-function operator definition consists of:

1. outgoing soft Wilson lines $Y_n, Y_{\bar n}$ in the representations carried by the two energetic charges;
2. for every test function h on $[0,\infty)$, a renormalized composite insertion $h_{\mathcal{R}_\mu}(\widehat{\ell}_e)$;
3. a normalization factor N_R, equal to the dimension of the color representation in the fundamental two-jet case, together with the convention that the identity insertion has unit matrix element.

The shape function $F_e(\ell,\mu;\mathcal{R})$ is the distribution on $[0,\infty)$ defined by

$$\int_0^\infty \mathrm{d}\ell\, h(\ell)F_e(\ell,\mu;\mathcal{R}) = \frac{1}{N_R}\,\mathrm{tr}\langle\Omega|\overline{\mathrm{T}}\Big(Y_{\bar n}^\dagger Y_n\Big)\, h_{\mathcal{R}_\mu}(\widehat{\ell}_e)\,\mathrm{T}\Big(Y_n^\dagger Y_{\bar n}\Big)\,|\Omega\rangle_{\mathcal{R}_\mu}. \tag{50.47}$$

At finite regulator with a positive self-adjoint measurement operator $\widehat{\ell}_e$, this pairing is the spectral measure of $\widehat{\ell}_e$ in the Wilson-line state. After renormalization it is a scheme-dependent distributional coordinate. The normalization and first moment are

$$\int_0^\infty \mathrm{d}\ell\, F_e(\ell,\mu;\mathcal{R}) = 1, \qquad \Omega_1^e(\mu;\mathcal{R}) = \int_0^\infty \mathrm{d}\ell\,\ell\, F_e(\ell,\mu;\mathcal{R}), \tag{50.48}$$

whenever the displayed moments exist in the chosen scheme.

The QFT object is the operator pairing (50.47). In a phenomenological analysis one often chooses a finite-dimensional positive family for F_e and fits its parameters to data. That fitted family is an additional statistical model for the matrix element (50.47). The lattice route to the same nonperturbative information must start from a finite gauge-field regulator as in Chapter 46 and a continuum reconstruction or matching statement as in Chapter 143. Because (50.47) contains lightlike Wilson-line geometry, a Euclidean calculation needs a separately specified quasi-, ratio-, or reconstruction observable and a matching theorem connecting it to the lightlike shape coordinate.

Controlled Approximation 50.19 (Leading endpoint shape-function convolution)**.** Let e be a dimensionless two-jet event shape and let Q be the hard scale. A leading shape-function description on an endpoint window $e \sim \Lambda_{\mathrm{QCD}}/Q$ consists of:

1. the operator definition of Definition 50.18;
2. a perturbative coefficient distribution $\mathrm{d}\sigma_{\mathrm{pert}}/\mathrm{d}e$ in the same subtraction scheme;
3. a Banach space $\mathcal{B}_{\mathrm{end}}$ of test functions supported in the endpoint window;
4. a remainder functional R_Q on $\mathcal{B}_{\mathrm{end}}$ with a stated bound, for example $\|R_Q\|_{\mathcal{B}^*_{\mathrm{end}}} \le CQ^{-2}$ in a single-soft-coordinate situation.

The approximation means that, for every $f \in \mathcal{B}_{\mathrm{end}}$,

$$\left\langle \frac{\mathrm{d}\sigma}{\mathrm{d}e}, f \right\rangle = \int_0^\infty \mathrm{d}\ell\, F_e(\ell, \mu; \mathcal{R}) \int \mathrm{d}e'\, \frac{\mathrm{d}\sigma_{\mathrm{pert}}}{\mathrm{d}e'}(e', Q, \mu; \mathcal{R})\, f\!\left(e' + \frac{\ell}{Q}\right) + R_Q(f). \tag{50.49}$$

Equivalently, when the distributions admit densities in the chosen chart,

$$\frac{\mathrm{d}\sigma}{\mathrm{d}e} = \int_0^\infty \mathrm{d}\ell\, F_e(\ell, \mu; \mathcal{R}) \frac{\mathrm{d}\sigma_{\mathrm{pert}}}{\mathrm{d}e}\left(e - \frac{\ell}{Q}, Q, \mu; \mathcal{R}\right) + R_Q(e). \tag{50.50}$$

The elementary consequences of the convolution are useful diagnostics for normalization and scheme bookkeeping. Taking $f(e) = 1$ in (50.49) and using (50.48) gives equality of the total weighted cross section up to $R_Q(1)$. Taking $f(e) = e$ gives

$$\int \mathrm{d}e\, e\, \frac{\mathrm{d}\sigma}{\mathrm{d}e} = \int \mathrm{d}e\, e\, \frac{\mathrm{d}\sigma_{\mathrm{pert}}}{\mathrm{d}e} + \frac{\Omega_1^e(\mu; \mathcal{R})}{Q} \int \mathrm{d}e\, \frac{\mathrm{d}\sigma_{\mathrm{pert}}}{\mathrm{d}e} + R_Q(e). \tag{50.51}$$

Thus the first nonperturbative moment translates the endpoint event shape by Ω_1^e/Q in this leading single-coordinate approximation. A finite change of subtraction convention may move a constant amount $\delta\ell$ between the perturbative coefficient and the shape coordinate:

$$F_e'(\ell) = F_e(\ell - \delta\ell), \qquad \frac{\mathrm{d}\sigma_{\mathrm{pert}}'}{\mathrm{d}e}(e) = \frac{\mathrm{d}\sigma_{\mathrm{pert}}}{\mathrm{d}e}\left(e + \frac{\delta\ell}{Q}\right). \tag{50.52}$$

The convolution is invariant under the paired transformation (50.52), modulo boundary and truncation terms. Hence a numerical value quoted for Ω_1^e is meaningful only with its event-shape definition, Wilson-line orientation, regulator, and subtraction scheme.

Track-based observables measure only charged hadrons. They are generally not IRC safe as ordinary partonic measurements, because a collinear splitting can change the charged energy fraction observed by the detector. The replacement input is a track function. For a parton species i, let $T_i(x,\mu)$ be the renormalized track coordinate, in a specified operator scheme, for the fraction $x \in [0,1]$ of the parent energy carried by charged tracks. At a reference nonperturbative scale this coordinate is naturally a probability measure. After renormalization it should be viewed as a scheme-dependent distributional coordinate whose normalization is fixed by the operator definition; when it has a density we write the same symbol for that density. Perturbative coefficients are then convolved with T_i rather than evaluated with a purely partonic charged-energy measurement.

Definition 50.20 (Track-function operator definition)**.** Fix a lightlike collinear direction n, the conjugate vector $\bar{n}$ with $n \cdot \bar{n} = 2$, and the SCET operator conventions of Definition 50.3. A track-function operator definition for a parton species i consists of:

1. a gauge-invariant collinear source $\mathcal{O}_i$, for example χ_n for a quark species or $\mathcal{B}^{\mu}_{n\perp}$ for a gluon species, together with the spin, color, and polarization averaging convention used to normalize the source;
2. a detector weight w_{tr} on stable color-singlet final-state particle species, with $w_{\mathrm{tr}} = 1$ for charged tracks and $w_{\mathrm{tr}} = 0$ for neutral particles in the idealized charged-track observable;
3. a positive charged collinear momentum operator $\bar{n} \cdot \widehat{P}_{\mathrm{tr}}$ obtained by weighting the stable final-state momentum operator with w_{tr}, and the total collinear momentum operator $\bar{n} \cdot \widehat{P}_{\mathrm{col}}$;
4. the bounded measurement operator
$$\widehat{x}_{\mathrm{tr}} = \frac{\bar{n} \cdot \widehat{P}_{\mathrm{tr}}}{\bar{n} \cdot \widehat{P}_{\mathrm{col}}}$$
on the positive-energy sector created by $\mathcal{O}_i$, where $0 \le \widehat{x}_{\mathrm{tr}} \le 1$;
5. a regulator and subtraction scheme $\mathcal{R}_\mu$ for the light-ray collinear matrix element and for the endpoint singularities of the measurement insertion.

For every test function h on $[0,1]$, the track function is the renormalized distribution defined by

$$\int_0^1 \mathrm{d}x\, h(x) T_i(x,\mu;\mathcal{R}) = \frac{1}{\mathcal{N}_i(\mu;\mathcal{R})} \langle \Omega | \overline{\mathcal{O}}_i(0)\, h_{\mathcal{R}_\mu}(\widehat{x}_{\mathrm{tr}})\, \mathcal{O}_i(0) | \Omega \rangle_{\mathcal{R}_\mu}. \tag{50.53}$$

The normalization factor $\mathcal{N}_i$ is fixed by the requirement that the pairing with $h = 1$ equals 1. At finite regulator this is the spectral distribution of a bounded charged-energy fraction in the inclusive collinear state created by the gauge-invariant source. In continuum QCD it is a renormalized distributional matrix element; its value is meaningful only after the source, detector weight, regulator, and subtraction scheme have all been specified.

This definition is the nonperturbative QCD object associated with the chosen collinear source. The parton label i labels that source in the factorized approximation. Gauge invariance enters through the Wilson-line building blocks χ_n and $\mathcal{B}_{n\perp}$, while the charged-track measurement is a color-singlet final-state measurement. The renormalization of (50.53) is separate from the renormalization of the hard partonic coefficient into which the track function is inserted.

Definition 50.21 (Paired track-function evolution structure)**.** Fix a renormalization scale μ. A finite-kernel track-function evolution structure consists of:

- a finite set $\mathcal{I}$ of parton species;

- for every ordered splitting $i \to jk$, an integrable kernel $K_{i\to jk}(z,\mu)$ on $0 < z < 1$;
- the paired loss rate

$$\Gamma_i(\mu) = \sum_{j,k\in\mathcal{I}} \int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu).$$

The associated evolution equation for track coordinates is

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}T_i(x,\mu) = \sum_{j,k\in\mathcal{I}} \int_0^1 \mathrm{d}z \int_0^1 \mathrm{d}x_1\,\mathrm{d}x_2\, K_{i\to jk}(z,\mu)\, T_j(x_1,\mu)T_k(x_2,\mu)\delta(x - zx_1 - (1-z)x_2) \\ - \Gamma_i(\mu)T_i(x,\mu). \tag{50.54}$$

In perturbative QCD the kernels are renormalized splitting distributions rather than honest integrable functions before smearing; the finite-kernel definition records the algebraic real–virtual pairing that the renormalized distributional equation must preserve.

Normalization and first moment of track-function evolution. Suppose the track functions in Definition 50.21 have unit normalization,

$$\int_0^1 \mathrm{d}x\, T_i(x,\mu) = 1.$$

The paired evolution (50.54) preserves this normalization. If

$$m_i(\mu) = \int_0^1 \mathrm{d}x\, x\, T_i(x,\mu)$$

is the charged-energy first moment, then

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}m_i(\mu) = \sum_{j,k} \int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu) \left[z\, m_j(\mu) + (1-z)m_k(\mu) - m_i(\mu)\right]. \tag{50.55}$$

Integrating (50.54) over x and using

$$\int_0^1 \mathrm{d}x\, \delta(x - zx_1 - (1-z)x_2) = 1,$$

because $0 \le zx_1 + (1-z)x_2 \le 1$, gives

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\int_0^1 \mathrm{d}x\, T_i(x,\mu) = \sum_{j,k} \int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu) \left[\left(\int T_j\right)\left(\int T_k\right) - \int T_i\right].$$

If all normalizations are 1, the bracket vanishes for every splitting channel. Hence the normalization is preserved.

Multiplying by x before integrating gives

$$\int_0^1 \mathrm{d}x\, x\, \delta(x - zx_1 - (1-z)x_2) = zx_1 + (1-z)x_2.$$

The gain term therefore contributes

$$\sum_{j,k}\int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu)\left[z\, m_j(\mu)\int T_k + (1-z)\, m_k(\mu)\int T_j\right].$$

Using unit normalization and subtracting the loss term $\Gamma_i m_i$ gives (50.55).

The same finite-kernel equation controls the whole moment tower. Define

$$m_i^{(r)}(\mu) = \int_0^1 \mathrm{d}x\, x^r T_i(x,\mu), \qquad m_i^{(0)} = 1,$$

and, when the exponential test function is admissible in the chosen distributional scheme,

$$M_i(\nu,\mu) = \int_0^1 \mathrm{d}x\, e^{\nu x} T_i(x,\mu).$$

Pairing (50.54) with $e^{\nu x}$ gives

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu} M_i(\nu,\mu) = \sum_{j,k}\int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu)\left[M_j(z\nu,\mu)M_k((1-z)\nu,\mu) - M_i(\nu,\mu)\right]. \tag{50.56}$$

Expanding both sides in powers of ν yields, for every $r \geq 0$,

$$\mu\frac{\mathrm{d}}{\mathrm{d}\mu} m_i^{(r)} = \sum_{j,k}\int_0^1 \mathrm{d}z\, K_{i\to jk}(z,\mu)\left[\sum_{a=0}^{r}\binom{r}{a} z^a (1-z)^{r-a} m_j^{(a)} m_k^{(r-a)} - m_i^{(r)}\right]. \tag{50.57}$$

The $r = 0$ member is normalization preservation and the $r = 1$ member is (50.55). For $r \geq 2$ the evolution of a single moment depends on lower and equal moments of daughter species. This is why track-based jet observables require a genuine distributional nonperturbative input, or an equivalently complete moment sequence in a specified scheme; a single average charged fraction is not stable under collinear renormalization.

Track functions are therefore nonperturbative inputs with perturbative evolution, not substitutes for IRC safety. The point is sharper than a terminological distinction: a track observable is calculable only after the observable has been lifted from a partonic measurement to a convolution with the nonperturbative track coordinates and the real–virtual pairing in Definition 50.21 has been specified.

Definition 50.22 (Finite track lift of an energy-measure observable)**.** Fix a partonic short-distance configuration with labeled partons

$$a = 1,\dots,n, \qquad (i_a, E_a, y_a),$$

where i_a is the parton species, $E_a > 0$ is the energy coordinate, and y_a is the angular coordinate in the detector patch. A finite track-function lift assigns to each label a an independent random variable $X_a \in [0,1]$ with law T_{i_a} and replaces the calorimetric energy measure by the random charged-track energy measure

$$\mu_{\mathrm{tr}} = \sum_{a=1}^{n} X_a E_a\, \delta_{y_a}.$$

For a smeared k-point energy polynomial with continuous kernel f,

$$\mathcal{E}_f(\mu) = \int f(y_1, \ldots, y_k)\, \mu(dy_1) \cdots \mu(dy_k),$$

the lifted partonic coefficient is the conditional expectation

$$\mathbb{E}_T\, \mathcal{E}_f(\mu_{\mathrm{tr}}).$$

This finite definition is the algebraic core of a track-based factorization formula. A QCD prediction additionally requires the operator definition of the track functions, their subtraction scheme and RG evolution, the short-distance coefficient into which this lift is inserted, and a remainder estimate for the leading-power track-factorization approximation.

The finite lift shows why track observables cannot be reduced to replacing each energy by the average charged fraction. Let

$$m_i^{(r)} = \int_0^1 x^r\, T_i(x)\, \mathrm{d}x$$

be the r-th track moment whenever this moment is defined in the chosen scheme. For the two-point polynomial one obtains

$$\begin{aligned}\mathbb{E}_T\, \mathcal{E}_f(\mu_{\mathrm{tr}}) = &\sum_{a \neq b} E_a E_b\, f(y_a, y_b)\, m_{i_a}^{(1)} m_{i_b}^{(1)} \\ &+ \sum_a E_a^2\, f(y_a, y_a)\, m_{i_a}^{(2)}.\end{aligned} \tag{50.58}$$

The second line is a diagonal term in the energy-measure polynomial. It is controlled by the second track moment, not by the square of the first moment. For a general k-point energy polynomial the exact finite formula is the following. Let

$$\alpha : \{1, \ldots, k\} \longrightarrow \{1, \ldots, n\}$$

record which short-distance parton supplies the energy in each detector slot. Independence of the finite track variables gives

$$\mathbb{E}_T\, \mathcal{E}_f(\mu_{\mathrm{tr}}) = \sum_{\alpha:\{1,\ldots,k\}\to\{1,\ldots,n\}} \left(\prod_{r=1}^{k} E_{\alpha(r)} \right) f\big(y_{\alpha(1)}, \ldots, y_{\alpha(k)}\big) \prod_{a \in \operatorname{im} \alpha} m_{i_a}^{(|\alpha^{-1}(a)|)}. \tag{50.59}$$

Thus each block of detector slots fed by the same short-distance label uses the corresponding higher track moment. For a three-point kernel, writing $f_{abc} = f(y_a, y_b, y_c)$, the formula separates into

$$\begin{aligned}\mathbb{E}_T\, \mathcal{E}_f(\mu_{\mathrm{tr}}) = &\sum_{\substack{a,b,c \\ \text{distinct}}} E_a E_b E_c\, f_{abc}\, m_{i_a}^{(1)} m_{i_b}^{(1)} m_{i_c}^{(1)} \\ &+ \sum_{a \neq b} E_a^2 E_b \left(f_{aab} + f_{aba} + f_{baa} \right) m_{i_a}^{(2)} m_{i_b}^{(1)} \\ &+ \sum_a E_a^3\, f_{aaa}\, m_{i_a}^{(3)}.\end{aligned} \tag{50.60}$$

The diagonal and partial-diagonal pieces are not optional refinements: they are part of the definition of the lifted observable. Omitting them, or replacing every track variable by its first moment, changes the observable whose short-distance coefficient is being computed.

The same bookkeeping explains the collinear composition law behind (50.54). If a parent with energy E is resolved into daughters with energy fractions z and $1-z$, then the track fraction assigned to the unresolved pair is

$$X = zX_1 + (1-z)X_2.$$

Thus

$$\mathbb{E}[X] = z\, m_j^{(1)} + (1-z)m_k^{(1)}, \tag{50.61}$$

$$\mathbb{E}[X^2] = z^2 m_j^{(2)} + (1-z)^2 m_k^{(2)} + 2z(1-z)m_j^{(1)}m_k^{(1)}. \tag{50.62}$$

A track-based observable is therefore not IRC safe as a bare partonic function. Rather, its collinear boundary is a renormalization problem for the whole sequence of track moments, or equivalently for the track distribution. This is the precise meaning of using track functions in a jet-substructure calculation.

50.8 Parton Showers

A parton shower is a stochastic implementation of soft and collinear factorized evolution. At leading soft-collinear order, a final-state branching probability for a parton of type i is built from the Sudakov factor

$$\Delta_i(t_1, t_0) = \exp\left[-\int_{t_0}^{t_1} \frac{\mathrm{d}t}{t} \sum_{i\to jk} \int \mathrm{d}z\, \frac{\alpha_s(\kappa(t,z))}{2\pi} P_{i\to jk}(z)\right], \tag{50.63}$$

where t is the shower ordering variable, z is the splitting fraction, $P_{i\to jk}$ is an Altarelli–Parisi splitting kernel, and $\kappa(t,z)$ is the scale at which the running coupling is evaluated. The probability for the next branching between t and $t+\mathrm{d}t$ is the Sudakov no-branching probability multiplied by the differential splitting kernel.

Different showers choose different evolution variables, recoil maps, momentum conservation prescriptions, and color structures. Angular-ordered showers encode color coherence through emission angles. Dipole and antenna showers use color-connected pairs as emitters. Many practical implementations use a leading-color approximation in which the color algebra is replaced by a planar color-flow structure; subleading-color corrections require additional operator information.

Controlled Approximation 50.23 (Shower accuracy)**.** A shower calculation has a stated logarithmic accuracy only for a specified class of observables and a specified matching or merging scheme. The basic Markov shower reproduces leading soft-collinear logarithms for observables compatible with its ordering variable. NLO-matched prescriptions such as MC@NLO or POWHEG replace the first hard emission and inclusive normalization by exact NLO matrix-element information while retaining the shower resummation for subsequent unresolved radiation. Multijet merging combines samples with different resolved parton multiplicities using a merging scale whose residual dependence is part of the perturbative uncertainty estimate.

50.9 Hadronization and Fragmentation Functions

Hadronization is the nonperturbative formation of outgoing hadrons from the high-energy QCD state produced by the short-distance interaction. In the exact theory it is simply time evolution in the physical Hilbert space of QCD. In phenomenological calculations it is represented by additional nonperturbative inputs after the perturbative hard, jet, and soft evolution has been organized.

For identified hadron production, the corresponding input is a fragmentation function. Let n^μ be a lightlike vector and let $\bar{n}^\mu$ satisfy $n \cdot \bar{n} = 2$. A quark fragmentation function may be represented by a light-ray operator with Wilson lines:

$$D_{h/q}(z,\mu) = \frac{1}{2zN_c} \sum_X \int \frac{\mathrm{d}y^+}{2\pi} \mathrm{e}^{-\mathrm{i}P_h^- y^+/z} \operatorname{tr}\left[\frac{\gamma \cdot \bar{n}}{2} \langle 0|W^\dagger(y^+) q(y^+)|hX\rangle\langle hX|\bar{q}(0)W(0)|0\rangle\right]_{\mathrm{ren}}. \tag{50.64}$$

Here P_h^- is the large light-cone momentum of the observed hadron, $z = P_h^-/k^-$ is the momentum fraction relative to the parent partonic coordinate k^-, W is the appropriate lightlike Wilson line, and the subscript indicates operator renormalization. This is a nonperturbative matrix-element definition, not a probability for a physical colored quark to exist as an external state. A regulator is part of the definition of the light-ray composite, and lightlike Wilson lines may require endpoint, cusp, or rapidity subtractions depending on the observable. The scale dependence of $D_{h/q}$ is governed by DGLAP evolution, while its boundary value at a finite scale is nonperturbative data.

Lund string and cluster hadronization models are phenomenological parametrizations of this nonperturbative stage. A string model uses color flux-tube breaking with fitted parameters for string tension, flavor production, and transverse momentum. A cluster model first organizes the partonic state into color-singlet clusters and then decays those clusters into hadrons with fitted rules. Their predictions therefore carry model and tuning uncertainties in addition to perturbative uncertainties.

The lattice formulation of Chapter 46 is the regulator-level nonperturbative definition of the gauge theory used in this volume. It computes Euclidean finite-volume correlation functions directly in terms of hadronic states. Real-time fragmentation functions and fully exclusive hadronization histories involve lightlike or timelike information, so their extraction from Euclidean lattice data requires additional reconstruction, finite-volume, or large-momentum matching ideas. This is a technical obstruction in the observable, not a license to replace the nonperturbative QCD input by a perturbative calculation.

50.10 Classes of QCD Final-State Observables

The useful separation is by the mathematical input required by the observable.

Total inclusive rates and IRC-safe event shapes.
The required input is renormalized fixed-order amplitudes, KLN cancellation, and resummation when hierarchical scales are measured.

IRC-safe jet cross sections.
The required input is an IRC-safe jet algorithm, fixed-order hard functions, PDFs for incom-

ing hadrons, and logarithmic resummation where jet vetoes or small radii introduce large logarithms.

Energy correlators.
The required input is the stress-tensor energy-flow operators on the physical Hilbert space, together with angular test kernels defining continuous functionals of the calorimetric measure. The density theorem 50.17 explains why smeared energy-correlator polynomials form a natural coordinate system for finite-resolution calorimetric observables. Partonic perturbation theory is used only after the detector observable has been defined.

Identified hadron spectra.
The required input is fragmentation functions or fracture functions, their operator renormalization, and nonperturbative boundary data.

Fully exclusive hadronization patterns.
The required input is the full QCD final-state distribution or a phenomenological model with stated fit parameters and model uncertainty.

This classification keeps the physics claims separated. Perturbative QCD computes short-distance coefficients and IRC-safe partonic representatives. Fragmentation functions, PDFs, shape functions, and hadronization models are additional nonperturbative data or controlled approximations with their own definitions and uncertainties. Energy correlators are especially valuable because they are nonperturbatively defined by the stress tensor and are insensitive, after smearing, to soft emissions and collinear recombination in the precise sense used in Controlled Approximation 50.2.

Chapter 51

Chiral Axial Anomalies

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

51.1 Classical Chiral Currents

Let ψ be a Dirac fermion in four dimensions. Throughout this chapter the Lorentzian metric is mostly plus and the Dirac adjoint is

$$\bar{\psi} := \mathrm{i}\psi^\dagger \gamma^0.$$

These are the gamma-matrix conventions developed in Chapter 40 and centralized in Section 40.16. The anomaly signs below use the same orientation, chirality matrix, and dimensional-continuation prescription. The flat oriented coordinate systems used in the perturbative calculations are fixed by

$$\epsilon^{01} = +1 \quad \text{in two dimensions}, \qquad \epsilon^{0123} = +1 \quad \text{in four dimensions}.$$

The symbols $\epsilon^{\mu\nu}$ and $\epsilon^{\mu\nu\rho\sigma}$ are totally antisymmetric with these normalizations. In four dimensions the chirality convention is

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3, \qquad \mathrm{tr}\big(\gamma_5\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\big) = 4\mathrm{i}\,\epsilon^{\mu\nu\rho\sigma}.$$

Gauge generators in this chapter use the same Hermitian convention as Chapter 45: if $A_\mu = A^a_\mu t^a$, then

$$[t^a, t^b] = \mathrm{i}f^c{}_{ab}t^c, \qquad \mathrm{tr}(t^a t^b) = \delta^{ab}$$

unless a different trace is explicitly declared. The trace-form anomaly expressions are written in terms of the matrix-valued curvature

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - \mathrm{i}[A_\mu, A_\nu],$$

so a change of generator normalization rescales the component fields and coupling coordinates but not the matrix trace formula itself. With this adjoint the Hermitian bilinear current associated with a real phase rotation contains an explicit factor of i. Couple ψ to a background or dynamical gauge field through

$$D_\mu\psi = \partial_\mu\psi - \mathrm{i}A_\mu\psi.$$

Definition 51.1 (Anomaly representative conventions)**.** An anomaly formula in this chapter means a renormalized local Ward identity for specified composite currents after four pieces of data have been fixed. First, the gauge and vector Ward identities that define the background coupling are preserved by the regulator and by the counterterm convention. Second, the remaining local term is represented in the Hermitian trace normalization stated above, namely $\mathrm{tr}(t^a t^b) = \delta^{ab}$ unless another trace is declared. Third, the orientation and chirality matrix are the displayed ones. Fourth, local counterterms have been chosen; changing them changes the representative of the anomaly but not its BRST cohomology class.

The perturbative triangle calculations below use dimensional reduction in the following restricted sense: the loop momentum is analytically continued while γ_5 and the antisymmetric tensor are kept in the physical two- or four-dimensional subspace. The heat-kernel calculation in the measure section is instead a spectral regulator for a Berezinian trace. No Pauli–Villars auxiliary field is used, and no claim is made that dimensional continuation by itself defines a nonperturbative fermionic path integral.

Warning 51.2 (Anomaly signs are tied to the full convention datum)*.* The anomaly coefficients in this chapter are not portable by changing one symbol at a time. The signs and factors use simultaneously the mostly-plus Dirac adjoint, $\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$, $\epsilon^{0123} = +1$, the Hermitian covariant derivative $D_\mu = \partial_\mu - \mathrm{i}A_\mu$, the curvature $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - \mathrm{i}[A_\mu, A_\nu]$, and the trace convention fixed in Chapter 45. Changing any one of these choices requires translating the whole convention datum, including the topological charge normalization and the local counterterm representative. Dimensional reduction below is only the perturbative regulator used to compute the displayed Ward-identity representative; it is not being used as a nonperturbative definition of the fermionic path integral.

Proposition 51.3 (Anomaly-coordinate comparison)**.** *Fix a regulated background-field groupoid $\mathcal{B}_\Lambda//\mathcal{G}_\Lambda$, with right action $A \mapsto A^g$, and a local regulator chart in which the chiral fermion functional is a scalar $W_\Lambda[A]$. Then the finite cochain*

$$C_\Lambda(g; A) = W_\Lambda[A^g] - W_\Lambda[A]$$

is the additive coordinate of the anomaly line. More precisely:

1. *functoriality of the groupoid action gives $C_\Lambda(gh; A) = C_\Lambda(h; A^g) + C_\Lambda(g; A)$;*
2. *a local counterterm $B_\Lambda[A]$ changes this coordinate by the coboundary $B_\Lambda[A^g] - B_\Lambda[A]$;*
3. *after choosing a local frame s_A for the anomaly line, the exponentiated transport cocycle is $\alpha_\Lambda(A, g) = \exp C_\Lambda(g; A)$, and the same counterterm is the inverse frame change $s_A \mapsto \exp(-B_\Lambda[A])s_A$;*

4. *the inflow bulk carries the inverse line coordinate* $\alpha_\Lambda(A,g)^{-1}$*;*
5. *differentiating* $C_\Lambda(\exp(t\zeta);A)$ *at* $t=0$*, then taking the local continuum representative, gives the consistent local anomaly density* $a_4^{(1)}(\zeta,A)$*, whose relative BRST class is the perturbative obstruction.*

Consequently local BRST cancellation removes the obstruction on the identity component of the background groupoid, while flat determinant- or Pfaffian-line holonomies on based loops remain separate global anomaly data.

Proof. The first identity is just the scalar form of functoriality:

$$W_\Lambda[A^{gh}]-W_\Lambda[A]=\big(W_\Lambda[(A^g)^h]-W_\Lambda[A^g]\big)+\big(W_\Lambda[A^g]-W_\Lambda[A]\big).$$

Replacing W_Λ by $W_\Lambda+B_\Lambda$ gives the displayed coboundary. If the line is locally framed by s_A and

$$T_g s_A=\alpha_\Lambda(A,g)s_{A^g},$$

then the frame $s'_A=\exp(-B_\Lambda[A])s_A$ gives

$$T_g s'_A=\exp(-B_\Lambda[A])\alpha_\Lambda(A,g)\exp(B_\Lambda[A^g])s'_{A^g},$$

which is the exponential of the same additive coboundary. The bulk inflow line is the inverse anomaly line, so its transport cocycle is α_Λ^{-1}, and tensoring boundary and bulk transports gives the identity transport.

For a one-parameter gauge transformation $g(t)=\exp(t\zeta)$, the derivative of the finite cocycle is

$$\left.\frac{d}{dt}\right|_{t=0}C_\Lambda(g(t);A)=\delta_\zeta W_\Lambda[A].$$

After subtracting local counterterms and passing to the continuum local functional, this derivative is represented by $\int_M a_4^{(1)}(\zeta,A)$. Differentiating the finite cocycle identity in two infinitesimal directions gives the Wess–Zumino consistency condition, and replacing the even gauge parameters by the odd ghost gives the relative BRST cocycle in $H^{1,4}(s\mid d)$, developed later in Proposition 51.9. A local counterterm changes the representative by the corresponding relative coboundary. This infinitesimal argument only sees the identity component of the background groupoid. A flat but nontrivial line holonomy along a based loop has zero local curvature and zero local descent class, but still prevents a gauge-invariant global scalar section; that global obstruction is the determinant/Pfaffian-line story developed in Chapter 153. □

For a mass m, the Dirac Lagrangian is

$$\mathcal{L}=-\bar\psi\gamma^\mu D_\mu\psi-m\bar\psi\psi.$$

When $m=0$, the classical equations of motion imply conservation of the vector and axial currents

$$j^\mu=\mathrm{i}\bar\psi\gamma^\mu\psi,\qquad j_5^\mu=\mathrm{i}\bar\psi\gamma^\mu\gamma_5\psi,\qquad \partial_\mu j^\mu=0,\qquad \partial_\mu j_5^\mu=0.$$

For $m\neq0$, the axial divergence becomes

$$\partial_\mu j_5^\mu=2\mathrm{i}m\,\bar\psi\gamma_5\psi$$

with the γ_5 convention stated above. Here $D_\mu \bar\psi = \partial_\mu \bar\psi + \mathrm{i}\bar\psi A_\mu$, and the classical equations of motion are $(\gamma^\mu D_\mu + m)\psi = 0$ and $(D_\mu \bar\psi)\gamma^\mu - m\bar\psi = 0$. Since $\{\gamma_5, \gamma^\mu\} = 0$, these equations give $\partial_\mu(\bar\psi\gamma^\mu\gamma_5\psi) = 2m\bar\psi\gamma_5\psi$; the explicit factor of i in j_5^μ gives the displayed normalization.

The corresponding infinitesimal transformations are

$$\delta_V \psi = \mathrm{i}\alpha\psi, \qquad \delta_A \psi = \mathrm{i}\beta\gamma_5\psi,$$

where α and β are constant real parameters. Classically, for massless fermions, both transformations are symmetries of the local Lagrangian. Quantum mechanically, the vector transformation is preserved when it is gauged consistently, while the axial current acquires a local divergence determined by the gauge background.

51.2 A Two-Dimensional Contact-Term Calculation

The local origin of an axial anomaly is already visible in a free two-dimensional Dirac fermion. Use the Lorentzian action

$$S_2 = -\int \mathrm{d}^2x\, \bar\psi\gamma^\mu\partial_\mu\psi, \qquad \{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}, \qquad \bar\psi = \mathrm{i}\psi^\dagger\gamma^0,$$

and define

$$\gamma := \gamma^0\gamma^1, \qquad \gamma^2 = 1, \qquad j^\mu = \mathrm{i}\bar\psi\gamma^\mu\psi, \qquad j_A^\mu = \mathrm{i}\bar\psi\gamma^\mu\gamma\psi.$$

The classical massless action is invariant under $\psi \mapsto \mathrm{e}^{\mathrm{i}\alpha}\psi$ and under $\psi \mapsto \mathrm{e}^{\mathrm{i}\beta\gamma}\psi$. The quantum question is the renormalized Ward identity obeyed by time-ordered current products. Consider

$$G_A^{\mu\nu}(x) := \langle\Omega|\,\mathrm{T}\; j_A^\mu(x) j^\nu(0)|\Omega\rangle.$$

At one loop the relevant momentum-space graph is shown in Figure 51.1; the figure fixes the loop momentum routing and distinguishes the axial-current insertion from the vector current insertion used in the Ward identity below.

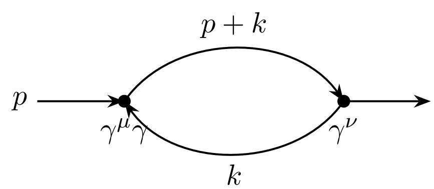

Figure 51.1: The two-dimensional current two-point function. The left insertion is the axial current and the right insertion is the vector current.

$$-\int \frac{\mathrm{d}^2k}{(2\pi)^2}\,\frac{\mathrm{tr}[\mathrm{i}\gamma^\nu(\not{p}+\not{k})\mathrm{i}\gamma^\mu\gamma\;\not{k}]}{(k^2-\mathrm{i}\epsilon)((p+k)^2-\mathrm{i}\epsilon)}.$$

Contracting with p_μ, Feynman parametrizing, and shifting $k \mapsto k - xp$ gives

$$\int \mathrm{d}^2x\, \mathrm{e}^{-\mathrm{i}p\cdot x}\partial_\mu G_A^{\mu\nu}(x) = \mathrm{i}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^2k}{(2\pi)^2}\,\frac{\mathrm{tr}(\gamma^\nu\;\not{k}\;\not{p}\gamma\;\not{k}) - x(1-x)p^2\,\mathrm{tr}(\gamma^\nu\gamma\;\not{p})}{(k^2+p^2x(1-x)-\mathrm{i}\epsilon)^2}. \tag{51.1}$$

The expression is a contact term, so its value depends on the regulator used to define the composite current. Continue the loop momentum to $D = 2-\epsilon$ dimensions while keeping the chirality matrix $\gamma = \gamma^0\gamma^1$ two-dimensional. Rotational averaging gives

$$\operatorname{tr}(\gamma^\nu \not{k} \not{p}\gamma \not{k}) \longmapsto \frac{k^2}{D}\operatorname{tr}(\gamma^\nu\gamma_\rho \not{p}\gamma\gamma^\rho) = \frac{2-D}{D}k^2 \operatorname{tr}(\gamma^\nu \not{p}\gamma).$$

The factor $2-D=\epsilon$ multiplies the logarithmic divergence of the loop integral and leaves a finite local term. With $\operatorname{tr}(\gamma^\nu\gamma \not{p}) = 2\epsilon^{\mu\nu}p_\mu$, one finds

$$\int \mathrm{d}^2x\, \mathrm{e}^{-\mathrm{i}p\cdot x}\partial_\mu G_A^{\mu\nu}(x) = -\frac{1}{\pi}\epsilon^{\mu\nu}p_\mu.$$

Equivalently,

$$\partial_\mu\langle\Omega|\,\mathrm{T}\; j_A^\mu(x)j^\nu(y)|\Omega\rangle = \frac{\mathrm{i}}{\pi}\epsilon^{\mu\nu}\partial_\mu\delta^{(2)}(x-y), \tag{51.2}$$

whereas the vector Ward identity is preserved:

$$\partial_\mu\langle\Omega|\,\mathrm{T}\; j^\mu(x)j^\nu(y)|\Omega\rangle = 0.$$

Now couple the vector current to a background $U(1)$ gauge field,

$$D_\mu = \partial_\mu - \mathrm{i}A_\mu, \qquad \Delta S = \int \mathrm{d}^2x\, j^\mu A_\mu.$$

Expanding time-ordered correlators in powers of A, the first-order term in (51.2) gives the local operator identity

$$\partial_\mu j_A^\mu(x) = \frac{1}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}(x), \qquad F_{\mu\nu} := \partial_\mu A_\nu - \partial_\nu A_\mu. \tag{51.3}$$

Thus the anomaly is already present before any interaction among the fermions: it is the finite remnant of a regulated contact term in a composite-current Ward identity.

Proposition 51.4 (Two-dimensional axial contact term)**.** *For the massless two-dimensional Dirac fermion with current conventions of this section, choose the renormalized current representative whose vector Ward identity is preserved. Then the axial-vector current product obeys*

$$\partial_\mu\langle\Omega|\,\mathrm{T}\; j_A^\mu(x)j^\nu(y)|\Omega\rangle = \frac{\mathrm{i}}{\pi}\epsilon^{\mu\nu}\partial_\mu\delta^{(2)}(x-y), \qquad \partial_\mu\langle\Omega|\,\mathrm{T}\; j^\mu(x)j^\nu(y)|\Omega\rangle = 0.$$

Coupling j^μ to a background Abelian gauge field with $D_\mu = \partial_\mu - \mathrm{i}A_\mu$ gives the local operator identity

$$\partial_\mu j_A^\mu = \frac{1}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}.$$

Proof. The one-loop contraction of $p_\mu\langle j_A^\mu j^\nu\rangle$ reduces, after Feynman parametrization, to (51.1). In dimensional reduction the term with two loop momenta contains the factor $(2-D)/D$, because only the physical two-dimensional gamma matrices anticommute with γ. This evanescent factor multiplies the logarithmic ultraviolet divergence of the integral and leaves the finite polynomial $-\pi^{-1}\epsilon^{\mu\nu}p_\mu$. Fourier inversion gives the displayed contact term. The vector-current representative is fixed by subtracting the local contact term that would otherwise violate the vector Ward identity.

Expanding the background-field insertion $\exp(\mathrm{i}\int j^\mu A_\mu)$ to first order and using the contact term gives

$$\partial_\mu j_A^\mu(x) = \frac{1}{\pi}\epsilon^{\mu\nu}\partial_\mu A_\nu(x) = \frac{1}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu}(x),$$

where the last equality uses antisymmetry of $\epsilon^{\mu\nu}$. □

51.3 Contour Charges and Anomalous Charge Transport

The contact term has a geometric interpretation. In Euclidean two-space, a conserved current j^μ defines a charge on a closed contour C,

$$Q_C = \int_C j^\mu n_\mu \, \mathrm{d}s,$$

where n_μ is the outward unit normal to the contour. If $\partial_\mu j^\mu = 0$ away from operator insertions, the contour can be deformed through regions with no insertions. Figure 51.2 shows the allowed contour deformation and the point at which an attempted deformation would cross an operator insertion, where the contact term enters the Ward identity.

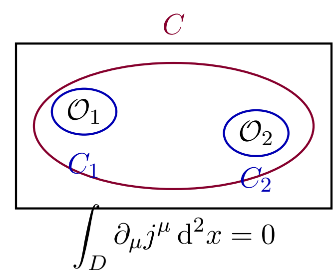

Figure 51.2: For a conserved current, the charge contour can be moved from small circles around operator insertions to a larger contour without changing the insertion.

If C encloses all insertions and can be moved to infinity, the ordinary global transformation leaves the correlation function invariant.

For the anomalous axial current the small contour still gives the local action of the axial rotation on an operator. The difference between the charge on a large contour and the sum of charges on small contours is the flux of the anomaly through the interpolating domain D, as displayed in Figure 51.3:

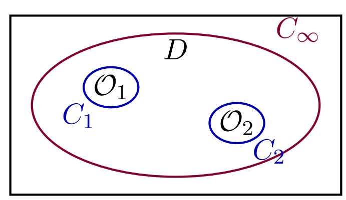

Figure 51.3: For the axial current in a background field, deforming the contour across the domain D changes the charge by the integral of the anomalous divergence.

Using (51.3),

$$\Delta Q_A = Q_{A,C_\infty} - \sum_i Q_{A,C_i} = \int_D \mathrm{d}^2 x \, \partial_\mu j^\mu_A = \frac{1}{2\pi} \int_D \mathrm{d}^2 x \, \epsilon^{\mu\nu} F_{\mu\nu}. \tag{51.4}$$

Therefore an axial rotation by α multiplies the correlation function by the background-dependent phase

$$\exp(\mathrm{i}\alpha \Delta Q_A).$$

Equivalently, in the background-field effective action the transformation shifts the action by

$$\Delta S = \frac{\alpha}{2\pi}\int d^2x\,\epsilon^{\mu\nu}F_{\mu\nu}.$$

51.4 The Four-Dimensional Triangle Contact Term

The four-dimensional axial anomaly is produced by an analogous regulated contact term with one higher short-distance singularity. For a massless Dirac fermion, study

$$\langle\Omega|\,\mathrm{T}\;j_5^\mu(x)j^\nu(y)j^\rho(z)|\Omega\rangle.$$

There are two oriented triangle graphs:

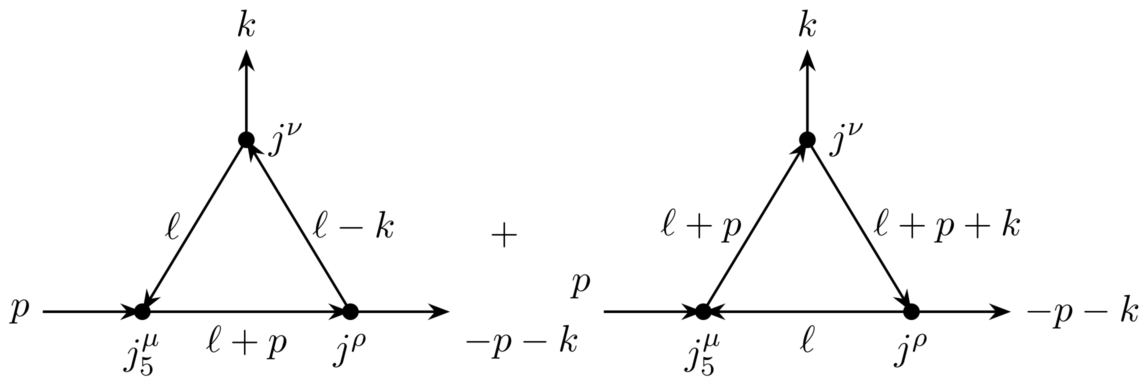

Figure 51.4: The two orientations of the one-axial, two-vector triangle. The regulator is chosen so that the vector-current Ward identities are preserved.

The divergence of the axial insertion is the Fourier transform of a local contact term. In the dimensional-reduction implementation of the perturbative regulator, set $D = 4-\epsilon$ and split the loop momentum as

$$\ell = \ell_\parallel + \ell_\perp,$$

where $\ell_\parallel$ lies in the physical four-dimensional subspace. Keep $\gamma_5 = -\mathrm{i}\gamma^{0123}$ four-dimensional, so that $\not\ell_\parallel$ anticommutes with γ_5 and $\not\ell_\perp$ commutes with γ_5. In the first triangle one uses

$$\not p\,\gamma_5 = \left[(\not\ell + \not p)\gamma_5 + \gamma_5\,\not\ell\right] - 2\,\not\ell_\perp\gamma_5.$$

The two bracketed terms are adjacent inverse-propagator numerators. In the two oriented triangle graphs they reduce one fermion propagator and become a pair of vector-current contact terms with opposite routing. Here is the cancellation explicitly for the leading routing in Figure 51.4. Set

$$D_0 = \ell^2, \qquad D_k = (\ell-k)^2, \qquad D_p = (\ell+p)^2.$$

The bracketed part of the first orientation gives

$$\mathcal{C}_1^{\nu\rho} = -\mathrm{i}\int\frac{d^D\ell}{(2\pi)^D}\left[\frac{\mathrm{tr}[\gamma_5\,\not\ell\gamma^\nu(\not\ell-\not k)\gamma^\rho]}{D_0D_k} + \frac{\mathrm{tr}[\gamma_5\gamma^\nu(\not\ell-\not k)\gamma^\rho(\not\ell+\not p)]}{D_kD_p}\right].$$

The first term came from the adjacent factor $(\not\ell + \not p)^2 = D_p$, after cyclically moving the first $(\not\ell + \not p)$ to the end of the trace; the second came from $\not\ell^2 = D_0$. The bracketed part of the opposite orientation is

$$\mathcal{C}_2^{\nu\rho} = -\mathrm{i}\int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\Bigg[\frac{\mathrm{tr}[\gamma_5 \not\ell\gamma^\rho(\not\ell + \not p + \not k)\gamma^\nu]}{\ell^2(\ell+p+k)^2} + \frac{\mathrm{tr}[\gamma_5\gamma^\rho(\not\ell + \not p + \not k)\gamma^\nu(\not\ell + \not p)]}{(\ell+p+k)^2 D_p}\Bigg].$$

The dimensional-reduction regulator is defined so that the reduced two-propagator integrals are translation invariant; this is the perturbative implementation of the vector Ward identities. In the second term of $\mathcal{C}_2$, set $\ell' = \ell + p + k$ and then rename ℓ' as ℓ. It has the same denominator $D_0 D_k$ as the first term of $\mathcal{C}_1$, while

$$\begin{aligned}
&\mathrm{tr}[\gamma_5 \not\ell\gamma^\nu(\not\ell - \not k)\gamma^\rho] = 4\mathrm{i}\epsilon^{\alpha\nu\beta\rho}\ell_\alpha(\ell-k)_\beta,\\
&\mathrm{tr}[\gamma_5\gamma^\rho \not\ell\gamma^\nu(\not\ell - \not k)] = 4\mathrm{i}\epsilon^{\rho\alpha\nu\beta}\ell_\alpha(\ell-k)_\beta = -4\mathrm{i}\epsilon^{\alpha\nu\beta\rho}\ell_\alpha(\ell-k)_\beta.
\end{aligned}$$

Thus these two terms cancel. In the first term of $\mathcal{C}_2$, set $\ell' = \ell + k$. It has the same denominator $D_k D_p$ as the second term of $\mathcal{C}_1$, and

$$\begin{aligned}
\mathrm{tr}[\gamma_5\gamma^\nu(\not\ell - \not k)\gamma^\rho(\not\ell + \not p)] &= 4\mathrm{i}\epsilon^{\nu\alpha\rho\beta}(\ell-k)_\alpha(\ell+p)_\beta,\\
\mathrm{tr}[\gamma_5(\not\ell - \not k)\gamma^\rho(\not\ell + \not p)\gamma^\nu] &= 4\mathrm{i}\epsilon^{\alpha\rho\beta\nu}(\ell-k)_\alpha(\ell+p)_\beta\\
&= -4\mathrm{i}\epsilon^{\nu\alpha\rho\beta}(\ell-k)_\alpha(\ell+p)_\beta.
\end{aligned}$$

The bracketed contact terms therefore cancel pairwise once the vector Ward identities are imposed by the regulator. The entire axial contact term is carried by the evanescent $\ell_\perp$ contribution. For the first orientation this contribution is

$$2\mathrm{i}\int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\frac{\mathrm{tr}[\gamma_5 \not\ell_\perp \not\ell\gamma^\nu(\not\ell - \not k)\gamma^\rho(\not\ell + \not p)]}{D_0 D_k D_p}.$$

The coefficient of the local two-vector contact term is obtained by keeping the part with two external momenta and no physical loop momentum in the γ_5-trace. Terms with a symmetric pair of physical loop momenta contracted into the antisymmetric tensor vanish after rotational averaging, and terms with an unpaired perpendicular gamma matrix or the wrong number of physical gamma matrices have zero γ_5-trace. Using

$$\not\ell_\perp \not\ell_\perp = \ell_\perp^2, \qquad \mathrm{tr}\Big(\gamma_5\gamma^\nu\gamma^\alpha\gamma^\rho\gamma^\beta\Big) = 4\mathrm{i}\epsilon^{\nu\alpha\rho\beta},$$

one obtains

$$\begin{aligned}
\mathrm{tr}[\gamma_5 \not\ell_\perp \not\ell\gamma^\nu(\not\ell - \not k)\gamma^\rho(\not\ell + \not p)]_{\mathrm{local}} &= -\ell_\perp^2 k_\alpha p_\beta\,\mathrm{tr}\Big(\gamma_5\gamma^\nu\gamma^\alpha\gamma^\rho\gamma^\beta\Big)\\
&= 4\mathrm{i}\,\ell_\perp^2\,\epsilon^{\nu\rho\alpha\beta}k_\alpha p_\beta.
\end{aligned}$$

Thus the first orientation contributes

$$-8\,\epsilon^{\nu\rho\alpha\beta}k_\alpha p_\beta\, I(k,p), \qquad I(k,p) := \int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\frac{\ell_\perp^2}{D_0 D_k D_p}.$$

The opposite orientation gives the same local tensor after $(\nu, k) \leftrightarrow (\rho, -p-k)$.

It remains to evaluate $I(k,p)$. Take the external momenta nonexceptional during the ultraviolet computation; the contact coefficient extracted below is independent of this infrared choice. Feynman parametrization gives

$$I(k,p) = 2\int_0^1 \mathrm{d}x \int_0^1 \mathrm{d}y \int_0^1 \mathrm{d}z\, \delta(1-x-y-z) \int \frac{\mathrm{d}^D r}{(2\pi)^D} \frac{r_\perp^2}{(r^2+\Delta)^3},$$
$$r = \ell - yk + zp,$$
$$\Delta = y(1-y)k^2 + z(1-z)p^2 + 2yz\, k\cdot p - \mathrm{i}0.$$

The shift does not change the perpendicular component because p and k lie in the physical four-dimensional subspace. In the continued $D = 4-\epsilon$ dimensional rotation-invariant integral,

$$\int \mathrm{d}^D r\, r_\perp^2 f(r^2) = \frac{D-4}{D} \int \mathrm{d}^D r\, r^2 f(r^2) = -\frac{\epsilon}{4-\epsilon} \int \mathrm{d}^D r\, r^2 f(r^2).$$

Therefore

$$\begin{aligned}\int \frac{\mathrm{d}^D r}{(2\pi)^D} \frac{r_\perp^2}{(r^2+\Delta)^3} &= \frac{D-4}{D} \int \frac{\mathrm{d}^D r}{(2\pi)^D} \frac{r^2}{(r^2+\Delta)^3} \\ &= \frac{D-4}{4} \frac{\Gamma(2-D/2)}{(4\pi)^{D/2}} \Delta^{D/2-2} \\ &= -\frac{1}{32\pi^2} + O(\epsilon).\end{aligned}$$

Since

$$2\int_0^1 \mathrm{d}x \int_0^1 \mathrm{d}y \int_0^1 \mathrm{d}z\, \delta(1-x-y-z) = 1$$

and $\Delta^{-\epsilon/2} = 1 + O(\epsilon)$, the required scalar integral is

$$I(k,p) = -\frac{1}{32\pi^2}.$$

With the sign convention of (51.6), this gives

$$\partial_\mu \langle \Omega |\, \mathrm{T}\, j_5^\mu(x) j^\nu(y) j^\rho(0) | \Omega \rangle = \frac{1}{2\pi^2} \epsilon^{\nu\rho\alpha\beta} \partial_\alpha \delta^{(4)}(x) \partial_\beta \delta^{(4)}(y). \tag{51.5}$$

The local coefficient is independent of the long-distance state; it is fixed by the regulated short-distance singularity of the current product.

Coupling the vector current to a background field,

$$\Delta S = \int \mathrm{d}^4 x\, A_\mu j^\mu,$$

and expanding the time-ordered exponential to second order, the contact term (51.5) yields

$$\partial_\mu j_5^\mu = \frac{1}{16\pi^2} \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$$

for a unit-charge Dirac fermion in the convention of (51.6). A fermion of electric charge q coupled with electromagnetic coupling e replaces F by eqF, giving the factor $e^2 q^2$ in the next section.

Proposition 51.5 (Four-dimensional axial contact term)**.** *For a massless four-dimensional Dirac fermion, in the anomaly representative of Definition 51.1, the regulated one-axial two-vector current product has local divergence*

$$\partial_\mu \langle \Omega | \, \mathrm{T} \; j_5^\mu(x) j^\nu(y) j^\rho(0) | \Omega \rangle = \frac{1}{2\pi^2} \epsilon^{\nu\rho\alpha\beta} \partial_\alpha \delta^{(4)}(x) \partial_\beta \delta^{(4)}(y).$$

Consequently, after coupling the vector current to a background Abelian field and preserving the vector Ward identity, a unit-charge Dirac fermion obeys

$$\partial_\mu j_5^\mu = \frac{1}{16\pi^2} \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}$$

in the massless theory.

Proof. Contracting the axial vertex in the two oriented triangles writes the numerator as vector-current contact terms plus the evanescent $\ell_\perp$ term. Translation invariance of the dimensionally reduced two-propagator integrals is precisely the regulator statement that the vector Ward identities are preserved; with this prescription the vector-contact terms cancel pairwise between the two orientations. The remaining local piece is

$$-8 \, \epsilon^{\nu\rho\alpha\beta} k_\alpha p_\beta I(k,p)$$

from one orientation, with the opposite orientation contributing the corresponding exchanged tensor. The Feynman-parameter integral has the regulator-independent local limit

$$I(k,p) = \int \frac{\mathrm{d}^{4-\epsilon}\ell}{(2\pi)^{4-\epsilon}} \frac{\ell_\perp^2}{\ell^2 (\ell-k)^2 (\ell+p)^2} = -\frac{1}{32\pi^2},$$

because the factor $D-4$ from $\ell_\perp^2$ cancels the logarithmic ultraviolet pole. Substituting this value and Fourier transforming gives (51.5).

The background-field identity follows by expanding the time-ordered exponential to second order. The factor 1/2 in the exponential is cancelled by the two identical vector insertions in the contact term, and antisymmetrizing the two derivatives of A rewrites the result as $\epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}/(16\pi^2)$ in the normalization of (51.6). ☐

51.5 The Abelian Axial Anomaly

For a Dirac fermion of electric charge q coupled to an electromagnetic field with coupling e, the renormalized axial current may be chosen so that

$$\partial_\mu j_5^\mu = 2im \, \bar{\psi} \gamma_5 \psi + \frac{e^2 q^2}{16\pi^2} \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}. \tag{51.6}$$

The coefficient is fixed by the short-distance singularity of the triangle diagram with one axial-current insertion and two vector-current insertions. The vector Ward identity is imposed because the vector current is the current coupled to the gauge field. The remaining local term appears in the axial Ward identity.

Equation (51.6) is a statement about a renormalized composite operator identity. Each symbol in it has a prescribed meaning: $F_{\mu\nu}$ is the electromagnetic field strength, $\epsilon^{\mu\nu\rho\sigma}$ is the four-dimensional antisymmetric symbol with the orientation fixed at the start of the chapter, $\mathrm{i}m\bar{\psi}\gamma_5\psi$ is the pseudoscalar mass-breaking operator in the mostly-plus adjoint convention, and j_5^μ is the renormalized current whose vector-current Ward identities have been preserved.

The factor relating this component formula to the heat-kernel trace below is as follows. Define

$$\widetilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\rho\sigma}, \qquad F = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu \wedge \mathrm{d}x^\nu.$$

Then

$$F_{\mu\nu}\widetilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}, \qquad F \wedge F = \frac{1}{4}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}\,\mathrm{d}^4x.$$

The local heat-kernel trace (51.8) gives the index density $(32\pi^2)^{-1}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}_R(F_{\mu\nu}F_{\rho\sigma})$. The Dirac axial Ward identity has twice this density because the chiral change of variables rotates ψ and $\bar{\psi}$ with the same sign, giving the prefactor $2\mathrm{i}$ in (51.7). For a single charge-one Abelian Dirac fermion, the representation trace is trivial and

$$2 \cdot \frac{1}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} = \frac{1}{16\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma},$$

which is the coefficient in (51.6); a field of charge eq contributes the additional factor e^2q^2.

51.6 Measure Derivation

The same coefficient is obtained from the Berezinian change of variables in a regulated fermion path integral. The construction uses the finite-dimensional Berezin calculus of Chapter 40; the object that transforms is an ordered Berezinian density on a finite set of odd coefficients, not a Borel measure on a set of fermion fields.

Work first on a compact Euclidean spin four-manifold, or in a finite box with elliptic boundary conditions, so that the Euclidean Dirac operator

$$\mathcal{D}_A = \gamma^\mu(\partial_\mu - \mathrm{i}A_\mu)$$

has a discrete L^2-orthonormal eigenbasis after the infrared regulator has been fixed. The local formula obtained below is independent of this infrared auxiliary choice. Let P_Λ be the spectral projection onto the span

$$V_\Lambda = \mathrm{span}\{\varphi_n :\ |\lambda_n| \le \Lambda\}, \qquad \mathcal{D}_A\varphi_n = \lambda_n\varphi_n.$$

The regulated fermion variables are odd coordinates

$$\psi_\Lambda(x) = \sum_{n\in I_\Lambda} c_n\varphi_n(x), \qquad \bar{\psi}_\Lambda(x) = \sum_{n\in I_\Lambda} \bar{c}_n\varphi_n^\dagger(x),$$

with ordered Berezinian density

$$\Omega_\Lambda = \prod_{n\in I_\Lambda} d\bar{c}_n\, dc_n.$$

An infinitesimal local chiral rotation

$$\psi(x) \mapsto \mathrm{e}^{\mathrm{i}\beta(x)\gamma_5}\psi(x), \qquad \bar{\psi}(x) \mapsto \bar{\psi}(x)\mathrm{e}^{\mathrm{i}\beta(x)\gamma_5},$$

acts on V_Λ by the finite matrix

$$U_{\Lambda,\beta} = 1 + \mathrm{i}P_\Lambda \beta\gamma_5 P_\Lambda + O(\beta^2),$$

where β denotes the multiplication operator by the smooth function $\beta(x)$. The inverse determinant in the odd Berezinian transformation law gives, with the convention that J_Λ is the factor multiplying the transformed finite-dimensional Berezin integral,

$$\log J_\Lambda = 2\mathrm{i}\ \mathrm{tr}_{V_\Lambda}(P_\Lambda\beta\gamma_5 P_\Lambda) + O(\beta^2).$$

The factor of 2 records that ψ and $\bar{\psi}$ are rotated with the same chiral sign.

The sharp projection P_Λ may be replaced, for the local asymptotic calculation, by the smooth gauge-covariant spectral regulator

$$\exp(-\mathcal{D}_A^2/M^2).$$

This is the heat-kernel regulator of the Berezinian trace. It introduces no regulator field; M is the ultraviolet scale in the heat semigroup of the elliptic operator $\mathcal{D}_A^2$. In the terminology of Table 11.1, this is a spectral regulator for an operator trace, not a Pauli–Villars auxiliary-field or determinant-ratio regulator. The regulated logarithm used below is

$$\log J_M = 2\mathrm{i} \lim_{M\to\infty} \mathrm{Tr}\left[\beta\,\gamma_5 \exp\left(-\mathcal{D}_A^2/M^2\right)\right], \tag{51.7}$$

where Tr is the trace over spacetime, spin, and internal indices. Equation (51.7) is therefore a regulated finite-mode Berezinian statement followed by a heat-kernel asymptotic limit. It is the measure-language counterpart of the dimensionally regulated triangle computation above, in the scheme where the vector gauge Ward identity is preserved and the axial Ward identity carries the local term.

The heat-kernel expansion gives the local limit

$$\lim_{M\to\infty} \mathrm{tr}_{\mathrm{spin}}\left[\gamma_5 \exp\left(-\mathcal{D}_A^2/M^2\right)\right](x,x) = \frac{1}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}_R(F_{\mu\nu}F_{\rho\sigma}), \tag{51.8}$$

with tr_R the trace in the fermion representation. The anomaly density is therefore the heat-kernel limit of the regulated Berezinian traces of γ_5 over cutoff eigenspaces. Finite-dimensional cyclic trace manipulations at fixed cutoff do not remove (51.8), because the regulator is part of the definition of the composite current.

The local heat-kernel density becomes a Fredholm index after the following global data are specified. The analytic input is the spin Dirac case of the Atiyah–Singer index theorem.[1]

Quoted Theorem 51.6 (Spin Dirac index theorem, four-dimensional form)**.** *Let M be a smooth compact oriented Riemannian spin four-manifold without boundary. Let $S = S^+ \oplus S^-$ be its*

Soc. 78 (1975), 405–432 and 79 (1976), 71–99.

complex spinor bundle, let $E_R \to M$ be a smooth Hermitian vector bundle associated to the fermion representation R, and let ∇^E be a smooth unitary connection with curvature F_R in the same gauge convention as the local anomaly calculation. The chiral Dirac operator

$$\mathcal{D}_{A,+} : \Gamma(S^+ \otimes E_R) \longrightarrow \Gamma(S^- \otimes E_R)$$

is elliptic and hence has finite-dimensional kernel and cokernel. Its Fredholm index is

$$\operatorname{index} \mathcal{D}_{A,+} = \dim\ker \mathcal{D}_{A,+} - \dim\ker \mathcal{D}_{A,-} = \int_M \big[\widehat{A}(TM)\,\mathrm{ch}(E_R, \nabla^E)\big]_4, \tag{51.9}$$

where $[\cdots]_4$ denotes the four-form part of the Chern–Weil form, $\widehat{A}(TM)$ is the $\widehat{A}$-class of the tangent bundle, and $\mathrm{ch}(E_R, \nabla^E)$ is the Chern character form of the gauge bundle. The operator $\mathcal{D}_{A,-}$ is the opposite-chirality Dirac operator $\Gamma(S^- \otimes E_R) \to \Gamma(S^+ \otimes E_R)$.

Index mechanism and four-form normalization. The quoted theorem imports the global equality between a Fredholm index and a characteristic number. The part used by the anomaly calculation can be made more explicit. Let

$$\mathcal{D}_A = \begin{pmatrix} 0 & \mathcal{D}_{A,-} \\ \mathcal{D}_{A,+} & 0 \end{pmatrix}$$

be the self-adjoint Dirac operator on $S \otimes E_R$, and let Γ_5 denote the Euclidean chirality operator, acting by $+1$ on S^+ and by -1 on S^-. For every $t > 0$, elliptic heat-kernel theory makes $\Gamma_5 \mathrm{e}^{-t\mathcal{D}_A^2}$ trace class, and the McKean–Singer cancellation gives

$$\mathrm{Tr}\Big(\Gamma_5 \mathrm{e}^{-t\mathcal{D}_A^2}\Big) = \dim\ker \mathcal{D}_{A,+} - \dim\ker \mathcal{D}_{A,-}. \tag{51.10}$$

Indeed, every positive eigenvector of $\mathcal{D}_{A,-}\mathcal{D}_{A,+}$ is paired by $\mathcal{D}_{A,+}$ with a positive eigenvector of $\mathcal{D}_{A,+}\mathcal{D}_{A,-}$, with the same eigenvalue and opposite chirality contribution. The heat supertrace is therefore independent of t, and the index is the small-t integral of the local supertrace coefficient.

The local coefficient is the analytic part of the index theorem. In the heat-kernel proof it is obtained from the Lichnerowicz formula, Chern–Weil invariance, and Getzler rescaling of the Clifford variables. The pure gauge coefficient can be checked locally, and this check fixes the convention used in the anomaly density. Choose normal coordinates at a point x, trivialize E_R so that the connection one-form vanishes at x, and write $\Gamma^{\mu\nu} = \frac{1}{2}[\Gamma^\mu, \Gamma^\nu]$. The gauge-curvature endomorphism in the square of the Dirac operator is

$$\mathcal{E}_F(x) = \frac{1}{2}\Gamma^{\mu\nu} F_{R,\mu\nu}(x).$$

Terms with fewer than four Clifford matrices have zero Γ_5-supertrace. The first pure gauge term that survives in the diagonal heat-kernel parametrix is therefore

$$(4\pi t)^{-2}\frac{t^2}{2}\,\mathrm{tr}_{\mathrm{spin},R}\left(\Gamma_5 \mathcal{E}_F^2\right).$$

Using

$$\mathrm{tr}_{\mathrm{spin}}\left(\Gamma_5 \Gamma^{\mu\nu}\Gamma^{\rho\sigma}\right) = 4\epsilon^{\mu\nu\rho\sigma}, \qquad \epsilon^{0123} = +1,$$

one obtains

$$(4\pi)^{-2}\frac{1}{2}\frac{1}{4}\,4\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}_R(F_{R,\mu\nu}F_{R,\rho\sigma}) = \frac{1}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}_R(F_{R,\mu\nu}F_{R,\rho\sigma}).$$

The spin-curvature terms in the same Getzler expansion assemble with the pure gauge term into the Chern–Weil form $\widehat{A}(TM)\operatorname{ch}(E_R,\nabla^E)$. With the chapter's anti-Hermitian curvature convention $\mathsf{F}_R = -\mathrm{i}F_R$, the Chern character appearing in Theorem 51.6 is

$$\operatorname{ch}(E_R,\nabla^E) = \operatorname{tr}_R\exp\left(\frac{\mathrm{i}\mathsf{F}_R}{2\pi}\right) = \operatorname{tr}_R\exp\left(\frac{F_R}{2\pi}\right).$$

Consequently the gauge part of the four-form is

$$\left[\operatorname{ch}(E_R,\nabla^E)\right]_4 = \frac{1}{2(2\pi)^2}\operatorname{tr}_R(F_R\wedge F_R) = \frac{1}{32\pi^2}\epsilon^{\mu\nu\rho\sigma}\operatorname{tr}_R(F_{\mu\nu}F_{\rho\sigma})\,\mathrm{d}^4x. \tag{51.11}$$

The first equality is Chern–Weil algebra; the second uses $F_R = \frac{1}{2}F_{\mu\nu}\mathrm{d}x^\mu\wedge\mathrm{d}x^\nu$ and the orientation $\epsilon^{0123} = +1$. This explains why the local Berezinian density (51.8) and the global Fredholm index have the same coefficient once the closed spin hypotheses of the theorem are imposed.

On a flat four-torus or on $\mathbb{R}^4$ after compactification by a smooth finite-action connection for which no boundary contribution is present, the tangent-bundle factor contributes only 1, and the gauge part of (51.9) becomes the density computed in (51.8):

$$\operatorname{index}\mathcal{D}_{A,+} = n_+ - n_- = \frac{1}{32\pi^2}\int_M \epsilon^{\mu\nu\rho\sigma}\operatorname{tr}_R(F_{\mu\nu}F_{\rho\sigma})\,\mathrm{d}^4x. \tag{51.12}$$

Here $n_+ = \dim\ker\mathcal{D}_{A,+}$ and $n_- = \dim\ker\mathcal{D}_{A,-}$, equivalently the numbers of zero modes of chirality $+1$ and -1 in the convention of this chapter. The equality between the integrated heat-kernel density and this integer uses the global hypotheses in the theorem. Without those hypotheses the local Ward identity still has the density (51.8), but its integral is not by itself a Fredholm index.

If M has a boundary, assume first that the Riemannian metric and the gauge connection have product form on a collar $u\in[0,\varepsilon)$ of ∂M. In this collar the chiral Dirac operator can be written

$$\mathcal{D}_A = \gamma(n)\big(\partial_u + B_A\big),$$

where n is the outward unit normal and B_A is the self-adjoint tangential Dirac operator on ∂M. Let

$$\eta_{B_A}(s) = \sum_{\lambda\in\operatorname{Spec}(B_A)\setminus\{0\}}\operatorname{sign}(\lambda)|\lambda|^{-s}$$

for $\operatorname{Re}s$ large, continued meromorphically to $s=0$, and let $h_{B_A} = \dim\ker B_A$. With the APS boundary condition $P_{\geq 0}\psi|_{\partial M} = 0$, where $P_{\geq 0}$ is the spectral projection of B_A onto nonnegative eigenvalues, the Atiyah–Patodi–Singer theorem gives

$$\operatorname{index}\mathcal{D}^{\mathrm{APS}}_{A,+} = \int_M\left[\widehat{A}(TM)\operatorname{ch}(E_R,\nabla^E)\right]_4 - \frac{\eta_{B_A}(0)+h_{B_A}}{2}. \tag{51.13}$$

For non-product data one either deforms to product form near the boundary, or includes the corresponding local transgression term; the sum of the bulk, local boundary, and spectral terms is the invariant integer. The appearance of η_{B_A} shows that boundary or interface anomaly data include spectral terms in addition to the bulk density. Boundary extension, global-anomaly, and inflow applications use (51.13); the local Ward identity in the present chapter uses only the bulk density before this spectral correction is imposed.

51.7 Nonabelian Flavor and Gauge Anomalies

Definition 51.7 (Trace anomaly coefficient)**.** For several Weyl fermions, let T^A be a generator of a global symmetry current and let t^a, t^b be generators of gauge or background gauge fields. The Hermitian generator and curvature conventions are those stated in (45.1), (45.12), and (45.16); in particular the default basis has $\mathrm{tr}(t^a t^b) = \delta^{ab}$. The mixed anomaly coefficient is

$$\mathcal{A}^{Aab} = \frac{1}{2}\left[\mathrm{tr}_{\mathrm{left}}\big(T^A\{t^a, t^b\}\big) - \mathrm{tr}_{\mathrm{right}}\big(T^A\{t^a, t^b\}\big)\right]. \tag{51.14}$$

With background field strengths $F^a_{\mu\nu}$, the corresponding current identity has the form

$$\partial_\mu J^\mu_A = \frac{1}{32\pi^2}\mathcal{A}^{Aab}\epsilon^{\mu\nu\rho\sigma}F^a_{\mu\nu}F^b_{\rho\sigma} + \text{explicit breaking terms}. \tag{51.15}$$

The factor $1/2$ in (51.14) is part of the definition of $\mathcal{A}^{Aab}$; it compensates for the two identical vector insertions in the anticommutator. For a single Dirac fermion with an axial generator acting by $+1$ on the left-handed component and -1 on the right-handed component, and with a unit Abelian vector charge, this definition gives $\mathcal{A} = 2$, so (51.15) reduces to the coefficient $1/(16\pi^2)$ in (51.6).

Proposition 51.8 (Cubic gauge obstruction)**.** *For left-handed Weyl fermions in representations R_i of a gauge group, the cubic part of the one-loop local consistent gauge anomaly vanishes if and only if*

$$\sum_i \mathrm{tr}_{R_i}\big(t^a\{t^b, t^c\}\big) = 0 \qquad \textit{for all } a, b, c. \tag{51.16}$$

If this tensor is nonzero for a dynamical gauge symmetry, no local counterterm can make the corresponding one-loop effective action satisfy the Slavnov–Taylor identity in that background-field chart. If the tensor vanishes, this cubic local obstruction is absent; maintaining the full Slavnov–Taylor identities then reduces to the absence of the remaining BRST-anomaly classes in the chosen theory and regulator scheme.

Proof from local descent. The obstruction is computed in the perturbative local BRST bicomplex on a contractible coordinate chart of the bundle of background connections. The anti-Hermitian curvature $\mathsf{F} = \mathsf{F}^a t^a$ is an even two-form, so the exterior products $\mathsf{F}^a\mathsf{F}^b\mathsf{F}^c$ are symmetric under interchange of a, b, c. Therefore the degree-three invariant polynomial of one left-handed Weyl fermion depends on the representation only through the symmetric cubic tensor:

$$\mathrm{tr}_R(\mathsf{F}^3) = \mathrm{tr}_R(t^{(a}t^b t^{c)})\mathsf{F}^a\mathsf{F}^b\mathsf{F}^c.$$

Equivalently, after one gauge variation has been converted into a ghost and two curvatures are read as external gauge-field insertions, the same tensor is written as

$$\mathrm{tr}_R\big(t^a\{t^b, t^c\}\big)$$

up to the conventional normalization already fixed in (51.14). Right-handed Weyl fermions contribute with the opposite sign because the chirality projector entering the regulated fermion determinant is reversed.

The descent map sends the invariant polynomial to a local representative $I_4^{(1)} \in \Omega^{4,1}_{\mathrm{loc}}$:

$$\mathrm{tr}_R(\mathsf{F}^3) = \mathrm{d}I_5^{(0)}, \qquad sI_5^{(0)} = \mathrm{d}I_4^{(1)}.$$

Changing the subtraction convention for the one-loop effective action adds a local counterterm $B_4^{(0)}$, and the anomaly representative shifts by

$$I_4^{(1)} \longmapsto I_4^{(1)} + sB_4^{(0)} + \mathrm{d}B_3^{(1)}.$$

Thus counterterms change representatives inside the same class of $H^{1,4}(s \mid \mathrm{d})$. The cohomological input used here is the local BRST-classification theorem: for four-dimensional chiral Yang–Mills theories in this polynomial local setting, the semisimple cubic gauge part of $H^{1,4}(s \mid \mathrm{d})$ is generated by the descent classes of the degree-three invariant polynomials $\mathrm{tr}_R(\mathsf{F}^3)$. The vanishing of the total symmetric cubic tensor therefore removes precisely this local class, while a nonzero tensor gives a class outside the image of local counterterm variations.

The non-removability of a nonzero cubic tensor can also be seen without using the full local BRST classification. Restrict the background to a maximal torus T with Lie algebra $\mathfrak{t}$. Since an invariant polynomial on a complex semisimple Lie algebra is determined by its restriction to a Cartan subalgebra, a nonzero cubic invariant has a nonzero restriction to $\mathfrak{t}$. Indeed, regular semisimple elements are conjugate to $\mathfrak{t}$ and form a Zariski-dense subset; an invariant polynomial that vanishes on $\mathfrak{t}$ therefore vanishes on all regular semisimple elements and hence identically. Thus a nonzero semisimple cubic gauge anomaly can be detected after Abelianizing to commuting gauge fields

$$A = A^i H_i, \qquad F^i = \mathrm{d}A^i.$$

On this Abelianized chart the cubic anomaly representative has the form

$$\int_M C_{i;jk}\lambda^i F^j F^k, \qquad C_{i;jk} = C_{i;kj},$$

and its invariant cubic coordinate is the completely symmetric part of $C_{i;jk}$. The most general cubic local counterterm that can change this λFF coefficient has, modulo gauge-invariant terms and total derivatives, the form

$$B_4 = \frac{1}{2}H_{ij,k}A^i A^j F^k, \qquad H_{ij,k} = -H_{ji,k}.$$

Using $\delta_\lambda A^i = \mathrm{d}\lambda^i$, $\delta_\lambda F^i = 0$, and $\mathrm{d}F^i = 0$, its variation on a closed spacetime is

$$\delta_\lambda \int_M B_4 = -\int_M H_{ij,k}\lambda^i F^j F^k.$$

Since $F^j F^k = F^k F^j$, the effective shift of the coefficient symmetric in the two curvature labels is

$$\Delta C_{i;jk} = -\frac{1}{2}\big(H_{ij,k} + H_{ik,j}\big).$$

The complete symmetrization over i, j, k vanishes identically because H is antisymmetric in its first two labels. Therefore local counterterms cannot change the fully symmetric Cartan coefficient of the Abelianized anomaly. By the Cartan-restriction argument above, a nonzero semisimple cubic invariant tensor cannot be removed by a local counterterm. This elementary Abelianized calculation is the part of the obstruction that the anomaly-matching and WZW sections use repeatedly.

The cubic gauge part of the anomaly polynomial for a left-handed Weyl fermion in R_i is proportional to $\mathrm{tr}_{R_i}(\mathsf{F}^3)$. Expanding $\mathsf{F} = \mathsf{F}^a t^a$, the coefficient of $\mathsf{F}^a\mathsf{F}^b\mathsf{F}^c$ is the completely symmetric tensor $\mathrm{tr}_{R_i}(t^{(a}t^bt^{c)})$, equivalently $\frac{1}{6}\,\mathrm{tr}_{R_i}$ summed over all permutations. In component Ward identities the same tensor is written as $\mathrm{tr}_{R_i}(t^a\{t^b,t^c\})$, with the conventional factor absorbed into the anomaly coefficient. Summing over fermions gives (51.16).

A local counterterm changes the anomaly representative by a BRST coboundary. The Abelianized counterterm calculation above already proves that a nonzero semisimple cubic invariant tensor cannot be removed by changing local counterterms. The remaining use of local BRST cohomology is the converse classification statement: in the polynomial local perturbative Yang–Mills setting, once this invariant-polynomial coefficient vanishes, the semisimple cubic gauge-anomaly class itself is absent. Other anomaly classes, global anomaly holonomies, and regulator-specific Slavnov–Taylor restoration conditions are separate data. The last sentence is therefore not an all-purpose nonperturbative existence theorem; it is the perturbative BRST consistency reduction in a specified gauge-fixed regularized framework. □

51.8 Consistency Condition and Descent

The anomaly of a gauge symmetry is constrained before any coefficient is computed. Let $W[A]$ be the renormalized effective action for a background gauge field A. Under an infinitesimal gauge transformation with parameter $\zeta=\zeta^at^a$, write

$$\delta_\zeta W[A]=\mathcal{A}(\zeta,A).$$

Here the infinitesimal action on a functional $F[A]$ is the derivation

$$\delta_\zeta F[A]=\int_M \mathrm{d}^4x\,\frac{\delta F}{\delta A^a_\mu(x)}\,(D_\mu\zeta)^a(x),\qquad D_\mu\zeta=\partial_\mu\zeta+[A_\mu,\zeta]_{\mathrm{H}},\tag{51.17}$$

understood either after introducing a regulator that makes the functional derivatives ordinary finite-dimensional derivatives, or in the formal local functional calculus. The gauge parameters are external test functions and are not varied by δ_{ζ_i}. With these conventions the variations close on the connection:

$$[\delta_{\zeta_1},\delta_{\zeta_2}]A_\mu=D_\mu[\zeta_1,\zeta_2]_{\mathrm{H}}.\tag{51.18}$$

Indeed,

$$\delta_{\zeta_1}\delta_{\zeta_2}A_\mu-\delta_{\zeta_2}\delta_{\zeta_1}A_\mu=[D_\mu\zeta_1,\zeta_2]_{\mathrm{H}}-[D_\mu\zeta_2,\zeta_1]_{\mathrm{H}},$$

and expanding D_μ gives

$$[\partial_\mu\zeta_1,\zeta_2]_{\mathrm{H}}+[\zeta_1,\partial_\mu\zeta_2]_{\mathrm{H}}+[[A_\mu,\zeta_1]_{\mathrm{H}},\zeta_2]_{\mathrm{H}}+[\zeta_1,[A_\mu,\zeta_2]_{\mathrm{H}}]_{\mathrm{H}}=\partial_\mu[\zeta_1,\zeta_2]_{\mathrm{H}}+[A_\mu,[\zeta_1,\zeta_2]_{\mathrm{H}}]_{\mathrm{H}},$$

where the last equality is the Jacobi identity. Equation (51.18) implies, by the chain rule,

$$[\delta_{\zeta_1},\delta_{\zeta_2}]F[A]=\delta_{[\zeta_1,\zeta_2]_{\mathrm{H}}}F[A]$$

for every functional F in the same differentiability class. Applying this identity to $W[A]$, and using $\mathcal{A}(\zeta,A)=\delta_\zeta W[A]$, gives

$$\delta_{\zeta_1}\mathcal{A}(\zeta_2,A)-\delta_{\zeta_2}\mathcal{A}(\zeta_1,A)=\mathcal{A}([\zeta_1,\zeta_2]_{\mathrm{H}},A).\tag{51.19}$$

This is the Wess–Zumino consistency condition. It is an integrability condition: a proposed local expression for $\mathcal{A}$ is the gauge variation of a single effective action only if its first variations satisfy the gauge-algebra commutator above. In BRST language, replace ζ by the ghost c. The anomaly is a local ghost-number-one functional $\mathcal{A}(c, A)$ obeying

$$s\mathcal{A} = 0, \tag{51.20}$$

and adding a local counterterm $X[A]$ shifts it by

$$\mathcal{A} \longmapsto \mathcal{A} + sX.$$

Thus the possible local gauge anomalies are cohomology classes of the BRST differential at ghost number one.

The local form of this statement is the relative cohomology described in Chapter 47. Let

$$\Omega^{p,q}_{\mathrm{loc}}$$

be the vector space of local p-forms of ghost number q, built from the background connection, the ghost, and finitely many derivatives, with coefficients that are polynomial or formal power series in the fields in the chosen local coordinate chart. In the abstract cohomological notation $H(s \mid d)$, write d for the spacetime exterior derivative; in the connection formulas below the same exterior derivative is denoted d. The derivative d has bidegree $(1, 0)$,

$$d : \Omega^{p,q}_{\mathrm{loc}} \longrightarrow \Omega^{p+1,q}_{\mathrm{loc}},$$

and the BRST differential has bidegree $(0, 1)$,

$$s : \Omega^{p,q}_{\mathrm{loc}} \longrightarrow \Omega^{p,q+1}_{\mathrm{loc}}.$$

Both are odd with respect to total degree, and with the sign convention used here

$$d^2 = 0, \qquad s^2 = 0, \qquad sd + ds = 0. \tag{51.21}$$

Thus $\Omega^{\bullet,\bullet}_{\mathrm{loc}}$ is a bicomplex. For a four-dimensional integrated anomaly, choose a representative

$$a^{(1)}_4 \in \Omega^{4,1}_{\mathrm{loc}}.$$

It is a relative cocycle when there exists $a^{(2)}_3 \in \Omega^{3,2}_{\mathrm{loc}}$ such that

$$sa^{(1)}_4 - da^{(2)}_3 = 0. \tag{51.22}$$

Two representatives define the same relative class when there exist $b^{(0)}_4 \in \Omega^{4,0}_{\mathrm{loc}}$ and $b^{(1)}_3 \in \Omega^{3,1}_{\mathrm{loc}}$ such that

$$a^{(1)}_4 \sim a^{(1)}_4 + sb^{(0)}_4 + db^{(1)}_3. \tag{51.23}$$

The quotient of cocycles by this equivalence relation is

$$H^{1,4}(s \mid d).$$

Proposition 51.9 (Local anomalies as relative BRST classes)**.** *At the level of local functionals, a four-dimensional consistent gauge anomaly with local density $a^{(1)}_4$ determines a class $[a^{(1)}_4] \in H^{1,4}(s \mid d)$. Changing the renormalized effective action by a local counterterm changes $a^{(1)}_4$ by the coboundary (51.23). Conversely, a representative of $H^{1,4}(s \mid d)$ defines a local functional whose BRST variation obeys the infinitesimal Wess–Zumino consistency condition.*

Proof. Write the anomalous variation as

$$\delta_\zeta W[A] = \int_M a_4^{(1)}(\zeta, A).$$

Replacing the even parameter ζ by the odd ghost gives $\int_M a_4^{(1)}(c, A)$. The BRST differential s is the Chevalley–Eilenberg differential for infinitesimal gauge transformations, with the field-dependent term in $sc = -\frac{1}{2}[c, c]$ included. Equation (51.19) is precisely the statement that this ghost-number-one integrated functional is a Chevalley–Eilenberg cocycle, hence

$$s \int_M a_4^{(1)} = 0.$$

For a local density this means that $sa_4^{(1)}$ integrates to zero for all compactly supported field and ghost configurations. In the local variational bicomplex, the algebraic Poincare lemma identifies such local top forms with total derivatives modulo globally topological terms fixed separately by the chosen bundle sector. Thus there exists $a_3^{(2)} \in \Omega^{3,2}_{\mathrm{loc}}$ with

$$sa_4^{(1)} = da_3^{(2)},$$

which is (51.22). If $W[A]$ is changed by a local counterterm $\int_M b_4^{(0)}$, its anomalous variation changes by

$$s \int_M b_4^{(0)} = \int_M sb_4^{(0)},$$

and adding an identically integrated total derivative changes the local representative by $db_3^{(1)}$. This is exactly the equivalence (51.23); it is the statement that a finite local counterterm changes the representative but not the relative cohomology class.

Conversely, if (51.22) holds, then on a closed spacetime, or with boundary conditions for which the boundary integral is part of the specified inflow problem, the integrated BRST variation of $\int_M a_4^{(1)}$ vanishes. Expanding s in ghosts recovers the antisymmetrized commutator of two ordinary gauge variations, while $sc = -\frac{1}{2}[c, c]$ supplies the term with gauge parameter $[\zeta_1, \zeta_2]$. This is exactly the infinitesimal Wess–Zumino consistency condition (51.19). □

Finite-regulator scheme meaning of the class. The relative class above is the infinitesimal local shadow of a finite regulator statement. Let $\mathcal{B}_\Lambda$ be a regulated space of background fields, let $\mathcal{G}_\Lambda$ be the regulated background gauge group acting on the right, $A \mapsto A^g$, and suppose a local chart of the regulated determinant line has been chosen so that the fermion functional is written as a scalar $W_\Lambda[A]$. Its finite anomaly cochain is

$$C_\Lambda(g; A) = W_\Lambda[A^g] - W_\Lambda[A]. \tag{51.24}$$

At this stage the statement is an identity in the regulated chart; continuum content enters after locality, convergence, and counterterm estimates have been supplied. Functoriality of the gauge action gives the exact groupoid cocycle equation

$$C_\Lambda(gh; A) = C_\Lambda(h; A^g) + C_\Lambda(g; A), \tag{51.25}$$

with the order fixed by $(A^g)^h = A^{gh}$. Differentiating (51.25) at $g = \exp(t\zeta_1)$, $h = \exp(t\zeta_2)$, and then taking the local continuum representative gives the Wess–Zumino condition (51.19); replacing the even parameters by the ghost gives the relative BRST cocycle (51.22).

Changing the regulated Lagrangian by a finite local counterterm $B_\Lambda[A]$, or choosing a determinant-line frame whose scalar logarithm differs by $B_\Lambda[A]$, replaces W_Λ by $W_\Lambda + B_\Lambda$ and hence

$$C_\Lambda(g;A) \longmapsto C_\Lambda(g;A) + B_\Lambda[A^g] - B_\Lambda[A]. \tag{51.26}$$

The infinitesimal local density changes by $a_4^{(1)} \mapsto a_4^{(1)} + sb_4^{(0)} + db_3^{(1)}$, exactly as in (51.23). Thus regulator and subtraction choices that remain within the same local background-field scheme change the representative, not the relative cohomology class. A nonzero local class means that no local counterterm in that perturbative gauge-fixed scheme can turn the regulated determinant chart into a gauge-invariant scalar effective action. The statement is local and perturbative: vanishing of this class is the condition that removes this obstruction, while an order-by-order construction of a gauge theory must still build the counterterms and verify the Slavnov–Taylor or BV quantum master identities in the chosen regulator. Flat global holonomies of the determinant or Pfaffian line are separate finite-background data and are treated in Chapter 153.

For four-dimensional chiral fermions, this relative cohomology class is represented by the descent of a six-form anomaly polynomial. To state the normalization without hiding convention-dependent factors, introduce the anti-Hermitian connection

$$\mathsf{A} = -\mathrm{i}A, \qquad \mathsf{F} = \mathrm{d}\mathsf{A} + \mathsf{A}^2 = -\mathrm{i}F,$$

where A and F are the Hermitian gauge potential and curvature used in the Yang–Mills chapters. Let c be the corresponding odd anti-Hermitian ghost. On the descent variables,

$$s\mathsf{A} = \mathrm{d}\mathsf{c} + [\mathsf{A},\mathsf{c}], \qquad s\mathsf{c} = -\mathsf{c}^2, \qquad s\mathsf{F} = [\mathsf{F},\mathsf{c}]. \tag{51.27}$$

Products of differential forms below include both matrix multiplication and wedge product with total-degree Koszul signs. For a left-handed Weyl fermion in a representation R, define the six-form

$$I_6^R = \kappa\ \mathrm{tr}_R(\mathsf{F}^3), \qquad \kappa = \frac{\mathrm{i}}{24\pi^2}$$

in the Euclidean effective-action convention. Removing the overall Euclidean phase gives the corresponding Lorentzian Ward-identity normalization. A right-handed Weyl fermion contributes with the opposite sign. For a set of left- and right-handed Weyl fermions,

$$I_6 = \kappa\left[\sum_{i\in L}\mathrm{tr}_{R_i}(\mathsf{F}^3) - \sum_{j\in R}\mathrm{tr}_{R_j}(\mathsf{F}^3)\right].$$

The Chern–Simons five-form $I_5^{(0)}$ is any local form satisfying

$$I_6 = \mathrm{d}I_5^{(0)}.$$

For one left-handed representation R, a standard representative is

$$I_{5,R}^{(0)} = \kappa\ \mathrm{tr}_R\left(\mathsf{A}(\mathrm{d}\mathsf{A})^2 + \frac{3}{2}\mathsf{A}^3\mathrm{d}\mathsf{A} + \frac{3}{5}\mathsf{A}^5\right), \qquad \mathrm{d}I_{5,R}^{(0)} = I_6^R.$$

The numerical coefficients in this representative are fixed by the Chern–Weil homotopy, not by convention. Set

$$\mathsf{A}_t = t\mathsf{A}, \qquad \mathsf{F}_t = \mathrm{d}\mathsf{A}_t + \mathsf{A}_t^2 = t\,\mathrm{d}\mathsf{A} + t^2\mathsf{A}^2.$$

For the invariant polynomial $P(X) = \kappa\ \mathrm{tr}_R(X^3)$, the Bianchi identity for F_t and cyclicity of the trace give

$$\frac{\mathrm{d}}{\mathrm{d}t}P(\mathsf{F}_t) = 3\kappa\,\mathrm{d}\ \mathrm{tr}_R(\mathsf{A}\,\mathsf{F}_t^2).$$

Since $\mathsf{F}_0 = 0$, integration in t gives

$$I_{5,R}^{(0)} = 3\kappa\int_0^1 \mathrm{tr}_R\Big[\mathsf{A}\big(t\,\mathrm{d}\mathsf{A} + t^2\mathsf{A}^2\big)^2\Big]\,\mathrm{d}t.$$

Expanding the square and using cyclicity with the form degrees $\deg\mathsf{A} = 1$, $\deg\mathrm{d}\mathsf{A} = 2$, one obtains

$$\begin{aligned} I_{5,R}^{(0)} &= \kappa\ \mathrm{tr}_R\Big[3\int_0^1 t^2\mathrm{d}t\,\mathsf{A}(\mathrm{d}\mathsf{A})^2 \\ &\qquad + 3\int_0^1 t^3\mathrm{d}t\,\mathsf{A}\big((\mathrm{d}\mathsf{A})\mathsf{A}^2 + \mathsf{A}^2\mathrm{d}\mathsf{A}\big) + 3\int_0^1 t^4\mathrm{d}t\,\mathsf{A}^5\Big] \\ &= \kappa\ \mathrm{tr}_R\left(\mathsf{A}(\mathrm{d}\mathsf{A})^2 + \frac{3}{2}\mathsf{A}^3\mathrm{d}\mathsf{A} + \frac{3}{5}\mathsf{A}^5\right). \end{aligned}$$

Thus the factors $1, \frac{3}{2}, \frac{3}{5}$ are the explicit transgression integrals $3\int_0^1 t^2\mathrm{d}t$, $3\int_0^1 2t^3\mathrm{d}t$, and $3\int_0^1 t^4\mathrm{d}t$. They use only the fixed trace convention and the matrix-valued differential-form product. A different path of connections or a different Chern–Simons representative changes $I_5^{(0)}$ by an exact form and hence changes $I_4^{(1)}$ only by a relative coboundary of the kind already displayed in (51.23). Because $sI_6 = 0$ and $I_6 = \mathrm{d}I_5^{(0)}$,

$$\mathrm{d}(sI_5^{(0)}) = -s(\mathrm{d}I_5^{(0)}) = -sI_6 = 0.$$

The algebraic Poincare lemma on local forms then gives the first descent equation

$$sI_5^{(0)} = \mathrm{d}I_4^{(1)}(\mathsf{c}, \mathsf{A}). \tag{51.28}$$

Applying s again and using (51.21) gives a second descent equation

$$sI_4^{(1)} = \mathrm{d}I_3^{(2)} \tag{51.29}$$

for some $I_3^{(2)} \in \Omega_{\mathrm{loc}}^{3,2}$. Hence $I_4^{(1)}$ is a representative of $H^{1,4}(s \mid d)$ in the convention of (51.22). Replacing the ghost c by an even infinitesimal parameter λ gives the ordinary gauge variation

$$\delta_\lambda\mathsf{A} = \mathrm{d}\lambda + [\mathsf{A}, \lambda], \qquad \delta_\lambda I_5^{(0)} = \mathrm{d}I_4^{(1)}(\lambda, \mathsf{A}).$$

In the same left-handed convention,

$$I_{4,R}^{(1)}(\mathsf{c}, \mathsf{A}) = \kappa\ \mathrm{tr}_R\left[\mathsf{c}\,\mathrm{d}\left(\mathsf{A}\,\mathrm{d}\mathsf{A} + \frac{1}{2}\mathsf{A}^3\right)\right],$$

up to adding d-exact terms and BRST-exact local counterterm variations. The relative coefficient $\frac{1}{2}$ in this four-form is the corresponding homotopy coefficient $6\int_0^1(1-t)t^2\mathrm{d}t = \frac{1}{2}$; the coefficient of $\mathsf{A}\mathrm{d}\mathsf{A}$ is $6\int_0^1(1-t)t\mathrm{d}t = 1$. This is the same descent calculation as above, now evaluated on the vertical gauge direction $\delta_\lambda \mathsf{A} = \mathrm{d}\lambda + [\mathsf{A},\lambda]$. The displayed $\mathsf{c}\,\mathrm{d}(\cdots)$ representative is chosen because its integrated form pairs directly with the effective-action variation (51.30); the equivalent $\mathrm{d}\mathsf{c}$-representatives differ from it by exact local forms. The consistent anomaly is

$$\delta_\lambda W[\mathsf{A}] = \int_M I_4^{(1)}(\lambda,\mathsf{A}). \tag{51.30}$$

The cancellation condition (51.16) is precisely the vanishing of the six-form polynomial I_6 for the gauged symmetry, or equivalently the vanishing of the symmetric cubic tensor

$$d^{abc} = \sum_{i\in L}\mathrm{tr}_{R_i}\big(t^{(a}t^bt^{c)}\big) - \sum_{j\in R}\mathrm{tr}_{R_j}\big(t^{(a}t^bt^{c)}\big).$$

If this polynomial is nonzero only for a background field coupled to a global symmetry, it is an anomaly to be matched rather than an inconsistency.

The representative $I_4^{(1)}$ is not the invariant datum by itself. A local four-dimensional counterterm can move the anomaly among the currents, or equivalently change the Chern–Simons representative $I_5^{(0)}$ by a local transgression. In an Abelianized chart with several background one-forms A^a, the elementary Bardeen counterterm

$$B_4 = h_{ab,c}\,A^aA^bF^c, \qquad h_{ab,c} = -h_{ba,c},$$

changes a representative written as

$$I_4^{(1)} = d_{abc}\,\lambda^aF^bF^c$$

to one with

$$d'_{abc} = d_{abc} + \frac{1}{2}\big(h_{ab,c}+h_{ac,b}\big).$$

The completely symmetric part is unchanged:

$$d'_{(abc)} = d_{(abc)}.$$

This finite algebra is the local form of the statement that counterterms alter representatives but not the six-form polynomial I_6. Consequently, when the next chapter matches the pion Wess–Zumino–Witten functional to the microscopic flavor anomaly, the coefficient being compared is the symmetric cohomology coordinate carried by I_6, not an arbitrary distribution of the anomaly among particular background currents.

Abelianized descent coordinate used in WZW matching. The coefficient comparison in the Wess–Zumino–Witten application uses a particularly simple projection of the same relative class. Restrict the background connection to a commuting finite-dimensional subspace of the flavor Lie algebra, so that

$$A = A^aT_a, \qquad F^a = \mathrm{d}A^a, \qquad [T_a,T_b] = 0$$

inside the chosen test subspace. The degree-three invariant polynomial then reduces to

$$I_6 = C_{abc}\,F^aF^bF^c,$$

where $C_{abc} = C_{(abc)}$ is the symmetric coefficient obtained from the trace in the representation under discussion, multiplied by the normalization factor fixed above. On this Abelianized slice a Chern–Simons representative and its infinitesimal descent are not hidden behind non-Abelian notation:

$$I_5^{(0)} = C_{abc}\, A^a F^b F^c, \qquad \delta_\lambda I_5^{(0)} = C_{abc}\, \mathrm{d}\lambda^a F^b F^c = \mathrm{d}\Big(C_{abc}\lambda^a F^b F^c\Big), \tag{51.31}$$

using $\mathrm{d}F^a = 0$. Thus the displayed $\lambda\, \mathrm{d}A\, \mathrm{d}A$ term is not a low-order approximation to a different anomaly. It is the Abelianized coordinate of the same descent class whose full non-Abelian representatives differ by the coboundaries described in (51.23).

For a compact connected semisimple flavor group, the invariant cubic polynomial is determined by its restriction to a Cartan subalgebra; equivalently, its symmetric trilinear coefficient is recovered from the homogeneous cubic function $P(x) = C_{abc}x^a x^b x^c$ by the polarization identity

$$\begin{aligned} C(x, y, z) = \frac{1}{6}\big[&P(x + y + z) - P(x + y) - P(x + z) - P(y + z) \\ &+ P(x) + P(y) + P(z)\big]. \end{aligned} \tag{51.32}$$

Consequently matching the coefficient of $\mathrm{Tr}(\alpha\, \mathrm{d}A\, \mathrm{d}A)$ for arbitrary commuting flavor backgrounds fixes the symmetric cubic anomaly coordinate. It does not fix a preferred current representative, and it does not choose a Bardeen convention; those choices affect $I_4^{(1)}$ by local counterterm coboundaries while leaving C_{abc} unchanged.

51.9 Index-Normalized Anomaly Polynomials

The descent representative above is written in the effective-action normalization convenient for Ward identities. For global comparisons, especially when gravitational backgrounds are included, it is useful to keep a second normalization whose periods are the ones supplied by the Dirac index. Let ∇^{TM} be a Riemannian connection on the tangent bundle with anti-Hermitian curvature R, and let ∇^E be a unitary connection on the fermion bundle E_R with anti-Hermitian curvature F_R. Define the Chern–Weil forms

$$\mathrm{ch}_R(\mathsf{F}_R) = \mathrm{tr}_R \exp\bigg(\frac{\mathrm{i}\mathsf{F}_R}{2\pi}\bigg), \qquad p_1(TM) = -\frac{1}{8\pi^2}\, \mathrm{tr}_{TM}(\mathsf{R}^2), \tag{51.33}$$

where tr_{TM} is the trace in the defining real tangent representation after complexification. The six-form anomaly polynomial for a single left-handed Weyl fermion in R, in the index normalization, is

$$\mathcal{I}_6(R) = \big[\widehat{A}(TM)\, \mathrm{ch}_R(\mathsf{F}_R)\big]_6. \tag{51.34}$$

A right-handed Weyl fermion contributes the negative of (51.34); equivalently it may be rewritten as a left-handed fermion in the conjugate representation and then the same formula may be applied to the left-handed list.

Expanding

$$\widehat{A}(TM) = 1 - \frac{1}{24}p_1(TM) + O(\deg 8)$$

and keeping six-forms gives

$$\mathcal{I}_6(R) = \frac{1}{6}\, \mathrm{tr}_R \left(\frac{\mathrm{i}\mathsf{F}_R}{2\pi}\right)^3 - \frac{1}{24}\, p_1(TM)\ \mathrm{tr}_R \left(\frac{\mathrm{i}\mathsf{F}_R}{2\pi}\right). \tag{51.35}$$

The first term is the cubic gauge or flavor anomaly. The second term is the mixed gauge-gravitational anomaly. It is present only for symmetries whose generator has a nonzero trace over the chiral fermion representation. Thus it vanishes for a semisimple gauge group in any representation with traceless Lie algebra generators, but it is a genuine constraint for a gauged $U(1)$.

The relation between $\mathcal{I}_6$ and the effective-action normalization used in (51.30) is as follows. Choose a Chern–Simons form $\mathcal{I}_5^{(0)}$ with

$$d\mathcal{I}_5^{(0)} = \mathcal{I}_6, \qquad \delta_\lambda \mathcal{I}_5^{(0)} = d\mathcal{I}_4^{(1)}(\lambda).$$

Then the Euclidean anomalous variation of a left-handed determinant is

$$\delta_\lambda W_E = 2\pi\mathrm{i} \int_M \mathcal{I}_4^{(1)}(\lambda). \tag{51.36}$$

The anti-Hermitian form I_6 of the previous section is this same descent data after multiplying by $2\pi\mathrm{i}$ and rewriting the connection as $\mathsf{A} = -\mathrm{i}A$. Keeping both notations visible prevents a common coefficient error: the index-normalized polynomial is a characteristic class, whereas the Ward identity carries the additional factor $2\pi\mathrm{i}$ and the chosen Lorentzian continuation.

Example 51.10 (Four-dimensional $U(1)$ anomaly polynomial)**.** Let a left-handed Weyl fermion have integer charge q under a background $U(1)$ connection A with curvature $F = dA$. In the Hermitian curvature notation $\mathrm{i}\mathsf{F}_R = qF$, and (51.35) becomes

$$\mathcal{I}_6(q) = \frac{q^3}{6(2\pi)^3} F^3 - \frac{q}{24(2\pi)} p_1(TM) F. \tag{51.37}$$

The cubic $U(1)^3$ coefficient is $\sum_i q_i^3$ over left-handed Weyl fields. The mixed gravitational-$U(1)$ coefficient is $\sum_i q_i$. If the $U(1)$ is gauged, both sums must vanish, in addition to the mixed nonabelian-$U(1)$ coefficients

$$\sum_i q_i \, T_{G_a}(R_i) = 0$$

for each simple nonabelian factor G_a, where $\mathrm{tr}_{R_i}(t^a t^b) = T_{G_a}(R_i)\delta^{ab}$ in the chosen generator normalization.

Example 51.11 ($SU(N)$ cubic anomaly in fundamental coordinates)**.** Let $G = SU(N)$, $N \geq 3$, and choose a reference symmetric tensor

$$d_\square^{abc} = \mathrm{tr}_\square\big(t^{(a} t^b t^{c)}\big)$$

in the monograph trace convention. For an irreducible representation R define $A(R)$ by

$$\mathrm{tr}_R\big(t^{(a} t^b t^{c)}\big) = A(R) d_\square^{abc}.$$

This equation defines the cubic-anomaly coordinate; rescaling all generators rescales both sides and leaves $A(R)$ unchanged. The conjugate representation obeys $A(\overline{R}) = -A(R)$, and every real representation has $A(R) = 0$. In particular,

$$A(\square) = 1, \qquad A(\overline{\square}) = -1, \qquad A(\mathrm{adj}) = 0.$$

Therefore a chiral $SU(N)$ gauge theory containing $n_{\square}$ left-handed fundamentals, $n_{\overline{\square}}$ left-handed antifundamentals, and any number of left-handed adjoints has cubic gauge anomaly

$$d^{abc}_{\text{total}} = (n_{\square} - n_{\overline{\square}})d^{abc}_{\square}. \tag{51.38}$$

A vectorlike Dirac fundamental consists, in a left-handed description, of one $\square$ and one $\overline{\square}$; its contribution to (51.38) vanishes.

Example 51.12 (One Standard Model generation)**.** Use left-handed Weyl fields

$$Q_L : (3,2)_{1/6}, \qquad u^c : (\overline{3},1)_{-2/3}, \qquad d^c : (\overline{3},1)_{1/3},$$
$$L_L : (1,2)_{-1/2}, \qquad e^c : (1,1)_1.$$

The mixed nonabelian-$U(1)_Y$ sums, with the common quadratic index of the fundamental factored out, are

$$SU(3)^2U(1)_Y : \quad 2\left(\frac{1}{6}\right) - \frac{2}{3} + \frac{1}{3} = 0,$$

and

$$SU(2)^2U(1)_Y : \quad 3\left(\frac{1}{6}\right) - \frac{1}{2} = 0.$$

The cubic and mixed gravitational hypercharge sums are

$$\begin{aligned} \sum_{\text{Weyl}} Y^3 &= 6\left(\frac{1}{6}\right)^3 + 3\left(-\frac{2}{3}\right)^3 + 3\left(\frac{1}{3}\right)^3 + 2\left(-\frac{1}{2}\right)^3 + 1 = 0, \\ \sum_{\text{Weyl}} Y &= 6\left(\frac{1}{6}\right) + 3\left(-\frac{2}{3}\right) + 3\left(\frac{1}{3}\right) + 2\left(-\frac{1}{2}\right) + 1 = 0. \end{aligned} \tag{51.39}$$

The same field list contains $3 + 1 = 4$ weak doublets, so the finite $SU(2)$ anomaly discussed in Chapter 55 is absent for each generation. These cancellations are arithmetic consequences of the charge assignments; they do not follow from perturbative renormalizability alone.

Remark 51.13 (Anomaly matching as equality of anomaly lines)*.* Consider an RG flow from a ultraviolet theory $\mathcal{Q}_{\text{UV}}$ to an infrared description $\mathcal{Q}_{\text{IR}}$, and suppose a background-field groupoid $\mathcal{B}(M)$ for a global symmetry is defined along the flow. Assume that the regulator and the integrating-out procedure preserve this background coupling up to local counterterms. Then the UV and IR partition functions are sections of anomaly lines whose ratio is a local counterterm line. Consequently the anomaly classes of $\mathcal{Q}_{\text{UV}}$ and $\mathcal{Q}_{\text{IR}}$ agree in the quotient by local counterterms. At a finite cutoff, splitting the fields into high- and low-energy variables is a change of variables in the regulated path integral, together with an ordinary integration over the high-energy variables. Under a background gauge transformation, the regulated Berezinian or bosonic density changes by a local phase representing the UV anomaly. The integral over high-energy modes produces an effective functional of the low-energy variables and backgrounds. Any dependence on the arbitrary separating scale is a local functional of the backgrounds and the retained sources, because the modes integrated out have no singularities at distances larger than the cutoff scale used in the split. Thus changing the scale changes the anomaly representative by a gauge variation of a local counterterm.

Taking the continuum and infrared limits within the assumed background-field chart gives two sections over the same background groupoid. Their transformation laws differ only by the local counterterm accumulated during the flow. Passing to the anomaly class, where local counterterm variations are quotiented, gives equality. If the symmetry is spontaneously broken, the Goldstone fields and Wess–Zumino–Witten functional provide one possible infrared section of the same line; if the infrared theory is topological, its invertible response supplies the section. The statement does not assert a unique infrared realization, only equality of the background anomaly class.

51.10 Anomaly Inflow for Local Anomalies

The descent equations have a second interpretation when the four-dimensional theory is placed on the boundary of a five-dimensional invertible response. Let X be an oriented five-manifold with boundary $\partial X = M$, and let A_X be a smooth background connection on X whose restriction to M is the four-dimensional connection A. The local Chern–Simons functional

$$W_X^{\mathrm{bulk}}[\mathsf{A}_X] = -\int_X I_5^{(0)}(\mathsf{A}_X) \tag{51.40}$$

has gauge variation

$$\delta_\lambda W_X^{\mathrm{bulk}} = -\int_X \mathrm{d}I_4^{(1)}(\lambda, \mathsf{A}_X) = -\int_M I_4^{(1)}(\lambda, \mathsf{A}). \tag{51.41}$$

Writing the four-dimensional effective action in (51.30) as $W_M[\mathsf{A}]$, one obtains the bulk-boundary identity

$$\delta_\lambda \left(W_M[\mathsf{A}] + W_X^{\mathrm{bulk}}[\mathsf{A}_X] \right) = \int_M I_4^{(1)}(\lambda, \mathsf{A}) - \int_{\partial X} I_4^{(1)}(\lambda, \mathsf{A}_X) = 0, \tag{51.42}$$

where the boundary orientation on ∂X is the orientation of M. This is anomaly inflow. The boundary theory by itself transforms by the consistent anomaly; the bulk Chern–Simons response transforms by the opposite boundary term. The gauge-invariant object is the combined bulk-boundary system.

In the Callan–Harvey realization, X is a physical gapped bulk or a domain-wall geometry, and M supports chiral modes localized at the wall. Integrating out the massive bulk modes produces a Chern–Simons response whose coefficient jumps across the wall. The jump supplies precisely the term $-\int_M I_4^{(1)}$ in (51.41), while the localized chiral modes supply $+\int_M I_4^{(1)}$. The boundary chiral modes retain their consistent anomaly, and gauge invariance is a property of the combined bulk-boundary system.

The formula (51.40) is local in a chosen trivialization. On topologically nontrivial bundles the Chern–Simons form is defined patchwise, and the exponentiated bulk functional must be defined by differential-geometric data with integral periods, equivalently by an invertible five-dimensional field theory whose curvature is the anomaly polynomial I_6. The local descent computation fixes the infinitesimal variation. Global questions require the finite version: a closed five-manifold carrying a background field is assigned a phase, and cutting it open gives the anomalous transformation law of a boundary theory. That finite form is the starting point of the global-anomaly discussion in Chapter 55.

51.11 Consistent and Covariant Currents

The current obtained by differentiating the effective action,

$$J^{a\mu}_{\text{cons}}(x) = \frac{\delta W[A]}{\delta A^a_\mu(x)},$$

is the consistent current. Its anomaly is the variation of a functional and therefore obeys the Wess–Zumino consistency condition. This integrability is the reason that the consistent anomaly is the object classified by $H^{1,4}(s \mid d)$. More precisely, the anomaly class modulo local counterterms is the consistent descent class represented by $\int_M I_4^{(1)}$; covariant Ward identities are obtained after taking a local differential of this class and adding a Bardeen–Zumino polynomial.

The consistent current need not transform covariantly under background gauge transformations. There is a local polynomial current

$$J^{a\mu}_{\text{BZ}}(A)$$

called the Bardeen–Zumino current, whose addition gives a covariant current

$$J^{a\mu}_{\text{cov}} = J^{a\mu}_{\text{cons}} + J^{a\mu}_{\text{BZ}}.$$

In the anti-Hermitian form convention used in the descent formula above, the dual three-form of the Bardeen–Zumino current for one left-handed fermion in the representation R may be chosen as

$$\star J^a_{\text{BZ}} = \kappa\, \mathrm{tr}_R \left[T^a_R \left(\mathsf{AF} + \mathsf{FA} - \frac{1}{2}\mathsf{A}^3 \right) \right], \qquad \kappa = \frac{\mathrm{i}}{24\pi^2}, \tag{51.43}$$

where T^a_R is the anti-Hermitian generator used to vary A, products include wedge product and matrix multiplication, and $\star J^a_{\text{BZ}}$ denotes

$$\star J^a_{\text{BZ}} = \frac{1}{3!}\epsilon_{\mu\nu\rho\sigma} J^{a\mu}_{\text{BZ}} \mathrm{d}x^\nu \wedge \mathrm{d}x^\rho \wedge \mathrm{d}x^\sigma.$$

Equivalently, with

$$\mathsf{A} = \mathsf{A}_\mu \mathrm{d}x^\mu, \qquad \mathsf{F} = \frac{1}{2}\mathsf{F}_{\rho\sigma}\mathrm{d}x^\rho \wedge \mathrm{d}x^\sigma,$$

the component current is the local polynomial

$$J^{a\mu}_{\text{BZ}} = \frac{\kappa}{2}\,\epsilon^{\mu\nu\rho\sigma}\, \mathrm{tr}_R \left[T^a_R \left(\mathsf{A}_\nu \mathsf{F}_{\rho\sigma} + \mathsf{F}_{\rho\sigma}\mathsf{A}_\nu - \mathsf{A}_\nu \mathsf{A}_\rho \mathsf{A}_\sigma \right) \right]. \tag{51.44}$$

Expanding

$$\mathsf{F}_{\rho\sigma} = \partial_\rho \mathsf{A}_\sigma - \partial_\sigma \mathsf{A}_\rho + [\mathsf{A}_\rho, \mathsf{A}_\sigma]$$

and using antisymmetry of $\epsilon^{\mu\nu\rho\sigma}$ gives the derivative form

$$J^{a\mu}_{\text{BZ}} = \kappa\,\epsilon^{\mu\nu\rho\sigma}\, \mathrm{tr}_R \left[T^a_R \left(\mathsf{A}_\nu \partial_\rho \mathsf{A}_\sigma + \partial_\rho \mathsf{A}_\sigma\, \mathsf{A}_\nu + \frac{1}{2}\mathsf{A}_\nu \mathsf{A}_\rho \mathsf{A}_\sigma + \mathsf{A}_\rho \mathsf{A}_\sigma \mathsf{A}_\nu \right) \right]. \tag{51.45}$$

The two displayed component expressions are the same polynomial written once with F and once with $\partial\mathsf{A}$. The ordering of matrices in (51.45) is part of the convention; replacing it by a commutative shorthand would lose the distinction between consistent and covariant currents for a nonabelian background.

Abelian calibration of the Bardeen–Zumino factor. The simplest check of the normalization is the one-generator commuting subspace. Let

$$I_6 = C\,\mathsf{F}^3, \qquad \mathsf{F} = \mathrm{d}\mathsf{A},$$

where C includes the trace and the factor κ. The corresponding Chern–Simons and consistent descent forms are

$$I_5^{(0)} = C\,\mathsf{A}\mathsf{F}^2, \qquad I_4^{(1)}(\lambda, \mathsf{A}) = C\,\lambda\,\mathsf{F}^2. \tag{51.46}$$

Thus the consistent Ward identity carries the coefficient C. In the same Abelianized coordinate the Bardeen–Zumino current (51.43) reduces to

$$\star J_{\mathrm{BZ}} = 2C\,\mathsf{A}\mathsf{F}, \qquad \mathrm{d}\star J_{\mathrm{BZ}} = 2C\,\mathsf{F}^2, \tag{51.47}$$

because $\mathsf{A}^3 = 0$ for a single one-form and $\mathrm{d}\mathsf{F} = 0$. The covariant Ward representative obtained by improving the current is therefore

$$C\,\lambda\,\mathsf{F}^2 + 2C\,\lambda\,\mathsf{F}^2 = 3C\,\lambda\,\mathsf{F}^2. \tag{51.48}$$

This factor of three is a normalization check, not a new anomaly class. The first term is the descent representative of the effective-action variation; the additional two units are the local divergence of the Bardeen–Zumino polynomial. In the nonabelian case the same statement is encoded by the ordered polynomial in (51.45); the covariant current transforms covariantly, but it is not in general the differential of a local effective action. For a set of Weyl fermions, sum (51.43) over left-handed representations and subtract the corresponding right-handed representations, in parallel with the anomaly polynomial I_6. The divergence of J_{cov} is gauge covariant and is often the most compact local expression of the anomaly. However, J_{cov} is generally not the functional derivative of a local effective action. Thus it is not the current that appears directly in the integrability condition (51.19). The consistent anomaly is the cohomology class. The covariant anomaly is obtained from a particular representative by applying the local differential of that class and adding the Bardeen–Zumino polynomial; it is a covariant representative of the Ward identity, not a representative of a second obstruction class. Gauge-anomaly cancellation is therefore a statement about the consistent class; after that class vanishes, covariant currents may be used as convenient representatives of gauge-covariant Ward identities.

51.12 Local Counterterms and Preserved Currents

An anomaly representative depends on the choice of local counterterms, while its cohomology class does not. Let B denote background gauge fields for a set of currents, and let $W[B]$ be the renormalized generating functional. Adding a local functional $I_{\mathrm{ct}}[B]$ changes

$$W[B] \longmapsto W[B] + I_{\mathrm{ct}}[B].$$

If a background gauge transformation with parameter ζ has anomaly

$$\delta_\zeta W[B] = \mathcal{A}(\zeta, B),$$

then after the counterterm shift

$$\mathcal{A}(\zeta, B) \longmapsto \mathcal{A}(\zeta, B) + \delta_\zeta I_{\mathrm{ct}}[B].$$

The second term is BRST-exact in the local functional complex. It can move the displayed divergence among currents that are coupled to backgrounds, but it cannot remove a nonzero anomaly class.

This distinction is essential when one of the currents is gauged dynamically. The gauge current must satisfy the Slavnov–Taylor identity; otherwise the gauge-fixed state space cannot be quotiented to a positive physical Hilbert space. For a vector and an axial current coupled to background fields, a Bardeen counterterm can shift the local expression of the anomaly between vector and axial Ward identities. The convention used in (51.6) is the one in which the vector gauge Ward identity is preserved and the axial current carries the anomaly. For a purely global symmetry, by contrast, the anomaly is allowed and becomes an RG-invariant background response to be matched by the infrared theory.

51.13 The Strong CP Parameter

In QCD with N_f quark flavors, the Euclidean gauge action may include the topological term

$$\mathrm{i}\theta\,\frac{1}{32\pi^2}\int \epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma})\,\mathrm{d}^4x.$$

The complex quark mass matrix M was introduced in (45.68). A flavor-singlet axial rotation changes the phase of $\det M$ and, by the anomaly, shifts θ. With the convention used in this chapter, the invariant CP-odd parameter is

$$\bar{\theta} = \theta + \arg\det M. \tag{51.49}$$

If the sign convention for γ_5 or for the topological density is reversed, both transformation laws change together and the invariant combination is correspondingly rewritten. The invariant statement is that only the anomaly-invariant combination of the topological angle and the quark mass phase is physically meaningful.

51.14 Topological Charge Sectors and Periodicity

For gauge group $SU(N_c)$ on a compact Euclidean four-manifold, or on $\mathbb{R}^4$ with finite-action boundary conditions so that the connection extends to a bundle over S^4, the topological charge is

$$Q[A] = \frac{1}{32\pi^2}\int \epsilon^{\mu\nu\rho\sigma}\,\mathrm{tr}(F_{\mu\nu}F_{\rho\sigma})\,\mathrm{d}^4x.$$

With F regarded as the matrix-valued curvature of the fundamental connection and with the matrix trace convention fixed in Chapter 45, $Q[A] \in \mathbb{Z}$. This integer statement is a Chern–Weil statement about the curvature form; rewriting it in components must use the same generator normalization as the one used to define $F = A^a t^a$. The Euclidean functional integral decomposes formally into connected components of fixed topological charge:

$$Z(\theta) = \sum_{Q\in\mathbb{Z}} \mathrm{e}^{\mathrm{i}\theta Q} Z_Q.$$

This expression makes the 2π-periodicity in θ manifest when no additional global identifications modify the allowed bundles or background fields.

The axial anomaly explains why θ cannot be assigned independently of the fermion mass phases. A flavor-singlet chiral rotation changes the fermion measure by a phase proportional to $Q[A]$ and changes $\arg\det M$ by the opposite amount in the mass term. The sector decomposition therefore gives the same invariant parameter $\bar\theta = \theta + \arg\det M$ as the local anomalous Ward identity. The local identity and the topological decomposition are two presentations of the same anomalous Jacobian in a gauge background with nonzero topological charge.

51.15 Topological Susceptibility as a Regulated Cumulant

The phrase "topological susceptibility" is often used as if it were a number attached directly to a formal continuum expression $\langle Q^2\rangle/V_4$. The object needed in QCD is more precise: it is a thermodynamic and continuum limit of a cumulant in a specified regulator.

Definition 51.14 (Finite-regulator theta data)**.** Fix a gauge-invariant Euclidean regulator on an oriented four-volume V_4. Finite-regulator theta data consist of nonnegative sector weights $Z_{\Lambda,V_4,Q}$, $Q \in \mathbb{Z}$, for the vectorlike theory at $\theta = 0$, such that

$$Z_{\Lambda,V_4}(\theta) = \sum_{Q\in\mathbb{Z}} \mathrm{e}^{\mathrm{i}\theta Q} Z_{\Lambda,V_4,Q} \tag{51.50}$$

is finite for θ in a neighborhood of zero. The finite-regulator vacuum-energy density near $\theta = 0$ is

$$E_{\Lambda,V_4}(\theta) = -\frac{1}{V_4}\log Z_{\Lambda,V_4}(\theta), \tag{51.51}$$

where the logarithm is the branch continuous from $\theta = 0$.

Remark 51.15 (Finite-volume susceptibility identity). For every finite-regulator theta data set,

$$E''_{\Lambda,V_4}(0) = \frac{1}{V_4}\left(\langle Q^2\rangle_{\Lambda,V_4,0} - \langle Q\rangle^2_{\Lambda,V_4,0}\right), \tag{51.52}$$

where the expectation is with respect to the positive weights $Z_{\Lambda,V_4,Q}/Z_{\Lambda,V_4}(0)$. If CP is preserved at $\theta = 0$, then $\langle Q\rangle_{\Lambda,V_4,0} = 0$, and the right hand side is $V_4^{-1}\langle Q^2\rangle_{\Lambda,V_4,0}$. Differentiate (51.50):

$$Z'(0) = \mathrm{i}\sum_Q Q Z_Q, \qquad Z''(0) = -\sum_Q Q^2 Z_Q,$$

where the regulator and volume labels are suppressed. Hence

$$\frac{\mathrm{d}^2}{\mathrm{d}\theta^2}\log Z(\theta)\bigg|_{\theta=0} = \frac{Z''(0)}{Z(0)} - \left(\frac{Z'(0)}{Z(0)}\right)^2 = -\langle Q^2\rangle + \langle Q\rangle^2.$$

Multiplying by $-1/V_4$ gives (51.52). CP sends $Q \mapsto -Q$; if the $\theta = 0$ weights are CP invariant, the first moment vanishes.

Proposition 51.16 (Finite-regulator theta-cumulant hierarchy)**.** *For finite-regulator theta data, define the charge cumulants at $\theta = 0$ by*

$$\mathcal{K}_Q(t) = \log \left\langle \mathrm{e}^{tQ} \right\rangle_{\Lambda,V_4,0} = \sum_{n\geq 1} \kappa_n^{(Q)} \frac{t^n}{n!}. \tag{51.53}$$

Then, in the analytic neighborhood where Definition 51.14 applies,

$$E_{\Lambda,V_4}(\theta) - E_{\Lambda,V_4}(0) = -\frac{1}{V_4}\,\mathcal{K}_Q(\mathrm{i}\theta), \qquad \partial_\theta^n E_{\Lambda,V_4}(0) = -\frac{\mathrm{i}^n}{V_4}\,\kappa_n^{(Q)}. \tag{51.54}$$

If the $\theta = 0$ weights are CP invariant, all odd charge cumulants vanish and the finite-volume expansion can be written

$$E_{\Lambda,V_4}(\theta) - E_{\Lambda,V_4}(0) = \frac{1}{2}\chi_{\Lambda,V_4}\theta^2 \left(1 + b_{2,\Lambda,V_4}\theta^2 + b_{4,\Lambda,V_4}\theta^4 + O(\theta^6)\right), \tag{51.55}$$

with

$$\chi_{\Lambda,V_4} = \frac{\kappa_2^{(Q)}}{V_4}, \qquad b_{2,\Lambda,V_4} = -\frac{\kappa_4^{(Q)}}{12\kappa_2^{(Q)}}, \qquad b_{4,\Lambda,V_4} = \frac{\kappa_6^{(Q)}}{360\kappa_2^{(Q)}}, \tag{51.56}$$

provided $\kappa_2^{(Q)} \neq 0$.

These are finite-volume identities, not yet continuum statements. In the thermodynamic limit the derivatives in (51.54) must be taken on a selected analytic branch of the vacuum energy; branch crossings or spontaneous CP breaking can obstruct a single Taylor series. In addition, if the renormalization convention permits adding a local vacuum counterterm $f_{\mathrm{ct}}(\theta)$, then the displayed derivatives shift by $f_{\mathrm{ct}}^{(n)}(0)$. The same counterterm convention must therefore be used for χ_{top}, b_2, b_4, and any Witten–Veneziano matching data.

Proof. Divide (51.50) by $Z_{\Lambda,V_4}(0)$. The ratio is the characteristic function $\langle \mathrm{e}^{\mathrm{i}\theta Q}\rangle_{\Lambda,V_4,0}$, hence

$$\log \frac{Z_{\Lambda,V_4}(\theta)}{Z_{\Lambda,V_4}(0)} = \mathcal{K}_Q(\mathrm{i}\theta).$$

Subtracting $E_{\Lambda,V_4}(0)$ from (51.51) gives the first identity in (51.54); differentiating gives the second. CP invariance pairs the Q and $-Q$ sector weights, so $\mathcal{K}_Q(t) = \mathcal{K}_Q(-t)$ and the odd cumulants vanish. Expanding the even part gives

$$E(\theta) - E(0) = \frac{\kappa_2^{(Q)}}{2V_4}\theta^2 - \frac{\kappa_4^{(Q)}}{24V_4}\theta^4 + \frac{\kappa_6^{(Q)}}{720V_4}\theta^6 + \cdots.$$

Comparison with (51.55) gives (51.56). The last paragraph is the definition of branchwise differentiability and local counterterm covariance for the finite-volume identities just derived. □

Proposition 51.17 (Local density form and contact convention)**.** *Assume that the finite regulator is placed on a closed four-volume, such as a periodic box, or on a volume with boundary data for which the topological charge is fixed, and that it supplies a regulated local density $q_{\Lambda,V_4}(x)$ satisfying*

$$Q = \int_{V_4} q_{\Lambda,V_4}(x)\,\mathrm{d}^4 x \tag{51.57}$$

configuration by configuration. Then the finite-volume susceptibility is equivalently, with the integrals interpreted as the regulator's finite sum or integral,

$$E''_{\Lambda,V_4}(0) = \frac{1}{V_4}\int_{V_4} \mathrm{d}^4x \int_{V_4} \mathrm{d}^4y \left\langle q_{\Lambda,V_4}(x) q_{\Lambda,V_4}(y)\right\rangle^{\mathrm{c}}_{\Lambda,V_4,0}. \tag{51.58}$$

If the regulator and state are translation invariant on a periodic volume, this reduces to the zero-momentum two-point function

$$E''_{\Lambda,V_4}(0) = \int_{V_4} \mathrm{d}^4x \left\langle q_{\Lambda,V_4}(x) q_{\Lambda,V_4}(0)\right\rangle^{\mathrm{c}}_{\Lambda,V_4,0}. \tag{51.59}$$

Proof. Insert (51.57) into the finite cumulant:

$$\langle Q^2\rangle - \langle Q\rangle^2 = \int_{V_4} \mathrm{d}^4x \int_{V_4} \mathrm{d}^4y \left(\langle q_{\Lambda,V_4}(x) q_{\Lambda,V_4}(y)\rangle - \langle q_{\Lambda,V_4}(x)\rangle\langle q_{\Lambda,V_4}(y)\rangle\right).$$

Dividing by V_4 and using (51.52) gives (51.58). Translation invariance sets the connected correlator equal to a function of $x - y$; the double integral is then V_4 times the integral over one relative coordinate. □

The continuum formula $\chi_{\mathrm{top}} = \int \mathrm{d}^4x \,\langle q(x)q(0)\rangle^{\mathrm{c}}$ is therefore not a bare multiplication rule for two formal $F\widetilde{F}$ densities at coincident points. It is the limit of the regulated zero-momentum curvature above, with the contact term selected by the same local θ-counterterm convention used in Definition 51.18. Changing the convention by an additive local vacuum-energy term $\frac{1}{2}c_\theta\theta^2$ shifts both $E''(0)$ and the integrated contact part of the density two-point function by c_θ. Thus Witten–Veneziano matching uses the renormalized zero-momentum curvature of pure Yang–Mills, not an unrenormalized point-split product with its contact term silently discarded.

Definition 51.18 (Topological susceptibility)**.** The topological susceptibility of a continuum theory in a specified phase and regulator class is the limit

$$\chi_{\mathrm{top}} = \lim_{\Lambda\to\infty}\lim_{V_4\to\infty} E''_{\Lambda,V_4}(0), \tag{51.60}$$

when this limit exists and is independent of the allowed regulator choices after the local counterterm convention for the theta term has been fixed. For pure Yang–Mills we write the corresponding quantity as χ_{YM}.

This definition intentionally separates three facts which are often conflated. The finite identity (51.52) is elementary. The existence and regulator independence of (51.60) is a nonperturbative statement about the theory. The use of χ_{YM} inside a chiral effective description with dynamical quarks is a further large-N_c matching assumption, developed in the next chapter.

51.16 Theta Branches and Cluster Decomposition

The sector sum $\sum_Q \mathrm{e}^{\mathrm{i}\theta Q} Z_Q$ explains 2π-periodicity, but it does not by itself identify a pure infinite-volume vacuum. In a theory with several large-volume branches the thermodynamic limit selects the branch of smallest energy density, except at degeneracy loci where a phase-selection prescription is needed. Cluster decomposition is the local diagnostic that one has chosen a pure phase rather than a convex mixture.

Definition 51.19 (Theta-branch data)**.** Theta-branch data for a regulated Euclidean gauge theory in a volume V_4 consists of a finite or countable branch set $\mathcal{B}$, branch partition functions $Z_{\Lambda,V_4,\beta}(\theta)$, and local normalized states $\omega_{\Lambda,V_4,\beta,\theta}$ on gauge-invariant observables, such that

$$Z_{\Lambda,V_4}(\theta) = \sum_{\beta\in\mathcal{B}} Z_{\Lambda,V_4,\beta}(\theta), \qquad p_{\Lambda,V_4,\beta}(\theta) = \frac{Z_{\Lambda,V_4,\beta}(\theta)}{Z_{\Lambda,V_4}(\theta)}. \tag{51.61}$$

When the limits exist, write

$$E_\beta(\theta) = -\lim_{\Lambda\to\infty}\lim_{V_4\to\infty}\frac{1}{V_4}\log Z_{\Lambda,V_4,\beta}(\theta) \tag{51.62}$$

for the branch energy density. The data are 2π-periodic by branch relabeling when there is a bijection $T : \mathcal{B} \to \mathcal{B}$ with

$$E_{T\beta}(\theta + 2\pi) = E_\beta(\theta). \tag{51.63}$$

Remark 51.20 (Thermodynamic branch selection)*.* Assume a finite branch set and a fixed θ at which the limiting branch energies $E_\beta(\theta)$ exist. If a unique branch β_* satisfies

$$E_{\beta_*}(\theta) < E_\beta(\theta) \qquad \text{for every } \beta \neq \beta_*, \tag{51.64}$$

and if each branch partition function has the form

$$Z_{\Lambda,V_4,\beta}(\theta) = \exp\{-V_4E_\beta(\theta) + o(V_4)\} \tag{51.65}$$

uniformly over the finite branch set, then

$$\lim_{\Lambda\to\infty}\lim_{V_4\to\infty} p_{\Lambda,V_4,\beta_*}(\theta) = 1, \qquad \lim_{\Lambda\to\infty}\lim_{V_4\to\infty} p_{\Lambda,V_4,\beta}(\theta) = 0 \quad (\beta \neq \beta_*). \tag{51.66}$$

For $\beta \neq \beta_*$,

$$\frac{Z_{\Lambda,V_4,\beta}(\theta)}{Z_{\Lambda,V_4,\beta_*}(\theta)} = \exp\{-V_4(E_\beta(\theta) - E_{\beta_*}(\theta)) + o(V_4)\}.$$

The exponent tends to $-\infty$ because the energy-density gap is positive. Since the branch set is finite, the sum of all nonminimal ratios tends to zero. Dividing the branch weights by Z_{Λ,V_4,β_*} gives (51.66).

Remark 51.21 (Cluster test for mixtures of theta branches)*.* Let $\{\omega_\beta\}_{\beta\in\mathcal{B}}$ be translation-invariant pure states for gauge-invariant local observables, and assume each branch clusters: for local observables $\mathcal{O}, \mathcal{P}$,

$$\lim_{|a|\to\infty} \omega_\beta(\mathcal{O}(a)\mathcal{P}(0)) = \omega_\beta(\mathcal{O})\omega_\beta(\mathcal{P}). \tag{51.67}$$

For a convex combination

$$\omega = \sum_{\beta\in\mathcal{B}} p_\beta\omega_\beta, \qquad p_\beta \geq 0, \qquad \sum_\beta p_\beta = 1, \tag{51.68}$$

one has

$$\lim_{|a|\to\infty} [\omega(\mathcal{O}(a)\mathcal{P}(0)) - \omega(\mathcal{O})\omega(\mathcal{P})] = \mathrm{Cov}_p\big(\omega_\beta(\mathcal{O}), \omega_\beta(\mathcal{P})\big). \tag{51.69}$$

Thus the mixture clusters for all local observables only if the branch labels cannot be distinguished by local one-point functions on the support of p_β, or if the mixture is supported on a single branch. Using the branch clustering assumption,

$$\lim_{|a|\to\infty} \omega(\mathcal{O}(a)\mathcal{P}(0)) = \sum_\beta p_\beta \omega_\beta(\mathcal{O})\omega_\beta(\mathcal{P}).$$

The product of the one-point functions in the mixed state is

$$\omega(\mathcal{O})\omega(\mathcal{P}) = \left(\sum_\beta p_\beta \omega_\beta(\mathcal{O})\right)\left(\sum_\gamma p_\gamma \omega_\gamma(\mathcal{P})\right).$$

Their difference is precisely the covariance of the two branch-dependent one-point functions with respect to the probability distribution p.

Remark 51.22 (Theta vacua as theorem, hypothesis, and convention)*.* At finite regulator the sector decomposition, cumulant identity, and branch mixture algebra above are exact. A continuum statement that theta labels superselection sectors requires additional input: the existence of the continuum gauge theory, the infinite-volume limits of the local states, the cluster property inside a selected branch, and the action of large gauge transformations or theta-shift automorphisms on the physical representation. The monograph therefore uses "theta vacuum" only after these data have been specified. Otherwise it speaks of a theta parameter in the regulated action or of a theta-branch hypothesis.

51.17 The BPST Instanton and the Semiclassical Vertex

We now construct the basic finite-action representative of the sector $Q = 1$. This section is Euclidean: coordinates are x^μ, $\mu = 1, \dots, 4$, the metric is $\delta_{\mu\nu}$, and $\epsilon_{1234} = +1$. The chapter's gauge-field convention remains Hermitian, so

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu - \mathrm{i}[A_\mu, A_\nu].$$

For explicit $SU(2)$ formulas it is economical to use the auxiliary basis

$$T_a = \frac{\sigma_a}{2}, \qquad [T_a, T_b] = \mathrm{i}\epsilon^c{}_{ab} T_c, \qquad \mathrm{tr}(T_a T_b) = \frac{1}{2}\delta_{ab}.$$

This is only a coordinate choice for the displayed solution. The monograph's default trace-delta basis is $t_a = \sqrt{2}\, T_a$. If

$$\mathcal{L}_{\text{here}} = -\frac{1}{4g_{\text{YM}}^2} \mathrm{tr}_\delta(F_{\mu\nu}F^{\mu\nu})$$

is rewritten in the T_a basis, then the corresponding half-trace coupling is $g_{\text{ht}} = \sqrt{2}\, g_{\text{YM}}$. Thus the familiar instanton action $8\pi^2/g_{\text{ht}}^2$ is the same number as $4\pi^2/g_{\text{YM}}^2$ in the active trace-delta coupling coordinate.

Define the self-dual 't Hooft symbols by

$$\eta^a_{ij} = \epsilon_{aij}, \qquad \eta^a_{i4} = \delta_{ai}, \qquad \eta^a_{4i} = -\delta_{ai}, \qquad i, j, a = 1, 2, 3,$$

so that

$$\eta^a_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}\eta^a_{\rho\sigma}, \qquad \sum_{a,\mu,\nu} \eta^a_{\mu\nu}\eta^a_{\mu\nu} = 12.$$

The contraction identity used below is

$$\epsilon^a{}_{bc}\eta^b_{\mu\rho}\eta^c_{\nu\sigma}y^\rho y^\sigma = r^2\eta^a_{\mu\nu} + y_\mu\eta^a_{\nu\lambda}y^\lambda - y_\nu\eta^a_{\mu\lambda}y^\lambda. \tag{51.70}$$

It follows by checking the three possible positions of the index 4 in the defining equations for η, and then using antisymmetry in μ, ν. This identity is the finite-dimensional algebraic input that turns the apparently inhomogeneous derivative and commutator terms in the curvature into a multiple of $\eta^a_{\mu\nu}$. Let $a^\mu \in \mathbb{R}^4$ and $\rho > 0$. Put $y = x - a$ and $r^2 = y_\mu y_\mu$. The BPST one-instanton in regular gauge is

$$A_\mu(x) = \frac{2\,\eta^a_{\mu\nu}y^\nu}{r^2+\rho^2}\,T_a. \tag{51.71}$$

Write $f = r^2 + \rho^2$ and $A_\mu = A^a_\mu T_a$. Since

$$\partial_\mu A^a_\nu - \partial_\nu A^a_\mu = -\frac{4}{f}\,\eta^a_{\mu\nu} - \frac{4}{f^2}\left(y_\mu\eta^a_{\nu\lambda}y^\lambda - y_\nu\eta^a_{\mu\lambda}y^\lambda\right)$$

and

$$\epsilon^a{}_{bc}A^b_\mu A^c_\nu = \frac{4}{f^2}\left(r^2\eta^a_{\mu\nu} + y_\mu\eta^a_{\nu\lambda}y^\lambda - y_\nu\eta^a_{\mu\lambda}y^\lambda\right),$$

the curvature convention $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + \epsilon^a{}_{bc}A^b_\mu A^c_\nu$ gives

$$F_{\mu\nu}(x) = -\frac{4\rho^2}{(r^2+\rho^2)^2}\,\eta^a_{\mu\nu}T_a. \tag{51.72}$$

Hence $F_{\mu\nu} = \widetilde{F}_{\mu\nu}$, where $\widetilde{F}_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}F_{\rho\sigma}$. The connection is smooth at $r = 0$. At infinity it is gauge-equivalent to a pure gauge of winding one. Equivalently, applying the gauge transformation

$$g(y) = \frac{y_4\mathbf{1} + \mathrm{i}y_i\sigma_i}{r}, \qquad g : S^3_\infty \to SU(2),$$

produces the singular-gauge representative

$$A^{\text{sing}}_\mu(x) = \frac{2\rho^2\,\bar{\eta}^a_{\mu\nu}y^\nu}{r^2(r^2+\rho^2)}\,T_a,$$

where $\bar{\eta}$ is the anti-self-dual 't Hooft symbol obtained from η by reversing the signs of the components with one index equal to 4. This representative decays as r^{-3} at infinity and has a gauge-coordinate singularity at $y = 0$. The two representatives describe the same smooth connection on the one-instanton bundle over S^4.

The action saturation is an algebraic consequence of self-duality. In the half-trace component convention,

$$S^{\text{ht}}_E = \frac{1}{4g^2_{\text{ht}}}\int_{\mathbb{R}^4} \mathrm{d}^4x\, F^a_{\mu\nu}F^a_{\mu\nu}.$$

Completing the square gives, for any finite-action field in the sector of charge k,

$$S^{\text{ht}}_E = \frac{1}{8g^2_{\text{ht}}}\int (F^a_{\mu\nu} \mp \widetilde{F}^a_{\mu\nu})^2\,\mathrm{d}^4x \pm \frac{1}{4g^2_{\text{ht}}}\int F^a_{\mu\nu}\widetilde{F}^a_{\mu\nu}\,\mathrm{d}^4x \geq \frac{8\pi^2}{g^2_{\text{ht}}}|k|. \tag{51.73}$$

Equality holds precisely for self-dual fields when $k > 0$ and anti-self-dual fields when $k < 0$. For (51.72),

$$F^a_{\mu\nu} F^a_{\mu\nu} = \frac{192\rho^4}{(r^2+\rho^2)^4}, \qquad \int_{\mathbb{R}^4} \frac{\rho^4 \, \mathrm{d}^4 x}{(r^2+\rho^2)^4} = \frac{\pi^2}{6},$$

where the last integral is

$$2\pi^2 \int_0^\infty \frac{\rho^4 r^3 \, \mathrm{d}r}{(r^2+\rho^2)^4} = \pi^2 \int_0^\infty \frac{\rho^4 u \, \mathrm{d}u}{(u+\rho^2)^4} = \frac{\pi^2}{6}.$$

Therefore

$$\int_{\mathbb{R}^4} F^a_{\mu\nu} F^a_{\mu\nu} \, \mathrm{d}^4 x = 32\pi^2, \qquad S_E^{\mathrm{ht}} = \frac{8\pi^2}{g_{\mathrm{ht}}^2}.$$

Because the field is self-dual,

$$Q[A] = \frac{1}{32\pi^2} \int F^a_{\mu\nu} \widetilde{F}^a_{\mu\nu} \, \mathrm{d}^4 x = 1.$$

In the trace-delta coupling coordinate used elsewhere in this monograph this same saddle contributes the exponential

$$\exp\left(-\frac{4\pi^2}{g_{\mathrm{YM}}^2} + \mathrm{i}\theta \right) = \exp\left(-\frac{8\pi^2}{g_{\mathrm{ht}}^2} + \mathrm{i}\theta \right). \tag{51.74}$$

Lemma 51.23 (BPST one-instanton data)**.** *With the self-dual symbols and $SU(2)$ half-trace generators $T_a = \sigma_a/2$ used in this section, the connection*

$$A_\mu(x) = \frac{2\, \eta^a_{\mu\nu} (x-a)^\nu}{(x-a)^2 + \rho^2} \, T_a, \qquad \rho > 0,$$

has curvature

$$F_{\mu\nu}(x) = -\frac{4\rho^2}{((x-a)^2+\rho^2)^2} \, \eta^a_{\mu\nu} T_a.$$

It is self-dual, has topological charge $Q = 1$, and has Euclidean action

$$S_E^{\mathrm{ht}} = \frac{8\pi^2}{g_{\mathrm{ht}}^2} = \frac{4\pi^2}{g_{\mathrm{YM}}^2}$$

when rewritten in the trace-delta coupling coordinate of the Yang–Mills chapters.

Proof. Differentiating the displayed connection gives the derivative term written above, and the commutator term is $\epsilon^a{}_{bc} A^b_\mu A^c_\nu$. The contraction identity (51.70) cancels the inhomogeneous $y_\mu \eta^a_{\nu\lambda} y^\lambda - y_\nu \eta^a_{\mu\lambda} y^\lambda$ terms and leaves (51.72). Since $\eta^a_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}\eta^a_{\rho\sigma}$, this curvature is self-dual.

The square-completion identity (51.73) gives the lower bound $8\pi^2|Q|/g_{\mathrm{ht}}^2$, saturated by a self-dual field with $Q > 0$. For the displayed curvature,

$$F^a_{\mu\nu} F^a_{\mu\nu} = \frac{192\rho^4}{(r^2+\rho^2)^4}, \qquad \int_{\mathbb{R}^4} \frac{\rho^4 \, \mathrm{d}^4 x}{(r^2+\rho^2)^4} = \frac{\pi^2}{6},$$

so $\int F^a_{\mu\nu} F^a_{\mu\nu} = 32\pi^2$. Self-duality then gives

$$Q = \frac{1}{32\pi^2} \int F^a_{\mu\nu} \widetilde{F}^a_{\mu\nu} \, \mathrm{d}^4 x = 1$$

and $S_E^{\mathrm{ht}} = 8\pi^2/g_{\mathrm{ht}}^2$. Finally, $\mathrm{tr}_\delta(t_a t_b) = \delta_{ab}$ with $t_a = \sqrt{2}\, T_a$ implies $g_{\mathrm{ht}} = \sqrt{2}\, g_{\mathrm{YM}}$, hence the trace-delta action is $4\pi^2/g_{\mathrm{YM}}^2$. □

Figure 51.5 plots the radial content of the same normalization check. In the dimensionless variable $u = r/\rho$, the normalized action-density profile and the cumulative topological charge are

$$\frac{F^a_{\mu\nu}F^a_{\mu\nu}(r)}{F^a_{\mu\nu}F^a_{\mu\nu}(0)} = \frac{1}{(1+u^2)^4}, \qquad \frac{1}{32\pi^2}\int_{|x-a|\le R} F^a_{\mu\nu}F^a_{\mu\nu}\,\mathrm{d}^4x = 1 - \frac{3}{(1+u^2)^2} + \frac{2}{(1+u^2)^3}.$$

The second formula is the radial integral in the proof of Lemma 51.23 before the limit $R/\rho \to \infty$.

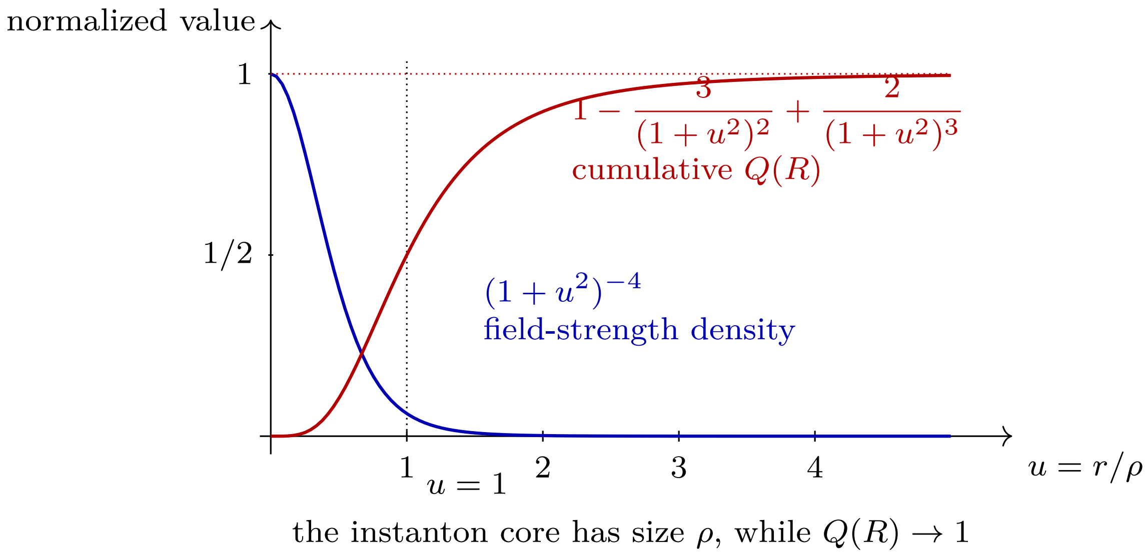

Figure 51.5: Radial BPST instanton profile in units of its size ρ. The blue curve is the normalized density $F^a_{\mu\nu}F^a_{\mu\nu}(r)/F^a_{\mu\nu}F^a_{\mu\nu}(0)$; the red curve is the cumulative topological charge inside radius $R = \rho u$. The plot makes the localized core and the normalization $Q = 1$ visible rather than merely repeating the algebraic formulas.

The bosonic zero modes are tangent vectors to the moduli of solutions modulo gauge transformations. For $SU(2)$, $k = 1$, the smooth moduli are

$$a^\mu \in \mathbb{R}^4, \qquad \rho \in \mathbb{R}_{>0}, \qquad U \in SU(2)/\mathbb{Z}_2.$$

Thus there are

$$4 + 1 + 3 = 8$$

bosonic zero modes: four translations, one dilation, and three global gauge orientations. For an $SU(N_c)$ instanton obtained by embedding the above $SU(2)$ solution, the orientation moduli are enlarged, and the one-instanton bosonic moduli space has dimension $4N_c$ before quotienting possible global identifications. The reason for the number $4N_c$ is local and elementary. The center and size contribute $4+1$ parameters. The embedded $SU(2)$ orientation is the orbit of the embedding under $SU(N_c)$, whose stabilizer is $SU(N_c-2)\times U(1)$. Hence the orientation dimension is

$$(N_c^2 - 1) - \big((N_c-2)^2 - 1\big) - 1 = 4N_c - 5,$$

and adding center and size gives $4N_c$. The precise global quotient by the center and by stabilizers affects the coordinate range, not this local dimension count.

Definition 51.24 (Framed ADHM quotient)**.** Let $W \simeq \mathbb{C}^{N_c}$ be the framing vector space and $K \simeq \mathbb{C}^k$ the instanton vector space. A framed $U(N_c)$ ADHM quadruple of charge k is

$$(B_1, B_2, I, J) \in \mathrm{End}(K)^2 \oplus \mathrm{Hom}(W, K) \oplus \mathrm{Hom}(K, W),$$

with moment maps

$$\begin{aligned} \mu_{\mathbb{C}} &:= [B_1, B_2] + IJ \in \mathrm{End}(K), \\ \mu_{\mathbb{R}} &:= [B_1, B_1^\dagger] + [B_2, B_2^\dagger] + II^\dagger - J^\dagger J \in \mathrm{Herm}(K). \end{aligned} \tag{51.75}$$

The unitary group $U(K)$ acts by

$$(B_1, B_2, I, J) \longmapsto (gB_1g^{-1}, gB_2g^{-1}, gI, Jg^{-1}). \tag{51.76}$$

The smooth framed ADHM quotient is the stable part of

$$\mathcal{M}_{k,N_c}^{\mathrm{ADHM}} := \{\, \mu_{\mathbb{C}} = 0,\ \mu_{\mathbb{R}} = 0 \,\}/U(K). \tag{51.77}$$

Here stability means that there is no proper subspace $S \subset K$ which contains $I(W)$ and is preserved by both B_1 and B_2. On this stable locus the framed gauge data have no residual endomorphism of K invisible to the framing.

The ADHM construction identifies the smooth quotient (51.77) with the framed smooth instanton moduli space on $\mathbb{R}^4$, after matching the chosen orientation convention for self-duality versus anti-self-duality. The full transform also builds the connection from the finite-dimensional linear algebra. The calculation needed for the semiclassical measure at this stage is the local quotient dimension and the boundary behavior of the quotient, which follow directly from Definition 51.24.

Proposition 51.25 (ADHM quotient dimension at smooth stable points)**.** *At a point of $\mu_{\mathbb{C}}^{-1}(0) \cap \mu_{\mathbb{R}}^{-1}(0)$ where the stable $U(K)$ action is free and the moment map is transverse to zero, the framed ADHM quotient $\mathcal{M}_{k,N_c}^{\mathrm{ADHM}}$ has local real dimension*

$$\dim_{\mathbb{R}} \mathcal{M}_{k,N_c}^{\mathrm{ADHM}} = 4kN_c.$$

The trace parts of B_1 and B_2 give the four center coordinates of the instanton configuration. The centered quotient therefore has local real dimension $4kN_c - 4$.

Proof. The real dimension of the unconstrained variables is

$$2\dim_{\mathbb{C}}\big(\mathrm{End}(K)^2\big) + 2\dim_{\mathbb{C}} \mathrm{Hom}(W, K) + 2\dim_{\mathbb{C}} \mathrm{Hom}(K, W) = 4k^2 + 4kN_c.$$

The complex equation $\mu_{\mathbb{C}} = 0$ imposes k^2 complex conditions, hence $2k^2$ real conditions. The real moment-map equation $\mu_{\mathbb{R}} = 0$ imposes k^2 real conditions because $\mathfrak{u}(K)$ has real dimension k^2. Transversality makes these conditions independent at the point under consideration.

Finally one divides by $U(K)$, whose real dimension is k^2. Freeness on the stable locus means that this quotient subtracts exactly k^2 dimensions locally. Thus

$$(4k^2 + 4kN_c) - 2k^2 - k^2 - k^2 = 4kN_c.$$

The equations contain only commutators of B_1, B_2 and the products $IJ, II^\dagger, J^\dagger J$. Shifting

$$B_\alpha \longmapsto B_\alpha + c_\alpha \mathbf{1}_K, \qquad \alpha = 1, 2,$$

leaves the moment maps unchanged. The two complex numbers $\operatorname{tr} B_1/k$ and $\operatorname{tr} B_2/k$ are therefore the four real translation coordinates in the complex structure used to write $\mathbb{R}^4 \simeq \mathbb{C}^2$. Removing them gives centered dimension $4kN_c - 4$. □

The stability condition is also where the small-instanton boundary first appears algebraically. If a stable ADHM tuple degenerates so that a nonzero subspace of K decouples from the framing, the quotient leaves the smooth instanton stratum and records instanton charge concentrated at points of $\mathbb{R}^4$. The Uhlenbeck boundary has strata of the form

$$\mathcal{M}^{\text{smooth}}_{k-\ell,N_c} \times \operatorname{Sym}^{\ell}(\mathbb{R}^4), \qquad 1 \le \ell \le k,$$

where ℓ units of charge have collapsed to pointlike ideal instantons. For a path integral this compactification carries analytic content: whether the semiclassical integral is finite depends on the determinant, operator insertions, and regulator behavior near these boundary strata.

Definition 51.26 (ADHM quotient density)**.** Equip the affine ADHM space

$$\mathbb{A}_{k,N_c} = \operatorname{End}(K)^2 \oplus \operatorname{Hom}(W,K) \oplus \operatorname{Hom}(K,W)$$

with the flat Hermitian metric

$$\|(\delta B_1, \delta B_2, \delta I, \delta J)\|^2 = \operatorname{tr}_K(\delta B_1 \delta B_1^\dagger) + \operatorname{tr}_K(\delta B_2 \delta B_2^\dagger) + \operatorname{tr}_K(\delta I \delta I^\dagger) + \operatorname{tr}_W(\delta J^\dagger \delta J).$$

On the free, stable, regular locus

$$Z^{\text{reg}}_{k,N_c} := \{\mu_{\mathbb{C}} = 0,\ \mu_{\mathbb{R}} = 0\}_{\text{stable,reg}} \subset \mathbb{A}_{k,N_c},$$

let $V_X \subset T_X Z^{\text{reg}}_{k,N_c}$ be the tangent space to the $U(K)$-orbit and let

$$H_X := V_X^{\perp} \cap T_X Z^{\text{reg}}_{k,N_c}.$$

The differential of the quotient map identifies H_X with the tangent space of the smooth quotient at $[X]$. The *ADHM quotient density* $\mathrm{d}\nu^{\text{ADHM}}_{k,N_c}$ is the Riemannian density induced by this quotient metric.

This density is a finite-dimensional object. It is not yet the complete semiclassical Yang–Mills weight: the latter also contains the nonzero-mode determinants, coupling-coordinate convention, operator renormalization, and the treatment of the boundary strata. The quotient density is the part of the measure fixed by the classical zero-mode geometry.

Proposition 51.27 (Coarea form of the ADHM quotient density)**.** *Fix an* Ad*-invariant inner product on $\mathfrak{u}(K)$ and let $\mathrm{d}\operatorname{vol}_{U(K)}$ be the associated left-invariant Riemannian density on $U(K)$. Choose an orthonormal basis $\{\xi_A\}_{A=1}^{k^2}$ of $\mathfrak{u}(K)$, and let $\xi_A^{\#}(X)$ denote the corresponding infinitesimal orbit vector at $X \in Z^{\text{reg}}_{k,N_c}$. Define the orbit Gram matrix*

$$M_{AB}(X) := \langle \xi_A^{\#}(X), \xi_B^{\#}(X) \rangle_{\mathbb{A}}.$$

If F is a compactly supported smooth $U(K)$-invariant function on Z^{reg}_{k,N_c}, then

$$\int_{\mathcal{M}^{\text{ADHM}}_{k,N_c}} F([X])\, \mathrm{d}\nu^{\text{ADHM}}_{k,N_c}([X]) = \frac{1}{\operatorname{Vol} U(K)} \int_{Z^{\text{reg}}_{k,N_c}} \frac{F(X)}{\sqrt{\det M(X)}}\, \mathrm{d}\operatorname{vol}_Z(X). \tag{51.78}$$

Equivalently, if $J_\mu(X)$ is the coarea Jacobian

$$J_\mu(X) := \det\!\big(D\mu_X D\mu_X^*\big)^{1/2}, \qquad \mu = (\operatorname{Re}\mu_{\mathbb{C}}, \operatorname{Im}\mu_{\mathbb{C}}, \mu_{\mathbb{R}}),$$

then the same density may be represented distributionally on the ambient affine space by

$$\int_{\mathcal{M}^{\mathrm{ADHM}}_{k,N_c}} F\,\mathrm{d}\nu^{\mathrm{ADHM}}_{k,N_c} = \frac{1}{\operatorname{Vol} U(K)} \int_{\mathbb{A}_{k,N_c}} F(X)\,\delta(\mu(X))\,\frac{J_\mu(X)}{\sqrt{\det M(X)}}\,\mathrm{d}X, \tag{51.79}$$

on any compact set where the regularity and freeness hypotheses hold. The delta function in (51.79) *is normalized with respect to the Euclidean density on the real target of* μ *induced by the same trace pairings.*

Proof. The restricted flat metric on Z^{reg}_{k,N_c} gives the orthogonal splitting

$$T_X Z^{\mathrm{reg}}_{k,N_c} = H_X \oplus V_X.$$

In local product coordinates (y,θ), where y is a quotient coordinate and θ^A are group coordinates near the identity, the metric is block diagonal at the chosen slice if H_X is used as the horizontal distribution. The horizontal block is the quotient metric, while the vertical block is precisely $M_{AB}(X)$. Therefore the Riemannian density on the level set factorizes as

$$\mathrm{d}\operatorname{vol}_Z = \sqrt{\det M(X)}\,\mathrm{d}\operatorname{vol}_{U(K)}\ \mathrm{d}\nu^{\mathrm{ADHM}}_{k,N_c}.$$

Because the flat metric and the moment-map equations are $U(K)$-invariant, $\det M(X)$ is constant along each orbit. Integrating an invariant function over the group coordinate gives (51.78).

For the ambient-space expression, apply the ordinary finite-dimensional coarea formula to the submersion μ:

$$\int_{\mathbb{A}_{k,N_c}} h(X)\,\delta(\mu(X))\,J_\mu(X)\,\mathrm{d}X = \int_{\mu^{-1}(0)} h(X)\,\mathrm{d}\operatorname{vol}_Z(X)$$

for compactly supported h in the regular locus. Taking $h = F/\sqrt{\det M}$ gives (51.79). $\square$

Remark 51.28 (Classical zero-mode density versus determinant weight). Equations (51.78) and (51.79) define the classical zero-mode density on the smooth ADHM quotient. They do not decide whether the instanton contribution to a continuum QFT observable is finite near a small-instanton stratum. That question depends on the nonzero-mode determinant, the operator insertions, and the renormalization scheme. This is why the Uhlenbeck boundary is part of the measure problem rather than an afterthought about topology.

Proposition 51.29 (Charge-one ADHM chart and the instanton orientation orbit)**.** *Let* $W \simeq \mathbb{C}^{N_c}$ *with its Hermitian inner product and let* $K \simeq \mathbb{C}$*. The centered charge-one framed* $U(N_c)$ *ADHM data are a pair*

$$I \in \operatorname{Hom}(W,K), \qquad J \in \operatorname{Hom}(K,W),$$

obeying

$$IJ = 0, \qquad II^\dagger - J^\dagger J = 0, \tag{51.80}$$

with $(I,J) \neq (0,0)$*, modulo the* $U(1)$ *action*

$$(I,J) \longmapsto (e^{\mathrm{i}\alpha} I, e^{-\mathrm{i}\alpha} J).$$

After identifying I *with a vector* $u \in W$ *by the Hermitian metric and writing* J *as a vector* $v \in W$*, the equations are*

$$\langle u,v\rangle = 0, \qquad \|u\| = \|v\| = \rho > 0. \tag{51.81}$$

For fixed ρ, the quotient is the homogeneous space

$$V_2(\mathbb{C}^{N_c})/U(1) \simeq U(N_c)/(U(N_c-2)\times U(1)), \tag{51.82}$$

where $V_2(\mathbb{C}^{N_c})$ is the Stiefel manifold of ordered orthonormal two-frames, $U(0)$ is interpreted as the trivial group when $N_c = 2$, and the $U(1)$ in the quotient acts by the common phase of the two frame vectors. Equivalently, for $N_c \geq 3$, after restricting to the special unitary framing, the connected orbit has the same local form

$$SU(N_c)/(SU(N_c-2)\times U(1))$$

up to a finite central quotient. For $N_c = 2$ this specialization is the usual $SU(2)/\mathbb{Z}_2$ orientation orbit. In every case the real dimension is $4N_c-5$. Adding the size ρ and the four center coordinates gives the local real dimension $4N_c$ of the charge-one instanton moduli space.

Proof. For $K \simeq \mathbb{C}$, the ADHM endomorphisms $B_1, B_2 \in \mathrm{End}(K)$ are complex numbers. They commute and therefore contribute no centered ADHM equation; their real and imaginary parts are the four center coordinates of the instanton. The remaining ADHM equations are exactly (51.80): $IJ = 0$ is the complex moment-map equation and $II^\dagger - J^\dagger J = 0$ is the real moment-map equation for the $U(1)$ acting on K.

Use the Hermitian metric to identify the row I with a vector $u \in W$ by $I(w) = \langle u, w\rangle$, and identify J with $v = J(1)$. Then $IJ = I(v) = \langle u, v\rangle$, while

$$II^\dagger = \|u\|^2\,\mathrm{id}_K, \qquad J^\dagger J = \|v\|^2\,\mathrm{id}_K\,.$$

Thus (51.80) is equivalent to (51.81). Since $(I, J) \neq (0, 0)$, the common norm is a positive number ρ. Dividing by ρ gives an ordered orthonormal two-frame $(u/\rho, v/\rho)$.

The $U(1)$ ADHM quotient sends $(u, v) \mapsto (e^{-\mathrm{i}\alpha}u, e^{-\mathrm{i}\alpha}v)$, namely the common phase of the ordered frame. The unitary group $U(N_c)$ acts transitively on ordered orthonormal two-frames. The stabilizer of the common-phase equivalence class of the reference frame (e_1, e_2) consists of an arbitrary unitary transformation on the orthogonal complement together with a common phase on the two displayed vectors, hence is $U(N_c-2)\times U(1)$. This proves (51.82). Its dimension is

$$\dim_{\mathbb{R}} U(N_c) - \dim_{\mathbb{R}} U(N_c-2) - \dim_{\mathbb{R}} U(1) = N_c^2 - (N_c-2)^2 - 1 = 4N_c - 5.$$

The size contributes one more dimension and the center contributes four. □

Cone structure and the small-instanton boundary. On the positive-size charge-one stratum, the centered ADHM quotient is the metric cone over the orientation orbit

$$\mathcal{O}_{N_c} = U(N_c)/(U(N_c-2)\times U(1)).$$

With the quotient metric induced from the flat metric $\|dI\|^2 + \|dJ\|^2$, its volume density has the local radial form

$$\rho^{4N_c-5}\,\mathrm{d}\rho\,\mathrm{d}\Omega_{N_c}, \tag{51.83}$$

for an invariant density $\mathrm{d}\Omega_{N_c}$ on $\mathcal{O}_{N_c}$. The endpoint $\rho = 0$ is the small-instanton boundary: the two-frame collapses to $(I, J) = (0, 0)$, the stabilizer jumps, and the positive-size quotient no longer supplies a smooth manifold chart. The equations (51.81) are homogeneous in (u, v). Hence every positive-size solution is uniquely written as $\rho(\hat{u},\hat{v})$, with $(\hat{u},\hat{v}) \in V_2(\mathbb{C}^{N_c})$ and $\rho > 0$, modulo the same common phase. The flat metric on (I, J) scales as

$$\|dI\|^2 + \|dJ\|^2 = c\,\mathrm{d}\rho^2 + \rho^2\,\mathrm{d}s^2_{\mathcal{O}_{N_c}}$$

for a positive constant c depending only on the normalization of ρ. A metric cone over a d-dimensional base has radial volume density proportional to $\rho^d\mathrm{d}\rho$ times the base density. Here $d = \dim_{\mathbb{R}} \mathcal{O}_{N_c} = 4N_c - 5$, giving (51.83). At $\rho = 0$ the frame vectors vanish and no two-frame remains; this is precisely the finite-dimensional ADHM model of the small-instanton degeneration.

The regulated collective-coordinate measure is the one constructed in Theorem 45.12. In a finite gauge-fixed regulator its local bosonic factor has the form

$$\mathrm{d}\mu^{\mathrm{bos}}_{k=1,\Lambda} = \frac{\Delta_{\mathrm{FP},\Lambda}(A_z)}{\mathrm{Vol}(\Gamma_z)} \frac{\sqrt{\det G^{(\Lambda)}_{ab}(z)}\,\mathrm{d}^4a\,\mathrm{d}\rho\,\mathrm{d}\Omega_{SU(N_c)/(SU(N_c-2)\times U(1))}}{\det{}'_{\Lambda}(L_{A_z})^{1/2}}, \tag{51.84}$$

multiplied by the exponential (51.74). Here z denotes the center, size, and orientation coordinates; $G^{(\Lambda)}_{ab}$ is the zero-mode Gram matrix induced by the regulated gauge-field inner product; L_{A_z} is the gauge-fixed quadratic operator on nonzero bosonic fluctuations; and Γ_z is the residual stabilizer left by the chosen slice. Equation (51.84) is not yet a continuum formula. Taking $\Lambda \to \infty$ requires combining the determinant, the coupling coordinate, and the normalization of the local operator insertions in a specified renormalization scheme. What is scheme independent at this stage is the topological sector, the zero-mode count, the finite-regulator construction of the measure, and the exponential action.

Finite-regulator nonzero-mode determinants. The symbol "determinant constant" hides several different objects unless the regulator is kept explicit. At fixed Λ, in a gauge slice near an instanton A_z, let

$$L^{\mathrm{bos}}_{\Lambda,z} : N_z\mathcal{M}_\Lambda \longrightarrow N_z\mathcal{M}_\Lambda$$

be the bosonic Hessian on the normal modes to the collective-coordinate manifold, and let

$$M^{\mathrm{gh}}_{\Lambda,z} : C^{\mathrm{gh}}_{\Lambda,z} \longrightarrow C^{\mathrm{gh}}_{\Lambda,z}$$

be the finite Faddeev–Popov ghost operator with residual stabilizer zero modes removed. For a fermion multiplet R, write

$$\mathcal{D}^R_{\Lambda,z} : \mathcal{S}^{R,+}_{\Lambda,z} \longrightarrow \mathcal{S}^{R,-}_{\Lambda,z}$$

for the regulated chiral Dirac operator. Its zero modes are not included in the nonzero-mode determinant; they are the Grassmann collective coordinates whose saturation is described below. The nonzero-mode determinant factor is

$$\mathcal{W}^{\mathrm{nz}}_\Lambda(z) := \frac{\det{}' M^{\mathrm{gh}}_{\Lambda,z}}{\det{}' M^{\mathrm{gh}}_{\Lambda,0}} \left(\frac{\det L^{\mathrm{bos}}_{\Lambda,0}}{\det{}' L^{\mathrm{bos}}_{\Lambda,z}}\right)^{1/2} \bigotimes_R \frac{\mathrm{Pf}\,{}'\mathcal{D}^R_{\Lambda,z}}{\mathrm{Pf}\,\mathcal{D}^R_{\Lambda,0}}. \tag{51.85}$$

The reference subscript 0 denotes the corresponding finite-regulator operator in the chosen topologically trivial background and in the same normalization of fields and gauge-group density. The primes mean that collective-coordinate zero modes, residual gauge zero modes, and fermion zero modes have been removed before taking the finite determinant or Pfaffian.

For a vectorlike Dirac pair, after choosing the standard conjugate pairing, the fermion factor in (51.85) is an ordinary scalar. For a genuinely chiral fermion it is a vector in the appropriate determinant or Pfaffian line over the background A_z; a scalar appears only after pairing this vector with the fermion zero-mode insertions and with any anomaly-inflow or determinant-line trivialization specified by the theory. This is the same determinant-line convention used in Chapter 153. Thus an instanton amplitude is not a number until the anomaly-line pairing and zero-mode saturation have also been specified.

With this notation the finite-regulator one-instanton contribution in a single smooth chart, for insertions whose fermion zero-mode and anomaly-line pairings have been specified, has the finite chart expression

$$\mathrm{d}\mu_{\Lambda,Q=1}(z) = \exp[-S_\Lambda(A_z)]\, \mathcal{W}_\Lambda^{\mathrm{nz}}(z)\, \mathrm{d}\nu_{\Lambda,\mathcal{M}}(z), \tag{51.86}$$

where $\mathrm{d}\nu_{\Lambda,\mathcal{M}}$ is the zero-mode density from (45.63), or equivalently the ADHM quotient density of Definition 51.26 after matching the ADHM coordinates to the regulated gauge-field slice. Formula (51.86) is a finite-dimensional statement. The continuum expression is the assertion that the product of $\mathcal{W}_\Lambda^{\mathrm{nz}}$, the coupling coordinate in S_Λ, and the renormalized operator insertions has a limit in the chosen scheme.

The finite Gaussian origin of (51.85) is as follows. A real bosonic normal integral with positive quadratic form L gives $(\det L)^{-1/2}$ up to the universal power of 2π already accounted for in the stationary-phase convention. A complex ghost Berezin integral gives $\det M^{\mathrm{gh}}$. A real fermionic quadratic form gives a Pfaffian; a complex chiral determinant is the corresponding determinant-line version of the same finite exterior-algebra construction. Removing zero modes before taking these determinants is not optional: the removed directions are precisely the collective coordinates or the fermion variables which must be integrated or saturated separately.

Finally, changing the finite-regulator Lagrangian by a local counterterm $C_\Lambda[A]$ multiplies (51.86) by $\exp[-C_\Lambda(A_z) + C_\Lambda(0)]$. If the one-instanton chart reduces this difference to

$$C_\Lambda(A_z) - C_\Lambda(0) = c_0(\Lambda) + c_1(\Lambda)\log(\mu\rho) + R_\Lambda(\rho, U),$$

then c_0 changes the scheme-dependent overall constant, c_1 changes the displayed power of $\mu\rho$, and the remainder R_Λ is part of the unresolved boundary and continuum-limit analysis. Counterterms are therefore not an after-the-fact correction to a pre-existing determinant constant; they are part of the regulated path-integral Lagrangian whose finite determinant factor is being defined.

Small-instanton boundary exponent. For the charge-one stratum the Uhlenbeck boundary is reached by $\rho \to 0$ at fixed center a and orientation U. The local boundary question is therefore a statement about the ρ-asymptotics of the finite-regulator density after the nonzero-mode determinant and the renormalized insertions have been paired. Let $\mathcal{X}$ denote the insertions under consideration, including the fermion zero-mode factors needed to obtain a scalar from the determinant line. A *one-instanton boundary exponent estimate* for $\mathcal{X}$ consists of numbers $\beta_{\mathcal{X}} \in \mathbb{R}$ and $\delta > 0$, and a locally bounded function $A_{\mathcal{X}}(a, U)$, such that in a fixed compact set of centers and in a fixed orientation chart the renormalized finite-regulator chart density has a limit of the form

$$\mathrm{d}\mu_{Q=1,\mathcal{X}} = C_{\mathcal{X}}(\mu)\, \rho^{\,b_0+\beta_{\mathcal{X}}-5}\big(A_{\mathcal{X}}(a, U) + O(\rho^\delta)\big)\, \mathrm{d}^4 a\, \mathrm{d}\rho\, \mathrm{d}\Omega_{N_c}. \tag{51.87}$$

The $b_0 - 5$ part is the universal scale and one-loop running content in (51.93). The exponent $\beta_{\mathcal{X}}$ records the net small-size contribution of the renormalized operator insertions, fermion zero-mode wavefunctions, masses or sources used to saturate zero modes, and any residual determinant factor which has a finite power-law boundary behavior. Logarithms may be included by allowing $A_{\mathcal{X}}$ to be a polynomial in $\log(\mu\rho)$; they leave the power threshold below unchanged.

On this boundary chart the local integral over $0 < \rho < \epsilon$ is controlled by

$$\int_0^{\epsilon} \rho^{\,b_0+\beta_{\mathcal{X}}-5} \,(\log(\mu\rho))^q \,\mathrm{d}\rho, \qquad q \in \mathbb{Z}_{\geq 0}.$$

It is locally finite at $\rho = 0$ precisely when

$$b_0 + \beta_{\mathcal{X}} > 4. \tag{51.88}$$

At equality the logarithmic integral diverges, and below equality the power integral diverges. Thus asymptotic freedom, $b_0 > 0$, is a statement about the running coupling at short distance, while small-instanton local integrability of a chosen observable requires the stronger observable-dependent condition (51.88). For the vacuum-density power with no extra small-ρ insertion factor $\beta_{\mathcal{X}} = 0$, the local boundary test is $b_0 > 4$. Different correlators have different $\beta_{\mathcal{X}}$, and center collisions with local operator insertions introduce additional boundary faces which must be analyzed separately from the pure $\rho \to 0$ face.

This boundary exponent estimate is weaker than a complete multi-instanton measure theorem. It isolates the analytic estimate needed near a single collapsed charge. Higher charge involves simultaneous collisions of several instantons, partial Uhlenbeck strata $\mathcal{M}_{k-\ell,N_c} \times \mathrm{Sym}^{\ell}(\mathbb{R}^4)$, and determinant behavior transverse to each stratum.

Definition 51.30 (Uhlenbeck boundary-face integrability datum)**.** Fix an instanton charge k, a gauge group $SU(N_c)$, and a scalar insertion datum $\mathcal{X}$ including fermion-zero-mode and anomaly-line pairings. A Uhlenbeck boundary-face integrability datum consists of:

(i) a bubbling charge $1 \leq \ell \leq k$, a residual smooth charge $k - \ell$, and a chart on the open Uhlenbeck stratum

$$\mathcal{M}^{\mathrm{smooth}}_{k-\ell,N_c} \times \mathrm{Conf}_{\ell}(\mathbb{R}^4)/S_{\ell},$$

with the pointlike instanton centers kept away from each other and from the local insertions;

(ii) transverse gluing scales $0 < \rho_\alpha < \epsilon$, angular variables ω_α, and boundary exponents $A_\alpha(\mathcal{X})$ for the ℓ collapsed charge units;

(iii) if some pointlike centers approach each other or an insertion support, collision distances $0 < d_\beta < \epsilon$ and collision exponents $G_\beta(\mathcal{X})$;

(iv) a finite-regulator density bound, uniform on compact subsets of the residual smooth stratum and angular variables, of the form

$$|\mathrm{d}\mu_{k,\mathcal{X}}| \leq C \,\mathrm{d}\nu^{\mathrm{sm}}_{k-\ell} \prod_{\alpha=1}^{\ell} \rho_\alpha^{A_\alpha(\mathcal{X})-1}(1+|\log\rho_\alpha|)^{q_\alpha}\,\mathrm{d}\rho_\alpha\,\mathrm{d}\omega_\alpha \prod_{\beta} d_\beta^{G_\beta(\mathcal{X})-1}(1+|\log d_\beta|)^{s_\beta}\,\mathrm{d}d_\beta\,\mathrm{d}\zeta_\beta, \tag{51.89}$$

with nonnegative integers q_α, s_β.

The exponents A_α and G_β are part of the analytic instanton-measure problem. Classical ADHM dimension counts identify the boundary coordinates; determinant, insertion, and counterterm estimates supply the powers in (51.89).

Proposition 51.31 (Uhlenbeck face dimension and local integrability budget)**.** *At a smooth residual instanton and ℓ distinct pointlike ideal instantons, the open Uhlenbeck stratum*

$$\mathcal{M}^{\mathrm{smooth}}_{k-\ell,N_c} \times \mathrm{Conf}_\ell(\mathbb{R}^4)/S_\ell$$

has local real codimension

$$4\ell(N_c - 1) \tag{51.90}$$

inside the smooth charge-k ADHM dimension count. If the ℓ pointlike charges are grouped into r collision clusters, the diagonal collision stratum contributes the additional codimension $4(\ell - r)$.

For a boundary-face datum satisfying (51.89), the local absolute integral over the displayed boundary variables is finite whenever

$$A_\alpha(\mathcal{X}) > 0 \quad \textit{for every } \alpha, \qquad G_\beta(\mathcal{X}) > 0 \quad \textit{for every } \beta. \tag{51.91}$$

If one displayed exponent is zero and the leading coefficient on that face has nonzero integral over the remaining bounded variables, the corresponding local integral has a logarithmic divergence. If one displayed exponent is negative under the same nonvanishing condition, the divergence is a power divergence.

Proof. The smooth framed charge-k dimension from Proposition 51.25 is $4kN_c$. On the open Uhlenbeck stratum with ℓ distinct ideal points, the residual smooth instanton part has dimension $4(k-\ell)N_c$, and the unordered configuration space of ℓ distinct points in $\mathbb{R}^4$ has local dimension 4ℓ. The codimension is therefore

$$4kN_c - \big(4(k-\ell)N_c + 4\ell\big) = 4\ell(N_c - 1),$$

which proves (51.90). If the ℓ ideal points lie on a diagonal with r distinct collision clusters, the point-configuration dimension drops from 4ℓ to $4r$, so the extra diagonal codimension is $4(\ell - r)$.

For the integrability statement, the compact residual and angular variables contribute only a finite multiplicative constant in the stated chart. Each scale integral is reduced to

$$\int_0^\epsilon t^{A-1}(1 + |\log t|)^q \, \mathrm{d}t.$$

With $u = -\log t$, this is bounded at $t = 0$ exactly when $A > 0$. At $A = 0$ it is the integral of a nonzero polynomial in u over an infinite ray, hence logarithmic in the cutoff scale. For $A < 0$, the antiderivative has a negative power of the cutoff scale. Applying this one-dimensional criterion to every ρ_α and d_β proves the product criterion and the two divergence alternatives. ☐

For the charge-one boundary chart, there are no point-collision variables and

$$A_1(\mathcal{X}) = b_0 + \beta_{\mathcal{X}} - 4.$$

Thus Proposition 51.31 recovers (51.88). For $k > 1$ it also records the extra data which a multi-instanton measure calculation must provide: every bubbling scale, every diagonal collision of ideal instantons, and every collision of an ideal instanton center with an inserted operator has its own exponent. A formula for the smooth ADHM quotient density and a one-loop determinant on the principal stratum become a continuum multi-instanton contribution only after these face estimates are supplied in one compatible regulator and renormalization scheme.

51.17.1 Scale and Running-Coupling Content of the One-Instanton Density

The preceding finite-regulator formula separates the zero-mode Jacobian from the determinant on nonzero fluctuations. The continuum one-instanton density contains three universal pieces which can be fixed before computing the scheme-dependent determinant constant. First, the moduli

$$a^\mu \in \mathbb{R}^4, \qquad \rho \in \mathbb{R}_{>0}$$

are the center and size of the instanton, while the remaining $4N_c - 5$ coordinates are dimensionless orientation coordinates on the embedded $SU(2)$ orbit. The translation-size part of a scale-covariant local density must therefore be

$$\frac{\mathrm{d}^4 a\, \mathrm{d}\rho}{\rho^5}.$$

Indeed a and ρ both have length dimension one, so $\mathrm{d}^4 a\, \mathrm{d}\rho/\rho^5$ is dimensionless and is invariant under the simultaneous dilation $a \mapsto \lambda a$, $\rho \mapsto \lambda\rho$. The power ρ^{-5} is the four-dimensional center plus one-dimensional scale volume element. It is the product of the zero-mode Jacobian and the nonzero-mode determinant after their regulator-dependent powers of ρ have been combined.

Second, the number of bosonic zero modes is $m = 4N_c$. In the semiclassical expansion of an action $S[A]/g_{\mathrm{ht}}^2$, replacing the zero-mode amplitudes by collective coordinates contributes one factor g_{ht}^{-1} for each bosonic zero mode. Equivalently, after absorbing normalization constants independent of g_{ht} into the orientation measure and determinant convention, the zero-mode normalization supplies

$$g_{\mathrm{ht}}^{-4N_c} = \left(\frac{8\pi^2}{g_{\mathrm{ht}}^2}\right)^{2N_c} \times \text{constant}.$$

This is the origin of the power multiplying the one-instanton density. The constant depends on the precise normalization of the path-integral density and of the invariant volume on the orientation orbit.

One-loop running factor in the one-instanton density. Use the common half-trace coupling $g_{\mathrm{ht}}(\mu)$ in the BPST subsection, and suppose the one-instanton density is renormalized in a mass-independent scheme through one loop. Let

$$\mu\frac{\mathrm{d}g_{\mathrm{ht}}}{\mathrm{d}\mu} = -\frac{b_0}{16\pi^2} g_{\mathrm{ht}}^3 + O(g_{\mathrm{ht}}^5), \qquad b_0 = \frac{11}{3}N_c - \frac{2}{3}N_f. \tag{51.92}$$

Then the part of the one-instanton measure fixed by scale covariance, zero-mode normalization, and one-loop RG invariance is

$$\mathrm{d}\mu_1^{\mathrm{univ}} = C_{\mathcal{S},N_c,N_f}\, \frac{\mathrm{d}^4 a\, \mathrm{d}\rho}{\rho^5}\, \mathrm{d}\Omega_{N_c} \left(\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)}\right)^{2N_c} (\mu\rho)^{b_0} \exp\left[-\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)} + \mathrm{i}\theta\right] \left(1 + O(g_{\mathrm{ht}}^2)\right). \tag{51.93}$$

Here $\mathrm{d}\Omega_{N_c}$ is a chosen invariant density on the local orientation orbit

$$SU(N_c)/(SU(N_c - 2) \times U(1)),$$

with the evident $SU(2)/\mathbb{Z}_2$ specialization when $N_c = 2$. The coefficient $C_{\mathcal{S},N_c,N_f}$ is a finite constant depending on the regulator, subtraction convention, and normalization of $\mathrm{d}\Omega_{N_c}$; obtaining it requires the full renormalized determinant calculation in the chosen scheme. The factors

$\mathrm{d}^4a\,\mathrm{d}\rho/\rho^5$, $\mathrm{d}\Omega_{N_c}$, and $(8\pi^2/g_{\mathrm{ht}}^2)^{2N_c}$ have just been fixed by dimension, orientation invariance, and the $4N_c$ bosonic zero modes. It remains to determine the power of $\mu\rho$ at one loop. Write the unknown power as α and apply $\mu\mathrm{d}/\mathrm{d}\mu$ to the logarithm of the density factor

$$g_{\mathrm{ht}}^{-4N_c}(\mu\rho)^{\alpha}\exp\left[-\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)}\right].$$

The derivative is

$$\alpha - 4N_c\,\frac{\beta(g_{\mathrm{ht}})}{g_{\mathrm{ht}}} + \frac{16\pi^2}{g_{\mathrm{ht}}^3}\,\beta(g_{\mathrm{ht}}).$$

Substituting (51.92) gives

$$\alpha - b_0 + O(g_{\mathrm{ht}}^2).$$

RG invariance of a physical one-instanton contribution through one loop therefore fixes $\alpha = b_0$. The derivative of the zero-mode power starts at order g_{ht}^2, so it belongs to the next perturbative order and is absorbed into the higher-loop correction multiplying (51.93). The finite constant $C_{\mathcal{S},N_c,N_f}$ is outside this argument because RG invariance fixes scale dependence, while the constant term is set by the actual regularized determinant and measure normalization.

Proposition 51.32 (Pure-gauge Pauli–Villars determinant constant)**.** *In pure $SU(N)$ Yang–Mills, $N \geq 2$, use the common half-trace coupling $g_{\mathrm{PV}}(\mu)$ and the Pauli–Villars determinant convention of the one-instanton calculation [63, 65]. For gauge-invariant insertions, integrate the embedded orientation orbit with the corresponding Haar normalization. Then the one-loop, one-instanton density is*

$$\mathrm{d}n_{I,N}^{\mathrm{PV}} = \frac{\mathrm{d}^4a\,\mathrm{d}\rho}{\rho^5}\,C_N^{\mathrm{PV}}\left(\frac{8\pi^2}{g_{\mathrm{PV}}^2(\mu)}\right)^{2N}(\mu\rho)^{11N/3}\exp\left[-\frac{8\pi^2}{g_{\mathrm{PV}}^2(\mu)} + \mathrm{i}\theta\right]\left(1 + O(g_{\mathrm{PV}}^2)\right), \tag{51.94}$$

where the finite constant is

$$C_N^{\mathrm{PV}} = \frac{2^{2-2N}}{\pi^2(N-1)!(N-2)!}\,\exp\left[-\alpha(1) - 2(N-2)\alpha\left(\frac{1}{2}\right)\right]. \tag{51.95}$$

Here

$$\alpha(1) = 0.443307\ldots, \qquad \alpha\left(\frac{1}{2}\right) = 0.145873\ldots.$$

Equivalently, in the conventional rounded form,

$$C_N^{\mathrm{PV}} = \frac{0.466\,\exp[-1.679\,N]}{(N-1)!(N-2)!} \quad \textit{to the displayed precision.} \tag{51.96}$$

For example $C_3^{\mathrm{PV}} \simeq 1.51 \times 10^{-3}$.

Proof. The orientation-integrated singular-gauge collective-coordinate calculation gives, after the Pauli–Villars zero-mode mass factors have been combined with the logarithmic determinant into $(\mu\rho)^{11N/3}$, the residual zero-mode coefficient

$$\frac{2^{4N+2}\pi^{4N-2}}{(N-1)!(N-2)!}\,g_{\mathrm{PV}}^{-4N}.$$

Rewriting

$$g_{\mathrm{PV}}^{-4N}=\left(\frac{8\pi^2}{g_{\mathrm{PV}}^2}\right)^{2N}(8\pi^2)^{-2N}$$

turns this residual coefficient into

$$\frac{2^{2-2N}}{\pi^2(N-1)!(N-2)!}\left(\frac{8\pi^2}{g_{\mathrm{PV}}^2}\right)^{2N}.$$

The finite part of the nonzero-mode determinant contributes

$$\exp\left[-\alpha(1)-2(N-2)\alpha\left(\frac{1}{2}\right)\right],$$

where $\alpha(1)$ is the $SU(2)$ vector-ghost block and the $2(N-2)$ copies of $\alpha(1/2)$ are the additional doublet blocks in the embedded $SU(2)\subset SU(N)$ decomposition. Multiplying these two factors gives (51.95); combining it with the classical action and logarithmic determinant gives (51.94). Taking logarithms of (51.95) yields

$$\log C_N^{\mathrm{PV}}=\log(0.466\ldots)-1.679\ldots\,N-\log((N-1)!)-\log((N-2)!),$$

which is the rounded form (51.96). □

Proposition 51.33 (Heat-kernel source of the instanton logarithm)**.** *In the same background-field gauge and half-trace convention, the logarithmic part of the charge-k nonzero-mode fluctuation determinant has*

$$\partial_{\log\mu}\log\mathcal{W}_{\log}^{\mathrm{nz}}=k\left[\frac{11}{3}C_2(G)-\frac{4}{3}\sum_{\text{Dirac }R}T(R)\right]. \tag{51.97}$$

For vectorlike $SU(N_c)$ QCD with N_f Dirac fundamentals this coefficient is kb_0, with b_0 as in (51.92)*. Hence, in a charge-one BPST chart,*

$$\log\mathcal{W}_{\log}^{\mathrm{nz}}(a,\rho,U;\mu)=b_0\log(\mu\rho)+\log\mathcal{W}_{\mathrm{fin}}^{\mathrm{nz}}(U;\mathcal{S}), \tag{51.98}$$

up to higher-loop and local finite-subtraction terms in the chosen scheme. Equivalently, if $X_\kappa=8\pi^2/g_{\mathrm{ht}}^2(\kappa)$ and $X_\Lambda=X_\mu+b_0\log(\Lambda/\mu)$ at one loop, then

$$\exp[-X_\Lambda+\mathrm{i}\theta]\,(\Lambda\rho)^{b_0}=\exp[-X_\mu+\mathrm{i}\theta]\,(\mu\rho)^{b_0}. \tag{51.99}$$

The factor $(\mu\rho)^{b_0}$ in (51.93) *is therefore the logarithmic shadow of the nonzero-mode fluctuation spectrum plus coupling renormalization, while the finite constant still requires the full spectral determinant calculation.*

Proof. The small-proper-time expansion of (51.131) is local in the gauge background. With background-field gauge fixing, the vector fluctuation and ghost complex contribute the coefficient $(11/3)C_2(G)$ multiplying the topological charge in the logarithmic counterterm, and a Dirac fermion in representation R contributes $-(4/3)T(R)$. Summing the fields gives (51.97). For a fundamental Dirac fermion of $SU(N_c)$, $T(\square)=1/2$, so the matter term is $-2N_f/3$. The coefficient in this convention is therefore

$$\frac{11}{3}N_c-\frac{2}{3}N_f=b_0.$$

A BPST connection with size ρ is obtained from the unit-size connection by translation, global orientation, and dilation. After the zero modes are removed, the logarithmic scale dependence of the determinant can therefore depend on the size only through the dimensionless combination $\mu\rho$, apart from finite scheme-dependent terms. This gives (51.98). Finally, the one-loop running of X_κ gives $X_\Lambda = X_\mu + b_0 \log(\Lambda/\mu)$; substituting this identity into the cutoff expression proves (51.99). □

Fermion zero modes are controlled by the index theorem already stated in (51.12). In the conventional half-trace notation, a left-handed Weyl fermion in representation R has

$$n_+ - n_- = 2T_R\, k, \qquad \mathrm{tr}_R(T_R^a T_R^b) = T_R \delta^{ab}. \tag{51.100}$$

For a fundamental Weyl fermion of $SU(N_c)$, $T_\square = 1/2$, so a $k = 1$ instanton has one normalizable zero mode of the chirality selected by the self-dual background. The anti-instanton has the opposite chirality. In the trace-delta convention the numerical value called T_R is doubled, but the topological density and the coupling coordinate are correspondingly rewritten; the integer kernel dimension in (51.100) is the invariant statement.

The zero modes determine the Grassmann selection rule. Expand a massless fermion in an instanton background as

$$\psi(x) = \sum_{\alpha=1}^{n_0} \xi_\alpha \psi_{0,\alpha}(x) + \sum_{\lambda\neq 0} \xi_\lambda \psi_\lambda(x),$$

where $\psi_{0,\alpha}$ are the zero modes and ξ_α are odd coefficients. The quadratic fermion action contains no term involving ξ_α. Therefore the Berezin integral over zero-mode variables vanishes unless operator insertions supply every missing ξ_α. This is the finite-dimensional Berezin rule $\int \mathrm{d}\xi\, 1 = 0$, $\int \mathrm{d}\xi\, \xi = 1$ applied after the spectral decomposition of the regulated fermion field.

Proposition 51.34 (Instanton sectors as physical correlator contributions)**.** *Fix a finite regulator, a $Q = 1$ instanton chart with collective coordinate $z = (a, \rho, U)$, smooth chart domain $\mathcal{U}_{Q=1}$, and renormalized insertions $\mathcal{O}_1, \ldots, \mathcal{O}_r$. After gauge fixing, collective coordinate separation, and integration of nonzero fluctuations, the instanton sector contribution has the form*

$$\big\langle \mathcal{O}_1 \cdots \mathcal{O}_r \big\rangle_{Q=1,\Lambda} = \int_{\mathcal{U}_{Q=1}} \mathrm{e}^{-S_\Lambda(A_z)+\mathrm{i}\theta}\, \mathcal{W}_\Lambda^{\mathrm{nz}}(z)\, \mathcal{Z}^0_{\mathcal{O},\Lambda}(z)\, \mathrm{d}\nu_{\Lambda,\mathcal{M}}(z), \tag{51.101}$$

provided the determinant/Pfaffian line has been paired with the fermion zero-mode and anomaly-line data to produce a scalar density. Here $\mathcal{W}_\Lambda^{\mathrm{nz}}$ is the nonzero-mode determinant datum from (51.85), while $\mathcal{Z}^0_{\mathcal{O},\Lambda}(z)$ is the finite Berezin coefficient

$$\mathcal{Z}^0_{\mathcal{O},\Lambda}(z) = \int \mathrm{d}\xi_{n_0} \cdots \mathrm{d}\xi_1\, \mathcal{O}^0_{1,\Lambda}(z,\xi) \cdots \mathcal{O}^0_{r,\Lambda}(z,\xi)\, \exp[-S^0_{\mathrm{lift},\Lambda}(z,\xi)]. \tag{51.102}$$

The superscript 0 means that each insertion and each mass, Yukawa, or source term has been restricted to the zero-mode subspace. If the integrand in (51.102) does not contain the monomial $\xi_1 \cdots \xi_{n_0}$, then $\mathcal{Z}^0_{\mathcal{O},\Lambda}(z) = 0$. If it does contain that monomial, the coefficient of that monomial is the only part of the insertions which is seen by the instanton sector.

Proof. At finite cutoff the gauge-fixed fields split into collective coordinates, normal bosonic modes, ghosts, fermion zero modes, and fermion nonzero modes. Gaussian integration over the normal bosonic and ghost variables gives the determinant factors already isolated in $\mathcal{W}_\Lambda^{\rm nz}$; Gaussian or Pfaffian integration over fermion nonzero modes gives the remaining nonzero-mode determinant-line factor. None of these operations integrates over the zero-mode variables ξ_α, because the quadratic fermion operator vanishes on them. The only finite-dimensional integral left in the fermionic zero-mode sector is (51.102). Berezin integration extracts the coefficient of the ordered top monomial $\xi_1 \cdots \xi_{n_0}$. All terms missing at least one zero-mode variable therefore vanish, while terms containing the top monomial contribute exactly their coefficient. Multiplying this coefficient by the bosonic collective-coordinate density and the nonzero-mode determinant gives (51.101). $\square$

Thus the moduli space is not the physical answer; it is the domain of a semiclassical amplitude. The physical question is which insertions, masses, or sources saturate the fermion zero modes, what nonzero-mode determinant and counterterm scheme define $\mathcal{W}_\Lambda^{\rm nz}$, and whether the resulting a, ρ, U integral is finite at its boundary faces.

From collective coordinates to an amplitude. For later use, it is helpful to compress the $Q = 1$ calculation into the ordered finite-regulator pipeline

$$K^E_{\Lambda,\mathcal{J}}(z) = \mathrm{e}^{-S_\Lambda(A_z)+\mathrm{i}\theta}\, \mathcal{W}_\Lambda^{\rm nz}(z)\, \mathcal{Z}^0_{\mathcal{J},\Lambda}(z)\, \mathrm{d}\nu_{\Lambda,\mathcal{M}}(z), \qquad G^{E,Q=1}_{\Lambda,\mathcal{J}} = \int_{\mathcal{U}_{Q=1}} K^E_{\Lambda,\mathcal{J}}(z). \tag{51.103}$$

The first factor selects the topological sector and its classical action; the last factor is the collective-coordinate density; the middle two factors are where the fluctuation and fermion-saturation calculation enters. A semiclassical local vertex is obtained only after replacing $K^E_{\Lambda,\mathcal{J}}$ on a declared window by a leading kernel and then projecting it onto an observable coordinate:

$$\mathcal{A}^{Q=1}_{\rm phys}[\mathcal{J}] = \operatorname*{Proj}_{\rm phys} \operatorname*{Cont}_{\mathcal{S}} \int_{\mathcal{U}_{\rm win}} K^E_{{\rm lead},\mathcal{J}}(z) + R_{\rm det} + R_{\rm zm} + R_{\rm src} + R_{\rm Schur} + R_\rho + R_{\rm cont} + R_{\rm spec} + R_{\rm IR} + R_{\rm cut}. \tag{51.104}$$

Here the determinant residual includes the nonzero-mode spectrum and local counterterms; $R_{\rm zm}$ records the zero-mode projection or derivative expansion of the sources; $R_{\rm src}$ records the color-singlet, hadronic, or OPE matching layer; $R_{\rm Schur}$ records finite nonzero-mode corrections to the zero-mode block; R_ρ is the size and Uhlenbeck-face endpoint remainder; and the final four terms are the continuation, spectral-projection, infrared, and unitarity-cut remnants needed before a physical amplitude is asserted.

This ordering is part of the content of the instanton calculation. The ADHM or BPST moduli space supplies the domain and the collective-coordinate Jacobian. It does not supply the nonzero-mode determinant, the fermion zero-mode Berezin coefficient, the source-to-observable matching, or the endpoint estimates. Conversely, the local 't Hooft operator is the small-size, source-adiabatic coordinate of (51.103); the four-point amplitude calculation keeps the zero-mode form factors, determinant normalization, external source residues, and size tails inside the same integral until a hard, screened, thermal, or Wilsonian window justifies separating them.

For vectorlike QCD with N_f massless Dirac fundamentals, a $Q = 1$ instanton supplies one zero mode for each flavor in one chirality sector. The semiclassical functional integral therefore generates the following leading local term in the derivative expansion around external fields whose variation scale is much larger than ρ:

$$\mathcal{L}_{\mathrm{inst}} = \int_0^\infty \frac{\mathrm{d}\rho}{\rho^5}\, C_{N_c,N_f}(\rho,\mu) \exp\!\left(-\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)} + \mathrm{i}\theta\right) \det_{1\le f,f'\le N_f} \left[\rho^3 \bar\psi_{Rf}\psi_{Lf'}\right] + \text{anti-instanton conjugate} \tag{51.105}$$

after integrating over the instanton center and color orientation and after contracting spin and color indices as dictated by the zero-mode wavefunctions and gauge invariance. The determinant is over flavor indices; it is the local tensor compatible with the nonabelian chiral flavor symmetry. For flavor diagonal external sources it reduces to the corresponding alternating sum of products of N_f bilinears. At one loop

$$C_{N_c,N_f}(\rho,\mu) = C^{(0)}_{N_c,N_f}\left(\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)}\right)^{2N_c} (\rho\mu)^{b_0}\left(1 + O(g_{\mathrm{ht}}^2(\mu))\right), \qquad b_0 = \frac{11}{3}N_c - \frac{2}{3}N_f,$$

where b_0 is defined by $\mu\, \mathrm{d}g_{\mathrm{ht}}/\mathrm{d}\mu = -b_0 g_{\mathrm{ht}}^3/(16\pi^2) + O(g_{\mathrm{ht}}^5)$. The scale and coupling dependence is the universal content of the running-factor calculation above; the constant $C^{(0)}_{N_c,N_f}$ is fixed only after choosing the determinant and orientation-volume normalization. The dimensionless factors $\rho^3\bar\psi_R\psi_L$ in (51.105) record the normalization of the external zero-mode wavefunctions in the local limit; changing the regularization scheme changes $C^{(0)}_{N_c,N_f}$ and higher-loop factors, not the zero-mode tensor or the selection rule. When the external fields vary on the scale ρ, the same zero-mode integration gives a nonlocal kernel rather than the local determinant in (51.105). Its regulator-independent selection rule is

$$\Delta Q_A = 2N_f$$

for the anomalous axial charge, in agreement with the integrated anomaly. Small quark masses may replace missing fermion insertions by mass factors, because the mass term pairs the corresponding zero-mode variables.

Proposition 51.35 (Flavor determinant from the instanton zero modes)**.** *In the $Q = 1$ sector of vectorlike $SU(N_c)$ QCD, let $\lambda_f, \widetilde\lambda_f$, $f = 1,\dots,N_f$, denote the two Grassmann zero-mode coefficients paired by the local source matrix $B = (B_{ff'})$. Choose the zero-mode orientation so that*

$$\int \prod_{f=N_f}^{1} \mathrm{d}\widetilde\lambda_f\, \mathrm{d}\lambda_f\, \exp\!\left(\sum_{f,f'=1}^{N_f} \widetilde\lambda_f B_{ff'}\lambda_{f'}\right) = \det B. \tag{51.106}$$

For slowly varying external quark fields, $B_{ff'} = \rho^3\bar\psi_{Rf}\psi_{Lf'}$, and (51.106) is precisely the flavor determinant in (51.105). If instead all zero modes are saturated by the quark mass term, the same finite-dimensional calculation replaces B by the mass-overlap matrix $B^{(m)}_{ff'}(z)$. Its phase is the phase of $\det M$*, so the one-instanton vacuum term has phase* $\exp[\mathrm{i}(\theta + \arg\det M)]$*, up to the real positive overlap and determinant normalizations.*

Proof. Expand the exponential in (51.106). Every contributing top-degree term must contain each $\widetilde\lambda_f$ once and each λ_f once. Such a term is specified by a permutation $\sigma \in S_{N_f}$:

$$\prod_{f=1}^{N_f} \widetilde\lambda_f B_{f,\sigma(f)}\lambda_{\sigma(f)}.$$

Reordering the $\lambda_{\sigma(f)}$ variables into the chosen Berezin orientation gives the sign $\operatorname{sgn}\sigma$. Berezin integration therefore extracts

$$\sum_{\sigma\in S_{N_f}} \operatorname{sgn}\sigma \prod_{f=1}^{N_f} B_{f,\sigma(f)} = \det B.$$

For $B_{ff'} = \rho^3\bar{\psi}_{Rf}\psi_{Lf'}$, this gives the local $2N_f$-fermion operator. If B is supplied by the mass term, each zero-mode overlap is real after the same regulator and zero-mode orientation have been fixed, so the only flavor phase is $\arg\det M$. □

Proposition 51.36 (Two-flavor channel content of the local instanton vertex)**.** *For $N_f = 2$, set*

$$\Phi_{ff'} = \bar{q}_{Rf}q_{Lf'}, \qquad S_{ff'} = \bar{q}_f q_{f'}, \qquad P_{ff'} = \bar{q}_f \mathrm{i}\gamma_5 q_{f'}.$$

With the chiral projectors used in this chapter,

$$\Phi = \frac{1}{2}(S + \mathrm{i}P). \tag{51.107}$$

Write the scalar and pseudoscalar flavor matrices in the Pauli basis as

$$S = s_0\mathbf{1} + \vec{s}\cdot\vec{\tau}, \qquad P = p_0\mathbf{1} + \vec{p}\cdot\vec{\tau}.$$

Then the local instanton plus anti-instanton flavor factor is

$$\begin{aligned} \mathrm{e}^{\mathrm{i}\theta}\det\Phi + \mathrm{e}^{-\mathrm{i}\theta}\det\Phi^\dagger = \frac{\cos\theta}{2}&\left(s_0^2 - \vec{s}^{\,2} - p_0^2 + \vec{p}^{\,2}\right) \\ &- \sin\theta\left(s_0p_0 - \vec{s}\cdot\vec{p}\right). \end{aligned} \tag{51.108}$$

At $\theta = 0$, the one-instanton local vertex therefore separates the isosinglet scalar, isotriplet scalar, isosinglet pseudoscalar, and isotriplet pseudoscalar channels as

$$\det\Phi + \det\Phi^\dagger = \frac{1}{2}\left(s_0^2 - \vec{s}^{\,2} - p_0^2 + \vec{p}^{\,2}\right). \tag{51.109}$$

The determinant is invariant under $\Phi \mapsto V_R^\dagger\Phi V_L$, $V_L, V_R \in SU(2)$, but under the flavor-singlet axial rotation $q \mapsto \mathrm{e}^{\mathrm{i}\alpha\gamma_5}q$ it carries phase $\det\Phi \mapsto \mathrm{e}^{-4\mathrm{i}\alpha}\det\Phi$. Hence $\mathrm{e}^{\mathrm{i}\theta}\det\Phi + \text{conjugate}$ is the local channel form of the same anomalous $U(1)_A$ selection rule as (51.105): a compensating $\theta \mapsto \theta + 4\alpha$ keeps the $Q = 1$ contribution in the same coordinate.

This channel decomposition is only the zeroth local term of the source convolution. The coefficient multiplying (51.108) is still the size/orientation/nonzero-mode determinant integral discussed below. The formula therefore explains which chiral channels the zero modes select; it is not a standalone prediction of scalar or pseudoscalar bound-state masses.

Proof. The projector identity gives

$$\bar{q}_R q_L = \bar{q}P_L q = \frac{1}{2}(\bar{q}q - \bar{q}\gamma_5 q) = \frac{1}{2}(\bar{q}q + \mathrm{i}\,\bar{q}\mathrm{i}\gamma_5 q),$$

which is (51.107). For any matrix $X = x_0\mathbf{1} + \vec{x}\cdot\vec{\tau}$, the Pauli relation $\tau_a\tau_b = \delta_{ab}\mathbf{1} + \mathrm{i}\epsilon_{abc}\tau_c$ gives $\det X = x_0^2 - \vec{x}^{\,2}$. Applying this to $X = S + \mathrm{i}P$ gives

$$\det(S + \mathrm{i}P) = s_0^2 - \vec{s}^{\,2} - p_0^2 + \vec{p}^{\,2} + 2\mathrm{i}(s_0p_0 - \vec{s}\cdot\vec{p}).$$

Since $\det\Phi = \frac{1}{4}\det(S+\mathrm{i}P)$, taking $\mathrm{e}^{\mathrm{i}\theta}\det\Phi+\mathrm{e}^{-\mathrm{i}\theta}\det\Phi^\dagger$ proves (51.108). The $\theta=0$ specialization is immediate.

Finally, an $SU(2)_L \times SU(2)_R$ rotation multiplies Φ by unit-determinant matrices on the two sides, so its determinant is unchanged. For $q \mapsto \mathrm{e}^{\mathrm{i}\alpha\gamma_5}q$, one has $\bar{q}_R q_L \mapsto \mathrm{e}^{-2\mathrm{i}\alpha}\bar{q}_R q_L$, hence $\det\Phi \mapsto \mathrm{e}^{-4\mathrm{i}\alpha}\det\Phi$. □

Controlled Approximation 51.37 (Instanton contribution to two-flavor chiral source curvatures)**.** Suppose the finite-regulator $Q=\pm1$ calculation, including the size/orientation integral, nonzero-mode determinant, source normalization, and local derivative expansion, supplies a finite coefficient $\kappa^{(2)}_{\mathrm{inst}}(\mu)$ multiplying the local $N_f=2$ source density of Proposition 51.36. Equivalently, for constant renormalized scalar and pseudoscalar source coordinates

$$S = s_0\mathbf{1}+\vec{s}\cdot\vec{\tau}, \qquad P = p_0\mathbf{1}+\vec{p}\cdot\vec{\tau},$$

the instanton part of the source generating-density coordinate $\mathcal{W}=V_4^{-1}\log Z$ has quadratic term

$$\begin{aligned}\mathcal{W}^{(2)}_{\mathrm{inst}} = \kappa^{(2)}_{\mathrm{inst}}\left[\frac{\cos\theta}{2}\left(s_0^2-\vec{s}^{\,2}-p_0^2+\vec{p}^{\,2}\right)-\sin\theta\,(s_0p_0-\vec{s}\cdot\vec{p})\right]\\ +O(J^3,\partial J),\end{aligned} \tag{51.110}$$

where J denotes the collection of source coordinates. Define the local source curvatures by differentiating $\mathcal{W}$ at zero source:

$$\chi_\sigma = \partial^2_{s_0}\mathcal{W}, \quad \chi_{\delta_a} = \partial^2_{s_a}\mathcal{W}, \quad \chi_\eta = \partial^2_{p_0}\mathcal{W}, \quad \chi_{\pi_a} = \partial^2_{p_a}\mathcal{W}, \qquad \text{no sum on } a.$$

Then the local instanton contribution is

$$\chi^{\mathrm{inst}}_\sigma = \chi^{\mathrm{inst}}_{\pi_a} = \kappa^{(2)}_{\mathrm{inst}}\cos\theta, \qquad \chi^{\mathrm{inst}}_{\delta_a} = \chi^{\mathrm{inst}}_\eta = -\kappa^{(2)}_{\mathrm{inst}}\cos\theta, \tag{51.111}$$

and the CP-odd source-mixing curvatures are

$$\partial_{s_0}\partial_{p_0}\mathcal{W}^{(2)}_{\mathrm{inst}} = -\kappa^{(2)}_{\mathrm{inst}}\sin\theta, \qquad \partial_{s_a}\partial_{p_b}\mathcal{W}^{(2)}_{\mathrm{inst}} = \kappa^{(2)}_{\mathrm{inst}}\sin\theta\,\delta_{ab}. \tag{51.112}$$

At $\theta=0$, the two $U(1)_A$-paired differences supplied by this finite-activity term are therefore

$$(\chi_{\pi_a}-\chi_{\delta_a})_{\mathrm{inst}} = (\chi_\sigma-\chi_\eta)_{\mathrm{inst}} = 2\kappa^{(2)}_{\mathrm{inst}}. \tag{51.113}$$

Equations (51.111)–(51.113) are source-curvature statements in the declared local window. The full zero-momentum QCD susceptibilities also contain connected long-distance propagation, Goldstone poles in the chiral limit, ordinary perturbative and confining contributions, and finite contact-term conventions. Thus the instanton calculation identifies the $U(1)_A$-violating local curvature it adds to the generating functional. A spectrum statement additionally requires the color-singlet spectral representation, long-distance matrix elements, and the continuum/volume limits in the chosen QCD phase.

Proposition 51.38 (Axial Ward ledger for the instanton source curvatures)**.** *The local two-flavor instanton source functional* (51.110) *obeys the finite-dimensional anomalous singlet-axial Ward identity*

$$\left[4\partial_\theta+2p_0\partial_{s_0}+2\sum_{a=1}^{3}p_a\partial_{s_a}-2s_0\partial_{p_0}-2\sum_{a=1}^{3}s_a\partial_{p_a}\right]\mathcal{W}^{(2)}_{\mathrm{inst}} = O(J^3,\partial J). \tag{51.114}$$

Here the source coordinates transform as the mass/source spurions in the finite-regulator path integral:

$$\delta_\alpha S = 2\alpha P, \qquad \delta_\alpha P = -2\alpha S, \qquad \delta_\alpha \theta = 4\alpha.$$

Thus the same anomalous Jacobian which shifts θ also rotates the local scalar and pseudoscalar source coordinates. The susceptibility splittings in (51.113) are the second-source derivatives of the same anomalous Ward identity which produces the 't Hooft vertex.

More explicitly, for each paired coordinate s, p, with $s = s_0, p = p_0$ or $s = s_a, p = p_a$, define

$$\chi_s = \partial_s^2 \mathcal{W}_{\text{inst}}^{(2)}, \qquad \chi_p = \partial_p^2 \mathcal{W}_{\text{inst}}^{(2)}, \qquad m_{sp} = \partial_s \partial_p \mathcal{W}_{\text{inst}}^{(2)}$$

at zero source. Then the differentiated Ward identity gives

$$\partial_\theta \chi_s = m_{sp}, \qquad \partial_\theta \chi_p = -m_{sp}, \qquad \chi_s - \chi_p = -2\,\partial_\theta m_{sp}. \tag{51.115}$$

For the singlet pair this is the (σ, η) relation; for a triplet pair it is the (δ_a, π_a) relation, so reversing the order of the difference gives the positive $\pi_a - \delta_a$ splitting displayed above.

Proof. Under an infinitesimal singlet axial rotation, $S + \mathrm{i}P \mapsto (1 - 2\mathrm{i}\alpha)(S + \mathrm{i}P)$, which gives $\delta S = 2\alpha P$ and $\delta P = -2\alpha S$. The anomaly shifts the source-sector theta coordinate by $\delta\theta = 4\alpha$ for $N_f = 2$. Consequently the infinitesimal Ward vector field is the operator displayed in (51.114).

Let

$$A = s_0^2 - \vec{s}^{\,2} - p_0^2 + \vec{p}^{\,2}, \qquad B = s_0 p_0 - \vec{s} \cdot \vec{p}.$$

The source rotation gives

$$\delta_\alpha A = 8\alpha B, \qquad \delta_\alpha B = -2\alpha A.$$

The theta derivative of the quadratic part of (51.110) contributes

$$4\alpha\, \kappa_{\text{inst}}^{(2)} \left[-\frac{\sin\theta}{2} A - \cos\theta\, B \right],$$

whereas the source rotation contributes

$$\kappa_{\text{inst}}^{(2)} \left[4\alpha \cos\theta\, B + 2\alpha \sin\theta\, A \right].$$

The two terms cancel, proving (51.114) to the declared local order.

Now apply ∂_s^2, ∂_p^2, and $\partial_s\partial_p$ to the one-pair form of the Ward identity $(4\partial_\theta + 2p\partial_s - 2s\partial_p)\mathcal{W} = 0$, and then set all sources to zero. The three resulting identities are

$$4\partial_\theta \chi_s - 4m_{sp} = 0, \qquad 4\partial_\theta \chi_p + 4m_{sp} = 0, \qquad 4\partial_\theta m_{sp} + 2\chi_s - 2\chi_p = 0,$$

which are exactly (51.115). □

Proposition 51.39 (Mixed mass-source expansion of the instanton determinant)**.** *In the same $Q = 1$ QCD zero-mode sector, let M be the mass-overlap matrix and let B be the matrix supplied by external bilinear sources or by a specified zero-mode-paired operator insertion. Ordinary external fermion wave packets are represented instead by the differentiated linear-source construction below. With $[N_f] = \{1, \ldots, N_f\}$, write M_{I^c, J^c} for the submatrix obtained by deleting the rows $I \subset [N_f]$*

and columns $J \subset [N_f]$, and write $B_{I,J}$ for the corresponding $I \times J$ source submatrix, both with increasing orders; empty determinants are 1*. Then*

$$\det(M+B) = \sum_{r=0}^{N_f} \sum_{\substack{I,J\subset[N_f]\\|I|=|J|=r}} (-1)^{\sum_{i\in I} i+\sum_{j\in J} j} \det M_{I^c,J^c} \det B_{I,J}. \tag{51.116}$$

Thus a correlator with r zero-mode-paired external insertions is not obtained by appending those insertions to an already-formed vacuum determinant. It is the degree-r part of the same finite Berezin determinant; the unobserved $N_f - r$ zero-mode pairs must be saturated by the complementary mass minor. Equivalently, for increasing $I = (i_1 < \cdots < i_r)$, $J = (j_1 < \cdots < j_r)$, and $\pi \in S_r$, the coefficient of $\prod_{\ell=1}^{r} B_{i_\ell, j_{\pi(\ell)}}$ in $\det(M+B)$ is

$$(-1)^{\sum I+\sum J} \operatorname{sgn}(\pi) \det M_{I^c,J^c}. \tag{51.117}$$

For $N_f = 2$,

$$\begin{aligned}\det(M+B) = \det M &+ M_{22}B_{11} - M_{21}B_{12} - M_{12}B_{21} + M_{11}B_{22}\\ &+ B_{11}B_{22} - B_{12}B_{21}.\end{aligned} \tag{51.118}$$

The last line is the massless four-fermion 't Hooft vertex. The middle line is the mixed amplitude in which one flavor is supplied by an external zero-mode pair and the other by a mass insertion. If a flavor is neither externally inserted nor present in the complementary mass minor, the instanton contribution to that correlator vanishes.

Proof. Apply the determinant expansion to $M + B$. Each contributing permutation $\sigma \in S_{N_f}$ chooses, for every row, either an M-entry or a B-entry. Let I be the set of rows where a B-entry was chosen and let $J = \sigma(I)$. Reordering the rows and columns so that the B-block appears in the I, J positions gives the cofactor sign $(-1)^{\sum I+\sum J}$. Summing over the restriction of σ to I gives $\det B_{I,J}$, while summing over the complementary restriction gives $\det M_{I^c,J^c}$. This proves (51.116). Extracting a particular source monomial from $\det B_{I,J}$ gives the $\operatorname{sgn}(\pi)$ factor in (51.117). The displayed two-flavor formula is the specialization to $N_f = 2$. □

Proposition 51.40 (Fermion determinant factor versus zero-mode determinant)**.** *Fix the same finite-regulator $Q = 1$ chart $z = (a, \rho, U)$ for vectorlike $SU(N_c)$ QCD, and add a mass matrix and an even bilinear source. Let $\mathcal{K}_{\Lambda,z}(M, B)$ be the finite Dirac bilinear between the right and left fermion coefficient spaces in this background. Decompose these finite spaces into instanton zero-mode subspaces and nonzero-mode complements. In block form,*

$$\mathcal{K}_{\Lambda,z}(M,B) = \begin{pmatrix} K_{00} & K_{0\mathrm{n}} \\ K_{\mathrm{n}0} & K_{\mathrm{nn}} \end{pmatrix}, \tag{51.119}$$

where K_{00} acts between the zero-mode coefficient spaces and K_{nn} acts on the nonzero-mode complements. If K_{nn} is invertible, then

$$\det \mathcal{K}_{\Lambda,z}(M,B) = \det K_{\mathrm{nn}} \det\!\left(K_{00} - K_{0\mathrm{n}} K_{\mathrm{nn}}^{-1} K_{\mathrm{n}0}\right). \tag{51.120}$$

Thus the finite nonzero-mode fermion determinant and the zero-mode saturation determinant are separate factors before the collective-coordinate integral is performed.

In the leading local semiclassical approximation, where the mass/source bilinear is restricted to the zero-mode subspace after the nonzero modes have supplied their determinant ratio, the Schur complement in (51.120) *reduces to*

$$K_{00}^{\mathrm{eff}}(z) = M^0(z) + B^0(z), \qquad M^0_{ff'}(z) = \rho\, M_{ff'}(\mu), \qquad B^0_{ff'}(z) = \rho^3 \bar\psi_{Rf}\psi_{Lf'} + \cdots. \tag{51.121}$$

The dots denote derivative corrections to the local source approximation and the spin-color contractions fixed by the normalized zero-mode wavefunctions. More generally, the Schur correction $-K_{0\mathrm{n}}K_{\mathrm{nn}}^{-1}K_{\mathrm{n}0}$ *is a finite nonzero-mode-propagator correction in the same regulator and scheme. Consequently the light-fermion part of a one-instanton chart has the structure*

$$\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}(z;\mu)\,\det K_{00}^{\mathrm{eff}}(z), \tag{51.122}$$

after trivial-sector normalization and local counterterms in the scheme $\mathcal{S}$*. The finite factor* $\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}$ *is the fermion nonzero-mode determinant datum. It is not determined by the Berezin determinant* $\det(M^0+B^0)$*. In particular, in the diagonal massive vacuum specialization the factor* $\prod_f(m_f\rho)$ *is the zero-mode saturation determinant; the remaining finite spectral determinant is an additional input to the physical amplitude.*

Proof. At fixed cutoff the fermion path integral is a finite Berezin Gaussian, hence equals the determinant of its finite bilinear matrix after the chosen trivial-sector normalization. Decompose the finite coefficient spaces into the zero-mode subspace and its complement. Gaussian integration over the nonzero-mode variables first gives the Schur complement of the lower-right block, which is exactly (51.120). The determinant of K_{nn} is the fermionic part of the nonzero-mode determinant factor in $\mathcal{W}^{\mathrm{nz}}_{\Lambda}$. The determinant of the Schur complement is the finite Berezin integral over the zero-mode coefficients. When the source and mass insertions are projected to the zero-mode subspace, this second determinant is the determinant of $M^0 + B^0$, whose minor expansion is Proposition 51.39. If the source or mass also couples zero and nonzero modes, the same finite Gaussian integral produces the displayed Schur correction. Since $\det K_{\mathrm{nn}}$ multiplies every zero-mode minor, no zero-mode algebra can determine its finite value. □

Proposition 51.41 (Finite source-frame covariance of the light-fermion determinant)**.** *In the setting of Proposition 51.40, write the finite zero-mode source functional as*

$$\mathcal{V}^{0,\mathcal{S}}_{\mathrm{inst}}(z) = \mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}(z;\mu)\,\det K_{00}^{\mathrm{eff}}(z). \tag{51.123}$$

Let $Z_R, Z_L \in \mathrm{GL}(N_f,\mathbb{C})$ *be a finite change of the right and left zero-mode source frames, so that the same source insertion is represented by*

$$K_{00}^{\mathrm{eff}\,\prime} = Z_R K_{00}^{\mathrm{eff}} Z_L. \tag{51.124}$$

Then the same finite-regulator amplitude coordinate is represented only if

$$\mathcal{R}^{\mathcal{S}\,\prime}_{\mathrm{f},\Lambda} = \frac{\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}}{\det Z_R\,\det Z_L}, \qquad \mathcal{R}^{\mathcal{S}\,\prime}_{\mathrm{f},\Lambda}\det K_{00}^{\mathrm{eff}\,\prime} = \mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}\det K_{00}^{\mathrm{eff}}. \tag{51.125}$$

If the finite scheme is also changed by a local fermion determinant counterterm $\Delta C_{\mathrm{f}}(z)$*, then the determinant coordinate is instead multiplied by* $\exp[-\Delta C_{\mathrm{f}}(z)]$*:*

$$\mathcal{R}^{\mathcal{S}'}_{\mathrm{f},\Lambda} = \mathrm{e}^{-\Delta C_{\mathrm{f}}(z)}\frac{\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}}{\det Z_R\,\det Z_L}. \tag{51.126}$$

Thus a numerical value for $\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}$ is not a standalone output of the zero-mode determinant. It has meaning only together with the finite source frame, local counterterm convention, and operator normalization used to extract the physical correlator.

Proof. Equation (51.124) and determinant multiplicativity give

$$\det K^{\mathrm{eff}\,\prime}_{00} = \det Z_R \,\det K^{\mathrm{eff}}_{00}\, \det Z_L.$$

The inverse transformation of $\mathcal{R}^{\mathcal{S}}_{\mathrm{f},\Lambda}$ in (51.125) is therefore exactly what preserves the finite product (51.123). A finite local counterterm changes the regulated determinant density by the exponential of minus the counterterm difference between the instanton and trivial sectors, as in (51.86); this gives (51.126). The final statement follows because source-frame changes and local counterterms act on the finite spectral determinant factor, while the Berezin determinant records only the zero-mode saturation algebra. □

Proposition 51.42 (Mass/source RG transport of the instanton vertex)**.** *Work in a mass-independent renormalization scheme in the same $Q = 1$ vectorlike QCD chart. Let $\gamma_m(g)$ be the anomalous dimension of the quark mass coordinate in the convention*

$$\mu\frac{\mathrm{d}M}{\mathrm{d}\mu} = -\gamma_m(g)M, \qquad \mu\frac{\mathrm{d}J}{\mathrm{d}\mu} = -\gamma_m(g)J, \tag{51.127}$$

where J is a renormalized source coordinate coupled to the same chiral scalar density as the mass matrix. Let $M^0(z) = \rho M$, and let $J^0(z)$ be the zero-mode projection of J, a linear function of J with the same anomalous transport as J. Let $\mathcal{R}^{\mathcal{S}}_{\mathrm{f}}(z;\mu)$ denote the finite light-fermion nonzero-mode determinant factor in the source convention of Proposition 51.40. If, at the logarithmic accuracy under consideration,

$$(\mu\partial_\mu + \beta(g)\partial_g)\log \mathcal{R}^{\mathcal{S}}_{\mathrm{f}}(z;\mu) = N_f\,\gamma_m(g), \tag{51.128}$$

then the zero-mode source functional

$$\mathcal{V}^0_{\mathrm{inst}}(z; M, J, \mu) = \mathcal{R}^{\mathcal{S}}_{\mathrm{f}}(z;\mu)\,\det\bigl(M^0(z) + J^0(z)\bigr) \tag{51.129}$$

obeys

$$\left[\mu\partial_\mu + \beta(g)\partial_g - \gamma_m(g)\sum_{f,f'}\left(M_{ff'}\frac{\partial}{\partial M_{ff'}} + J_{ff'}\frac{\partial}{\partial J_{ff'}}\right)\right]\mathcal{V}^0_{\mathrm{inst}} = 0. \tag{51.130}$$

Thus the mass/source determinant is not an RG-invariant number by itself. The source functional is covariant only after the finite nonzero-mode determinant factor and the source renormalization convention are included. The symbol J denotes the source coordinate before differentiation. The scalar-density operator obtained after differentiating the generating functional uses the corresponding operator normalization; in the local operator convention that differentiated insertion has the $B^0_{ff'} = \rho^3\bar\psi_{Rf}\psi_{Lf'} + \cdots$ normalization of (51.121).

In particular, for diagonal masses and $J = 0$, the anomalous-dimension part of the vacuum factor

$$\mathcal{R}^{\mathcal{S}}_{\mathrm{f}}(\mu)\prod_{f=1}^{N_f} m_f(\mu)$$

is scale invariant at the same logarithmic accuracy. The phase $\theta + \arg\det M$ is unaffected by the positive real mass renormalization factor; it is fixed instead by the anomalous chiral rotation described in (51.49). After differentiating (51.129) r times with respect to J and setting $J = 0$, the resulting mixed mass/source minor has the RG covariance of an r-fold insertion of the renormalized scalar density, rather than the covariance of a vacuum activity.

Proof. The matrix $M^0(z) + J^0(z)$ is homogeneous of degree one in the source coordinates M and J, while the projection factors depending on ρ, U, and the normalized zero-mode wavefunctions are collective coordinate data and are not acted on by the source anomalous dimension. The determinant is therefore homogeneous of degree N_f:

$$\sum_{f,f'} \left(M_{ff'} \frac{\partial}{\partial M_{ff'}} + J_{ff'} \frac{\partial}{\partial J_{ff'}} \right) \det(M^0 + J^0) = N_f \det(M^0 + J^0).$$

Combining this identity with (51.128) gives (51.130). Setting $J = 0$ gives the vacuum statement. Differentiating the source-functional equation r times with respect to J transfers r source anomalous-dimension terms from the transport operator to the differentiated coefficient, which is the usual Callan–Symanzik covariance of r renormalized scalar-density insertions. The phase statement follows from a separate observation. In a vectorlike mass-independent scheme, multiplicative mass renormalization changes the magnitude of M. The anomalous flavor-singlet chiral rotation changes $\arg\det M$ and θ in opposite directions. □

Proposition 51.43 (Proper-time determinant and zero-mode source functional)**.** *Fix a finite-regulator $Q = 1$ chart $z = (a, \rho, U)$, a background gauge slice, and a proper-time determinant prescription with renormalization scale μ. For each positive nonzero-mode operator $P_{\Lambda,z}$ in the instanton background, compared with the corresponding operator $P_{\Lambda,0}$ in the trivial sector, define the regulated logarithmic determinant ratio by*

$$K_\Lambda(P_z, P_0; \mu) = -\int_{\epsilon_\Lambda}^{\infty} \frac{\mathrm{d}t}{t}\, r(t\mu^2) \left(\mathrm{Tr}'\, e^{-tP_{\Lambda,z}} - \mathrm{Tr}\, e^{-tP_{\Lambda,0}} \right) + C^{\mathrm{loc}}_{\Lambda,P}(z; \mu), \tag{51.131}$$

where r is a smooth cutoff profile with $r(0) = 1$, the prime removes collective-coordinate, residual-gauge, and fermion zero modes as appropriate, and $C^{\mathrm{loc}}_{\Lambda,P}$ is the chosen local subtraction in the instanton background relative to the trivial background. The determinant density in (51.86) is then

$$\log \mathcal{W}^{\mathrm{nz}}_{\Lambda,\mathrm{pt}}(z; \mu) = K_\Lambda(M^{\mathrm{gh}}_z, M^{\mathrm{gh}}_0; \mu) - \frac{1}{2} K_\Lambda(L^{\mathrm{bos}}_z, L^{\mathrm{bos}}_0; \mu) + \sum_R K^{\mathrm{pf,R}}_\Lambda(z, 0; \mu), \tag{51.132}$$

with $K^{\mathrm{pf,R}}_\Lambda$ the Pfaffian or determinant-line version of the same nonzero-mode construction for the fermion multiplet R.

For two massless Dirac flavors there are two distinct source constructions. An even bilinear source supplies an independent finite matrix $B(z)$ in the zero-mode action $\sum_{f,f'} \widetilde{\lambda}_f B_{ff'}(z) \lambda_{f'}$; its zero-mode factor is $\det B(z)$, as in Proposition 51.35. Ordinary external fermion wave packets are instead introduced by odd generating coordinates. Let $\bar{\chi}_A, \chi_B$, $A, B = 1, 2$, be the four external source coordinates and set

$$\alpha_f(z) = \sum_{A=1}^{2} \bar{\chi}_A R_{Af}(z), \qquad \beta_f(z) = \sum_{B=1}^{2} L_{fB}(z) \chi_B, \tag{51.133}$$

where R_{Af} and L_{fB} are the zero-mode overlaps of the Ath right-handed and Bth left-handed external slots with the normalized instanton zero-mode wavefunction. With the same Berezin orientation used in (51.106), the differentiated source coefficient is

$$[\bar{\chi}_1\bar{\chi}_2\chi_1\chi_2]\prod_{f=1}^{2}\alpha_f(z)\prod_{f=1}^{2}\beta_f(z) = \det R(z)\,\det L(z). \tag{51.134}$$

Thus the one-instanton generating-functional contribution is

$$\begin{aligned}\mathcal{G}^{(4)}_{\eta,\Lambda,Q=1}[\bar{\chi},\chi] &= \int_{\mathcal{U}_{Q=1}} \exp[-S_\Lambda(A_z)+\mathrm{i}\theta]\,\mathcal{W}^{\mathrm{nz}}_{\Lambda,\mathrm{pt}}(z;\mu)\prod_{f=1}^{2}\alpha_f(z)\prod_{f=1}^{2}\beta_f(z)\,\mathrm{d}\nu_{\Lambda,\mathcal{M}}(z),\\ G^{(4)}_{\eta,\Lambda,Q=1} &= [\bar{\chi}_1\bar{\chi}_2\chi_1\chi_2]\,\mathcal{G}^{(4)}_{\eta,\Lambda,Q=1}[\bar{\chi},\chi].\end{aligned} \tag{51.135}$$

A c-number matrix formed as a single outer product $u_f v_{f'}$ is not this four-slot coefficient; for $N_f = 2$ its determinant vanishes. The small-t expansion of (51.131) supplies the local counterterms and the universal $(\mu\rho)^{b_0}$ factor, while the finite remainder fixes the scheme-dependent numerical constant in the selected source functional. Thus the physics calculation consists of the regulated fluctuation determinant, the zero-mode source differentiation, and the collective-coordinate integral as a single object.

Proof. For a finite positive operator P, the identity $\log\det P = -\int_\epsilon^\infty \mathrm{d}t\,t^{-1}\,\mathrm{Tr}\,e^{-tP}$ holds up to the subtraction convention at the lower endpoint. Applying this identity to the instanton and trivial-sector operators and adding the chosen local counterterm gives (51.131). Bosonic Gaussian integration contributes the exponent $-1/2$, ghost Berezin integration contributes $+1$, and fermionic nonzero modes contribute the Pfaffian or determinant-line factor, giving (51.132). Zero modes have already been removed from the traces and determinants, so their finite Berezin integral is exactly the calculation in Proposition 51.35 for an even bilinear source matrix. For linear external sources, expanding $\prod_f \alpha_f \prod_f \beta_f$ and extracting the $\bar{\chi}_1\bar{\chi}_2\chi_1\chi_2$ coefficient gives $\det R\,\det L$; this is the source-differentiated correlator coefficient, not the determinant of a single c-number outer product. Multiplication by the collective-coordinate density and the classical instanton exponential gives (51.135). Finally, the heat-kernel expansion of the trace difference at small t separates local counterterms, the coefficient of $\log(\mu\rho)$, and the finite determinant constant; RG invariance identifies the universal logarithmic coefficient with b_0 in the displayed one-loop density. □

Proposition 51.44 (Instanton zero-mode density form factor and local limit)**.** *In a BPST $Q = 1$ background, after the spin and color tensors of one fundamental zero-mode line are factored out, the radial scalar envelope which weights a local mass, Yukawa, or bilinear source is*

$$h_\rho(y) = \frac{2\rho^2}{\pi^2(y^2+\rho^2)^3}, \qquad \int_{\mathbb{R}^4} h_\rho(y)\,\mathrm{d}^4y = 1. \tag{51.136}$$

Thus a zero-mode-paired source matrix entry has the form

$$B^{(s)}_{ff'}(a,\rho,U) = \rho^{d_s}\int_{\mathbb{R}^4} h_\rho(y)\,\mathcal{B}_{ff'}(a+y;U)\,\mathrm{d}^4y, \tag{51.137}$$

where $d_s = 1$ for a mass source and $d_s = 3$ for the local quark-bilinear source in (51.105). Equivalently, with the Fourier convention

$$\widehat{h}_\rho(q) = \int_{\mathbb{R}^4} \mathrm{e}^{\mathrm{i}q\cdot y} h_\rho(y)\, \mathrm{d}^4 y,$$

one has the exact form factor

$$\widehat{h}_\rho(q) = zK_1(z), \qquad z = \rho|q|, \tag{51.138}$$

where K_1 is the modified Bessel function. Hence a zero-mode-paired source with Fourier momentum q is not represented by the local vertex until $z \ll 1$. The small-momentum expansion is

$$zK_1(z) = 1 + \frac{z^2}{2}\left[\log\frac{z}{2} + \gamma_{\mathrm{E}} - \frac{1}{2}\right] + O(z^4 \log z), \tag{51.139}$$

so the first nonlocal correction is $q^2\rho^2\log(|q|\rho)$, not an ordinary analytic Taylor coefficient. At $z \gg 1$,

$$zK_1(z) = \sqrt{\frac{\pi z}{2}}\,\mathrm{e}^{-z}\left(1 + \frac{3}{8z} + O(z^{-2})\right), \tag{51.140}$$

which displays the suppression of source components varying on scales shorter than the instanton size. This is the density form factor for a local bilinear or mass-source insertion. A differentiated correlator with four ordinary external fermion slots instead uses the Fourier transforms of the individual zero-mode wavefunctions in those slots; their product reduces to the local bilinear density only after the slot wavefunctions are fused into a bilinear source and the local limit is taken. In position space, for $U_R = R/\rho$,

$$\int_{|y|<R} h_\rho(y)\, \mathrm{d}^4 y = \frac{U_R^4}{(1+U_R^2)^2}, \qquad \int_{|y|>R} h_\rho(y)\, \mathrm{d}^4 y = \frac{1+2U_R^2}{(1+U_R^2)^2}. \tag{51.141}$$

The first correction to a local Taylor expansion is more delicate. The truncated second moment is

$$M_2(R) := \int_{|y|<R} |y|^2 h_\rho(y)\, \mathrm{d}^4 y = 2\rho^2\left[\log(1+U_R^2) + \frac{2}{1+U_R^2} - \frac{1}{2(1+U_R^2)^2} - \frac{3}{2}\right], \tag{51.142}$$

and rotational invariance gives

$$\int_{|y|<R} y^\mu y^\nu h_\rho(y)\, \mathrm{d}^4 y = \frac{\delta^{\mu\nu}}{4} M_2(R).$$

Consequently the leading local term in (51.137) is $\rho^{d_s}\mathcal{B}_{ff'}(a;U)$, with a tail bounded by the second quantity in (51.141). But the would-be two-derivative coefficient grows as $4\rho^2\log(R/\rho) + O(\rho^2)$ as $R/\rho \to \infty$. The local 't Hooft vertex is therefore the zeroth adiabatic term of the zero-mode source convolution; higher-derivative terms require the external wave-packet, mass, or infrared regulator that cuts off the zero-mode tail. In momentum space the same statement is the logarithm in (51.139).

Proof. The normalized radial envelope in (51.136) is the scalar part of the product of two normalized fundamental zero-mode wavefunctions in the BPST background. Using $\mathrm{d}^4 y = 2\pi^2 r^3 \mathrm{d}r$ and $u = r/\rho$,

$$\int_{\mathbb{R}^4} h_\rho(y)\, \mathrm{d}^4 y = 4\int_0^\infty \frac{u^3}{(1+u^2)^3}\, \mathrm{d}u = 1.$$

For the Fourier transform, use the Schwinger representation

$$\frac{1}{(y^2+\rho^2)^3} = \frac{1}{2}\int_0^\infty s^2 \mathrm{e}^{-s(y^2+\rho^2)}\,\mathrm{d}s.$$

Then

$$\begin{aligned}\widehat{h}_\rho(q) &= \rho^2 \int_0^\infty \exp\Big[-\rho^2 s - \frac{q^2}{4s}\Big]\,\mathrm{d}s\\ &= \rho|q|\,K_1(\rho|q|),\end{aligned}$$

where the last step is the standard integral representation of the modified Bessel function. The small-z and large-z formulas are the corresponding standard asymptotic expansions of K_1; the logarithmic small-z term is the momentum-space reflection of the logarithmically divergent second moment computed below.

The same integral cut off at U_R gives

$$4\int_0^{U_R} \frac{u^3}{(1+u^2)^3}\,\mathrm{d}u = 1 - \frac{2}{1+U_R^2} + \frac{1}{(1+U_R^2)^2} = \frac{U_R^4}{(1+U_R^2)^2},$$

and subtracting from one gives the tail formula in (51.141). For the second moment,

$$M_2(R) = 4\rho^2 \int_0^{U_R} \frac{u^5}{(1+u^2)^3}\,\mathrm{d}u.$$

With $t = 1+u^2$, this antiderivative is

$$2\rho^2\left[\log t + \frac{2}{t} - \frac{1}{2t^2} - \frac{3}{2}\right]_{t=1}^{1+U_R^2},$$

which is (51.142). Rotational invariance in four Euclidean dimensions gives the displayed $\delta^{\mu\nu}/4$ tensor moment. The Taylor expansion of $\mathcal{B}(a+y;U)$ then yields the zeroth local term and the $(M_2(R)/8)\partial^2\mathcal{B}(a;U)$ contribution inside the ball $|y|<R$, while the exterior contribution is controlled by the tail mass times the appropriate supremum norm of the source. Since $\log(1+U_R^2) = 2\log(R/\rho)+o(1)$, the full second moment is logarithmically infrared sensitive. $\square$

Proposition 51.45 (Individual BPST zero-mode slot form factor)**.** *For an ordinary external fermion slot one must use the Fourier transform of a single normalized BPST zero-mode wave-function, not the density form factor $\widehat{h}_\rho$ of Proposition 51.44. In the standard singular-gauge momentum-space convention for a charge-one instanton [63, 66], the spin-color tensor and the scalar radial function separate as*

$$\widetilde{\psi}^\alpha_{0,i}(p;\rho,U) = \sqrt{2}\,\phi'_\rho(|p|)\big(\widehat{p}\,\epsilon U\big)^\alpha_i, \qquad \phi_\rho(p) = \pi\rho^2\big[I_0(t)K_0(t) - I_1(t)K_1(t)\big], \quad t = \frac{\rho|p|}{2}. \tag{51.143}$$

Here I_ν and K_ν are modified Bessel functions, U is the color orientation, and $\widehat{p} = p/|p|$. After the adjacent free Dirac operator and fixed Fourier-normalization constants are assigned to the external-slot amputation convention, the dimensionless scalar slot form factor is

$$F_{\mathrm{zm}}(t) := -t\frac{\mathrm{d}}{\mathrm{d}t}\big[I_0(t)K_0(t) - I_1(t)K_1(t)\big] = 2t\big[I_0(t)K_1(t) - I_1(t)K_0(t)\big] - 2I_1(t)K_1(t). \tag{51.144}$$

It is normalized by

$$F_{\mathrm{zm}}(0) = 1, \tag{51.145}$$

while at large momentum

$$F_{\mathrm{zm}}(t) = \frac{3}{4t^3} + O(t^{-5}) = \frac{6}{(\rho|p|)^3} + O((\rho|p|)^{-5}). \tag{51.146}$$

Thus the individual external zero-mode slot has a power tail. The exponential large-momentum suppression in (51.140) *belongs to the fused bilinear density* h_ρ*, not to a single differentiated fermion slot.*

Proof. The first formula is the standard Fourier-Bessel transform of the normalized singular-gauge fundamental zero mode after its hedgehog spin-color tensor has been extracted. Differentiating $\Phi(t) = I_0(t)K_0(t) - I_1(t)K_1(t)$ and using

$$I_0' = I_1, \qquad I_1' = I_0 - \frac{I_1}{t}, \qquad K_0' = -K_1, \qquad K_1' = -K_0 - \frac{K_1}{t}$$

gives the second expression in (51.144). The small-t expansions $I_0(t) = 1 + O(t^2)$, $I_1(t) = t/2 + O(t^3)$, and $K_1(t) = t^{-1} + O(t \log t)$ give $F_{\mathrm{zm}}(0) = 1$. The standard large-t asymptotic expansions of I_ν and K_ν show that the constant, t^{-1}, and t^{-2} terms cancel in (51.144); the first nonzero term is $3/(4t^3)$. □

Proposition 51.46 (Amputation and source typing of the instanton kernel)**.** *Work in the finite-regulator $Q = 1$ chart of Proposition 51.43, and suppose an auxiliary infrared deformation or source scheme has been chosen in which the external quark fields used to probe the kernel have isolated nonzero external pole-residue factors. For differentiated linear source slots, let $Z_A^R(p_{R,A})$ and $Z_B^L(p_{L,B})$ be the adjacent unamputated pole residues for the two right-handed and two left-handed slots. After the spin and color external covectors are fixed, write the zero-mode overlap matrices as*

$$\begin{aligned} R_{Af}^{\mathrm{unamp}}(z) &= Z_A^R(p_{R,A})\, R_{Af}^{\mathrm{amp}}(z), \\ L_{fB}^{\mathrm{unamp}}(z) &= L_{fB}^{\mathrm{amp}}(z)\, Z_B^L(p_{L,B}), \qquad A, B, f = 1, 2. \end{aligned} \tag{51.147}$$

The four-slot coefficient from (51.134) *obeys*

$$\det R^{\mathrm{unamp}}(z) \det L^{\mathrm{unamp}}(z) = \left(\prod_{A=1}^{2} Z_A^R\right) \left(\prod_{B=1}^{2} Z_B^L\right) \det R^{\mathrm{amp}}(z) \det L^{\mathrm{amp}}(z). \tag{51.148}$$

Consequently the source-amputated differentiated four-fermion kernel is

$$\mathcal{M}_{\Lambda,Q=1}^{(4),\mathrm{amp}} = \int_{\mathcal{U}_{Q=1}} \exp[-S_\Lambda(A_z) + \mathrm{i}\theta]\, \mathcal{W}_{\Lambda,\mathrm{pt}}^{\mathrm{nz}}(z;\mu)\, \det R^{\mathrm{amp}}(z) \det L^{\mathrm{amp}}(z)\, \mathrm{d}\nu_{\Lambda,\mathcal{M}}(z). \tag{51.149}$$

Amputation removes only the adjacent external propagator residues. It does not remove the individual instanton zero-mode Fourier overlaps, the spin-color orientation tensors, the nonzero-mode determinant, or the collective-coordinate integral.

For an independent even bilinear source matrix the source type is different. If $B^{\mathrm{unamp}} = D_R B^{\mathrm{amp}} D_L$, with D_R, D_L diagonal residue matrices in flavor space, then

$$\det B^{\mathrm{unamp}} = \det D_R\, \det B^{\mathrm{amp}}\, \det D_L. \tag{51.150}$$

For a local bilinear source carrying momentum $q_{ff'}$, the BPST density form factor of Proposition 51.44 gives a representative entry

$$B^{\mathrm{amp}}_{ff'}(a,\rho,U)=\rho^3\mathrm{e}^{\mathrm{i}q_{ff'}\cdot a}\,\widehat{h}_\rho(q_{ff'})\,\mathcal{T}_{ff'}(U;q_{ff'}),\qquad q_{ff'}=p_{R,f}-p_{L,f'}. \tag{51.151}$$

This bilinear-source formula is not the determinant of a single c-number outer product of external wave packets. Ordinary external fermions use (51.147) *and the source differentiation in* (51.134).

Proof. The linear source overlaps in (51.133) attach each external slot to one normalized zero-mode wavefunction. The chosen infrared scheme supplies one adjacent pole residue per external slot; removing those residues gives (51.147). Applying the determinant to the right-slot matrix and to the left-slot matrix gives (51.148). Multiplying the unamputated differentiated Green kernel by the inverse product of the same four residues therefore gives (51.149).

For an even bilinear source, the zero-mode action already contains a matrix entry $B_{ff'}$. Row and column residue factors then multiply that matrix on the left and right, so ordinary determinant multiplicativity gives (51.150). The density form factor in (51.151) comes from the product of two zero-mode wavefunctions in a fused bilinear source. Linear external slots are differentiated before the sources are set to zero, so a single rank-one c-number matrix never appears as the four-fermion coefficient. □

Proposition 51.47 (Plane-wave assembly of the one-instanton four-fermion amplitude)**.** *Stay in the $N_f=2$ source-amputated setup of Proposition 51.46, and suppose the center coordinate factorizes from the regulated collective-coordinate density:*

$$\mathrm{d}\nu_{\Lambda,\mathcal{M}}(z)=\mathcal{J}_\Lambda(\rho,U)\,\mathrm{d}^4a\,\mathrm{d}\rho\,\mathrm{d}\Omega(U).$$

Let

$$\mathcal{P}=\sum_{A=1}^{2}p_{R,A}-\sum_{B=1}^{2}p_{L,B}.$$

For plane-wave external slots, write the individual amputated zero-mode overlaps in the form

$$R^{\mathrm{amp}}_{Af}(a,\rho,U)=\rho^{3/2}\mathrm{e}^{\mathrm{i}p_{R,A}\cdot a}\mathcal{R}_{Af}(\rho,U;p_{R,A}),\qquad L^{\mathrm{amp}}_{fB}(a,\rho,U)=\rho^{3/2}\mathrm{e}^{-\mathrm{i}p_{L,B}\cdot a}\mathcal{L}_{fB}(\rho,U;p_{L,B}),$$

where $\mathcal{R}$ and $\mathcal{L}$ are obtained from the Fourier transforms of the individual normalized zero-mode wavefunctions, with the chosen spin-color external covectors already contracted. Then the source-differentiated zero-mode coefficient in (51.149) *has the factorized form*

$$\begin{aligned}\det R^{\mathrm{amp}}(a,\rho,U)\det L^{\mathrm{amp}}(a,\rho,U)&=\rho^6\,\mathrm{e}^{\mathrm{i}\mathcal{P}\cdot a}\,\mathfrak{A}_2^{\mathrm{lin}}(\rho,U;\{p_R,p_L\}),\\ \mathfrak{A}_2^{\mathrm{lin}}&=\det\mathcal{R}(\rho,U;\{p_R\})\,\det\mathcal{L}(\rho,U;\{p_L\}).\end{aligned} \tag{51.152}$$

A separate bilinear-source specialization is obtained by inserting (51.151) *into* $\det B^{\mathrm{amp}}$. *In that case $F(z)=zK_1(z)$ appears through the density form factor and*

$$\det B^{\mathrm{amp}}=\rho^6\mathrm{e}^{\mathrm{i}\mathcal{P}\cdot a}\left[F(\rho|q_{11}|)F(\rho|q_{22}|)\mathcal{T}_{11}\mathcal{T}_{22}-F(\rho|q_{12}|)F(\rho|q_{21}|)\mathcal{T}_{12}\mathcal{T}_{21}\right],\qquad q_{ff'}=p_{R,f}-p_{L,f'},$$

provided B^{amp} is an independent bilinear source matrix. If $B^{\mathrm{amp}}_{ff'}=u_fv_{f'}$ is only a c-number outer product, the two-flavor determinant is zero. Consequently the center integral in infinite volume gives the distributional factor

$$\int_{\mathbb{R}^4}\mathrm{d}^4a\,\mathrm{e}^{\mathrm{i}\mathcal{P}\cdot a}=(2\pi)^4\delta^{(4)}(\mathcal{P}), \tag{51.153}$$

and the source-amputated one-instanton contribution may be written as

$$\begin{aligned}\mathcal{M}^{(4),\mathrm{amp}}_{\Lambda,Q=1} = \mathrm{e}^{\mathrm{i}\theta}(2\pi)^4\delta^{(4)}(\mathcal{P}) \int \exp[-S_\Lambda(A_{\rho,U})]\, \mathcal{W}^{\mathrm{nz}}_{\Lambda,\mathrm{pt}}(\rho,U;\mu) \\ \times \rho^6\, \mathfrak{A}^{\mathrm{lin}}_2(\rho,U;\{p_R,p_L\})\, \mathcal{J}_\Lambda(\rho,U)\,\mathrm{d}\rho\,\mathrm{d}\Omega(U).\end{aligned} \tag{51.154}$$

The anti-instanton term has the conjugate chirality structure and the phase $\mathrm{e}^{-\mathrm{i}\theta}$*.*

Thus the instanton calculation does not first create a local vertex and then decorate it. The finite-regulator amplitude is assembled from four load-bearing pieces: the center integral, the individual zero-mode Fourier-overlap tensors, the nonzero-mode determinant, and the size integral. The local 't Hooft operator is obtained only after the external slots have been fused into a local bilinear source, the support of the ρ*-integral lies in the small-momentum regime of the relevant zero-mode form factors, and the determinant remainder has been replaced by the finite constant of the chosen scheme.*

Proof. In $\det R^{\mathrm{amp}}$, both permutation terms contain the same phase $\mathrm{e}^{\mathrm{i}(p_{R,1}+p_{R,2})\cdot a}$. In $\det L^{\mathrm{amp}}$, both permutation terms contain the same phase $\mathrm{e}^{-\mathrm{i}(p_{L,1}+p_{L,2})\cdot a}$. The product therefore carries $\mathrm{e}^{\mathrm{i}\mathcal{P}\cdot a}$. The four individual zero-mode overlaps carry the conventional total power ρ^6, leaving $\det\mathcal{R}\,\det\mathcal{L}$ as the nontrivial form-factor and orientation coefficient. This proves (51.152). Translation invariance of the center coordinate then gives (51.153) in infinite volume, or the corresponding Kronecker delta on a finite periodic regulator. Substituting the factorized coefficient and collective-coordinate density into (51.149) gives (51.154). The bilinear-source formula follows from the same phase count applied to (51.151); the final rank-one warning is the elementary identity $\det(uv^T) = 0$ for two-component c-number vectors. □

Proposition 51.48 (Orientation projection in the instanton four-slot kernel)**.** *The global* $SU(2)$ *orientation in the embedded BPST core enters the amplitude as a projection of colored zero-mode tensors onto invariant color tensors. Normalize Haar measure by* $\int_{SU(2)}\mathrm{d}U = 1$*, and let* ${U_i}^\alpha$ *denote the fundamental matrix element carrying a core two-dimensional index* α *to a color index* i*. Then*

$$\int_{SU(2)} {U_i}^\alpha\,\mathrm{d}U = 0, \qquad \int_{SU(2)} {U_i}^\alpha\overline{{U_j}^\beta}\,\mathrm{d}U = \frac{1}{2}\delta_{ij}\delta^{\alpha\beta}, \tag{51.155}$$

and, because $\wedge^2\mathbb{C}^2$ *is the trivial representation of* $SU(2)$*,*

$$\int_{SU(2)} {U_i}^\alpha {U_j}^\beta\,\mathrm{d}U = \frac{1}{2}\varepsilon_{ij}\varepsilon^{\alpha\beta}. \tag{51.156}$$

Consequently two differentiated external zero-mode slots with core source vectors $v_A, v_B \in \mathbb{C}^2$ *have orientation average*

$$\int_{SU(2)} (Uv_A)_i(Uv_B)_j\,\mathrm{d}U = \frac{1}{2}\varepsilon_{ij}\,\varepsilon_{\alpha\beta}v_A^\alpha v_B^\beta = \frac{1}{2}\varepsilon_{ij}\det(v_A,v_B). \tag{51.157}$$

For an $N_f = 2$ *differentiated four-slot source, the four slots share the same orientation variable. One must therefore use the single four-point Haar projector, not the product of two two-point averages. When all four selected slots have been written as fundamental* $SU(2)$ *core indices, set*

$$A_{i_1i_2j_1j_2} = \varepsilon_{i_1i_2}\varepsilon_{j_1j_2}, \qquad B_{i_1i_2j_1j_2} = \varepsilon_{i_1j_1}\varepsilon_{i_2j_2},$$

and use the same symbols with upper core indices. Then

$$\begin{aligned}\int_{SU(2)} & U_{i_1}{}^{\alpha_1} U_{i_2}{}^{\alpha_2} U_{j_1}{}^{\beta_1} U_{j_2}{}^{\beta_2}\,\mathrm{d}U \\ &= \frac{1}{3} A_{i_1 i_2 j_1 j_2} A^{\alpha_1\alpha_2\beta_1\beta_2} - \frac{1}{6} A_{i_1 i_2 j_1 j_2} B^{\alpha_1\alpha_2\beta_1\beta_2} \\ &\quad - \frac{1}{6} B_{i_1 i_2 j_1 j_2} A^{\alpha_1\alpha_2\beta_1\beta_2} + \frac{1}{3} B_{i_1 i_2 j_1 j_2} B^{\alpha_1\alpha_2\beta_1\beta_2}.\end{aligned} \tag{51.158}$$

If the left slots are kept as conjugate or dual slots instead, they must first be converted to the chosen fundamental convention by the $SU(2)$ pseudoreal ε-tensor, or else the corresponding mixed $U\overline{U}$ Weingarten projector must be used. Contracting (51.158) with core source vectors $v_1^R, v_2^R, v_1^L, v_2^L$ gives

$$A_{i_1 i_2 j_1 j_2}\left[\frac{1}{3}\Delta_{12|34} - \frac{1}{6}\Delta_{13|24}\right] + B_{i_1 i_2 j_1 j_2}\left[-\frac{1}{6}\Delta_{12|34} + \frac{1}{3}\Delta_{13|24}\right], \tag{51.159}$$

where

$$\Delta_{12|34} = \varepsilon_{\alpha_1\alpha_2} v_1^{R,\alpha_1} v_2^{R,\alpha_2}\, \varepsilon_{\beta_1\beta_2} v_1^{L,\beta_1} v_2^{L,\beta_2}, \qquad \Delta_{13|24} = \varepsilon_{\alpha_1\beta_1} v_1^{R,\alpha_1} v_1^{L,\beta_1}\, \varepsilon_{\alpha_2\beta_2} v_2^{R,\alpha_2} v_2^{L,\beta_2}.$$

Thus the color-orientation collective coordinate is a genuine part of the amplitude rather than a passive coordinate volume: it enforces the full invariant four-slot projector. A product of right and left flavor determinants appears only after the Berezin source coefficient and the final color-singlet source contraction impose that additional structure. For an $SU(N_c)$ instanton embedded through an $SU(2)$ subgroup, the full orientation-orbit integral is the corresponding $SU(N_c)$-invariant projection with a convention dependent normalization; the displayed $SU(2)$ core identity is the local finite projection used by the zero-mode tensor.

Proof. There is no nonzero invariant vector in the fundamental representation, so the one-slot average vanishes. The mixed two-point average is an intertwiner $\mathbb{C}^2 \otimes (\mathbb{C}^2)^* \to \mathbb{C}^2 \otimes (\mathbb{C}^2)^*$, hence Schur orthogonality makes it a multiple of $\delta_{ij}\delta^{\alpha\beta}$. Contracting $i = j$ and $\alpha = \beta$ gives 2, so the multiple is $1/2$.

Similarly, the average of $U_i{}^{\alpha} U_j{}^{\beta}$ is an invariant tensor in $\wedge^2\mathbb{C}^2 \otimes \wedge^2(\mathbb{C}^2)^*$, and must be $c\,\varepsilon_{ij}\varepsilon^{\alpha\beta}$. Contracting with $\varepsilon^{ij}\varepsilon_{\alpha\beta}$ gives

$$4c = \int \varepsilon^{ij}\varepsilon_{\alpha\beta} U_i{}^{\alpha} U_j{}^{\beta}\,\mathrm{d}U = 2\int \det U\,\mathrm{d}U = 2,$$

so $c = 1/2$. Multiplying the averaged matrix elements by the two source vectors gives (51.157).

For four slots, the invariant subspace of $(\mathbb{C}^2)^{\otimes 4}$ is two-dimensional. Use the two spanning invariant tensors A and B above. Their Gram matrix is

$$\begin{pmatrix} \langle A, A\rangle & \langle A, B\rangle \\ \langle B, A\rangle & \langle B, B\rangle \end{pmatrix} = \begin{pmatrix} 4 & 2 \\ 2 & 4 \end{pmatrix}, \qquad G^{-1} = \begin{pmatrix} \frac{1}{3} & -\frac{1}{6} \\ -\frac{1}{6} & \frac{1}{3} \end{pmatrix}.$$

The Haar average is the orthogonal projection onto this invariant subspace, with one copy of G^{-1} connecting the color invariant basis to the core invariant basis. This gives (51.158). Contracting that projector with the four core source vectors gives (51.159). The calculation uses one shared Haar variable throughout; replacing it by a product of two two-slot averages would project two independent orientations and gives the wrong four-slot normalization. □

The qualification in Proposition 51.46 is essential. Colored quark legs in confining QCD do not define ordinary physical asymptotic states. The displayed object is an auxiliary source-amputated, or partonic hard-kernel, coordinate useful for matching the finite-regulator Green function to the local effective operator. Gauge-invariant amplitudes must contract the same instanton kernel with color-singlet external operators, hadronic matrix elements, or a separately specified infrared deformation. This is the amplitude-level content of the original one-instanton computation of 't Hooft [63]: collective coordinates, nonzero-mode fluctuation determinants, fermion zero-mode saturation, and external-leg normalization are one calculation.

Controlled Approximation 51.49 (Color-singlet matching of the instanton kernel)**.** Stay in the finite-regulator $Q = 1$ setup of Proposition 51.46, but replace the auxiliary colored external quark representatives by renormalized gauge-invariant source families. Local examples are chiral color-singlet bilinears $\bar{q}_{Rf}\Gamma q_{Lf'}$; nonlocal examples must include the Wilson line which makes the two quark fields a color singlet. In a selected $N_f = 2$ chirality-violating channel, suppose that the zero-mode projection of the chosen source family has the short-distance form

$$B^{\mathcal{J}}_{AB}(z) = \sum_{f,f'=1}^{2} \Phi^R_{Af}(z;\mu)\, B^{\mathrm{amp}}_{ff'}(z)\, \Phi^L_{f'B}(z;\mu) + B^{\mathrm{rem}}_{AB}(z), \tag{51.160}$$

where A, B label two independent color-singlet source coordinates, Φ^R, Φ^L are the source-to-zero-mode overlap matrices in the chosen renormalization scheme, and B^{rem} collects higher-dimension source components, soft channels not represented by the hard zero-mode kernel, and terms outside the selected chirality structure. The corresponding gauge-invariant source correlator receives the one-instanton contribution

$$G^{(4)}_{\mathcal{J},\Lambda,Q=1} = \int_{\mathcal{U}_{Q=1}} \exp[-S_\Lambda(A_z) + \mathrm{i}\theta]\, \mathcal{W}^{\mathrm{nz}}_{\Lambda,\mathrm{pt}}(z;\mu)\, \det B^{\mathcal{J}}(z)\, \mathrm{d}\nu_{\Lambda,\mathcal{M}}(z), \tag{51.161}$$

up to the same remainder specification. If the overlap matrices are square and vary only on scales which are soft compared with the hard instanton support, then pointwise in z

$$\det B^{\mathcal{J}}(z) = \det \Phi^R(z;\mu)\, \det B^{\mathrm{amp}}(z)\, \det \Phi^L(z;\mu) + \text{terms containing } B^{\mathrm{rem}}. \tag{51.162}$$

Thus the zero-mode form factors appropriate to the selected source family, the orientation tensor, the nonzero-mode determinant, and the size integral remain the short-distance instanton kernel; the color-singlet source overlaps are an additional matching layer, not a replacement for the fluctuation calculation.

For stable hadron external states, the physical amplitude is obtained only after applying the usual color-singlet spectral or LSZ extraction to the gauge-invariant correlator. For example, if interpolating sources $\mathcal{I}_H, \mathcal{I}_{H'}$ have nonzero isolated overlaps $Z_H, Z_{H'}$ with stable finite-volume states in the sense of Proposition 49.54, then a termwise semiclassical extraction requires the same pole-residue operation:

$$\mathcal{A}^{(Q=1)}_{H'\leftarrow H} = \left(\overline{Z}_{H'} Z_H\right)^{-1} \operatorname*{Res}_{H',H} G_{\mathcal{I}^\dagger_{H'}\,\mathcal{X}\,\mathcal{I}_H,\Lambda,Q=1}, \tag{51.163}$$

where $\mathcal{X}$ is the chosen gauge-invariant current or source product and the residue notation means the finite-volume large-time projection, or the corresponding infinite-volume pole extraction when it exists. The BPST calculation does not determine $Z_H, Z_{H'}$, the hadronic matrix element of the induced 't Hooft operator, or the long-distance part of $\Phi^{R,L}$. Those are nonperturbative QCD data. In a hard OPE or factorization regime, the small-ρ instanton calculation can supply a Wilson coefficient multiplying a gauge-invariant operator such as $\det[\bar{q}_R q_L]_\mu$; outside such a regime (51.161) is a source correlator, not a prediction for a hadronic amplitude by itself.

The finite-regulator bookkeeping behind (51.160) is entirely finite-dimensional. At finite regulator the fermion fields have finitely many odd coefficients, and every regulated source has a finite expansion in those coefficients. Restricting the source to the instanton zero-mode subspace produces a finite-dimensional polynomial in the zero-mode variables. The hypothesis (51.160) says that, in the chosen hard channel, the part of this polynomial which is bilinear in the right and left zero-mode variables factors through the same amputated zero-mode kernel B^{amp}, with source-dependent overlap maps on the two sides. Substituting this zero-mode source matrix into the Berezin coefficient in Proposition 51.35 gives $\det B^{\mathcal{J}}(z)$, and multiplying by the determinant density and collective-coordinate measure gives (51.161).

The determinant relation (51.162) is the finite identity

$$\det(\Phi^R B^{\mathrm{amp}} \Phi^L) = \det \Phi^R \, \det B^{\mathrm{amp}} \, \det \Phi^L,$$

applied pointwise in the collective coordinate. If the overlaps vary with z, the same identity still holds pointwise but the overlap factors must remain inside the collective-coordinate integral. Finally, because $G_{\mathcal{I}_{H'}^\dagger, \mathcal{X}\, \mathcal{I}_H, \Lambda, Q=1}$ is a correlator of gauge-invariant sources, the hadronic extraction is the standard spectral-residue operation for color-singlet correlators. Applying that operation termwise in a controlled semiclassical expansion gives (51.163); it never produces an ordinary colored-quark S-matrix element.

Controlled Approximation 51.50 (Euclidean instanton kernel to physical amplitude)**.** Let $G^{E,Q=1}_{\mathcal{J},\Lambda}$ be the finite-regulator gauge-invariant Euclidean source correlator obtained from the one-instanton chart after zero modes, nonzero-mode determinants, source projections, and collective coordinates have all been paired. Let

$$\mathcal{A}^{\mathrm{lead}}_{\mathrm{inst}} = \operatorname*{Proj}_{\mathrm{phys}} \operatorname*{Cont}_{\mathcal{S}} G^{E,Q=1}_{\mathcal{J},\mathrm{lead}}$$

denote the result of first replacing the finite-regulator density by the declared leading instanton kernel, then analytically continuing on a specified sheet $\mathcal{S}$, and finally applying the chosen physical projection: a stable-particle pole residue, an inclusive spectral weight, or a hard OPE coefficient. The corresponding physical one-instanton contribution $\mathcal{A}^{Q=1}_{\mathrm{phys}}$ differs from this coordinate by

$$\mathcal{A}^{Q=1}_{\mathrm{phys}} - \mathcal{A}^{\mathrm{lead}}_{\mathrm{inst}} = R_{\mathrm{reg}} + R_{\mathrm{cont}} + R_{\mathrm{spec}} + R_{\mathrm{IR}} + R_{\mathrm{cut}} + R_{\mathrm{match}} + R_\rho. \tag{51.164}$$

Here R_{reg} records finite-volume, cutoff, and order-of-limits errors between the regulated Euclidean sector and its continuum source correlator; R_{cont} records analytic-continuation and sheet choices, including thresholds and singularities crossed by the chosen continuation; R_{spec} records the pole, spectral, or OPE projection error; R_{IR} records confinement, massless radiation, inclusive-sum, or external Wilson-line data not contained in a colored partonic kernel; R_{cut} records unitarity-cut and conjugate-sector effects, including instanton–anti-instanton sectors needed before an S-matrix statement can obey an optical theorem; R_{match} records the matching from the chosen source family to the local operator or hadronic observable; and R_ρ is the remaining instanton-size endpoint and determinant-tail contribution after the selected hard, screened, or Wilsonian window has been declared.

If on the selected kinematic window each residual satisfies

$$|R_\kappa| \le \varepsilon_\kappa, \qquad \kappa \in \{\mathrm{reg}, \mathrm{cont}, \mathrm{spec}, \mathrm{IR}, \mathrm{cut}, \mathrm{match}, \rho\},$$

then

$$\left|\mathcal{A}^{Q=1}_{\mathrm{phys}} - \mathcal{A}^{\mathrm{lead}}_{\mathrm{inst}}\right| \le \sum_\kappa \varepsilon_\kappa. \tag{51.165}$$

The point is not to add another approximation. It is to identify where the physics lives after the moduli-space and determinant calculation has been done. In a weakly coupled Higgsed theory, a thermal screened regime, or a hard Euclidean OPE window, the physical projection and endpoint controls can sometimes be declared explicitly. In confining zero-temperature QCD, a colored four-slot kernel is only a short-distance source coordinate until the gauge-invariant spectral or OPE projection and the long-size remainder have been supplied.

Controlled Approximation 51.51 (Instanton cut pairing for inclusive rates)**.** Stay in the source channel of ControlledApproximation 51.50. After the determinant, zero-mode, orientation, and source-matching factors have been assembled, write a finite one-instanton amplitude coordinate as

$$A_I[\mathcal{J}] = \mathrm{e}^{\mathrm{i}\theta} \int_{\mathcal{U}_I} K_I(z;\mathcal{J})\, \mathrm{d}\nu_I(z), \tag{51.166}$$

where z denotes the collective coordinates and finite fluctuation/source data retained in the chosen regulator. The conjugate channel has an anti-instanton density

$$A_{\bar I}[\mathcal{J}^\dagger] = \mathrm{e}^{-\mathrm{i}\theta} \int_{\mathcal{U}_{\bar I}} K_{\bar I}(\bar z;\mathcal{J}^\dagger)\, \mathrm{d}\nu_{\bar I}(\bar z).$$

A leading inclusive spectral weight or cut rate associated to this amplitude has the paired form

$$\Gamma^{(0)}_{I\bar I}[\mathcal{J}] = \int_{\mathcal{U}_I\times\mathcal{U}_{\bar I}} K_I(z;\mathcal{J})\, K_{\bar I}(\bar z;\mathcal{J}^\dagger)\, \mathcal{C}^{(0)}_{\mathrm{cut}}(z,\bar z)\, \mathrm{d}\nu_I(z)\, \mathrm{d}\nu_{\bar I}(\bar z). \tag{51.167}$$

Here $\mathcal{C}^{(0)}_{\mathrm{cut}}$ contains the chosen leading final-state sum, on-shell or spectral projector, relative $I\bar I$ separation and orientation weight, and leading relative fluctuation determinant. At the factorized level the topological phases cancel in the cut channel,

$$\mathrm{e}^{\mathrm{i}\theta}\mathrm{e}^{-\mathrm{i}\theta} = 1, \qquad \mathrm{e}^{\mathrm{i}\theta}\mathrm{e}^{\mathrm{i}\theta} = \mathrm{e}^{2\mathrm{i}\theta}.$$

Thus a same-charge pair belongs to a charge-two amplitude sector rather than to the amplitude-times-conjugate contribution to a neutral inclusive rate. The semiclassical exponential is correspondingly e^{-2S_I} at this factorized cut level.

The full cut kernel can be organized as

$$\mathcal{C}_{\mathrm{cut}} = \mathcal{C}^{(0)}_{\mathrm{cut}}(1+\delta_{\mathrm{cut}}), \qquad |\delta_{\mathrm{cut}}(z,\bar z)| \le \varepsilon_{\mathrm{cut}},$$

where δ_{cut} absorbs the difference between the declared leading cut package and the actual final-state sum, relative $I\bar I$ interaction, valley or quasi-zero-mode treatment, and nonzero-mode determinant ratio. If

$$M^{(0)}_{I\bar I} = \int |K_I(z;\mathcal{J})|\, |K_{\bar I}(\bar z;\mathcal{J}^\dagger)|\, |\mathcal{C}^{(0)}_{\mathrm{cut}}(z,\bar z)|\, \mathrm{d}\nu_I(z)\, \mathrm{d}\nu_{\bar I}(\bar z) < \infty,$$

then the exact cut contribution satisfies

$$\left|\Gamma_{I\bar{I}}[\mathcal{J}] - \Gamma^{(0)}_{I\bar{I}}[\mathcal{J}]\right| \le \varepsilon_{\text{cut}} M^{(0)}_{I\bar{I}}. \tag{51.168}$$

This is the concrete finite-regulator content of the R_{cut} entry in (51.164). The local 't Hooft vertex supplies the chirality-violating amplitude kernel. Inclusive cross sections, decay rates, and spectral weights require the conjugate anti-instanton density, final-state cut, and relative $I\bar{I}$ fluctuation determinants and interactions in addition to that kernel.

Proposition 51.52 (One-instanton amplitude assembly and error budget)**.** *Fix a finite-regulator $Q = 1$ chart and a gauge-invariant source channel. Let*

$$\mathcal{A}^{\mathcal{J}}_{\Lambda,Q=1} = \int_{\mathcal{U}_{Q=1}} \mathcal{K}_{\text{ex}}(z)\,\mathrm{d}z \tag{51.169}$$

denote the exact one-instanton contribution to the selected source correlator after gauge fixing but before replacing any finite factor by its semiclassical leading term. Choose a controlled subdomain $\mathcal{U}_{\text{hard}} \subset \mathcal{U}_{Q=1}$ and a leading density

$$\mathcal{K}_{\text{lead}}(z) = \mathrm{e}^{\mathrm{i}\theta}\mathcal{C}^{\mathcal{S}}_{\text{pg}}(z)\,\mathcal{R}^{\mathcal{S}}_{\text{f}}(z;\mu)\left(\frac{8\pi^2}{g^2_{\text{ht}}(\mu)}\right)^{2N_c}\exp\left[-\frac{8\pi^2}{g^2_{\text{ht}}(\mu)}\right](\mu\rho)^{b_0}\rho^{-5}\,\mathcal{Z}^0_{\text{lead}}(z). \tag{51.170}$$

Here $\mathcal{C}^{\mathcal{S}}_{\text{pg}}(z)$ is the pure-gauge collective-coordinate and determinant density in the chosen convention. In the Pauli-Villars convention after the embedded orientation orbit has been integrated it contains $C^{\text{PV}}_{N_c}$; in an unintegrated orientation chart it contains the corresponding orientation density instead of an already-integrated orbit volume. The factor $\mathcal{R}^{\mathcal{S}}_{\text{f}}$ is the light-fermion nonzero-mode determinant factor in the same source scheme, and $\mathcal{Z}^0_{\text{lead}}$ is the leading zero-mode source coefficient. Depending on the source type, $\mathcal{Z}^0_{\text{lead}}$ is one of $\det(M^0 + J^0)$, $\det R^{\text{amp}} \det L^{\text{amp}}$, or the color-singlet determinant $\det B^{\mathcal{J}}$ after the source matching of (51.160).

Suppose that on $\mathcal{U}_{\text{hard}}$ the exact density decomposes as

$$\mathcal{K}_{\text{ex}} = \mathcal{K}_{\text{lead}}\big(1 + \varepsilon_{\text{det}} + \varepsilon_{\text{zm}} + \varepsilon_{\text{src}}\big) + \Delta_{\text{Schur}}, \tag{51.171}$$

where ε_{det} records the higher-loop and finite determinant remainder after the chosen determinant convention, ε_{zm} records the zero-mode projection or local-source truncation error, ε_{src} records the color-singlet source-matching or hadronic/OPE matching remainder, and Δ_{Schur} records the finite nonzero-mode Schur correction from (51.120). Then

$$\mathcal{A}^{\mathcal{J}}_{\Lambda,Q=1} = \mathcal{A}^{\mathcal{J}}_{\text{lead}} + R_{\text{det}} + R_{\text{zm}} + R_{\text{src}} + R_{\text{Schur}} + R_{\text{end}}, \tag{51.172}$$

with

$$\mathcal{A}^{\mathcal{J}}_{\text{lead}} = \int_{\mathcal{U}_{\text{hard}}} \mathcal{K}_{\text{lead}}(z)\,\mathrm{d}z, \qquad R_{\text{end}} = \int_{\mathcal{U}_{Q=1}\setminus\mathcal{U}_{\text{hard}}} \mathcal{K}_{\text{ex}}(z)\,\mathrm{d}z.$$

Moreover, whenever the right-hand side is absolutely integrable,

$$\begin{aligned}\big|\mathcal{A}^{\mathcal{J}}_{\Lambda,Q=1} - \mathcal{A}^{\mathcal{J}}_{\text{lead}}\big| \le{}& \int_{\mathcal{U}_{\text{hard}}} |\mathcal{K}_{\text{lead}}|\big(|\varepsilon_{\text{det}}| + |\varepsilon_{\text{zm}}| + |\varepsilon_{\text{src}}|\big)\,\mathrm{d}z \\ &+ \int_{\mathcal{U}_{\text{hard}}} |\Delta_{\text{Schur}}|\,\mathrm{d}z + \int_{\mathcal{U}_{Q=1}\setminus\mathcal{U}_{\text{hard}}} |\mathcal{K}_{\text{ex}}|\,\mathrm{d}z.\end{aligned} \tag{51.173}$$

Thus replacing the finite-regulator instanton contribution by the local 't Hooft operator, or by a hard source-amputated kernel, is justified only after the determinant remainder, zero-mode/source projection, matching remainder, Schur correction, and endpoint integral have all been controlled in the same scheme.

Proof. Split the exact integral into the chosen hard/source domain and its complement:

$$\int_{\mathcal{U}_{Q=1}} \mathcal{K}_{\text{ex}} = \int_{\mathcal{U}_{\text{hard}}} \mathcal{K}_{\text{ex}} + \int_{\mathcal{U}_{Q=1}\setminus\mathcal{U}_{\text{hard}}} \mathcal{K}_{\text{ex}}.$$

Substituting (51.171) on $\mathcal{U}_{\text{hard}}$ gives the five remainders in (51.172). The bound (51.173) is the triangle inequality. The content is the identification of the separate physical origins of the five terms: collective-coordinate geometry supplies only $\mathcal{J}_{\text{coll}}$ or, equivalently, the collective part of $\mathcal{C}^{\mathcal{S}}_{\text{pg}}$ and the integration domain; the fluctuation determinant, light-fermion nonzero-mode factor, zero-mode source coefficient, source matching, and endpoint behavior are independent load-bearing inputs to the amplitude. □

Consequently an instanton moduli-space measure by itself is never the computed QFT amplitude. It becomes a physical contribution only after it is multiplied by the nonzero-mode fluctuation determinant, the correctly typed zero-mode source coefficient, the source or hadron matching data, and an endpoint estimate for the selected kinematic regime. The original one-instanton calculation is deep precisely because it performs this whole assembly, rather than because it merely parametrizes the BPST collective coordinates.

Controlled Approximation 51.53 (Hard-momentum size window)**.** Consider the $N_f = 2$ source-amputated four-fermion kernel (51.149) in a kinematic region where the hard arguments of the zero-mode form factors are

$$|k_\ell| = c_\ell Q, \qquad c_\ell > 0, \qquad \ell = 1, \dots, m,$$

with Q much larger than the infrared scale of the theory. For differentiated external fermion slots, $m = 4$ and the $\mathcal{F}_\ell$ below are the individual amputated zero-mode form factors of Proposition 51.45. In the singular-gauge normalization, $\mathcal{F}_\ell(c_\ell Q\rho) = F_{\text{zm}}(c_\ell Q\rho/2)$, up to the fixed spin-color tensor already included in $\mathcal{C}_{\text{hard}}$. For a fused bilinear source, $m = 2$ and $\mathcal{F}_\ell(z) = zK_1(z)$. Keep only the one-loop universal density, the total four-zero-mode power ρ^6, and the dimensionless hard form-factor product $\prod_{\ell=1}^m \mathcal{F}_\ell(c_\ell Q\rho)$. Choosing $\mu = Q$, the corresponding size factor has the form

$$\mathcal{I}_{\text{hard}}(Q) = \exp\left[-\frac{8\pi^2}{g^2_{\text{ht}}(Q)} + \mathrm{i}\theta\right] \left(\frac{8\pi^2}{g^2_{\text{ht}}(Q)}\right)^{2N_c} Q^{b_0} \int_0^\infty \rho^{\,b_0+1} \prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell Q\rho)\,\mathrm{d}\rho \times \mathcal{C}_{\text{hard}}, \tag{51.174}$$

up to finite determinant remainders, orientation tensors, source normalizations, and higher-loop matching factors. With $s = Q\rho$,

$$Q^{b_0} \int_0^\infty \rho^{\,b_0+1} \prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell Q\rho)\,\mathrm{d}\rho = Q^{-2} \int_0^\infty s^{\,b_0+1} \prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell s)\,\mathrm{d}s. \tag{51.175}$$

This Q^{-2} is the engineering dimension of the source-amputated four-fermion coefficient after the renormalization point has been set to $\mu = Q$. If the one-loop running exponential is instead traded for the RG-invariant scale

$$\Lambda_{\text{ht}}^{b_0} = Q^{b_0} \exp\left[-\frac{8\pi^2}{g^2_{\text{ht}}(Q)}\right] \quad \text{at one-loop order,}$$

then the same hard factor is

$$\mathcal{I}_{\mathrm{hard}}(Q) = \mathrm{e}^{\mathrm{i}\theta} \left(\frac{8\pi^2}{g_{\mathrm{ht}}^2(Q)} \right)^{2N_c} \Lambda_{\mathrm{ht}}^{b_0} \, Q^{-b_0-2} \, \mathcal{J}_{b_0}(\mathbf{c};\mathcal{F}) \, \mathcal{C}_{\mathrm{hard}}, \tag{51.176}$$

with

$$\mathcal{J}_{b_0}(\mathbf{c};\mathcal{F}) = \int_0^\infty s^{\,b_0+1} \prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell s) \, \mathrm{d}s.$$

Thus the semiclassical exponential and the size measure together become a power-suppressed hard coefficient. The remaining displayed $(8\pi^2/g_{\mathrm{ht}}^2(Q))^{2N_c}$ is the familiar one-loop collective-mode Jacobian prefactor; higher-loop matching changes the logarithmic factor and scheme coordinate, not the endpoint mechanism described here. The small-ρ endpoint is finite in asymptotically free QCD because the integrand behaves as ρ^{b_0+1}. The large-ρ endpoint depends on which source construction is being used. For fused bilinear density entries, $zK_1(z)$ gives the exponential cutoff

$$\prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell Q\rho) = O((Q\rho)^\gamma \exp[-d(\mathbf{c})Q\rho]) \,, \qquad d(\mathbf{c}) > 0, \qquad Q\rho \to \infty.$$

For differentiated singular-gauge fermion slots, however, (51.146) gives only the power behavior

$$\prod_{\ell=1}^{m} F_{\mathrm{zm}}(c_\ell Q\rho/2) = O\big((Q\rho)^{-3m}\big) \qquad (c_\ell > 0).$$

The large-ρ part of the size integral is then controlled only if

$$b_0 + 1 - 3m < -1. \tag{51.177}$$

For the $N_f = 2$ four-slot hard kernel, $m = 4$, so this condition is $b_0 < 10$; in $SU(3)$ QCD with two Dirac fundamentals, $b_0 = 29/3$, and the margin is $1/3$. If a determinant monomial contains a soft slot with $c_\ell = 0$, or if the power test fails, the hard source profile has not by itself produced a controlled large-size instanton amplitude. This is a physical endpoint condition in the amplitude integral, not a cutoff on the instanton moduli space. The approximation is controlled only when the dominant range also has $1/\rho$ in the weak-coupling regime.

Controlled Approximation 51.54 (Hard-size dominance versus endpoint convergence)**.** The convergence test in (51.177) is not yet a dominance statement. In the notation of (51.174), set

$$\mathcal{F}_{\mathrm{hard}}(s) = \prod_{\ell=1}^{m} \mathcal{F}_\ell(c_\ell s), \qquad a = b_0 + 1.$$

After the change of variables $s = Q\rho$, the absolute tail of the one-loop hard size integral outside the band $\rho \le R/Q$ is

$$Q^{b_0} \int_{R/Q}^{\infty} \rho^{\,b_0+1} \, |\mathcal{F}_{\mathrm{hard}}(Q\rho)| \, \mathrm{d}\rho = Q^{-2} \int_R^\infty s^{\,a} \, |\mathcal{F}_{\mathrm{hard}}(s)| \, \mathrm{d}s. \tag{51.178}$$

Thus a statement that the amplitude is dominated by instantons of size $\rho \sim Q^{-1}$ requires a bound on the right-hand tail in addition to the formal local vertex.

For example, suppose that for $s \geq s_0$

$$|\mathcal{F}_{\mathrm{hard}}(s)| \leq C_\infty s^{-\sigma}, \qquad \sigma > b_0 + 2.$$

Then for $R \geq s_0$,

$$Q^{b_0} \int_{R/Q}^{\infty} \rho^{\,b_0+1} \, |\mathcal{F}_{\mathrm{hard}}(Q\rho)| \, \mathrm{d}\rho \leq Q^{-2} \, \frac{C_\infty \, R^{\,b_0+2-\sigma}}{\sigma - b_0 - 2}. \tag{51.179}$$

If instead the fused bilinear-density source gives $|\mathcal{F}_{\mathrm{hard}}(s)| \leq C_\infty s^\gamma e^{-ds}$, $d > 0$, then the corresponding tail is bounded by

$$Q^{-2} C_\infty \int_R^\infty s^{\,b_0+1+\gamma} e^{-ds} \, \mathrm{d}s,$$

and is exponentially small once R is large. The two source constructions therefore have different endpoint control.

For the differentiated singular-gauge four-slot $SU(3)$, $N_f = 2$ hard kernel, the individual zero-mode form factors have $\sigma = 3m = 12$, while $b_0 = 29/3$. Hence

$$b_0 + 2 - \sigma = -\frac{1}{3}.$$

The contribution from $\rho > R/Q$ is only $O(R^{-1/3})$, up to the spin-color and c_ℓ-dependent constants. The size integral is convergent, but the convergence margin is narrow: claiming that the one-instanton hard kernel is numerically dominated by $\rho \sim Q^{-1}$ requires an additional estimate showing that this slowly decaying tail is small in the chosen source and kinematic window. This is a physical endpoint-control hypothesis on the amplitude, not a property of the BPST moduli coordinates alone.

The same statement is often clearer per logarithmic size shell. Define the absolute log-shell density after the hard change of variables by

$$\mathfrak{s}_{\mathrm{hard}}(s) = s^{\,b_0+2} \, |\mathcal{F}_{\mathrm{hard}}(s)|, \qquad Q^{b_0} \rho^{\,b_0+1} |\mathcal{F}_{\mathrm{hard}}(Q\rho)| \, \mathrm{d}\rho = Q^{-2} \mathfrak{s}_{\mathrm{hard}}(s) \, \mathrm{d} \log s. \tag{51.180}$$

If $|\mathcal{F}_{\mathrm{hard}}(s)| \leq C_\infty s^{-\sigma}$, the shell and the tail both decay with the exponent

$$\Delta = \sigma - b_0 - 2.$$

For the $SU(3)$, $N_f = 2$ differentiated four-slot kernel, $\Delta = 1/3$. One extra decade in the cutoff R then suppresses the tail by only $10^{-1/3}$, and a tenfold suppression of this power-tail majorant requires three decades in R. With the normalized bound used in (51.179), the tail estimate is

$$3R^{-1/3};$$

making this smaller than 0.1 requires $R > 27000$. This number is not a prediction of the amplitude. It is a warning about evidence: a formally hard one-instanton coefficient is not physically dominated by small instantons until the chosen source profile, kinematics, or matching calculation improves this log-shell bound.

Controlled Approximation 51.55 (Hard source envelope with physical screening)**.** The hard and screened size estimates above address different failures of the same amplitude integral. A hard source can suppress large instantons through external form factors, while a physical Higgs, thermal, or medium scale can screen them through the fluctuation determinant. When both mechanisms are present, the dominant size is not obtained by choosing whichever formula is more convenient. It is fixed by the combined size density.

Assume that in the selected one-instanton channel the absolute value of the fully assembled density is bounded in the retained window by

$$|\mathcal{K}(\rho)| \le K_0\, \rho^{A-1} \exp[-dQ\rho - m_{\rm scr}^2\rho^2], \qquad A > 0, \quad d > 0, \quad m_{\rm scr} > 0. \tag{51.181}$$

Here $A = b_0 + \beta_{\mathcal{X}} - 4$ contains the collective density, determinant convention, and zero-mode/source power of the chosen amplitude channel. The coefficient dQ is a proven exponential envelope for the hard form factors or source wave packets; it is absent for the differentiated individual zero-mode slots unless such a stronger source bound has actually been supplied. The scale $m_{\rm scr}$ is a physical screening mass from the same regulated problem, not a hand-inserted cutoff.

The absolute logarithmic size shell of the majorant is

$$\rho^A \exp[-dQ\rho - m_{\rm scr}^2\rho^2]\, \mathrm{d}\log\rho.$$

Its stationary point solves

$$2m_{\rm scr}^2\rho_*^2 + dQ\rho_* - A = 0, \qquad \rho_* = \frac{2A}{dQ + \sqrt{d^2Q^2 + 8Am_{\rm scr}^2}}. \tag{51.182}$$

Thus the hard-only shell $A/(dQ)$ and the screened-only shell $\sqrt{A/2}/m_{\rm scr}$ are limiting coordinates of one combined problem:

$$\frac{\rho_*}{A/(dQ)} = \frac{2}{1 + \sqrt{1 + 8Am_{\rm scr}^2/(d^2Q^2)}}.$$

The two limiting diagnostics are

$$\epsilon_{\rm hard} = \frac{Am_{\rm scr}}{dQ}, \qquad \epsilon_{\rm scr} = \frac{dQ}{m_{\rm scr}}\sqrt{\frac{A}{2}}.$$

If $\epsilon_{\rm hard} \ll 1$, the hard envelope sets the shell and screening is a perturbation. If $\epsilon_{\rm scr} \ll 1$, the physical screening scale sets the shell and the hard source is only a slowly varying factor. In the intermediate regime the two suppressions cooperate and the dominant size is smaller than either pure estimate.

This criterion is deliberately stronger than convergence. A hard instanton coefficient is a controlled short-distance object only if the combined shell and a surrounding tail bound lie inside a weak-coupling region,

$$\Lambda_{\rm QCD}\rho_* \ll 1$$

or inside the corresponding Higgs/thermal weak-coupling window. If ρ_* is instead set by a soft screening scale comparable to the confinement scale, the formula is at best an absolute majorant on a semiclassical coordinate; it is not a derivation of a physical QCD amplitude. This is exactly the point hidden by a moduli-space-only discussion: the collective coordinate supplies the integration variable, but the determinant, zero-mode form factors, physical screening, and endpoint estimate decide whether the instanton sector contributes a controlled observable coefficient.

Controlled Approximation 51.56 ($SU(3)$, two-flavor hard instanton coefficient)**.** Specialize the source-amputated four-slot construction to vectorlike $SU(3)$ QCD with $N_f = 2$ Dirac fundamentals. Use the Pauli–Villars pure-gauge convention of Proposition 51.32, choose a finite normalization of the light-fermion nonzero-mode determinant in the same scheme, and suppose all four differentiated external zero-mode slots are hard:

$$|k_\ell| = c_\ell Q, \qquad c_\ell > 0, \qquad \ell = 1, \ldots, 4.$$

Let $\mathcal{P}_{\mathrm{orient}}$ denote the shared $SU(2)$ orientation projector of (51.158), contracted with the chosen spin-color source covectors. In the leading one-instanton hard window, the short coefficient multiplying the selected four-fermion source tensor has the form

$$\begin{aligned} C^{(4)}_{\mathrm{inst}}(Q;R) = \mathrm{e}^{\mathrm{i}\theta}\, C_3^{\mathrm{PV}}\, \mathcal{R}_{\mathrm{f}}^{\mathrm{PV}}(Q) \left(\frac{8\pi^2}{g^2_{\mathrm{ht}}(Q)}\right)^6 \Lambda_{\mathrm{ht}}^{29/3}\, Q^{-35/3} \\ \times \mathcal{P}_{\mathrm{orient}} \int_0^R s^{32/3} \prod_{\ell=1}^4 F_{\mathrm{zm}}(c_\ell s/2)\,\mathrm{d}s + R_{\mathrm{det}} + R_{\mathrm{zm}} + R_{\mathrm{src}} + R_{\mathrm{Schur}} + R_{s>R}. \end{aligned} \tag{51.183}$$

Here $C_3^{\mathrm{PV}} \simeq 1.51 \times 10^{-3}$ is the orientation-integrated pure-gauge constant in (51.94), while $\mathcal{R}_{\mathrm{f}}^{\mathrm{PV}}$ is not fixed by the pure-gauge determinant calculation; it is the finite light-fermion nonzero-mode determinant factor of the same regulator and source normalization, with the finite-frame covariance fixed by Proposition 51.41. The five remainders are the determinant, zero-mode/source, source-matching, Schur, and endpoint residuals of Proposition 51.52.

The powers in (51.183) are fixed as follows. For $SU(3)$ with two Dirac fundamentals,

$$b_0 = \frac{11}{3}3 - \frac{2}{3}2 = \frac{29}{3}.$$

The four differentiated zero-mode slots supply ρ^6, so the size integrand before form factors is ρ^{b_0+1}. After $s = Q\rho$ and the one-loop trade $\exp[-8\pi^2/g^2_{\mathrm{ht}}(Q)]Q^{b_0} = \Lambda_{\mathrm{ht}}^{b_0}$, the hard coefficient carries

$$\Lambda_{\mathrm{ht}}^{29/3} Q^{-29/3-2} = \Lambda_{\mathrm{ht}}^{29/3} Q^{-35/3}.$$

Thus the dimension of the coefficient is -2, as required for a source-amputated four-fermion operator. This dimension count is not a standalone amplitude: the orientation projector, the light-fermion determinant, the zero-mode form factors, and the endpoint residual are still part of the calculation.

The endpoint term is especially restrictive. From (51.146),

$$F_{\mathrm{zm}}(c_\ell s/2) = 6 c_\ell^{-3} s^{-3} + O(s^{-5}), \qquad s \to \infty.$$

Therefore

$$\int_R^\infty s^{32/3} \prod_{\ell=1}^4 F_{\mathrm{zm}}(c_\ell s/2)\,\mathrm{d}s = 3 \cdot 6^4 \left(\prod_{\ell=1}^4 c_\ell^{-3}\right) R^{-1/3} + O(R^{-7/3}). \tag{51.184}$$

So even this hard four-slot coefficient has only a slow $R^{-1/3}$ endpoint tail unless the external source construction supplies stronger suppression. This is the amplitude-level warning in 't Hooft's calculation: the BPST moduli measure, the determinant constant, and the zero-mode tensor do not yet give a controlled physical four-point contribution until the hard-source tail and the remaining remainders have been bounded in the same scheme.

Controlled Approximation 51.57 (Instanton size-factor split)**.** Let $K_\Lambda(\rho;\mu,\mathcal{J})$ denote the fully paired finite-regulator one-instanton size integrand for a selected source family: the center phase, orientation tensor, nonzero-mode determinant, zero-mode source coefficient, and any anomaly-line pairing have already been included. Fix a finite upper regulator $\rho_{\max}$ and a factorization scale μ_I with

$$0 < \rho_I := \mu_I^{-1} < \rho_{\max}.$$

Then the exact finite-regulator contribution on this size window has the split

$$\mathcal{A}_\Lambda^{[0,\rho_{\max}]} = \mathcal{A}_\Lambda^{<}(\mu_I) + \mathcal{A}_\Lambda^{>}(\mu_I), \qquad \mathcal{A}_\Lambda^{<}(\mu_I) = \int_0^{\rho_I} K_\Lambda(\rho)\,\mathrm{d}\rho, \quad \mathcal{A}_\Lambda^{>}(\mu_I) = \int_{\rho_I}^{\rho_{\max}} K_\Lambda(\rho)\,\mathrm{d}\rho. \tag{51.185}$$

If K_Λ is continuous at ρ_I, the factorization-scale derivatives are the boundary flux through the artificial cut:

$$\partial_{\log\mu_I}\mathcal{A}_\Lambda^{<}(\mu_I) = -\rho_I K_\Lambda(\rho_I), \qquad \partial_{\log\mu_I}\mathcal{A}_\Lambda^{>}(\mu_I) = +\rho_I K_\Lambda(\rho_I). \tag{51.186}$$

Thus $\mathcal{A}_\Lambda^{[0,\rho_{\max}]}$ is independent of μ_I, while the short-size piece alone is not.

The semiclassical local 't Hooft vertex is therefore a Wilsonian object. If one replaces K_Λ by the one-loop small-size approximation $K_{\mathrm{sc}}^{<}$ only for $0 < \rho < \rho_I$, then

$$C_{\mathrm{inst}}^{<}(\mu_I;\mathcal{J}) = \int_0^{\rho_I} K_{\mathrm{sc}}^{<}(\rho;\mu,\mathcal{J})\,\mathrm{d}\rho$$

is a short-instanton coefficient. Its $-\rho_I K_{\mathrm{sc}}^{<}(\rho_I)$ scale derivative is cancelled only by the long-distance matrix element or remainder assigned to $\rho > \rho_I$, up to the matching error between K_Λ and $K_{\mathrm{sc}}^{<}$ near the cut. Discarding that long part leaves a spurious μ_I-dependence whose size is precisely the boundary density. For a hard external scale Q, choosing $\rho_I = R/Q$ identifies this boundary term with the same large-size tail diagnostic in (51.178). The computed short-instanton coefficient is useful only when this boundary flux and the remaining $\rho > \rho_I$ contribution are controlled by the physical source, screening scale, phase, or matching calculation under consideration.

Controlled Approximation 51.58 (Short-instanton OPE coefficient)**.** The short side of ControlledApproximation 51.57 becomes a local 't Hooft vertex only after it is projected onto a renormalized local operator basis. Let $\{[O_I]_\mu\}_{I\in\mathcal{B}}$ be a finite source-normalized basis in the selected quantum-number channel, containing $[\det(\bar{q}_R q_L)]_\mu$ and any operators of the same dimension and symmetry which are retained by the chosen hard OPE. Suppose the short-size part of a gauge-invariant source correlator admits the expansion

$$G_{\mathcal{J},\Lambda}^{<}(\mu_I) = \sum_{I\in\mathcal{B}} C_I^{<}(\mu_I,\mu)\ \langle \mathcal{J}\,[O_I]_\mu\rangle + R_{\mathrm{OPE}}^{<}(\mu_I,\mu). \tag{51.187}$$

The coefficient $C_I^{<}$ is obtained by integrating the small-size instanton density, the nonzero-mode determinant, the zero-mode source coefficient, and the orientation tensor against the projector onto $[O_I]_\mu$, over $0 < \rho < \rho_I = \mu_I^{-1}$. For the leading $N_f = 2$ determinant channel, this is the coefficient of $[\det(\bar{q}_R q_L)]_\mu$; derivative operators, mass insertions, and source-matching remnants belong either to the retained basis or to $R_{\mathrm{OPE}}^{<}$.

This projection has two different scale laws. The renormalization scale μ is the composite-operator scale. In the convention of Chapter 34,

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu}[O_I]_\mu = -\gamma_{IK}(\mu)[O_K]_\mu.$$

Therefore the coefficient row must obey

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu} C_K^{<}(\mu_I,\mu) = \sum_{I\in\mathcal{B}} C_I^{<}(\mu_I,\mu)\,\gamma_{IK}(\mu) \tag{51.188}$$

up to the truncation error $R_{\mathrm{OPE}}^{<}$. A finite operator-frame change $[\widetilde{O}_A]_\mu = M_{AI}(\mu)[O_I]_\mu$ changes the displayed coefficient by the inverse rule

$$\widetilde{C}_A^{<} = C_I^{<}(M^{-1})_{IA}, \qquad \sum_A \widetilde{C}_A^{<}[\widetilde{O}_A]_\mu = \sum_I C_I^{<}[O_I]_\mu. \tag{51.189}$$

Thus the local 't Hooft vertex coefficient is not a scheme-independent number; only its pairing with the renormalized operator basis and matrix elements is.

The factorization scale μ_I is different. If $K_I^{\mathrm{OPE}}(\rho;\mu)$ is the $[O_I]_\mu$-projected short-size integrand, then

$$\partial_{\log\mu_I} C_I^{<}(\mu_I,\mu) = -\rho_I K_I^{\mathrm{OPE}}(\rho_I;\mu). \tag{51.190}$$

This artificial boundary flow is not cancelled by operator anomalous dimensions. It is cancelled by the long-size matrix element or remainder, as in (51.186). Consequently a standalone local 't Hooft operator with no declared μ_I, no operator scheme, and no long-distance remainder is not a physical instanton amplitude.

This hard-size window is the amplitude counterpart of the local 't Hooft vertex. The local operator records the $Q\rho \ll 1$ tensor and selection rule, while (51.174) records how the same zero modes and fluctuation determinant enter an actual hard correlator. It also explains why the mass-saturated vacuum activity below is a different object: a vacuum theta term has no external form factor to exclude $\rho \to \infty$, so its large-size behavior is an infrared question, not a semiclassical prediction.

Thus the $Q = 1$ amplitude is the microscopic origin of the $U(1)_A$ selection rule. The determinant in (51.105) carries axial charge $2N_f$; equivalently, a mass-saturated instanton contribution depends on the CP-odd combination $\bar{\theta} = \theta + \arg\det M$ from (51.49). This gives the same anomalous Jacobian in the coordinate system where the fermion zero modes of the instanton background have been integrated.

Controlled Approximation 51.59 (Mass-saturated vacuum activity and the size integral)**.** Assume vectorlike $SU(N_c)$ QCD with N_f Dirac fundamentals, a diagonal renormalized mass matrix $M(\mu)$, and a one-instanton size window $\rho_- < \rho < \rho_+$ in which the one-loop density and the leading zero-mode mass overlaps are valid. In the same local normalization as (51.105), saturating one Dirac zero-mode pair by the mass term supplies the dimensionless factor $m_f(\mu)\rho$. Thus the mass-saturated one-instanton vacuum activity in this window has the form

$$\zeta_m^{[\rho_-,\rho_+]}(\mu) = \mathcal{C}_{\mathcal{S},N_c,N_f}\left(\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)}\right)^{2N_c} \exp\left[-\frac{8\pi^2}{g_{\mathrm{ht}}^2(\mu)}\right] |\det M(\mu)|\,\mu^{b_0} \int_{\rho_-}^{\rho_+} \rho^{\,b_0+N_f-5}\,\mathrm{d}\rho, \tag{51.191}$$

up to higher-loop/operator-renormalization factors of the chosen scheme. The constant $\mathcal{C}_{\mathcal{S},N_c,N_f}$ contains the pure-gauge orientation and determinant convention together with the light-fermion nonzero-mode factor $\mathcal{R}_{\mathrm{f}}^{\mathcal{S}}$ of Proposition 51.40, evaluated in the same small-mass window. It does not include the displayed $\prod_f(m_f\rho)$ factor: that product is the zero-mode saturation determinant. The corresponding $Q = 1$ vacuum term carries the phase

$$V_4\zeta_m^{[\rho_-,\rho_+]}\exp[\mathrm{i}(\theta + \arg\det M)]\,, \tag{51.192}$$

while the anti-instanton term carries the complex conjugate phase.

The displayed size integral isolates the two endpoint questions:

$$\int_{\rho_-}^{\rho_+} \rho^{\,b_0+N_f-5}\,\mathrm{d}\rho = \begin{cases} \dfrac{\rho_+^{\,b_0+N_f-4} - \rho_-^{\,b_0+N_f-4}}{b_0+N_f-4}, & b_0+N_f \neq 4, \\ \log(\rho_+/\rho_-), & b_0+N_f = 4. \end{cases} \tag{51.193}$$

The small-size endpoint is locally finite precisely when $b_0 + N_f > 4$. For $SU(3)$, this margin is

$$b_0 + N_f - 4 = 7 + \frac{N_f}{3},$$

so the mass-saturated one-instanton vacuum term is not obstructed at $\rho = 0$ in the asymptotically free range. The same positive power means that extending the one-loop formula to $\rho_+ = \infty$ would give an infrared power divergence. That divergence is not a new ultraviolet counterterm; it says that the zero-temperature large-size region is outside the controlled weak-coupling instanton calculation. A finite dilute activity therefore requires an additional physical infrared cutoff or mechanism, such as a Higgs scale, a thermal screening scale, or a separately justified confining/chiral-dynamics input.

If one quark is massless and no external source saturates its zero modes, $\det M = 0$ and the vacuum activity (51.191) vanishes. This is compatible with nonzero instanton contributions to fermionic correlators: those correlators use the source-differentiated zero-mode coefficient in (51.135) instead of the mass determinant in (51.191).

Proposition 51.60 (Screened one-instanton size integral)**.** *Let a selected one-instanton amplitude channel have the one-loop small-size density*

$$K_{\mathrm{sc}}(\rho) = K_0\,\rho^{A-1}, \qquad A = b_0 + \beta_{\mathcal{X}} - 4 > 0,$$

after the collective-coordinate density, nonzero-mode determinant convention, and zero-mode source coefficient have been assembled. Suppose a physical infrared mechanism in the same regulated problem contributes a positive screening factor

$$\exp[-m_{\mathrm{scr}}^2\rho^2], \qquad m_{\mathrm{scr}} > 0,$$

for example from Higgsing, thermal screening, or a declared source envelope. The screened leading contribution is then

$$\mathcal{A}_{\mathrm{scr}}^{(0)} = K_0 \int_0^\infty \rho^{A-1} \mathrm{e}^{-m_{\mathrm{scr}}^2\rho^2}\,\mathrm{d}\rho = \frac{K_0}{2}\, m_{\mathrm{scr}}^{-A}\,\Gamma\!\left(\frac{A}{2}\right). \tag{51.194}$$

In the leading screened density, even moments of the instanton size are

$$\left\langle \rho^{2n}\right\rangle_0 = m_{\mathrm{scr}}^{-2n}\frac{\Gamma(A/2+n)}{\Gamma(A/2)}, \qquad m_{\mathrm{scr}}^2\langle\rho^2\rangle_0 = \frac{A}{2}. \tag{51.195}$$

If $A > 1$, the logarithmic size-shell density $\rho^A \exp[-m_{\mathrm{scr}}^2\rho^2]$ is stationary at

$$m_{\mathrm{scr}}^2\rho_{\mathrm{shell}}^2 = \frac{A}{2}, \tag{51.196}$$

while the ordinary $\mathrm{d}\rho$*-density is stationary at*

$$m_{\mathrm{scr}}^2\rho_{\mathrm{dens}}^2 = \frac{A-1}{2}. \tag{51.197}$$

For $SU(3)$ *with* $N_f = 2$ *massive Dirac fundamentals in the mass-saturated vacuum channel,* $\beta_{\mathcal{X}} = N_f$ *and*

$$A = b_0 + N_f - 4 = \frac{23}{3}.$$

Thus the screened leading activity is proportional to

$$m_{\mathrm{scr}}^{-23/3}\Gamma(23/6), \qquad m_{\mathrm{scr}}^2\langle\rho^2\rangle_0 = \frac{23}{6}, \qquad m_{\mathrm{scr}}^2\rho_{\mathrm{shell}}^2 = \frac{23}{6}.$$

This is a controlled amplitude formula only when the same physical screening scale keeps the dominant shell inside the weak-coupling and finite-regulator window. Sending $m_{\mathrm{scr}} \to 0$ *recovers the infrared divergence of* (51.193)*; the screened formula is not a license to use the one-loop instanton density at arbitrarily large size.*

Proof. The substitution $u = m_{\mathrm{scr}}^2\rho^2$ gives

$$\int_0^\infty \rho^{A-1}\mathrm{e}^{-m_{\mathrm{scr}}^2\rho^2}\,\mathrm{d}\rho = \frac{1}{2}m_{\mathrm{scr}}^{-A}\int_0^\infty u^{A/2-1}\mathrm{e}^{-u}\,\mathrm{d}u,$$

which is (51.194). Dividing the same integral with A replaced by $A+2n$ by the $n=0$ integral gives (51.195). The stationary-shell formulas come from differentiating $A\log\rho - m_{\mathrm{scr}}^2\rho^2$ for the $\mathrm{d}\log\rho$ shell and $(A-1)\log\rho - m_{\mathrm{scr}}^2\rho^2$ for the ordinary density. The $SU(3)$, $N_f = 2$ specialization substitutes $b_0 = 29/3$ and $\beta_{\mathcal{X}} = 2$. □

Controlled Approximation 51.61 (Thermal determinant screening of the size integral)**.** Consider weak-coupling finite-temperature $SU(N_c)$ QCD with N_f light Dirac fundamentals and a one-instanton amplitude channel whose zero-temperature small-size density has the form used in Proposition 51.60. The leading high-temperature fluctuation determinant around the periodic one-instanton background supplies the Gaussian size weight

$$K_T(\rho) = K_0\,\rho^{A-1}\exp[-m_T^2\rho^2]\,\exp[R_T(\rho)], \qquad m_T^2 = \pi^2T^2\,\frac{2N_c+N_f}{3}. \tag{51.198}$$

Here R_T denotes the nonquadratic finite-temperature determinant and caloron-shape remainder in the same regulator and source convention. In the trace-delta coupling convention of Chapter 130, (130.2) gives

$$\frac{m_D^2}{g_{\mathrm{YM}}^2} = T^2\,\frac{2N_c+N_f}{3}$$

for fundamental Dirac matter, so $m_T^2 = \pi^2 m_D^2/g_{\mathrm{YM}}^2$. The thermal instanton cutoff is therefore a determinant response of the plasma, not a classical bound on the BPST moduli space.

If the chosen amplitude window controls the residual by

$$|R_T(\rho)| \le \varepsilon_T,$$

define the Gaussian approximation

$$\mathcal{A}_T^G = \frac{K_0}{2}\left(\pi^2T^2\frac{2N_c+N_f}{3}\right)^{-A/2}\Gamma\left(\frac{A}{2}\right) \tag{51.199}$$

and the absolute Gaussian majorant

$$\mathcal{M}_T^G = \frac{|K_0|}{2}\left(\pi^2 T^2 \frac{2N_c + N_f}{3}\right)^{-A/2} \Gamma\left(\frac{A}{2}\right). \tag{51.200}$$

Since $|e^{R_T(\rho)} - 1| \le e^{\varepsilon_T} - 1$, the general source-projected amplitude satisfies the manifestly positive estimate

$$\left|\mathcal{A}_T - \mathcal{A}_T^G\right| \le \left(e^{\varepsilon_T} - 1\right)\mathcal{M}_T^G \tag{51.201}$$

whenever the same size window contains the support of the amplitude. The stronger positive-activity form

$$\left|\mathcal{A}_T - \mathcal{A}_T^G\right| \le \left(e^{\varepsilon_T} - 1\right)\mathcal{A}_T^G$$

is allowed only when $K_0 \ge 0$ and the residual is real in the selected channel, so that the integrand is a positive activity density. If $K_0 = e^{i\varphi}|K_0|$ has a fixed phase and R_T is real, the same proof gives the fixed-phase estimate with $|\mathcal{A}_T^G|$ on the right-hand side. For a genuinely complex source amplitude, only (51.201) is an absolute-error bound. The leading thermal size moments are the moments in (51.195) with $m_{\rm scr} = m_T$; in a complex channel they are moments of the Gaussian majorant, not probability moments of the amplitude itself.

For the mass-saturated $SU(3)$, $N_f = 2$ vacuum channel,

$$m_T^2 = \frac{8}{3}\pi^2 T^2, \qquad A = \frac{23}{3},$$

so

$$\mathcal{A}_T^G = \frac{K_0}{2}\left(\frac{8}{3}\pi^2 T^2\right)^{-23/6} \Gamma\left(\frac{23}{6}\right), \qquad \pi^2 T^2 \langle \rho^2 \rangle_G = \pi^2 T^2 \rho_{\rm shell}^2 = \frac{23}{16}. \tag{51.202}$$

The formula is useful only in a regime where the periodic-instanton determinant, the residual R_T, and the source or volume limits are controlled. Near the thermal transition, or in zero-temperature QCD after sending $T \to 0$, it does not replace the large-size dynamics by a semiclassical prediction.

Controlled Approximation 51.62 (Dilute instanton gas as an amplitude expansion)**.** Suppose the regulated one-instanton and one-anti-instanton amplitudes obtained above admit finite, translation-invariant vacuum activities ζ_Λ per Euclidean four-volume after the size, orientation, nonzero-mode determinant, and any required zero-mode mass-overlap factors have all been included. Assume further that the multi-instanton cluster expansion has a window in which overlap corrections, instanton–anti-instanton interactions, and boundary-face remainders contribute $o(V_4)$ to $\log Z$. Then the leading dilute-gas theta dependence is not a new moduli-space statement; it is the Poisson sum of the already constructed amplitudes:

$$\frac{Z_{\rm dig}(\bar\theta)}{Z_0} = \sum_{n_+, n_- \ge 0} \frac{(V_4\zeta_\Lambda)^{n_+}}{n_+!}\frac{(V_4\zeta_\Lambda)^{n_-}}{n_-!} e^{i(n_+ - n_-)\bar\theta} = \exp\left(2V_4\zeta_\Lambda \cos\bar\theta\right). \tag{51.203}$$

Thus the vacuum-energy difference in this approximation is

$$E_{\rm dig}(\bar\theta) - E_{\rm dig}(0) = 2\zeta_\Lambda(1 - \cos\bar\theta), \tag{51.204}$$

and the topological-charge cumulants at $\bar\theta = 0$ obey

$$\kappa_{2m}(Q) = 2V_4\zeta_\Lambda, \qquad \kappa_{2m+1}(Q) = 0, \qquad \chi_{\rm top}^{\rm dig} = 2\zeta_\Lambda. \tag{51.205}$$

Equivalently, writing

$$E_{\mathrm{dig}}(\bar\theta) - E_{\mathrm{dig}}(0) = \frac{1}{2}\chi_{\mathrm{top}}^{\mathrm{dig}}\bar\theta^2\left(1 + b_2^{\mathrm{dig}}\bar\theta^2 + O(\bar\theta^4)\right)$$

gives $b_2^{\mathrm{dig}} = -1/12$.

This is a controlled semiclassical amplitude expansion only when the activity is finite and dilute in the relevant correlation volume. If a massless quark zero mode is not saturated by a mass or source, the vacuum activity for this term vanishes; instanton sectors may still contribute to fermionic correlators such as (51.135). If the ρ-integral is infrared divergent, if small-instanton boundary terms are not controlled, or if instanton interactions are not negligible, then the Poisson form (51.203) has not been derived. In particular, this dilute four-dimensional gas is not a derivation of confinement in zero-temperature Yang–Mills. Its output is the conditional theta-dependence and zero-mode-saturated amplitude data above.

Controlled Approximation 51.63 (First cluster correction to the dilute instanton gas)**.** The Poisson formula (51.203) is the zeroth term in a cluster expansion. The collective-coordinate chart supplies the integration variables, while the finite-regulator amplitude scheme must also supply finite two-body connected cluster integrals $\mathfrak{B}_{\sigma\tau}$, $\sigma,\tau \in \{+,-\}$, after all relative centers, sizes, orientations, nonzero-mode determinants, zero-mode saturations, and interaction remainders in the selected window have been included. With $z_+ = \zeta_\Lambda \mathrm{e}^{\mathrm{i}\bar\theta}$ and $z_- = \zeta_\Lambda \mathrm{e}^{-\mathrm{i}\bar\theta}$, the first Mayer correction to the logarithm has the local form

$$\frac{1}{V_4}\log\frac{Z_{\mathrm{cl}}(\bar\theta)}{Z_0} = z_+ + z_- + \frac{1}{2}\sum_{\sigma,\tau=\pm} z_\sigma z_\tau\,\mathfrak{B}_{\sigma\tau} + O(\zeta_\Lambda^3). \tag{51.206}$$

Assume CP symmetry in this window, so

$$\mathfrak{B}_{++} = \mathfrak{B}_{--} =: \mathfrak{B}_2, \qquad \mathfrak{B}_{+-} = \mathfrak{B}_{-+} =: \mathfrak{B}_0.$$

Then

$$\frac{1}{V_4}\log\frac{Z_{\mathrm{cl}}(\bar\theta)}{Z_0} = 2\zeta_\Lambda\cos\bar\theta + \zeta_\Lambda^2\big(\mathfrak{B}_2\cos(2\bar\theta) + \mathfrak{B}_0\big) + O(\zeta_\Lambda^3). \tag{51.207}$$

The neutral instanton–anti-instanton molecule $\mathfrak{B}_0$ changes the vacuum pressure and the validity of the dilute expansion, but it cancels from the energy difference $E(\bar\theta) - E(0)$ at this order. The same-charge clusters carry topological charge ± 2, and therefore generate a second theta harmonic:

$$E_{\mathrm{cl}}(\bar\theta) - E_{\mathrm{cl}}(0) = 2\zeta_\Lambda(1-\cos\bar\theta) + \zeta_\Lambda^2\mathfrak{B}_2(1-\cos(2\bar\theta)) + O(\zeta_\Lambda^3). \tag{51.208}$$

Consequently

$$\chi_{\mathrm{top}}^{\mathrm{cl}} = 2\zeta_\Lambda + 4\zeta_\Lambda^2\mathfrak{B}_2 + O(\zeta_\Lambda^3), \qquad \partial_{\bar\theta}^4 E_{\mathrm{cl}}\big|_0 = -2\zeta_\Lambda - 16\zeta_\Lambda^2\mathfrak{B}_2 + O(\zeta_\Lambda^3), \tag{51.209}$$

and, in the expansion convention of (51.204),

$$b_2^{\mathrm{cl}} = -\frac{1+8\zeta_\Lambda\mathfrak{B}_2}{12(1+2\zeta_\Lambda\mathfrak{B}_2)} + O(\zeta_\Lambda^2) = -\frac{1}{12} - \frac{1}{2}\zeta_\Lambda\mathfrak{B}_2 + O(\zeta_\Lambda^2). \tag{51.210}$$

Thus $b_2 = -1/12$ is not a universal instanton prediction. It is the Poisson limit of independent $Q = \pm 1$ amplitudes. The first same-charge connected cluster already changes the fourth theta curvature, while a neutral instanton–anti-instanton molecule first tests the cluster expansion and neutral observables rather than the theta dependence at this order.

The identities above are only as controlled as the two-body cluster integrals. They require a single regulator and source convention for the one-body amplitudes, relative collective-coordinate measure, fluctuation determinants, zero-mode overlap factors, and boundary-face estimates. They do not derive $\mathfrak{B}_{\sigma\tau}$ from ADHM data without the determinant and interaction estimates, nor do they prove that the omitted three-body and higher clusters are small.

Controlled Approximation 51.64 (Thermal dilute topological susceptibility)**.** Combine the thermal determinant-screened one-instanton activity of ControlledApproximation 51.61 with the dilute-gas hypothesis in ControlledApproximation 51.62. Write the Gaussian one-instanton activity per Euclidean four-volume in a positive mass/source-saturated channel as

$$\zeta_T^G = \frac{K_{T,0}}{2}\left(\pi^2 T^2\,\frac{2N_c+N_f}{3}\right)^{-A/2}\Gamma\!\left(\frac{A}{2}\right), \qquad A = b_0 + \beta_{\mathcal{X}} - 4, \tag{51.211}$$

where $K_{T,0}$ contains the collective-coordinate normalization, zero-temperature nonzero-mode determinant convention, mass/source zero-mode-saturation coefficient, and any finite source-frame normalization in the selected channel. Here $K_{T,0} \ge 0$ and the residual is real; otherwise one has a source amplitude controlled by the majorant (51.200), not a positive dilute-gas activity. If the finite-temperature determinant residual obeys $|R_T(\rho)| \le \varepsilon_T$ on the same size window, the exact positive activity ζ_T satisfies

$$\left|\zeta_T - \zeta_T^G\right| \le \left(\mathrm{e}^{\varepsilon_T} - 1\right)\zeta_T^G. \tag{51.212}$$

Consequently the leading dilute topological susceptibility and fourth theta curvature are

$$\chi_{\mathrm{top}}^{T,\mathrm{dig}} = 2\zeta_T, \qquad \partial_\theta^4 E_T^{\mathrm{dig}}\big|_{\theta=0} = -2\zeta_T, \qquad b_2^{T,\mathrm{dig}} = -\frac{1}{12}, \tag{51.213}$$

with Gaussian approximants obtained by replacing ζ_T by ζ_T^G. The susceptibility error is bounded by

$$\left|\chi_{\mathrm{top}}^{T,\mathrm{dig}} - \chi_{\mathrm{top}}^{T,G}\right| \le \left(\mathrm{e}^{\varepsilon_T} - 1\right)\chi_{\mathrm{top}}^{T,G}, \qquad \chi_{\mathrm{top}}^{T,G} = 2\zeta_T^G. \tag{51.214}$$

For mass-saturated $SU(3)$, $N_f = 2$ QCD,

$$A = \frac{23}{3}, \qquad \chi_{\mathrm{top}}^{T,G} = K_{T,0}\left(\frac{8}{3}\pi^2 T^2\right)^{-23/6}\Gamma\!\left(\frac{23}{6}\right).$$

After the one-loop action has been traded for $\Lambda_{\mathrm{ht}}^{29/3}$ in the hard convention used above, this is the dimension-four scaling

$$\chi_{\mathrm{top}}^{T,G} \propto |m_u m_d|\,\Lambda_{\mathrm{ht}}^{29/3}\,T^{-23/3} \tag{51.215}$$

up to the displayed finite determinant, source-frame, and running-mass coordinates. This is a statement about the theta curvature of a dilute, screened thermal instanton ensemble. It is not a proof that isolated instantons dominate the topological susceptibility near the crossover or at zero temperature.

Proposition 51.65 (Zero-mode overlap determinant in an instanton ensemble)**.** *Fix a finite-volume, finite-regulator vectorlike $SU(N_c)$ QCD background which contains n_+ instanton cores and n_- anti-instanton cores in a window where the individual zero modes are identifiable and have* *been orthonormalized. Let ψ_I^+, $I = 1, \dots, n_+$, denote the isolated zero-mode basis in the chirality sector carried by the instanton cores and let $\psi_{\bar J}^-$, $\bar J = 1, \dots, n_-$, denote the opposite-chirality basis carried by the anti-instanton cores. The leading overlap matrix is*

$$T_{I\bar J} = \langle \psi_I^+, \mathcal{D}_E[A_{\rm ens}]\psi_{\bar J}^- \rangle, \qquad T : \mathbb{C}^{n_-} \longrightarrow \mathbb{C}^{n_+}, \tag{51.216}$$

where $A_{\rm ens}$ is the chosen multi-lump gauge field. After the nonzero-mode determinant and source-convention factors have been separated as in Proposition 51.40, the one-flavor massive Dirac operator restricted to this near-zero-mode subspace is

$$\mathcal{D}_{\rm zm}(m) = \begin{pmatrix} m\,\mathbf{1}_{n_+} & T \\ -T^\dagger & m\,\mathbf{1}_{n_-} \end{pmatrix} + E_{\rm zm}, \tag{51.217}$$

where $E_{\rm zm}$ collects Gram errors, regulator chirality-breaking terms, and Schur-complement terms from the nonzero-mode sector. If $s_1, \dots, s_r$ are the singular values of T, $r = \min(n_+, n_-)$, then in the leading projected block $E_{\rm zm} = 0$,

$$\det \mathcal{D}_{\rm zm}(m) = m^{|n_+ - n_-|} \prod_{\alpha=1}^{r} \left(m^2 + s_\alpha^2\right), \tag{51.218}$$

and, for real $m > 0$,

$$\operatorname{Tr} \mathcal{D}_{\rm zm}(m)^{-1} = \frac{|n_+ - n_-|}{m} + 2m \sum_{\alpha=1}^{r} \frac{1}{m^2 + s_\alpha^2}. \tag{51.219}$$

For N_f Dirac flavors with masses m_f, the zero-mode part of the leading-block fermion determinant is the product of (51.218) over f. Hence, inside the leading projected block, a sector with $n_+ \neq n_-$ has $|n_+ - n_-|$ unpaired zero modes at $m = 0$, while a balanced instanton–anti-instanton ensemble can acquire small near-zero Dirac eigenvalues from the singular values of T.

The corresponding exact statement for the full finite-regulator Dirac operator requires stronger hypotheses. If the regulator preserves an exact chiral/index structure and the full gauge field has topological charge $Q = n_+ - n_-$, then the full massless operator has $|Q|$ index-protected zero modes of the corresponding chirality, up to the usual convention for whether one counts the kernel of $\mathcal{D}$ or $\mathcal{D}^\dagger$. A generic nonzero $E_{\rm zm}$ may lift zero modes of the leading projected block; when $E_{\rm zm}$ is small, the lifted near-zero eigenvalues are controlled by the finite-dimensional perturbation size of $E_{\rm zm}$, while the index-protected kernel survives only in an index-preserving setup.

Proof. The massless Euclidean Dirac operator anticommutes with γ_5, so in a chiral zero-mode basis it has only off-diagonal matrix elements at leading order. The choice of signs in (51.217) is the anti-Hermitian Euclidean convention; replacing it by an equivalent Hermitian convention changes phases, not the positive factors below. Take a singular-value decomposition $T = U\Sigma V^\dagger$. The unitary change of basis $\mathrm{diag}(U, V)$ preserves the determinant and decomposes the block with $E_{\rm zm} = 0$ into r two-dimensional blocks

$$\begin{pmatrix} m & s_\alpha \\ -s_\alpha & m \end{pmatrix}$$

plus $|n_+ - n_-|$ unpaired one-dimensional m-blocks. Each paired block has determinant $m^2 + s_\alpha^2$ and inverse trace $2m/(m^2 + s_\alpha^2)$; each unpaired block contributes m to the determinant and

$1/m$ to the trace. Multiplying these factors gives (51.218) and (51.219). Different flavors have independent Grassmann coefficient spaces, so their finite determinants multiply.

The exact-kernel statement is a separate index input. The displayed singular-value reduction diagonalizes the projected leading block with $E_{\mathrm{zm}} = 0$. Adding E_{zm} changes the finite matrix being diagonalized; ordinary finite-dimensional perturbation estimates bound the movement of the leading-block eigenvalues by the size of this remainder, but they do not turn the leading block count into an index theorem. Exact full-operator zero modes follow only when the regulator supplies an exact chiral index and the total charge of the full background is the stated $Q = n_+ - n_-$. $\square$

Controlled Approximation 51.66 (Instanton-liquid spectral-density criterion)**.** The determinant (51.218) is the finite linear-algebra core of the instanton-liquid mechanism [66]. It is not a statement about the instanton moduli space by itself. A physical ensemble measure must also include the bosonic action, collective-coordinate Jacobians, pure-gauge and fermionic nonzero-mode determinants, instanton–anti-instanton interactions, regulator remainders E_{zm}, and the determinant reweighting from the overlap matrix. Suppose that, after all those weights are included, the positive singular-value density

$$\rho_{\mathrm{zm},\mathcal{V}_4}(s) = \frac{1}{\mathcal{V}_4}\left\langle \sum_\alpha \delta(s - s_\alpha)\right\rangle_{\mathrm{ens}} \tag{51.220}$$

has a thermodynamic limit $\rho_{\mathrm{zm}}(s)$ continuous at $s = 0$, and that the unpaired topological zero-mode density $|n_+ - n_-|/\mathcal{V}_4$ vanishes in the same limit. Then the zero-mode-zone contribution to the scalar-source derivative has the Banks–Casher form

$$\Sigma_{\mathrm{zm}} = \lim_{m\downarrow 0}\int_0^\infty \frac{2m\,\rho_{\mathrm{zm}}(s)}{m^2+s^2}\,\mathrm{d}s = \pi\rho_{\mathrm{zm}}(0), \tag{51.221}$$

in the normalization of (135.19)–(135.20).

This is a criterion, not a derivation of the QCD chiral condensate. The hard physics is the generation and control of a finite density of small singular values of the overlap matrix after the fluctuation determinants and interactions are included. A dilute Poisson gas with finite isolated activities gives theta-cumulants as in (51.205); it does not by itself prove $\rho_{\mathrm{zm}}(0) > 0$. Conversely, if a controlled ensemble has a nonzero near-zero singular-value density, then the instanton zero modes have become physical near-zero Dirac eigenstates, and the connection to chiral symmetry breaking is the spectral statement above rather than another collective-coordinate volume formula.

Controlled Approximation 51.67 (Zero-mode-zone $U(1)_A$ susceptibility criterion)**.** The same leading zero-mode-zone block distinguishes two different physical questions. A nonzero $\rho_{\mathrm{zm}}(0)$ gives the condensate criterion (51.221); restoration of the $U(1)_A$-paired isovector scalar and pseudoscalar susceptibilities is a stronger infrared test. Use the source convention of (135.22) and the local curvature normalization of (51.110)–(51.113). For a finite leading block with positive singular values s_α, define the zero-mode-zone spectral contribution to the $U(1)_A$-odd splitting by

$$\Delta^{\mathrm{zm}}_{\pi-\delta}(m;\mathcal{V}_4) = \frac{2|n_+ - n_-|}{\mathcal{V}_4 m^2} + \frac{4m^2}{\mathcal{V}_4}\sum_\alpha \frac{1}{(m^2+s_\alpha^2)^2}. \tag{51.222}$$

The first term is the exact topological zero-mode pole in this projected coordinate; it must be removed by taking the thermodynamic limit before the chiral limit, just as in the Banks–Casher statement. The paired term follows directly from the source derivatives of a two-dimensional chiral block: for $D_{\alpha,m} = \left(\begin{smallmatrix} m & s_\alpha \\ -s_\alpha & m \end{smallmatrix}\right)$ and $\gamma_5 = \mathrm{diag}(1,-1)$,

$$\mathrm{Tr}(D_{\alpha,m}^{-1}\gamma_5 D_{\alpha,m}^{-1}\gamma_5) + \mathrm{Tr}(D_{\alpha,m}^{-1}D_{\alpha,m}^{-1}) = \frac{4m^2}{(m^2+s_\alpha^2)^2}.$$

The plus sign is the Euclidean source sign: differentiating twice with respect to the scalar source gives $-\,\mathrm{Tr}\, D^{-1}D^{-1}$, whereas the pseudoscalar source $i\gamma_5 p$ gives $+\,\mathrm{Tr}\, D^{-1}\gamma_5 D^{-1}\gamma_5$.

Assume now that the ensemble measure in (51.220) has a thermodynamic limit, the topological zero-mode density vanishes first, and the ultraviolet part of the near-zero-zone density is locally dominated so that the small-s behavior controls the chiral singularity. Then

$$\Delta^{\mathrm{zm}}_{\pi-\delta}(m) = 4m^2 \int_0^\infty \frac{\rho_{\mathrm{zm}}(s)}{(m^2+s^2)^2}\,\mathrm{d}s. \tag{51.223}$$

Consequently

$$\rho_{\mathrm{zm}}(s) = \rho_0 + o(1) \quad\Longrightarrow\quad \Delta^{\mathrm{zm}}_{\pi-\delta}(m) = \frac{\pi\rho_0}{m} + o(m^{-1}), \tag{51.224}$$

$$\rho_{\mathrm{zm}}(s) = c_1 s + o(s) \quad\Longrightarrow\quad \Delta^{\mathrm{zm}}_{\pi-\delta}(m) = 2c_1 + o(1), \tag{51.225}$$

$$\rho_{\mathrm{zm}}(s) = O(s^{1+\epsilon}), \quad \epsilon > 0 \quad\Longrightarrow\quad \Delta^{\mathrm{zm}}_{\pi-\delta}(m) \longrightarrow 0 \tag{51.226}$$

under the same local domination hypothesis. Thus an instanton ensemble that produces a Banks–Casher condensate automatically leaves a divergent $U(1)_A$-odd zero-mode-zone susceptibility. Even an ensemble with $\rho_{\mathrm{zm}}(0) = 0$ can retain a finite $U(1)_A$-odd remnant if the near-zero density is only linear. Suppression of this channel in the chiral limit requires a stronger depletion of the overlap singular values than the vanishing of the condensate alone.

This criterion is deliberately phrased in terms of the weighted ensemble spectral density, not the geometry of isolated instantons. The ADHM or collective-coordinate measure supplies only part of the input. The physical question is whether the full fluctuation determinant, fermion determinant, instanton–anti-instanton interaction, and regulator remainder produce a specific near-zero singular-value law for T; that law is what decides the π-δ channel.

For the electroweak $SU(2)_L$ gauge theory, the same zero-mode logic applies to every left-handed doublet. For one generation there are three colored quark doublets and one lepton doublet, hence four $SU(2)_L$ doublet zero modes. For N_g generations the corresponding minimal fermion operator contains

$$\mathcal{O}_{\mathrm{EW}} \propto \prod_{r=1}^{N_g} \bigl(q_{Lr} q_{Lr} q_{Lr} \ell_{Lr}\bigr), \tag{51.227}$$

with weak, color, spinor, and flavor contractions fixed by the zero-mode wavefunctions and by gauge invariance. It changes baryon and lepton numbers by

$$\Delta B = \Delta L = N_g, \qquad \Delta(B-L) = 0, \qquad \Delta(B+L) = 2N_g.$$

At zero temperature the amplitude is exponentially suppressed by the instanton action. The real-time high-temperature process is instead organized around the sphaleron barrier discussed in Section 45.6; both effects are controlled by the same anomalous relation between topological charge and fermion-number violation.

51.18 Anomalous Pion Couplings

The axial anomaly has observable low-energy consequences. In two-flavor QCD, the neutral pion couples to the electromagnetic topological density through the anomalous divergence of the axial isospin current:

$$\partial_\mu J^\mu_{5,3} = \frac{e^2}{16\pi^2}\,\mathrm{tr}\big(T_3 Q^2\big)\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma} + \text{mass terms.}$$

Here Q is the quark charge matrix and T_3 is the third generator of flavor $SU(2)$. The same anomaly is reproduced in the pion effective theory by the Wess–Zumino–Witten term introduced in the next chapter.

Chapter 52

The Schwinger Model: Two-Dimensional Quantum Electrodynamics

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

52.1 Definition, Gauge Group, and Observable Sector

The Schwinger model is quantum electrodynamics in 1+1 spacetime dimensions with one massless Dirac field. We use coordinates $x^\mu = (t, x)$,

$$\eta_{\mu\nu} = \mathrm{diag}(-, +), \qquad \epsilon^{01} = +1, \qquad \gamma = \gamma^0\gamma^1.$$

The two-dimensional spinor conventions are those of Section 40.16. Let a_μ be a real Abelian gauge representative and let $e > 0$ be the charge of the dynamical Dirac field. The compact $U(1)$ connection is $e\,a_\mu$; this convention is important because external probes will be allowed to have charge Q with respect to a_μ. Thus

$$D_\mu\psi = \partial_\mu\psi - \mathrm{i}ea_\mu\psi, \qquad F_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu, \qquad E = F_{01}.$$

The local representative Lagrangian is

$$\mathcal{L}_{\mathrm{Sch}} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \bar{\psi}\gamma^\mu D_\mu\psi = \frac{1}{2}E^2 - \bar{\psi}\gamma^\mu\partial_\mu\psi + e\,a_\mu J^\mu, \tag{52.1}$$

where

$$J^\mu = \mathrm{i}\bar{\psi}\gamma^\mu\psi, \qquad J^\mu_A = \mathrm{i}\bar{\psi}\gamma^\mu\gamma\psi. \tag{52.2}$$

With these definitions eJ^μ is the dynamical electric current. Gauge representatives are related by

$$a_\mu \mapsto a_\mu + \partial_\mu\xi, \qquad \psi \mapsto \mathrm{e}^{\mathrm{i}e\xi}\psi, \qquad \bar{\psi} \mapsto \bar{\psi}\,\mathrm{e}^{-\mathrm{i}e\xi}.$$

On a spatial circle of circumference L, the gauge group includes large transformations with $\xi(x+L) - \xi(x) = 2\pi n/e$. Equivalently, the holonomy $\exp(\mathrm{i}e\oint a_x \mathrm{d}x)$ is the compact gauge-invariant zero-mode coordinate. The local computations below may be performed on the line and then lifted to the circle by including the compact zero mode and the large-gauge identifications.

A possible theta density is

$$\mathcal{L}_\theta = \frac{e\theta}{2\pi}E. \tag{52.3}$$

On a closed Euclidean two-manifold the curvature of $e\,a$ has integral periods, so $\theta \sim \theta + 2\pi$. In the massless theory an anomalous axial rotation shifts θ, and the local spectrum is independent of θ. In the massive deformation this shift is no longer a symmetry, and θ becomes a physical parameter.

Definition 52.1 (Probe-charge convention)**.** A static external probe of charge Q is defined by the conserved external current j^μ_{ext} coupled through

$$S_{\mathrm{probe}} = \int a_\mu j^\mu_{\mathrm{ext}}\,\mathrm{d}^2x.$$

A straight worldline carries the phase $\exp(\mathrm{i}Q\int a_\mu \mathrm{d}x^\mu)$. The dynamical Dirac field has $Q = e$. A probe with $Q/e \in \mathbb{Z}$ can be screened by dynamical charged particles; a probe with nonintegral Q/e is a fractional probe relative to the dynamical charge lattice.

The canonical momentum conjugate to a_x is E, while a_0 is a Lagrange multiplier. Including an external charge density $\rho_{\mathrm{ext}} = j^0_{\mathrm{ext}}$, variation of a_0 gives the operator Gauss law

$$\partial_x E + eJ^0 + \rho_{\mathrm{ext}} = 0. \tag{52.4}$$

This equation is a constraint on states and on correlation functions with line insertions. It is not optional data added after quantization; it is the local gauge-invariance condition of the theory.

Definition 52.2 (Local sector)**.** The local gauge-invariant sector of the massless Schwinger model is the local operator algebra generated, after renormalization, by $F_{\mu\nu}$, by gauge-invariant currents such as J^μ, and by neutral composite fields. The bare fermion field ψ is not a gauge-invariant local observable. Charged sectors are described by line-dressed charged insertions or by states on a spatial manifold with prescribed electric flux at infinity. The exact solution below is first a solution of the local gauge-invariant sector and of specified external line probes.

52.2 Current Algebra, Anomaly, and the Electric-Field Equation

In two dimensions the vector and axial currents are Hodge dual. With the gamma-matrix and orientation conventions fixed above,

$$J^\mu_A = -\epsilon^{\mu\nu}J_\nu. \tag{52.5}$$

The vector current is exactly conserved as a consequence of gauge symmetry:

$$\partial_\mu J^\mu = 0.$$

The axial current is not conserved. The two-dimensional anomaly formula of Chapter 51, applied to the background connection $A_\mu = ea_\mu$, gives the renormalized operator identity

$$\partial_\mu J_A^\mu = \frac{e}{2\pi}\epsilon^{\mu\nu}F_{\mu\nu} = \frac{e}{\pi}E. \tag{52.6}$$

The identity includes the finite contact term chosen in the definition of the axial-vector current correlator. It is not the Euler-Lagrange equation of the classical massless Dirac action.

Proposition 52.3 (Anomaly-induced massive electric field)**.** *In the absence of external line insertions, the gauge-invariant electric field of the massless Schwinger model obeys*

$$(\Box - m_{\mathrm{Sch}}^2)E = 0, \qquad m_{\mathrm{Sch}}^2 = \frac{e^2}{\pi}, \qquad \Box = \partial_\mu\partial^\mu. \tag{52.7}$$

Proof. The Maxwell equation obtained from (52.1) is the renormalized local operator identity

$$\partial_\nu F^{\nu\mu} + eJ^\mu = 0.$$

Here it is tested in the sector with no external line insertion. With external Wilson lines, the right side would acquire the corresponding distributional endpoint or worldline current, and the homogeneous equation below would be replaced by an inhomogeneous screened-field equation. Since $F^{10} = E$ and $F^{01} = -E$, its two components are

$$\partial_x E + eJ^0 = 0, \qquad -\partial_t E + eJ^1 = 0.$$

Hence

$$J^0 = -\frac{1}{e}\partial_x E, \qquad J^1 = \frac{1}{e}\partial_t E.$$

Using (52.5), $J_A^0 = -J^1$ and $J_A^1 = -J^0$. Therefore

$$\partial_\mu J_A^\mu = -\partial_t J^1 - \partial_x J^0 = \frac{1}{e}(-\partial_t^2 + \partial_x^2)E = \frac{1}{e}\Box E.$$

Comparing this distributional consequence of Maxwell's equation with the anomaly identity (52.6), with the same local contact-term convention for the axial current, gives $\Box E/e = eE/\pi$, which is (52.7). $\Box$

This derivation uses only gauge invariance, the exact current anomaly, and the Maxwell equation. It already proves that the local electric field creates a massive neutral particle. Bosonization gives a stronger statement: it identifies the entire current-electric-field sector as a free massive scalar theory and gives exact formulas for line-probe response.

52.3 Bosonization of the Current Sector

The conservation law for J^μ implies locally that J^μ is the Hodge dual of a derivative. The normalization is not arbitrary; it is fixed by the current algebra of one Dirac fermion.

Theorem 52.4 (Current-sector bosonization)**.** *Let the free massless Dirac field be quantized in the vacuum sector with the current normalization* (52.2)*. The gauge-invariant Abelian current subalgebra is represented by the derivative algebra of a real scalar field* φ*, normalized by*

$$\mathcal{L}_\varphi = -\frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi, \qquad [\widehat{\varphi}(t,x), \partial_0\widehat{\varphi}(t,y)] = \mathrm{i}\delta(x-y),$$

through

$$J^\mu = \frac{1}{\sqrt{\pi}}\epsilon^{\mu\nu}\partial_\nu\varphi, \qquad J_A^\mu = -\frac{1}{\sqrt{\pi}}\partial^\mu\varphi. \tag{52.8}$$

Equivalently, after the same local contact-term convention is fixed on both sides, the current-generating functional satisfies

$$Z_{\mathrm{Dirac}}[b] = \int \mathcal{D}\varphi\, \exp\left\{\mathrm{i}\int \mathrm{d}^2x\left[-\frac{1}{2}\partial_\mu\varphi\partial^\mu\varphi + \frac{1}{\sqrt{\pi}}b_\mu\epsilon^{\mu\nu}\partial_\nu\varphi\right]\right\}. \tag{52.9}$$

This is the Lorentzian continuation of the Euclidean current-generating functional. When the local current algebra is extended by charge-one fermion vertex operators, the scalar is compact with period $\sqrt{\pi}$*; this compactification data is invisible to the derivative current algebra alone.*

Proof. The first step fixes the normalization independently of any path-integral argument. The equal-time commutator of the Dirac current, defined by gauge-invariant point splitting and with the vector Ward identity preserved, is

$$[\widehat{J}^0(t,x), \widehat{J}^1(t,y)] = -\frac{\mathrm{i}}{\pi}\partial_x\delta(x-y). \tag{52.10}$$

This Schwinger term follows directly from the short-distance singularity of the two chiral components of a free massless Dirac field. If (52.8) holds, then

$$J^0 = \frac{1}{\sqrt{\pi}}\partial_x\varphi, \qquad J^1 = -\frac{1}{\sqrt{\pi}}\partial_t\varphi,$$

and the canonical scalar commutator gives exactly (52.10). Hence the coefficient in (52.8) is forced.

It remains to prove that the same scalar gives all current correlators. Work first in Euclidean signature on the plane, and couple a real Schwartz one-form $b = b_\mu \mathrm{d}x^\mu$ to the conserved vector current. The Hodge decomposition on $\mathbb{R}^2$ gives

$$b_\mu = \partial_\mu\lambda + \epsilon_{\mu\nu}\partial^\nu\rho,$$

up to harmonic zero modes, which are absent for Schwartz sources. The vector Ward identity removes the exact part $\partial_\mu\lambda$, so the generating functional depends on ρ and on local contact conventions only. The transverse coupling can be written as an axial pure gauge:

$$b_\mu J^\mu = \epsilon_{\mu\nu}\partial^\nu\rho\, J^\mu = -\partial_\mu\rho\, J_A^\mu,$$

with the current convention (52.2). A local axial rotation $\psi \mapsto e^{\mathrm{i}\rho\gamma_5}\psi$ removes this coupling from the free Dirac action. The entire change of the determinant is the Fujikawa Jacobian for the same contact-term convention that gives (52.6); in the present normalization,

$$\log \frac{Z_{\mathrm{Dirac}}[b]}{Z_{\mathrm{Dirac}}[0]} = -\frac{1}{2\pi}\int_{\mathbb{R}^2} \mathrm{d}^2x\, \partial_\mu\rho\,\partial^\mu\rho.$$

Equivalently, in momentum space,

$$W_E[b] = \frac{1}{2\pi}\int \frac{\mathrm{d}^2p}{(2\pi)^2}\, b_\mu(-p)\left(\delta^{\mu\nu} - \frac{p^\mu p^\nu}{p^2}\right) b_\nu(p). \tag{52.11}$$

where $Z_{\mathrm{Dirac}}[b] = \exp[-W_E[b]]Z_{\mathrm{Dirac}}[0]$. This derivation is exact: after the source is removed by the axial rotation, there is no remaining interaction, and the anomaly Jacobian is quadratic in ρ.

The Euclidean scalar representative gives the same functional. With action

$$S_E[\varphi; b] = \int \mathrm{d}^2x \left[\frac{1}{2}\partial_\mu\varphi\partial^\mu\varphi - \frac{\mathrm{i}}{\sqrt{\pi}} b_\mu\epsilon^{\mu\nu}\partial_\nu\varphi\right],$$

the Gaussian integral over φ, modulo the constant zero mode, gives (52.11), because

$$\epsilon^{\mu\alpha}p_\alpha\epsilon^{\nu\beta}p_\beta = p^2\delta^{\mu\nu} - p^\mu p^\nu.$$

Functional differentiation of the identical Gaussian source functional gives all Euclidean current distributions, with the already fixed local contact terms. Analytic continuation gives (52.9) and the Lorentzian current formula (52.8).

The compact period is fixed only after adjoining charged fields. A charge-one fermion operator is represented by a vertex operator whose monodromy with the current has unit charge; with the current normalization above, the fermion mass operator has the local representative $\cos(2\sqrt{\pi}\,\varphi)$. Single-valuedness of this local neutral operator gives $\varphi \sim \varphi + \sqrt{\pi}$. This compactification datum does not enter the local derivative current correlators, which are the only bosonization data used in the gauge-invariant Schwinger-model calculations below. □

52.4 Exact Bosonized Gauge Theory

Lemma 52.5 (Exact bosonized local gauge sector)**.** *In the massless Schwinger model, the gauge-invariant local current and electric-field sector is represented by the bosonic Lagrangian*

$$\mathcal{L}_{\mathrm{bos}} = -\frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{e}{\sqrt{\pi}}a_\mu\epsilon^{\mu\nu}\partial_\nu\varphi + \frac{e\theta}{2\pi}E. \tag{52.12}$$

On a fixed local electric-flux branch this representative is equivalent to

$$\mathcal{L}_{\mathrm{eff}} = -\frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi - \frac{1}{2}\frac{e^2}{\pi}\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right)^2. \tag{52.13}$$

The electric field is the massive scalar field

$$E = -\frac{e}{\sqrt{\pi}}\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right), \qquad (\Box - m_{\mathrm{Sch}}^2)E = 0, \qquad m_{\mathrm{Sch}}^2 = \frac{e^2}{\pi}. \tag{52.14}$$

Proof. Set $b_\mu = ea_\mu$ in the current-sector identity (52.9). Adding the Maxwell term and the theta density (52.3) gives (52.12). Since $-\frac{1}{4}F_{\mu\nu}F^{\mu\nu} = \frac{1}{2}E^2$ in the mostly-plus convention and

$$a_\mu \epsilon^{\mu\nu}\partial_\nu\varphi = a_0\partial_x\varphi - a_x\partial_t\varphi = E\varphi + \partial_\mu(\cdots),$$

the same local branch is represented, up to a boundary term, by

$$\mathcal{L}_{\text{bos}} = -\frac{1}{2}\partial_\mu\varphi\,\partial^\mu\varphi + \frac{1}{2}E^2 + E\left(\frac{e}{\sqrt{\pi}}\varphi + \frac{e\theta}{2\pi}\right). \tag{52.15}$$

In two spacetime dimensions E carries no independent transverse propagating gauge degree of freedom. Its local stationary equation is

$$E = -\frac{e}{\sqrt{\pi}}\varphi - \frac{e\theta}{2\pi}.$$

Substitution into (52.15) gives (52.13). The Euler-Lagrange equation from (52.13) is

$$\Box\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right) = \frac{e^2}{\pi}\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right),$$

and multiplying by $-e/\sqrt{\pi}$ gives the electric-field equation in (52.14). $\square$

The lemma is an exact equality for the local current and electric-field sector of the massless theory. Gauge-variant fermion fields, compact-boson vertex operators, and gauge lines belong to the charged-sector data; the local neutral algebra is the sector described above.

Remark 52.6 (Theta periodicity and branches). The local expression (52.13) is written on one electric-flux branch. In the compact theory, large gauge transformations and the compactness $\varphi \sim \varphi + \sqrt{\pi}$ identify the branch obtained by $\theta \mapsto \theta + 2\pi$ with the branch obtained by shifting φ. A formulation on a spatial circle keeps the holonomy zero mode and sums over the corresponding integer electric-flux sectors. The massless theory is independent of θ, because an axial rotation shifts θ and no fermion mass term obstructs this shift.

Figure 52.1 displays two gauge-invariant consequences of the same calculation: the local electric field has a massive pole with $m_{\text{Sch}}^2 = e^2/\pi$, and the static kernel changes from the unscreened one-dimensional Coulomb kernel to a screened Yukawa kernel.

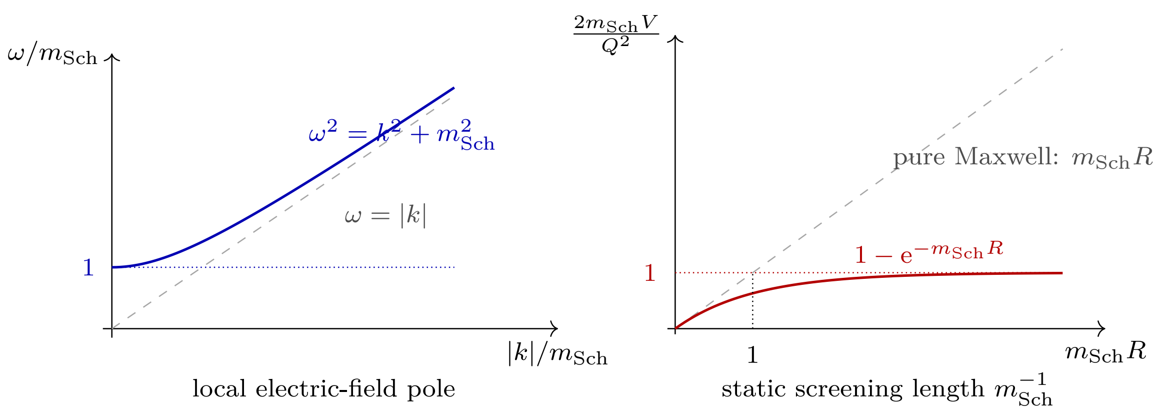

Figure 52.1: Two observable faces of the same massless Schwinger-model calculation. The anomaly-fixed current algebra gives the electric field a massive neutral pole, and the same mass changes the static probe potential from a linearly growing Maxwell kernel to the screened form derived below.

52.5 Static Probes and Screening

The response to external static charges is a line-observable question, not a statement about the local particle spectrum alone. For a neutral pair

$$\rho_{\mathrm{ext}}(x) = Q\delta(x - R/2) - Q\delta(x + R/2),$$

pure Maxwell theory in one spatial dimension gives a constant electric field between the probes. With the Gauss law $\partial_x E + \rho_{\mathrm{ext}} = 0$ in the interval between dynamical charges,

$$V_{\mathrm{pure}}(R) = \frac{Q^2}{2} R.$$

Screened static potential in the massless model. For the neutral static probe pair

$$\rho_R(x) = Q\delta(x - R/2) - Q\delta(x + R/2), \qquad R \geq 0,$$

the massless Schwinger model gives the static energy normalized by $V_{\mathrm{Sch}}(0) = 0$

$$V_{\mathrm{Sch}}(R) = Q^2 \left(G_{m_{\mathrm{Sch}}}(0) - G_{m_{\mathrm{Sch}}}(R)\right) = \frac{Q^2}{2m_{\mathrm{Sch}}} \left(1 - \mathrm{e}^{-m_{\mathrm{Sch}} R}\right), \tag{52.16}$$

where

$$\left(-\partial_x^2 + m^2\right) G_m(x) = \delta(x), \qquad G_m(x) = \frac{\mathrm{e}^{-m|x|}}{2m}.$$

Consequently the static force decays exponentially at distance m_{Sch}^{-1}, and there is no asymptotic linear electric string in the massless model.

Integrating out the massless current sector changes the static Coulomb kernel from $(-\partial_x^2)^{-1}$ to $(-\partial_x^2 + m_{\mathrm{Sch}}^2)^{-1}$. Equivalently, the temporal representative in Coulomb gauge obeys the screened static equation

$$\left(-\partial_x^2 + m_{\mathrm{Sch}}^2\right) a_0(x) = \rho_R(x).$$

The work needed to assemble the neutral pair from the coincident configuration is the positive quadratic form

$$V_{\mathrm{Sch}}(R) = \frac{1}{2} \int \frac{\mathrm{d}k}{2\pi} \frac{|\rho_R(k)|^2}{k^2 + m_{\mathrm{Sch}}^2}, \qquad \rho_R(k) = Q\big(\mathrm{e}^{-\mathrm{i}kR/2} - \mathrm{e}^{\mathrm{i}kR/2}\big). \tag{52.17}$$

Since

$$|\rho_R(k)|^2 = 2Q^2(1 - \cos kR),$$

equation (52.17) becomes

$$Q^2 \int \frac{\mathrm{d}k}{2\pi} \frac{1 - \cos kR}{k^2 + m_{\mathrm{Sch}}^2} = Q^2 \left(G_{m_{\mathrm{Sch}}}(0) - G_{m_{\mathrm{Sch}}}(R)\right).$$

The displayed Green function follows by solving the ordinary differential equation away from $x = 0$, imposing decay at infinity, and matching the jump $-G_m'(0^+) + G_m'(0^-) = 1$. This gives (52.16).

This screening statement is compatible with (52.7). The local electric field creates a massive neutral particle, while external flux is screened because the induced charge density can rearrange over the length scale m_{Sch}^{-1}. These are two different gauge-invariant observables whose common origin is the same anomaly-fixed current algebra.

52.6 Massive Fermion Variant and Fractional-Probe Confinement

Now add a Dirac mass $M\bar{\psi}\psi$. The axial rotation that removed θ in the massless theory also rotates the mass phase, so the physical parameter is the relative phase between the mass and the theta term. Choosing $M > 0$ real, bosonization gives the sine-Gordon perturbation

$$\Delta\mathcal{L}_M = \kappa M \cos(2\sqrt{\pi}\,\varphi + \theta). \tag{52.18}$$

The constant $\kappa > 0$ has mass dimension one and is fixed by the normalization of the renormalized composite mass operator. Equivalently, κ is the magnitude of the chiral condensate in the massless theory in the corresponding normal-ordering scheme. The scheme dependence of κ is exactly compensated by the scheme dependence of the renormalized mass M.

After eliminating E on a local branch, the scalar potential is

$$V_M(\varphi) = \frac{1}{2}\,\frac{e^2}{\pi}\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right)^2 - \kappa M \cos(2\sqrt{\pi}\,\varphi + \theta). \tag{52.19}$$

The quadratic term should again be understood together with the integer flux branches of the compact gauge theory. The cosine is periodic under $\varphi \mapsto \varphi + \sqrt{\pi}$; the electric term records which flux branch is being used.

Proposition 52.7 (Fractional-probe string tension at small fermion mass)**.** *Fix the normalization of the renormalized mass operator by* (52.18) *and take M small. A static probe pair with charges Q and $-Q$ shifts the effective theta angle in the interval between the probes by*

$$\theta_{\text{inside}} = \theta + \frac{2\pi Q}{e} \mod 2\pi. \tag{52.20}$$

The leading large-R energy-density shift in that interval is

$$\Delta\varepsilon_Q(\theta) = \kappa M\left[\cos\theta - \cos\!\left(\theta + \frac{2\pi Q}{e}\right)\right] + O(M^2), \tag{52.21}$$

with the physical branch chosen by minimizing over integer electric-flux sectors. At $\theta = 0$ the leading fractional-probe string tension is

$$\sigma(Q) = \kappa M\left(1 - \cos\frac{2\pi Q}{e}\right) + O(M^2). \tag{52.22}$$

It vanishes for $Q/e \in \mathbb{Z}$ and is positive, to this order, for nonintegral Q/e.

Proof. The external worldlines impose Gauss-law discontinuities. Across a probe of charge Q, the electric flux changes by Q. In the action, the theta term contributes

$$\int \mathrm{d}^2x\,\frac{e\theta}{2\pi}E.$$

Therefore a region in which the background electric flux is shifted by Q is equivalently described, in the bosonized scalar branch, by replacing θ by $\theta + 2\pi Q/e$. This proves (52.20).

For $M = 0$, the axial shift symmetry makes the vacuum energy independent of θ. To first order in M, ordinary perturbation theory around the massless Schwinger vacuum gives the vacuum-energy density

$$\varepsilon(\theta) = -\kappa M \cos\theta + O(M^2),$$

where the same κ appears in the renormalized mass perturbation (52.18). The interval between widely separated probes has energy density $\varepsilon(\theta + 2\pi Q/e)$, while the exterior vacuum has $\varepsilon(\theta)$. Their difference is (52.21). At $\theta = 0$ this is (52.22). If Q/e is an integer, the theta shift is 2π-periodic and the leading string tension vanishes; if $Q/e \notin \mathbb{Z}$, the shifted interval lies in a different point of the theta circle and has positive leading energy density at $\theta = 0$. $\square$

This is confinement of fractional test charges, not confinement of the dynamical unit-charged fermion. The latter belongs to the charge lattice that can screen integral probes.

52.7 Mechanisms Isolated by the Exact Solution

The model is useful because several mechanisms that are intertwined in higher-dimensional gauge theories become separately computable:

object	exact statement in the Schwinger model
local anomaly	$\partial_\mu J^\mu_A = (e/\pi)E$
local electric-field spectrum	E creates a scalar of $m^2_{\mathrm{Sch}} = e^2/\pi$
massless probe response	$V(R) = Q^2(1 - \mathrm{e}^{-m_{\mathrm{Sch}}R})/(2m_{\mathrm{Sch}})$
mass perturbation	$M\bar{\psi}\psi \leftrightarrow \kappa M \cos(2\sqrt{\pi}\varphi + \theta)$
fractional-probe confinement	$\sigma(Q) = \kappa M(1 - \cos(2\pi Q/e)) + O(M^2)$

Each line refers to a specified gauge-invariant local observable or to an explicit external line probe. This separation is essential: a massive electric-field two-point function, a screened Wilson-line potential, and a linear potential for fractional probes in the massive deformation are different physical statements, even though in this exactly solvable theory they are controlled by the same current algebra and anomaly.

Chapter 53

Large-N Two-Dimensional QCD and the Light-Front Bound-State Equation

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

53.1 Regulated Theory and Light-Front Coordinates

Two-dimensional QCD is a useful solvable gauge-theory laboratory precisely because the gauge field has no local propagating polarization but still imposes a nontrivial nonabelian Gauss law. The model considered in this chapter has gauge group $SU(N_c)$, N_f Dirac fermions in the fundamental representation, and the same trace convention as the four-dimensional QCD chapter:

$$\begin{aligned} \mathrm{tr}_\square(t^a t^b) &= \delta^{ab}, \\ (t^a)^i{}_j (t^a)^k{}_\ell &= \delta^i{}_\ell \delta^k{}_j - \frac{1}{N_c}\delta^i{}_j \delta^k{}_\ell. \end{aligned} \tag{53.1}$$

The second identity is the fundamental completeness relation in this normalization; it is the same color algebra used in Chapter 49. The coupling g_2 has mass dimension one, and the local action is written in the connection normalization

$$S = \int \mathrm{d}^2 x \left[-\frac{1}{4g_2^2}\,\mathrm{tr}_\square(F_{\mu\nu}F^{\mu\nu}) - \bar{q}(\gamma^\mu D_\mu + m)q \right], \qquad D_\mu = \partial_\mu - \mathrm{i}A_\mu. \tag{53.2}$$

For several flavors and masses, m is replaced by a diagonal mass matrix. The large-N_c coupling coordinate used below is

$$\lambda_2 := g_2^2 N_c. \tag{53.3}$$

It has dimensions of mass squared. Because the generator normalization is fixed by (53.1), no hidden factor of $1/2$ is allowed in this definition.

Use light-front coordinates

$$x^{\pm} = \frac{x^0 \pm x^1}{\sqrt{2}}, \qquad \mathrm{d}s^2 = -2\,\mathrm{d}x^+\mathrm{d}x^-, \tag{53.4}$$

and take x^+ as time. The momentum p^+ is conjugate to x^-, and a massive on-shell particle has

$$2p^+p^- = m^2, \qquad p^+ > 0.$$

The light-front Hamiltonian is P^-, while the invariant mass of a state with no transverse momentum in two dimensions is

$$M^2 = 2P^+P^-. \tag{53.5}$$

The general light-front regulator datum, including the mass-shell measure, the role of positive p^+, and the separate zero-mode/constraint sector, is Definition 145.16; this chapter is its large-N_c two-dimensional gauge-theory specialization.

The manipulations below are made at finite regulator before continuum limits are discussed. A convenient regulator is to put x^- on a circle of length $2\pi R$, remove or separately constrain the zero mode, impose a finite harmonic resolution $K = RP^+$, and only then study $K \to \infty$. Equivalently one may use smooth cutoffs in p^+ and a principal-value prescription for the instantaneous kernel. The zero mode of the gauge constraint is not a harmless detail: it fixes the color-neutral sector and the global electric-flux data. The bound-state equation derived below is the continuum form of the regulated color-singlet two-body problem after this constraint has been imposed.

53.2 Light-Front Gauge Constraint

Choose light-front gauge

$$A_- = 0.$$

Then $F_{+-} = -\partial_- A_+$. The A_+ field is nondynamical; it is the Lagrange-multiplier remnant of Gauss law written in a gauge where the constraint can be solved explicitly. The part of the regulated light-front action depending on A_+ has the form

$$S[A_+] = \int \mathrm{d}x^+\mathrm{d}x^- \left[\frac{1}{2g_2^2}(\partial_- A_+^a)(\partial_- A_+^a) + A_+^a J^{+a}\right], \tag{53.6}$$

where J^{+a} is the color current of the dynamical light-front fermion component. The sign convention in (53.6) is fixed by $\mathrm{d}s^2 = -2\mathrm{d}x^+\mathrm{d}x^-$ and by the action (53.2). Variation of A_+^a gives

$$-\frac{1}{g_2^2}\partial_-^2 A_+^a + J^{+a} = 0. \tag{53.7}$$

Let

$$G := (-\partial_-^2)^{-1}$$

on the zero-mode-free subspace selected by the regulator. On the infinite line, G has kernel $-|x^-|/2$ as an inverse of $-\partial_-^2$ on test functions of total integral zero; on the circle the corresponding kernel is the periodic zero-average Green function. Solving (53.7) and substituting back gives the positive instantaneous Coulomb Hamiltonian

$$P^-_{\text{inst}} = \frac{g_2^2}{2}\int \mathrm{d}x^-\mathrm{d}y^-\, J^{+a}(x^-)\, G(x^- - y^-)\, J^{+a}(y^-), \tag{53.8}$$

with the zero-mode sector understood as above.

Finite-regulator Gauss-law reduction. At finite light-front regulator, after the A_+ zero mode has been either fixed by the color-neutral Gauss-law constraint or kept as a separate compact degree of freedom, the nonzero-mode integration over A_+ is an ordinary Gaussian integration. The equivalence with the instantaneous Hamiltonian (53.8) is the following square completion. On the nonzero-mode regulated space, $-\partial_-^2$ is a positive invertible symmetric operator. Integrating (53.6) by parts in x^- gives

$$S[A_+] = \int \mathrm{d}x^+ \left[-\frac{1}{2g_2^2}\langle A_+, \partial_-^2 A_+\rangle + \langle A_+, J^+\rangle\right].$$

Completing the square with

$$A_+ = -g_2^2(-\partial_-^2)^{-1}J^+ + A'_+$$

separates a Gaussian in A'_+ from the current-current term. In the Hamiltonian P^-, the latter appears with the positive kernel G as in (53.8). The completion of the square does not determine the zero mode; that mode is exactly the global Gauss-law constraint and must be part of the regulator datum.

53.3 Planar Color-Singlet Mesons

Consider one quark flavor of mass m_1 and one antiquark flavor of mass m_2. A color-singlet light-front meson state of total momentum $P^+ > 0$ has the leading large-N_c form

$$|P^+;\phi\rangle = \frac{1}{\sqrt{N_c}}\sum_{i=1}^{N_c}\int_0^1 \mathrm{d}x\, \phi(x)\, b_i^\dagger(xP^+)d^{\dagger i}((1-x)P^+)|\Omega\rangle \tag{53.9}$$

after a choice of light-front creation-operator normalization. The function ϕ is a wavefunction on $0 < x < 1$. Its endpoint behavior is part of the domain of the mass operator. For positive renormalized endpoint masses, normalizability and finiteness of the mass expectation force sufficient vanishing at $x = 0, 1$; in the chiral limit an endpoint-constant wavefunction is allowed by the subtracted Coulomb kernel below.

The free light-front Hamiltonian contributes

$$P^-_{\text{kin}} = \frac{1}{2P^+}\left[\frac{m_1^2}{x} + \frac{m_2^2}{1-x}\right]$$

on the component with momentum fraction x. The instantaneous interaction (53.8) transfers longitudinal momentum between the quark and antiquark. The planar color contraction follows from (53.1): the first term preserves the singlet with coefficient N_c, while the second term is suppressed by N_c^{-1} in the normalized singlet matrix element. The real exchange kernel and the quark and antiquark self-energy terms combine into a subtracted principal value operator.

Definition 53.1 (Subtracted 't Hooft operator)**.** For $\gamma_2 > 0$ and endpoint masses $m_1^2, m_2^2 \geq 0$, define

$$(\mathcal{M}^2\phi)(x) = \left[\frac{m_1^2}{x} + \frac{m_2^2}{1-x}\right]\phi(x) + \gamma_2 \ \mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y. \tag{53.10}$$

The principal value is best defined by the quadratic form (53.13). For smooth test functions, it is the finite part obtained by applying the same cutoff to real exchange and self-energy terms before removing the cutoff. In the large-N_c QCD normalization of this chapter,

$$\gamma_2 = \frac{\lambda_2}{\pi} \tag{53.11}$$

for the standard continuum principal-value convention. A finite DLCQ regulator may instead take γ_2 as its displayed matrix coefficient and use (53.11) as the continuum matching condition.

Theorem 53.2 (Planar light-front meson equation)**.** *Assume the finite light-front regulator described above, take $N_c \to \infty$ with $\lambda_2 = g_2^2 N_c$ fixed and N_f fixed, and restrict to the color-singlet one-quark-one-antiquark sector with endpoint masses m_1, m_2 fixed in the chosen renormalization scheme. If the regulated planar Hamiltonians converge on this sector to the subtracted operator of Definition 53.1, then the leading large-N_c meson masses are the spectral values M^2 satisfying*

$$M^2\phi(x) = \left[\frac{m_1^2}{x} + \frac{m_2^2}{1-x}\right]\phi(x) + \frac{\lambda_2}{\pi} \ \mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y. \tag{53.12}$$

Proof. The free term follows from $M^2 = 2P^+P^-$: a quark with momentum xP^+ contributes $m_1^2/(2xP^+)$ to P^-, and the antiquark contributes $m_2^2/(2(1-x)P^+)$. Multiplication by $2P^+$ gives the endpoint mass operator.

For the interaction, write the current in momentum modes. At finite regulator, the kernel $G = (-\partial_-^2)^{-1}$ contributes a factor $(k^+)^{-2}$ for a nonzero exchanged longitudinal momentum k^+, with the zero mode excluded by Gauss law. Acting on the singlet state (53.9), the color algebra (53.1) gives a leading contraction $\delta^i{}_\ell \delta^k{}_j$ and a subleading trace subtraction. Hence the leading interaction is proportional to $g_2^2 N_c = \lambda_2$.

The real exchange term alone has a nonintegrable $1/(x-y)^2$ singularity. The self-energy terms generated by the same instantaneous Hamiltonian are the terms in which the exchanged longitudinal momentum leaves and returns to the same fermion line. With a common regulator for the real and self-energy pieces, their sum is the finite-part difference

$$\mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y.$$

The coefficient of this subtracted kernel is λ_2/π in the continuum momentum convention used for light-front creation operators. The assumed convergence of the regulated planar Hamiltonians then gives (53.12). The statement is deliberately phrased with the regulator-convergence hypothesis exposed: the algebra above derives the finite-regulator reduction and the planar kernel, while the continuum operator domain is an analytic input. □

Remark 53.3 (Relation to the unsubtracted form). A common finite-part coordinate writes the same regulated planar equation in the form

$$M^2\phi(x) = \left[\frac{\widetilde{m}_1^2}{x} + \frac{\widetilde{m}_2^2}{1-x}\right]\phi(x) - \frac{\lambda_2}{\pi}\ \mathrm{PV}\int_0^1 \frac{\phi(y)}{(x-y)^2}\,\mathrm{d}y.$$

It is a different finite-part coordinate for the same planar bound-state equation. The singular term proportional to $\phi(x)$ has been assigned to the endpoint masses $\widetilde{m}_i^2$. The subtracted form (53.12) displays the real–self-energy pairing and has a positive quadratic form, so it is the convention used in this monograph.

53.4 Quadratic Form, Positivity, and the Chiral Limit

Positive form of the subtracted kernel. For a real smooth function ϕ on $[0,1]$,

$$\int_0^1 \mathrm{d}x\,\phi(x)\,\mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y = \frac{1}{2}\int_0^1 \mathrm{d}x\int_0^1 \mathrm{d}y\,\frac{(\phi(x)-\phi(y))^2}{(x-y)^2}. \tag{53.13}$$

This identity is an elementary symmetrization of the principal-value kernel, but it is the useful way to remember the sign. Regulate the singularity by deleting $|x-y|<\epsilon$. The regulated bilinear expression is

$$I_\epsilon = \int_0^1 \mathrm{d}x\int_{|x-y|>\epsilon} \mathrm{d}y\,\phi(x)\frac{\phi(x)-\phi(y)}{(x-y)^2}.$$

Interchange x and y in the same integral. Since $(x-y)^2=(y-x)^2$, the average of the two equal expressions is

$$I_\epsilon = \frac{1}{2}\int_{|x-y|>\epsilon} \mathrm{d}x\,\mathrm{d}y\,\frac{(\phi(x)-\phi(y))^2}{(x-y)^2}.$$

For smooth ϕ, the numerator is $O((x-y)^2)$ near the diagonal, so the right hand side has a finite $\epsilon \downarrow 0$ limit. This proves (53.13). Adding the endpoint mass terms gives nonnegative contributions when $m_i^2 \geq 0$. Thus, for $m_1^2, m_2^2, \gamma_2 \geq 0$, the quadratic form of $\mathcal{M}^2$ is nonnegative on its form domain.

In the equal-mass chiral limit $m_1 = m_2 = 0$, the constant wavefunction

$$\phi_0(x) = 1$$

lies in the kernel of the subtracted Coulomb operator. Therefore

$$M_0^2 = 0$$

in the leading planar equation. This massless meson is a special feature of the large-N_c two-dimensional model and of the order of limits used here. General statements about four-dimensional QCD and the Schwinger-model mass generation of Chapter 52 require their own local gauge dynamics and anomaly structure.

53.5 Endpoint Exponents

The endpoint behavior of the wavefunction is part of the domain of the light-front mass operator. It is fixed by the cancellation of the leading singular terms in the same finite-part convention that defines (53.10).

Lemma 53.4 (Endpoint finite part)**.** *Let $0 < \beta < 1$, and define*

$$I_\beta(x) := \mathrm{PV}\int_0^1 \frac{x^\beta - y^\beta}{(x-y)^2}\,\mathrm{d}y.$$

As $x \downarrow 0$,

$$I_\beta(x) = \bigl(\pi\beta\cot(\pi\beta) - 1\bigr)x^{\beta-1} + O(1). \tag{53.14}$$

The analogous right-endpoint statement follows by replacing x with $1-x$.

Proof. Set $y = xt$. Then

$$I_\beta(x) = x^{\beta-1}\,\mathrm{PV}\int_0^{1/x} \frac{1-t^\beta}{(1-t)^2}\,\mathrm{d}t.$$

The tail from $1/x$ to ∞ contributes $O(x^{1-\beta})$ to the integral in t, hence $O(1)$ to $I_\beta(x)$. It remains to compute the finite part

$$C(\beta) := \mathrm{PV}\int_0^\infty \frac{1-t^\beta}{(1-t)^2}\,\mathrm{d}t.$$

Integrating by parts with the pole at $t = 1$ removed symmetrically gives

$$C(\beta) = -1 + \beta\,\mathrm{PV}\int_0^\infty \frac{t^{\beta-1}}{1-t}\,\mathrm{d}t.$$

The principal-value integral is

$$\mathrm{PV}\int_0^\infty \frac{t^{\beta-1}}{1-t}\,\mathrm{d}t = \int_0^1 \frac{t^{\beta-1} - t^{-\beta}}{1-t}\,\mathrm{d}t = \psi(1-\beta) - \psi(\beta) = \pi\cot(\pi\beta),$$

where $\psi = \Gamma'/\Gamma$, and the last equality is the logarithmic derivative of Euler's reflection formula $\Gamma(\beta)\Gamma(1-\beta) = \pi/\sin(\pi\beta)$. Thus $C(\beta) = \pi\beta\cot(\pi\beta) - 1$, proving (53.14). $\square$

Lemma 53.5 (Endpoint exponents)**.** *Suppose an eigenfunction of (53.10) has nonzero leading behavior*

$$\phi(x) = c_1 x^{\beta_1} + o(x^{\beta_1}), \qquad \phi(x) = c_2(1-x)^{\beta_2} + o((1-x)^{\beta_2}),$$

with $c_1, c_2 \neq 0$ and $0 \le \beta_i < 1$. For $m_i^2 > 0$, the endpoint exponents lie in $0 < \beta_i < 1$ and obey

$$\frac{m_i^2}{\gamma_2} = 1 - \pi\beta_i\cot(\pi\beta_i), \qquad i = 1, 2. \tag{53.15}$$

For $m_i^2 = 0$, the allowed leading exponent is $\beta_i = 0$ in the subtracted convention.

Proof. Near $x = 0$, the endpoint mass term in (53.10) gives

$$m_1^2 c_1 x^{\beta_1 - 1}.$$

Lemma 53.4 gives the singular part of the subtracted Coulomb term,

$$\gamma_2 c_1 \big(\pi\beta_1 \cot(\pi\beta_1) - 1\big) x^{\beta_1 - 1}.$$

The eigenvalue term $M^2\phi(x)$ is only $O(x^{\beta_1})$. Therefore the coefficient of x^{β_1-1} must vanish, giving (53.15) for $i = 1$. The right endpoint is identical after $x \mapsto 1 - x$.

The function $F(\beta) = 1 - \pi\beta\cot(\pi\beta)$ is positive and strictly increasing from 0 to $+\infty$ on $0 < \beta < 1$. Indeed

$$F'(\beta) = \pi^2\beta\csc^2(\pi\beta) - \pi\cot(\pi\beta) = \frac{\pi}{\sin^2(\pi\beta)}\big(\pi\beta - \sin(\pi\beta)\cos(\pi\beta)\big) > 0,$$

because $\pi\beta > \sin(\pi\beta)\cos(\pi\beta)$ for $0 < \beta < 1$. Hence each positive m_i^2/γ_2 determines a unique exponent. When $m_i^2 = 0$, the same equation has the endpoint solution $\beta_i = 0$, which is the constant endpoint behavior used in the massless chiral solution above. □

53.6 Closed Form Domain and Discrete Spectrum

The endpoint analysis determines the local asymptotics of eigenfunctions, but it is not by itself a definition of the spectral problem. The continuum object is the self-adjoint operator associated with the closed positive form that was already visible in (53.13). This is the coordinate in which the statement "the spectrum of the 't Hooft equation" has a precise Hilbert-space meaning.

Let

$$\mathcal{H} = L^2((0,1), \mathrm{d}x)$$

and, for $m_1^2, m_2^2, \gamma_2 \geq 0$, define

$$\begin{aligned} \mathfrak{q}_{m_1,m_2,\gamma_2}[\phi] := &\int_0^1 \left(\frac{m_1^2}{x} + \frac{m_2^2}{1-x}\right) |\phi(x)|^2 \,\mathrm{d}x \\ &+ \frac{\gamma_2}{2}\int_0^1 \mathrm{d}x \int_0^1 \mathrm{d}y\, \frac{|\phi(x) - \phi(y)|^2}{(x-y)^2}. \end{aligned} \tag{53.16}$$

The form domain is

$$\mathcal{Q}_{m_1,m_2,\gamma_2} = \left\{\phi \in L^2(0,1) \ :\ \mathfrak{q}_{m_1,m_2,\gamma_2}[\phi] < \infty\right\}. \tag{53.17}$$

When an endpoint mass is positive, the corresponding weighted L^2 term in (53.16) is part of the definition: for example $m_1^2 > 0$ requires $\int_0^1 x^{-1}|\phi(x)|^2 \mathrm{d}x < \infty$. When the endpoint mass is zero, that endpoint weight is absent. This is why the constant wavefunction is admissible in the double chiral limit but not for a positive endpoint mass.

Proposition 53.6 (Self-adjoint 't Hooft mass operator)**.** *For $m_1^2, m_2^2 \geq 0$ and $\gamma_2 > 0$, the form $\mathfrak{q}_{m_1,m_2,\gamma_2}$ on $\mathcal{H} = L^2(0,1)$ is densely defined, nonnegative, and closed. Hence there is a unique nonnegative self-adjoint operator $\mathcal{M}^2_{m_1,m_2,\gamma_2}$ such that*

$$\mathfrak{q}_{m_1,m_2,\gamma_2}[\eta, \phi] = \langle \eta, \mathcal{M}^2_{m_1,m_2,\gamma_2}\phi\rangle_{L^2}$$

for all $\eta \in \mathcal{Q}_{m_1,m_2,\gamma_2}$ and all ϕ in the operator domain. On smooth functions for which the displayed principal value exists and the endpoint terms are integrable, this operator acts by

$$(\mathcal{M}^2_{m_1,m_2,\gamma_2}\phi)(x) = \left(\frac{m_1^2}{x} + \frac{m_2^2}{1-x}\right)\phi(x) + \gamma_2\,\mathrm{PV}\int_0^1 \frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y.$$

Its resolvent is compact. Therefore its spectrum consists of eigenvalues of finite multiplicity, accumulating only at $+\infty$. If $m_1 = m_2 = 0$, the constant functions are precisely the zero eigenspace. If at least one endpoint mass is positive, zero is not an eigenvalue.

Proof. The domain is dense because $C_c^\infty(0,1)$ lies in $\mathcal{Q}_{m_1,m_2,\gamma_2}$ and is dense in $L^2(0,1)$. Positivity is immediate from (53.16). For closedness, let (ϕ_n) be Cauchy in the form norm

$$\|\phi\|^2_{\mathcal{Q}} = \|\phi\|^2_{L^2} + \mathfrak{q}_{m_1,m_2,\gamma_2}[\phi].$$

Then $\phi_n \to \phi$ in L^2 for some ϕ. Passing to a subsequence gives almost-everywhere convergence. Fatou's lemma applied to the endpoint weights and to the positive measure on $(0,1)^2 \setminus \{x=y\}$ gives

$$\mathfrak{q}_{m_1,m_2,\gamma_2}[\phi] \le \liminf_{n\to\infty} \mathfrak{q}_{m_1,m_2,\gamma_2}[\phi_n],$$

so $\phi \in \mathcal{Q}_{m_1,m_2,\gamma_2}$. Applying the same lower semicontinuity to $\phi_n - \phi_m$ and then sending $m,n \to \infty$ shows that $\phi_n \to \phi$ in the form norm. Thus the form is closed. The representation theorem for densely defined closed nonnegative forms gives the unique nonnegative self-adjoint operator associated with the form.

For a smooth ϕ and a smooth test function η, regulate the singularity by deleting $|x-y| < \epsilon$. Symmetrizing the bilinear form gives

$$\frac{\gamma_2}{2}\int_{|x-y|>\epsilon} \frac{(\overline{\eta(x)}-\overline{\eta(y)})(\phi(x)-\phi(y))}{(x-y)^2}\,\mathrm{d}x\,\mathrm{d}y = \gamma_2\int_0^1 \overline{\eta(x)}\int_{|x-y|>\epsilon}\frac{\phi(x)-\phi(y)}{(x-y)^2}\,\mathrm{d}y\,\mathrm{d}x.$$

The finite part as $\epsilon \downarrow 0$ is exactly the principal-value operator displayed above. The endpoint multiplication terms are ordinary weighted L^2 pairings. This proves the agreement with the differential form of the equation on the smooth core where all terms are defined.

It remains to identify the spectral type. The double integral in (53.16) is the homogeneous $H^{1/2}$-seminorm on the interval, up to the harmless normalization convention for the finite interval. More explicitly, extending ϕ to a function on a slightly larger interval by a bounded extension operator and then periodizing on a circle, the kernel form controls

$$\sum_{n\in\mathbb{Z}} |n|\,|\widehat{\phi}_n|^2$$

on the extension, while $\|\phi\|^2_{L^2}$ controls the $n=0$ coefficient. The diagonal argument for Fourier series then gives compactness of the unit ball of $H^{1/2}$ in L^2: truncate to $|n| \le N$, obtain compactness in the finite-dimensional truncated space, and make the tail uniformly small by the $H^{1/2}$ bound. The endpoint weights only shrink the form domain, so the embedding $\mathcal{Q}_{m_1,m_2,\gamma_2} \hookrightarrow L^2(0,1)$ is compact. A closed semibounded form with compact form-domain embedding has compact resolvent: $(\mathcal{M}^2_{m_1,m_2,\gamma_2}+1)^{-1}$ maps L^2 boundedly into the form domain and then compactly back to L^2. Therefore the spectrum is purely discrete with finite multiplicities and no finite accumulation point.

Finally, $\mathfrak{q}[\phi] = 0$ forces $|\phi(x) - \phi(y)|^2 = 0$ for almost every pair (x, y), hence ϕ is almost everywhere constant. If both endpoint masses vanish, these constants indeed have zero form value. If at least one endpoint mass is positive, a nonzero constant has infinite or positive endpoint-weighted form value, so only the zero vector can have zero form value. □

Remark 53.7 (Spectral coordinates). The eigenvalues can be characterized by the Rayleigh–Ritz principle applied to $\mathfrak{q}_{m_1,m_2,\gamma_2}$. This is the continuum statement behind the finite DLCQ matrices below: finite-dimensional approximations are useful only insofar as their forms converge to (53.16) in a sense strong enough to control these variational values. Changing the endpoint mass coordinate or the zero-mode prescription changes the form and hence changes the spectral problem being approximated.

53.7 Finite DLCQ Matrix and Numerical Benchmark

The finite matrix used in Chapter 145 is the DLCQ discretization of the subtracted form above. Fix $K \geq 3$, grid points

$$x_n = \frac{n}{K}, \qquad n = 1, \ldots, K-1,$$

and a coefficient $\gamma_2 > 0$. Define

$$(M_K^2)_{nm} = \delta_{nm} \left[\frac{m_1^2}{x_n} + \frac{m_2^2}{1 - x_n} + \gamma_2 K \sum_{\substack{j=1 \\ j \neq n}}^{K-1} \frac{1}{(n-j)^2} \right] - (1 - \delta_{nm}) \frac{\gamma_2 K}{(n-m)^2}. \tag{53.18}$$

Then, for $v \in \mathbb{R}^{K-1}$,

$$v^T M_K^2 v = \sum_{n=1}^{K-1} \left[\frac{m_1^2}{x_n} + \frac{m_2^2}{1 - x_n} \right] v_n^2 + \gamma_2 K \sum_{1 \leq n < m \leq K-1} \frac{(v_n - v_m)^2}{(n-m)^2}. \tag{53.19}$$

This identity is the finite-dimensional shadow of (53.13). It also fixes the sign of the off-diagonal matrix elements. In the massless case, the constant vector is an exact zero mode of the kernel part at every K, matching the continuum constant solution.

Controlled Approximation 53.8 (DLCQ use of the 't Hooft equation)**.** A DLCQ calculation of two-dimensional large-N_c QCD must state the harmonic resolution K, the treatment of zero modes, the endpoint mass coordinate, the coefficient γ_2 and its matching to λ_2/π, the normalization of finite eigenvectors, and the extrapolation model for $K \to \infty$. A finite eigenvalue of (53.18) is an eigenvalue of a regulated matrix; it becomes a continuum meson mass only after these convergence data are supplied.

The companion script

```
calculation-checks/thooft_model_checks.py
```

verifies the finite color normalization, the quadratic-form identity (53.19), positivity for positive endpoint masses, and the exact massless constant zero mode of the subtracted kernel.

53.8 Scope of the Two-Dimensional Large-N_c Construction

The model gives an exact leading-planar bound-state equation in a genuine confining gauge theory. Its content is the following precise construction.

1. The meson equation follows from a gauge constraint, the color-singlet Hilbert-space sector, and planar color algebra.
2. The absence of transverse gauge polarizations in $1 + 1$ dimensions makes the gauge field a constraint variable while preserving a nontrivial nonabelian Coulomb kernel.
3. Large-N_c factorization makes one-meson sectors stable at leading order. Meson interactions and widths are organized by subleading powers of $1/N_c$.
4. The light-front construction is a statement about a declared regulator, a zero-mode prescription, and an endpoint-mass coordinate. Changing any of these data changes the operator whose spectrum is being studied.

Thus two-dimensional large-N_c QCD is a benchmark for confinement, bound-state equations, light-front regularization, and the relation between gauge constraints and color-singlet Hilbert-space sectors. Its comparison with four-dimensional QCD is structural rather than literal: the four-dimensional theory has propagating gluons, running coupling, spin-dependent interactions, and multi-particle channels that require the separate developments of the later QCD chapters.

Chapter 54

The Standard Model as a Hybrid Quantum Field Theory

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The Standard Model used in physics is not presently a single completed constructive definition of a four-dimensional continuum QFT. It is a precise hybrid object whose components have different mathematical statuses: nonperturbative QCD, understood through its continuum Wightman target and through lattice regulators used to define hadronic matrix elements; the renormalized electroweak chiral gauge theory, defined order by order in perturbation theory in the same sense in which perturbative QED is defined; hybrid coupling data that pairs perturbative electroweak fields and sources with specified gauge-invariant local QCD operators; lower-energy weak effective theories; and matching maps between overlapping regimes. No physical ultraviolet cutoff is a parameter of a Standard Model prediction. Cutoffs and regulators enter either as auxiliary devices that are removed or absorbed into renormalized coordinates, or as extra data in a different Wilsonian or SMEFT problem. The purpose of this chapter is to write the hybrid object without hiding these domains of validity. Within each domain the standard formulae are derived as statements about explicit fields, couplings, operators, and observables. Assertions about higher energies, large field values, or physics beyond this field content require additional mathematical data; they are not supplied merely by drawing a perturbative RG curve or by writing a formal Lagrangian.

The local representation theory is developed first, because it fixes the charges, anomalies, mass coordinates, and operator coordinates that every perturbative, effective, or nonperturbative realization must reproduce. The hybrid definition of the full object is then assembled after these components have been made explicit. Until that point, the phrase “the Standard Model” in a local formula means the corresponding renormalized perturbative electroweak construction together with the stated QCD and matching data, not an assumed constructive theorem and not a finite-cutoff theory.

54.1 Gauge and Matter Data

Convention 54.1 (Electroweak charge and trace normalizations)**.** The hypercharge coordinate is normalized by

$$Q_{\mathrm{em}} = T_L^3 + Y,$$

where T_L^3 is the third generator of the weak $SU(2)_L$ doublet in the standard electroweak normalization. For transparent mass and charge formulae, this chapter temporarily uses the conventional explicit-coupling fields $\mathcal{G}_\mu, \mathcal{W}_\mu, \mathcal{B}_\mu$. The conversion to the monograph's Yang–Mills convention of Chapter 45 is

$$A_\mu^{(3)} = g_3 \mathcal{G}_\mu^A T^A, \qquad A_\mu^{(2)} = g_2 \mathcal{W}_\mu^a \tau^a, \qquad A_\mu^{(1)} = g_1 \mathcal{B}_\mu Y,$$

where T^A and $\tau^a = \sigma^a/2$ are the conventional half-trace generators, normalized by $\mathrm{tr}(\tau^a\tau^b) = \frac{1}{2}\delta^{ab}$ in the fundamental weak doublet. If $t^a = \sqrt{2}\,\tau^a$ denotes the trace-delta basis used in Chapter 45, then $g_{2,\mathrm{mono}} = g_2/\sqrt{2}$ in a matter vertex. The invariant kinetic terms are equivalently written as explicit-coupling kinetic terms for $\mathcal{G}, \mathcal{W}, \mathcal{B}$ or as $-\frac{1}{4g^2}\,\mathrm{tr}(F_{\mu\nu}F^{\mu\nu})$ for the coupling-absorbed connections.

Definition 54.2 (One-generation left-Weyl representation)**.** For one generation, written as left-handed Weyl fields, the representation is

field	$SU(3)_c \times SU(2)_L$	Y
$Q_L = (u_L, d_L)$	$(\mathbf{3}, \mathbf{2})$	$1/6$
u^c	$(\overline{\mathbf{3}}, \mathbf{1})$	$-2/3$
d^c	$(\overline{\mathbf{3}}, \mathbf{1})$	$1/3$
$L_L = (\nu_L, e_L)$	$(\mathbf{1}, \mathbf{2})$	$-1/2$
e^c	$(\mathbf{1}, \mathbf{1})$	$1.$

Here u^c, d^c, e^c are left-handed charge-conjugate fields, not right-handed fields in the same representation. A gauge-singlet neutrino field, if included in the same left-handed convention as ν^c, has representation $(\mathbf{1}, \mathbf{1})_0$ and does not affect the local gauge anomaly sums.

Definition 54.3 (Minimal Higgs and Yukawa sector)**.** The minimal Higgs scalar is

$$H \in (\mathbf{1}, \mathbf{2})_{1/2}.$$

Set

$$\widetilde{H} := \mathrm{i}\sigma^2 H^*, \qquad \widetilde{H} \in (\mathbf{1}, \mathbf{2})_{-1/2},$$

where the second statement uses the pseudoreality of the $SU(2)$ doublet. In the left-handed Weyl convention of Definition 54.2, the renormalizable Yukawa sector is

$$\mathcal{L}_Y = -(Y_u)_{IJ}\,(Q_L^I H)\,u^{cJ} - (Y_d)_{IJ}\,(Q_L^I \widetilde{H})\,d^{cJ} - (Y_e)_{IJ}\,(L_L^I \widetilde{H})\,e^{cJ} + \text{Hermitian conjugate},$$

where $I, J = 1, 2, 3$ are generation labels and all gauge indices are contracted by the invariant tensors of $SU(3)_c$ and $SU(2)_L$. In components, $(QH)u^c$ abbreviates the contraction of the two

Weyl spinor indices by $\epsilon_{\alpha\beta}$, the two weak doublet indices by ϵ_{ij}, and the color indices by the natural $\mathbf{3} \otimes \overline{\mathbf{3}} \to \mathbf{1}$ pairing. The displayed Y_u, Y_d, Y_e are complex 3×3 matrices of local coupling coordinates.

Definition 54.4 (Local Standard Model charge and bundle data)**.** The local Standard Model charge algebra is

$$\mathfrak{g}_{\mathrm{SM}} = \mathfrak{su}(3)_c \oplus \mathfrak{su}(2)_L \oplus \mathfrak{u}(1)_Y.$$

The corresponding covering compact group for local representation and bundle bookkeeping is

$$\widetilde{G}_{\mathrm{SM}} = SU(3)_c \times SU(2)_L \times U(1)_y,$$

where $y := 6Y$ is the integer hypercharge coordinate for the compact $U(1)$ factor. The Lie-algebra generator appearing in the electroweak covariant derivative is still $Y = y/6$. A representation-theoretic global form is a quotient

$$G_{\mathrm{SM}} = \widetilde{G}_{\mathrm{SM}}/\Gamma, \qquad \Gamma \subset Z(\widetilde{G}_{\mathrm{SM}}),$$

for which the local fields in Definitions 54.2 and 54.3 descend to representations of G_{SM}. On a spin four-manifold M, let S_L denote the left-handed spinor bundle and let $E_R := P \times_{G_{\mathrm{SM}}} R$ be the vector bundle associated to a representation R. The local classical field data consist of P, a connection on P, left-Weyl fields in $\Gamma(S_L \otimes E_R)$ for the three generations of the representations in Definition 54.2, a Higgs field in $\Gamma(E_H)$ for $H \in (\mathbf{1}, \mathbf{2})_{1/2}$, and the local Yang–Mills, scalar, and Yukawa action. The perturbative electroweak quantum theory further requires gauge fixing or BV data, a subtraction scheme, and the renormalized construction of Green functions and operator insertions as formal power series to all orders in the electroweak couplings. A cutoff regulator may be introduced in a proof or computation, but then it is an auxiliary regularization device to be removed or matched away; it is not the definition of the electroweak sector and it is not a parameter in the Standard Model prediction.

The product $\widetilde{G}_{\mathrm{SM}}$ in Definition 54.4 is not, by itself, the gauge group of a completed quantum Standard Model. In the hybrid definition of Definition 54.37, the $SU(3)_c$ factor belongs to the nonperturbative QCD Wightman component, while $SU(2)_L \times U(1)_Y$ belongs to the all-orders renormalized perturbative electroweak component; their coupling is mediated by the operator coupling $\mathcal{C}_{\text{QCD-EW}}$. The product notation records the common local charge assignments, anomaly sums, and possible bundle/global-form bookkeeping that these components must share. The hybrid definition treats the color sector, the electroweak perturbative sector, and their coupling map as distinct pieces of structure rather than as one declared nonperturbative path integral with all gauge factors on the same footing.

The quotient Γ is invisible in the Lie algebra and in local perturbative vertices, but it changes the allowed bundles, line operators, and higher-form backgrounds in any formulation where those objects are defined. Those global questions belong to the generalized-symmetry analysis in Chapter 113. This chapter uses only the local representation-theoretic data unless a bundle or line operator is explicitly mentioned.

Remark 54.5 (Electroweak perturbation theory and optional cutoffs). The baseline electroweak component of the hybrid Standard Model is $\mathfrak{D}^{\mathrm{pert}}_{\mathrm{EW}}$: an all-orders renormalized perturbative chiral gauge theory, formulated after gauge fixing or in BV language, with a specified subtraction and composite-operator scheme. It is not a finite-cutoff theory. In a proof or computation one may introduce a cutoff-like parameter for electroweak fields, external sources, or a weak effective theory; such a parameter is then auxiliary regularization data or extra Wilsonian/EFT data for a different problem, not a hidden ultraviolet cutoff in the Standard Model prediction framework. The color sector is not thereby made into a cutoff sector of the same path integral; it is supplied through the QCD component $\mathfrak{D}^{\mathrm{W}}_{\mathrm{QCD}}$, with lattice or other nonperturbative regulators used only to approximate the required gauge-invariant QCD matrix elements.

One could instead pose a separate formal construction problem in which the QCD sector is kept as a continuum Wightman theory while an ultraviolet regulator is placed only on electroweak perturbative fields and sources. Such a construction would have to define mixed generating functionals whose coefficients are QCD Wightman distributions of the gauge-invariant operators in Definition 54.35; it would also have to specify the extension of those distributions at coincident points, the contact-term scheme, and the electroweak Ward or BV identities at finite electroweak cutoff. This is a coherent possible formalization of the hybrid viewpoint, but it is additional mathematical data beyond $\mathfrak{D}^{\mathrm{pert}}_{\mathrm{EW}}$, it is not the usual textbook path integral, and it is not ordinarily how Standard Model phenomenological computations are presented.

This is different from postulating a single ultraviolet-regulated path integral for the full local product data $SU(3)_c \times SU(2)_L \times U(1)_Y$. Such a full cutoff formulation would have to regulate the $SU(3)_c$ gauge fields and the chiral electroweak fields in one coupled object, choose the phase of the chiral determinant, provide reflection or reconstruction data, and formulate a continuum-limit problem for the coupled theory. That stronger object is the kind of data discussed later in Definition 54.40; it is not the baseline Standard Model prediction framework used in this chapter.

The kernel of the minimal local representation content is a finite center-charge calculation. Let $y := 6Y$ be the integer hypercharge coordinate, so the minimal fields have

$$y(Q_L, u^c, d^c, L_L, e^c, H) = (1, -4, 2, -3, 6, 3).$$

Let $\omega_3 = \exp(2\pi\mathrm{i}/3)$. The element

$$z = \big(\omega_3, -1, \exp(\mathrm{i}\pi/3)\big) \in SU(3)_c \times SU(2)_L \times U(1)_y \tag{54.1}$$

acts trivially on every field in Definitions 54.2 and 54.3. It generates a cyclic subgroup $\mathbb{Z}_6$ of the center, and the minimal local field content descends through any quotient by a subgroup of this $\mathbb{Z}_6$:

$$\Gamma = 1, \quad \mathbb{Z}_2, \quad \mathbb{Z}_3, \quad \mathbb{Z}_6.$$

For a representation with color triality $t \in \mathbb{Z}/3\mathbb{Z}$, weak doublet parity $s \in \mathbb{Z}/2\mathbb{Z}$, and integer hypercharge y, the element z acts by the phase

$$\exp\left[2\pi\mathrm{i}\left(\frac{t}{3} + \frac{s}{2} + \frac{y}{6}\right)\right].$$

For the six minimal representations the triples (t, s, y) are

$$\begin{array}{c|c} Q_L & (1,1,1) \\ u^c & (-1,0,-4) \\ d^c & (-1,0,2) \\ L_L & (0,1,-3) \\ e^c & (0,0,6) \\ H & (0,1,3). \end{array}$$

In each row $t/3+s/2+y/6$ is an integer. Thus z acts trivially. The element has order six, because its three center components have orders three, two, and six. Since every subgroup of a trivially acting central subgroup also acts trivially, the four displayed quotients are allowed by the minimal representation content. Distinguishing these global forms requires line-operator and bundle data, not only the local Lie algebra.

Gauge invariance of the minimal Yukawa sector. The three terms in Definition 54.3 are precisely the gauge-invariant local monomials that are bilinear in the listed left-handed Weyl fields, linear in H or $\widetilde{H}$, and of engineering dimension at most four, up to flavor tensors and Hermitian conjugation. Lorentz invariance forces the two left-handed Weyl spinor indices in each fermion bilinear to be contracted by the antisymmetric invariant tensor of $SL(2,\mathbb{C})$. Color invariance requires Q_L to pair with either u^c or d^c, because the quark singlet contraction is $\mathbf{3}\otimes\overline{\mathbf{3}}\to\mathbf{1}$; the lepton bilinear is already color neutral. Weak $SU(2)$-invariance then forces the remaining weak doublet index to be contracted with either H or $\widetilde{H}$ by the invariant tensor of the doublet representation.

The hypercharge sums determine which Higgs doublet occurs:

$$\frac{1}{6}+\frac{1}{2}-\frac{2}{3}=0,\qquad \frac{1}{6}-\frac{1}{2}+\frac{1}{3}=0,\qquad -\frac{1}{2}-\frac{1}{2}+1=0.$$

Thus Q_LHu^c, $Q_L\widetilde{H}d^c$, and $L_L\widetilde{H}e^c$ are gauge invariant. The opposite choices of H and $\widetilde{H}$ have nonzero hypercharge, hence do not define local gauge-invariant monomials in the left-handed convention. Power counting excludes additional renormalizable matter monomials with more fields or derivatives in this minimal field content. Flavor indices are spectators for the local charge algebra, so the allowed coefficients are the three arbitrary complex flavor matrices shown above.

Flavor rotations of the fermion fields remove unphysical parameters; the remaining charged-current quark mixing is encoded in the CKM matrix. If neutrino masses are included through dimension-five or singlet-neutrino operators, a separate PMNS mixing matrix appears in the lepton sector.

54.2 Flavor Coordinates and Charged Currents

The Yukawa matrices are not themselves the physical flavor parameters. A physical statement must specify which field redefinitions have already been used and which current is being observed.

Definition 54.6 (Quark mass coordinates and CKM matrix)**.** After evaluating the Higgs field at H_0, define the complex quark mass matrices

$$M_u=\frac{v}{\sqrt{2}}Y_u,\qquad M_d=\frac{v}{\sqrt{2}}Y_d.$$

Choose singular-value decompositions

$$(U_L^u)^\dagger M_uU_R^u=D_u,\qquad (U_L^d)^\dagger M_dU_R^d=D_d, \tag{54.2}$$

where $U_L^u,U_R^u,U_L^d,U_R^d\in U(3)$ and D_u,D_d are diagonal with nonnegative entries. The Cabibbo–Kobayashi–Maskawa matrix is

$$V_{\mathrm{CKM}}:=(U_L^u)^\dagger U_L^d. \tag{54.3}$$

It is the coefficient matrix in the charged weak current written in quark mass coordinates:

$$J_\mu^+ = \overline{u}_{L,a}\gamma_\mu (V_{\text{CKM}})_{ab} d_{L,b}, \qquad J_\mu^- = (J_\mu^+)^\dagger.$$

Here u_L, d_L denote mass-basis left-handed quark fields. The neutral gauge currents remain diagonal in flavor in these coordinates.

Flavor parameter counting. For n quark generations with nondegenerate masses, the pair of complex Yukawa matrices (Y_u, Y_d) contains

$$2n \quad \text{quark masses,} \qquad \frac{n(n-1)}{2} \quad \text{mixing angles,} \qquad \frac{(n-1)(n-2)}{2} \quad \text{CP-odd phases.}$$

In particular, two generations allow one mixing angle and no CKM CP phase, while three generations allow three angles and one CKM CP phase. The two complex $n \times n$ Yukawa matrices contain $4n^2$ real parameters. In the absence of Yukawa couplings the quark kinetic and gauge terms have flavor symmetry

$$U(n)_Q \times U(n)_u \times U(n)_d.$$

The Yukawa matrices break this group to the diagonal baryon-number $U(1)_B$, which does not change Y_u or Y_d. Therefore $3n^2 - 1$ real parameters are removable by flavor-coordinate choices. The physical quark-sector parameter count is

$$4n^2 - (3n^2 - 1) = n^2 + 1.$$

Among these are $2n$ nonnegative singular values, namely the quark masses. Thus the mixing matrix carries

$$n^2 + 1 - 2n = (n-1)^2$$

parameters. A unitary $n \times n$ matrix has n^2 real parameters. After the masses have been diagonalized, the $2n$ quark mass eigenfields may be rephased, but the common baryon-number rephasing leaves V_{CKM} unchanged. Hence $2n - 1$ phases are unphysical in V_{CKM}. The remaining $(n-1)^2$ parameters split into $n(n-1)/2$ real rotation angles and

$$(n-1)^2 - \frac{n(n-1)}{2} = \frac{(n-1)(n-2)}{2}$$

phases.

In the quark mass basis of Definition 54.6, the neutral electromagnetic, gluon, and Z-boson currents are flavor diagonal at tree level. Flavor change in the renormalizable gauge currents is confined to the charged current and is controlled by V_{CKM}. The gluon and photon couple to generators proportional to the identity in generation space. A unitary change of mass coordinates therefore gives

$$\overline{q}_L U_L^\dagger \gamma_\mu T U_L q_L = \overline{q}_L \gamma_\mu T q_L$$

whenever T acts only on color or electric charge and not on generation. The Z-current is a linear combination of T_L^3 and Q_{em}. Within the up sector and within the down sector these charges are again generation-independent, so the same unitarity cancellation applies. The charged current is different because it pairs the up component of Q_L with the down component before the two independent left singular-vector matrices have been chosen. Its flavor matrix is therefore $(U_L^u)^\dagger U_L^d = V_{\text{CKM}}$.

Definition 54.7 (Jarlskog invariant)**.** For three generations, a rephasing-invariant CKM CP-odd coordinate is

$$J_{\mathrm{CKM}} = \operatorname{Im}\left(V_{us}V_{cb}V_{ub}^{*}V_{cs}^{*}\right).$$

Equivalently, any expression $\operatorname{Im}(V_{ij}V_{kl}V_{il}^{*}V_{kj}^{*})$ with distinct i, k and distinct j, l is a rephasing-invariant quartet. For a three-by-three unitary matrix these quartets are related by unitarity and carry the same magnitude, with signs fixed by row and column orientation.

Rephasing invariance of J_{CKM}. Under mass-basis quark rephasings

$$V_{ij} \longmapsto \mathrm{e}^{\mathrm{i}\alpha_i}V_{ij}\mathrm{e}^{-\mathrm{i}\beta_j},$$

the quantity J_{CKM} is invariant. For $n = 2$ the corresponding quartet invariant vanishes after rephasing, so a two-generation charged current has no intrinsic CKM CP phase. The phase of the quartet

$$V_{us}V_{cb}V_{ub}^{*}V_{cs}^{*}$$

is multiplied by

$$\mathrm{e}^{\mathrm{i}\alpha_u}\mathrm{e}^{-\mathrm{i}\beta_s}\mathrm{e}^{\mathrm{i}\alpha_c}\mathrm{e}^{-\mathrm{i}\beta_b}\mathrm{e}^{-\mathrm{i}\alpha_u}\mathrm{e}^{\mathrm{i}\beta_b}\mathrm{e}^{-\mathrm{i}\alpha_c}\mathrm{e}^{\mathrm{i}\beta_s} = 1.$$

Thus its imaginary part is a coordinate-independent CP-odd function of the charged current. The equality of magnitudes of the different three-generation quartets follows directly from row and column orthogonality. For example, if $i \neq k$ and j, l, n are the three column labels, row orthogonality gives

$$V_{ij}V_{kj}^{*} + V_{il}V_{kl}^{*} + V_{in}V_{kn}^{*} = 0.$$

Multiplying by $V_{kl}V_{il}^{*}$ and taking imaginary parts gives

$$\operatorname{Im}(V_{ij}V_{kl}V_{il}^{*}V_{kj}^{*}) = -\operatorname{Im}(V_{in}V_{kl}V_{il}^{*}V_{kn}^{*}).$$

Column orthogonality gives the analogous relation for fixed column pair and varying rows. Combining the row and column relations moves any quartet with distinct row labels and distinct column labels to any other such quartet; interchanging the ordered row pair or the ordered column pair changes the sign. For two generations, the flavor-counting paragraph above shows that all phases in a 2×2 unitary charged-current matrix are removable by quark-field rephasings. A representative can therefore be chosen real, and every quartet imaginary part is zero in that coordinate.

54.3 Electroweak Breaking and Mass Coordinates

The word "breaking" in this section refers to a local field coordinate around a Higgs background and to the stabilizer of that background. Gauge redundancy is not a global symmetry acting faithfully on the physical Hilbert space, and it is not literally broken. The physical content of the Brout–Englert–Higgs phase is the spectrum, currents, and gauge-invariant operator algebra described in the renormalized perturbative construction after gauge fixing or BV treatment, or in a nonperturbative construction if one has been supplied. The formulas below are the tree-level mass and coupling coordinates of that local electroweak chart.

Definition 54.8 (Electroweak scalar chart)**.** The minimal renormalizable electroweak scalar potential is

$$V(H) = \lambda\left(H^\dagger H - \frac{v^2}{2}\right)^2, \qquad \lambda > 0.$$

In the local field-space chart used below,

$$H(x) = \frac{1}{\sqrt{2}}\begin{pmatrix}\chi_1(x) + \mathrm{i}\chi_2(x)\\ v + h(x) + \mathrm{i}\chi_3(x)\end{pmatrix}.$$

The reference vacuum vector is

$$H_0 = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\ v\end{pmatrix}$$

in the same chart. Here $v > 0$ and $\lambda > 0$ are renormalized coordinates in the perturbative electroweak construction. The fields χ_1, χ_2, χ_3 are local coordinates tangent to the gauge orbit through H_0, while h is the radial scalar coordinate.

Proposition 54.9 (Electromagnetic stabilizer and weak-boson masses)**.** *In the convention of Convention 54.1, the stabilizer of H_0 inside the local group $SU(2)_L \times U(1)_Y$ is generated by*

$$Q_{\mathrm{em}} = T_L^3 + Y.$$

The quadratic gauge-boson mass coordinates are

$$W_\mu^\pm = \frac{1}{\sqrt{2}}(\mathcal{W}_\mu^1 \mp \mathrm{i}\mathcal{W}_\mu^2), \qquad Z_\mu = \frac{g_2\mathcal{W}_\mu^3 - g_1\mathcal{B}_\mu}{\sqrt{g_1^2+g_2^2}}, \qquad A_\mu = \frac{g_1\mathcal{W}_\mu^3 + g_2\mathcal{B}_\mu}{\sqrt{g_1^2+g_2^2}},$$

with

$$m_W = \frac{g_2 v}{2}, \qquad m_Z = \frac{v}{2}\sqrt{g_1^2+g_2^2}, \qquad m_A = 0.$$

The coupling of the massless field is

$$e = g_2\sin\theta_W = g_1\cos\theta_W, \qquad \tan\theta_W = \frac{g_1}{g_2}.$$

Proof. The weak generator $T_L^3 = \mathrm{diag}(1/2, -1/2)$ acts on H_0 by $-H_0/2$, while the hypercharge generator acts by $H_0/2$. Hence $(T_L^3 + Y)H_0 = 0$. The generators T_L^1 and T_L^2 move H_0 into the upper component, and a general combination $aT_L^3 + bY$ annihilates H_0 only when $a = b$. Therefore the one-dimensional stabilizer Lie algebra is spanned by Q_{em}.

The covariant derivative in the explicit-coupling convention is

$$D_\mu H = \left(\partial_\mu - \mathrm{i}g_2\mathcal{W}_\mu^a\tau^a - \mathrm{i}g_1\mathcal{B}_\mu Y\right)H.$$

Using

$$\tau^1 H_0 = \frac{v}{2\sqrt{2}}\begin{pmatrix}1\\0\end{pmatrix}, \qquad \tau^2 H_0 = \frac{v}{2\sqrt{2}}\begin{pmatrix}-\mathrm{i}\\0\end{pmatrix}, \qquad \tau^3 H_0 = -\frac{1}{2}H_0, \qquad YH_0 = \frac{1}{2}H_0,$$

the quadratic term from $(D_\mu H)^\dagger(D^\mu H)$ at $H = H_0$ is

$$(D_\mu H_0)^\dagger(D^\mu H_0) = \frac{v^2}{8}\left[g_2^2(\mathcal{W}_\mu^1\mathcal{W}^{1\mu} + \mathcal{W}_\mu^2\mathcal{W}^{2\mu}) + (-g_2\mathcal{W}_\mu^3 + g_1\mathcal{B}_\mu)^2\right].$$

The charged part is $(g_2^2 v^2/4)W_\mu^+ W^{-\mu}$, so $m_W^2 = g_2^2 v^2/4$. The neutral quadratic form has rank one: the massive unit vector is Z_μ, the null vector is A_μ, and comparison with the real-vector mass term $\frac{1}{2}m_Z^2 Z_\mu Z^\mu$ gives $m_Z^2 = (g_1^2+g_2^2)v^2/4$.

Finally invert the neutral rotation:

$$\mathcal{W}_\mu^3 = \frac{g_2 Z_\mu + g_1 A_\mu}{\sqrt{g_1^2+g_2^2}}, \qquad \mathcal{B}_\mu = \frac{-g_1 Z_\mu + g_2 A_\mu}{\sqrt{g_1^2+g_2^2}}.$$

The coefficient of A_μ in $g_2 \mathcal{W}_\mu^3 T_L^3 + g_1 \mathcal{B}_\mu Y$ is

$$\frac{g_1 g_2}{\sqrt{g_1^2+g_2^2}}\,(T_L^3+Y).$$

This proves the displayed electromagnetic coupling and identifies the massless gauge field with the connection for the unbroken stabilizer. □

This is the nonabelian mass-matrix construction of Chapter 45 applied to the $(\mathbf{2})_{1/2}$ scalar representation. The three coordinates χ_1, χ_2, χ_3 are gauge-orbit coordinates in a local chart; in an R_ξ gauge they remain as unphysical fields paired by BRST, while in a unitary-gauge chart they are removed locally.

Higgs radial mass coordinate. In the scalar chart of Definition 54.8, the potential restricted to the radial coordinate is

$$V(h) = \lambda\left(vh + \frac{h^2}{2}\right)^2 = \lambda v^2 h^2 + \lambda v h^3 + \frac{\lambda}{4}h^4.$$

Consequently the radial scalar mass coordinate is

$$m_h^2 = 2\lambda v^2.$$

The cubic and quartic self-interaction coefficients in the potential are λv and $\lambda/4$, respectively, in this field coordinate. In the unitary local chart $H = (0, (v+h)/\sqrt{2})^T$,

$$H^\dagger H - \frac{v^2}{2} = vh + \frac{h^2}{2}.$$

Substitution into $V(H)$ gives the displayed polynomial. The Lorentzian Lagrangian contains $-V$, while the standard real-scalar mass term is $-\frac{1}{2}m_h^2 h^2$. Comparing the quadratic coefficients gives $m_h^2 = 2\lambda v^2$.

Custodial $SU(2)$ and the tree-level ρ coordinate. Set

$$\Sigma := (\widetilde{H}, H).$$

The scalar kinetic term with $g_1 = 0$ and the scalar potential are invariant under

$$\Sigma \longmapsto U_L \Sigma U_R^\dagger, \qquad U_L, U_R \in SU(2),$$

and the vacuum $\Sigma_0 = (v/\sqrt{2})\mathbf{1}_2$ preserves the diagonal subgroup $SU(2)_V$. With hypercharge gauged as the T^3_R subgroup, the tree-level mass ratio

$$\rho_{\text{tree}} := \frac{m_W^2}{m_Z^2 \cos^2 \theta_W}$$

is equal to 1. The identity

$$\frac{1}{2}\,\mathrm{tr}(\Sigma^\dagger \Sigma) = H^\dagger H$$

shows that the scalar potential depends only on $\mathrm{tr}(\Sigma^\dagger\Sigma)$, hence is invariant under left and right multiplication by unitary matrices. With $g_1 = 0$, the covariant derivative acts only by left $SU(2)_L$ multiplication, so the right $SU(2)_R$ remains a global symmetry of the scalar kinetic term. The vacuum equation $U_L \Sigma_0 U_R^\dagger = \Sigma_0$ is equivalent to $U_L = U_R$, giving the diagonal stabilizer.

The hypercharge gauge field gauges only the T^3_R direction and therefore breaks the global $SU(2)_R$ explicitly, but the mass formulae of Proposition 54.9 still give

$$\cos\theta_W = \frac{g_2}{\sqrt{g_1^2 + g_2^2}}, \qquad m_W^2 = \frac{g_2^2 v^2}{4}, \qquad m_Z^2 = \frac{(g_1^2 + g_2^2)v^2}{4}.$$

Substitution gives $\rho_{\text{tree}} = 1$. Radiative corrections and higher-dimensional operators are separate coordinates of the electroweak EFT; they are not part of this tree-level identity.

54.4 Gauge-Anomaly Cancellation

Definition 54.10 (Gauge-anomaly coefficients for the local field content)**.** For a collection of left-handed Weyl fermions in representations R_i of $\mathfrak{g}_{\mathrm{SM}}$, the perturbative gauge-anomaly tensor is the symmetric cubic functional

$$\mathcal{A}(X, Y, Z) = \sum_i \mathrm{tr}_{R_i}\big(X\{Y, Z\}\big), \qquad X, Y, Z \in \mathfrak{g}_{\mathrm{SM}},$$

with spectator multiplicities included in the trace. For a mixed $G^2U(1)_Y$ component, this reduces to the sum of hypercharge times the quadratic index of the G-representation. For the mixed gravitational-$U(1)_Y$ anomaly, the coefficient is the sum of hypercharges over all left-handed Weyl components, again including spectator multiplicities.

Proposition 54.11 (SM anomaly cancellation)**.** *For the one-generation representation of Definition 54.2, all perturbative local gauge anomalies and the mixed gravitational-hypercharge anomaly vanish. The finite $SU(2)_L$ anomaly also vanishes generation by generation.*

Proof. The calculation uses only the representation table and the fact that all fermions have been written as left-handed Weyl fields. For the pure $SU(3)_c^3$ anomaly, the two weak components of Q_L contribute two fundamental color representations, while u^c and d^c contribute two antifundamentals. Since the cubic index changes sign under complex conjugation,

$$2A(\mathbf{3}) - A(\mathbf{3}) - A(\mathbf{3}) = 0.$$

The pure $SU(2)_L^3$ perturbative anomaly vanishes because the symmetric cubic invariant d^{abc} of $\mathfrak{su}(2)$ is zero. Mixed $SU(3)_c U(1)_Y^2$ and $SU(2)_L U(1)_Y^2$ components vanish because they contain $\mathrm{tr}_R(T^a)$ for a semisimple generator.

For $SU(3)_c^2 U(1)_Y$, one generation gives

$$\mathcal{A}[SU(3)^2 U(1)_Y] = 2\left(\frac{1}{6}\right) T(\mathbf{3}) + \left(-\frac{2}{3}\right) T(\overline{\mathbf{3}}) + \left(\frac{1}{3}\right) T(\overline{\mathbf{3}}) = 0.$$

Here $T(\overline{\mathbf{3}}) = T(\mathbf{3})$, and the factor 2 is the weak doublet multiplicity. For $SU(2)_L^2 U(1)_Y$,

$$\mathcal{A}[SU(2)^2 U(1)_Y] = 3\left(\frac{1}{6}\right) T(\mathbf{2}) + \left(-\frac{1}{2}\right) T(\mathbf{2}) = 0.$$

Here the factor 3 is the color multiplicity of Q_L. For the cubic hypercharge anomaly, include the full dimensions of the nonabelian representations:

$$\begin{aligned}\mathcal{A}[U(1)_Y^3] &= 6\left(\frac{1}{6}\right)^3 + 3\left(-\frac{2}{3}\right)^3 + 3\left(\frac{1}{3}\right)^3 + 2\left(-\frac{1}{2}\right)^3 + 1^3 \\ &= 0.\end{aligned}$$

The mixed gravitational-hypercharge anomaly coefficient is

$$6\left(\frac{1}{6}\right) + 3\left(-\frac{2}{3}\right) + 3\left(\frac{1}{3}\right) + 2\left(-\frac{1}{2}\right) + 1 = 0.$$

Finally, the finite $SU(2)$ anomaly of Chapter 55 is absent because each generation contains four left-handed $SU(2)_L$ doublets: three colored quark doublets and one lepton doublet. The number of doublets is therefore even. These equalities are finite representation-theoretic constraints on the regulated fermion determinant line; they are not consequences of perturbative renormalizability alone. □

54.5 Baryon and Lepton Number as Global Data

Definition 54.12 (Classical B, L, and $B-L$ charges)**.** In the left-handed Weyl convention, assign baryon and lepton charges

field	B	L
Q_L	$1/3$	0
u^c	$-1/3$	0
d^c	$-1/3$	0
L_L	0	1
e^c	0	-1
ν^c, if included	0	$-1.$

The signs for conjugate fields are the charges of the left-handed conjugate fields themselves. These assignments are statements about global-current coordinates in the local Lagrangian; whether a global symmetry survives in the quantum theory is determined by its anomaly polynomial and by possible operator insertions.

$B+L$ anomaly and $B-L$ mixed-gauge cancellation. For one generation of the minimal representation without ν^c, the mixed $SU(2)_L^2U(1)_B$ and $SU(2)_L^2U(1)_L$ anomaly coefficients are both nonzero:

$$\mathcal{A}[SU(2)_L^2U(1)_B] = T(\mathbf{2}), \qquad \mathcal{A}[SU(2)_L^2U(1)_L] = T(\mathbf{2}).$$

Their difference vanishes, so $B-L$ has no mixed $SU(2)_L^2$ anomaly. The mixed $SU(3)_c^2U(1)_{B-L}$ anomaly also vanishes. The gravitational and cubic anomalies of $B-L$ vanish generation by generation only after a gauge-singlet ν^c with $B-L=1$ is included. The $SU(2)^2U(1)$ coefficient is the sum of the global charge times the quadratic index of each weak doublet, with color multiplicity included. For baryon number only Q_L contributes, giving

$$3\left(\frac{1}{3}\right)T(\mathbf{2}) = T(\mathbf{2}).$$

For lepton number only L_L contributes, giving $T(\mathbf{2})$. Thus $B+L$ is anomalous and $B-L$ cancels in the $SU(2)^2$ channel. For $SU(3)^2(B-L)$, the common $T(\mathbf{3})$ factors out and the coefficient is

$$2\left(\frac{1}{3}\right) - \frac{1}{3} - \frac{1}{3} = 0,$$

where the factor 2 is the weak multiplicity of Q_L.

For the mixed gravitational anomaly of $B-L$, including multiplicities but not ν^c, one obtains

$$6\left(\frac{1}{3}\right) + 3\left(-\frac{1}{3}\right) + 3\left(-\frac{1}{3}\right) + 2(-1) + 1 = -1.$$

The cubic $U(1)_{B-L}^3$ coefficient gives the same value:

$$6\left(\frac{1}{3}\right)^3 + 3\left(-\frac{1}{3}\right)^3 + 3\left(-\frac{1}{3}\right)^3 + 2(-1)^3 + 1^3 = -1.$$

Adding a singlet ν^c with $B-L=1$ contributes $+1$ to each of these two anomaly coefficients and cancels them. This is a finite anomaly calculation, not a statement that a singlet neutrino has been observed or that one has chosen a particular neutrino-mass mechanism.

Remark 54.13 (Sphalerons as transitions between electroweak sectors). The $SU(2)_L$ anomaly means that an electroweak gauge-field history with topological charge Q_{top} changes the global charges by $\Delta B = \Delta L = N_g Q_{\text{top}}$, where N_g is the number of generations, while $\Delta(B-L)=0$. This statement assumes a field history whose boundary conditions make the $SU(2)$ second Chern number an integer; on more general backgrounds the corresponding statement must be formulated in terms of the anomaly inflow class. The sphaleron is the unstable static configuration at the top of the minimal barrier between neighboring electroweak sectors, as described in Chapter 45. Rates in a thermal state require real-time finite-temperature dynamics and are not fixed by the topological selection rule alone.

54.6 Higher-Dimensional Operator Coordinates

Definition 54.14 (SMEFT coupling chart)**.** Fix a regulator, a local operator basis, and a subtraction scheme. The corresponding Standard-Model effective coupling chart below a scale Λ is the local functional

$$S_{\mathrm{EFT}} = S_{\mathrm{SM}}^{\mathrm{ren}} + \sum_{d>4} \Lambda^{4-d} \sum_{A\in\mathcal{B}_d} C_A^{(d)}(\mu) \int_{M_4} \mathcal{O}_A^{(d)}(\mu), \tag{54.4}$$

where $\mathcal{B}_d$ is a specified basis of gauge-invariant local operators of engineering dimension d, after quotienting by total derivatives and by the chosen field-redefinition equations of motion. The symbol Λ is a reference scale used to write dimensionless Wilson coordinates in an effective theory beyond the renormalizable Standard Model. It is not a hidden cutoff parameter of Standard Model predictions. If the same expansion is interpreted as a Wilsonian theory with a physical cutoff, that interpretation is additional regulator and matching data. The coordinates $C_A^{(d)}(\mu)$ are not observables by themselves; an observable uses them together with the operator scheme, matching map, field domain, and matrix elements.

Definition 54.15 (Weinberg operator in the left-handed convention)**.** With only the minimal fields of Definitions 54.2 and 54.3, the derivative-free dimension-five lepton-number-violating operator is

$$\mathcal{O}_5^{IJ} = \epsilon^{\alpha\beta}\big(\epsilon_{ij}L^I_{\alpha i}H_j\big)\big(\epsilon_{k\ell}L^J_{\beta k}H_\ell\big), \tag{54.5}$$

with symmetric flavor coefficient $C_5^{IJ} = C_5^{JI}$. In the convention

$$\Delta\mathcal{L}_5 = -\frac{1}{2\Lambda}C_5^{IJ}\mathcal{O}_5^{IJ} + \text{Hermitian conjugate}, \tag{54.6}$$

the neutral-lepton Majorana mass matrix in the electroweak scalar chart is

$$(M_\nu)^{IJ} = \frac{v^2}{2\Lambda}C_5^{IJ}. \tag{54.7}$$

To verify (54.7), set $H = H_0$. The weak contraction $\epsilon_{ij}L^I_iH_j$ selects the neutral component of L^I and gives

$$\epsilon_{ij}L^I_{\alpha i}H_{0,j} = \frac{v}{\sqrt{2}}\,\nu^I_\alpha.$$

Substitution into (54.6) gives

$$\Delta\mathcal{L}_5 = -\frac{1}{2}\left(\frac{v^2}{2\Lambda}C_5^{IJ}\right)\epsilon^{\alpha\beta}\nu^I_\alpha\nu^J_\beta + \text{Hermitian conjugate},$$

which is the displayed Majorana mass coordinate. The symmetry of C_5^{IJ} follows because the Lorentz contraction of two left-handed Weyl fields is symmetric in the flavor labels after the anticommutation of the fields is combined with the antisymmetry of $\epsilon^{\alpha\beta}$.

Integrating out singlet neutrinos at tree level. Add gauge-singlet left-handed fields ν^{cA} with

$$\Delta\mathcal{L} = -Y_\nu^{IA}(L^IH)\nu^{cA} - \frac{1}{2}M_{AB}\nu^{cA}\nu^{cB} + \text{Hermitian conjugate},$$

where M is a nonsingular complex symmetric matrix and spinor and weak indices are contracted as in (54.5). At tree level and to leading order in external momenta over the singular values of M, the dimension-five coefficient obeys

$$\frac{C_5}{\Lambda} = Y_\nu M^{-1}Y_\nu^T$$

up to the conventional overall sign that can be changed by rephasing Majorana fields. The algebraic equation for the heavy singlet field, after suppressing derivative corrections, is

$$M_{AB}\nu^{cB} + Y_\nu^{IA}(L^I H) = 0.$$

Thus

$$\nu^{cA} = -(M^{-1})^{AB} Y_\nu^{IB}(L^I H).$$

Substituting this solution back into the quadratic expression in ν^c gives a local operator quadratic in (LH) with coefficient $\frac{1}{2}Y_\nu M^{-1} Y_\nu^T$, with the sign depending on the convention used to order the Grassmann variables in the Majorana bilinear. Comparing with Definition 54.15 gives the displayed matching coordinate. The statement is a tree-level EFT matching computation, not a claim that singlet neutrinos are part of the minimal Standard Model field content.

Definition 54.16 (Dimension-six quotient space)**.** Let $\mathcal{V}_6$ be the complex vector space of local polynomial gauge-invariant densities of engineering dimension six built from

$$G^A_{\mu\nu}, \quad W^I_{\mu\nu}, \quad B_{\mu\nu}, \quad H, \quad D_\mu, \quad q, \ell, u, d, e,$$

where q, ℓ, u, d, e denote the standard chiral Standard-Model fields in four-component notation. This notation is a bookkeeping device for this basis: q, ℓ are the left-handed fields Q_L, L_L, while u, d, e are the right-handed conjugates of the left-handed Weyl fields (u^c, d^c, e^c) used in Definition 54.2. Let $\partial\mathcal{V}_5 \subset \mathcal{V}_6$ be total derivatives and let $\mathcal{E}_6 \subset \mathcal{V}_6/\partial\mathcal{V}_5$ be the subspace generated by

$$\frac{\delta S^{\mathrm{ren}}_{\mathrm{SM}}}{\delta\Phi}\,\mathcal{F}_\Phi + \text{Hermitian conjugate,} \tag{54.8}$$

where Φ runs over the SM fields and $\mathcal{F}_\Phi$ is any gauge-covariant local polynomial of dimension $6 - \dim(\delta S^{\mathrm{ren}}_{\mathrm{SM}}/\delta\Phi)$. A dimension-six SMEFT basis is an ordered basis of the quotient

$$\mathcal{Q}_6 := \mathcal{V}_6/(\partial\mathcal{V}_5 + \mathcal{E}_6), \tag{54.9}$$

together with a Hermiticity convention and a flavor-index convention for its coefficients.

Equation-of-motion operators as coordinates. Let $S^{\mathrm{ren}}_{\mathrm{SM}}$ be the renormalized SM action in the chosen regularization and subtraction scheme. Assume the regulator treats the near-identity local field change below as an allowed coordinate change, with its Jacobian either trivial in dimensional regularization or absorbed into local counterterms in a local cutoff scheme. The infinitesimal local change of field coordinates

$$\Phi \longmapsto \Phi + \Lambda^{-2}\mathcal{F}_\Phi(\Phi) \tag{54.10}$$

changes the action, to order Λ^{-2}, by an element of $\mathcal{E}_6$. Therefore coefficients multiplying elements of $\mathcal{E}_6$ are not invariant coordinates of the effective theory; they are removed by the quotient in Definition 54.16.

Taylor expansion of the action as a functional gives

$$S^{\mathrm{ren}}_{\mathrm{SM}}[\Phi + \Lambda^{-2}\mathcal{F}_\Phi] = S^{\mathrm{ren}}_{\mathrm{SM}}[\Phi] + \Lambda^{-2}\sum_\Phi \int_{M_4} \frac{\delta S^{\mathrm{ren}}_{\mathrm{SM}}}{\delta\Phi(x)}\mathcal{F}_\Phi(x) + O(\Lambda^{-4}).$$

Boundary terms produced by moving derivatives between $\delta S/\delta\Phi$ and $\mathcal{F}_\Phi$ lie in $\partial\mathcal{V}_5$. Thus the order-Λ^{-2} shift is exactly of the form (54.8). The statement is a coordinate statement inside a specified renormalized perturbative or regulated effective path integral; it does not say that the corresponding composite operator insertion vanishes as a distribution without specifying the operator-renormalization scheme. If the chosen scheme produces a local Jacobian for the field redefinition, that Jacobian changes local coupling coordinates in the same EFT chart; it does not make the equation-of-motion operator an independent observable.

Definition 54.17 (Warsaw-type dimension-six basis)**.** For a baryon-number preserving coupling chart with no singlet neutrino fields, one convenient ordered basis of $\mathcal{Q}_6$ is the Warsaw-type basis. Write

$$\widetilde{X}_{\mu\nu} := \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}X^{\rho\sigma}, \qquad H^\dagger i\overleftrightarrow{D}_\mu H := iH^\dagger D_\mu H - i(D_\mu H)^\dagger H,$$

and

$$H^\dagger i\overleftrightarrow{D}^I_\mu H := iH^\dagger\tau^I D_\mu H - i(D_\mu H)^\dagger\tau^I H.$$

The bosonic part contains the following fifteen one-generation operator types:

$$\begin{aligned}
X^3:&\quad O_G,\ O_{\widetilde{G}},\ O_W,\ O_{\widetilde{W}},\\
H^6:&\quad O_H = (H^\dagger H)^3,\\
H^4D^2:&\quad O_{H\Box} = (H^\dagger H)\Box(H^\dagger H),\quad O_{HD} = |H^\dagger D_\mu H|^2,\\
X^2H^2:&\quad O_{HG}, O_{H\widetilde{G}}, O_{HW}, O_{H\widetilde{W}}, O_{HB}, O_{H\widetilde{B}}, O_{HWB}, O_{H\widetilde{W}B}.
\end{aligned}$$

Here

$$\begin{aligned}
O_G = f^{ABC}G^{A\nu}_\mu G^{B\rho}_\nu G^{C\mu}_\rho,&\quad O_{\widetilde{G}} = f^{ABC}\widetilde{G}^{A\nu}_\mu G^{B\rho}_\nu G^{C\mu}_\rho,\\
O_W = \epsilon^{IJK}W^{I\nu}_\mu W^{J\rho}_\nu W^{K\mu}_\rho,&\quad O_{\widetilde{W}} = \epsilon^{IJK}\widetilde{W}^{I\nu}_\mu W^{J\rho}_\nu W^{K\mu}_\rho,
\end{aligned}$$

and $O_{HX} = (H^\dagger H)X_{\mu\nu}X^{\mu\nu}$, $O_{H\widetilde{X}} = (H^\dagger H)\widetilde{X}_{\mu\nu}X^{\mu\nu}$ for $X = G, W, B$, while

$$O_{HWB} = (H^\dagger\tau^I H)W^I_{\mu\nu}B^{\mu\nu}, \qquad O_{H\widetilde{W}B} = (H^\dagger\tau^I H)\widetilde{W}^I_{\mu\nu}B^{\mu\nu}.$$

The two-fermion part contains nineteen operator types:

$$\begin{aligned}
\psi^2H^3:&\quad O_{eH}, O_{uH}, O_{dH},\\
\psi^2H^2D:&\quad O^{(1)}_{H\ell}, O^{(3)}_{H\ell}, O^{(1)}_{Hq}, O^{(3)}_{Hq}, O_{He}, O_{Hu}, O_{Hd}, O_{Hud},\\
\psi^2XH:&\quad O_{eB}, O_{eW}, O_{uG}, O_{uW}, O_{uB}, O_{dG}, O_{dW}, O_{dB}.
\end{aligned}$$

The first line means the Yukawa monomials of Definition 54.3 multiplied by $(H^\dagger H)$. The H^2D line is generated by the templates

$$(H^\dagger i\overleftrightarrow{D}_\mu H)(\bar\psi\gamma^\mu\psi), \qquad (H^\dagger i\overleftrightarrow{D}^I_\mu H)(\bar\psi\tau^I\gamma^\mu\psi),$$
$$(\widetilde{H}^\dagger iD_\mu H)(\bar u\gamma^\mu d),$$

with the displayed labels specifying the allowed SM representations. The dipole line means $(\bar\psi\sigma^{\mu\nu}\psi')HX_{\mu\nu}$, with H or $\widetilde{H}$ chosen so that the monomial has the same gauge quantum numbers as the corresponding Yukawa monomial.

The baryon-number preserving four-fermion part contains twenty-five one-generation operator types:

$$\begin{aligned}
LL:&\quad O_{\ell\ell}, O_{qq}^{(1)}, O_{qq}^{(3)}, O_{\ell q}^{(1)}, O_{\ell q}^{(3)},\\
RR:&\quad O_{ee}, O_{uu}, O_{dd}, O_{eu}, O_{ed}, O_{ud}^{(1)}, O_{ud}^{(8)},\\
LR_{\text{vector}}:&\quad O_{\ell e}, O_{\ell u}, O_{\ell d}, O_{qe}, O_{qu}^{(1)}, O_{qu}^{(8)}, O_{qd}^{(1)}, O_{qd}^{(8)},\\
LR_{\text{scalar/tensor}}:&\quad O_{\ell edq}, O_{\ell equ}^{(1)}, O_{\ell equ}^{(3)}, O_{quqd}^{(1)}, O_{quqd}^{(8)}.
\end{aligned}$$

Flavor labels I, J, K, L are part of the coefficient coordinates. When flavor labels are restored, Hermiticity and exchange symmetries must be fixed before counting real parameters. Thus the basis is an ordered coordinate system with specified flavor and reality conventions.

Definition 54.18 (Baryon-violating dimension-six classes)**.** If baryon number is not imposed as a restriction on the effective couplings, four additional gauge-invariant dimension-six classes are allowed. In standard chiral four-component notation they may be represented as

$$\begin{aligned}
O_{duq\ell} &= \epsilon_{abc}\epsilon_{ij}(d^aCu^b)(q^{ci}C\ell^j),\\
O_{qque} &= \epsilon_{abc}\epsilon_{ij}(q^{ai}Cq^{bj})(u^cCe),\\
O_{qqq\ell} &= \epsilon_{abc}\epsilon_{i\ell}\epsilon_{jk}(q^{ai}Cq^{bj})(q^{ck}C\ell^\ell),\\
O_{duue} &= \epsilon_{abc}(d^aCu^b)(u^cCe).
\end{aligned}$$

Each class carries flavor labels and changes B and L by one unit with $\Delta(B-L)=0$. In the minimal SM definition used here these coefficients are set to zero by imposing baryon number on the effective couplings; in a more general effective theory they are independent coordinates constrained by proton-decay observables.

Field-content exhaustion at dimension six. Assume the field dimensions

$$\dim H = 1, \qquad \dim D = 1, \qquad \dim X_{\mu\nu} = 2, \qquad \dim \psi = \frac{3}{2}.$$

Every Lorentz-invariant local monomial of total engineering dimension six, after integration by parts and algebraic identities but before imposing the equations of motion, has one of the following field contents:

$$X^3, \quad H^6, \quad H^4D^2, \quad X^2H^2, \quad \psi^2H^3, \quad \psi^2H^2D, \quad \psi^2XH, \quad \psi^4.$$

Consequently Definitions 54.17 and 54.18 are exhaustive as a dimension-six field-content classification. A Lorentz scalar must contain an even number of spinor fields, so the number of fermions is $0, 2$, or 4; six fermions already have dimension nine. With no fermions, nonnegative integer solutions of

$$n_H + n_D + 2n_X = 6$$

that cannot be reduced by integration by parts or by commutators of covariant derivatives are represented by H^6, H^4D^2, X^2H^2, and X^3. Terms with one field strength and only Higgs fields have uncontracted Lorentz indices unless derivatives are present; after commuting derivatives, their field-strength part is absorbed into the displayed classes or into the equation-of-motion quotient.

With two fermions, the remaining engineering dimension is three. The only possibilities are H^3, H^2D, and XH, giving ψ^2H^3, ψ^2H^2D, and ψ^2XH. With four fermions, the fermions already have dimension six, so no additional H, D, or X may appear. Gauge invariance and the finite Fierz identities then select the contractions listed in the basis definitions. The latter selection is a finite algebraic basis choice inside $\mathcal{Q}_6$, while the enumeration above establishes that no further field-content class exists.

54.7 QCD Theta Angle and Quark-Mass Phase

Proposition 54.19 (Physical strong-CP phase coordinate)**.** *In the quark sector with nonsingular mass matrices, the invariant phase coordinate involving the QCD theta angle and the quark mass matrices is*

$$\overline{\theta} = \theta_3 + \arg\det(M_u M_d) \quad \textit{mod } 2\pi. \tag{54.11}$$

Equivalently, replacing M_u, M_d by positive diagonal mass matrices by chiral flavor-coordinate changes shifts the coefficient of $\mathrm{tr}(F \wedge F)$ *by the opposite amount, leaving $\overline{\theta}$ unchanged.*

Proof. Work first with one massive Dirac quark in the fundamental color representation and write its mass as $me^{\mathrm{i}\varphi}$, $m > 0$. The field redefinition

$$q \longmapsto \exp\left(-\frac{\mathrm{i}\varphi}{2}\gamma_5\right) q$$

changes the mass term to $m\bar{q}q$. In the path integral this field redefinition is an anomalous axial rotation whose Jacobian is fixed by the chiral anomaly. With the anomaly convention fixed in Chapter 51, the above rotation shifts the coefficient of the QCD topological density by

$$\theta_3 \longmapsto \theta_3 + \varphi.$$

Thus removing the phase of the mass increases the theta coordinate by exactly that phase.

For several quarks, choose nonsingular complex mass matrices and perform singular-value decompositions

$$M_u = U_{uL}^{-1} D_u U_{uR}, \qquad M_d = U_{dL}^{-1} D_d U_{dR},$$

with D_u, D_d positive diagonal. The vector parts of these flavor coordinate changes have no QCD anomaly. The anomalous part is the product of the axial determinant phases, and the anomalous Jacobian is additive over the left-handed Weyl components in the fundamental color representation. The total phase removed from the two mass matrices is

$$\arg\det M_u + \arg\det M_d = \arg\det(M_u M_d) \qquad \text{mod } 2\pi.$$

Therefore the mass-diagonalizing coordinate change sends

$$\theta_3 \longmapsto \theta_3 + \arg\det(M_u M_d),$$

while the transformed positive diagonal mass matrices have zero determinant phase. The value assigned to the pair (θ_3, M_u, M_d) by $\theta_3 + \arg\det(M_u M_d)$ is therefore unchanged by this coordinate choice. Conversely, any further nonsingular chiral flavor coordinate change shifts θ_3 by the phase removed from the determinant of $M_u M_d$, so the same combination is the invariant coordinate on this mass chart. If one quark mass matrix has a zero singular value, the determinant phase is not a coordinate on the chart and the theta dependence is a different question; the proposition does not assume such a chart exists. □

The empirical bound on $\overline{\theta}$ is a bound on the coefficient of a specific CP-odd QCD operator in the Standard Model definition. It is not a principle for choosing parameters.

54.8 One-Loop Running in a Minimal Coupling Chart

Renormalization-group formulae in the Standard Model are statements about a renormalized coordinate system for couplings and masses. The equations below use dimensional regularization and minimal subtraction in a mass-independent unbroken-representation chart with three active generations and one Higgs doublet. Threshold matching, the broken-phase expansion, and higher-dimensional Wilson coefficients in an EFT extension are separate data. The explicit-coupling convention is the one fixed in Convention 54.1. Write

$$t := \log \mu, \qquad \beta_x := \frac{\mathrm{d}x}{\mathrm{d}t}.$$

The hypercharge coupling g_1 is the coupling to Y, not the grand-unified rescaling of it.

Lemma 54.20 (One-loop gauge beta coefficients)**.** *For three generations and one Higgs doublet, the one-loop gauge beta functions in the convention above are*

$$(4\pi)^2\beta_{g_1} = \frac{41}{6}g_1^3, \qquad (4\pi)^2\beta_{g_2} = -\frac{19}{6}g_2^3, \qquad (4\pi)^2\beta_{g_3} = -7g_3^3. \tag{54.12}$$

Proof. Use the one-loop coefficient in a gauge theory with left-handed Weyl fermions and complex scalars,

$$b_G = -\frac{11}{3}C_2(G) + \frac{2}{3}\sum_{\text{Weyl } f} T_G(R_f) + \frac{1}{3}\sum_{\text{complex } s} T_G(R_s), \qquad (4\pi)^2\beta_g = b_G g^3. \tag{54.13}$$

This is the background-field one-loop pole coefficient derived in Chapter 49; here we only evaluate the representation sums in the Standard Model coupling chart. For $U(1)_Y$ the same formula is read with $T_G(R)$ replaced by Y^2, including all nonabelian spectator multiplicities. One generation contributes

$$\begin{aligned}\sum_{\text{Weyl}} Y^2 &= 6\left(\frac{1}{6}\right)^2 + 3\left(-\frac{2}{3}\right)^2 + 3\left(\frac{1}{3}\right)^2 + 2\left(-\frac{1}{2}\right)^2 + 1^2\\ &= \frac{10}{3}.\end{aligned}$$

Three generations give 10, and the Higgs doublet contributes

$$\sum_{\text{scalar}} Y^2 = 2\left(\frac{1}{2}\right)^2 = \frac{1}{2}.$$

Thus

$$b_1 = \frac{2}{3}\cdot 10 + \frac{1}{3}\cdot\frac{1}{2} = \frac{41}{6}.$$

For $SU(2)_L$, $C_2(SU(2)) = 2$ and $T(\mathbf{2}) = 1/2$ in the conventional half-trace normalization used for the explicit coupling g_2. One generation has three quark doublets and one lepton doublet, hence

$$\sum_{\text{Weyl}} T_{SU(2)} = 3 \cdot \frac{1}{2} + \frac{1}{2} = 2.$$

For three generations this is 6, and the Higgs doublet contributes 1/2. Therefore

$$b_2 = -\frac{11}{3} \cdot 2 + \frac{2}{3} \cdot 6 + \frac{1}{3} \cdot \frac{1}{2} = -\frac{19}{6}.$$

For $SU(3)_c$, $C_2(SU(3)) = 3$ and $T(\mathbf{3}) = T(\overline{\mathbf{3}}) = 1/2$. One generation contributes

$$2 \cdot \frac{1}{2} + \frac{1}{2} + \frac{1}{2} = 2,$$

where the factor 2 is the weak multiplicity of Q_L. Three generations give 6, and there is no colored scalar in the minimal field content. Thus

$$b_3 = -\frac{11}{3} \cdot 3 + \frac{2}{3} \cdot 6 = -7.$$

□

Remark 54.21 (Hypercharge normalization). If $g_1^{\text{GUT}} := \sqrt{5/3}\, g_1$, then

$$(4\pi)^2 \beta_{g_1^{\text{GUT}}} = \frac{41}{10} (g_1^{\text{GUT}})^3.$$

This is only a coordinate change. The electroweak mass formulae in this chapter use the unrescaled g_1.

Controlled Approximation 54.22 (One-loop top-Higgs subsystem)**.** Restrict the minimal Standard Model coupling chart to the invariant subspace in which the only nonzero Yukawa singular value is the top coordinate y_t. In the same minimal-subtraction convention,

$$(4\pi)^2 \beta_{y_t} = y_t \left[\frac{9}{2} y_t^2 - 8 g_3^2 - \frac{9}{4} g_2^2 - \frac{17}{12} g_1^2 \right], \tag{54.14}$$

and

$$\begin{aligned} (4\pi)^2 \beta_\lambda = {} & 24\lambda^2 + 12\lambda y_t^2 - 6 y_t^4 - 3\lambda(3g_2^2 + g_1^2) \\ & + \frac{3}{8} \left[2g_2^4 + (g_2^2 + g_1^2)^2 \right]. \end{aligned} \tag{54.15}$$

The restriction to one Yukawa singular value is a coordinate restriction, not an estimate. In the left-handed matrix coordinates Y_u, Y_d, Y_e, the one-loop pole coefficients needed here are

$$\begin{gathered} (4\pi)^2 \beta_{Y_u} = Y_u \left[\frac{3}{2} \left(Y_u^\dagger Y_u - Y_d^\dagger Y_d \right) + T_Y - G_u \right], \\ T_Y := \operatorname{tr}\left(3Y_u^\dagger Y_u + 3Y_d^\dagger Y_d + Y_e^\dagger Y_e \right), \qquad G_u := 8g_3^2 + \frac{9}{4} g_2^2 + \frac{17}{12} g_1^2, \end{gathered} \tag{54.16}$$

and

$$(4\pi)^2\beta_\lambda = 24\lambda^2 - 3\lambda(3g_2^2 + g_1^2) + \frac{3}{8}\big[2g_2^4 + (g_2^2 + g_1^2)^2\big] + 4\lambda T_Y - 2Q_Y, \tag{54.17}$$
$$Q_Y := \mathrm{tr}\Big(3(Y_u^\dagger Y_u)^2 + 3(Y_d^\dagger Y_d)^2 + (Y_e^\dagger Y_e)^2\Big).$$

Their scope is the one-loop minimal-subtraction pole calculation for the renormalizable electroweak coordinate chart with the active fields stated above. The primitive pole integrals are the logarithmic one-loop two-, three-, and four-point integrals already used in the renormalization chapters; the present chapter needs the group and multiplicity bookkeeping in this particular chart.

The coefficient accounting is as follows. The self-Yukawa part of (54.16) is the sum of the Yukawa vertex pole and the external-field pole terms. Gauge exchange and gauge wave-function pole terms give G_u. In the unrescaled $Q = T^3 + Y$ convention, those pole factors assemble to

$$G_u = 8g_3^2 + \frac{9}{4}g_2^2 + \frac{17}{12}g_1^2.$$

For β_λ, the scalar fish graphs give $24\lambda^2$; the gauge corrections linear in λ give $-3\lambda(3g_2^2 + g_1^2)$; the pure gauge four-Higgs pole gives the positive polynomial

$$\frac{3}{8}\left[2g_2^4 + (g_2^2 + g_1^2)^2\right];$$

the Yukawa wave-function and vertex poles give $4\lambda T_Y$; and the closed-fermion box gives $-2Q_Y$, with the minus sign from the fermion loop.

Equations (54.16)–(54.17) immediately show preservation of the one-singular-value subspace. If $Y_d = Y_e = 0$, their beta functions are proportional to Y_d and Y_e in the full matrix equations, so they remain zero. If Y_u has only one nonzero singular value, unitary flavor coordinates put it in the form

$$Y_u = \mathrm{diag}(0, 0, y_t).$$

Then $T_Y = 3y_t^2$, $Q_Y = 3y_t^4$, and (54.16) gives

$$(4\pi)^2\beta_{y_t} = y_t\left[\frac{3}{2}y_t^2 + 3y_t^2 - 8g_3^2 - \frac{9}{4}g_2^2 - \frac{17}{12}g_1^2\right],$$

which is (54.14). Substituting the same T_Y and Q_Y in (54.17) gives (54.15).

The statement is an equation for renormalized perturbative coordinates. It does not assert a non-perturbative electroweak continuum limit, and it does not turn the running of λ into a principle for choosing ultraviolet boundary data. It also is not the full physical Standard Model trajectory unless the remaining Yukawa singular values and all higher-dimensional coordinates are consistently set to zero in the chosen chart; its role here is to isolate the leading top-Higgs mechanism in the quartic running.

54.9 Higgs Quartic Running and Large-Field Claims

The running quartic $\lambda(\mu)$ is a coordinate in a chosen subtraction scheme. The sign of this coordinate is a useful perturbative fact, but it is not by itself an observable and it is not a theorem about a nonperturbatively constructed Standard Model. A statement often called "Higgs vacuum stability" therefore has to say which mathematical object it concerns. It may concern a minimal-subtraction trajectory, a perturbative effective potential, a semiclassical decay functional, or an additional Wilsonian EFT extension. These are different objects. The large-field effective-potential analysis is meaningful only after the subtraction scheme, gauge convention, field range, perturbative error estimate, omitted higher-dimensional operators if an EFT extension is being used, and the relation between a background Higgs coordinate and the observable or decay problem have been specified.

Definition 54.23 (High-scale RG continuation)**.** Fix coupling coordinates $c^A(\mu)$. In the minimal perturbative electroweak chart these include

$$g_1(\mu), \qquad g_2(\mu), \qquad g_3(\mu), \qquad y_t(\mu), \qquad \lambda(\mu), \qquad \dots .$$

Also fix a subtraction scheme, a loop order, and matching data $c^A(\mu_0)$ at a reference scale. A high-scale RG continuation to $\mu_1 > \mu_0$ is the solution of the specified ordinary differential equation

$$\frac{\mathrm{d}c^A}{\mathrm{d}\log\mu} = \beta^A(c) \tag{54.18}$$

on an interval where the perturbative chart and its error estimate are specified. This continuation is not the assertion that the Standard Model has a physical cutoff μ_1. It is a continuation of renormalized coordinates inside a perturbative scheme. To reinterpret μ_1 as a Wilsonian cutoff, one must change the problem by adding a Wilsonian QFT definition at scale μ_1, a matching map from that definition to the low-energy coordinates, and a proof or controlled hypothesis that the observables under discussion are reproduced in the overlap regime.

Remark 54.24 (Scope of minimal-subtraction running)*.* The minimal-subtraction beta functions are obtained from the pole parts of renormalized 1PI coordinate changes in dimensional regularization. Solving (54.18) transports coordinates in this renormalized coupling chart. A Wilsonian cutoff theory is different data: it requires a finite regulator or BV pushforward, a cutoff-dependent local action or half-density, and a statement that low-momentum observables are preserved by integrating out degrees of freedom. The ordinary differential equation for minimal-subtraction coordinates supplies only the coordinate transport. Treating the endpoint of that trajectory as a physical high-cutoff Wilsonian EFT is an additional assumption about the theory under discussion, and the assumption must be stated with its regulator or BV data and its matching map.

Remark 54.25 (Extensions beyond the Standard Model)*.* A proposed extension of the Standard Model is an additional mathematical hypothesis, not an explanation by itself. If it is used only through finitely many higher-dimensional operators, it is a choice of EFT coordinates together with matching assumptions. If it is claimed to be an ultraviolet completion, the claim requires a regulator or constructive framework at least as explicit as the ones demanded in Definition 54.40 and Remark 54.24. A perturbative Lagrangian, a high-scale RG trajectory, or a phenomenological motivation is not by itself such a theory.

Definition 54.26 (Quartic positivity in a specified chart)**.** Fix a subtraction scheme, a gauge for the perturbative effective potential if one is used, a loop order, matching maps from measured pole or threshold observables to coupling coordinates at μ_0, and a scale interval $I = [\mu_0, \mu_1]$. Specify whether I is only a high-scale RG continuation in the sense of Definition 54.23, or whether an additional Wilsonian or constructive definition is being attached to the endpoint. A quartic-positivity statement on I is the claim that the solution of the specified RG equations satisfies

$$\lambda(\mu) > 0, \qquad \mu \in I, \tag{54.19}$$

with an error estimate that includes threshold matching, loop truncation, input-parameter uncertainties, and the effect of higher-dimensional operators in the chosen coupling chart. It is a statement about perturbative coordinates. It is not a nonperturbative vacuum statement unless the additional regulator and observable data below make it one.

Definition 54.27 (Metastability in a specified semiclassical calculation)**.** In the same chart, a metastability claim is not the assertion $\lambda(\mu) < 0$. It is a semiclassical statement about a false-vacuum decay functional: one must specify the gauge-fixed effective action used for the bounce calculation, the fluctuation determinant convention, the renormalization scale-setting prescription, the spacetime volume or cosmological history against which the rate is compared, and the higher-dimensional operators retained in the field range of the bounce. The output is an inequality of the form

$$\Gamma_{\text{decay}}\, \mathcal{V}_4 < \varepsilon, \tag{54.20}$$

with a specified uncertainty. The sign of λ along an RG trajectory is one input to such a calculation, not the calculation itself. It becomes a prediction of a QFT only after the path integral, field range, and omitted operator remainder are controlled in the regime sampled by the bounce.

Large-field EFT expansion requires a field-domain hypothesis. Let h be the radial Higgs coordinate defined by

$$H^\dagger H = \frac{h^2}{2}.$$

In a coupling chart whose scalar potential is

$$V_{\le 6}(h) = \lambda \left(\frac{h^2 - v^2}{2}\right)^2 + \frac{C_H}{\Lambda^2}\left(\frac{h^2}{2}\right)^3 \tag{54.21}$$

the large-field quartic approximation is controlled only for h^2/Λ^2 in the specified EFT range. More precisely, for $h \gg v$,

$$V_{\le 6}(h) = \frac{\lambda}{4} h^4 \left[1 + \frac{C_H}{2\lambda}\frac{h^2}{\Lambda^2} + O\!\left(\frac{v^2}{h^2}\right)\right], \tag{54.22}$$

whenever $\lambda \neq 0$. Therefore a sign statement about the dimension-four coordinate λ alone is not a statement about the large-field potential unless the higher-dimensional coordinates and the field range have been specified. More generally, an operator

$$\frac{C_n}{\Lambda^{2n-4}}(H^\dagger H)^n, \qquad n \ge 3, \tag{54.23}$$

contributes, relative to the quartic term, by the factor

$$\frac{C_n}{\lambda\, 2^{\,n-2}}\left(\frac{h^2}{\Lambda^2}\right)^{n-2}. \tag{54.24}$$

Thus a finite truncation of the large-field potential is a controlled EFT statement only in a field domain where the omitted tower is bounded by a specified remainder.

Substituting $H^\dagger H = h^2/2$ gives

$$\lambda\left(\frac{h^2 - v^2}{2}\right)^2 = \frac{\lambda}{4}h^4 - \frac{\lambda v^2}{2}h^2 + \frac{\lambda v^4}{4}$$

and

$$\frac{C_H}{\Lambda^2}\left(\frac{h^2}{2}\right)^3 = \frac{C_H}{8\Lambda^2}h^6.$$

Factoring $\lambda h^4/4$ from the large-field expression gives (54.22). The ratio of the dimension-six term to the quartic term grows as h^2/Λ^2. Thus the EFT coupling chart, not only the dimension-four coordinate, is part of the statement.

For the general operator (54.23), substitution of $H^\dagger H = h^2/2$ gives

$$\frac{C_n}{\Lambda^{2n-4}}\frac{h^{2n}}{2^n}.$$

Dividing by $\lambda h^4/4$ gives (54.24). If h^2/Λ^2 is not small, or if the coefficients C_n are not bounded by a stated matching hypothesis, no finite truncation gives a controlled statement about the potential in that region.

Remark 54.28 (Large-field claims in the hybrid definition). The definition contains the electroweak sector as a renormalized perturbative chiral gauge theory and supplies matching maps to lower-energy EFTs and nonperturbative QCD inputs. A nonperturbative large-field stability or metastability theorem for the Higgs coordinate would require further data: a probability measure, Hilbert space, or operator algebra for the full chiral electroweak theory, or a Wilsonian/EFT construction with a declared field range and matching map. Minimal-subtraction coordinate transport has the scope described in Remark 54.24. If one changes the problem to an EFT extension with higher-dimensional operators, the large-field expansion displayed above shows that such a statement also samples the omitted operator coordinates unless the field range and matching assumptions control them. The baseline hybrid definition therefore supports conditional perturbative statements about a chosen coupling chart or decay functional; an unconditional QFT theorem about Higgs large-field stability or metastability is a separate construction problem.

Remark 54.29 (One-loop source of downward quartic running). In the one-loop top-Higgs subsystem of Controlled Approximation 54.22, the beta function at $\lambda = 0$ is

$$(4\pi)^2\beta_\lambda\big|_{\lambda=0} = -6y_t^4 + \frac{3}{8}\left[2g_2^4 + (g_2^2 + g_1^2)^2\right]. \tag{54.25}$$

Thus the top-Yukawa term supplies the negative entry in this minimal-subtraction quartic beta function. The statement belongs to the specified perturbative coupling chart.

Set $\lambda = 0$ in (54.15). The terms $24\lambda^2$, $12\lambda y_t^2$, and $-3\lambda(3g_2^2 + g_1^2)$ vanish, leaving exactly (54.25). The negative sign of the top term is the closed-fermion-loop sign recorded in the coefficient accounting of Controlled Approximation 54.22. No scheme-independent observable is obtained until the matching inputs and the observable or decay functional have been specified.

Definition 54.30 (Data required for a Higgs large-field claim)**.** A Higgs large-field claim in the hybrid Standard Model definition has a precise meaning only after specifying:

1. the input observables and matching maps used to determine $g_1, g_2, g_3, y_t, \lambda$ and the relevant higher-dimensional coefficients at the reference scale;
2. the subtraction scheme, loop order, threshold convention, and scale interval for the RG evolution;
3. whether the endpoint of the scale interval is only a formal RG continuation of renormalized coordinates or is being supplemented by an additional Wilsonian, lattice, BV, or constructive definition;
4. whether the output is a quartic-positivity statement in the sense of Definition 54.26 or a metastability statement in the sense of Definition 54.27;
5. the treatment of $O_H = (H^\dagger H)^3$ and every other retained higher-dimensional operator whose contribution is not uniformly small over the field range;
6. a remainder estimate for perturbative truncation and for omitted operators.

Without these data, a sentence about "vacuum stability" has no definite mathematical content in this chapter. Even with these data, the result is conditional unless a theorem or controlled argument relates the chosen perturbative quantity to the claimed observable or decay problem.

54.10 Precision Electroweak Self-Energy Coordinates

Precision electroweak fits use a finite-dimensional projection of the renormalized electroweak two-point functions. The projection is meaningful only after the input scheme, subtraction scheme, and class of observables have been fixed. This section defines the S, T, U coordinates as such a two-point projection.

Definition 54.31 (Transverse self-energy difference)**.** Fix a reference electroweak coupling chart with the same input values of α_{em}, G_F, and m_Z. Let

$$s_W := \frac{g_1}{\sqrt{g_1^2 + g_2^2}}, \qquad c_W := \frac{g_2}{\sqrt{g_1^2 + g_2^2}}, \qquad e := g_2 s_W = g_1 c_W,$$

so that $m_W^2 = c_W^2 m_Z^2$ at tree level in the chart of Proposition 54.9. For $V, V' \in \{W, Z, \gamma\}$, define $\Delta\Pi_{VV'}(q^2)$ to be the difference between the renormalized transverse 1PI two-point scalar in the chart under study and the corresponding scalar in the reference chart, with identical external-current normalization. Thus

$$\Delta\Gamma^{\mu\nu}_{VV'}(q)\big|_{\mathrm{trans}} = -\mathrm{i}\left(\eta^{\mu\nu} - \frac{q^\mu q^\nu}{q^2}\right)\Delta\Pi_{VV'}(q^2), \tag{54.26}$$

on conserved external currents. The electromagnetic on-shell conditions are chosen so that

$$\Delta\Pi_{\gamma\gamma}(0) = 0, \qquad \Delta\Pi_{Z\gamma}(0) = 0. \tag{54.27}$$

Assume, for the definition below, that the self-energy differences are analytic at $q^2 = 0$ on the relevant sheet and write $\Delta\Pi'_{VV'}(0) := \mathrm{d}\Delta\Pi_{VV'}(q^2)/\mathrm{d}q^2|_{q^2=0}$.

Definition 54.32 (S, T, U two-point coordinates)**.** Under the hypotheses of Definition 54.31, the Peskin–Takeuchi S, T, U coordinates are the three finite combinations

$$\begin{aligned}
\alpha_{\rm em} S &= 4s_W^2 c_W^2 \left[\Delta\Pi'_{ZZ}(0) - \frac{c_W^2 - s_W^2}{s_W c_W}\Delta\Pi'_{Z\gamma}(0) - \Delta\Pi'_{\gamma\gamma}(0)\right], \\
\alpha_{\rm em} T &= \frac{\Delta\Pi_{WW}(0)}{m_W^2} - \frac{\Delta\Pi_{ZZ}(0)}{m_Z^2}, \\
\alpha_{\rm em} U &= 4s_W^2 \left[\Delta\Pi'_{WW}(0) - c_W^2\Delta\Pi'_{ZZ}(0) - 2s_W c_W \Delta\Pi'_{Z\gamma}(0) - s_W^2\Delta\Pi'_{\gamma\gamma}(0)\right].
\end{aligned} \tag{54.28}$$

Here $\alpha_{\rm em} := e^2/(4\pi)$. These are coordinates on the two-point part of the electroweak coupling chart, not on the full space of all possible four-fermion, vertex, and detector corrections.

Remark 54.33 (What the T coordinate measures). Suppose the only low-momentum effect in the two-point chart is a shift of the charged and neutral weak mass coordinates,

$$m_W^2 \mapsto m_W^2 + \delta m_W^2, \qquad m_Z^2 \mapsto m_Z^2 + \delta m_Z^2,$$

with s_W, c_W held fixed by the chosen input convention and with $\Delta\Pi_{WW}(0) = \delta m_W^2$, $\Delta\Pi_{ZZ}(0) = \delta m_Z^2$. Then

$$\alpha_{\rm em} T = \frac{\delta m_W^2}{m_W^2} - \frac{\delta m_Z^2}{m_Z^2} \tag{54.29}$$

and the first-order shift of

$$\rho := \frac{m_W^2}{m_Z^2 c_W^2}$$

is

$$\delta\rho = \alpha_{\rm em} T + O(\delta^2). \tag{54.30}$$

The first equality is exactly the definition of T after the stated identification of the zero-momentum self-energies with mass-coordinate shifts. For the second, use the tree identity $m_W^2 = m_Z^2 c_W^2$ and expand

$$\rho_{\rm shifted} = \frac{m_W^2 + \delta m_W^2}{(m_Z^2 + \delta m_Z^2)c_W^2} = \left(1 + \frac{\delta m_W^2}{m_W^2}\right)\left(1 + \frac{\delta m_Z^2}{m_Z^2}\right)^{-1}.$$

The first-order Taylor expansion of $(1+x)^{-1}$ gives

$$\rho_{\rm shifted} = 1 + \frac{\delta m_W^2}{m_W^2} - \frac{\delta m_Z^2}{m_Z^2} + O(\delta^2),$$

which proves (54.30). This is the precise sense in which T records custodial-symmetry breaking in a two-point electroweak chart.

Controlled Approximation 54.34 (Domain of the S, T, U projection)**.** The S, T, U coordinates are a three-dimensional projection of a much larger matching problem. They are adequate only in the following restricted two-point chart: all corrections to the relevant electroweak observables enter through the analytic transverse two-point functions in Definition 54.31, and only the constant and first-derivative Taylor coefficients at $q^2 = 0$ are retained. After the input coordinates $\alpha_{\rm em}$, G_F, and m_Z are fixed, the remaining three input-independent two-point combinations can be chosen as the coordinates S, T, U in Definition 54.32.

The tree exchange amplitudes of conserved external fermion currents are obtained by inverting the quadratic form of the gauge fields and contracting with the current vertices. To first order in $\Delta\Pi$, the correction is

$$D_0(q)\,\Delta\Pi(q^2)\,D_0(q),$$

where D_0 is the tree propagator matrix in the same current basis. Under the analyticity hypothesis, the correction through order q^2 depends only on $\Delta\Pi_{VV'}(0)$ and $\Delta\Pi'_{VV'}(0)$. Electromagnetic gauge invariance and the on-shell electromagnetic normalization impose (54.27). Finite redefinitions of the three input coordinates α_{em}, G_F, and m_Z remove three further linear combinations: the electric charge normalization, the charged-current normalization used to define G_F, and the reference neutral-pole mass.

The combinations displayed in (54.28) are a convenient basis of the remaining three-dimensional quotient. The T coordinate is the residual custodial mass-ratio coordinate by Remark 54.33; the S coordinate is the neutral-current derivative combination that remains after the photon charge normalization is removed; and U is the corresponding charged-minus-neutral derivative coordinate. If nonanalytic thresholds, nonlocal detector functionals, vertex corrections, box corrections, or independent local four-fermion operators are kept at the same order, they are additional coordinates of the matched prediction and are not represented by S, T, U alone.

54.11 The Hybrid Definition

Definition 54.35 (QCD–electroweak coupling data)**.** Let $\mathfrak{D}^{\mathrm{W}}_{\mathrm{QCD}}$ be a Wightman QFT with Hilbert space $\mathcal{H}_{\mathrm{QCD}}$, vacuum Ω_{QCD}, and a net or common domain of color-gauge-invariant local operator-valued distributions. A QCD–electroweak coupling data $\mathcal{C}_{\text{QCD-EW}}$ consist of the following items.

1. A finite or countable list of renormalized color-gauge-invariant local QCD fields

   $$\mathcal{O}_A(x) \in \mathcal{O}^{\mathrm{inv}}_{\mathrm{QCD}},$$

   including the flavor vector and axial currents, charged weak currents, electromagnetic current, and scalar or pseudoscalar quark-density operators needed after an electroweak scalar chart is chosen. Each $\mathcal{O}_A$ is an operator-valued tempered distribution, with its domain, normalization, and composite-operator scheme specified.

2. The transformation laws of these operators under the flavor and electroweak source symmetries that are to be gauged perturbatively, together with their Ward identities, anomaly contact terms, and current-conservation or partial-conservation equations.

3. A local perturbative interaction functional

   $$I_{\mathrm{int}}[\varphi_{\mathrm{EW}};\mathcal{O}] = \sum_A \int_{M_4} \varphi^A_{\mathrm{EW}}(x)\,\mathcal{O}_A(x), \tag{54.31}$$

   where φ^A_{EW} denotes the corresponding perturbative electroweak field, source, or composite expression. The product in (54.31) is required to be invariant under the electroweak gauge symmetry after the perturbative gauge-fixing or BV formulation has been specified.

4. A prescription for mixed correlators as formal series in electroweak couplings whose coefficients are Wightman distributions of the QCD operators $\mathcal{O}_A$, combined with the perturbative electroweak propagators and vertices. The prescription includes the renormalization of coincident insertions and the contact-term scheme.

Remark 54.36 (Hybrid coupling is additional structure). The data $\mathcal{C}_{\text{QCD-EW}}$ in Definition 54.35 is not determined by separately giving a nonperturbative QCD Wightman theory and a perturbative electroweak Lagrangian. It is additional mathematical structure needed to define the hybrid Standard Model prediction framework.

A nonperturbative QCD Wightman theory contains physical local fields only in the color-gauge-invariant operator algebra. The colored quark fields that appear in a gauge-fixed perturbative Lagrangian are not, by themselves, Wightman fields on the physical QCD Hilbert space. Therefore an electroweak boson or Higgs fluctuation cannot be coupled to a nonperturbative QCD sector by reusing a colored perturbative quark line. The coupling has to be expressed through color-gauge-invariant QCD operator-valued distributions: for example the electromagnetic current, charged weak currents, neutral currents, and scalar density operators. Their normalizations, contact terms, Ward identities, and anomaly conventions determine the coefficients of mixed correlators with electroweak external fields.

At order n in the electroweak couplings, a mixed correlator is a finite sum of perturbative electroweak kernels paired with QCD Wightman distributions of the form

$$\big\langle \Omega_{\text{QCD}}, \mathcal{O}_{A_1}(x_1)\cdots\mathcal{O}_{A_n}(x_n)\mathcal{X}_1(y_1)\cdots\mathcal{X}_m(y_m)\Omega_{\text{QCD}}\big\rangle, \tag{54.32}$$

where the $\mathcal{X}_i$ are the QCD operators appearing in the observable. The distribution (54.32), its extension to coincident points, and its Ward identities are not supplied by the electroweak perturbative Lagrangian. Conversely, the pure QCD Wightman theory does not know which electroweak source or gauge field multiplies which operator. Thus the hybrid coupling structure is logically necessary.

Definition 54.37 (Hybrid Standard Model definition)**.** The Standard Model is used in this monograph through the following hybrid definition, not as a single completed constructive theorem for a four-dimensional continuum QFT:

$$\mathfrak{D}_{\text{SM}} = \big(\mathfrak{D}^{\text{W}}_{\text{QCD}}, \mathfrak{D}^{\text{pert}}_{\text{EW}}, \mathcal{C}_{\text{QCD-EW}}, \mathfrak{D}_{\text{weak EFT}}, \mathcal{M}\big).$$

Here $\mathfrak{D}^{\text{W}}_{\text{QCD}}$ denotes the nonperturbative continuum QCD Wightman theory selected by the $SU(3)_c$ gauge theory with quark matter; in constructive and computational practice it is approached through finite lattice regulators and a continuum-limit problem of the kind stated in Hypothesis 46.9. When a concrete lattice regulator is needed for a hadronic matrix element, it will be denoted $\mathfrak{D}^{\text{lat}}_{\text{QCD}}$; this notation refers to the regulator used to approximate the QCD component, not to a cutoff definition of the full Standard Model. $\mathfrak{D}^{\text{pert}}_{\text{EW}}$ denotes the renormalized electroweak chiral gauge theory with Higgs field, constructed as a perturbative formal power series to all orders after gauge fixing or BV treatment, anomaly cancellation, and a subtraction scheme have been fixed; $\mathcal{C}_{\text{QCD-EW}}$ is the hybrid coupling data of Definition 54.35; $\mathfrak{D}_{\text{weak EFT}}$ is the tower of lower-energy effective theories obtained by integrating out massive weak fields and heavy flavors; and $\mathcal{M}$ is the matching data fixing parameters and local operators between overlapping regimes. The symbol $\mathfrak{D}^{\text{pert}}_{\text{EW}}$ is not a finite-cutoff definition and is not a claim that a nonperturbative four-dimensional chiral electroweak continuum construction has been supplied.

Definition 54.38 (Matching data in the hybrid Standard Model)**.** The symbol $\mathcal{M}$ in Definition 54.37 consists of the following specified data for the observable class under consideration:

1. a sequence of scales or windows where adjacent descriptions overlap;
2. renormalized parameter charts for $g_3, g_2, g_1, \lambda, v$, the Yukawa matrices, theta angles, and, when an EFT extension is being used, higher-dimensional Wilson coordinates;
3. threshold matching maps when $W, Z, h, t, b, c, \tau, \ldots$ are removed from the active field content;
4. anomalous-dimension matrices for the chosen operator bases between thresholds;
5. the QCD–electroweak coupling data $\mathcal{C}_{\text{QCD-EW}}$, including the scheme for the currents, scalar densities, contact terms, and Ward identities entering the observable;
6. nonperturbative QCD matrix elements, defined by $\mathfrak{D}^{\text{lat}}_{\text{QCD}}$ or by another explicitly specified nonperturbative regulator, for hadronic operators;
7. the error model or remainder statement attached to each perturbative, lattice, or combined extrapolation.

A numerical precision claim is well defined only after these choices and their error estimates are specified.

Remark 54.39 (Logical parts of the hybrid definition). Definition 54.37 separates nonperturbative QCD input, perturbative electroweak definitions, their hybrid operator coupling, lower-energy effective theories, and observable-specific matching. These parts cannot be replaced by one another without adding an extra theorem or hypothesis.

First, the QCD sector is the nonperturbative part of the definition. It is intended as a continuum Wightman QFT with gauge-invariant local and extended observables, while compact lattice link variables, Haar measure, and finite Grassmann algebra for quarks provide the concrete nonperturbative regulators used to define approximating matrix elements. The existence of the four-dimensional continuum limit with the desired physical spectrum is still a theorem-level constructive problem, but the logical role of this component is not perturbative electroweak renormalization.

Second, the electroweak sector is a perturbatively renormalizable chiral gauge theory. Its perturbative consistency uses anomaly cancellation, BRST or BV Ward identities, and the local power-counting analysis of the BEH phase. This defines renormalized Green functions and operator insertions as formal power series to all orders in the chosen subtraction scheme. A standalone nonperturbative continuum construction is not supplied by these facts. The hypercharge $U(1)$ coupling is not asymptotically free, and the four-dimensional scalar quartic sector lies on the same marginal-triviality boundary discussed in Chapters 11 and 38. Moreover, a fully satisfactory interacting lattice construction of a four-dimensional chiral gauge theory with the Standard Model representation content is a separate problem, related to the determinant-line and chiral-lattice issues in Chapter 146.

Third, the coupling of these two parts is not automatic. It is mediated by the color-gauge-invariant QCD operator insertions specified in $\mathcal{C}_{\text{QCD-EW}}$. This is the point at which nonperturbative hadronic matrix elements enter electroweak amplitudes and where contact terms and Ward identities must be fixed.

Fourth, physical predictions are extracted in regimes where a controlled object is available. High-energy short-distance processes use perturbative renormalization and factorization with explicitly stated infrared-safe observables. Low-energy hadronic weak processes use QCD matrix elements defined by the QCD regulator together with weak effective operators matched at the electroweak scale. Precision electroweak observables use finite-order renormalized perturbation theory. A cut-off parameter is not part of the prediction; any auxiliary regulator dependence has been removed or absorbed into the stated renormalized coordinates and operator scheme.

54.12 Chiral Lattice Status of the Electroweak Sector

The statement that the electroweak sector is a chiral gauge theory has a precise regulator consequence. Vectorlike lattice fermions define a finite Grassmann integral by an ordinary determinant. A chiral gauge theory instead requires a gauge-covariant choice of a subspace of left-handed lattice fermions, and the corresponding fermion integral is a section of a determinant line over the finite gauge-field space. The phase of that section is part of the regulator, not an optional convention.

Definition 54.40 (Finite chiral-gauge regulator data)**.** A finite chiral-gauge regulator for the Standard Model representation content consists of the following data at lattice spacing a and finite volume:

1. compact lattice gauge fields for the chosen global form of the local product data $SU(3)_c \times SU(2)_L \times U(1)_Y$, with a local gauge action;
2. a local gauge-covariant lattice Dirac operator, for example an overlap/Ginsparg–Wilson operator satisfying (146.4);
3. chiral projectors assigning Q_L, L_L to left-handed subspaces and u^c, d^c, e^c to the conjugate left-handed representations of Definition 54.2;
4. a gauge-invariant, local, and reflection-compatible choice of phase of the chiral fermion determinant line over lattice gauge fields;
5. lattice Higgs and Yukawa terms whose gauge quantum numbers reduce to Definition 54.3 in the scaling window;
6. uniform locality and reflection-positivity, or a specified replacement reconstruction route, strong enough to define a candidate continuum local QFT.

Proposition 54.41 (Local anomaly cancellation as determinant-line obstruction)**.** *For finite chiral-gauge regulator data in the sense of Definition 54.40, gauge invariance of the chiral determinant line requires the perturbative gauge anomaly coefficients of Proposition 54.11 to vanish. It also requires the finite $SU(2)$ doublet-parity condition in that proposition.*

Proof. At finite lattice spacing the chiral fermion integral is not an ordinary complex-valued determinant. For each background lattice gauge field A, let $V_L(A)$ and $W_L(A)$ be the finite-dimensional left-handed domain and range selected by the chosen chiral projectors, and let

$$D_A^+ : V_L(A) \longrightarrow W_L(A)$$

be the chiral Dirac map. The Berezin integral of the left-handed fermions is an element of the determinant line

$$\mathcal{L}_A = \det W_L(A)^* \otimes \det V_L(A).$$

As A varies, these lines form a complex line bundle over the finite gauge-field space. A gauge-invariant chiral regulator must therefore supply a nonvanishing section of $\mathcal{L}$ whose pullback by every finite gauge transformation agrees with the natural action on the determinant line. This is stronger than choosing a phase at one background: the phase must be transported consistently around every gauge loop.

Choose a local determinant connection compatible with the finite regulator. For infinitesimal gauge variations generated by Lie-algebra-valued functions α, β, the curvature evaluated on the corresponding gauge-orbit tangent vectors is the obstruction to path-independent phase transport. The locality and continuum-limit requirements in Definition 54.40 force the leading local part of this curvature to be the standard descent two-form whose coefficient is the symmetric gauge-anomaly tensor of Chapter 51. Thus, in a small gauge two-cell,

$$\mathrm{hol}_{\mathcal{L}}(\alpha, \beta) = \exp\left(2\pi \mathrm{i} \int_M \omega^2_{\mathrm{anom}}(\alpha, \beta; A) + \text{higher lattice-spacing terms}\right),$$

where the local polynomial ω^2_{anom} is linear in the anomaly coefficients of the representation. If one of these coefficients is nonzero, one can choose local α, β and a smooth background approximated by the lattice fields so that the displayed local term is nonzero. The holonomy around a sufficiently small gauge two-cell is then not one, so no gauge-equivariant nonvanishing phase section can exist. Hence the perturbative local anomaly coefficients must vanish. The finite sums in Proposition 54.11 are exactly those coefficients for the Standard Model representation content.

There is also a global obstruction not detected by the local curvature. For the weak $SU(2)$ factor, $\pi_4(SU(2)) \cong \mathbb{Z}_2$. Transporting a single left-handed $SU(2)$ doublet around a representative nontrivial loop changes the sign of the corresponding Pfaffian line. With N_2 doublets, the sign is $(-1)^{N_2}$; a gauge-invariant phase is possible only if N_2 is even. One Standard Model generation contains three colored quark doublets and one lepton doublet, hence $N_2 = 4$, and the finite sign obstruction is absent generation by generation. $\square$

Remark 54.42 (Scope of the anomaly-obstruction calculation)*.* The vanishing of the local curvature obstruction and the $SU(2)$ parity obstruction is necessary regulator data. A complete finite chiral-gauge regulator still has to construct a gauge-invariant local phase functional, prove the required locality and reflection or reconstruction properties, and control the four-dimensional continuum scaling limit.

Remark 54.43 (Lattice QCD inside the hybrid Standard Model)*.* The lattice regulators used to approximate the QCD component $\mathfrak{D}^{\mathrm{W}}_{\mathrm{QCD}}$ in Definition 54.37 supply nonperturbative definitions of gauge-invariant QCD matrix elements after the electroweak matching data have selected the relevant color-singlet operators. They do so because lattice QCD uses the color gauge group and quark fields as a vectorlike fermion system for the purpose of strong-interaction matrix elements. Its finite Grassmann integral is an ordinary determinant, or a controlled product of determinants, coupled to compact $SU(3)_c$ links. The electroweak theory before matching has chiral assignments: Q_L is an $SU(2)_L$ doublet while u^c, d^c are weak singlets with different hypercharges, and L_L, e^c have the analogous chiral electroweak assignment. A finite regulator for that system must solve the determinant line and phase problem in Definition 54.40.

The hybrid construction avoids conflating these two uses. For hadronic weak observables, the weak fields are first matched onto gauge-invariant local operators such as four-quark, semileptonic, or electromagnetic-current operators. The QCD lattice regulator then computes the matrix elements of those color-singlet operators. This gives a valid matched prediction after the map $\mathcal{M}$ is specified; a nonperturbative construction of the microscopic chiral electroweak gauge theory is the distinct finite-regulator problem described above.

Definition 54.44 (Standard Model prediction)**.** A Standard Model prediction for an observable O, in the sense used in this chapter, is a number or distribution obtained only after the following data are specified:

1. the energy regime and the component of the hybrid definition used in that regime: nonperturbative QCD input, renormalized perturbative electroweak theory, a lower-energy EFT, or an additional Wilsonian/EFT extension;
2. the gauge-invariant local operator, infrared-safe inclusive observable, or detector functional representing O;
3. the matching map from the adjacent higher-energy description, including the scheme and normalization of all operator coordinates;
4. the perturbative, lattice, or combined expansion parameter and the associated remainder or systematic-error class;
5. the positivity, unitarity, gauge-invariance, and infrared-safety statements needed for the observable.

54.13 Fermi Theory as a Matched Low-Energy Layer

The tree-level Fermi coefficient is a matched low-energy coefficient, obtained by solving the massive charged-vector equation in a derivative expansion. Let $J^{\pm}_{\mu}$ be the charged left-handed weak currents normalized so that the massive charged-vector part of the electroweak EFT is

$$\mathcal{L}_{\mathrm{cc}} = -\frac{g_2}{\sqrt{2}}\big(J^{+}_{\mu}W^{+\mu} + J^{-}_{\mu}W^{-\mu}\big) + m_W^2 W^{+}_{\mu}W^{-\mu} + \cdots ,$$

where the dots include the $W^{\pm}$ kinetic term and interactions. In the low-energy EFT for external momenta $p^2 \ll m_W^2$, eliminating $W^{\pm}$ at leading order gives

$$\mathcal{L}_{\mathrm{Fermi}} = -\frac{g_2^2}{2m_W^2}J^{+}_{\mu}J^{-\mu} + O(p^2/m_W^4).$$

Therefore, with the current convention used here,

$$\mathcal{L}_{\mathrm{Fermi}} = -\frac{4G_F}{\sqrt{2}}J^{+}_{\mu}J^{-\mu} \qquad \Longleftrightarrow \qquad \frac{G_F}{\sqrt{2}} = \frac{1}{2v^2}.$$

At tree level and to leading order in derivatives, the charged vector is an auxiliary variable with algebraic Lagrangian

$$m_W^2 W^{+}_{\mu}W^{-\mu} - a(J^{+}_{\mu}W^{+\mu} + J^{-}_{\mu}W^{-\mu}), \qquad a := \frac{g_2}{\sqrt{2}}.$$

The equations obtained by varying W^+ and W^- independently are

$$m_W^2 W_\mu^- = aJ_\mu^-, \qquad m_W^2 W_\mu^+ = aJ_\mu^+.$$

Substitution gives

$$\left(\frac{a^2}{m_W^2} - 2\frac{a^2}{m_W^2}\right) J_\mu^+ J^{-\mu} = -\frac{g_2^2}{2m_W^2} J_\mu^+ J^{-\mu}.$$

Including the kinetic operator replaces m_W^{-2} by the low-momentum expansion of the massive propagator,

$$\frac{1}{m_W^2 - p^2} = \frac{1}{m_W^2} + O(p^2/m_W^4),$$

in the local derivative expansion. The mass formula from Proposition 54.9 gives

$$\frac{g_2^2}{2m_W^2} = \frac{2}{v^2}.$$

Comparing with $-4G_F J_\mu^+ J^{-\mu}/\sqrt{2}$ proves $G_F/\sqrt{2} = 1/(2v^2)$.

The equality is a tree-level matching statement in the electroweak EFT. QCD renormalization of hadronic weak operators, electromagnetic corrections, CKM factors, and matrix elements of the resulting four-fermion operators are separate parts of the low-energy matching problem.

54.14 Muon $g-2$ as a Hybrid Prediction

The anomalous magnetic moment of the muon is a useful organizing example because it is a single low-energy form-factor coordinate whose Standard Model evaluation uses all parts of $\mathfrak{D}_{\mathrm{SM}}$: perturbative QED, perturbative electroweak matching, and nonperturbative QCD current correlators.

Definition 54.45 (Muon Pauli-coordinate observable)**.** Let $\ell = \mu$ be the charged-lepton field in the low-energy EFT and let J^μ_{em} be the electromagnetic current normalized so that the muon has charge $-e$, $e > 0$. Since the muon has weak decay channels, the magnetic moment used here is the real Pauli-operator coordinate in the low-energy effective Hamiltonian for a one-muon wave packet, equivalently the real part of the Pauli form factor obtained after matching the $\mu\mu\gamma$ vertex and separating absorptive decay operators. In the zero-width projection used for this matching, define the Dirac–Pauli form factors by

$$\langle p', \sigma' | J^\mu_{\mathrm{em}}(0) | p, \sigma\rangle = -\frac{\mathrm{i}e}{(2\pi)^3}\bar{u}_{\sigma'}(p')\left[\gamma^\mu F_1^\mu(k^2) + \frac{1}{m_\mu} S^{\mu\nu} k_\nu F_2^\mu(k^2)\right] u_\sigma(p), \qquad k := p - p', \tag{54.33}$$

with $S^{\mu\nu} := -\mathrm{i}[\gamma^\mu, \gamma^\nu]/4$ in the mostly-plus spinor convention of Section 40.16. The charge normalization is $F_1^\mu(0) = 1$. The muon anomalous magnetic moment is

$$a_\mu := \frac{g_\mu - 2}{2} := F_2^\mu(0). \tag{54.34}$$

In the QED hard-kernel convention of Chapter 43,

$$a_\mu^{\mathrm{QED},1} = \frac{\alpha}{2\pi}, \qquad \alpha := \frac{e^2}{4\pi}. \tag{54.35}$$

Chapter 43 defines a form-factor basis (F, G) in which $F_2^{\mathrm{DP}}(0) = -G(0)$. The one-loop vertex calculation gives $G(0) = -\alpha/(2\pi)$. Substituting this relation into Definition 54.45 gives $a_\mu = F_2^\mu(0) = \alpha/(2\pi)$ at first order in QED. The lepton mass enters the loop integral but cancels from the zero-transfer dimensionless coefficient, as shown explicitly in Proposition 43.6.

Definition 54.46 (Matched decomposition through a specified order)**.** Fix a renormalization scheme, an input-parameter chart, and a maximum order in the electromagnetic, weak, and QCD matching expansions. The corresponding Standard Model value for a_μ is written

$$a_\mu^{\mathrm{SM}} = a_\mu^{\mathrm{QED}} + a_\mu^{\mathrm{EW}} + a_\mu^{\mathrm{HVP}} + a_\mu^{\mathrm{HLbL}} + a_\mu^{\mathrm{rem}}. \tag{54.36}$$

Here a_μ^{QED} contains the purely leptonic and photon contributions in the low-energy QED EFT; a_μ^{EW} contains diagrams or matched Pauli-operator coefficients with at least one W, Z, h, or weak Goldstone/ghost representative in a gauge-fixed computation; a_μ^{HVP} contains contributions in which the photon propagator is corrected by the gauge-invariant hadronic electromagnetic current two-point function; a_μ^{HLbL} contains the hadronic electromagnetic four-current contribution coupled to the muon line by photons; and a_μ^{rem} records the specified higher-order remainder and any separation-scheme convention.

Controlled Approximation 54.47 (Leading electroweak Pauli coefficient)**.** In the broken-phase electroweak coupling chart, and at leading order in m_μ^2/m_W^2, m_μ^2/m_Z^2, and m_μ^2/m_h^2, the one-loop weak contribution to the muon Pauli coordinate is

$$a_\mu^{\mathrm{EW},1} = \frac{G_F m_\mu^2}{8\sqrt{2}\pi^2}\left[\frac{5}{3} + \frac{1}{3}(1 - 4s_W^2)^2\right] + O\!\left(\frac{G_F m_\mu^4}{m_W^2}\right), \tag{54.37}$$

where $s_W^2 = g_1^2/(g_1^2 + g_2^2)$ in the convention $Q = T^3 + Y$.

The weak contribution is the coefficient of the dimension-five Pauli operator

$$\frac{e}{4m_\mu} a_\mu \, \bar{\mu}[\gamma^\mu, \gamma^\nu]\mu \, F_{\mu\nu} \tag{54.38}$$

in the low-energy QED EFT obtained after integrating out W, Z, h. At one loop the coefficient is obtained by matching the on-shell $\mu\mu\gamma$ vertex in the electroweak theory to the same vertex in the low-energy EFT, expanded in external momenta over m_W, m_Z, m_h. Gauge-parameter dependence cancels in the sum of vector, Goldstone, and ghost representatives because the Pauli operator is electromagnetic-gauge invariant and the matching is performed between physical on-shell matrix elements.

The charged-current W-sector diagrams give the heavy-vector coefficient

$$\frac{G_F m_\mu^2}{8\sqrt{2}\pi^2}\,\frac{5}{3}. \tag{54.39}$$

The neutral-current Z-sector contribution depends on the vector coupling of the Z to the muon. With

$$J_Z^\mu = \bar{\mu}\gamma^\mu\big(g_L P_L + g_R P_R\big)\mu, \qquad g_L = -\frac{1}{2} + s_W^2, \qquad g_R = s_W^2,$$

the vector-minus-axial combination entering the leading Pauli coefficient reduces, after using $G_F/\sqrt{2} = 1/(2v^2)$, to

$$\frac{G_F m_\mu^2}{8\sqrt{2}\pi^2}\,\frac{1}{3}(1 - 4s_W^2)^2. \tag{54.40}$$

The Higgs contribution is suppressed by an additional factor m_μ^2/m_h^2 because both the Higgs coupling and the chirality flip are proportional to the muon Yukawa coordinate. Adding the charged and neutral leading terms gives (54.37). This is a short-distance matching statement in the electroweak EFT; higher weak loops and mixed electroweak-hadronic terms are separate entries in a_μ^{rem} unless explicitly included in the specified order. A complete proof in this monograph requires the explicit one-loop Pauli projection for the charged-vector, neutral-vector, Goldstone, and ghost representatives. Until that appendix-level calculation is supplied, the displayed formula is used only as the convention-fixed leading matching coefficient, not as a theorem established here.

Definition 54.48 (Hadronic vacuum polarization from QCD current data)**.** Let

$$J^\mu_{\mathrm{had}} = \sum_q Q_q\, \bar{q}\gamma^\mu q \tag{54.41}$$

be the quark part of the electromagnetic current, with the sum taken over the active quark fields in the chosen low-energy QCD description and with the current renormalized in the specified regulator. The connected transverse current two-point function defines a scalar polarization by

$$\mathrm{i}\int \mathrm{d}^4x\, \mathrm{e}^{\mathrm{i}q\cdot x}\langle\Omega|\,\mathrm{T}\, J^\mu_{\mathrm{had}}(x)J^\nu_{\mathrm{had}}(0)|\Omega\rangle_{\mathrm{conn}} = (q^\mu q^\nu - q^2\eta^{\mu\nu})\Pi_{\mathrm{had}}(q^2) + \text{local contact terms}. \tag{54.42}$$

The charge-subtracted coordinate is

$$\widehat{\Pi}_{\mathrm{had}}(q^2) := \Pi_{\mathrm{had}}(q^2) - \Pi_{\mathrm{had}}(0), \tag{54.43}$$

where the subtraction is part of the electromagnetic input normalization.

Dispersive leading-HVP formula. Assume the hadronic current two-point function has a positive spectral representation and no massless hadronic state in the electromagnetic channel. Let

$$R_{\mathrm{had}}(s) := \frac{\sigma(e^+e^- \to \text{hadrons}; s)}{4\pi\alpha^2/(3s)} \tag{54.44}$$

be the spectral density in the standard electromagnetic normalization. QED vacuum-polarization effects are removed according to the same input scheme. The leading HVP contribution is then

$$a_\mu^{\mathrm{HVP,LO}} = \frac{1}{3}\left(\frac{\alpha}{\pi}\right)^2 \int_{s_0}^\infty \frac{\mathrm{d}s}{s}\, K_{\mathrm{HVP}}(s)\, R_{\mathrm{had}}(s), \tag{54.45}$$

where s_0 is the hadronic threshold and

$$K_{\mathrm{HVP}}(s) := \int_0^1 \mathrm{d}x\, \frac{x^2(1-x)}{x^2 + (1-x)s/m_\mu^2}. \tag{54.46}$$

This is a formula derived from two inputs, not an independent theorem about QCD. First, the photon-line insertion in the one-loop Pauli form-factor calculation gives the Euclidean-momentum representation

$$a_\mu^{\mathrm{HVP,LO}} = \frac{\alpha}{\pi}\int_0^1 \mathrm{d}x\,(1-x)\big[-4\pi\alpha\,\widehat{\Pi}_{\mathrm{had}}(-Q_x^2)\big], \qquad Q_x^2 := \frac{x^2}{1-x}m_\mu^2, \tag{54.47}$$

with the same Pauli projection as in Proposition 43.6. The once-subtracted spectral representation of the hadronic current correlator is

$$-4\pi\alpha\,\widehat{\Pi}_{\rm had}(-Q^2) = \frac{\alpha}{3\pi}\int_{s_0}^{\infty} \mathrm{d}s\,\frac{Q^2}{s(s+Q^2)}R_{\rm had}(s). \tag{54.48}$$

Substituting $Q^2 = Q_x^2$ into (54.47), interchange the positive x- and s-integrals, and use

$$(1-x)\frac{Q_x^2}{s+Q_x^2} = \frac{x^2(1-x)}{x^2+(1-x)s/m_\mu^2}.$$

This gives (54.45). The formula is therefore not a perturbative expansion of QCD: all hadronic dynamics is in the spectral function $R_{\rm had}$, equivalently in the current-current correlator of Definition 54.48.

Definition 54.49 (Euclidean lattice HVP coordinate)**.** In a Euclidean nonperturbative QCD regulator, define the zero-spatial-momentum current correlator

$$G(t) := \frac{1}{3}\sum_{i=1}^{3}\int_{\mathbb{R}^3} \mathrm{d}^3\vec{x}\,\langle J^i_{\rm had}(t,\vec{x})J^i_{\rm had}(0,\vec{0})\rangle_E, \qquad t\geq 0, \tag{54.49}$$

with the conserved or renormalized lattice current specified as part of $\mathfrak{D}^{\rm lat}_{\rm QCD}$. The subtracted Euclidean polarization is then equivalently encoded by

$$\widehat{\Pi}_E(Q^2) = \int_0^{\infty} \mathrm{d}t\,G(t)\left[t^2 - \frac{4}{Q^2}\sin^2\!\left(\frac{Qt}{2}\right)\right], \tag{54.50}$$

which fixes the normalization convention for $G(t)$ relative to $\widehat{\Pi}_E$; on a finite lattice the corresponding current renormalization factor is part of the regulator data. Combining this identity with the Euclidean form of (54.47) gives

$$a_\mu^{\rm HVP,LO} = \left(\frac{\alpha}{\pi}\right)^2\int_0^{\infty} \mathrm{d}t\,\widetilde{K}_\mu(t)\,G(t), \tag{54.51}$$

where $\widetilde{K}_\mu$ is the positive QED kernel obtained by performing the Q^2- or Feynman-parameter integral after inserting (54.50). The lattice prediction additionally requires continuum, infinite-volume, physical-mass, isospin-breaking, and QED correction data; these are entries of $\mathcal{M}$, not optional refinements.

Definition 54.50 (Hadronic light-by-light coordinate)**.** The hadronic light-by-light contribution is defined from the connected Euclidean four-current correlator

$$\Pi_{\mu\nu\rho\sigma}(x,y,z) := \langle J^\mu_{\rm had}(x)J^\nu_{\rm had}(y)J^\rho_{\rm had}(z)J^\sigma_{\rm had}(0)\rangle_{E,\rm conn} \tag{54.52}$$

by convolution with the exactly known QED muon-line kernel $\mathcal{K}_{\mu\nu\rho\sigma}(x,y,z;m_\mu)$:

$$a_\mu^{\rm HLbL} = \int \mathrm{d}^4x\,\mathrm{d}^4y\,\mathrm{d}^4z\,\mathcal{K}_{\mu\nu\rho\sigma}(x,y,z;m_\mu)\,\Pi^{\mu\nu\rho\sigma}(x,y,z), \tag{54.53}$$

with the current normalization, contact-term subtraction, finite-volume treatment, and QED infrared regulator specified in $\mathcal{M}$. Dispersive descriptions of the same coordinate decompose the four-current spectral data into intermediate-channel amplitudes; lattice descriptions compute the four-current Schwinger function directly. The equality of these descriptions, when both are available, is a nontrivial matching statement about the same QCD-defined current correlator.

Remark 54.51 (Data needed for the a_μ prediction). A value assigned to a_μ^{SM} is a Standard Model prediction in the sense of Definition 54.44 only after the following data have been specified:

1. the lepton-sector QED perturbative order and charge scheme;
2. the electroweak input scheme and the order of weak matching;
3. the HVP source, either a dispersive spectral function with its radiative-correction convention or a lattice current correlator with its continuum and infinite-volume extrapolations;
4. the HLbL four-current treatment and its contact-term convention;
5. the combination rule for correlations among input parameters and systematic uncertainties.

Definition 54.45 identifies a_μ as a single Pauli-form-factor coordinate. The decomposition (54.36) is not a decomposition of the observable itself; it is a decomposition of its computation in a specified low-energy matching scheme. The QED and electroweak entries are perturbative Pauli-operator matching coefficients. The HVP and HLbL entries are functionals of gauge-invariant QCD current correlators, defined either by a spectral representation or by a finite regulator such as the lattice. Changing any item in the list changes the coordinate map from the hybrid Standard Model definition to the number called a_μ^{SM}. Thus the listed data are necessary for the five requirements in Definition 54.44.

Open Problem 54.52 (Constructive Standard Model). Construct a continuum local QFT realizing the Standard Model representation content, gauge symmetry, anomaly cancellation, BEH phase, QCD confinement data, and weak interactions with positivity, locality, covariance, and a controlled relation to the observed parameter regime. A solution may be a single nonperturbative construction or a theorem explaining why the hybrid definition above has a universal continuum domain for the specified observables. No such theorem is assumed in this monograph.

Chapter 55

Global Anomalies, Spontaneous Symmetry Breaking, and Pions

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The four-dimensional orientation convention is the one used in the local anomaly calculation of Chapter 51:

$$\epsilon^{0123} = +1, \qquad \widetilde{F}^{\mu\nu} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma} F_{\rho\sigma}$$

for any two-form F. This convention is used for the perturbative triangle contact terms, Wess–Zumino–Witten functional, and electromagnetic specialization below.

55.1 Background Fields and Anomaly Data

Let a quantum field theory have an exact internal global symmetry G_f. The symmetry acts on local fields and local operators, and on Hilbert spaces obtained after choosing a phase. To test the symmetry as a property of local correlation functions, introduce a nondynamical G_f-connection B on spacetime M. The background-field generating functional is

$$Z[B] = \int [D\Phi] \, \exp\{\mathrm{i}S[\Phi; B]\},$$

where Φ denotes the dynamical fields and B is held fixed as an external datum. Let $\mathcal{B}$ be the space of allowed background fields and $\mathcal{G}_\mathrm{f}$ the group of background gauge transformations. If $g \in \mathcal{G}_\mathrm{f}$, write B^g for the transformed connection.

Definition 55.1 (Background anomaly cocycle)**.** The background anomaly is the equivalence class, under local counterterms, of phases $\mathcal{A}_g[B]$ in the transformation law

$$Z[B^g] = \exp\{\mathrm{i}\mathcal{A}_g[B]\}\, Z[B], \tag{55.1}$$

where $g \in \mathcal{G}_\mathrm{f}$. The zero class is the class for which there exists a local counterterm $C[B]$ making the transformed functional invariant under all background gauge transformations. Multiplying $Z[B]$ by $\exp\{\mathrm{i}C[B]\}$ changes the representative by

$$\mathcal{A}_g[B] \longmapsto \mathcal{A}_g[B] + C[B^g] - C[B].$$

Thus the anomaly is represented by the equivalence class of $\mathcal{A}_g[B]$ under local-counterterm shifts.

Remark 55.2 (Finite cocycle and Wess–Zumino consistency)*.* The phases in (55.1) obey a cocycle identity. Applying h and then g gives the same transformed background as applying gh, hence

$$\mathcal{A}_{gh}[B] = \mathcal{A}_g[B^h] + \mathcal{A}_h[B] \mod 2\pi. \tag{55.2}$$

The infinitesimal part of this cocycle is the local Wess–Zumino consistency condition developed in the preceding chapter. A finite anomaly may also have a purely finite part: its differential on the identity component of $\mathcal{G}_\mathrm{f}$ vanishes, but the cocycle (55.2) is nontrivial on another component or on a noncontractible loop in background-field space.

Equation (55.1) gives

$$Z[B^{gh}] = \exp\{\mathrm{i}\mathcal{A}_{gh}[B]\}Z[B].$$

The same background is obtained by first applying h and then applying g:

$$Z[(B^h)^g] = \exp\{\mathrm{i}\mathcal{A}_g[B^h]\}Z[B^h] = \exp\{\mathrm{i}\mathcal{A}_g[B^h] + \mathrm{i}\mathcal{A}_h[B]\}Z[B].$$

The two answers differ by an integer multiple of 2π in the exponent, which is (55.2). Differentiating the finite identity at the identity element of $\mathcal{G}_\mathrm{f}$ gives the infinitesimal consistency condition for the corresponding local anomaly representative.

Geometrically, the background-field construction assigns a complex line to each gauge-equivalence class of B, and $Z[B]$ is a section of this anomaly line. Local counterterms change a trivialization of the line. When the anomaly is represented by an invertible field theory on a five-dimensional manifold Y with $\partial Y = M$, equality of boundary variations identifies the phase in (55.1). The local Chern–Simons version of this bulk-boundary identity was described in Chapter 51; below we use mapping tori to state the finite version needed for global anomalies.

Figure 55.1 records the anomaly-matching statement in background-field language: microscopic and infrared descriptions are compared as sections of the same anomaly line over background gauge fields.

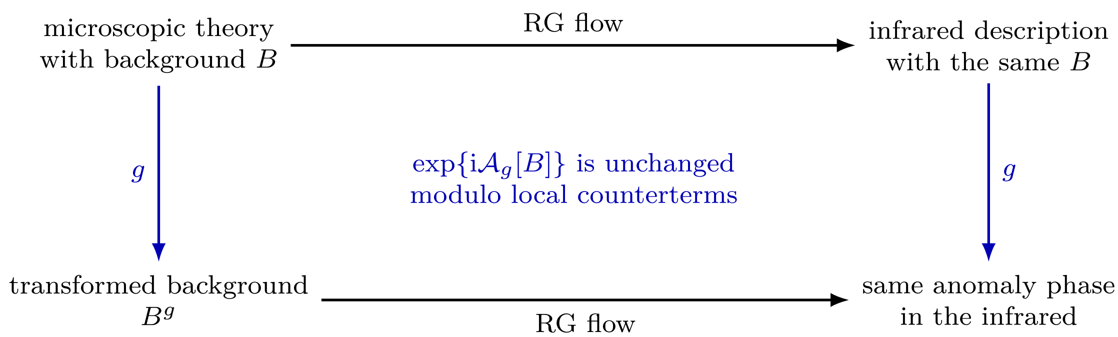

Figure 55.1: Anomaly matching is equality of background-response classes. The ultraviolet and infrared functionals may use different fields, but their transformation cocycles agree after local counterterm conventions are identified.

55.2 Anomaly Matching

Remark 55.3 (Anomaly matching as equality of background-response classes). Let a microscopic theory with exact global symmetry G_f flow to an infrared description. Couple both descriptions to the same background B. If the ultraviolet generating functional transforms as in (55.1), then the infrared functional must obey

$$Z_{\mathrm{IR}}[B^g] = \exp\{\mathrm{i}\mathcal{A}_g[B]\}\, Z_{\mathrm{IR}}[B]$$

after possible local counterterms have been matched. The equality of the equivalence class of $\mathcal{A}_g[B]$ modulo counterterms is 't Hooft anomaly matching.

The matching object is the cocycle class $[\mathcal{A}]$ defined by (55.2). Different infrared descriptions may carry the same class: massless fermions can produce it through their determinant or Pfaffian line, Goldstone fields can produce it through a Wess–Zumino–Witten functional, and a topological sector can produce it through an invertible response. The assumptions are that the symmetry remains exact along the flow, the background-field coupling is kept fixed, and any modes removed between two scales contribute only local background counterterms to the long-distance functional. Under these assumptions the cocycle class is unchanged by RG flow.

Let Λ_{UV} and Λ_{IR} be two scales in the same theory, with the same background field B coupled to the same conserved current multiplet. Integrating out modes between the two scales gives

$$Z_{\mathrm{UV}}[B] = \exp\{\mathrm{i}C_{\mathrm{mid}}[B]\}\, Z_{\mathrm{IR}}[B],$$

where $C_{\mathrm{mid}}[B]$ is local in the background at the scale where the infrared description is defined. Applying g and using Definition 55.1 gives

$$Z_{\mathrm{UV}}[B^g] = \exp\{\mathrm{i}C_{\mathrm{mid}}[B^g]\}\exp\{\mathrm{i}\mathcal{A}_g^{\mathrm{IR}}[B]\}Z_{\mathrm{IR}}[B].$$

The ultraviolet transformation law gives the same quantity as

$$\exp\{\mathrm{i}\mathcal{A}_g^{\mathrm{UV}}[B]\}\exp\{\mathrm{i}C_{\mathrm{mid}}[B]\}Z_{\mathrm{IR}}[B].$$

Therefore

$$\mathcal{A}_g^{\mathrm{UV}}[B] = \mathcal{A}_g^{\mathrm{IR}}[B] + C_{\mathrm{mid}}[B^g] - C_{\mathrm{mid}}[B] \mod 2\pi,$$

which is equality of the local-counterterm equivalence classes.

55.3 A Perturbative Example of a Global Anomaly

The local triangle computation already distinguishes two uses of a current. Consider a four-dimensional massless Dirac fermion with vector and axial currents

$$j^\mu = \mathrm{i}\bar{\psi}\gamma^\mu\psi, \qquad j_A^\mu = \mathrm{i}\bar{\psi}\gamma^\mu\gamma_5\psi.$$

The preceding chapter fixed the regularization convention in which the vector current coupled to an ordinary $U(1)$ gauge field is preserved and the axial current carries the $j_A jj$ anomaly. To test the axial $U(1)$ itself as a background symmetry, couple a background gauge field A_μ to j_A^μ,

$$\Delta S = \int \mathrm{d}^4x\, A_\mu j_A^\mu.$$

Gauge invariance of this background coupling would require the Ward identity for the vector-current divergence in the three-point function with two axial insertions:

$$\partial_\mu \langle\Omega|\, \mathrm{T}\ j^\mu(x) j_A^\nu(y) j_A^\rho(z)|\Omega\rangle.$$

The same oriented triangle graphs as in the local axial anomaly appear, with two γ_5 insertions. In the $D = 4 - \epsilon$ regulator, split $\ell = \ell_\| + \ell_\perp$ and keep γ_5 four-dimensional. The trace term that remains after imposing the two axial-vector external Ward identities is proportional to

$$\ell_\perp^2(-4\mathrm{i})\epsilon^{\nu\rho\alpha\beta}(k-2\ell)_\alpha p_\beta.$$

The loop integral is symmetric under permutations of the three external momenta $k, p, -k-p$. Its finite local part is linear in the external momenta, hence

$$\epsilon^{\nu\rho\alpha\beta}(k-2\ell)_\alpha p_\beta \longmapsto \frac{1}{3}\epsilon^{\nu\rho\alpha\beta}k_\alpha p_\beta$$

inside the regulated contact term. With the conventions of the preceding chapter this gives

$$\partial_\mu \langle\Omega|\, \mathrm{T}\ j^\mu(x) j_A^\nu(y) j_A^\rho(z)|\Omega\rangle = -\frac{1}{6\pi^2}\epsilon^{\nu\rho\alpha\beta}\partial_\alpha\delta^{(4)}(x-z)\partial_\beta\delta^{(4)}(y-z). \tag{55.3}$$

Expanding the background-field effective action

$$\mathrm{e}^{\mathrm{i}\Gamma[A]} = \int D\psi\, \exp\left\{\mathrm{i}S_0[\psi] + \mathrm{i}\int \mathrm{d}^4x\, A_\mu j_A^\mu\right\}$$

to second order in A, equation (55.3) implies

$$\Gamma[A + \mathrm{d}\zeta] - \Gamma[A] = \int \mathrm{d}^4x\, \zeta(x)\, \frac{1}{48\pi^2}\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}. \tag{55.4}$$

Proposition 55.4 (Axial background obstruction)**.** *In the vector-current-preserving regularization convention used above, the massless Dirac fermion has a nontrivial anomaly for the axial $U(1)$ background. More precisely, no four-dimensional local counterterm depending only on the axial background A, within this convention, can make $\Gamma[A]$ invariant under all compactly supported infinitesimal background transformations $A \mapsto A + \mathrm{d}\zeta$. Therefore the axial background cannot be promoted to an ordinary dynamical gauge field unless additional matter or topological data cancels the class represented by* (55.4)*.*

Proof. Gauge invariance of an Abelian background functional would require $\delta_\zeta \Gamma[A] = 0$ for every test function ζ. Equation (55.4) gives instead

$$\delta_\zeta \Gamma[A] = \frac{1}{48\pi^2} \int_{M_4} \zeta \, \epsilon^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}.$$

Since $F \wedge F$ can be varied independently in a compact spacetime region, this distribution is not identically zero. A local counterterm would change the right hand side by a local Abelian Wess–Zumino coboundary. In the single-background Abelian complex there is no four-form local functional whose infinitesimal variation is $\zeta \, F \wedge F$: the only possible Chern–Simons primitive $A \wedge F$ is a three-form, while $A \wedge A \wedge F$ vanishes for an Abelian one-form. Equivalently, the class whose descent gives $\zeta F \wedge F$ is the nonzero six-form anomaly polynomial proportional to $F \wedge F \wedge F$. Thus the obstruction cannot be removed without changing the theory, changing the symmetry being gauged, or adding another sector with the opposite anomaly. $\square$

Thus the axial rotation is a symmetry of the classical massless action in flat space without background flux, but its quantum coupling to an axial background is anomalous: the partition function is naturally a section of an anomaly line rather than a function on the quotient by axial background gauge transformations.

55.4 Example: A Finite SU(2) Anomaly

Let (M, σ_M) be a compact spin four-manifold and let $G_{\mathrm{f}} = SU(2)$. The spin structure σ_M is part of the background datum: a Weyl fermion is not defined on a merely oriented four-manifold. A change of σ_M, when several spin structures exist, is a change of the fermionic QFT background and may change the Pfaffian line and its anomaly. Consider one left-handed Weyl fermion valued in the fundamental representation of $SU(2)$. For an $SU(2)$ background connection B, the Euclidean Weyl operator is

$$D^+_{B,\sigma_M} : \Gamma(S_+ \otimes E_B) \longrightarrow \Gamma(S_- \otimes E_B),$$

where $S_\pm$ are the positive and negative chirality spin bundles and E_B is the associated rank-two complex vector bundle. The fundamental representation of $SU(2)$ is pseudoreal, so the fermion functional integral defines a Pfaffian line over the space of structured backgrounds (M, σ_M, B).

Let $g : M \to SU(2)$ be a background gauge transformation, and choose a smooth path of background connections B_t, $t \in [0,1]$, from $B_0 = B$ to $B_1 = B^g$. Identifying the two ends of $M \times [0,1]$ by g gives the mapping torus

$$X_g = (M \times [0,1]) / \big((x,1) \sim (x,0) \text{ by } g\big)$$

with an induced $SU(2)$ bundle E_g. The spin structure on $M \times [0,1]$ is the product one from σ_M; gluing the two ends by the identity diffeomorphism of M and the internal gauge transformation g gives a spin structure σ_g on X_g. Thus the invariant below is a function of (X_g, σ_g, E_g), not just of the oriented manifold and the vector bundle. If the spin structure on M is changed, or if the mapping-torus spin structure is twisted by an allowed $\mathbb{Z}_2$ flat line, the mod-two index may change.

Let $\mathcal{D}_{X_g,\sigma_g,E_g}$ be the five-dimensional real Dirac operator coupled to this bundle, and define its mod-two index by

$$\zeta(X_g, \sigma_g, E_g) = \dim \ker \mathcal{D}_{X_g,\sigma_g,E_g} \mod 2.$$

The analytic framework behind this statement is the Dai–Freed formulation of fermion anomalies. For a family of chiral Dirac operators, the determinant or Pfaffian is a section of a line over background-field space, and the holonomy of this line around a closed loop of backgrounds is computed by the Atiyah–Patodi–Singer eta-invariant of the Dirac operator on the associated mapping torus. In the present pseudoreal $SU(2)$ fundamental case the real structure refines the Dai–Freed holonomy to the mod-two-index sign

$$\mathrm{Hol}_{\mathrm{DF}}(X_g, \sigma_g, E_g) = (-1)^{\zeta(X_g,\sigma_g,E_g)}. \tag{55.5}$$

Equivalently, cutting the mapping torus open gives the APS-boundary description of the same Pfaffian transport. Therefore the Pfaffian transforms by

$$\frac{\mathrm{Pf}(D^+_{B^g,\sigma_M})}{\mathrm{Pf}(D^+_{B,\sigma_M})} = (-1)^{\zeta(X_g,\sigma_g,E_g)}. \tag{55.6}$$

For $M = S^4$ and g representing the nontrivial class in $\pi_4(SU(2)) \simeq \mathbb{Z}_2$, the five-dimensional mod-two index theorem gives $\zeta(X_g, \sigma_g, E_g) = 1$ for one fundamental Weyl doublet. The following proposition is the QFT consequence of this index-theoretic input.

Proposition 55.5 (Finite $SU(2)$ anomaly criterion for doublets)**.** *Let n left-handed Weyl fermions transform as fundamental doublets of a background $SU(2)$ symmetry on a compact spin four-manifold (M, σ_M). For a closed loop of backgrounds represented by the mapping torus (X_g, σ_g, E_g), the product Pfaffian line has holonomy*

$$\mathrm{Hol}(X_g, \sigma_g, E_g) = (-1)^{n\,\zeta(X_g,\sigma_g,E_g)}.$$

For the test family $M = S^4$ with g the generator of $\pi_4(SU(2)) \simeq \mathbb{Z}_2$, one has $\zeta(X_g, \sigma_g, E_g) = 1$. Hence an odd number of doublets has a finite $SU(2)$ anomaly. This obstruction is not detected by the local cubic descent calculation, because $SU(2)$ has no independent symmetric cubic invariant.

Proof. For one pseudoreal Weyl doublet the fermionic functional integral is not an ordinary complex determinant function on the space of backgrounds; it is a section of the real Pfaffian line associated with D^+_{B,σ_M}. Equation (55.6) states that parallel transport of this line around the background loop represented by (X_g, σ_g, E_g) multiplies the Pfaffian by $(-1)^{\zeta(X_g,\sigma_g,E_g)}$. This is the Dai–Freed holonomy specialized to the pseudoreal $SU(2)$ doublet, where the eta phase reduces to the mod-two index sign.

For n independent doublets the Grassmann integral factors before the fermions are coupled by any $SU(2)$-invariant mass term, and the anomaly line is the tensor product of the n one-doublet Pfaffian lines. Holonomy is multiplicative under tensor product, so the sign is the n-th power of the one-doublet sign:

$$\mathrm{Hol}(X_g, \sigma_g, E_g) = \left((-1)^{\zeta(X_g,\sigma_g,E_g)}\right)^n = (-1)^{n\,\zeta(X_g,\sigma_g,E_g)}.$$

For the Witten mapping torus over S^4, the mod-two index input gives $\zeta = 1$. The holonomy around the nontrivial loop is therefore $(-1)^n$.

If the $SU(2)$ is gauged, the fermion measure must descend from the space of connections to the quotient by gauge transformations. A loop in the quotient whose lifted Pfaffian line has holonomy -1 prevents such a single-valued descent: after going around the loop, a putative gauge-invariant partition function would have to equal its negative. Thus odd n is inconsistent with gauging this $SU(2)$ symmetry. If the same $SU(2)$ is kept as a background global symmetry, the same sign is an anomaly class that must be reproduced by any infrared description. Since the local cubic invariant $d^{abc} = \mathrm{tr}(t^a\{t^b, t^c\})$ vanishes for $\mathfrak{su}(2)$, this anomaly is a finite global obstruction rather than an infinitesimal local descent anomaly. $\square$

55.5 Anomaly Inflow and Mapping Tori

The finite anomaly in (55.1) is represented by a five-dimensional invertible response. Its holonomy on a mapping torus gives the finite transformation phase. In the form needed here, an invertible anomaly theory assigns a phase

$$\mathcal{I}_5[Y, \sigma_Y, B_Y] \in U(1)$$

to every closed five-manifold Y equipped with a chosen spin structure σ_Y, global-symmetry background B_Y, and any additional geometric structures required by the fermions. If $(M, \sigma_M) = \partial(Y, \sigma_Y)$, the same theory assigns an anomaly line over the space of boundary backgrounds, and the four-dimensional partition function $Z[M, \sigma_M, B]$ is a vector in that line. Choosing a filling (Y, σ_Y, B_Y) trivializes the line by multiplying by the bulk phase. Changing the filling changes the trivialization by the phase of the closed structured five-manifold obtained by gluing the two fillings.

For a finite background gauge transformation g, choose a path B_t from B to B^g and identify the two ends by g. The resulting mapping torus X_g carries the induced background B_g. The inflow statement is the equality

$$\frac{Z[M, \sigma_M, B^g]}{Z[M, \sigma_M, B]} = \mathcal{I}_5[X_g, \sigma_g, B_g], \tag{55.7}$$

after a choice of local counterterm convention. On the identity component of the background gauge group, cutting the mapping torus open reduces (55.7) to the descent formula of the preceding chapter. Infinitesimally, the five-dimensional Chern–Simons response varies by the boundary term $-\int_M I_4^{(1)}$, while the boundary generating functional varies by $+\int_M I_4^{(1)}$. For a disconnected component, the mapping-torus phase can remain nontrivial even when the local polynomial anomaly vanishes.

The $SU(2)$ example above is exactly of this finite type. Its anomaly theory assigns

$$\mathcal{I}_5^{SU(2)}[X_g, \sigma_g, E_g] = (-1)^{\zeta(X_g, \sigma_g, E_g)} \tag{55.8}$$

to the mapping torus with the induced rank-two bundle. Equation (55.6) is therefore the mapping-torus inflow law (55.7). An odd number of fundamental Weyl doublets has nontrivial $\mathcal{I}_5^{SU(2)}$; an even number has the trivial product phase for this test, and the Pfaffian line has no sign holonomy around the generator detected by X_g.

This language is also the precise version of the symmetry-protected topological interpretation of anomalies. A gapped short-range-entangled five-dimensional phase with symmetry G_{f} and no intrinsic topological order has an invertible response $\mathcal{I}_5$. A four-dimensional theory with anomaly $\mathcal{I}_5$ can occur as a boundary whose anomalous transformation is cancelled by the inverse bulk response. In mathematical treatments, deformation classes of fully extended reflection-positive invertible responses with a specified tangential and G_{f}-background structure are often organized by characters of the corresponding bordism groups, together with possible free Chern–Simons or theta-type terms. This cobordism organization is a classification framework for invertible responses; each use in QFT still requires specifying the background fields, spin or pin structure, locality assumptions, and the normalization of the fermion determinant or Pfaffian line.

55.6 Low-Degree Homotopy Groups in Four-Dimensional Applications

The preceding example used $\pi_4(SU(2))$ because a gauge transformation on the compactified four-space S^4 is a map $S^4 \to G$. Other nearby homotopy groups enter different constructions. If a principal G-bundle on S^4 is described by transition data on the equator, the transition function is a map $S^3 \to G$, so the instanton number is controlled by $\pi_3(G)$ and by the normalization of the corresponding characteristic class. If a four-dimensional nonlinear sigma model has target G and its Wess–Zumino term is written by extending a field $U : M^4 \to G$ to a five-manifold, the quantization is governed by the integral cohomology class of the closed five-form used in the Wess–Zumino functional. For the standard simple-group case $G = SU(N)$, $N \geq 3$, this quantization is tested on maps $S^5 \to G$, hence by $\pi_5(G) \simeq \mathbb{Z}$. Thus π_3, π_4, π_5 play different roles and should not be conflated.

The following table records the low-degree groups most often met for compact connected classical gauge groups. The entries for $SO(N)$ with $N \geq 7$, $U(N)$ with $N \geq 3$, $SU(N)$ with $N \geq 3$, and $Sp(N)$ with $N \geq 2$ are the stable values in the displayed range, as given by Bott periodicity. For $d \geq 2$, $SO(N)$ and $Spin(N)$ have the same π_d; their π_1 differs because $Spin(N) \to SO(N)$ is the universal double cover.

G	$\pi_1(G)$	$\pi_2(G)$	$\pi_3(G)$	$\pi_4(G)$	$\pi_5(G)$
$U(1)$	$\mathbb{Z}$	0	0	0	0
$U(N),\ N \geq 3$	$\mathbb{Z}$	0	$\mathbb{Z}$	0	$\mathbb{Z}$
$SU(2) \simeq Sp(1)$	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$SU(N),\ N \geq 3$	0	0	$\mathbb{Z}$	0	$\mathbb{Z}$
$SO(N),\ N \geq 7$	$\mathbb{Z}_2$	0	$\mathbb{Z}$	0	0
$Spin(N),\ N \geq 7$	0	0	$\mathbb{Z}$	0	0
$Sp(N),\ N \geq 2$	0	0	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$

The low-rank orthogonal groups are exceptional because of accidental isomorphisms:

G	$\pi_3(G)$	$\pi_4(G)$	$\pi_5(G)$
$Spin(3) \simeq SU(2)$	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$Spin(4) \simeq SU(2) \times SU(2)$	$\mathbb{Z}^2$	$\mathbb{Z}_2^2$	$\mathbb{Z}_2^2$
$Spin(5) \simeq Sp(2)$	$\mathbb{Z}$	$\mathbb{Z}_2$	$\mathbb{Z}_2$
$Spin(6) \simeq SU(4)$	$\mathbb{Z}$	0	$\mathbb{Z}$.

For simply connected exceptional compact groups

$$G = G_2, F_4, E_6, E_7, E_8$$

one has

$$\pi_1(G) = \pi_2(G) = 0, \qquad \pi_3(G) \simeq \mathbb{Z}, \qquad \pi_4(G) = \pi_5(G) = 0.$$

There are further low-degree torsion groups in special cases, for example $\pi_6(SU(2)) \simeq \mathbb{Z}_{12}$, $\pi_6(SU(3)) \simeq \mathbb{Z}_6$, and $\pi_6(G_2) \simeq \mathbb{Z}_3$. These become relevant in higher-dimensional global-anomaly questions.

This table is a guide to the first topological obstructions, not a replacement for the anomaly itself. A modern finite anomaly is a phase of the fermion determinant or Pfaffian line, and in its most invariant formulation it is an invertible field theory on one higher dimension. Homotopy groups detect important test families of backgrounds; the complete torsion classification can depend on spin structure, global form of the group, matter representation, and bordism data.

55.7 Vacuum Sectors and Locality

Spontaneous symmetry breaking is a statement about phases of an infinite-volume quantum system. A useful comparison is a one-dimensional quantum mechanical Hamiltonian

$$H = \frac{P^2}{2} + V(x), \qquad V(x) = V(-x),$$

where V has two degenerate minima at $x = \pm a$. Figure 55.2 uses this double-well model to fix the finite-volume comparison: the exact ground state is symmetric, while localized wave packets approximate broken-sector states only after the infinite-volume limit is taken.

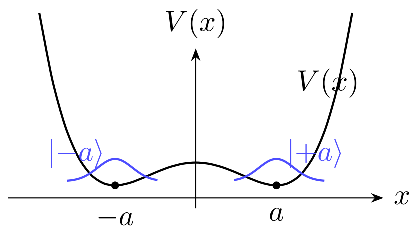

Figure 55.2: A finite-dimensional double well has localized semiclassical states near the two minima, but the exact ground state is a symmetric superposition.

The localized semiclassical states $|+a\rangle$ and $|-a\rangle$ combine into Hamiltonian eigenstates

$$|\psi_\pm\rangle = \frac{1}{\sqrt{2}}\big(|+a\rangle \pm |-a\rangle\big).$$

The splitting between them is exponentially small in the Euclidean tunneling action,

$$\Delta E \sim \mathrm{e}^{-S_0}, \qquad -\ddot{x} + V'(x) = 0, \qquad x(\pm\infty) = \pm a.$$

For a local quantum field theory with the analogous set of homogeneous minima, the tunneling action is proportional to the spatial volume. In the infinite-volume limit the transition amplitude between distinct homogeneous phases is suppressed as

$$\exp(-S_0 \ \mathrm{Vol}) \longrightarrow 0.$$

The pure vacua therefore define distinct phases rather than two nearly degenerate levels of one finite-dimensional Hamiltonian.

Locality gives the corresponding superselection statement. Let $\{|\Omega_i\rangle\}$ be translation-invariant pure vacua in infinite volume. For any local operator $\mathcal{A}(x)$, the vacuum matrix

$$A_{ij} := \langle\Omega_i|\mathcal{A}(0)|\Omega_j\rangle$$

can be chosen diagonal in the phase label. One way to see the constraint is to compare two local operators $\mathcal{A}(x)$ and $\mathcal{B}(y)$ at large spacelike separation. Insert the vacuum sector decomposition and use cluster decomposition in a pure phase:

$$\langle\Omega_i|\mathcal{A}(x)\mathcal{B}(y)|\Omega_j\rangle = \sum_k A_{ik}B_{kj} + \text{terms vanishing as } |x-y| \to \infty.$$

For spacelike separation, locality gives $[\mathcal{A}(x), \mathcal{B}(y)] = 0$, hence the vacuum matrices satisfy

$$\sum_k A_{ik}B_{kj} = \sum_k B_{ik}A_{kj}$$

for all local $\mathcal{A}, \mathcal{B}$. The commuting family of vacuum matrices is equivalently decomposed into its characters. In a character representation every element of the vacuum-sector algebra acts by a scalar. If a local observable had an off-diagonal matrix element between two distinct characters, multiplication by another element of the algebra would give different left and right scalar actions unless the two characters were equal. Thus, in the pure-sector basis, local operators do not connect distinct phases:

$$\langle\Omega_i|\mathcal{A}(x)|\Omega_j\rangle = 0 \qquad (i \neq j).$$

This is superselection by locality and clustering, not a finite-volume level splitting statement.

55.8 Spontaneous Symmetry Breaking

Definition 55.6 (Internal spontaneous symmetry breaking datum)**.** Consider a Lorentz-invariant quantum theory in infinite spatial volume with an exact continuous internal symmetry group G. Choose one pure phase and let $|\Omega\rangle$ be its vacuum vector. The unbroken subgroup is

$$H = \{h \in G : U(h)|\Omega\rangle = |\Omega\rangle\}.$$

The symmetry is spontaneously broken from G to H when H is a proper subgroup. Let $\mathfrak{g} = \mathrm{Lie}(G)$ and $\mathfrak{h} = \mathrm{Lie}(H)$. Choose an H-stable complement $\mathfrak{m}$ so that

$$\mathfrak{g} = \mathfrak{h} \oplus \mathfrak{m}, \qquad [\mathfrak{h}, \mathfrak{m}] \subset \mathfrak{m}.$$

Elements $T_i \in \mathfrak{h}$ generate unbroken transformations and elements $X_a \in \mathfrak{m}$ generate broken directions.

Definition 55.7 (Goldstone effective action in CCWZ coordinates)**.** Goldstone fields are local coordinates on the coset G/H. A coset representative may be written

$$\xi(\pi(x)) = \exp\left\{\frac{\mathrm{i}}{f}\pi^a(x)X_a\right\}. \tag{55.9}$$

For $g \in G$, the defining nonlinear action is

$$g\,\xi(\pi) = \xi(\pi')\,h(g,\pi), \qquad h(g,\pi) \in H. \tag{55.10}$$

The compensator $h(g,\pi)$ is determined by the chosen coset section and by the requirement that $g\xi(\pi)$ be written again in the form $\xi(\pi')H$.

The Maurer–Cartan form decomposes as

$$\xi^{-1}\mathrm{d}\xi = \mathrm{i}e^a X_a + \mathrm{i}\omega^i T_i. \tag{55.11}$$

The one-forms $e^a = e^a_\mu \mathrm{d}x^\mu$ are the covariant vielbein on the Goldstone target G/H, while ω^i is an H-connection. If G/H carries an invariant metric G_{ab} on the broken tangent space, the leading Goldstone action is

$$S_{\text{Goldstone}} = \frac{f^2}{2}\int G_{ab}\, e^a_\mu e^{b\mu}\,\mathrm{d}^4x + \cdots\,. \tag{55.12}$$

The ellipsis denotes higher-derivative terms and explicit symmetry-breaking terms. No potential appears for exact Goldstone coordinates because constant maps into G/H label symmetry-related vacua.

55.9 Goldstone Theorem as a Spectral Statement

Proposition 55.8 (Goldstone spectral pole from a broken current)**.** *The spectral input behind* (55.12) *is as follows. Assume a conserved current j^μ_A, a local operator $\mathcal{O}$, and a nonzero order parameter*

$$\langle\Omega, [Q_A, \mathcal{O}(0)]\Omega\rangle = \langle\Omega, \delta_A\mathcal{O}(0)\Omega\rangle \neq 0, \tag{55.13}$$

where Q_A is obtained as the infinite-volume limit of smeared charges. Assume also that local contact ambiguities in the time-ordered product have been fixed so that the nonlocal part of the mixed current-operator distribution has the Lorentz-covariant scalar spectral form near $p = 0$: modulo a local polynomial in p,

$$\widehat{G}^\mu_A(p)_{\text{nonloc}} = p^\mu F_A(p^2) + \widehat{G}^\mu_{A,\perp}(p), \qquad p_\mu\widehat{G}^\mu_{A,\perp}(p) = 0,$$

where F_A is a scalar boundary-value distribution with a Källén–Lehmann representation in the broken channel. The Ward identity for the time-ordered distribution is

$$\partial_\mu\langle\Omega, T\{j^\mu_A(x)\mathcal{O}(0)\}\Omega\rangle = -\mathrm{i}\delta^{(4)}(x)\langle\Omega, \delta_A\mathcal{O}(0)\Omega\rangle. \tag{55.14}$$

Fourier transforming gives a distribution $\widehat{G}^\mu_A(p)$ satisfying

$$p_\mu\widehat{G}^\mu_A(p) = \langle\Omega, \delta_A\mathcal{O}(0)\Omega\rangle.$$

Since the right-hand side is nonzero at $p = 0$, $F_A(p^2)$ must contain a $1/(p^2 - \mathrm{i}0)$-type massless singularity. In the Källén–Lehmann language this singularity is a massless contribution to the current-operator spectral measure.

Proof. Let $c_A = \langle\Omega, \delta_A\mathcal{O}(0)\Omega\rangle \neq 0$. Integrating (55.14) against a test function equal to one near the origin gives the broken-charge matrix element (55.13); Fourier transformation converts the distributional divergence into multiplication by p_μ. After the chosen local contact polynomial has been separated, the transverse part drops out and the Ward identity reads, for the nonlocal scalar channel,

$$p^2F_A(p^2) + p_\mu P^\mu_A(p) = c_A,$$

where $P_A^\mu(p)$ is the remaining local polynomial vector contribution. The contraction $p_\mu P_A^\mu(p)$ has no constant term at $p = 0$. If F_A were regular at $p^2 = 0$, then $p^2 F_A(p^2)$ would also vanish at the origin as a boundary-value distribution modulo higher-order local polynomial terms, contradicting $c_A \neq 0$. Thus the nonlocal scalar channel contains

$$F_A(p^2) = \frac{c_A}{p^2 - \mathrm{i}0} + \text{less singular terms}$$

up to the sign fixed by the Fourier convention. In a scalar spectral representation

$$F_A(p^2) = \int_0^\infty \frac{\mathrm{d}\nu_A(\mu^2)}{p^2 + \mu^2 - \mathrm{i}0} + \text{local polynomial},$$

such an inverse p^2 boundary value is precisely an atom of $\mathrm{d}\nu_A$ at $\mu^2 = 0$. This is the massless Goldstone contribution to the spectral measure. □

Equivalently, for each broken direction there are zero-mass one-particle states $|\pi_a(p)\rangle$ created by the current:

$$\langle \Omega | j_A^\mu(0) | \pi_a(p) \rangle = \mathrm{i} F_{Aa} p^\mu, \qquad p^2 = 0. \tag{55.15}$$

If the translation generators have spectrum contained in the closed forward light cone and the vacuum is the unique translation-invariant vector in the chosen phase, the matrix F_{Aa} has rank equal to the number of broken generators. These massless states are the quanta described by the Goldstone coordinates $\pi^a(x)$.

Remark 55.9 (Goldstone theorem and gauged directions). The spectral argument above is a theorem about a global symmetry current acting on the physical positive Hilbert space. It assumes that Q_A is a charge defined on physical states and that $\delta_A \mathcal{O}$ is the variation of a gauge-invariant local observable or of a local field in an ordinary positive-metric representation.

Gauge redundancy is different. In a covariant gauge-fixed description the state space before the physical quotient is a Krein space, as in Chapter 47, and physical states are BRST cohomology classes. A scalar coordinate that moves along a gauged orbit is then a would-be Goldstone coordinate, not by itself a physical massless particle. At the level of gauge theories with scalar matter, this is the Brout–Englert–Higgs mechanism developed in Section 45.5. At quadratic order in the Abelian Higgs model, using here the conventional explicit-coupling coordinate $D_\mu = \partial_\mu - \mathrm{i} g A_\mu$, write

$$\phi(x) = \frac{1}{\sqrt{2}}\big(v + h(x) + \mathrm{i}\pi(x)\big), \qquad m_A = gv.$$

The scalar kinetic term contains

$$|D_\mu \phi|^2 = \frac{1}{2}(\partial_\mu h)^2 + \frac{1}{2}(\partial_\mu \pi - m_A A_\mu)^2 + \text{higher powers of } h, \pi, A. \tag{55.16}$$

Equivalently, away from zeros of $v + h$, the gauge-invariant vector

$$\mathcal{A}_\mu = A_\mu - \frac{1}{m_A}\partial_\mu \pi$$

has the Proca mass term $\frac{1}{2} m_A^2 \mathcal{A}_\mu \mathcal{A}^\mu$ at quadratic order. In an R_ξ gauge one instead uses the gauge-fixing functional

$$F_\xi = \partial^\mu A_\mu + \xi m_A \pi,$$

which cancels the $A_\mu\partial^\mu\pi$ mixing and assigns the unphysical fields π and the Faddeev–Popov ghosts the gauge-dependent mass $\sqrt{\xi}\,m_A$. The longitudinal gauge polarization, the would-be Goldstone coordinate, and the ghost-antighost variables form BRST doublet or quartet sectors, so they have no independent positive-norm particle states in the BRST cohomology. The physical spectrum contains a massive vector particle with three polarizations and the gauge-invariant scalar excitation h, plus any Goldstone particles associated with broken global symmetries that remain after the gauge redundancy has been quotiented.

55.10 The $U(1)$ Goldstone Model

The spectral conclusion is realized explicitly by a complex scalar field with

$$\mathcal{L} = -\partial_\mu\phi^*\partial^\mu\phi - V(|\phi|).$$

Figure 55.3 displays the vacuum circle and the radial/angular coordinates used to separate the massive radial excitation from the Goldstone mode.

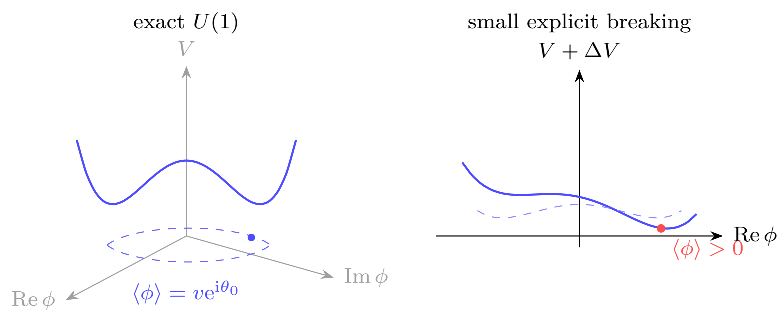

Figure 55.3: For a $U(1)$-invariant potential minimized at $|\phi| = v$, the minima form a circle of vacua. A small deformation $\Delta V = -\epsilon\,\mathrm{Re}\,\phi$ selects one point on that circle.

The $U(1)$ current is

$$j^\mu = -\mathrm{i}(\phi^*\partial^\mu\phi - \phi\partial^\mu\phi^*).$$

Write

$$\phi(x) = r(x)\mathrm{e}^{\mathrm{i}\theta(x)}.$$

Then

$$\mathcal{L} = -\partial_\mu r\,\partial^\mu r - V(r) - r^2\partial_\mu\theta\,\partial^\mu\theta, \qquad j^\mu = 2r^2\partial^\mu\theta.$$

The charge $Q = \int \mathrm{d}^3x\, j^0$ generates the shift of the angular field,

$$[Q, \theta(x)] = \mathrm{i},$$

with the sign fixed by the current convention. If $V(r)$ is minimized at $r = v > 0$, write $r = v + \rho$. The quadratic Lagrangian contains

$$-\partial_\mu\rho\,\partial^\mu\rho - \frac{1}{2}V''(v)\rho^2 - v^2\partial_\mu\theta\,\partial^\mu\theta.$$

The radial field ρ is massive when $V''(v) > 0$, while θ is a massless field whose constant shifts move along the vacuum circle.

A small explicit symmetry-breaking deformation selects a phase. For example,

$$\Delta V(\phi) = -\epsilon \ \mathrm{Re}\,\phi, \qquad \epsilon > 0,$$

chooses the vacuum with $\theta = 0$. In the angular effective theory,

$$\Delta\mathcal{L} = \epsilon v \cos\theta = \epsilon v - \frac{\epsilon v}{2}\theta^2 + O(\theta^4),$$

so the Goldstone boson becomes a pseudo-Goldstone boson with

$$m_\theta^2 \propto \frac{\epsilon}{v}.$$

This is the prototype for the pion mass generated by small quark masses.

Remark 55.10 (Masses in the $U(1)$ Goldstone model)*.* With the mostly-plus kinetic convention used in this volume, define canonical small-fluctuation fields near the vacuum by

$$h = \sqrt{2}\,\rho, \qquad \pi = \sqrt{2}\,v\,\theta.$$

If $V'(v) = 0$ and $V''(v) > 0$, then the radial excitation has

$$m_h^2 = \frac{1}{2}V''(v),$$

while the angular excitation is massless when the $U(1)$ symmetry is exact. For the explicit breaking $\Delta V = -\epsilon\,\mathrm{Re}\,\phi$, the angular excitation at $\theta = 0$ has, to first order in ϵ,

$$m_\pi^2 = \frac{\epsilon}{2v} + O(\epsilon^2).$$

The quadratic kinetic terms are

$$-\partial_\mu\rho\,\partial^\mu\rho - v^2\partial_\mu\theta\,\partial^\mu\theta = -\frac{1}{2}\partial_\mu h\,\partial^\mu h - \frac{1}{2}\partial_\mu\pi\,\partial^\mu\pi.$$

Expanding the symmetric potential gives

$$-V(v+\rho) = -V(v) - \frac{1}{2}V''(v)\rho^2 + O(\rho^3) = -V(v) - \frac{1}{4}V''(v)h^2 + O(h^3),$$

which is the canonical mass term $-\frac{1}{2}m_h^2h^2$ with $m_h^2 = V''(v)/2$. No term depending on a constant θ is allowed by the exact shift symmetry, so π has no mass term. The explicit breaking contributes

$$\epsilon v\cos\theta = \epsilon v - \frac{\epsilon v}{2}\theta^2 + O(\theta^4) = \epsilon v - \frac{\epsilon}{4v}\pi^2 + O(\pi^4),$$

and therefore $m_\pi^2 = \epsilon/(2v)$ in canonical normalization.

55.11 Chiral Symmetry of Massless QCD

Let $q_L^I = P_Lq^I$ and $q_R^I = P_Rq^I$, $I = 1, \dots, N_f$, be massless quark fields in the fundamental representation of the color gauge group. The connected continuous flavor symmetry acting faithfully on local gauge-invariant operators has Lie algebra

$$\mathfrak{su}(N_f)_L \oplus \mathfrak{su}(N_f)_R \oplus \mathfrak{u}(1)_B.$$

For local current algebra computations this Lie algebra is represented by

$$SU(N_f)_L \times SU(N_f)_R \times U(1)_B.$$

The precise global form includes finite quotients by common center actions; those quotients matter for global background fields and are developed later. The anomaly derived in the preceding chapter removes the axial $U(1)_A$ rotation from the exact continuous quantum symmetry group.

The left and right transformations act by

$$q_L \longmapsto Lq_L, \qquad q_R \longmapsto Rq_R, \qquad (L, R) \in SU(N_f)_L \times SU(N_f)_R.$$

Conjecture 55.11 (Chiral symmetry breaking in QCD)**.** *For four-dimensional $SU(N_c)$ QCD with N_f light fundamental quarks in the range where the infrared theory is confining rather than conformal, the infinite-volume vacuum selected by equal positive quark masses has a nonzero chiral order parameter in the subsequent massless limit:*

$$\lim_{m\downarrow 0}\lim_{V\to\infty} \langle \bar{q}_{R,J} q_{L,I}\rangle_{m,V} = \Sigma_0\, \delta_{IJ}, \qquad \Sigma_0 \neq 0. \tag{55.17}$$

The unbroken continuous nonabelian flavor symmetry in this phase is the diagonal vector subgroup $SU(N_f)_V$.

Conjecture 55.11 is a dynamical assertion about the QCD vacuum. It is not presently a theorem derived from the four-dimensional continuum QCD Lagrangian or from a completed continuum limit of lattice QCD. Lattice simulations and phenomenology give strong evidence for the small-N_f theory, while semiclassical instanton calculations do not supply a controlled derivation of the infrared condensate. The pion effective theory below is the low-energy theory conditional on this chiral breaking phase.

In the phase described by Conjecture 55.11, the bilinear condensate has an orientation that can be chosen as

$$\Sigma_{IJ} = \langle \bar{q}_{R,J} q_{L,I}\rangle = \Sigma_0\, \delta_{IJ},$$

so that the stabilizer is the diagonal subgroup. More explicitly, before choosing the orientation of the vacuum, write

$$A_{IJ} := \langle \bar{q}_{R,J} q_{L,I}\rangle.$$

Under $SU(N_f)_L \times SU(N_f)_R$,

$$A \longmapsto R^\dagger A L.$$

A choice of L and R can diagonalize A. If the vacuum is invariant under the non-chiral subgroup, then A is proportional to the identity. The unbroken transformations are precisely $L = R$. The breaking pattern is therefore

$$SU(N_f)_L \times SU(N_f)_R \longrightarrow SU(N_f)_V. \tag{55.18}$$

Given this dynamical input, the number of Goldstone bosons is $N_f^2 - 1$.

Definition 55.12 (QCD Goldstone target)**.** Conditional on the breaking pattern (55.18), the Goldstone target is

$$\frac{SU(N_f)_L \times SU(N_f)_R}{SU(N_f)_V} \simeq SU(N_f).$$

The coordinate $U \in SU(N_f)$ is chosen with left flavor as the row index and right flavor as the column index. With this index convention it parameterizes the condensate orientation relative to the reference condensate $U = 1$, and the left and right flavor groups act by

$$U \longmapsto LUR^{-1}.$$

This is the index convention used by the mass spurion and the pion effective action below; it is the same physical orientation as the bilinear matrix $A_{IJ} = \langle \bar{q}_{R,J} q_{L,I} \rangle$ above, written with the opposite choice of displayed row and column indices. The diagonal subgroup $L = R$ fixes the reference orientation $U = 1$ and acts on the tangent space at $U = 1$ by the adjoint representation of $\mathfrak{su}(N_f)$.

At $\theta = 0$, the non-chiral flavor symmetry is constrained by the positivity structure of the Euclidean vectorlike theory. The statement has a precise theorem boundary.

Hypothesis 55.13 (Euclidean measure needed for Vafa–Witten positivity)**.** For the vectorlike theory with equal positive quark masses $m > 0$, assume that there is a family of gauge-invariant Euclidean finite-regulator measures $d\nu_{m,\Lambda}(A)$. If a continuum statement is claimed, assume in addition that the gauge-invariant Schwinger functions and the source functionals for the order parameters used below have a continuum limit, denoted $d\nu_m(A)$ in this paragraph, with the following properties:

i. expectations of gauge-invariant polynomially bounded fermion bilinears and their source deformations are defined at the regulator level and converge in the limit in which the Vafa–Witten conclusion is asserted;

ii. the full regulator measure, including the gauge action and the vectorlike fermion discretization or determinant, is reflection positive for a Euclidean time reflection, and this positivity is preserved by the limiting Schwinger functions. Thus OS reconstruction applies to the observables used in the argument;

iii. the Dirac operator and fermion regulator have vectorlike determinant positivity in each fixed gauge-field background. In the continuum notation this is the anti-Hermiticity and eigenvalue pairing statement

$$\det(\not{D}_A + m) = \prod_{\lambda > 0} (\lambda^2 + m^2)\, m^{n_0(A)} \geq 0;$$

on a lattice it is replaced by the corresponding positivity property of the chosen vectorlike fermion action;

iv. the infinite-volume and small-mass limits used to select a phase exist for the order parameters under consideration.

At finite lattice spacing, these hypotheses are properties to verify for the chosen lattice gauge and fermion action. The Wilson plaquette gauge action is reflection positive in the sense described in Chapter 46, and standard vectorlike fermion discretizations must be checked with their own reflection-positivity and determinant-positivity conditions. These properties are not automatic for an arbitrary regulator or gauge-fixed expression. For the four-dimensional continuum gauge theory, the existence of $d\nu_m(A)$ with the required locality, reflection positivity, and scaling limits is part of the Yang–Mills/QCD construction problem; the finite-lattice positivity argument is therefore not, by itself, a construction of continuum QCD.

Under Hypothesis 55.13, the determinant factor in each fixed gauge-field background is non-negative, and for equal masses the fermion determinant and gauge measure are invariant under $SU(N_f)_V$. A vector-flavor-breaking external source may then be averaged over the compact vector flavor group without decreasing the Euclidean functional integral. In the infinite-volume limit this convexity/positivity comparison rules out a lower vacuum energy for a vector-flavor-breaking orientation. Taking the small-mass limit therefore selects, when the limit exists, a vacuum preserving $SU(N_f)_V$. This is the Vafa–Witten positivity argument in the form needed here. It does not by itself prove the existence of the chiral condensate; it constrains the orientation of the condensate once the vectorlike massive regulator and its reflection-positive measure have been constructed.

The complex phase of Σ_0 is tied to the topological angle. A flavor-singlet axial rotation would rotate Σ_0, but the same transformation is anomalous and shifts θ. Thus the invariant structure are the condensate orientation together with the anomaly-invariant combination of θ and the quark-mass phase discussed in the preceding chapter.

55.12 Topological Susceptibility and the Singlet Axial Direction

The nonabelian pion field below takes values in $SU(N_f)$, because the axial $U(1)_A$ rotation is anomalous at finite N_c. At large N_c the anomaly is suppressed in the singlet meson sector in a precise sense: the pure Yang–Mills topological susceptibility remains $O(1)$, while $f_\pi^2 = O(N_c)$. The resulting singlet mass is therefore $O(N_c^{-1})$. This paragraph is a conditional large-N_c matching statement, not a proof of the pure Yang–Mills continuum limit or of the full QCD chiral phase.

Hypothesis 55.14 (Large-N_c singlet theta matching)**.** Fix N_f while $N_c \to \infty$, and assume the following inputs.

1. Pure $SU(N_c)$ Yang–Mills has a topological susceptibility χ_{YM} in the sense of Definition 51.18, with $\chi_{\mathrm{YM}} = O(N_c^0)$.
2. In the branch near $\vartheta = 0$, the pure Yang–Mills vacuum energy has the local expansion
$$E_{\mathrm{YM}}(\vartheta) = E_{\mathrm{YM}}(0) + \frac{1}{2}\chi_{\mathrm{YM}}\vartheta^2 + O(\vartheta^4/N_c^2), \tag{55.19}$$
while 2π-periodicity is restored by the usual branch label $\vartheta \mapsto \vartheta + 2\pi k$.
3. The chiral effective field may be enlarged locally from $SU(N_f)$ to $U(N_f)$ near the identity:
$$\widehat{U} = \exp\left(\frac{2\mathrm{i}}{f_\pi}(\eta_0 T^0 + \pi^a T^a)\right), \qquad T^0 = \frac{\mathbf{1}_{N_f}}{\sqrt{2N_f}}, \qquad \mathrm{Tr}(T^A T^B) = \frac{1}{2}\delta^{AB}. \tag{55.20}$$
The leading kinetic term is
$$\frac{f_\pi^2}{4}\,\mathrm{Tr}(\partial_\mu \widehat{U}\partial^\mu \widehat{U}^\dagger), \tag{55.21}$$
so that η_0 is canonically normalized.
4. To leading order in the fixed-N_f large-N_c expansion and at vanishing quark masses, the theta dependence enters the singlet effective potential through
$$\vartheta = \theta - \mathrm{i}\log\det\widehat{U} \tag{55.22}$$

on the branch near $\widehat{U} = 1$. With the convention $U \mapsto LUR^{-1}$, a common axial change of variables sends $\theta \mapsto \theta - 2N_f\alpha$ and $\mathrm{i}\log\det\widehat{U} \mapsto \mathrm{i}\log\det\widehat{U} - 2N_f\alpha$, so this is the invariant coordinate. When the mass term aligns $\widehat{U}$ with the phase of M, it reduces to the microscopic strong-CP phase $\theta + \arg\det M$.

Witten–Veneziano mass formula from the large-N_c matching input. Under Hypothesis 55.14, the singlet field η_0 has, in the chiral limit and at leading fixed-N_f large N_c,

$$m_{\eta_0}^2 = \frac{2N_f}{f_\pi^2}\chi_{\mathrm{YM}} + O(N_c^{-2}). \tag{55.23}$$

Equivalently, because $f_\pi^2 = O(N_c)$ while $\chi_{\mathrm{YM}} = O(1)$, the singlet mass squared is $O(N_c^{-1})$.

Since the non-singlet generators are traceless,

$$-\mathrm{i}\log\det\widehat{U} = \frac{2\eta_0}{f_\pi}\operatorname{Tr}T^0 = \frac{\sqrt{2N_f}}{f_\pi}\eta_0 \tag{55.24}$$

on the branch near the identity. Substituting (55.22) into the local Yang–Mills branch (55.19) gives the singlet potential

$$V_{\mathrm{singlet}}(\eta_0;\theta) = \frac{1}{2}\chi_{\mathrm{YM}}\left(\theta + \frac{\sqrt{2N_f}}{f_\pi}\eta_0\right)^2 + O(N_c^{-2})$$

in the effective Lagrangian. At fixed $\theta = 0$, the quadratic term is

$$\frac{1}{2}\left(\frac{2N_f\chi_{\mathrm{YM}}}{f_\pi^2}\right)\eta_0^2.$$

The kinetic term (55.21) gives $\frac{1}{2}\partial_\mu\eta_0\partial^\mu\eta_0$, because $\operatorname{Tr}(T^0T^0) = 1/2$. The displayed coefficient is therefore the mass squared.

Theta-curvature matrix and the screening direction. The finite-regulator cumulant identity (51.52) fixes the sign of the pure Yang–Mills curvature:

$$\chi_{\mathrm{YM}} = E''_{\mathrm{YM}}(0) \geq 0$$

when the limit exists in a CP-invariant branch. In the local singlet chart set

$$a := \frac{\sqrt{2N_f}}{f_\pi}, \qquad V(\theta,\eta_0) = \frac{1}{2}\chi_{\mathrm{YM}}(\theta + a\eta_0)^2.$$

The Hessian in the coordinate pair (θ,η_0) is the rank-one matrix

$$H_{\theta,\eta} = \chi_{\mathrm{YM}}\begin{pmatrix}1 & a\\ a & a^2\end{pmatrix}. \tag{55.25}$$

Thus $H_{\theta,\eta}(-a,1)^T = 0$: shifting θ and η_0 so that $\theta + a\eta_0$ is fixed is the massless-quark screening direction. By contrast, the fixed-θ curvature in the η_0 direction is

$$\partial_{\eta_0}^2 V|_{\theta=0} = a^2\chi_{\mathrm{YM}} = \frac{2N_f}{f_\pi^2}\chi_{\mathrm{YM}},$$

which is exactly the mass coefficient in (55.23). The mixed derivative $\partial_\theta \partial_{\eta_0} V = a\chi_{\mathrm{YM}}$ records the sign of the anomaly-invariant coordinate $\theta - \mathrm{i}\log\det \widehat{U}$; reversing that sign would give the same positive mass but the opposite singlet screening convention.

Controlled Approximation 55.15 (Residual-controlled Witten–Veneziano matching)**.** The preceding rank-one matrix is the leading local Hessian in the chiral, fixed-N_f, large-N_c matching window. If the comparison is made in the exact massless full-QCD theory, with a continuum and regulator convention which preserves the anomalous axial Ward identity, the first residual cannot be an arbitrary symmetric 2×2 matrix. With at least one exactly massless quark the θ-angle is removable by an anomalous chiral rotation, so the full vacuum energy is independent of θ. Therefore the local residual must preserve the screening vector:

$$H^{\mathrm{loc}}_{\theta,\eta}(-a, 1)^T = 0.$$

In the two-variable local Hessian this condition forces the residual to stay in the same anomaly-invariant coordinate. Thus write

$$H^{\mathrm{loc}}_{\theta,\eta} = \chi_{\mathrm{eff}} \begin{pmatrix} 1 & a \\ a & a^2 \end{pmatrix} = (\chi_{\mathrm{YM}} + \delta\chi) \begin{pmatrix} 1 & a \\ a & a^2 \end{pmatrix}, \qquad a = \frac{\sqrt{2N_f}}{f_\pi}, \tag{55.26}$$

with $\chi_{\mathrm{eff}} > 0$ in the selected local branch. The scalar $\delta\chi$ records the declared large-N_c, branch-selection, and local counterterm uncertainty in the same renormalization convention as χ_{YM}; it shifts the fixed-θ singlet curvature and the mixed curvature together. At fixed θ, the singlet potential curvature in the leading field coordinate is

$$H^{\mathrm{loc}}_{\eta\eta} = a^2 \chi_{\mathrm{eff}} = \frac{2N_f}{f_\pi^2}(\chi_{\mathrm{YM}} + \delta\chi). \tag{55.27}$$

But minimizing the same local quadratic form over the singlet field gives

$$\chi^{m=0,\mathrm{loc}}_{\mathrm{QCD}} = \chi_{\mathrm{eff}} - \frac{(a\chi_{\mathrm{eff}})^2}{a^2 \chi_{\mathrm{eff}}} = 0. \tag{55.28}$$

The exact zero in (55.28) is part of the massless matching condition, not an optional cancellation imposed after the fact.

A physical pole mass also requires the kinetic normalization of the singlet field. At the same order at which $\delta\chi$ is kept, write the local quadratic kinetic term in the η_0 coordinate as

$$\frac{1}{2} Z_0\, \partial_\mu \eta_0 \partial^\mu \eta_0, \qquad F_0^2 := Z_0 f_\pi^2. \tag{55.29}$$

Then the mass statement is the one-field generalized eigenvalue

$$m^2_{\eta_0,\mathrm{phys}} = \frac{H^{\mathrm{loc}}_{\eta\eta}}{Z_0} = \frac{2N_f}{F_0^2}(\chi_{\mathrm{YM}} + \delta\chi), \tag{55.30}$$

while (55.27) is the corresponding potential curvature in the leading field coordinate. Thus the usable uncertainty statement is: if $|\delta\chi| \le r_\chi$, $|Z_0 - 1| \le r_Z < 1$, and the leading comparison mass is $m^2_{\mathrm{WV},0} = 2N_f \chi_{\mathrm{YM}}/f_\pi^2$, then

$$\left| m^2_{\eta_0,\mathrm{phys}} - m^2_{\mathrm{WV},0} \right| \le \frac{2N_f}{f_\pi^2} \frac{r_\chi + \chi_{\mathrm{YM}} r_Z}{1 - r_Z}, \qquad \chi^{m=0,\mathrm{loc}}_{\mathrm{QCD}} \equiv 0. \tag{55.31}$$

The first term in the numerator is the potential-curvature uncertainty; the second is the independent singlet decay-constant or wavefunction uncertainty. The anomalous Ward identity fixes the screening coordinate of the potential. It does not fix Z_0.

If one intentionally leaves this massless Ward-compatible setting, for example by keeping finite quark masses or by introducing an explicit symmetry-breaking regulator/counterterm error, one may add a separate Ward-breaking matrix $B = (b_{ij})$:

$$H^{\mathrm{break}}_{\theta,\eta} = \chi_{\mathrm{eff}} \begin{pmatrix} 1 & a \\ a & a^2 \end{pmatrix} + \begin{pmatrix} b_{\theta\theta} & b_{\theta\eta} \\ b_{\theta\eta} & b_{\eta\eta} \end{pmatrix}. \tag{55.32}$$

For $a^2\chi_{\mathrm{eff}} + b_{\eta\eta} > 0$, the Schur complement of (55.32) is

$$\chi^{\mathrm{loc}}_{\mathrm{break}} = \frac{\chi_{\mathrm{eff}} b_{\eta\eta} + a^2\chi_{\mathrm{eff}} b_{\theta\theta} + b_{\theta\theta}b_{\eta\eta} - 2a\chi_{\mathrm{eff}} b_{\theta\eta} - b^2_{\theta\eta}}{a^2\chi_{\mathrm{eff}} + b_{\eta\eta}}. \tag{55.33}$$

This last quantity is a diagnostic for the declared breaking source or for finite-mass physics. It is not the theta curvature of the exactly massless, symmetry-preserving full-QCD theory. Equations (55.26)–(55.31) are the local bookkeeping needed before comparing a measured η' mass, a lattice χ_{YM}, and a full-QCD topological susceptibility. They do not prove the Yang–Mills continuum limit, the large-N_c expansion, or the absence of branch crossings; they state how those inputs enter the observable singlet curvature once a local branch and counterterm convention have been fixed.

With nonzero quark masses the same caveat becomes a matrix statement. For the neutral fields retained in the effective theory, write

$$\mathcal{L}_2 = \frac{1}{2}K_{AB}\partial_\mu\varphi^A\partial^\mu\varphi^B - \frac{1}{2}H_{AB}\varphi^A\varphi^B + \cdots .$$

The physical pseudoscalar masses are the generalized eigenvalues

$$\det(H - m^2K) = 0, \tag{55.34}$$

so η_0-octet potential mixing, kinetic mixing, and the singlet wavefunction residual must be separated from the pure-Yang–Mills theta curvature. The scalar formula (55.30) is the chiral, unmixed, single-field specialization of (55.34).

Remark 55.16 (Why this does not contradict massless-quark theta independence). If the quark masses vanish and η_0 is included as a dynamical field, the vacuum minimizes $\theta+\sqrt{2N_f}\eta_0/f_\pi$. Thus the full massless QCD vacuum energy is locally independent of θ, and its topological susceptibility vanishes, while the curvature in the singlet field direction at fixed θ is nonzero. The susceptibility in (55.23) is the pure Yang–Mills susceptibility χ_{YM}, not the full massless-QCD susceptibility. This is the local Hessian form of the anomalous axial Ward identity and of the Leutwyler–Smilga small-mass constraint [64]: for positive small quark masses, $\chi_{\mathrm{QCD}} = \Sigma(\sum_i m_i^{-1})^{-1} + O(m^2)$, so the curvature vanishes when any one quark mass is taken to zero.

Controlled Approximation 55.17 (Instanton determinant as a chiral spurion potential)**.** Assume, in addition to the chiral phase hypothesis above, that the regulated one-instanton amplitude of Chapter 51 has been matched at a scale μ to a local color-singlet determinant source and that the instanton and anti-instanton sectors form a dilute finite-activity expansion in the sense of

(51.62). Denote the resulting renormalized activity in the chosen chiral scheme by $\zeta_\chi(\mu) > 0$. Then the zero-mode determinant and its anti-instanton conjugate induce the local singlet potential

$$\begin{aligned} V^{\chi}_{\text{inst}}(\widehat{U};\theta) = 2\zeta_\chi \left[1 - \cos\!\Big(\theta - \mathrm{i}\log\det\widehat{U}\Big)\right] \\ + \text{higher-derivative and higher-mass terms} + \text{multi-instanton terms}, \end{aligned} \tag{55.35}$$

on the same local branch as (55.22). Equivalently, in the $\widehat{U}$ convention of (55.20), the corresponding Lagrangian vertex is proportional to

$$\zeta_\chi\, \mathrm{e}^{\mathrm{i}\theta} \det\widehat{U} + \zeta_\chi\, \mathrm{e}^{-\mathrm{i}\theta} \det\widehat{U}^\dagger,$$

up to a field-independent constant in the potential. If the microscopic zero-mode determinant is written with the conjugate row/column convention, the displayed vertex is obtained by the corresponding transpose/conjugation conversion; the sign used here is fixed by the singlet coordinate (55.22).

In the η_0 chart and sign convention of (55.25), set

$$a = \frac{\sqrt{2N_f}}{f_\pi}, \qquad \theta - \mathrm{i}\log\det\widehat{U} = \theta + a\eta_0 \quad \text{on the chosen exponential branch.}$$

Expanding (55.35) gives

$$V^{\chi}_{\text{inst}}(\theta,\eta_0) = \zeta_\chi(\theta + a\eta_0)^2 + O((\theta + a\eta_0)^4), \tag{55.36}$$

so its local curvature matrix is

$$H^{\text{inst}}_{\theta,\eta} = 2\zeta_\chi \begin{pmatrix} 1 & a \\ a & a^2 \end{pmatrix}. \tag{55.37}$$

The same coefficient $2\zeta_\chi$ is the topological susceptibility of the conditional dilute gas in (51.205). Therefore a regime in which ζ_χ is actually calculable would give the singlet mass contribution

$$\Delta m^2_{\eta_0,\text{inst}} = \frac{2N_f}{f_\pi^2}\,(2\zeta_\chi) = \frac{4N_f\zeta_\chi}{f_\pi^2}. \tag{55.38}$$

This is the dilute-instanton analogue of (55.23), with χ_{YM} replaced by the finite activity susceptibility $\chi^{\text{dig}}_{\text{top}} = 2\zeta_\chi$.

The qualification is part of the statement. In zero-temperature confining QCD the large-ρ part of the one-instanton activity and the multi-instanton interaction expansion are not controlled by the BPST calculation alone. Thus (55.35) is a valid chiral coordinate for a declared finite-activity semiclassical window, such as a weakly coupled Higgsed or sufficiently screened regime, but it is not a derivation of the physical η' mass from isolated instantons in ordinary QCD. The large-N_c Witten–Veneziano input above instead uses the pure Yang–Mills susceptibility as a nonperturbative datum.

For nonzero light-quark masses the singlet field mixes with the octet pseudoscalars. This mixing is part of the susceptibility argument at the level of observables: it is the finite mass-matrix step which turns the pure Yang–Mills theta curvature into a statement about the physical pseudoscalar spectrum. For $N_f = 3$, take the isospin limit

$$M = \operatorname{diag}(m, m, m_s), \qquad m_\pi^2 = 2B_0 m, \qquad m_K^2 = B_0(m + m_s),$$

and use the local $U(3)$ coordinates of (55.20) with

$$T^3 = \frac{1}{2}\,\mathrm{diag}(1,-1,0), \qquad T^8 = \frac{1}{2\sqrt{3}}\,\mathrm{diag}(1,1,-2), \qquad T^0 = \frac{1}{\sqrt{6}}\mathbf{1}_3.$$

Expanding the leading mass spurion $\frac{f_\pi^2}{4}\,\mathrm{Tr}(\chi\widehat{U}^\dagger + \widehat{U}\chi^\dagger)$ to quadratic order gives the neutral mass matrix

$$(M^2_{\mathrm{mass}})_{AB} = 4B_0\,\frac{1}{2}\,\mathrm{Tr}\big(M\{T^A,T^B\}\big), \qquad A,B \in \{3,8,0\}.$$

The isospin generator decouples:

$$M^2_{33} = m_\pi^2, \qquad M^2_{38} = M^2_{30} = 0.$$

Adding the anomalous singlet curvature

$$m_0^2 := \frac{2N_f}{f_\pi^2}\chi_{\mathrm{YM}} \qquad (N_f = 3)$$

only in the 00 entry gives the (η_8,η_0) block

$$M^2_{\eta_8\eta_0} = \begin{pmatrix} \frac{4m_K^2 - m_\pi^2}{3} & -\frac{2\sqrt{2}}{3}(m_K^2 - m_\pi^2) \\ -\frac{2\sqrt{2}}{3}(m_K^2 - m_\pi^2) & \frac{2m_K^2 + m_\pi^2}{3} + m_0^2 \end{pmatrix}. \tag{55.39}$$

Changing the sign convention for η_8 changes the sign of the off-diagonal entry, but not the eigenvalues. If those eigenvalues are denoted m_η^2 and $m_{\eta'}^2$ at this leading order, the trace gives

$$m_{\eta'}^2 + m_\eta^2 - 2m_K^2 = m_0^2 = \frac{2N_f}{f_\pi^2}\chi_{\mathrm{YM}}. \tag{55.40}$$

The determinant records the same mixing data in the product of the two eigenvalues:

$$m_\eta^2 m_{\eta'}^2 = m_\pi^2(2m_K^2 - m_\pi^2) + \frac{m_0^2}{3}(4m_K^2 - m_\pi^2). \tag{55.41}$$

Thus the usual phenomenological form

$$m_{\eta'}^2 + m_\eta^2 - 2m_K^2 = \frac{2N_f}{f_\pi^2}\chi_{\mathrm{YM}} + \text{controlled corrections}$$

requires the quark-mass potential, the normalization of f_π, and the large-N_c and chiral remainders to be stated in the same scheme. The chiral-limit result above fixes the normalization; the finite matrix (55.39) shows how that curvature enters a physical mass spectrum once light-quark masses are restored.

Choose Hermitian flavor generators T^a with $\mathrm{Tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$. These T^a are flavor generators used to parameterize the chiral target $SU(N_f)$; they are not the color gauge generators t^a of the Yang–Mills chapters, where the default convention is $\mathrm{tr}(t^at^b) = \delta^{ab}$. The half-trace flavor convention is kept here because, together with the factor $2/f_\pi$ below, it gives the canonical leading pion coordinates and is compatible with the axial-current normalization stated below. The pion field is the $SU(N_f)$-valued matrix

$$U(x) = \exp\left\{\frac{2\mathrm{i}}{f_\pi}\pi^a(x)T^a\right\}, \qquad U(x) \in SU(N_f), \tag{55.42}$$

transforming as

$$U(x) \longmapsto L\,U(x)\,R^{-1}. \tag{55.43}$$

The axial-current normalization is

$$\langle\Omega|A^{a\mu}(0)|\pi^b(p)\rangle = \mathrm{i} f_\pi p^\mu \delta^{ab}.$$

With this convention, the leading two-derivative chiral Lagrangian is

$$\mathcal{L}_2 = -\frac{f_\pi^2}{4}\,\mathrm{Tr}\big(D_\mu U^\dagger D^\mu U\big), \tag{55.44}$$

where the covariant derivative in external left and right flavor backgrounds ℓ_μ, r_μ is

$$D_\mu U = \partial_\mu U - \mathrm{i}\ell_\mu U + \mathrm{i}U r_\mu. \tag{55.45}$$

The minus sign in (55.44) is the mostly-plus metric convention used throughout this volume. Expanding (55.42) at $\ell_\mu = r_\mu = 0$ gives

$$\mathrm{Tr}(\partial_\mu U^\dagger \partial^\mu U) = \frac{2}{f_\pi^2}\,\partial_\mu\pi^a\partial^\mu\pi^a + O(\pi^3),$$

and hence the canonical leading kinetic term

$$\mathcal{L}_2 = -\frac{1}{2}\partial_\mu\pi^a\partial^\mu\pi^a + \cdots\,.$$

The same expansion also fixes the normalization of the derivative self-interactions.

55.13 Soft-Pion Ward Identity and the Adler Zero

The axial-current normalization above fixes the normalization of the one-pion pole in current correlators. Let $\Pi^a(x)$ be a local pion interpolating field in the low-energy theory, normalized by

$$\langle\Omega|\Pi^a(0)|\pi^b(p)\rangle = Z_\pi^{1/2}\delta^{ab}, \qquad p^2 = 0,$$

and let

$$G_a^\mu(x; x_1, \ldots, x_n) = \langle\Omega|T\{A_a^\mu(x)\Pi^{a_1}(x_1)\cdots\Pi^{a_n}(x_n)\}|\Omega\rangle$$

be the time-ordered distribution with one non-singlet axial current. In the massless theory, and with the anomalous $U(1)_A$ current excluded, the local Ward identity is

$$\begin{aligned}\partial_\mu G_a^\mu(x; x_1, \ldots, x_n) = -\mathrm{i}\sum_{j=1}^{n}\delta^{(4)}(x - x_j)&\\ \times \langle\Omega|T\{\Pi^{a_1}(x_1)\cdots\delta_A^a\Pi^{a_j}(x_j)\cdots\Pi^{a_n}(x_n)\}|\Omega\rangle.&\end{aligned} \tag{55.46}$$

Here δ_A^a denotes the infinitesimal transformation generated by the broken axial charge Q_A^a. Equation (55.46) is an identity of distributions: the right side consists of contact terms because the divergence of a conserved current inside a time-ordered product differentiates the step functions.

Fourier transform in x with momentum q entering the current and in the x_j with hard pion momenta p_j. Near $q^2 = 0$, the current insertion has the pion pole fixed by

$$\langle \Omega | A_a^\mu(0) | \pi^b(q) \rangle = \mathrm{i} f_\pi q^\mu \delta^{ab}.$$

Thus its singular part has the form

$$\widetilde{G}_a^\mu(q; \{p_j, a_j\}) = \frac{-\mathrm{i} f_\pi q^\mu}{q^2 - \mathrm{i}0}\, \widetilde{G}_{n+1}^{\,a, a_1, \dots, a_n}(q, p_1, \dots, p_n) + \widetilde{R}_a^\mu(q; \{p_j, a_j\}), \tag{55.47}$$

where $\widetilde{R}_a^\mu$ is regular at the current-channel pion pole in the soft region under consideration. Let $\mathcal{L}_{\{p_j\}}$ denote the hard external-pion LSZ operation

$$\mathcal{L}_{\{p_j\}} F = \left[\prod_{j=1}^n Z_\pi^{-1/2}\, \mathrm{i} p_j^2 \right] F \quad \text{followed by the massless on-shell boundary value } p_j^2 = 0,$$

with the same residue convention as in Chapter 18. Applying $\mathcal{L}_{\{p_j\}}$ to the Fourier transform of (55.46) and using (55.47) gives

$$f_\pi\, \mathcal{M}_{n+1}^{a, a_1, \dots, a_n}(q, p_1, \dots, p_n) = \mathcal{C}_a(q; \{p_j, a_j\}) + O(q), \tag{55.48}$$

where

$$\mathcal{C}_a(q; \{p_j, a_j\}) = \mathcal{L}_{\{p_j\}} \sum_{j=1}^n \widetilde{G}_n^{a_1, \dots, \delta_A^a a_j, \dots, a_n}(p_1, \dots, p_j + q, \dots, p_n)$$

is the sum of the LSZ-reduced contact terms; the superscript means that the j-th pion operator has been replaced by its renormalized axial variation. This formula is the soft-pion theorem in its current-algebra form: the leading soft pion is determined by the action of the broken charge on the hard external states.

Theorem 55.18 (Adler zero for chiral pion amplitudes)**.** *Assume the exact chiral limit, the symmetry-breaking pattern*

$$SU(N_f)_L \times SU(N_f)_R \longrightarrow SU(N_f)_V,$$

the axial-current normalization $\langle \Omega | A_a^\mu(0) | \pi^b(p) \rangle = \mathrm{i} f_\pi p^\mu \delta^{ab}$, and the existence of the pion scattering boundary values obtained by LSZ from time-ordered Green functions. Take the soft momentum $q \to 0$ at fixed nonexceptional hard momenta, with the hard-leg soft singularities treated by the LSZ-reduced Ward identity above and no additional threshold or collinear singular surface crossed. Then every connected purely pionic amplitude obeys

$$\mathcal{M}_{n+1}^{a, a_1, \dots, a_n}(q, p_1, \dots, p_n) = O(q). \tag{55.49}$$

The vanishing of the $O(q^0)$ term is the Adler zero.

Proof. The chiral target is the symmetric space $(SU(N_f)_L \times SU(N_f)_R)/SU(N_f)_V$. In local pion coordinates normalized by the axial current, a broken axial transformation has the expansion

$$\delta_A^a \pi^b = f_\pi \delta^{ab} + O(\pi^2/f_\pi), \tag{55.50}$$

with no term linear in the pion field. For $N_f = 2$ this is visible directly from (55.54): using $\pi^a = F_{\rm st}\xi^a$ and $F_{\rm st} = 2f_\pi$, the axial variation is $\delta_A^a \pi^b = f_\pi \delta^{ab} + O(\pi^2/f_\pi)$. The absence of a linear term is the representation-theoretic statement that $[\mathfrak{m}, \mathfrak{m}] \subset \mathfrak{h}$: a broken generator translates the origin of the coset and then rotates higher-order tangent data by the unbroken group, but it does not act as a one-pion-to-one-pion matrix at nonzero momentum.

Now evaluate the contact term $\mathcal{C}_a(0; \{p_j, a_j\})$ in (55.48). The constant part $f_\pi \delta^{aa_j}$ in (55.50) replaces the j-th interpolating field by the identity operator. After the hard LSZ operation it has no one-pion pole in p_j^2, hence gives zero. The remaining terms in $\delta_A^a \pi^{a_j}$ contain at least two pion fields at the same spacetime point. They are renormalized as part of the same symmetry-preserving Ward identity, so their projection onto a single hard-pion pole is fixed to vanish; otherwise the renormalized axial transformation would have a linear pion term, contrary to (55.50). Equivalently, the broken charge has no one-pion-to-one-pion matrix element; its possible vacuum term is supported only at zero total momentum and cannot replace a hard external pion. Therefore the LSZ-reduced contact term has no $O(q^0)$ contribution:

$$\mathcal{C}_a(0; \{p_j, a_j\}) = 0.$$

Equation (55.48) then gives (55.49). □

Figure 55.4 records the Ward-identity mechanism behind the Adler zero: the axial-current insertion is reduced by LSZ, the hard contact term has no $O(q^0)$ one-pion contribution, and the soft amplitude vanishes at leading order.

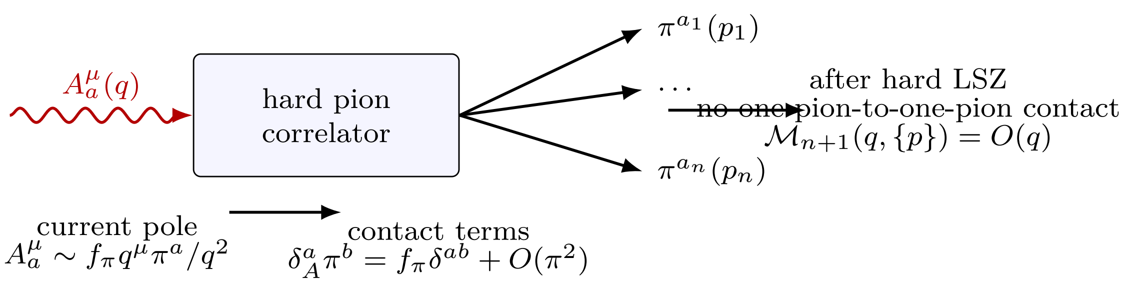

Figure 55.4: The soft-pion theorem follows by isolating the pion pole in the axial-current Ward identity. For purely pionic hard states in the chiral coset, the contact terms have no one-pion-to-one-pion component, so the leading soft term vanishes.

For external states that are not all pions, the same identity should be read before setting $\mathcal{C}_a(0) = 0$. A soft pion measures the action of the broken axial charge on the hard external sector. If the hard sector contains degenerate states connected by Q_A^a, the right side of (55.48) need not vanish. The Adler zero is the specialization to the pion S-matrix in the chiral coset.

For four pions, the theorem says that the analytic on-shell amplitude has a zero when one external pion momentum is taken soft. In the chiral limit this is the statement that the leading invariant amplitude below satisfies

$$A(s,t,u) = \frac{s}{f_\pi^2} + O(E^4/f_\pi^4), \qquad A \longrightarrow 0 \quad \text{as} \quad s,t,u \longrightarrow 0$$

in the single-soft analytic continuation. With a small common pion mass, the leading chiral formula becomes

$$A(s,t,u) = \frac{s - m_\pi^2}{f_\pi^2} + O(p^4),$$

so the zero is displaced to the corresponding Adler point in the analytically continued amplitude. The massive Adler point is not a physical threshold configuration; it is a Ward-identity zero of the analytic amplitude.

55.14 Low-Energy Pion Scattering

The two-derivative chiral Lagrangian determines the leading low-energy S-matrix of the Goldstone bosons, because every interaction is derivative and therefore ordered by powers of external momentum. For the $N_f = 2$ theory it is useful to write $SU(2) \simeq S^3$ in stereographic coordinates $\vec{\xi} = (\xi_1, \xi_2, \xi_3)$:

$$U(\xi) = \frac{1 - \vec{\xi}^{\,2} + 2\mathrm{i}\,\vec{\xi} \cdot \vec{\sigma}}{1 + \vec{\xi}^{\,2}}. \tag{55.51}$$

Let F_{st} denote the normalization used in these stereographic coordinates:

$$\mathcal{L}_2 = -\frac{F_{\mathrm{st}}^2}{16} \operatorname{Tr}(\partial_\mu U\, \partial^\mu U^\dagger) = -\frac{F_{\mathrm{st}}^2}{2} \frac{\partial_\mu \vec{\xi} \cdot \partial^\mu \vec{\xi}}{(1 + \vec{\xi}^{\,2})^2}. \tag{55.52}$$

With canonical fields

$$\vec{\pi} = F_{\mathrm{st}} \vec{\xi},$$

the expansion begins as

$$\mathcal{L}_2 = -\frac{1}{2} \partial_\mu \vec{\pi} \cdot \partial^\mu \vec{\pi} + \frac{1}{F_{\mathrm{st}}^2} \vec{\pi}^{\,2}\, \partial_\mu \vec{\pi} \cdot \partial^\mu \vec{\pi} + O(\pi^6/F_{\mathrm{st}}^4). \tag{55.53}$$

The infinitesimal $SU(2)_L \times SU(2)_R$ action in this chart is useful for organizing local terms. Write

$$L = \exp\!\left(\frac{\mathrm{i}}{2} \vec{\theta}_L \cdot \vec{\sigma}\right), \qquad R = \exp\!\left(\frac{\mathrm{i}}{2} \vec{\theta}_R \cdot \vec{\sigma}\right), \qquad \vec{\theta}_V = \frac{\vec{\theta}_L + \vec{\theta}_R}{2}, \qquad \vec{\theta}_A = \frac{\vec{\theta}_L - \vec{\theta}_R}{2}.$$

For $U \mapsto L U R^{-1}$, a direct computation from (55.51) gives

$$\delta \vec{\xi} = -\vec{\theta}_V \times \vec{\xi} + \frac{1}{2}(1 - \vec{\xi}^{\,2}) \vec{\theta}_A + \vec{\xi}(\vec{\xi} \cdot \vec{\theta}_A). \tag{55.54}$$

Thus the diagonal subgroup acts linearly on $\vec{\xi}$, while the axial directions act by a nonlinear shift plus higher powers of $\vec{\xi}$. Define

$$\vec{D}_\mu = \frac{\partial_\mu \vec{\xi}}{1 + \vec{\xi}^{\,2}}. \tag{55.55}$$

For constant transformation parameters,

$$\delta \vec{D}_\mu = -\vec{\theta}_V \times \vec{D}_\mu - (\vec{\xi} \times \vec{\theta}_A) \times \vec{D}_\mu. \tag{55.56}$$

The two independent four-derivative invariants relevant to four-pion scattering can be written as

$$(\vec{D}_\mu \cdot \vec{D}^\mu)^2, \qquad (\vec{D}_\mu \cdot \vec{D}_\nu)(\vec{D}^\mu \cdot \vec{D}^\nu),$$

up to integrations by parts and terms that first affect higher-point amplitudes. This coordinate choice is only a local chart on S^3; the scattering amplitude obtained from it is coordinate independent. In the axial-current normalization above, $T^a = \sigma^a/2$ and therefore

$$\exp\left(\frac{2\mathrm{i}}{f_\pi}\pi^a_{\mathrm{ax}}T^a\right) = 1 + \frac{\mathrm{i}}{f_\pi}\pi^a_{\mathrm{ax}}\sigma^a + O(\pi^2_{\mathrm{ax}}).$$

The stereographic chart has

$$\frac{1-\vec{\xi}^{\,2} + 2\mathrm{i}\,\vec{\xi}\cdot\vec{\sigma}}{1+\vec{\xi}^{\,2}} = 1 + 2\mathrm{i}\,\xi^a\sigma^a + O(\xi^2), \qquad \pi^a_{\mathrm{st}} = F_{\mathrm{st}}\xi^a.$$

Identifying the one-pion field defined by the axial current with the canonical stereographic field, $\pi^a_{\mathrm{ax}} = \pi^a_{\mathrm{st}}$, gives the conversion

$$F_{\mathrm{st}} = 2f_\pi. \tag{55.57}$$

A convention that rescales the stereographic coordinate rescales F_{st} and the coordinate field together; in the fixed chart (55.51) the numerical factor in (55.57) is part of the convention.

For

$$\pi^a(k_1) + \pi^b(k_2) \to \pi^c(k_3) + \pi^d(k_4),$$

use the Mandelstam variables

$$s = -(k_1+k_2)^2, \qquad t = -(k_1-k_3)^2, \qquad u = -(k_1-k_4)^2.$$

The metric is mostly plus, k_1, k_2 are incoming, and k_3, k_4 are outgoing. In the chiral limit used for the two-derivative Goldstone calculation, $k_i^2 = 0$, so

$$s + t + u = 0.$$

For equal nonzero pion masses the same convention gives $s+t+u = 4m_\pi^2$. The $SU(2)_V$-invariant amplitude has the form

$$\mathcal{A}_{ab\to cd} = \delta_{ab}\delta_{cd}A(s,t,u) + \delta_{ac}\delta_{bd}A(u,t,s) + \delta_{ad}\delta_{bc}A(t,s,u). \tag{55.58}$$

At order E^2/F^2_{st}, the four-pion vertex from (55.53) gives

$$A(s,t,u) = \frac{4s}{F^2_{\mathrm{st}}} + O(E^4/F^4_{\mathrm{st}}). \tag{55.59}$$

Equivalently, after converting to the convention in which the axial current matrix element defines f_π, this is the standard leading chiral theorem

$$A(s,t,u) = \frac{s}{f_\pi^2} + O(E^4/f_\pi^4).$$

Figure 55.5 displays the two levels of the chiral expansion used here: the leading two-derivative four-pion vertex and the next-order loop/local-counterterm structure.

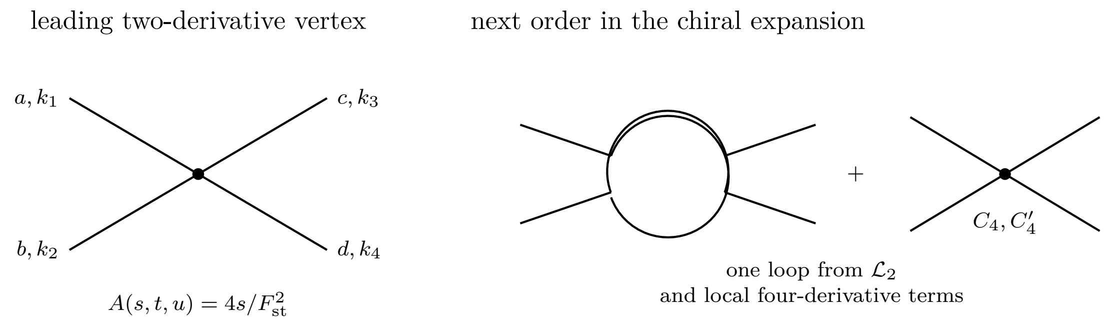

Figure 55.5: The leading pion scattering amplitude is fixed by the two-derivative nonlinear sigma model. At the next order, one-loop diagrams from $\mathcal{L}_2$ are combined with local four-derivative counterterms.

At order $E^4/F_{\rm st}^4$, the effective Lagrangian contains local four-derivative terms. In the stereographic $SU(2)$ chart these may be written, to the order needed for four-pion scattering, as

$$-\frac{C_4}{4F_{\rm st}^4}(\partial_\mu\vec{\pi}\cdot\partial^\mu\vec{\pi})^2 - \frac{C_4'}{4F_{\rm st}^4}(\partial_\mu\vec{\pi}\cdot\partial_\nu\vec{\pi})(\partial^\mu\vec{\pi}\cdot\partial^\nu\vec{\pi}).$$

The same order also receives one-loop contributions from two insertions of the two-derivative interaction. A regulator that does not preserve the nonlinearly realized symmetry may generate power terms that look like a potential on S^3; such terms must be absent in a symmetry-preserving scheme or canceled by symmetry-restoring local counterterms. After this local renormalization, the logarithmic part has the form

$$\begin{aligned} A(s,t,u) = \frac{4s}{F_{\rm st}^2} + \frac{1}{F_{\rm st}^4}\Bigg\{ \frac{1}{12\pi^2}\Bigg[& 3s^2\log\frac{\mu^2}{-s} \\ & + (u^2 - s^2 + 3t^2)\log\frac{\mu^2}{-t} \\ & + (t^2 - s^2 + 3u^2)\log\frac{\mu^2}{-u}\Bigg] \\ & - \frac{1}{2}C_4(\mu)s^2 - \frac{1}{2}C_4'(\mu)(t^2+u^2)\Bigg\} + O(E^6). \end{aligned} \tag{55.60}$$

Equivalently, in a Wilsonian cutoff notation in which the logarithms are written as $\log(\Lambda^2/-s)$, $\log(\Lambda^2/-t)$, and $\log(\Lambda^2/-u)$, the remaining cutoff dependence is absorbed by

$$C_4(\Lambda) = C_4(\mu) + \frac{2}{3\pi^2}\log\frac{\Lambda^2}{\mu^2}, \qquad C_4'(\Lambda) = C_4'(\mu) + \frac{4}{3\pi^2}\log\frac{\Lambda^2}{\mu^2}.$$

The finite constants $C_4(\mu)$ and $C_4'(\mu)$ are low-energy constants. Their values depend on the microscopic dynamics and on the subtraction convention, but the logarithmic dependence and the required μ-dependence are fixed by the low-energy effective theory.

55.15 Mass Spurions and Pseudo-Goldstone Bosons

Quark masses explicitly break the chiral symmetry. Introduce a complex mass matrix M through

$$\mathcal{L}_{\rm mass}^{\rm QCD} = -\bar{q}_L M q_R - \bar{q}_R M^\dagger q_L.$$

Treating M as a background spurion with

$$M \longmapsto LMR^{-1}$$

makes the microscopic mass term formally invariant under (L, R). The leading mass-dependent invariant in the pion Lagrangian is

$$\mathcal{L}_{\text{mass}} = \frac{f_\pi^2}{4} \operatorname{Tr}\big(\chi U^\dagger + U\chi^\dagger\big), \qquad \chi = 2B_0 M. \tag{55.61}$$

The low-energy constant B_0 is fixed by the chiral-limit condensate convention

$$\langle \bar{q}q \rangle_0 = -N_f f_\pi^2 B_0$$

at leading order. For two light flavors,

$$m_{\pi^\pm}^2 = B_0(m_u + m_d)$$

up to higher-order chiral and electromagnetic corrections. For degenerate light quarks $m_u = m_d = m_q$, this becomes $m_\pi^2 = 2B_0 m_q$. The condensate notation in this chapter is flavor-summed:

$$\Sigma_{\text{sum}} := \langle \bar{q}q \rangle_0 = \sum_{i=1}^{N_f} \langle \bar{q}_i q_i \rangle_0, \qquad \Sigma_{\text{fl}} := \frac{1}{N_f} \Sigma_{\text{sum}}.$$

The leading-order identity following from the two preceding equations is the flavor-summed form

$$m_{\pi^\pm}^2 f_\pi^2 = -(m_u + m_d) \frac{\langle \bar{q}q \rangle_0}{N_f}. \tag{55.62}$$

The conversion to the per-flavor condensate is

$$\Sigma_{\text{fl}} = \frac{\langle \bar{q}q \rangle_0}{N_f} = \langle \bar{u}u \rangle_0 = \langle \bar{d}d \rangle_0 \qquad (N_f = 2 \text{ isospin-symmetric vacuum}). \tag{55.63}$$

Using (55.63), the same leading-order statement is the per-flavor Gell-Mann–Oakes–Renner relation

$$m_\pi^2 f_\pi^2 = -(m_u + m_d)\langle \bar{u}u \rangle_0. \tag{55.64}$$

The factor of 2 is accounted for by the conversion between the flavor-summed condensate and the per-flavor condensate.

The same normalization can be seen directly in the $SU(2)$ stereographic chart. Let

$$M = \begin{pmatrix} m_u & 0 \\ 0 & m_d \end{pmatrix}.$$

In terms of the quark bilinear $\Phi^I{}_J = \bar{q}_L^I q_{R,J}$, the microscopic deformation has the form

$$\Delta\mathcal{L} = -\frac{m_u + m_d}{2} \operatorname{Tr}(\Phi + \Phi^\dagger) - \frac{m_u - m_d}{2} \operatorname{Tr}\big(\sigma_3(\Phi + \Phi^\dagger)\big).$$

Restricting the pion field to the $U(1) \subset SU(2)$ generated by σ_3,

$$U(\xi_3) = 1 + 2\mathrm{i}\xi_3\sigma_3 + \cdots = \begin{pmatrix} \mathrm{e}^{\mathrm{i}\theta} & 0 \\ 0 & \mathrm{e}^{-\mathrm{i}\theta} \end{pmatrix} + \cdots, \qquad \theta = 2\xi_3 + \cdots.$$

Since the kinetic term in (55.52) gives

$$\mathcal{L}_2 = -\frac{F_{\rm st}^2}{2}\partial_\mu\vec{\xi}\cdot\partial^\mu\vec{\xi} + \cdots\,,$$

the $U(1)$ comparison has radius $R = F_{\rm st}/2$. Expanding the mass deformation therefore gives

$$-\frac{1}{2}m_{ab}^2\pi_a\pi_b, \qquad m_{ab}^2 = \delta_{ab}\frac{4}{F_{\rm st}^2}(m_u+m_d)\left\langle -\frac{\bar{q}q}{2}\right\rangle_0,$$

which is the same leading relation as the B_0-notation after converting normalizations. Empirically,

$$m_{\pi^0} \simeq 135\,\mathrm{MeV}, \qquad m_{\pi^\pm} \simeq 140\,\mathrm{MeV},$$

with the splitting produced by isospin breaking and electromagnetism.

The chiral expansion counts $D_\mu U = O(p)$, external vector and axial backgrounds as $O(p)$, and M as $O(p^2)$. The functional obtained from $\mathcal{L}_2 + \mathcal{L}_{\rm mass}$ is therefore the leading generating functional for current Green functions at momenta small compared with the chiral-symmetry-breaking scale.

55.16 Chiral Perturbation Theory at NLO

Chiral perturbation theory is the effective expansion of the QCD current generating functional in powers of derivatives, external flavor fields, and quark masses around the chiral limit. Pion fields enter as local coordinates on the Goldstone manifold; the invariant expansion is organized by the orders of the functional's derivatives, sources, and spurion insertions. The expansion variables are assigned the orders

$$D_\mu U = O(p), \qquad \ell_\mu, r_\mu = O(p), \qquad F^L_{\mu\nu}, F^R_{\mu\nu} = O(p^2), \qquad \chi = 2B_0 M = O(p^2),$$

where the left and right field strengths in the conventions of (55.45) are

$$F^L_{\mu\nu} = \partial_\mu\ell_\nu - \partial_\nu\ell_\mu - \mathrm{i}[\ell_\mu,\ell_\nu], \qquad F^R_{\mu\nu} = \partial_\mu r_\nu - \partial_\nu r_\mu - \mathrm{i}[r_\mu, r_\nu].$$

A connected graph built from vertices of chiral order d_i and with L loops has total chiral order

$$\nu = 2 + 2L + \sum_i V_i(d_i - 2). \tag{55.65}$$

Indeed, each loop integration contributes p^4, each internal pion propagator contributes p^{-2}, and each vertex contributes p^{d_i}. For a connected graph, $L = I - \sum_i V_i + 1$, hence

$$4L - 2I + \sum_i V_i d_i = 2 + 2L + \sum_i V_i(d_i-2).$$

Thus one-loop graphs made only from $\mathcal{L}_2$ and tree graphs from the order-p^4 Lagrangian both contribute at next-to-leading order.

Controlled Approximation 55.19 (Chiral EFT truncation as a seminorm statement)**.** The power-counting identity (55.65) is only the graph algebra. To use it as a QCD statement one must also specify the observable topology in which the low-energy remainder is controlled. Fix a compact family K of external momenta and smooth flavor sources satisfying

$$|p_a| \le \epsilon\Lambda_\chi, \qquad \|\ell\|_K + \|r\|_K \le \epsilon\Lambda_\chi, \qquad \|\chi\|_K^{1/2} \le \epsilon\Lambda_\chi, \qquad 0 < \epsilon < 1,$$

together with a renormalization scheme for the local chiral coordinates. For a connected renormalized graph Γ let

$$\nu(\Gamma) = 2 + 2L(\Gamma) + \sum_d V_d(\Gamma)(d-2).$$

The useful truncation assertion is a family of seminorm estimates

$$p_K(\mathcal{A}_\Gamma) \le C_{\Gamma,K}\epsilon^{\nu(\Gamma)}$$

for the source derivatives or S-matrix coordinates under consideration, and, after retaining all graphs with $\nu \le N$,

$$p_K\left(\mathcal{A} - \sum_{\nu(\Gamma)\le N} \mathcal{A}_\Gamma\right) \le C_{K,N}\epsilon^{\nu_+(N)}, \qquad \nu_+(N) := \min\{\nu(\Gamma) : \nu(\Gamma) > N\}. \tag{55.66}$$

Equation (55.66) is not a convergence theorem for the full chiral series. It is the controlled EFT input that turns the formal graph dimension into a quantitative low-energy approximation on the declared compact source window. At $N = 4$ the retained data are precisely: tree graphs from $\mathcal{L}_2$, one-loop graphs from $\mathcal{L}_2$, and tree graphs from $\mathcal{L}_4$, including the source-contact terms. The first omitted families have $\nu = 6$: two-loop graphs from $\mathcal{L}_2$, one-loop graphs with one $\mathcal{L}_4$ vertex, and tree graphs from $\mathcal{L}_6$. Thus the $O(p^4)$ calculation below is meaningful only inside this remainder ledger; outside such a low-energy window the same local formulae are just coordinates, not controlled predictions.

For $N_f = 3$, the even-intrinsic-parity order-p^4 local functional is the Gasser–Leutwyler basis.[1] Write $\langle X\rangle_{\mathrm{f}}$ for the flavor trace $\operatorname{Tr} X$, and define

$$X_+ := \chi U^\dagger + U\chi^\dagger, \qquad X_- := \chi U^\dagger - U\chi^\dagger.$$

With the left/right convention $U \mapsto LUR^{-1}$, the local NLO Lagrangian is

$$\begin{aligned}
\mathcal{L}_4^{\mathrm{GL}} = {} & L_1\langle D_\mu U^\dagger D^\mu U\rangle_{\mathrm{f}}^2 + L_2\langle D_\mu U^\dagger D_\nu U\rangle_{\mathrm{f}}\langle D^\mu U^\dagger D^\nu U\rangle_{\mathrm{f}} \\
& + L_3\langle D_\mu U^\dagger D^\mu U D_\nu U^\dagger D^\nu U\rangle_{\mathrm{f}} + L_4\langle D_\mu U^\dagger D^\mu U\rangle_{\mathrm{f}}\langle X_+\rangle_{\mathrm{f}} \\
& + L_5\langle D_\mu U D^\mu U^\dagger X_+\rangle_{\mathrm{f}} + L_6\langle X_+\rangle_{\mathrm{f}}^2 + L_7\langle X_-\rangle_{\mathrm{f}}^2 \\
& + L_8\langle \chi U^\dagger \chi U^\dagger + U\chi^\dagger U\chi^\dagger\rangle_{\mathrm{f}} \\
& - \mathrm{i}L_9\langle F_L^{\mu\nu} D_\mu U D_\nu U^\dagger + F_R^{\mu\nu} D_\mu U^\dagger D_\nu U\rangle_{\mathrm{f}} \\
& + L_{10}\langle U^\dagger F_L^{\mu\nu} U F^R_{\mu\nu}\rangle_{\mathrm{f}} \\
& + H_1\langle F_L^{\mu\nu} F^L_{\mu\nu} + F_R^{\mu\nu} F^R_{\mu\nu}\rangle_{\mathrm{f}} + H_2\langle \chi^\dagger\chi\rangle_{\mathrm{f}}.
\end{aligned} \tag{55.67}$$

The constants $L_1, \dots, L_{10}$ multiply operators containing the pion field or its covariant derivatives. The contact constants H_1, H_2 affect only correlators of external sources and are required for

[1]The notation $L_1, \dots, L_{10}$ is the three-flavor basis introduced by Gasser and Leutwyler in the original chiral perturbation theory papers, translated here to the left/right convention $U \mapsto LUR^{-1}$.

renormalizing the source generating functional. The odd-intrinsic-parity anomaly sector is not part of $\mathcal{L}_4^{\mathrm{GL}}$; it is the Wess–Zumino–Witten functional constructed in the next section. For $N_f = 2$, Cayley–Hamilton identities reduce the number of independent even-parity p^4 invariants. The stereographic constants C_4, C_4' above are two-coordinate representatives of that reduced two-flavor sector; the L_i above are the standard three-flavor coordinates.

The L_i are renormalized coordinates on the space of local order-p^4 counterterms. In dimensional regularization one writes

$$L_i = L_i^r(\mu) + \Gamma_i \Lambda_{\mathrm{div}}, \qquad \mu \frac{\mathrm{d}L_i^r}{\mathrm{d}\mu} = -\frac{\Gamma_i}{16\pi^2},$$

where the three-flavor coefficients are

i	1	2	3	4	5	6	7	8	9	10
Γ_i	$\frac{3}{32}$	$\frac{3}{16}$	0	$\frac{1}{8}$	$\frac{3}{8}$	$\frac{11}{144}$	0	$\frac{5}{48}$	$\frac{1}{4}$	$-\frac{1}{4}$.

The μ-dependence of $L_i^r(\mu)$ cancels the logarithmic dependence from one-loop graphs built from $\mathcal{L}_2$. This cancellation is a low-energy theorem; the finite values of $L_i^r(\mu)$ encode microscopic QCD dynamics.

The simplest chiral logarithm appears in the two-flavor pion mass. Set $m_u = m_d = m_q$ and

$$M^2 := 2B_0 m_q.$$

The one-loop tadpole integral generated by the $\mathcal{L}_2$ four-pion vertices has renormalized logarithmic part

$$A^r(M^2) = \frac{M^2}{16\pi^2} \log \frac{M^2}{\mu^2}.$$

Expanding $\mathcal{L}_2$ in normal pion coordinates gives the logarithmic on-shell self-energy contribution

$$\Sigma_{\log}(M^2) = \frac{M^2}{2f^2} A^r(M^2) = \frac{M^4}{32\pi^2 f^2} \log \frac{M^2}{\mu^2},$$

where f is the chiral-limit value of f_π. The local two-flavor NLO constant usually denoted $l_3^r(\mu)$ contributes $2l_3^r(\mu)M^4/f^2$ to the mass. Hence

$$M_{\pi,\mathrm{phys}}^2 = M^2 \left[1 + \frac{M^2}{32\pi^2 f^2} \log \frac{M^2}{\mu^2} + \frac{2l_3^r(\mu)M^2}{f^2}\right] + O(M^6). \tag{55.68}$$

This is nonanalytic in the quark mass because $M^2 \propto m_q$. The renormalization-group coefficient of the two-flavor constant is

$$\mu \frac{\mathrm{d}l_3^r}{\mathrm{d}\mu} = \frac{1}{32\pi^2},$$

so differentiating the bracket in (55.68) with respect to $\log \mu$ gives

$$-\frac{M^2}{16\pi^2 f^2} + \frac{2M^2}{f^2} \frac{1}{32\pi^2} = 0.$$

Thus the scale dependence of the logarithm is exactly canceled by the running of the local NLO coordinate. The logarithm itself cannot be removed by a local counterterm because it is the long-distance contribution of pion propagation.

55.17 The Wess–Zumino–Witten Functional

The pion effective action must reproduce the global anomalies of the microscopic quarks. For $N_f \geq 3$, let M_4 be spacetime and choose a five-manifold B_5 with $\partial B_5 = M_4$. Extend $U : M_4 \to SU(N_f)$ to $\widetilde{U} : B_5 \to SU(N_f)$. Figure 55.6 fixes this filling convention for the Wess–Zumino–Witten functional: M_4 is the boundary and $\widetilde{U}$ is an extension over B_5.

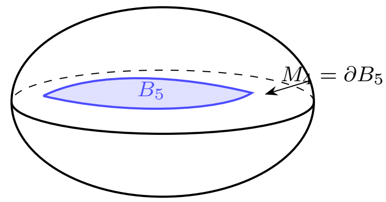

Figure 55.6: The Wess–Zumino functional is written by extending the spacetime field $U : M_4 \to SU(N_f)$ to a five-dimensional filling B_5. Changing the filling changes the integral by a quantized period.

Definition 55.20 (Ungauged Wess–Zumino functional)**.** The ungauged Wess–Zumino functional is

$$\Gamma_{\mathrm{WZ}}[U] = -\frac{\mathrm{i}}{240\pi^2} \int_{B_5} \mathrm{Tr}\big(\widetilde{U}^{-1}\mathrm{d}\widetilde{U}\big)^5. \tag{55.69}$$

The five-form is real after the factor $-\mathrm{i}$, because $\widetilde{U}^{-1}\mathrm{d}\widetilde{U}$ is anti-Hermitian. If two extensions are glued along M_4, the difference of Γ_{WZ} is the integral over a closed five-manifold. With the normalization in (55.69), this difference is 2π times an integer for maps representing $\pi_5(SU(N_f)) \simeq \mathbb{Z}$. Hence

$$\exp\{\mathrm{i}n\Gamma_{\mathrm{WZ}}[U]\}$$

is independent of the extension precisely when $n \in \mathbb{Z}$. This integer is the Wess–Zumino level.

Proposition 55.21 (Finite Wess–Zumino extension ambiguity)**.** *For $N_f \geq 3$, write*

$$\omega_5(U) = -\frac{\mathrm{i}}{240\pi^2}\,\mathrm{Tr}(U^{-1}\mathrm{d}U)^5.$$

Assume the standard generator normalization in which $\int_{S^5} g^*\omega_5 = 2\pi$ for a generator $[g] \in \pi_5(SU(N_f)) \simeq \mathbb{Z}$. If two fillings $(B_5, \widetilde{U})$ and $(B_5', \widetilde{U}')$ extend the same boundary field $U : M_4 \to SU(N_f)$, then

$$\Gamma_{\mathrm{WZ}}[B_5, \widetilde{U}] - \Gamma_{\mathrm{WZ}}[B_5', \widetilde{U}'] = 2\pi k, \qquad k \in \mathbb{Z}.$$

Consequently the exponentiated pion response $\exp\{\mathrm{i}n\Gamma_{\mathrm{WZ}}[U]\}$ *is a well-defined boundary functional for all allowed fillings exactly when $n \in \mathbb{Z}$.*

Proof. Glue B_5 to B_5' with the opposite orientation along their common boundary M_4. The result is a closed oriented five-manifold

$$X_5 = B_5 \cup_{M_4} (-B_5'),$$

and the two extensions glue to a map $\widehat{U} : X_5 \to SU(N_f)$. Additivity of the integral under gluing gives

$$\Gamma_{\mathrm{WZ}}[B_5, \widetilde{U}] - \Gamma_{\mathrm{WZ}}[B_5', \widetilde{U}'] = \int_{X_5} \widehat{U}^*\omega_5.$$

The normalized period assumption says that the right hand side lies in $2\pi\mathbb{Z}$; call it $2\pi k$. Changing the filling therefore multiplies the exponentiated level-n response by

$$\exp(2\pi i n k).$$

This factor is 1 for every possible extension ambiguity $k \in \mathbb{Z}$ if n is an integer. Conversely, the generator ambiguity $k = 1$ would give a nontrivial phase for any nonintegral level. Thus finite extension-independence is the integrality condition $n \in \mathbb{Z}$. $\square$

The finite integrality statement is separate from the infinitesimal anomaly coefficient comparison below. Local descent determines which multiple of the generator the pion functional must carry; the proposition says when that multiple exponentiates to an honest four-dimensional response rather than a choice of five-dimensional filling. In QCD the same integer is N_c, the number of color copies of a fundamental flavor Weyl fermion.

WZW level matching from the flavor descent coefficient. The equality between the QCD Wess–Zumino–Witten level and the number of colors is not an additional imported theorem. It is the coefficient matching of two representatives of the same infinitesimal background-anomaly class, after the flavor trace convention $\mathrm{Tr}(T^a T^b) = \frac{1}{2}\delta^{ab}$ and the unit-level normalization of Γ_{WZ} in (55.69) have been fixed. For massless QCD with N_c colors and $N_f \geq 3$ light flavors, gauge a left flavor background $A = A_\mu \mathrm{d}x^\mu$, set the right background to zero, and first retain the part quadratic in A. Matrix multiplication and wedge product are implicit in the following formulas.

The word "quadratic" here does not mean that the higher-background part of the anomaly is being discarded. The previous chapter showed that a local Bardeen counterterm can change a four-form representative $I_4^{(1)}$, but cannot change the completely symmetric degree-three coefficient of the six-form polynomial I_6. More explicitly, the Abelianized descent coordinate (51.31) proves that, on commuting flavor backgrounds, the boundary variation of the Chern–Simons representative is exactly $C_{abc}\alpha^a F^b F^c$, and the polarization identity (51.32) recovers the symmetric cubic coefficient from these commuting tests. The term $\mathrm{Tr}(\alpha\,\mathrm{d}A\,\mathrm{d}A)$ is the lowest-background coordinate of that same descent class in the convention fixed in (51.30). The $O(A^3)$ terms are the non-Abelian completion required by Wess–Zumino consistency inside the same class, up to local counterterm coboundaries. A single left-handed quark multiplet gives the consistent variation

$$\delta_\alpha \Gamma_{1\,\mathrm{color}}[A] = \frac{1}{48\pi^2}\int_{M_4} \mathrm{Tr}\big(\alpha\,\mathrm{d}A\,\mathrm{d}A\big) + O(A^3),$$

where $\alpha = \alpha^a T^a$. QCD has N_c identical color copies of this flavor representation, hence

$$\delta_\alpha \Gamma_{\mathrm{quark}}[A] = \frac{N_c}{48\pi^2}\int_{M_4} \mathrm{Tr}\big(\alpha\,\mathrm{d}A\,\mathrm{d}A\big) + O(A^3).$$

The gauged Wess–Zumino functional at level n has the corresponding Goldstone variation

$$\delta_\alpha\big(n\Gamma_{\mathrm{WZW}}[U; A, 0]\big) = \frac{n}{48\pi^2}\int_{M_4} \mathrm{Tr}\big(\alpha\,\mathrm{d}A\,\mathrm{d}A\big) + O(A^3).$$

Equality of the anomaly phases for arbitrary infinitesimal α and background A gives

$$n = N_c.$$

The comparison of the displayed quadratic term fixes the integer coefficient of the generator of the descent class. This is why the level is fixed by one coefficient rather than by a term-by-term comparison of a chosen representative. The remaining background terms are determined by the same relative BRST class after the counterterm convention has been chosen. When the flavor symmetry is coupled to background gauge fields, the Wess–Zumino functional is completed by local four-dimensional terms involving U, ℓ_μ, r_μ. The completed Wess–Zumino–Witten functional $\Gamma_{\mathrm{WZW}}[U; \ell, r]$ satisfies

$$\delta_{\alpha_L,\alpha_R}\Gamma_{\mathrm{WZW}}[U; \ell, r] = \mathcal{A}_{\mathrm{quark}}[\alpha_L, \alpha_R; \ell, r],$$

where $\mathcal{A}_{\mathrm{quark}}$ is the consistent flavor anomaly of the microscopic quarks. Thus the pion functional supplies exactly the anomaly phase required by (55.1). Equivalently, the gauged Wess–Zumino–Witten functional is a Goldstone-field realization of the same inflow class: its five-dimensional extension transgresses the microscopic anomaly polynomial, and its four-dimensional gauge variation is the boundary term that matches the quark anomaly.

55.18 ’t Hooft Anomaly Matching as an Infrared Constraint

Anomaly matching becomes a calculational constraint only after the symmetry, backgrounds, and counterterm convention have been fixed. The procedure is:

i. choose the exact global symmetry that is being tested and the class of allowed background fields;

ii. compute the ultraviolet background-gauge cocycle, or equivalently its infinitesimal Wess–Zumino representative on the identity component;

iii. write the most general proposed infrared response from massless fermions, Goldstone fields, and possible topological or invertible sectors;

iv. compare cocycle classes modulo local counterterms.

The comparison is not a comparison of Lagrangian terms or of a particular representative of a current. It is a comparison of the background response class $[\mathcal{A}]$ defined in (55.2). A candidate infrared phase with a unique gapped vacuum and no topological response has the zero class. Such a phase is ruled out when the ultraviolet class is nonzero. A candidate phase with Goldstone fields is allowed only if its Wess–Zumino–Witten term supplies the missing cocycle.

Remark 55.22 (Anomaly matching across spontaneous symmetry breaking). Suppose an exact global symmetry G_{f} is spontaneously broken to H, and the infrared fields consist of Goldstone coordinates on G/H together with possible additional massless or topological sectors. Let $[\mathcal{A}_{\mathrm{UV}}]$ be the ultraviolet background-anomaly class of Definition 55.1. The infrared description is compatible with the ultraviolet theory only if

$$[\mathcal{A}_{\mathrm{UV}}] = [\mathcal{A}_{\mathrm{Goldstone}}] + [\mathcal{A}_{\mathrm{extra}}]$$

as background-response classes modulo local counterterms. Here $[\mathcal{A}_{\mathrm{Goldstone}}]$ is produced by the gauged WZW functional whenever such a functional exists, and $[\mathcal{A}_{\mathrm{extra}}]$ is the class carried by the remaining infrared sector.

Along an RG trajectory with exact G_{f} background fields, the background-anomaly class is unchanged because changing scale changes the renormalized generating functional only by local background counterterms and by integrating out modes in a gauge-covariant manner. In the broken phase, the infrared generating functional decomposes into a Goldstone part and the functional of the remaining infrared sector, together with possible local couplings and background counterterms. Under a background gauge transformation, the phase of the product of the two nonlocal functionals is the sum of their cocycle representatives. The local couplings and local counterterms shift representatives by coboundaries. Passing to background-response classes therefore gives the displayed equality.

For massless QCD, restrict first to the connected nonabelian chiral symmetry

$$SU(N_f)_L \times SU(N_f)_R, \qquad N_f \geq 3,$$

and use the flavor generators T^a normalized by $\mathrm{Tr}(T^aT^b) = \frac{1}{2}\delta^{ab}$, as in the pion normalization above. Couple only a left background A and set the right background to zero. The ultraviolet theory contains N_c color copies of a left-handed Weyl fermion in the fundamental representation of $SU(N_f)_L$. The consistent anomaly representative is therefore

$$\delta_\alpha W_{\mathrm{UV}}[A] = \frac{N_c}{48\pi^2}\int_{M_4} \mathrm{Tr}\big(\alpha\,\mathrm{d}A\,\mathrm{d}A\big) + O(A^3), \tag{55.70}$$

where the $O(A^3)$ terms are fixed by the same descent class. A two-derivative pion sigma model without a Wess–Zumino–Witten term is invariant under background gauge transformations and would give zero on the right hand side of (55.70); it therefore cannot be the complete infrared response to the chiral backgrounds. A Goldstone theory with WZW level n gives

$$\delta_\alpha\big(n\Gamma_{\mathrm{WZW}}[U; A, 0]\big) = \frac{n}{48\pi^2}\int_{M_4} \mathrm{Tr}\big(\alpha\,\mathrm{d}A\,\mathrm{d}A\big) + O(A^3).$$

Matching (55.70) for arbitrary α and A forces

$$n = N_c. \tag{55.71}$$

This is the same equality obtained above from the Wess–Zumino functional, now read as a test of infrared phases. If the chiral symmetry were unbroken and the theory confined to a unique trivial gapped vacuum, there would be no massless determinant line, no Goldstone WZW term, and no topological response; that candidate would fail (55.70). An unbroken phase is not excluded by this argument if it contains massless composite fermions or a topological/invertible sector carrying exactly the same background cocycle. The matching condition constrains the infrared possibilities; it is not a proof of which dynamical phase QCD chooses.

The vector subgroup illustrates the same logic in a form that is often hidden by notation. Set $L = R = V$ and couple a single vector background v to both chiralities. In the anomaly coefficient (51.14), the left-handed and right-handed Dirac components have the same vector generator. Their contributions to the vector current anomaly cancel:

$$\mathcal{A}_V^{abc} = \frac{N_c}{2}\Big[\mathrm{Tr}\big(T^a\{T^b, T^c\}\big) - \mathrm{Tr}\big(T^a\{T^b, T^c\}\big)\Big] = 0. \tag{55.72}$$

Thus $SU(N_f)_V$ is an anomaly-free symmetry that can act on a purely massive color-singlet sector without requiring additional massless fields or a topological response. By contrast, a purely left chiral subgroup has the nonzero coefficient in (55.70); if it remained unbroken in a gapped infrared theory, its anomaly would have to be carried by some nontrivial infrared sector.

The positivity statement used earlier is logically separate but compatible with this anomaly test. Under Hypothesis 55.13, equal positive quark masses select a vacuum preserving the vector flavor group; taking the small-mass limit then aligns the chiral condensate with $SU(N_f)_V$ whenever the required limits exist. Anomaly matching then determines the response of the broken axial directions: the Goldstone target $SU(N_f)$ together with $N_c\Gamma_{\mathrm{WZW}}$ reproduces the ultraviolet chiral anomaly, while the unbroken vector subgroup remains nonanomalous. The two inputs have different status. The vector-alignment argument depends on Euclidean positivity and limiting assumptions; the anomaly matching equation is an exact background-response constraint once the ultraviolet symmetry and regulator convention are fixed.

For the electromagnetic specialization use the dual tensor defined at the start of the chapter and the flavor-generator normalization just stated, and fix

$$T^3 = \frac{\sigma_3}{2} = \frac{1}{2}\,\mathrm{diag}(1,-1).$$

Let q denote the dimensionless light-quark charge matrix, and embed electromagnetism by

$$\ell_\mu = r_\mu = e\,qA_\mu, \qquad q = \mathrm{diag}(q_1,\dots,q_{N_f}),$$

The relevant microscopic diagram is the quark triangle in Figure 55.7. The figure fixes the assignment of the axial flavor generator to one vertex and the two electromagnetic current insertions to the other vertices before the trace over light-quark charges is evaluated.

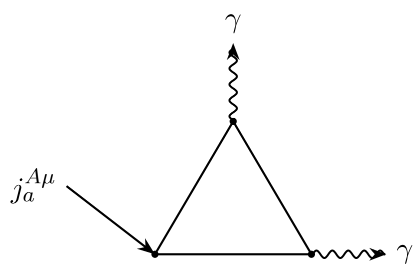

Figure 55.7: The electromagnetic background probes the axial $SU(2)$ flavor anomaly through the quark triangle with one axial-current insertion and two electromagnetic-current insertions.

Remark 55.23 (Electromagnetic specialization). The corresponding axial-flavor Ward identity is

$$\partial_\mu j_a^{A\mu} = -\frac{N_c e^2}{16\pi^2}\,\mathrm{Tr}(T^a\{q,q\})\,F_{\mu\nu}\widetilde{F}^{\mu\nu}.$$

The anticommutator records the two identical electromagnetic insertions in the triangle; since the charge matrix is diagonal,

$$\mathrm{Tr}(T^a\{q,q\}) = 2\,\mathrm{Tr}\big(T^a q^2\big)\,.$$

Equivalently,

$$\partial_\mu j_a^{A\mu} = -\frac{N_c e^2}{8\pi^2}\,\mathrm{Tr}\big(T^a q^2\big)\,F_{\mu\nu}\widetilde{F}^{\mu\nu}.$$

This is the same anomaly coefficient as the preceding chapter's Dirac-fermion formula, rewritten from $\epsilon^{\mu\nu\rho\sigma}F_{\mu\nu}F_{\rho\sigma}$ to $2F_{\mu\nu}\widetilde{F}^{\mu\nu}$. For $q = \mathrm{diag}(2/3,-1/3)$, the trace is nonzero only for $a=3$, where

$$\mathrm{Tr}\big(T^3 q^2\big) = \frac{1}{6}.$$

Thus

$$\mathrm{Tr}\big(T^3\{q,q\}\big) = \frac{1}{3}.$$

Consequently the gauged WZW functional contains the neutral-pion coupling

$$\mathcal{L}_{\pi^0\gamma\gamma} = \frac{N_c e^2}{16\pi^2 f_\pi}\,\mathrm{Tr}\big(T^3\{q,q\}\big)\;\pi^0 F_{\mu\nu}\widetilde{F}^{\mu\nu}, \tag{55.73}$$

namely

$$\mathcal{L}_{\pi^0\gamma\gamma} = \frac{N_c e^2}{48\pi^2 f_\pi}\pi^0 F_{\mu\nu}\widetilde{F}^{\mu\nu}.$$

For $N_c = 3$, the coefficient multiplying $\pi^0 F_{\mu\nu}\widetilde{F}^{\mu\nu}$ is $e^2/(16\pi^2 f_\pi)$. The coefficient is the low-energy coefficient required by matching the microscopic electromagnetic flavor anomaly.

Figure 55.8 records the low-energy vertex matched from that microscopic anomaly: one neutral pion couples to two photons with the coefficient fixed above.

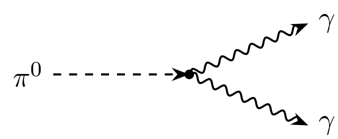

Figure 55.8: The electromagnetic flavor anomaly produces the local $\pi^0\gamma\gamma$ vertex in the pion effective action.

Writing

$$\mathcal{L}_{\pi^0\gamma\gamma} = \frac{g_{\pi\gamma\gamma}}{4}\,\pi^0 F_{\mu\nu}\widetilde{F}^{\mu\nu}$$

gives $g_{\pi\gamma\gamma} = e^2/(4\pi^2 f_\pi) = \alpha/(\pi f_\pi)$ for $N_c = 3$. The corresponding decay rate is

$$\Gamma(\pi^0 \to 2\gamma) = \frac{\alpha^2 m_{\pi^0}^3}{64\pi^3 f_\pi^2},$$

in the convention for f_π used above.

55.19 Conceptual Output of the Gauge-Dynamics Sequence

The dependencies established in this sequence are as follows. Gauge fields are local connections. Gauge fixing supplies local coordinates and ghosts. BRST cohomology defines physical states, local operators, counterterms, and anomaly candidates in the gauge-fixed formalism. QCD renormalization gives asymptotically free short-distance variables. Local anomalies are constrained by Wess–Zumino consistency and descent. Finite background anomalies are encoded by cocycles on background-field space. Exact anomaly classes are preserved along RG flow. Spontaneous symmetry breaking realizes these constraints through Goldstone fields and the Wess–Zumino–Witten functional.

Part V

Conformal Field Theory

Chapter 56

Fixed Points and Conformal Data

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

56.1 Local QFT Data Used in Fixed-Point Analysis

Let $D \geq 2$ be the spacetime dimension, let $d = D - 1$, and let $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$. The local Lorentzian data used in this volume are the following.

1. A Hilbert space $\mathcal{H}$ of physical states.
2. A strongly continuous unitary representation $U(\Lambda, a)$ of the proper orthochronous Poincare group, or of its spin cover when spinorial fields occur. The group law is
$$U(\Lambda', a')U(\Lambda, a) = U(\Lambda'\Lambda, \Lambda' a + a').$$
3. Self-adjoint generators P_μ and $J_{\mu\nu} = -J_{\nu\mu}$, normalized near the identity by
$$U(\Lambda, a) = 1 + \mathrm{i}a^\mu P_\mu + \frac{\mathrm{i}}{2}\omega^{\mu\nu} J_{\mu\nu} + O(a^2, \omega^2, a\omega), \qquad \Lambda^\mu{}_\nu = \delta^\mu{}_\nu + \omega^\mu{}_\nu.$$
The operators P_μ generate energy and momentum, while $J_{\mu\nu}$ generates spatial rotations and Lorentz boosts.
4. A Poincare-invariant unit vector $\Omega \in \mathcal{H}$, so $U(\Lambda, a)\Omega = \Omega$.

5. Local fields $\widehat{\Phi}_\alpha(x)$, understood as operator-valued distributions on a common invariant dense domain, with Poincare covariance

$$U(\Lambda,a)^{-1}\widehat{\Phi}_\alpha(x)U(\Lambda,a) = R(\Lambda)_\alpha{}^\beta\,\widehat{\Phi}_\beta(\Lambda x+a).$$

   Here R is the finite-dimensional Lorentz representation carried by the field component label α. Bosonic local fields commute, and fermionic local fields anticommute, after smearing with test functions whose supports are spacelike separated.

In addition, the discussion of conformal symmetry assumes a renormalized local stress tensor $\widehat{T}_{\mu\nu}(x)$. It is a symmetric tensor-valued operator distribution satisfying

$$\partial_\mu \widehat{T}^{\mu\nu} = 0, \qquad \widehat{T}^{\mu\nu} = \widehat{T}^{\nu\mu}. \tag{56.1}$$

where the conservation equation is distributional. When the spatial integrals exist with the chosen domain and infrared prescription, the translation and Lorentz generators are represented by

$$P^\mu = \int_{\Sigma_t} \mathrm{d}^d\vec{x}\,\widehat{T}^{0\mu}(t,\vec{x}). \tag{56.2}$$

and

$$J^{\mu\nu} = \int_{\Sigma_t} \mathrm{d}^d\vec{x}\,\big(x^\mu\widehat{T}^{0\nu}(t,\vec{x}) - x^\nu\widehat{T}^{0\mu}(t,\vec{x})\big). \tag{56.3}$$

with $\Sigma_t = \{x^0 = t\}$. These equations are operator equations after the same smearing, renormalization, and boundary conventions used to define $\widehat{T}_{\mu\nu}$.

Lorentz covariance of the stress tensor means

$$U(\Lambda,0)\widehat{T}_{\mu\nu}(x)U(\Lambda,0)^{-1} = \Lambda_\mu{}^\rho\Lambda_\nu{}^\sigma\widehat{T}_{\rho\sigma}(\Lambda x). \tag{56.4}$$

where indices on Λ are moved with $\eta_{\mu\nu}$. Hence $\widehat{T}^\mu{}_\mu(x)$ is a scalar local operator:

$$U(\Lambda,0)\widehat{T}^\mu{}_\mu(x)U(\Lambda,0)^{-1} = \widehat{T}^\mu{}_\mu(\Lambda x).$$

Remark 56.1 (Fixed points as supplied data, not universal ultraviolet origins). This volume analyzes the consequences of fixed-point data once those data have been constructed or assumed. A conformal perturbation problem starts with a specific fixed point $\mathcal{C}$, a specified family of scalar local operators O_A, and a prescription for the contact terms in products of $\int O_A$. The deformation coordinates g^A then describe a local chart near $\mathcal{C}$, not a general definition of QFT. In particular, the existence of an ultraviolet-complete theory does not follow from, nor is it equivalent to, being representable as a relevant deformation of an accessible CFT. Asymptotically free gauge theories are controlled in the ultraviolet by running local couplings and require a nonperturbative definition such as a lattice or other regulator framework; constructive and SPDE routes provide different fixed-point or continuum-limit data. The conformal methods developed below are used precisely where their hypotheses are present.

56.2 Renormalized Operators and the Trace Equation

Fix a renormalized coordinate chart $\{g_I(\mu)\}_{I\in\mathcal{I}}$ on a space of local scalar deformations. The index set $\mathcal{I}$ labels renormalized local insertions $[O_I]_\mu(x)$. In a Lagrangian presentation with bare scalar operators O_I^{bare}, write the interaction density as

$$\mathcal{L}_{\mathrm{int}}^{\mathrm{bare}} = \sum_I g_I^{\mathrm{bare}} O_I^{\mathrm{bare}}. \tag{56.5}$$

The renormalized insertions are defined by the response of the bare density to renormalized coordinates:

$$\delta\mathcal{L}_{\mathrm{int}}^{\mathrm{bare}} = \sum_I \delta g_I^{\mathrm{bare}} O_I^{\mathrm{bare}} = \sum_I \delta g_I(\mu)\, [O_I]_\mu. \tag{56.6}$$

This equation fixes the normalization and mixing convention for the local operators in the chosen scheme. The beta-function vector field is

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu} g_I(\mu) = \beta_I(g(\mu)). \tag{56.7}$$

Flat trace equation from a renormalized source-coordinate system. Assume that the renormalized chart $\{g_I(\mu), [O_I]_\mu\}_{I\in\mathcal{I}}$ is supplied by a local source functional whose constant Weyl variation is governed, in flat space, by the local RG vector field

$$\Delta_\sigma^{\mathrm{loc}} = \int \mathrm{d}^D x\, \sigma \left(2g_{\mu\nu}\frac{\delta}{\delta g_{\mu\nu}} + \beta_I(g)\frac{\delta}{\delta g_I}\right)$$

up to local anomaly/contact functionals and up to the divergence of a local virial current. Then, as a renormalized flat-space local-operator identity away from coincident insertions,

$$\widehat{T}^\mu{}_\mu = \sum_I \beta_I(g)\, [O_I]_\mu + \partial_\mu V^\mu. \tag{56.8}$$

The vector V^μ is a local vector operator recording the virial and improvement ambiguity in the chosen stress-tensor representative. Contact terms in (56.8) are not inferred from separated-point kernels; they are fixed together with the renormalized source Ward identities of the chart. Curvature terms appear after coupling the theory to a background metric, but vanish in the flat separated-point identity displayed here.

The source-coordinate system gives two descriptions of the same infinitesimal change of renormalization length. First, varying the metric by a constant Weyl factor $\delta_\sigma g_{\mu\nu} = 2\sigma g_{\mu\nu}$ gives, by the stress-tensor definition,

$$\delta_\sigma W = -\int \mathrm{d}^D x \sqrt{g}\, \sigma\, \langle T^\mu{}_\mu(x)\rangle\, .$$

Second, the same change expressed at fixed regulator is a displacement along the beta-function vector field in the renormalized coordinates:

$$\delta_\sigma W = -\int \mathrm{d}^D x \sqrt{g}\, \sigma\, \beta_I(g)\, \langle [O_I]_\mu(x)\rangle$$

with the sign fixed by the convention $\mu\, \mathrm{d}g_I/\mathrm{d}\mu = \beta_I$ and by (56.6). Equating the two descriptions, and restoring the possible local virial term produced by the choice of stress-tensor representative, gives (56.8) inside correlators at separated points. Local anomaly terms and derivatives of delta functions are exactly the contact terms belonging to the chosen source-coordinate system, so they do not modify the displayed separated-point flat-space operator identity.

Remark 56.2 (Scale invariance versus conformal invariance). At a fixed point the vanishing of the beta-function part of (56.8) gives

$$\widehat{T}^{\mu}{}_{\mu} = \partial_\mu V^\mu \tag{56.9}$$

in the flat-space local-operator quotient determined by the source-coordinate system. If $\widehat{T}^{\mu\nu}$ is symmetric and conserved, then

$$D^\mu = x_\nu \widehat{T}^{\mu\nu} - V^\mu \tag{56.10}$$

is a conserved dilatation current exactly when (56.9) holds. Conformal symmetry requires the stronger local statement that the virial class is removable by the allowed stress-tensor improvements. For the scalar improvement

$$\widehat{T}^{\mu\nu} \longmapsto \widehat{T}^{\mu\nu} + (\partial^\mu\partial^\nu - \eta^{\mu\nu}\partial^2)L,$$

the trace changes by $-(D-1)\partial^2 L$, so the trace can be removed when

$$V^\mu = (D-1)\partial^\mu L + J^\mu, \qquad \partial_\mu J^\mu = 0, \tag{56.11}$$

modulo the operator identities and contact-term convention of the source-coordinate system. More general improvement tensors enlarge the same quotient by the image of their trace-changing map. Thus the scale-to-conformal implication is the local problem of proving that this virial obstruction class vanishes.

In this stress-tensor framework, a scale-invariant but nonconformal local QFT is a theory for which (56.9) gives a conserved dilatation current $D^\mu = x_\nu \widehat{T}^{\mu\nu} - V^\mu$, while the class of V^μ is nonzero in the quotient by conserved currents and allowed improvement currents. Equivalently, the theory has a virial current of dimension $D-1$ whose divergence is the trace, but no admissible improvement makes the stress tensor traceless. This is the obstruction isolated by Polchinski's analysis of scale versus conformal invariance: $D^\mu = x_\nu T^{\mu\nu} - V^\mu$ may generate scale transformations even when there are no conserved special-conformal currents.[1]

The status is dimension-dependent. In $D = 2$, the Zamolodchikov–Polchinski argument proves the implication under explicit Hilbert-space positivity, locality, stress-tensor, vacuum, spectrum, and regularity hypotheses strong enough for the c-function and stress-tensor two-point analysis. In $D = 4$, the Luty–Polchinski–Rattazzi program and related anomaly/dilaton arguments give powerful conditional constraints, but this monograph does not use an unconditional theorem asserting that every unitary scale-invariant four-dimensional QFT is conformal. In $D = 3$ and $D > 4$, later uses of conformal symmetry likewise require the traceless improved stress tensor, the vanishing virial class, or the equivalent conformal Ward identities as part of the stated data. The cohomological formulation and references are given in Remark 35.7.

Virial class, improvement, and conformal currents. Let $T^{\mu\nu}$ be a symmetric conserved stress tensor in flat D-dimensional Minkowski space. Suppose that

$$T^{\mu}{}_{\mu} = \partial_\mu V^\mu$$

as a local operator identity in the chosen separated-point/contact chart. Then

$$D^\mu = x_\nu T^{\mu\nu} - V^\mu$$

[1] J. Polchinski, "Scale and conformal invariance in quantum field theory," *Nucl. Phys. B* **303** (1988) 226–236.

is a conserved dilatation current. If, for some scalar local operator L and conserved current J^μ,

$$V^\mu = (D-1)\partial^\mu L + J^\mu, \qquad \partial_\mu J^\mu = 0,$$

then the improved stress tensor

$$T^{\mu\nu}_{\rm imp} = T^{\mu\nu} + (\partial^\mu\partial^\nu - \eta^{\mu\nu}\partial^2)L$$

is symmetric, conserved, and traceless. Consequently, for every conformal Killing vector ξ^μ satisfying

$$\partial_\mu\xi_\nu + \partial_\nu\xi_\mu = \frac{2}{D}(\partial_\rho\xi^\rho)\eta_{\mu\nu},$$

the current $j^\mu_\xi = T^{\mu\nu}_{\rm imp}\xi_\nu$ is conserved. The divergence of the proposed dilatation current is

$$\partial_\mu D^\mu = T^\mu{}_\mu + x_\nu\partial_\mu T^{\mu\nu} - \partial_\mu V^\mu = 0.$$

The improvement term is symmetric. Its divergence vanishes because ordinary derivatives commute:

$$\partial_\mu(\partial^\mu\partial^\nu - \eta^{\mu\nu}\partial^2)L = \partial^\nu\partial^2 L - \partial^\nu\partial^2 L = 0.$$

Its trace is

$$\eta_{\mu\nu}(\partial^\mu\partial^\nu - \eta^{\mu\nu}\partial^2)L = -(D-1)\partial^2 L.$$

Therefore

$$T_{\rm imp}{}^\mu{}_\mu = \partial_\mu V^\mu - (D-1)\partial^2 L = \partial_\mu J^\mu = 0.$$

For a conformal Killing vector,

$$\partial_\mu j^\mu_\xi = T^{\mu\nu}_{\rm imp}\partial_\mu\xi_\nu = \frac{1}{2}T^{\mu\nu}_{\rm imp}(\partial_\mu\xi_\nu + \partial_\nu\xi_\mu) = \frac{1}{D}(\partial_\rho\xi^\rho)T_{\rm imp}{}^\mu{}_\mu = 0,$$

where conservation and symmetry of $T^{\mu\nu}_{\rm imp}$ were used. Thus the improved traceless representative supplies the currents for translations, rotations, dilatations, and special conformal transformations whenever the corresponding smeared charges are defined.

An RG fixed point in the coordinate chart is a point g_* satisfying

$$\beta_I(g_*) = 0 \qquad \text{for every } I \in \mathcal{I}. \tag{56.12}$$

At such a point the beta-function part of the trace vanishes. A flat-space conformal fixed point is obtained when the stress tensor can be chosen, by allowed improvements and contact-term conventions, so that

$$\widehat{T}^\mu{}_\mu = 0 \tag{56.13}$$

as a renormalized local operator equation in flat space. Equation (56.13), together with (56.1), is the local input from which the conformal currents and charges are derived in the next chapter.

The linearized RG flow near g_* records the scaling dimensions of deformations. Let

$$B_{IJ} = \left.\frac{\partial\beta_I}{\partial g_J}\right|_{g=g_*}.$$

Choose an eigenvector $v^{(a)}_J$ and write

$$g_I - g_{*I} = \lambda_a v^{(a)}_I + O(\lambda^2), \qquad \sum_J B_{IJ}v^{(a)}_J = -y_a v^{(a)}_I.$$

With the momentum scale μ as flow parameter,

$$\mu\frac{\mathrm{d}\lambda_a}{\mathrm{d}\mu} = -y_a\lambda_a + O(\lambda^2).$$

Equivalently, under a length rescaling $x \mapsto bx$, $b > 1$,

$$\lambda_a(b) = b^{y_a}\lambda_a + O(\lambda^2).$$

If the corresponding scalar perturbation is $\int \mathrm{d}^D x\, \lambda_a O_a(x)$, then

$$y_a = D - \Delta_a, \tag{56.14}$$

where Δ_a is the scaling dimension of O_a. Thus $y_a > 0$, $y_a = 0$, and $y_a < 0$ define relevant, marginal, and irrelevant directions, respectively, in the long-distance flow.

Linearized RG eigenvalues and operator dimensions. Assume that the beta-function vector field is differentiable at g_* and that the tangent direction $v^{(a)}$ is an ordinary eigenvector of $B_{IJ} = \partial\beta_I/\partial g_J|_{g_*}$ with eigenvalue $-y_a$. Let

$$O_a = \sum_I v_I^{(a)}[O_I]_*$$

be the corresponding scalar deformation operator in the linearized source chart. If O_a is a scaling operator at the fixed point, then its scaling dimension satisfies

$$\Delta_a = D - y_a.$$

If B has a Jordan block instead of a diagonal eigenspace, the corresponding operators form a logarithmic mixing block under scale transformations; the number $D - y_a$ is then the common diagonal scaling dimension of the block, not a complete diagonalization of the dilatation action.

Along the eigen-direction write

$$g_I(\mu) - g_{*I} = \lambda_a(\mu)v_I^{(a)} + O(\lambda_a^2).$$

The RG equation gives

$$\mu\frac{\mathrm{d}\lambda_a}{\mathrm{d}\mu} = -y_a\lambda_a + O(\lambda_a^2).$$

Changing the unit of length by $x \mapsto bx$, $b > 1$, corresponds to lowering the momentum scale by b^{-1}, hence

$$\lambda_a(b) = b^{y_a}\lambda_a + O(\lambda_a^2).$$

At the fixed point a scalar scaling operator obeys

$$O_a(x) \mapsto b^{-\Delta_a}O_a(b^{-1}x).$$

Therefore the integrated perturbation transforms as

$$\lambda_a \int \mathrm{d}^D x\, O_a(x) \mapsto \lambda_a b^{D-\Delta_a} \int \mathrm{d}^D x\, O_a(x).$$

Comparing this scaling of the coupling with $\lambda_a(b) = b^{y_a}\lambda_a$ gives $y_a = D - \Delta_a$. For a Jordan block, solving the linearized RG equation gives the same power b^{y_a} multiplied by polynomials in $\log b$, which is the RG form of logarithmic operator mixing.

56.3 Conformal Manifolds and Exactly Marginal Deformations

A marginal scalar operator at one fixed point is only a tangent candidate. A conformal manifold is a family of fixed-point data in which the tangent operators, contact terms, source normalizations, stress tensors, and redundant directions vary coherently. This section fixes the local meaning of that statement before the supersymmetric worked examples later in the monograph.

Definition 56.3 (Local conformal-family structure)**.** A local conformal-family structure of dimension r consists of the following objects.

1. A connected r-dimensional smooth or complex manifold $\mathcal{M}$ of parameters, with a base point λ_0.
2. For every $\lambda \in \mathcal{M}$, fixed-point local QFT data $\mathcal{C}_\lambda$: a Hilbert-space or Euclidean reconstruction structure, a stress-tensor source functional $W_\lambda[g, J]$, conformal Ward identities including their contact terms, and a specified local-operator space modulo null operators.
3. A vector bundle $\mathcal{V} \to \mathcal{M}$ whose fiber $\mathcal{V}_\lambda$ is the finite-dimensional space of renormalized scalar operators of dimension D that are allowed by the symmetries kept in the family, modulo total derivatives and null operators.
4. A tangent-operator map
$$\mathsf{I}_\lambda : T_\lambda\mathcal{M} \longrightarrow \mathcal{V}_\lambda, \qquad v \longmapsto O_v.$$
5. For every finite list of local operators away from collision diagonals, the separated-point distributions are differentiable in λ, and the derivative in the direction v is represented by the renormalized integrated insertion
$$\partial_v \langle X_1(x_1) \cdots X_n(x_n)\rangle_\lambda = -\left[\int_{\mathbb{R}^D} \mathrm{d}^D x \, \langle O_v(x) X_1(x_1) \cdots X_n(x_n)\rangle_\lambda\right]_{\mathrm{ren}}. \tag{56.15}$$
The brackets $[\cdots]_{\mathrm{ren}}$ include the local counterterms supported where x collides with one of the x_i and, on curved backgrounds, the corresponding source and metric contact terms.

The structure is a conformal family because every point λ already satisfies the fixed-point conditions and because (56.15) specifies how tangent vectors are represented in correlation functions.

The definition is local on $\mathcal{M}$. Global continuation of coordinates, preferred Lagrangian presentations, and discrete duality identifications require additional structure. A duality group, if present, acts on the local family after it has been defined as an isomorphism of the complete line-operator spectrum, local operator algebra, and source-contact chart.

Source-coordinate criterion for exact marginality. Let h^a, $a = 1, \ldots, m$, be local coordinates on a finite-dimensional space of candidate marginal source deformations at a fixed point $\mathcal{C}_0$. Let
$$\beta^\alpha(h), \qquad \alpha = 1, \ldots, s,$$
denote the obstruction functions in the chosen source-coordinate system: the components of the local RG vector field which must vanish for the deformed theory to remain conformal, together with any current-moment-map or virial obstruction that is part of the same Ward identity. Let

a redundancy group G_{red} act on the source coordinates by field redefinitions, flavor rotations, or other changes that do not change the fixed-point QFT structure. Its infinitesimal action is a distribution

$$\rho : \mathrm{Lie}(G_{\mathrm{red}}) \longrightarrow T_h\mathbb{R}^m.$$

The local conformal locus in this chart is

$$\mathcal{M}_{\mathrm{loc}} = \{h : \beta^\alpha(h) = 0\}/G_{\mathrm{red}}, \tag{56.16}$$

provided the quotient is taken only along orbits contained in the zero locus. If $d\beta|_{h_0}$ has constant rank r_β near the base point and the redundancy distribution has constant rank r_{red} tangent to $\beta^{-1}(0)$, then the local dimension in the source-coordinate system is

$$\dim \mathcal{M}_{\mathrm{loc}} = m - r_\beta - r_{\mathrm{red}}. \tag{56.17}$$

The substantive input behind (56.17) is the preceding source-coordinate system: all obstruction functions, all redundancies, and all contact-term conventions have to be known before the rank count is meaningful. This is the field-theoretic core of Leigh–Strassler type exact-marginality arguments in supersymmetric examples.

At second order in conformal perturbation theory, the obstruction functions are visible in the OPE. If O_a are scalar primaries of dimension D, then the collision region in

$$\int \mathrm{d}^D x\, \mathrm{d}^D y\, O_a(x) O_b(y)$$

is controlled by the $O_a(x)O_b(y)$ OPE. Terms proportional to another dimension-D scalar O_c, to a divergence of a dimension-$D-1$ vector, or to a source-contact counterterm are precisely the terms that can contribute to β^c, to a virial/current obstruction, or to a scheme change. The finite-dimensional chart above is therefore a compressed record of a distributional statement about collision singularities. A claim that a dimension-D operator is exactly marginal is justified only after these collision terms have been controlled to all orders in the proposed family, or after an independent nonperturbative construction of the family has been supplied.

Zamolodchikov metric. For a conformal-family structure, the separated two-point function of tangent operators has the form

$$\langle O_v(x) O_w(0)\rangle_\lambda = \frac{G_\lambda(v,w)}{|x|^{2D}} \qquad (x \neq 0), \tag{56.18}$$

after fixing the normalization of O_v by (56.15). Reflection positivity makes G_λ positive semidefinite on tangent candidates. Its null directions are redundant deformations: total derivatives, null operators, and infinitesimal source reparametrizations that vanish in separated-point correlators. After quotienting by these directions, G_λ is the Zamolodchikov metric on the local conformal family.

This metric is independent of the particular source coordinates in the usual tensorial sense. If $h^a = h^a(\lambda)$ and $\lambda^i = \lambda^i(h)$ are two coordinates on the same family, then

$$O_i = \frac{\partial h^a}{\partial \lambda^i} O_a \quad \text{modulo contact terms and redundant operators,}$$

so separated two-point functions give

$$G'_{ij} = \frac{\partial h^a}{\partial \lambda^i}\frac{\partial h^b}{\partial \lambda^j} G_{ab}. \tag{56.19}$$

Contact terms can change the distributional extension of (56.18) to $x = 0$, but they do not change the separated coefficient $G_\lambda(v, w)$. This distinction is essential when the same exactly marginal source also appears in local RG equations, curved-background Ward identities, or supersymmetric localization formulae.

Supersymmetric examples and global identifications. The supersymmetric volume contains worked source-coordinate examples of (56.16). In Chapter 90, the Klebanov–Witten chart has three holomorphic source coordinates and one independent beta-function constraint under the stated $\mathcal{N} = 1$, flavor-symmetry, and Wilsonian-scheme hypotheses, giving a two-complex-dimensional local conformal locus. In Chapter 97, four-dimensional $\mathcal{N} = 4$ Yang–Mills has the local coordinate

$$\tau = \frac{\theta}{2\pi} + \frac{4\pi \mathrm{i}}{g_{\mathrm{YM}}^2}, \qquad \operatorname{Im}\tau > 0,$$

so the local family is one complex dimensional before electric-magnetic duality identifications. The quotient by a subgroup of $PSL(2, \mathbb{Z})$ is a global statement about the line-operator lattice and global form of the gauge group, separate from the local exact-marginality proof. In Chapter 95, the standard $\mathcal{N} = 6$ ABJM specification at fixed integers (N, k) has no continuous conformal coupling: the Chern–Simons level is quantized and the superpotential coefficient is fixed by the supersymmetry completion. These examples illustrate the rule: a parameter belongs to a conformal manifold only if it is represented by a genuine tangent coordinate in a fixed QFT specification. The two-dimensional CFT volume gives the complementary symmetric-product example in Construction 66.32: seed exactly marginal directions and dressed two-cycle twist fields define the local tangent data of the compact $\mathcal{N} = (4, 4)$ conformal families, while the arithmetic quotient and singular loci are global CFT data.

56.4 RG Monotones and Fixed-Point Ordering

Let $\mathfrak{T}$ be a class of unitary Lorentzian QFTs equipped with renormalized stress-tensor source functionals and let an RG trajectory in $\mathfrak{T}$ have a UV endpoint $\mathcal{C}_{\mathrm{UV}}$ and an IR endpoint $\mathcal{C}_{\mathrm{IR}}$, each a CFT in the sense of the preceding section. The length scale R increases toward the infrared. An endpoint monotone is a real number $\mathfrak{M}(\mathcal{C})$, assigned to every endpoint CFT in the class, together with an interpolating quantity $\mathfrak{M}(R)$ on the trajectory such that

$$\lim_{R\to 0} \mathfrak{M}(R) = \mathfrak{M}(\mathcal{C}_{\mathrm{UV}}), \qquad \lim_{R\to\infty} \mathfrak{M}(R) = \mathfrak{M}(\mathcal{C}_{\mathrm{IR}}), \qquad \frac{\mathrm{d}}{\mathrm{d}\log R}\mathfrak{M}(R) \le 0.$$

The endpoint consequence is $\mathfrak{M}(\mathcal{C}_{\mathrm{UV}}) \ge \mathfrak{M}(\mathcal{C}_{\mathrm{IR}})$. This definition keeps the mathematical content in the class $\mathfrak{T}$: positivity, stress-tensor existence, analyticity, infrared behavior, and contact-term conventions are hypotheses on the trajectory, not decorations on the conclusion.

In two spacetime dimensions the fixed-point number is the Virasoro central charge c_{2d}. Under the hypotheses used in the Zamolodchikov–Polchinski formulation–unitarity, Poincare invariance, a normalizable vacuum, a local stress tensor, reflection positivity or Hilbert-space positivity, and regularity of the stress-tensor two-point distributions–write the Euclidean two-point functions in complex coordinates as

$$\begin{aligned} \langle T(z,\bar z)T(0)\rangle &= \frac{F(R)}{z^4}, \\ \langle T(z,\bar z)\Theta(0)\rangle &= \frac{G(R)}{z^3\bar z}, \\ \langle \Theta(z,\bar z)\Theta(0)\rangle &= \frac{H(R)}{z^2\bar z^2}, \qquad R=|z|, \qquad \Theta = T^\mu{}_\mu. \end{aligned} \tag{56.20}$$

The powers of $z, \bar z$ isolate the tensor weights, while the functions F, G, H depend only on R. Conservation of the stress tensor gives the Zamolodchikov combination

$$C(R) = 2F(R) - G(R) - \frac{3}{8}H(R) \tag{56.21}$$

with derivative

$$\frac{\mathrm{d}C(R)}{\mathrm{d}\log R} = -\frac{3}{4}H(R) \le 0. \tag{56.22}$$

Reflection positivity gives $H(R) \ge 0$. At a conformal endpoint $\Theta = 0$ at separated flat-space points, $G = H = 0$ and $F = c_{2d}/2$ in the normalization $\langle T(z)T(0)\rangle = c_{2d}/(2z^4)$, so $C(R)$ tends to the central charge of that endpoint. Thus $c_{\mathrm{UV}} \ge c_{\mathrm{IR}}$ for trajectories satisfying the displayed hypotheses.

In three spacetime dimensions a fixed-point quantity of central importance is the finite sphere free energy

$$F_{\mathcal{C}} = -\log |Z_{\mathcal{C}}(S^3)|,$$

after the local counterterms allowed on S^3 have been fixed. This quantity is part of conformal data once a scheme for the curved-background partition function has been declared. Monotonicity statements involving $F_{\mathcal{C}}$ require additional input about the RG trajectory and its regulated observables; they are not used here as definitions of a CFT. Gauge constraints, zero modes, topological sectors, and background counterterms must be included in the definition of $Z(S^3)$.

In four spacetime dimensions the endpoint quantity is the Euler coefficient a_{W} in the Weyl anomaly,

$$\langle T^\mu{}_\mu\rangle_g = \frac{1}{16\pi^2}\left(c_{\mathrm{W}}W^2 - a_{\mathrm{W}}E_4 + b_{\mathrm{D}}\nabla^2 R\right),$$

with the notation developed in Chapter 58. The standard Komargodski–Schwimmer construction should be read here as a conditional dilaton-dispersion argument, not as a theorem-level proof from the general axioms of four-dimensional QFT. Its input is a unitary Lorentz-invariant flow between CFT endpoints, a renormalized stress-tensor source functional along the flow, a weak spectator dilaton τ coupled by $g_{\mu\nu} = \mathrm{e}^{-2\tau}\eta_{\mu\nu}$, a controlled large-$f$ decoupling limit for the spectator sector, and an infrared prescription under which the dilaton scattering amplitude exists. Under these hypotheses, Wess–Zumino consistency for the mismatch of the UV and IR Weyl anomalies fixes the flat-space four-derivative dilaton interaction whose on-shell four-dilaton amplitude is

$$\mathcal{A}(s,t,u) = \frac{a_{\mathrm{UV}} - a_{\mathrm{IR}}}{f^4}\left(s^2+t^2+u^2\right) + O(p^6), \qquad s+t+u=0. \tag{56.23}$$

In the forward limit $t = 0$, this becomes

$$\mathcal{A}(s, 0, -s) = \frac{2(a_{\mathrm{UV}} - a_{\mathrm{IR}})}{f^4} s^2 + O(s^4).$$

If, in addition, the forward amplitude obeys the analyticity, crossing, polynomial boundedness, unitarity, and infrared-regulator conditions needed for the dispersion relation, and if the large-circle and small-circle contour contributions are controlled, Cauchy's theorem applied to $\mathcal{A}(s)/s^3$ gives the formal sum rule

$$a_{\mathrm{UV}} - a_{\mathrm{IR}} = \frac{f^4}{\pi} \int_0^\infty \mathrm{d}s \, \frac{\sigma_{\tau\tau}(s)}{s^2}, \tag{56.24}$$

where the optical theorem has been used in the form $\operatorname{Im} \mathcal{A}(s, 0) = s\, \sigma_{\tau\tau}(s)$. Under the same scattering assumptions, unitarity gives $\sigma_{\tau\tau}(s) \geq 0$, hence

$$a_{\mathrm{UV}} \geq a_{\mathrm{IR}}.$$

If such a positive cross-section representation is available with a scale cutoff, the same formal sum rule defines an interpolating quantity

$$a(\mu) = a_{\mathrm{UV}} - \frac{f^4}{\pi} \int_\mu^\infty \mathrm{d}s \, \frac{\sigma_{\tau\tau}(s)}{s^2}, \qquad \frac{\mathrm{d}a(\mu)}{\mathrm{d}\mu} = \frac{f^4}{\pi} \frac{\sigma_{\tau\tau}(\mu)}{\mu^2} \geq 0. \tag{56.25}$$

Thus $a(\mu)$ increases with the energy scale μ and decreases with the length scale $R \sim \mu^{-1}$, inside the same conditional scattering framework. This $a(\mu)$ is not by itself a nonperturbative local RG c-function constructed for every four-dimensional QFT. The coefficient c_{W} does not obey an analogous general endpoint inequality; its role in fixed-point data is through stress-tensor correlators, not through this dilaton sum rule.

Remark 56.4 (Status of the monotonicity statements). The preceding paragraphs state the monotonicity statements at the level at which this volume uses them. The two-dimensional result is a theorem after the analytic assumptions entering the $C(R)$ construction have been fixed. The three-dimensional sphere quantity is recorded here as fixed-point data; the core CFT volume does not use an entropic construction as a structural input. The four-dimensional dilaton discussion is an inspired and highly constraining physical argument whose conclusion follows only after the displayed source-functional, decoupling, infrared, analyticity, crossing, boundedness, and positivity assumptions have been supplied. The monograph does not treat it as a rigorous proof of a universal a-theorem, nor as a substitute for constructing the RG trajectory or proving that its endpoints satisfy the CFT hypotheses.[2]

56.5 Conformal Field Theory as Local Fixed-Point Data

The local data of a conformal field theory in flat D-dimensional space are organized as follows.

[2] For the two-dimensional construction see A. B. Zamolodchikov, "Irreversibility of the flux of the renormalization group in a 2D field theory," *JETP Lett.* **43** (1986) 730–732, and J. Polchinski, "Scale and conformal invariance in quantum field theory," *Nucl. Phys. B* **303** (1988) 226–236. For the four-dimensional dilaton argument see Z. Komargodski and A. Schwimmer, "On renormalization group flows in four dimensions," *JHEP* **12** (2011) 099, arXiv:1107.3987. For the three-dimensional sphere partition-function quantity see D. L. Jafferis, I. R. Klebanov, S. S. Pufu, and B. R. Safdi, "Towards the F-theorem," arXiv:1103.1181.

1. An algebraic vector space $\mathcal{V}_{\rm loc}$ of renormalized local operators, graded by scaling dimension after diagonalizing the dilatation action. Its elements are denoted $\mathcal{O}_A(x)$, with A labeling a basis or a collection of multiplets. In a unitary CFT this algebraic space maps, by radial quantization, to a dense subspace of the Hilbert space on S^{D-1}; the Hilbert completion contains general sphere states and is not itself the space of local operators.
2. A stress tensor $T_{\mu\nu}$ satisfying conservation, symmetry, and the flat-space tracelessness condition
$$\partial_\mu T^{\mu\nu} = 0, \qquad T^{\mu\nu} = T^{\nu\mu}, \qquad T^\mu{}_\mu = 0.$$
3. An action of the conformal algebra on $\mathcal{V}_{\rm loc}$, generated by the stress-tensor charges associated with conformal Killing fields.
4. Euclidean separated-point correlation functions
$$\langle \mathcal{O}_{A_1}(x_1) \cdots \mathcal{O}_{A_n}(x_n) \rangle, \qquad x_i \in \mathbb{R}^D,$$
interpreted as distributions on the configuration space $x_i \neq x_j$, together with contact-term extensions specified by the source Ward identities.

For unitary Lorentzian theories these Euclidean distributions are related to Wightman distributions by analytic continuation and reflection positivity, under the same reconstruction hypotheses used for ordinary Euclidean Green functions.

56.6 Source Functionals and Ward-Identity Contact Terms

The separated-point correlators in the preceding list are restrictions of distributions obtained from a source functional. Work in Euclidean signature for this construction. The fixed-point functional used here is the renormalized metric-and-operator source limit constructed in Section 35.2, specialized to a point of the RG flow where the beta functions vanish and to a stress-tensor improvement convention appropriate to the fixed point. Thus $g_{\mu\nu}$ is a smooth background metric, $J^A(x)$ are smooth compactly supported sources for a chosen local operator basis $\mathcal{O}_A$, and local functionals of g and J specify the contact-term chart. The sign normalization of W_* is the Euclidean free-energy, or effective-action, normalization $W_* = -\log Z_*$. The connected-log functional is denoted $K_* = \log Z_*$ when it is used.

Definition 56.5 (Status of fixed-point source brackets)**.** The fixed-point partition functional
$$Z_*[g, J] := \exp\{-W_*[g, J]\}$$
is source-functional data of the fixed point. The symbol $\langle \cdots \rangle_{g,*}$ used below denotes evaluation by this curved-background source functional. A literal Borel measure or an unregulated continuum path integral would require an additional construction. If a presentation of the CFT supplies only flat separated-point correlators, then a compatible curved-background functional $Z_*[g, J]$, including its contact-term and Weyl-anomaly extension, is an additional datum or theorem to be stated before the metric derivatives below are used. The bracket notation
$$\left\langle \exp\left(\int \mathrm{d}^D x \sqrt{g}\, J^A(x) \mathcal{O}_A(x)\right)\right\rangle_{g,*} := Z_*[g, J]$$
is a shorthand for that data. Its mathematical construction depends on the framework in which the fixed point has been supplied:

(i) in a constructive Euclidean model, $Z_*[g, J]$ is obtained from the constructed measure or generalized random field after the local source counterterms have been fixed;

(ii) in a lattice or Wilsonian construction, $Z_*[g, J]$ is the continuum limit of regulated source functionals in a specified topology of distributions, after tuning and renormalizing the source-coordinate system;

(iii) in an abstract CFT presentation, $Z_*[g, J]$ is a generating functional for a compatible family of Euclidean Schwinger distributions and contact-term extensions satisfying the stated Ward identities, positivity or reflection-positivity hypotheses when unitarity is required, and the reconstruction assumptions used in this volume;

(iv) in perturbative fixed-point calculations, $Z_*[g, J]$ is a formal power series whose coefficients are renormalized source distributions.

Thus the brackets in this section are typed by the chosen fixed-point construction. They are expectation brackets when a measure construction has been provided, continuum-limit brackets when a regulated limit has been proved or assumed as part of the data, and distributional generating brackets in an axiomatic or perturbative presentation.

Hypothesis 56.6 (Existence of the fixed-point source-coordinate system)**.** All differentiations of $W_*[g, J]$ below are made in a source-coordinate system with the following properties. There is an open neighborhood $\mathcal{U}_*$ of $(g, J) = (\delta, 0)$ in the Frechet space of smooth Euclidean metrics equal to $\delta_{\mu\nu}$ outside a compact set and smooth compactly supported operator sources. The functional W_* is a real-valued functional on $\mathcal{U}_*$, defined modulo local functionals of g and J, whose Gateaux derivatives of all orders exist as distributions. More explicitly, for every $(g, J) \in \mathcal{U}_*$ and every finite list of compactly supported metric and source variations

$$u_r = (h^{(r)}_{\mu\nu}, j^{(r)A}), \qquad r = 1, \ldots, n,$$

the multilinear functional

$$D_{u_1} \cdots D_{u_n} W_*[g, J]$$

is continuous in the test-function topology and is represented by a distribution on the corresponding Cartesian power of spacetime.

If the fixed point is supplied by a regulator, this hypothesis means that there are regulated functionals $Z_\Lambda[g, J]$ and local source counterterms $P_\Lambda[g, J]$ such that

$$W^{\mathrm{ren}}_\Lambda[g, J] = -\log Z_\Lambda[g, J] + P_\Lambda[g, J]$$

has distributional limits of all such source derivatives on $\mathcal{U}_*$:

$$D_{u_1} \cdots D_{u_n} W^{\mathrm{ren}}_\Lambda[g, J] \longrightarrow D_{u_1} \cdots D_{u_n} W_*[g, J] \quad \text{in } \mathcal{D}'.$$

Two regulators or subtraction prescriptions define the same source-coordinate system only after a transition function has been specified; their difference is allowed to be a local functional of the background fields, which changes only contact terms in source derivatives. Diffeomorphism and Weyl Ward identities for W_* are additional properties of this chart, including the anomaly functional when one is present. They are not consequences of flat separated correlators alone.

The definitions and Ward identities in the rest of this section are conditional on Hypothesis 56.6. In perturbative constructions the hypothesis is a statement about formal power series whose coefficients are renormalized source distributions. In a constructive, lattice, or Wilsonian construction it is a nonperturbative source-dependent scaling-limit theorem when proved; otherwise it is part of the CFT data being assumed.

For a regulated path-integral representative this convention reads

$$\exp\{-W_*[g,J]\} = \int \mathcal{D}_g\Phi\, \exp\left\{-S_*[\Phi;g] + \int \mathrm{d}^D x\, \sqrt{g}\, J^A(x)\mathcal{O}_A(x)\right\},$$

up to the local counterterms that define the source-coordinate system. The minus sign in the operator derivative below is forced by combining $W_* = -\log Z_*$ with the source term $+\int J^A\mathcal{O}_A$ in the exponent; a source written with the opposite sign would reverse this derivative convention. In an abstract CFT the displayed integral is replaced by the corresponding renormalized source functional; the first derivatives below are the definition of the associated contact-term convention. This paragraph uses the Euclidean plus-source coordinate. Relative to the positive-measure convention $Z_E[J_E] = \int \exp\{-S_E - \langle J_E, \mathcal{O}\rangle\}$ of Chapter 30, the local operator source here is $J^A = -J_E^A$. Relative to the Lorentzian convention $\exp\{\mathrm{i}\langle J_L, \mathcal{O}\rangle_L\}$ and the lower-half-plane Wick rotation of Chapter 16, it is $J^A = J_L^{\mathrm{W},A}$, with the tensor/spin index Wick factors inserted when the operator is not a scalar. The source-coordinate sign is therefore fixed before any Ward identity is differentiated. The stress tensor and local operators are the source derivatives

$$\langle T^{\mu\nu}(x)\rangle_{g,J} = -\frac{2}{\sqrt{g}(x)}\frac{\delta W_*[g,J]}{\delta g_{\mu\nu}(x)}, \qquad \langle \mathcal{O}_A(x)\rangle_{g,J} = -\frac{1}{\sqrt{g}(x)}\frac{\delta W_*[g,J]}{\delta J^A(x)}. \tag{56.26}$$

The stress-tensor derivative is written with respect to $g_{\mu\nu}$. The same convention may be written using $g^{\mu\nu}$ by the chain-rule identity (58.2). The sign in the first formula is the one induced by the Euclidean effective action convention. With

$$\delta_g S_*[\Phi;g] = -\frac{1}{2}\int \mathrm{d}^D x\, \sqrt{g}\, T^{\mu\nu}(x)\delta g_{\mu\nu}(x),$$

one has $\delta_g W_* = \langle \delta_g S_*\rangle$, hence

$$\delta_g W_* = -\frac{1}{2}\int \mathrm{d}^D x\, \sqrt{g}\, \langle T^{\mu\nu}(x)\rangle_{g,J}\, \delta g_{\mu\nu}(x).$$

The operator-source derivative has the same overall minus sign for a different reason: $J^A\mathcal{O}_A$ appears with a plus sign in the exponent of Z_*, while $W_* = -\log Z_*$. Higher derivatives define Euclidean Schwinger distributions. The source functional is defined up to local functionals of the background sources. This is the continuum CFT version of the contact-term coordinate freedom described in Section 34.5: the restriction to the configuration space $x_i \neq x_j$ is fixed by the linear operator normalization, while the extension across collision diagonals is fixed by the chosen local source-coordinate system. The trace identity used in this system is the contact-distribution identity of Proposition 35.3; the Weyl-anomaly functional and its Wess–Zumino consistency condition are part of the same source data, not consequences of separated-point correlators alone.

The Ward identities are identities of these source-dependent distributions. For an infinitesimal diffeomorphism generated by a compactly supported vector field ξ^μ,

$$\delta_\xi g_{\mu\nu} = \nabla_\mu\xi_\nu + \nabla_\nu\xi_\mu, \qquad \delta_\xi J^A = \xi^\mu\nabla_\mu J^A$$

for scalar sources. Invariance of $W_*[g, J]$ gives

$$\nabla_\mu \langle T^{\mu\nu}(x)\rangle_{g,J} = \langle \mathcal{O}_A(x)\rangle_{g,J} \nabla^\nu J^A(x), \tag{56.27}$$

with extra representation terms when the source carries spin indices. Differentiating this identity with respect to J and then setting $J = 0$ produces the contact terms in stress-tensor Ward identities. Equivalently, for scalar insertions

$$X = \mathcal{O}_{A_1}(x_1) \cdots \mathcal{O}_{A_n}(x_n),$$

the distributional translation Ward identity can be written in smeared form as

$$\int \mathrm{d}^D x\, \partial_\mu \xi_\nu(x)\, \langle T^{\mu\nu}(x) X\rangle = \sum_{i=1}^{n} \langle \mathcal{O}_{A_1}(x_1) \cdots (\xi^\rho \partial_\rho \mathcal{O}_{A_i})(x_i) \cdots \mathcal{O}_{A_n}(x_n)\rangle\,. \tag{56.28}$$

This equation is a compact way of recording the delta-function terms supported at $x = x_i$.

If the fixed point has no flat-space Weyl anomaly, the source-coordinate system for scalar primary operators of dimensions Δ_A may be chosen so that an infinitesimal Weyl transformation satisfies

$$\delta_\sigma g_{\mu\nu} = 2\sigma g_{\mu\nu}, \qquad \delta_\sigma J^A = (\Delta_A - D)\sigma J^A.$$

Differentiating the corresponding source Ward identity gives, for scalar primaries and in flat space,

$$\int \mathrm{d}^D x\, \sigma(x)\, \langle T^\mu{}_\mu(x) X\rangle = -\sum_{i=1}^{n} \Delta_{A_i} \sigma(x_i)\, \langle X\rangle + \mathcal{A}_\sigma[X]. \tag{56.29}$$

The term $\mathcal{A}_\sigma[X]$ is a local functional of the sources and background metric. It vanishes for flat separated-point correlators in a Weyl-invariant source scheme, but it must be specified when correlators are extended to coincident insertions or when the theory is placed on a curved background.

A scalar primary operator $\mathcal{O}$ has a scaling dimension $\Delta_{\mathcal{O}}$. For scalar primaries $\mathcal{O}_i$, separated-point scale covariance is

$$\langle \mathcal{O}_1(\lambda x_1) \cdots \mathcal{O}_n(\lambda x_n)\rangle = \lambda^{-\sum_i \Delta_i} \langle \mathcal{O}_1(x_1) \cdots \mathcal{O}_n(x_n)\rangle\,, \qquad \lambda > 0. \tag{56.30}$$

Operators with spin carry the corresponding finite-dimensional rotation or Lorentz matrices. The subsequent chapters derive these transformation laws from stress-tensor charges.

56.7 Ising Universality as a Fixed-Point Example

The statistical Ising model is a Euclidean lattice model whose microscopic state sum has a finite-dimensional diagonal trace representation. Let $\Lambda \subset \mathbb{Z}^D$ be a finite lattice. At every site $x \in \Lambda$ there is a spin variable $s_x = \pm 1$, represented in diagonal operator notation by

$$V_x = \mathrm{span}\{|\uparrow\rangle_x, |\downarrow\rangle_x\}, \qquad \widetilde{\mathcal{H}}_\Lambda = \bigotimes_{x\in\Lambda} V_x,$$

and by commuting diagonal operators $\widehat{S}_x$ with eigenvalues ± 1. With nearest-neighbor coupling normalized to one,

$$\widetilde{H} = -\sum_{\langle xx'\rangle} \widehat{S}_x \widehat{S}_{x'}.$$

The thermal expectation of an observable $\widehat{O}$ is

$$\langle \widehat{O} \rangle_{\beta_{\mathrm{T}}} = \frac{1}{Z}\,\mathrm{Tr}_{\widetilde{\mathcal{H}}_\Lambda}\left(\mathrm{e}^{-\beta_{\mathrm{T}}\widetilde{H}}\widehat{O}\right), \qquad Z = \mathrm{Tr}_{\widetilde{\mathcal{H}}_\Lambda}\,\mathrm{e}^{-\beta_{\mathrm{T}}\widetilde{H}}, \qquad \beta_{\mathrm{T}} = \frac{1}{T}. \tag{56.31}$$

The tilde distinguishes the finite-dimensional trace space of the statistical ensemble from the Hilbert space reconstructed from a continuum scaling limit.

Figure 56.1 keeps track of the finite Ising source construction used here: lattice spins, source insertions, and the thermal trace belong to the regulated statistical ensemble before the continuum CFT limit is taken.

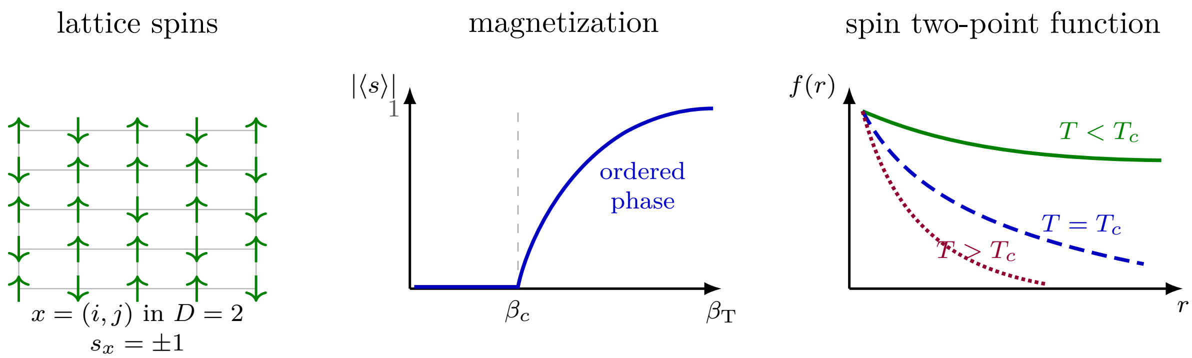

Figure 56.1: The Ising fixed point is reached by tuning the temperature. The finite lattice trace space defines the statistical ensemble, spontaneous magnetization appears for $T < T_c$, and the critical two-point function has power-law decay. In the two-point plot the ordered, critical, and disordered curves are solid, dashed, and dotted respectively.

In $D = 2$, write $S_{N,M}$ for the spin observable at $x = (N, M)$ and set

$$f_{N,M} = \langle S_{0,0} S_{N,M} \rangle_{\beta_{\mathrm{T}}} \simeq f(r), \qquad r = (N^2 + M^2)^{1/2},$$

for $r \gg 1$ and T close to T_c. The long-distance regimes are

$$f(r) \longrightarrow |\langle s \rangle|^2 > 0 \qquad (T < T_c),$$

$$f(r) \sim \mathrm{e}^{-r/\xi(T)} \qquad (T > T_c), \qquad \xi(T) \sim (T - T_c)^{-\nu},$$

and

$$f(r) \sim r^{-2\Delta_\sigma} \qquad (T = T_c). \tag{56.32}$$

The first numerical values to keep in view are

D	Δ_σ	ν
2	$\frac{1}{8}$	1
3	$0.5181488\ldots$	$0.629971\ldots$

where Δ_σ is the scaling dimension of the continuum spin field and ν is the correlation-length exponent.

Remark 56.7 (Numerical provenance in three dimensions). The $D = 3$ entries come from numerical conformal-bootstrap computations. They are obtained by applying crossing symmetry and reflection-positivity constraints to mixed four-point functions of σ, ε, and $T_{\mu\nu}$, followed by finite-dimensional semidefinite relaxations of the resulting bootstrap inequalities and numerical stability tests as the relaxation order changes. In such a computation the assumptions are the existence of a unitary three-dimensional CFT with the $\mathbb{Z}_2$ quantum numbers and operator gaps imposed in the search; the output is a small allowed region for low-lying CFT data. A constructive proof of the lattice scaling limit is a separate theorem. Chapter 64 develops the OPE, reflection-positivity, and crossing equations used by this method, but the present chapter records only the numerical CFT data and their provenance. A recent mixed-correlator computation including the stress tensor gives $\Delta_\sigma = 0.518148806(24)$ and $\Delta_\varepsilon = 1.41262528(29)$ for the leading $\mathbb{Z}_2$-odd and $\mathbb{Z}_2$-even scalar primaries of the critical Ising CFT; using $\Delta_\varepsilon = D - 1/\nu$ at $D = 3$ gives $\nu = 0.629970975\ldots$. The source is Chang, Dommes, Erramilli, Homrich, Kravchuk, Liu, Mitchell, Poland, and Simmons-Duffin, *Bootstrapping the 3d Ising Stress Tensor*, JHEP **03** (2025) 136, arXiv:2411.15300.

Definition 56.8 (Universal scaling functions in the Ising setting)**.** Fix a class $\mathfrak{R}$ of reflection-positive microscopic regulators with $\mathbb{Z}_2$ symmetry, one spinlike relevant direction, and one temperaturelike relevant direction. For each regulator $R \in \mathfrak{R}$, let a_R be the lattice spacing, let p_R denote microscopic couplings near the critical surface, and let $X_A^{(R)}(x)$ be lattice observables whose leading scaling fields are O_A. A separated n-point scaling function is a distributional limit on the configuration space $x_i \neq x_j$ of the form

$$\mathcal{F}_{A_1\ldots A_n}(x_1,\ldots,x_n;s) = \lim_{a_R\to 0}\prod_{i=1}^{n} Z_{A_i}^{(R)} \left\langle X_{A_1}^{(R)}(a_R^{-1}x_1)\cdots X_{A_n}^{(R)}(a_R^{-1}x_n)\right\rangle_{p_R(s)}^{\mathrm{conn}},$$

where $s = (s_t, s_h)$ are fixed continuum scaling coordinates for the thermal and magnetic relevant deformations, and $Z_A^{(R)}$ are multiplicative normalizations of the scaling fields. The scaling function is called universal for $\mathfrak{R}$ when any two regulators in $\mathfrak{R}$ give the same $\mathcal{F}$ after analytic changes of the relevant coordinates $(p_R - p_{R,c}) \mapsto (s_t, s_h)$, multiplicative field normalizations, and subtraction of analytic background terms in the free energy. This definition concerns separated-point kernels and their finite-size or thermodynamic limits. Critical temperatures, lattice metric factors, operator normalizations, analytic free-energy backgrounds, and contact-term extensions are regulator data rather than universal scaling functions.

Conditional consequence of complete CFT data. Assume that a regulator class $\mathfrak{R}$ has a continuum critical limit which is a unitary Euclidean CFT $\mathcal{C}_{\mathrm{Ising}}$, that the lattice spin and energy observables converge to the primary fields σ and ε after the normalizations in Definition 56.8, and that the OPE of $\mathcal{C}_{\mathrm{Ising}}$ converges as a distribution on every separated Euclidean configuration. Then the critical separated-point scaling functions are determined by the complete CFT data of $\mathcal{C}_{\mathrm{Ising}}$: the primary spectrum with spin and $\mathbb{Z}_2$ parity, two-point normalizations, and OPE coefficients.

If, in addition, the relevant deformation

$$S_{\mathcal{C}} \longmapsto S_{\mathcal{C}} + s_t \int \mathrm{d}^D x\, \varepsilon(x) + s_h \int \mathrm{d}^D x\, \sigma(x)$$

is constructed as a continuum source-dependent QFT with a specified renormalized contact-term chart, then the off-critical universal scaling functions in the variables s_t, s_h are the separated connected correlators of this deformed continuum theory. Their short-distance expansion near the critical point is obtained by conformal perturbation theory from the complete CFT data and the chosen deformation scheme. Their global massive scaling functions require the deformed continuum theory itself, because finitely many critical exponents such as Δ_σ and ν do not determine all massive correlation functions.

This paragraph records a conditional consequence of the stated convergence package. The convergence hypothesis is the substantive input: it identifies the critical scaling limit of the normalized lattice observables with the separated-point correlators of $\mathcal{C}_{\text{Ising}}$. The complete CFT data determine those correlators as follows. In a ball of configuration space where x_1 approaches x_2 with all other insertions separated, OPE convergence gives

$$O_{A_1}(x_1)O_{A_2}(x_2) = \sum_B C_{A_1A_2}{}^B(x_{12}, \partial_{x_2})\, O_B(x_2)$$

as an equality of distributions after pairing with test functions supported in that ball. The coefficient distributions $C_{A_1A_2}{}^B$ are fixed by the dimensions, spins, representation labels, two-point normalizations, and OPE coefficients. Iterating the OPE reduces an n-point function on such a configuration-space chart to a convergent sum of two- and three-point tensor structures with the same data. Compatibility of the convergent OPE expansions on overlapping charts is part of the CFT data through associativity/crossing. Hence the critical separated-point kernels are fixed by the complete CFT data.

For the deformed statement, the assumed continuum source-dependent QFT supplies a generating functional $W_{\mathcal{C}}[s_t, s_h; J]$. Its functional derivatives with respect to the sources J^A, restricted to separated points, are precisely the off-critical scaling functions in the chosen normalization and scaling-coordinate chart. Expanding $\exp[-s_t \int \varepsilon - s_h \int \sigma]$ near $s_t = s_h = 0$ expresses the short-distance coefficients as integrated CFT correlators. The specified renormalized contact-term chart is the datum that defines those integrals at coincident integration points. The full finite-s functions are therefore correlators of the relevantly deformed continuum theory.

Remark 56.9 (Status of the three-dimensional Ising scaling functions). For $D = 2$, the conformal data are exact data of the Ising minimal model, and many scaling limits of the planar lattice model are theorem-level objects. For $D = 3$, the statement that the nearest-neighbor Ising model and the scalar $\mathbb{Z}_2$-invariant ϕ^4 regulator class converge to a single unitary Ising CFT with the scaling functions of Definition 56.8 is a mathematically open continuum-limit statement. The numerical values displayed above are bootstrap estimates for the candidate CFT data. The parenthetical uncertainties attached to $\Delta_\sigma = 0.518148806(24)$ and $\Delta_\varepsilon = 1.41262528(29)$ are numerical uncertainties reported by the finite semidefinite bootstrap computation; they are neither convergence rates for the lattice spacing $a_R \to 0$ nor rigorous error bounds for a constructive lattice-to-CFT theorem. If a leading irrelevant exponent $\omega > 0$ and a regulator-dependent coefficient are supplied by a separate RG analysis, one may write corrections of the form $O(a_R^\omega)$ for specified observables, but such a rate is additional data beyond the two numbers in the table.

Remark 56.10 (Existence status in $D \geq 4$). The two-row table above records Ising fixed-point data in $D = 2, 3$. For $D \geq 4$, the existence question separates into the following cases. A free conformal field theory means a local conformal theory generated by fields obeying linear equations of motion whose vacuum correlators satisfy Wick factorization; its local operator space can be large, but its separated connected correlators are fixed by two-point data. A dynamically interacting CFT means a stress-tensor CFT whose separated correlators are not generated by Wick factorization from free conformal sectors and decoupled topological sectors.

There are explicit unitary Gaussian CFTs in $D \geq 4$: the improved massless scalar and massless Dirac field in every allowed integer dimension, and the Maxwell field in $D = 4$. These theories supply exact local conformal data, but they do not supply interacting fixed-point data. The Wilson–Fisher ϵ-expansion near $D = 4$ supplies formal perturbative conformal data at $D = 4 - \epsilon$. For nonintegral D, the usual Hilbert-space positivity condition of an integer-dimensional Lorentzian QFT is not literally available, and the analytic continuation of conformal representation theory contains negative-norm states in generic nonintegral dimension. The ϵ-expansion is therefore a powerful asymptotic computation of local CFT data, not by itself a construction of a unitary CFT at a fixed integer dimension.

For the positive-measure scalar route, four dimensions are also constrained by triviality theorems for critical Ising and ϕ^4_4-type scaling limits: within those hypotheses the continuum limits are Gaussian. This result blocks the simplest scalar construction of an interacting $D = 4$ CFT; it does not classify all possible four-dimensional fixed points. Gauge-theory mechanisms such as Banks–Zaks fixed points and later supersymmetric conformal gauge theories provide physically controlled fixed-point constructions under their own assumptions. In this core CFT volume, any such $D \geq 4$ interacting example is used only after its stress tensor, unitarity/positivity, locality, operator spectrum, and conformal Ward identities have been specified as part of the data. [3]

The same fixed-point basin can be represented by a scalar Euclidean lattice field theory, in the sense of Definition 56.8. Replace the two-valued spin by a real variable ϕ_x, use a $\mathbb{Z}_2$-even double-well single-site potential, and retain the finite Brillouin-zone cutoff. At long distance its action has the form

$$S_{\rm lat}[\phi] = \int \mathrm{d}^D x \left[\frac{1}{2} Z_\phi (\partial_\mu \phi)^2 + V(\phi) + \sum_A c_A \, \mathcal{O}_A^{\rm aniso}(\phi, \partial\phi) \right], \tag{56.33}$$

where the last sum consists of higher-derivative operators allowed by the hypercubic lattice symmetry. These terms display the finite cutoff and the breaking of $SO(D)$ rotations at the microscopic scale.

At $T = T_c$, equivalently at the tuned massless critical point, the correlation length is infinite in lattice units. The separated long-distance correlators are described by the Ising conformal field theory. For $D = 2, 3$, this is the infrared fixed point of the $\mathbb{Z}_2$-invariant massless scalar ϕ^4 fixed-point basin. The continuum fields obey the dictionary

$$\phi \longmapsto \sigma, \qquad [\phi^2] \longmapsto \varepsilon,$$

where σ is the spin field and ε is the thermal energy-density field after identity mixing has been subtracted. The thermal deformation

$$\Delta S_t = \int \mathrm{d}^D x \, u_t \, \varepsilon(x)$$

[3] For nonintegral-dimensional unitarity issues in the Wilson–Fisher expansion, see M. Hogervorst, S. Rychkov, and B. C. van Rees, "Unitarity violation at the Wilson-Fisher fixed point in $4 - \epsilon$ dimensions," arXiv:1512.00013. For four-dimensional scalar triviality, see M. Aizenman and H. Duminil-Copin, "Marginal triviality of the scaling limits of critical 4D Ising and ϕ^4_4 models," *Ann. of Math.* **194** (2021) 163–235. For the perturbative gauge-theory fixed-point mechanism, see T. Banks and A. Zaks, "On the phase structure of vector-like gauge theories with massless fermions," *Nucl. Phys. B* **196** (1982) 189–204.

has RG eigenvalue $y_t = D - \Delta_\varepsilon$. Since $\xi^{-1} \propto |u_t|^{1/y_t}$, comparison with $\xi \propto |T - T_c|^{-\nu}$ gives

$$\Delta_\varepsilon = D - \frac{1}{\nu}. \tag{56.34}$$

Figure 56.2 records the scalar cutoff presentation used to compare the Ising scaling direction with a local continuum field coordinate.

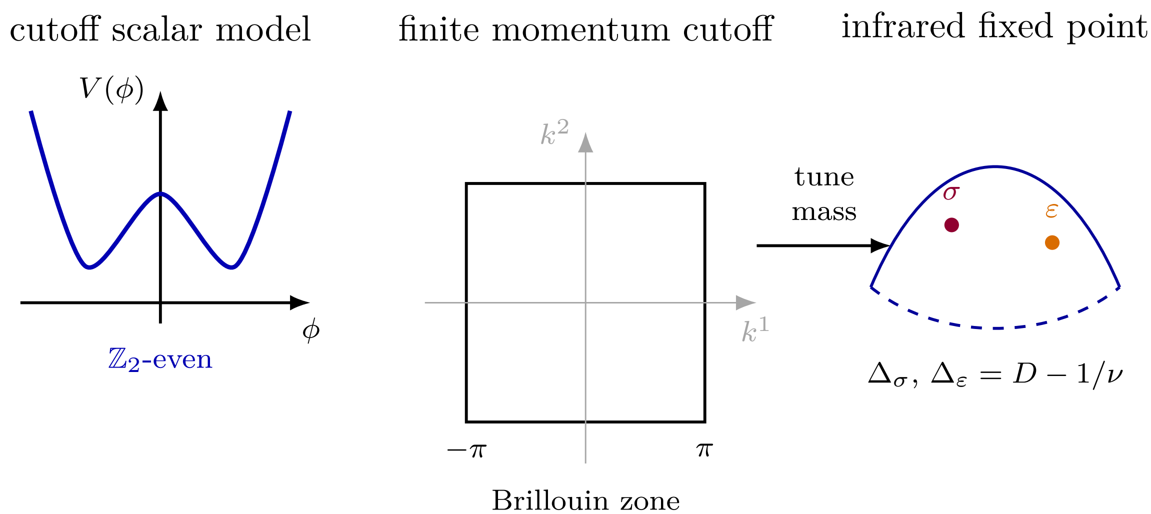

Figure 56.2: The scalar cutoff representation of the Ising fixed-point basin has a finite Brillouin-zone cutoff and lattice anisotropy. At the tuned critical point its long-distance operator data are those of the Ising conformal field theory.

Chapter 57

Conformal Killing Vectors and the Conformal Group

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- **$\hbar$.** 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

57.1 The Conformal Killing Equation

Work first in flat Euclidean space $(\mathbb{R}^D, \delta_{\mu\nu})$ with $D \geq 3$. Cartesian coordinates are denoted by x^μ, and repeated indices are contracted with $\delta_{\mu\nu}$. A smooth vector field $\epsilon^\mu(x)$ generates an infinitesimal coordinate transformation

$$x^\mu \longmapsto x^\mu + \epsilon^\mu(x).$$

Definition 57.1 (Euclidean conformal Killing vector)**.** A smooth vector field $\epsilon = \epsilon^\mu \partial_\mu$ on an open subset of $\mathbb{R}^D$ is a conformal Killing vector when the change of the metric is pointwise proportional to the metric:

$$\mathcal{L}_\epsilon \delta_{\mu\nu} = \partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu = 2\sigma_\epsilon(x)\delta_{\mu\nu}$$

for some scalar function σ_ϵ. Taking the trace gives

$$\sigma_\epsilon(x) = \frac{1}{D}\partial_\rho \epsilon^\rho(x).$$

Thus the conformal Killing equation is

$$\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu - \frac{2}{D}\delta_{\mu\nu}\partial_\rho \epsilon^\rho = 0. \tag{57.1}$$

Conformal current from a traceless stress tensor. Let $T_{\mu\nu}$ be symmetric, conserved, and traceless, and let ϵ obey (57.1). Then

$$J^\mu_\epsilon(x) = T^\mu{}_\nu(x)\epsilon^\nu(x)$$

is conserved. The charge

$$Q_\epsilon(\Sigma) = \int_\Sigma \mathrm{d}\sigma\, n_\mu J^\mu_\epsilon$$

on a closed codimension-one surface Σ depends only on the homology class of Σ relative to operator insertions. The divergence is

$$\partial_\mu J^\mu_\epsilon = (\partial_\mu T^\mu{}_\nu)\epsilon^\nu + T^{\mu\nu}\partial_\mu\epsilon_\nu = \frac{1}{2}T^{\mu\nu}(\partial_\mu\epsilon_\nu + \partial_\nu\epsilon_\mu) = \sigma_\epsilon T^\mu{}_\mu = 0.$$

Conservation makes the charge invariant under deformations of Σ that do not cross operator insertions. After analytic continuation to Lorentzian signature this formula is read on a spacelike Cauchy surface Σ. The measure $\mathrm{d}\sigma$ is the induced spatial volume form, n^μ is the future-directed unit timelike normal, and

$$Q_\epsilon(\Sigma) = \int_\Sigma \mathrm{d}\sigma\, n_\mu T^\mu{}_\nu\epsilon^\nu. \tag{57.2}$$

If Σ_1 and Σ_2 bound a spacetime region V containing no operator insertions, Stokes' theorem gives

$$Q_\epsilon(\Sigma_2) - Q_\epsilon(\Sigma_1) = \int_V \mathrm{d}^D x\, \partial_\mu J^\mu_\epsilon = 0.$$

This is the precise sense in which the charge depends on the homology class of the surface relative to insertions.

Figure 57.1 displays the conserved-charge surface-deformation statement: two spacelike slices homologous relative to the insertions define the same charge.

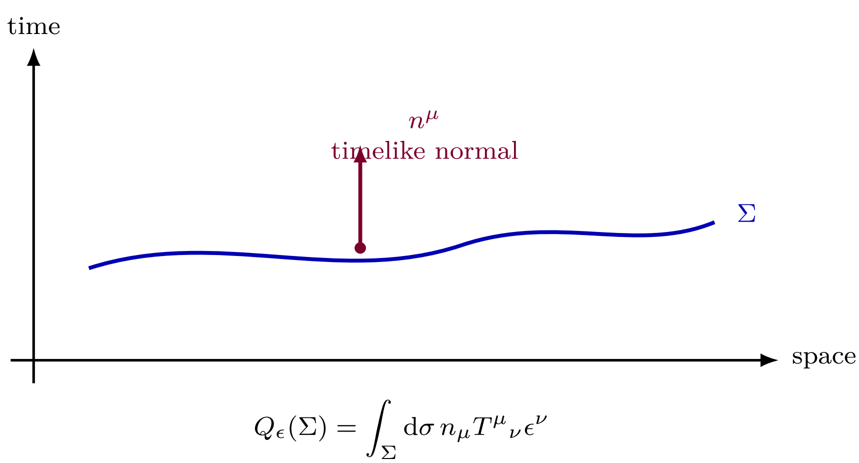

Figure 57.1: The Lorentzian conformal charge is the flux of the stress-tensor current through a spacelike slice. Current conservation and Stokes' theorem give independence under deformations of the slice through empty spacetime.

57.2 Solutions in Dimension at Least Three

Lemma 57.2 (Rigidity of the flat conformal factor)**.** *Let $D \geq 3$, and let ϵ solve the flat conformal Killing equation* (57.1) *on a connected open set. Then*

$$\partial_\mu \partial_\nu \sigma_\epsilon = 0.$$

Consequently σ_ϵ is affine-linear in x.

Proof. The conformal Killing equation is

$$\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu = 2\sigma_\epsilon \delta_{\mu\nu}.$$

Differentiate this identity and combine the three equations obtained by cyclically permuting (μ, ν, ρ). The result is

$$\partial_\mu \partial_\nu \epsilon_\rho = \delta_{\rho\nu} \partial_\mu \sigma_\epsilon + \delta_{\rho\mu} \partial_\nu \sigma_\epsilon - \delta_{\mu\nu} \partial_\rho \sigma_\epsilon. \tag{57.3}$$

Set

$$S_{\mu\nu} := \partial_\mu \partial_\nu \sigma_\epsilon.$$

Since third derivatives of ϵ_ρ commute, differentiating (57.3) with respect to x^κ and then interchanging κ and μ gives

$$\delta_{\rho\mu} S_{\kappa\nu} - \delta_{\mu\nu} S_{\kappa\rho} = \delta_{\rho\kappa} S_{\mu\nu} - \delta_{\kappa\nu} S_{\mu\rho}.$$

Contracting ρ with μ yields

$$(D-2) S_{\kappa\nu} = -\delta_{\kappa\nu} S_\lambda{}^\lambda.$$

Taking the trace gives

$$(2D-2) S_\lambda{}^\lambda = 0.$$

For $D \geq 3$, this implies $S_\lambda{}^\lambda = 0$, and then the preceding display gives $S_{\kappa\nu} = 0$. Thus all second derivatives of σ_ϵ vanish, so σ_ϵ is affine-linear on each connected component. □

Proposition 57.3 (Classification of flat conformal Killing vectors)**.** *For $D \geq 3$, every flat conformal Killing vector is at most quadratic in the Cartesian coordinates. More precisely, the general solution is*

$$\epsilon^\mu(x) = a^\mu + \omega^\mu{}_\nu x^\nu + \lambda x^\mu + c^\mu x^2 - 2(c \cdot x) x^\mu, \tag{57.4}$$

where a^μ, c^μ, and λ are constants and $\omega_{\mu\nu} = -\omega_{\nu\mu}$. These terms generate translations, rotations, dilatations, and special conformal transformations, respectively. Equivalently, the Lorentz and dilatation terms may be combined as $b^\mu{}_\nu x^\nu$, where $b_{\mu\nu}$ is either antisymmetric or proportional to $\delta_{\mu\nu}$.

Proof. By Lemma 57.2,

$$\sigma_\epsilon(x) = \lambda - 2c_\rho x^\rho$$

for constants λ and c_ρ, where the sign of c_ρ is chosen to match (57.4). Substituting this affine form in (57.3) gives

$$\partial_\mu \partial_\nu \epsilon_\rho = -2\delta_{\rho\nu} c_\mu - 2\delta_{\rho\mu} c_\nu + 2\delta_{\mu\nu} c_\rho, \tag{57.5}$$

The quadratic vector field

$$q_\rho(x) := c_\rho x^2 - 2(c \cdot x) x_\rho$$

has exactly the same Hessian,

$$\partial_\mu \partial_\nu q_\rho = -2\delta_{\rho\nu} c_\mu - 2\delta_{\rho\mu} c_\nu + 2\delta_{\mu\nu} c_\rho.$$

Hence $h_\rho := \epsilon_\rho - q_\rho$ has vanishing second derivatives. On a connected coordinate domain this means that each first derivative $\partial_\nu h_\rho$ is a constant $B_{\rho\nu}$, and integrating once more gives

$$\epsilon_\rho(x) = a_\rho + B_{\rho\nu} x^\nu + c_\rho x^2 - 2(c \cdot x) x_\rho. \tag{57.6}$$

This is the only integration step in the classification: the constant Hessian (57.5) leaves only the affine constants a_ρ and $B_{\rho\nu}$ undetermined.

It remains to impose the original first-order equation. The special conformal quadratic part satisfies

$$\partial_\mu q_\nu + \partial_\nu q_\mu = -4(c \cdot x)\delta_{\mu\nu}.$$

The constant term a_ρ contributes nothing. Therefore the symmetric part of $B_{\rho\nu}$ is fixed by the constant part of the conformal Killing equation:

$$B_{\rho\nu} + B_{\nu\rho} = 2\lambda \delta_{\rho\nu}.$$

Writing $B_{\rho\nu} = \omega_{\rho\nu} + \lambda\delta_{\rho\nu}$ with $\omega_{\rho\nu} = -\omega_{\nu\rho}$ gives (57.4).

Conversely, translations and rotations have $\sigma_\epsilon = 0$, the dilatation term λx^μ has $\sigma_\epsilon = \lambda$, and the quadratic term q^μ has $\sigma_\epsilon = -2c \cdot x$. Their sum therefore solves (57.1) with $\sigma_\epsilon = \lambda - 2c \cdot x$. The integration above shows that there are no further smooth local solutions in dimension $D \geq 3$. □

Definition 57.4 (Differential conformal generators)**.** The associated differential operators are

$$P_\mu = \partial_\mu, \qquad M_{\mu\nu} = x_\mu \partial_\nu - x_\nu \partial_\mu, \qquad D = x^\mu \partial_\mu, \tag{57.7}$$

and

$$K_\mu = x^2 \partial_\mu - 2x_\mu x^\rho \partial_\rho. \tag{57.8}$$

The signs in (57.8) are chosen so that the finite special conformal transformation below has parameter c^μ with denominator $1 + 2c \cdot x + c^2 x^2$.

Figure 57.2 makes explicit the finite-dimensional basis of conformal Killing fields in $D \geq 3$, including the dimension count that fails in the local $D = 2$ conformal problem treated later.

family	parameter	dimension	vector field $\epsilon = \epsilon^\mu \partial_\mu$	charge basis
translations	$a^\mu \in \mathbb{R}^D$	D	$\epsilon^\mu = a^\mu$	P_μ
rotations	$\omega_{\mu\nu} = -\omega_{\nu\mu}$	$D(D-1)/2$	$\epsilon^\mu = \omega^\mu{}_\nu x^\nu$	$M_{\mu\nu}$
dilatations	$\lambda \in \mathbb{R}$	1	$\epsilon^\mu = \lambda x^\mu$	D
special conformal	$c^\mu \in \mathbb{R}^D$	D	$\epsilon^\mu = c^\mu x^2 - 2(c \cdot x)x^\mu$	K_μ
total for $D \geq 3$		$(D+1)(D+2)/2$	the finite-dimensional Lie algebra generated by $P_\mu, M_{\mu\nu}, D, K_\mu$, isomorphic to $\mathfrak{so}(D+1, 1)$ in Euclidean signature	

Figure 57.2: The rigidity theorem for $D \geq 3$ leaves exactly $D + D(D-1)/2 + 1 + D = (D+1)(D+2)/2$ independent conformal Killing fields. The stress tensor pairs each vector field with the corresponding conserved charge $Q_\epsilon = \int_\Sigma \mathrm{d}\sigma\, n_\mu T^\mu{}_\nu \epsilon^\nu$. In $D = 2$, local holomorphic and antiholomorphic solutions replace this finite list, which is why the two-dimensional case is separated from the present chapter.

57.3 Charges and Vector Fields

Convention 57.5 (Charge sign convention)**.** Let $U_\epsilon(s)$ denote the one-parameter unitary family generated by Q_ϵ:

$$U_\epsilon(s) = \exp(\mathrm{i}sQ_\epsilon).$$

The normalization of Q_ϵ is fixed by translations and Lorentz transformations, whose charges are already part of the Poincare representation of the QFT. With this normalization, infinitesimal coordinate transformations compose through the ordinary Lie bracket of vector fields,

$$[\epsilon_1, \epsilon_2]^\mu = \epsilon_1^\nu \partial_\nu \epsilon_2^\mu - \epsilon_2^\nu \partial_\nu \epsilon_1^\mu. \tag{57.9}$$

Charge algebra from the vector-field bracket. Assume the charges Q_ϵ are represented on a common invariant domain and that no Schwinger contact term contributes to the finite-dimensional global conformal algebra. Then

$$[Q_{\epsilon_1}, Q_{\epsilon_2}] = -\mathrm{i}Q_{[\epsilon_1,\epsilon_2]}. \tag{57.10}$$

On local operators inserted away from the integration surfaces, the commutator of the two infinitesimal coordinate transformations is the infinitesimal transformation generated by the vector-field bracket (57.9). The sign in the charge commutator is fixed by $U_\epsilon(s) = \exp(\mathrm{i}sQ_\epsilon)$: the group commutator at order $s_1 s_2$ is generated by $-[Q_{\epsilon_1}, Q_{\epsilon_2}]$, whereas the geometric commutator is generated by $Q_{[\epsilon_1,\epsilon_2]}$. A possible discrepancy is a central local contact term; by hypothesis it is absent in the global algebra. Equation (57.10) is an operator statement on a common invariant domain, or equivalently a Ward identity for correlation functions with separated insertions. Possible central extensions or Schwinger terms are local contact terms; in dimensions $D \geq 3$ the global finite-dimensional conformal algebra has no central extension.

57.4 Finite Transformations

Definition 57.6 (Finite Euclidean conformal map)**.** A finite conformal transformation is a diffeomorphism

$$f : \mathbb{R}^D \supset U \longrightarrow f(U) \subset \mathbb{R}^D$$

whose Jacobian satisfies

$$\frac{\partial f^\rho}{\partial x^\mu}\frac{\partial f^\sigma}{\partial x^\nu}\delta_{\rho\sigma} = \Omega_f(x)^2 \delta_{\mu\nu}, \qquad \Omega_f(x) > 0. \tag{57.11}$$

For a transformation close to the identity,

$$f^\mu(x) = x^\mu + \epsilon^\mu(x) + O(\epsilon^2),$$

condition (57.11) reduces at first order to the conformal Killing equation (57.1). If f and h satisfy (57.11), then their composition satisfies it with Weyl factor

$$\Omega_{h\circ f}(x) = \Omega_h(f(x))\Omega_f(x).$$

Thus finite conformal maps form a group wherever the composed maps are defined. Expanding (57.11) to first order gives

$$\partial_\mu \epsilon_\nu + \partial_\nu \epsilon_\mu = 2\,\delta\Omega(x)\,\delta_{\mu\nu}.$$

Taking the trace fixes $\delta\Omega = D^{-1}\partial_\rho \epsilon^\rho$, hence (57.1). For composition, the chain rule gives the product of the two Jacobians, so the Weyl factor of $h \circ f$ is $\Omega_h(f(x))\Omega_f(x)$.

Translations, rotations, and dilatations are immediate examples. A further basic example is inversion,

$$I(x)^\mu = \frac{x^\mu}{x^2}, \qquad x^2 = \delta_{\mu\nu} x^\mu x^\nu. \tag{57.12}$$

Its Jacobian is

$$\frac{\partial I^\mu}{\partial x^\nu} = \frac{1}{x^2}\left(\delta^\mu{}_\nu - 2\frac{x^\mu x_\nu}{x^2}\right),$$

and the matrix in parentheses is orthogonal. Therefore

$$\Omega_I(x) = \frac{1}{x^2}.$$

Inversion is conformal but lies in a disconnected component of the full Euclidean conformal group: it cannot be reached by exponentiating a smooth path of conformal Killing vectors from the identity. The Jacobian is $1/x^2$ times $\delta^\mu{}_\nu - 2x^\mu x_\nu/x^2$. The latter matrix is an orthogonal reflection, so the pullback metric is $x^{-4}\delta_{\mu\nu}$, with Weyl factor $\Omega_I = 1/x^2$. Its determinant is $-|x|^{-2D}$, because the reflection has determinant -1. Thus inversion is orientation reversing on the stereographic chart, while every path starting at the identity through smooth conformal diffeomorphisms remains orientation-preserving until a singularity is reached. Hence inversion is not in the identity component generated by smooth conformal Killing vector flows.

Figure 57.3 fixes the inversion geometry: the unit sphere is mapped to itself, radial direction is reversed, and the Weyl factor is $\Omega_I = 1/x^2$.

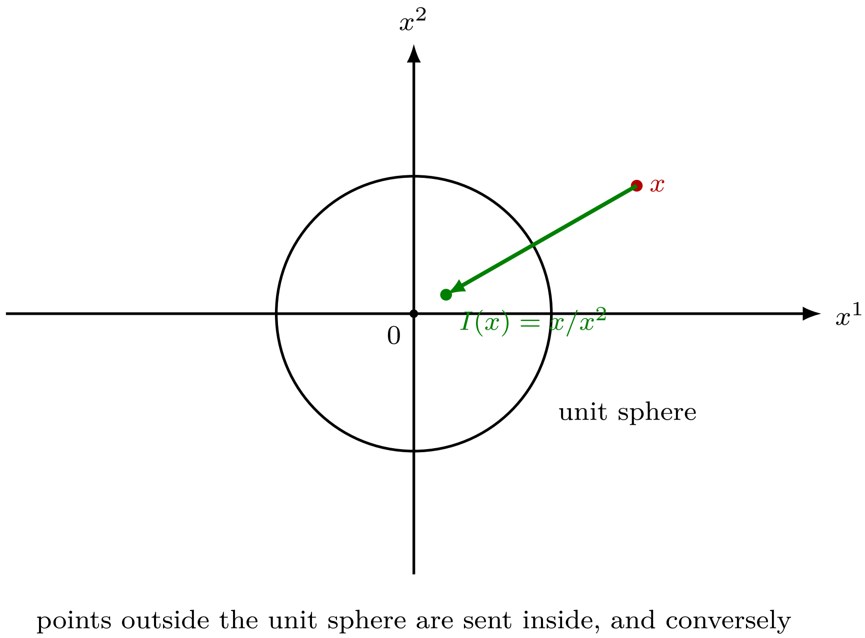

Figure 57.3: Euclidean inversion maps each ray through the origin to itself and sends the radial coordinate $r = |x|$ to $1/r$.

Special conformal transformations from inversion. The composition $I \circ T_c \circ I$, with $T_c(x) = x + c$, gives the special conformal transformation

$$x^\mu \longmapsto x'^\mu = \frac{x^\mu + c^\mu x^2}{1 + 2c \cdot x + c^2 x^2}. \tag{57.13}$$

Its infinitesimal vector field is the quadratic term in (57.4). Substituting $I(x) = x/x^2$, translating by c, and inverting once more gives

$$I(T_c(I(x)))^\mu = \frac{x^\mu + c^\mu x^2}{1 + 2c \cdot x + c^2 x^2}.$$

Expanding to first order in c gives $\delta x^\mu = c^\mu x^2 - 2(c \cdot x)x^\mu$.

The Poincare transformations, dilatations, and inversion generate all finite conformal transformations in $D > 2$, after restricting to domains on which the rational maps are defined.

57.5 Euclidean Compactification and the Radial Cylinder

Definition 57.7 (Euclidean conformal compactification)**.** The rational formulae above are local expressions for globally defined maps on the conformal compactification. The Euclidean compactification is the one-point compactification

$$\widehat{\mathbb{R}^D} = \mathbb{R}^D \cup \{\infty\} \simeq S^D.$$

In stereographic coordinates $x^\mu \in \mathbb{R}^D$, the unit sphere

$$S^D = \{N \in \mathbb{R}^{D+1} : N \cdot N = 1\}$$

is parametrized away from one pole by

$$N^\mu = \frac{2x^\mu}{1+x^2}, \qquad N^{D+1} = \frac{1-x^2}{1+x^2}, \qquad x^2 = \delta_{\mu\nu} x^\mu x^\nu. \tag{57.14}$$

The pullback of the round metric is

$$\mathrm{d}s^2_{S^D} = \frac{4\,\delta_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu}{(1+x^2)^2}. \tag{57.15}$$

Thus the flat metric and the round metric are in the same conformal class on the stereographic chart. The point $x = \infty$ is the omitted pole.

Theorem 57.8 (Finite Liouville rigidity for $D \geq 3$)**.** *Let $D \geq 3$, let $U, V \subset \mathbb{R}^D$ be connected open sets, and let $f : U \to V$ be a smooth diffeomorphism satisfying*

$$f^*\delta = \Omega_f^2 \delta, \qquad \Omega_f > 0.$$

Then f is the restriction to U of a Mobius transformation. More explicitly, after writing $I_p(x) = p + (x-p)/|x-p|^2$, either

$$f(x) = b + sRx$$

or

$$f(x) = b + sRI_p(x),$$

where $b, p \in \mathbb{R}^D$, $s > 0$, and $R \in O(D)$. Consequently the smooth finite conformal transformations in dimension $D \geq 3$ are generated, on their domains of definition, by translations, orthogonal transformations, positive dilatations, and inversion.

Proof. Write $\Omega_f = e^\varphi$. Let

$$F_i{}^\alpha = \partial_i f^\alpha, \qquad g_{ij} = F_i{}^\alpha F_j{}^\alpha = e^{2\varphi}\delta_{ij}.$$

The map $f : (U, g) \to (V, \delta)$ is a local isometry. Since the Euclidean connection on V has zero Christoffel symbols in the Cartesian coordinates f^α, the coordinate functions satisfy

$$\partial_i \partial_j f^\alpha = \Gamma^k{}_{ij}(g)\,\partial_k f^\alpha, \qquad \Gamma^k{}_{ij}(g) = \delta^k{}_i \partial_j \varphi + \delta^k{}_j \partial_i \varphi - \delta_{ij}\partial^k \varphi. \tag{57.16}$$

This is just the coordinate expression for preservation of the Levi-Civita connection by a local isometry.

The pullback metric $g = f^*\delta$ is flat. Equivalently, commuting the mixed third derivatives in (57.16) gives zero curvature for the connection $\Gamma(g)$. Direct substitution of the displayed Christoffel symbols gives

$$R_{ijk\ell}(g) = e^{2\varphi}\left(\delta_{i\ell}A_{jk} + \delta_{jk}A_{i\ell} - \delta_{ik}A_{j\ell} - \delta_{j\ell}A_{ik}\right), \tag{57.17}$$

where

$$A_{ij} = \partial_i \partial_j \varphi - \partial_i \varphi\, \partial_j \varphi + \frac{1}{2}|\nabla \varphi|^2 \delta_{ij}. \tag{57.18}$$

Because $R_{ijk\ell}(g) = 0$, contraction of i with ℓ in (57.17) yields

$$(D-2)A_{jk} + \delta_{jk}A_i{}^i = 0.$$

Taking the trace gives $(2D-2)A_i{}^i = 0$. Since $D \geq 3$, it follows that $A_i{}^i = 0$, hence $A_{jk} = 0$. Thus

$$\partial_i\partial_j\varphi = \partial_i\varphi\,\partial_j\varphi - \frac{1}{2}|\nabla\varphi|^2\delta_{ij}. \tag{57.19}$$

Set $q = e^{-\varphi} = \Omega_f^{-1}$. Differentiating q twice and using (57.19) gives

$$\partial_i\partial_j q = \rho\,\delta_{ij}, \qquad \rho = \frac{1}{2}q|\nabla\varphi|^2. \tag{57.20}$$

The left side has symmetric third derivatives, so

$$\partial_k\rho\,\delta_{ij} = \partial_j\rho\,\delta_{ik}.$$

Contracting i and j gives $(D-1)\partial_k\rho = 0$, hence ρ is constant on the connected set U. Therefore

$$q(x) = \alpha|x|^2 + \beta\cdot x + \gamma \tag{57.21}$$

for constants $\alpha, \gamma \in \mathbb{R}$ and $\beta \in \mathbb{R}^D$. Substitution of (57.21) back into (57.20), now in the form

$$\partial_i\partial_j q = \frac{|\nabla q|^2}{2q}\delta_{ij},$$

gives

$$4\alpha\gamma = |\beta|^2. \tag{57.22}$$

There are two cases. If $\alpha = 0$, then (57.22) gives $\beta = 0$, so $q = \gamma > 0$ is constant. Equation (57.16) has zero right side, hence $\partial_i\partial_j f^\alpha = 0$. Thus $f(x) = b + Ax$, and the conformal condition gives $A^TA = \gamma^{-2}\mathbf{1}$. Hence $A = sR$, with $s = \gamma^{-1} > 0$ and $R \in O(D)$.

If $\alpha \neq 0$, completing the square in (57.21) and using (57.22) gives

$$q(x) = \alpha|x-p|^2, \qquad p = -\frac{\beta}{2\alpha}.$$

Since $q > 0$ on U, one has $\alpha > 0$ and $p \notin U$. The inversion $I_p(x) = p + (x-p)/|x-p|^2$ maps U diffeomorphically to a connected open set. For $h = f \circ I_p$, the Weyl factor is

$$\Omega_h(z) = \Omega_f(I_p(z))\,\Omega_{I_p}(z) = \frac{|z-p|^2}{\alpha}\frac{1}{|z-p|^2} = \alpha^{-1}.$$

The previous constant-factor case applies to h, so

$$h(z) = b + \alpha^{-1}Rz$$

for some $b \in \mathbb{R}^D$ and $R \in O(D)$. Composing again with the involution I_p gives $f(x) = b + \alpha^{-1}RI_p(x)$.

The displayed forms are precisely compositions of translations, orthogonal maps, positive dilatations, and inversion. They extend to smooth maps of the one-point compactification $S^D = \mathbb{R}^D \cup \{\infty\}$: the pole p of I_p is sent to ∞, and ∞ is sent to an ordinary point. Thus the apparent singular denominators in flat coordinates are chart singularities on the compactification. The orientation-preserving connected component is generated by translations, rotations, positive dilatations, and special conformal transformations $I \circ T_c \circ I$; in the Euclidean ambient null-cone model this is the projective action of $SO_0(D+1,1)$. □

The radial cylinder used in radial quantization is the same compactification seen in a different conformal frame. On $\mathbb{R}^D \setminus \{0\}$, write

$$x^\mu = r n^\mu, \qquad r > 0, \qquad n \in S^{D-1}, \qquad \tau = \log r.$$

Then

$$\delta_{\mu\nu} \mathrm{d}x^\mu \mathrm{d}x^\nu = \mathrm{e}^{2\tau} \left(\mathrm{d}\tau^2 + \mathrm{d}\Omega_{D-1}^2 \right). \tag{57.23}$$

After the Weyl rescaling by r^{-2}, punctured flat space becomes the Euclidean cylinder $\mathbb{R}_\tau \times S^{D-1}$. The origin and infinity are the two ends $\tau = -\infty$ and $\tau = +\infty$. Inversion acts by

$$r \mapsto r^{-1}, \qquad \tau \mapsto -\tau, \qquad n \mapsto n.$$

Consequently the cylinder appearing in radial quantization is a Weyl representative of $\widehat{\mathbb{R}^D} \setminus \{0, \infty\}$, and radial time translations are ordinary dilatations in the flat stereographic chart. Substituting $x^\mu = e^\tau n^\mu$, with $n \cdot n = 1$, into the flat metric gives (57.23). Multiplication by $r^{-2} = e^{-2\tau}$ removes the Weyl factor and leaves the product cylinder metric. The inversion $x \mapsto x/x^2$ sends r to r^{-1}, hence τ to $-\tau$, and the flat-space dilatation flow is precisely translation in τ.

57.6 The Conformal Algebra

Lemma 57.9 (Euclidean conformal charge algebra)**.** *Let the quantum charges associated with the vector fields* (57.7) *and* (57.8) *be denoted by*

$$\widehat{P}_\mu, \qquad \widehat{J}_{\mu\nu}, \qquad \widehat{D}, \qquad \widehat{K}_\mu.$$

Their commutators are the charge realization of the Lie bracket of conformal Killing vector fields. In the Euclidean convention of this chapter, indices are contracted with $\delta_{\mu\nu}$, and the algebra is

$$[\widehat{D}, \widehat{P}_\mu] = \mathrm{i}\widehat{P}_\mu, \qquad [\widehat{D}, \widehat{K}_\mu] = -\mathrm{i}\widehat{K}_\mu, \qquad [\widehat{D}, \widehat{J}_{\mu\nu}] = 0, \tag{57.24}$$

$$[\widehat{P}_\mu, \widehat{K}_\nu] = 2\mathrm{i}(\delta_{\mu\nu}\widehat{D} - \widehat{J}_{\mu\nu}), \tag{57.25}$$

together with the Poincare commutators

$$[\widehat{J}_{\mu\nu}, \widehat{P}_\rho] = \mathrm{i}(\delta_{\rho\mu}\widehat{P}_\nu - \delta_{\rho\nu}\widehat{P}_\mu), \tag{57.26}$$

$$[\widehat{J}_{\mu\nu}, \widehat{J}_{\rho\sigma}] = \mathrm{i}(\delta_{\mu\rho}\widehat{J}_{\nu\sigma} - \delta_{\nu\rho}\widehat{J}_{\mu\sigma} - \delta_{\mu\sigma}\widehat{J}_{\nu\rho} + \delta_{\nu\sigma}\widehat{J}_{\mu\rho}). \tag{57.27}$$

All unlisted commutators among the $\widehat{P}_\mu$'s and among the $\widehat{K}_\mu$'s vanish.

Proof. The vector fields in Definition 57.4 obey ordinary Lie brackets. Since $D = x^\rho \partial_\rho$, $P_\mu = \partial_\mu$, and

$$K_\nu = x^2 \partial_\nu - 2x_\nu x^\rho \partial_\rho,$$

one computes on coordinate functions, hence on all smooth functions, that

$$[D, P_\mu] = -P_\mu, \qquad [D, K_\mu] = K_\mu.$$

For the mixed bracket,

$$\begin{aligned} [P_\mu, K_\nu] &= \partial_\mu(x^2)\partial_\nu - 2\partial_\mu(x_\nu x^\rho)\partial_\rho \\ &= 2x_\mu \partial_\nu - 2\delta_{\mu\nu} x^\rho \partial_\rho - 2x_\nu \partial_\mu \\ &= 2M_{\mu\nu} - 2\delta_{\mu\nu} D. \end{aligned}$$

The rotation brackets follow from

$$M_{\mu\nu} = x_\mu \partial_\nu - x_\nu \partial_\mu$$

and the same coefficient differentiation:

$$[M_{\mu\nu}, P_\rho] = \delta_{\rho\nu} P_\mu - \delta_{\rho\mu} P_\nu,$$
$$[M_{\mu\nu}, M_{\rho\sigma}] = \delta_{\nu\rho} M_{\mu\sigma} - \delta_{\mu\rho} M_{\nu\sigma} - \delta_{\nu\sigma} M_{\mu\rho} + \delta_{\mu\sigma} M_{\nu\rho}.$$

Finally $[P_\mu, P_\nu] = 0$. The fields K_μ are obtained from translations by conjugation with inversion, or by direct coefficient differentiation, so $[K_\mu, K_\nu] = 0$. Applying (57.10) converts these vector-field brackets into the displayed charge commutators. In particular $[P_\mu, K_\nu] = 2M_{\mu\nu} - 2\delta_{\mu\nu} D$ becomes $[\,\widehat{P}_\mu, \widehat{K}_\nu\,] = 2\mathrm{i}(\delta_{\mu\nu} \widehat{D} - \widehat{J}_{\mu\nu})$. □

The Euclidean conformal algebra is isomorphic to $\mathfrak{so}(D+1,1)$. Introduce indices

$$A, B = -1, 0, 1, \ldots, D$$

and a metric

$$\eta^{(D+1,1)}_{AB} = \mathrm{diag}(-1, +1, \ldots, +1),$$

where the negative entry is the (-1)-direction. The generators $\widehat{\mathcal{J}}_{AB} = -\widehat{\mathcal{J}}_{BA}$ are related to the conformal generators by

$$\widehat{\mathcal{J}}_{\mu\nu} = \widehat{J}_{\mu\nu}, \qquad \widehat{\mathcal{J}}_{0,-1} = \widehat{D}, \qquad \widehat{\mathcal{J}}_{0,\mu} = \frac{1}{2}(\widehat{P}_\mu - \widehat{K}_\mu), \qquad \widehat{\mathcal{J}}_{-1,\mu} = \frac{1}{2}(\widehat{P}_\mu + \widehat{K}_\mu).$$

Then

$$[\widehat{\mathcal{J}}_{AB}, \widehat{\mathcal{J}}_{CD}] = \mathrm{i}(\eta^{(D+1,1)}_{AC} \widehat{\mathcal{J}}_{BD} - \eta^{(D+1,1)}_{BC} \widehat{\mathcal{J}}_{AD} - \eta^{(D+1,1)}_{AD} \widehat{\mathcal{J}}_{BC} + \eta^{(D+1,1)}_{BD} \widehat{\mathcal{J}}_{AC}).$$

The displayed change of basis is invertible. Substituting it into Lemma 57.9 gives the $\mathfrak{so}(D+1,1)$ commutator: relations with only μ, ν indices are the rotation algebra, relations involving $0, -1$ reproduce the dilatation commutators, and the mixed relations reproduce (57.25). Since the basis change is invertible, this identifies the Lie algebras. The Lorentzian conformal algebra is obtained by analytic continuation of one physical coordinate and has real form $\mathfrak{so}(D,2)$; it is not the real form used in the Euclidean derivation above.

57.7 The Lorentzian Conformal Group and Its Cover

The preceding algebra statement does not by itself identify the group that acts on a Lorentzian Hilbert space. Let

$$M = \mathbb{R}^{1,D-1}, \qquad \eta^{\mathrm{L}}_{\mu\nu} = \mathrm{diag}(-1, +1, \ldots, +1), \qquad x^2 = \eta^{\mathrm{L}}_{\mu\nu} x^\mu x^\nu.$$

Introduce an ambient vector space

$$\mathbb{R}^{D,2} = \mathbb{R}X^+ \oplus \mathbb{R}X^- \oplus \mathbb{R}^{1,D-1}$$

with bilinear form

$$X \cdot Y = \eta^{\mathrm{L}}_{\mu\nu} X^\mu Y^\nu - \frac{1}{2}(X^+ Y^- + X^- Y^+). \tag{57.28}$$

Thus $X \cdot X = \eta^{\mathrm{L}}_{\mu\nu} X^\mu X^\nu - X^+ X^-$, and the form has signature $(D, 2)$. The conformal compactification of Minkowski space is the projective null cone

$$\overline{M} = \{X \in \mathbb{R}^{D,2} \setminus \{0\} : X \cdot X = 0\}/\mathbb{R}^\times. \tag{57.29}$$

Definition 57.10 (Lorentzian conformal compactification)**.** The compactified Lorentzian spacetime $\overline{M}$ is the projective null cone (57.29) in $\mathbb{R}^{D,2}$. The Poincare patch is the affine chart $X^+ \neq 0$.

The Poincare patch $X^+ \neq 0$ is identified with M by choosing the representative

$$X^+ = 1, \qquad X^\mu = x^\mu, \qquad X^- = x^2. \tag{57.30}$$

The null condition follows immediately from (57.28). Points with $X^+ = 0$ are the conformal boundary of this patch.

The same compactification is the Einstein cylinder. Write

$$x^\mu = (t, r\omega), \qquad r \geq 0, \qquad \omega \in S^{D-2},$$

and introduce null coordinates $u = t - r$, $v = t + r$. On the Poincare patch set

$$u = \tan\frac{T-\chi}{2}, \qquad v = \tan\frac{T+\chi}{2}, \qquad 0 \leq \chi \leq \pi.$$

Then

$$\eta^{\mathrm{L}}_{\mu\nu}\mathrm{d}x^\mu\mathrm{d}x^\nu = \Omega_{\mathrm{cyl}}(T,\chi)^{-2}\left(-\mathrm{d}T^2 + \mathrm{d}\chi^2 + \sin^2\chi\,\mathrm{d}\Omega^2_{D-2}\right), \tag{57.31}$$

where

$$\Omega_{\mathrm{cyl}}(T,\chi) = 2\cos\frac{T-\chi}{2}\cos\frac{T+\chi}{2}. \tag{57.32}$$

The metric in parentheses is the metric on $\mathbb{R}_T \times S^{D-1}$, the universal cover of the Lorentzian conformal compactification. The projective compactification (57.29) is obtained from $S^1_T \times S^{D-1}$ by the antipodal projective identification $(T, n) \sim (T + \pi, -n)$. Thus local Lorentzian conformal transformations are restrictions to a Poincare chart of diffeomorphisms of the compactified space, and their Hilbert-space action is naturally lifted to the cylinder cover $\mathbb{R}_T \times S^{D-1}$. The coordinate substitution $u = \tan((T-\chi)/2)$ and $v = \tan((T+\chi)/2)$ converts the Minkowski line element into (57.31); the trigonometric denominator is the Weyl factor (57.32). Periodic cylinder time gives the projective compactification with the antipodal identification displayed above, while the Hilbert-space representation uses the universal cover in the T-direction.

Definition 57.11 (Projective Lorentzian conformal group)**.** The group $O(D, 2)$ acts linearly on $\mathbb{R}^{D,2}$, preserves the null cone, and therefore acts on $\overline{M}$. Scalar matrices act trivially after projectivization, so the spacetime conformal transformations in the identity component are described by the projective group

$$G^{\mathrm{Lor}}_{\mathrm{conf}} = PO_0(D, 2), \tag{57.33}$$

the identity component of the projective orthogonal group. Equivalently, one may start from $SO_0(D, 2)$ and quotient by the finite central subgroup that acts trivially on projective null lines. The Lie algebra of $G^{\mathrm{Lor}}_{\mathrm{conf}}$ is $\mathfrak{so}(D, 2)$.

The standard finite transformations on the Poincare patch are restrictions of linear ambient transformations. Lorentz transformations $\Lambda \in SO_0(1, D-1)$ act by

$$X^\mu \mapsto \Lambda^\mu{}_\nu X^\nu, \qquad X^\pm \mapsto X^\pm.$$

Translations by a^μ act by

$$X^+ \mapsto X^+, \qquad X^\mu \mapsto X^\mu + a^\mu X^+, \qquad X^- \mapsto X^- + 2a\cdot X + a^2 X^+, \tag{57.34}$$

where $a \cdot X = \eta^{\mathrm{L}}_{\mu\nu} a^\mu X^\nu$. Dilatations with parameter λ act by

$$X^+ \mapsto e^{-\lambda} X^+, \qquad X^- \mapsto e^{\lambda} X^-, \qquad X^\mu \mapsto X^\mu, \tag{57.35}$$

which becomes $x^\mu \mapsto e^\lambda x^\mu$ after rescaling back to $X^+ = 1$. Special conformal transformations with parameter c^μ act by

$$X^- \mapsto X^-, \qquad X^\mu \mapsto X^\mu + c^\mu X^-, \qquad X^+ \mapsto X^+ + 2c \cdot X + c^2 X^-. \tag{57.36}$$

On the patch $X^+ = 1$, this gives

$$x^\mu \longmapsto \frac{x^\mu + c^\mu x^2}{1 + 2c \cdot x + c^2 x^2}, \tag{57.37}$$

where the transformation is read locally whenever the denominator is nonzero, and globally as a map of the compactification (57.29). These formulae show explicitly how the infinitesimal generators integrate to the connected projective conformal group. Each displayed ambient transformation preserves the bilinear form (57.28), hence preserves the null cone and its projectivization. On the affine chart $X^+ = 1$, divide the transformed representative by its new X^+-component. This gives translations, dilatations, Lorentz rotations, and (57.37) for special conformal transformations. Differentiating at the identity recovers the Lorentzian real form of the conformal Killing generators.

Definition 57.12 (Hilbert-space conformal group)**.** For Hilbert-space representation theory, the projective spacetime group is still not the final object. Let

$$\widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}} \longrightarrow G^{\mathrm{Lor}}_{\mathrm{conf}} \tag{57.38}$$

be the universal covering group. A unitary Lorentzian CFT carries a strongly continuous unitary representation

$$U : \widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}} \longrightarrow \mathcal{U}(\mathcal{H})$$

whose derived representation gives the self-adjoint conformal charges on a common invariant finite-energy domain. The need for the cover is not a minor global convention. The maximal compact subalgebra of $\mathfrak{so}(D,2)$ is $\mathfrak{so}(D) \oplus \mathfrak{so}(2)$. In the universal cover its corresponding subgroup is covered by

$$\mathrm{Spin}(D) \times \mathbb{R}, \tag{57.39}$$

where the $\mathbb{R}$ factor is generated by Lorentzian cylinder time. Under radial quantization this generator is the nonnegative cylinder Hamiltonian D_{rad}, and

$$U_{\mathrm{cyl}}(t) = \exp(-\mathrm{i} t D_{\mathrm{rad}}). \tag{57.40}$$

If one forced the representation to descend to the finite group with an $SO(2)$ cylinder-time factor, the operator $\exp(-2\pi \mathrm{i} D_{\mathrm{rad}})$ would have to be the identity. This would impose integrality of every scaling dimension in that Hilbert-space sector. A sector containing a nonintegral scaling dimension therefore cannot descend to the $SO(2)$ quotient. Spinorial local operators similarly require the spin cover of spatial rotations. Thus later references to the Lorentzian conformal group acting on the Hilbert space mean the universal cover $\widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}}$; its projection to $G^{\mathrm{Lor}}_{\mathrm{conf}}$ is the group acting on compactified spacetime points. The $\mathbb{R}$ factor in (57.39) covers the $SO(2)$ cylinder-time circle. A representation descends to the quotient by the 2π-translation kernel precisely when $\exp(-2\pi \mathrm{i} D_{\mathrm{rad}}) = 1$. If $D_{\mathrm{rad}} \psi = \Delta \psi$, this condition gives $\exp(-2\pi \mathrm{i} \Delta) = 1$. Thus every scaling dimension in the sector must be integral. A sector with any nonintegral Δ fails this descent condition, and spinorial sectors similarly require the spin cover of rotations.

Definition 57.13 (Local primary state)**.** The vacuum vector is invariant under $\widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}}$. A local primary state is a lowest energy vector for the $\mathbb{R}$-generator in (57.39), transforms in a finite-dimensional unitary representation of $\mathrm{Spin}(D)$, and generates a positive-energy module by the action of the noncompact translation generators. This is the group-theoretic meaning of the radial primary conditions used in later chapters.

57.8 Representation-Theoretic Conventions

The same Lie algebra appears in several representation-theoretic roles, and the distinctions matter. The Euclidean conformal group

$$G_E = SO_0(D+1,1)$$

acts on the compactified Euclidean sphere S^D, or through a chosen cover when spin structures are present.

Stabilizer of a Euclidean point. Fix the point $x=0$ in the flat chart of S^D. Its stabilizer in the identity component of the Euclidean conformal group has Lie algebra

$$\mathfrak{p}_E = \mathfrak{so}(D) \oplus \mathbb{R}D \oplus \mathrm{span}\{K_\mu\}.$$

Equivalently, at the group level and in the chosen chart, it is generated by rotations, positive dilatations, and special conformal transformations. Its Levi factor is $SO(D) \times \mathbb{R}_+$, and the special conformal transformations form the nilpotent radical. Translations do not fix the origin unless their parameter is zero. A rotation and a positive dilatation fix $x=0$ and act on the tangent space by λR, with $R \in SO(D)$ and $\lambda > 0$. The finite special conformal transformation

$$x^\mu \mapsto \frac{x^\mu + c^\mu x^2}{1 + 2c\cdot x + c^2 x^2}$$

also fixes $x=0$, and its derivative at $x=0$ is the identity; hence its generator lies in the nilpotent radical of the stabilizer. The infinitesimal classification in Proposition 57.3 shows that these exhaust the conformal Killing vectors vanishing at the origin. Thus the stabilizer has the displayed Lie algebra and Levi/nilpotent decomposition.

Definition 57.14 (Euclidean primary type)**.** A Euclidean primary type at the point $x=0$ is a finite-dimensional representation of the point stabilizer P_E with the following structure. The nilpotent radical generated by K_μ acts trivially; the rotation factor acts by a finite-dimensional representation ρ of $SO(D)$, or of $\mathrm{Spin}(D)$ when spin is present; and a positive dilatation $x \mapsto \lambda x$ acts by the character $\lambda^{-\Delta}$. The real number Δ is the Euclidean scaling dimension in the covariance convention used below.

A Euclidean primary operator is encoded by a covariant section of the homogeneous vector bundle associated to this P_E-representation. In a flat chart, the transformation law has the form

Definition 57.15 (Euclidean primary covariance law)**.**

$$U_E(f)\,\mathcal{O}_i^a(x)\,U_E(f)^{-1} = \Omega_f(x)^{-\Delta_i}\,\rho_i(R_f(x))^a{}_b\,\mathcal{O}_i^b(f(x)), \tag{57.41}$$

where $\Delta_i \in \mathbb{R}$ is the scaling dimension, ρ_i is a finite-dimensional representation of $\mathrm{Spin}(D)$ or $SO(D)$, and $R_f(x)$ is the local rotation obtained from the Jacobian after extracting the positive Weyl factor $\Omega_f(x)$. The fiber representation of P_E contains a noncompact dilation character $\lambda \mapsto \lambda^{-\Delta_i}$. For the real scaling dimensions relevant to reflection-positive CFT, this fiber action is an induced covariance representation rather than the Hilbert-space unitary representation. Euclidean correlators are covariance distributions for the associated bundles, while reflection positivity is the additional input that produces the Lorentzian Hilbert-space representation.

Definition 57.16 (Positive-energy representation)**.** The Lorentzian Hilbert-space representation is a strongly continuous unitary representation of the universal cover $\widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}}$. Let

$$K_{\mathrm{cov}} = \mathrm{Spin}(D) \times \mathbb{R}$$

denote the cover of the maximal compact subgroup, with the $\mathbb{R}$ factor generated by the cylinder Hamiltonian D_{rad}. A positive-energy representation means a unitary representation U for which

$$U(r(t)) = e^{-\mathrm{i}tD_{\mathrm{rad}}}, \qquad D_{\mathrm{rad}} \geq 0,$$

with $r(t) \in \widetilde{G}^{\mathrm{Lor}}_{\mathrm{conf}}$ the lifted cylinder-time rotation and D_{rad} self-adjoint. The finite-energy subspace is

$$\mathcal{H}_{\mathrm{fin}} = \bigoplus_{\Delta<\infty} \ker(D_{\mathrm{rad}} - \Delta), \tag{57.42}$$

whenever the spectrum is discrete with finite-dimensional eigenspaces, as assumed in the radial-reconstruction hypotheses. This algebraic direct sum is a common invariant domain for the derived conformal generators. On this domain,

$$P_\mu^\dagger = K_\mu, \qquad D_{\mathrm{rad}}^\dagger = D_{\mathrm{rad}}, \qquad J_{\mu\nu}^\dagger = J_{\mu\nu},$$

with the adjoints understood in the radial Hilbert-space inner product. The closure of each one-parameter generator is the self-adjoint generator supplied by Stone's theorem from the unitary group representation.

Definition 57.17 (Generalized Verma module of a conformal primary)**.** After complexification, let

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{so}(D+2, \mathbb{C}).$$

The radial grading decomposes it as

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{n}_- \oplus (\mathfrak{so}(D, \mathbb{C}) \oplus \mathbb{C}D_{\mathrm{rad}}) \oplus \mathfrak{n}_+, \qquad \mathfrak{n}_+ = \mathrm{span}_{\mathbb{C}}\{P_\mu\}, \quad \mathfrak{n}_- = \mathrm{span}_{\mathbb{C}}\{K_\mu\}. \tag{57.43}$$

A primary vector v of dimension Δ and spin representation ρ obeys

$$D_{\mathrm{rad}}v = \Delta v, \qquad K_\mu v = 0, \qquad \mathrm{Spin}(D) \text{ acts on } \mathrm{span}\{v\} \text{ by } \rho.$$

The corresponding algebraic highest-weight, or generalized Verma, module is

$$M(\Delta, \rho) = U(\mathfrak{n}_+) \otimes V_{\Delta,\rho}, \tag{57.44}$$

where $V_{\Delta,\rho}$ is the finite-dimensional $\mathfrak{so}(D, \mathbb{C}) \oplus \mathbb{C}D_{\mathrm{rad}}$-module on which $\mathfrak{n}_-$ acts trivially. Its level-n subspace is generated by n translations P_μ.

Proposition 57.18 (Null quotient and unitarity test)**.** *The radial two-point function defines a contravariant Hermitian form on $M(\Delta,\rho)$. The null radical of this form is a submodule, and the cyclic positive-energy quotient carried by the primary datum is*

$$L(\Delta,\rho) = M(\Delta,\rho)/\operatorname{Rad} M(\Delta,\rho) \tag{57.45}$$

when the quotient form is positive and the Hilbert-space sector generated by the primary has no further invariant subspace orthogonal to the cyclic descendant space. The algebraic unitarity test on the descendant module is positivity of every finite Gram matrix. Shortening occurs when a Gram matrix develops a null vector whose conformal descendants form a nonzero submodule.

Proof. Radial reflection sends translations through the origin to special conformal transformations, so on the algebraic descendant module the two-point pairing is contravariant with respect to the anti-involution

$$P_\mu^\dagger = K_\mu, \qquad D_{\mathrm{rad}}^\dagger = D_{\mathrm{rad}}, \qquad J_{\mu\nu}^\dagger = J_{\mu\nu}.$$

Let $R \subset M(\Delta,\rho)$ be the radical of this Hermitian form. If $r \in R$, then $(r,m) = 0$ for every descendant m. For any generator X of the complexified conformal algebra,

$$(Xr, m) = (r, X^\dagger m) = 0,$$

because $X^\dagger m$ is again a descendant. Hence $Xr \in R$, and R is a submodule. Quotienting by R gives a nondegenerate cyclic descendant module generated by the primary vector. It is the irreducible primary sector precisely when the Hilbert-space sector generated by the primary contains no further invariant subspace orthogonal to this cyclic descendant space; without this extra Hilbert-space condition the algebraic quotient only describes the cyclic part generated by the chosen primary.

The level decomposition of $M(\Delta,\rho)$ is finite dimensional at each level, because each level is generated by finitely many monomials in the D translation generators acting on the finite-dimensional spin space $V_{\Delta,\rho}$. Positivity of the Hermitian form on the algebraic direct sum is therefore equivalent to positivity of every finite Gram matrix at finite total level. When such a Gram matrix has a null vector, the radical argument above shows that the conformal descendants of that vector form a submodule. This is the algebraic shortening mechanism. □

The passage from the algebraic module $L(\Delta,\rho)$ to a group representation is a globalization problem. In the unitary CFT setting the globalization is supplied by the strongly continuous representation of $\widetilde{G}_{\mathrm{conf}}^{\mathrm{Lor}}$ on the radial Hilbert space, and $L(\Delta,\rho)$ is the K_{cov}-finite subspace generated by the primary. Descent from the universal cover to a quotient group is an additional condition: every element of the covering kernel must act trivially. For example, descent to an $SO(2)$ cylinder-time factor would require $\exp(-2\pi\mathrm{i}D_{\mathrm{rad}}) = 1$, hence integral scaling dimensions on the sector under consideration; spinorial sectors similarly require keeping the spin cover rather than $SO(D)$. Throughout the conformal block chapters, statements about conformal multiplets refer to these algebraic $\mathfrak{g}_{\mathbb{C}}$-modules together with the Hilbert-space globalization supplied by radial quantization.

57.9 Two Euclidean Dimensions

For $D = 2$, the local conformal Killing equation has infinitely many solutions. In complex coordinates

$$z = x^1 + \mathrm{i}x^2, \qquad \bar{z} = x^1 - \mathrm{i}x^2,$$

the local conformal transformations are

$$z \mapsto f(z), \qquad \bar{z} \mapsto \bar{f}(\bar{z})$$

in Euclidean signature, with f holomorphic in its domain. The global conformal transformations of the Riemann sphere are the Möbius maps

$$z \mapsto \frac{az+b}{cz+d}, \qquad ad - bc \neq 0.$$

In two real dimensions the conformal Killing equation is equivalent to the Cauchy–Riemann equations for the complex components of the infinitesimal coordinate change. Integrating locally gives holomorphic maps $z \mapsto f(z)$ and antiholomorphic maps in the conjugate coordinate. A globally defined biholomorphism of the compact Riemann sphere is a degree-one rational map: it is meromorphic on the sphere, has a meromorphic inverse, and therefore has topological degree one. Degree-one rational maps are precisely the displayed Möbius transformations, modulo the common rescaling of (a, b, c, d).

The infinite-dimensional enhancement has its own representation theory. The global Lorentzian conformal algebra factorizes, after passing to a cover, as $\mathfrak{sl}(2, \mathbb{R}) \oplus \mathfrak{sl}(2, \mathbb{R})$, while the local chiral stress-tensor modes generate Virasoro algebras with central charge. A global primary is annihilated by the global lowering generators, whereas a Virasoro primary is annihilated by all positive chiral modes $L_n, \bar{L}_n$ with $n > 0$. The two notions coincide only after restricting attention to the global subalgebra. The present core conformal-block discussion uses the finite-dimensional global conformal group; a full two-dimensional CFT volume must keep global blocks, Virasoro blocks, and their different null-module quotients separate.

Chapter 58

Stress Tensor, Weyl Structure, and Improvement

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

58.1 The Stress Tensor from Background Metrics

Definition 58.1 (Metric-source stress tensor)**.** Let a Euclidean local theory be coupled to a smooth background metric $g_{\mu\nu}$ on a D-dimensional manifold M. The stress tensor is defined by the first variation of the action or of the renormalized generating functional with respect to the metric. This chapter uses the contravariant-metric convention

$$\delta S[\Phi; g] = \frac{1}{2} \int_M \mathrm{d}^D x \, \sqrt{g} \, T_{\mu\nu}(x) \, \delta g^{\mu\nu}(x), \tag{58.1}$$

where Φ denotes the dynamical fields and $g = \det(g_{\mu\nu})$. Since $\delta g^{\mu\nu} = -g^{\mu\rho} g^{\nu\sigma} \delta g_{\rho\sigma}$, the same convention is equivalently

$$\delta S[\Phi; g] = -\frac{1}{2} \int_M \mathrm{d}^D x \, \sqrt{g} \, T^{\mu\nu}(x) \, \delta g_{\mu\nu}(x).$$

Equivalently, at the level of functional derivatives with all other sources held fixed,

$$T^{\mu\nu}(x) = -\frac{2}{\sqrt{g}(x)} \frac{\delta}{\delta g_{\mu\nu}(x)} = \frac{2}{\sqrt{g}(x)} g^{\mu\rho}(x) g^{\nu\sigma}(x) \frac{\delta}{\delta g^{\rho\sigma}(x)}. \tag{58.2}$$

The first differential operator acts on the functional written as a function of $g_{\mu\nu}$, and the second acts on the same functional written as a function of $g^{\mu\nu}$. This identity is only the chain rule applied to $\delta g^{\mu\nu} = -g^{\mu\rho}g^{\nu\sigma}\delta g_{\rho\sigma}$. This is the convention used by the metric derivative of the Euclidean source functional. At a regulator scale for which the metric-dependent functional integral is a well-defined regulated integral, let

$$Z[g] = \int \mathcal{D}_g\Phi \, \exp\{-S[\Phi; g]\}, \qquad \mathcal{W}[g] = -\log Z[g].$$

For variations supported away from boundary components, or with boundary conditions fixed so that no boundary term is produced, differentiating the regulated integral gives

$$\delta\mathcal{W}[g] = \langle \delta S[\Phi; g] \rangle_g = -\frac{1}{2}\int_M \mathrm{d}^D x \, \sqrt{g}\, \langle T^{\mu\nu}(x) \rangle_g \, \delta g_{\mu\nu}(x).$$

Therefore

$$\langle T^{\mu\nu}(x) \rangle_g = -\frac{2}{\sqrt{g}(x)} \frac{\delta\mathcal{W}[g]}{\delta g_{\mu\nu}(x)}.$$

After subtracting local metric counterterms, the same identity defines the renormalized source-coordinate system used in (56.26). If instead one writes $K[g] = \log Z[g]$, the right-hand side carries the opposite sign; the difference is only the choice between the logarithm of the partition function and the Euclidean effective action. With this sign convention, evaluating $T_{\mu\nu}$ on the flat metric gives the translation Noether tensor after adding the divergence term that makes the Noether tensor symmetric.

Remark 58.2 (Curved extensions and flat stress tensors). A flat classical action can have several curved extensions. For example,

$$S[\phi] = \int_{\mathbb{R}^D} \mathrm{d}^D x \left(\frac{1}{2}\partial_\mu\phi \, \partial^\mu\phi + \frac{1}{2}m^2\phi^2 \right)$$

may be extended as

$$S[\phi; g] = \int_M \mathrm{d}^D x \, \sqrt{g} \left(\frac{1}{2}g^{\mu\nu}\partial_\mu\phi \, \partial_\nu\phi + \frac{1}{2}m^2\phi^2 + \text{local curvature couplings} \right).$$

Curvature couplings that vanish on flat space still affect $T_{\mu\nu}$, because $T_{\mu\nu}$ is defined by varying $g_{\mu\nu}$ before setting $g_{\mu\nu} = \delta_{\mu\nu}$.

Diffeomorphism Ward identity for metric stress tensors. If the theory is invariant under diffeomorphisms of the background, then an infinitesimal vector field ξ^μ gives

$$\delta_\xi g^{\mu\nu} = -\nabla^\mu\xi^\nu - \nabla^\nu\xi^\mu.$$

Substituting this variation into (58.1) and integrating by parts gives

$$\nabla_\mu T^{\mu\nu} = 0 \tag{58.3}$$

as an operator equation away from insertions. In flat space this becomes $\partial_\mu T^{\mu\nu} = 0$. Symmetry of $T_{\mu\nu}$ follows from variation with respect to the symmetric tensor $g_{\mu\nu}$. The calculation is the source-form of Noether's identity. Insert $\delta_\xi g^{\mu\nu} = -\nabla^\mu\xi^\nu - \nabla^\nu\xi^\mu$ into Definition 58.1. The symmetry of $T_{\mu\nu}$ gives

$$\delta_\xi S = -\int_M \mathrm{d}^D x \, \sqrt{g}\, T_{\mu\nu}\nabla^\mu\xi^\nu.$$

Integrating by parts gives

$$\delta_\xi S = \int_M \mathrm{d}^D x \,\sqrt{g}\,(\nabla_\mu T^{\mu\nu})\xi_\nu$$

up to the boundary term excluded by the support or boundary conditions. Since the background-diffeomorphism variation is zero and ξ is arbitrary, the local identity $\nabla_\mu T^{\mu\nu} = 0$ follows away from operator insertions. At coincident insertions the same source argument gives the familiar contact terms; their precise form depends on which inserted operators transform under the diffeomorphism and on the chosen contact-term extension of the correlator.

58.2 Metric Perturbations and Stress Insertions

Set $g_{\mu\nu} = \delta_{\mu\nu} + \delta g_{\mu\nu}$, with δg smooth and compactly supported. To first order, the Euclidean path integral changes by the insertion

$$\exp[-\delta_g S] = \exp\left[-\frac{1}{2}\int_{\mathbb{R}^D} \mathrm{d}^D x\,\delta g^{\mu\nu}(x) T_{\mu\nu}(x)\right], \tag{58.4}$$

where indices on $\delta g^{\mu\nu}$ are raised with the flat metric at this order. Thus, for an operator product X supported away from $\mathrm{supp}(\delta g)$,

$$\langle X\rangle_{\delta+\delta g} = \langle X\rangle_\delta - \frac{1}{2}\int \mathrm{d}^D x\,\delta g^{\mu\nu}(x)\langle T_{\mu\nu}(x) X\rangle_\delta + O(\delta g^2).$$

Higher metric variations require a prescription for coincident products of stress tensors. The short-distance singularities in $T_{\mu\nu}(x)T_{\rho\sigma}(y)$ and the corresponding contact terms are part of the renormalized definition of the theory on curved backgrounds. This is a local ultraviolet statement: in a massless theory the distributional extension of stress-tensor products is used only after the infrared state or regulator has made the separated-point correlators meaningful on the test functions under consideration. In even dimensions these contact terms include the Weyl anomaly data. Expand the metric-source action to first order in δg using Definition 58.1. Since $\delta g^{\mu\nu} = -\delta g_{\mu\nu} + O(\delta g^2)$ around the flat metric, the first-order change of the Boltzmann weight is the exponential insertion in (58.4). Expanding that exponential to first order gives the displayed variation of $\langle X\rangle$. Higher functional derivatives differentiate products of metric variations at coincident points, so their definition requires the local extension of stress-tensor products as distributions.

58.3 Weyl Transformations

Definition 58.3 (Weyl transformation and trace insertion)**.** A Weyl transformation is a local rescaling of the background metric:

$$g_{\mu\nu}(x) \mapsto \mathrm{e}^{2\omega(x)} g_{\mu\nu}(x),$$

where ω is a smooth real function. Infinitesimally,

$$\delta_\omega g_{\mu\nu} = 2\omega g_{\mu\nu}, \qquad \delta_\omega g^{\mu\nu} = -2\omega g^{\mu\nu}.$$

The corresponding metric variation gives

$$\delta_\omega S = -\int_M \mathrm{d}^D x\,\sqrt{g}\,\omega(x)\,T^\mu{}_\mu(x).$$

Flat-space trace condition from Weyl invariance. Assume that the renormalized theory is coupled to a background metric, that the stress tensor is defined by metric variation as in (58.4), and that a choice of field Weyl transformations and allowed improvements has been made for which the renormalized functional is invariant under compactly supported Weyl rescalings in flat space, apart from curvature anomaly terms and contact terms on coincident insertions. Then, at separated flat-space points,

$$T^{\mu}{}_{\mu} = 0 \tag{58.5}$$

The action may assign Weyl transformations to the dynamical fields Φ. After including these field variations and the chosen improvement terms, Weyl invariance says that the first variation of every separated correlator under $\delta_\omega g_{\mu\nu} = 2\omega g_{\mu\nu}$ vanishes, modulo the stated anomaly and contact contributions. The metric-variation formula above gives

$$\delta_\omega \langle X\rangle = -\int \mathrm{d}^D x\, \omega(x)\, \langle T^{\mu}{}_{\mu}(x) X\rangle$$

for every operator product X supported away from $\mathrm{supp}(\omega)$. Since ω is an arbitrary smooth test function in the separated region, the distributional insertion of $T^{\mu}{}_{\mu}$ vanishes there. This is the local operator equation (58.5) at separated flat-space points.

The background metric is an external source for stress-tensor insertions and Ward identities.

In even dimensions, the renormalized generating functional may transform under a Weyl rescaling by a local curvature functional. At separated flat-space points the conformal Ward identities are governed by (58.5); the anomaly contributes contact terms and curved-space response data. The present volume records this contact-term distinction; the special two-dimensional extension of conformal symmetry is deferred to a separate treatment.

58.4 Weyl Anomaly Density and Contact Ward Identities

Definition 58.4 (Weyl anomaly density)**.** Define the trace anomaly density by

$$\delta_\omega \mathcal{W}[g] = -\int_M \mathrm{d}^D x\, \sqrt{g}\, \omega(x)\, \mathcal{A}[g](x), \qquad \mathcal{A}[g](x) = \langle T^{\mu}{}_{\mu}(x)\rangle_g\,. \tag{58.6}$$

This sign follows from the convention $\langle T^{\mu\nu}\rangle_g = -2g^{-1/2}\delta\mathcal{W}/\delta g_{\mu\nu}$ and $\delta_\omega g_{\mu\nu} = 2\omega g_{\mu\nu}$. The anomaly density is a local scalar of Weyl weight D, defined modulo the Weyl variation of local metric counterterms. Its functional derivatives are contact terms in stress-tensor Ward identities. More explicitly, let

$$X_{n-1} = T^{\rho_1\sigma_1}(x_1)\cdots T^{\rho_{n-1}\sigma_{n-1}}(x_{n-1}).$$

Tracing one stress tensor in an n-point distribution gives, away from separated-point terms,

$$g_{\mu\nu}(x)\, \langle T^{\mu\nu}(x) X_{n-1}\rangle = \left.\frac{\delta^{\,n-1}\mathcal{A}[g](x)}{\prod_{j=1}^{n-1}\delta g_{\rho_j\sigma_j}(x_j)}\right|_{g=\delta} + \text{index-variation contact terms.}$$

Here the denominator denotes the iterated functional derivative with respect to the displayed metric components. Thus anomaly coefficients are part of the metric-source definition of the stress-tensor correlators, even though $T^{\mu}{}_{\mu} = 0$ at separated flat-space points.

58.5 Classification of Conformal Anomalies

Wess–Zumino consistency for Weyl anomalies. The local anomaly density is constrained because Weyl transformations form an abelian group. Let

$$\mathbf{A}_\omega[g] := \int_M \mathrm{d}^D x \sqrt{g}\, \omega(x) \mathcal{A}[g](x).$$

The identity $[\delta_{\omega_1}, \delta_{\omega_2}]\mathcal{W}[g] = 0$ gives the Wess–Zumino consistency condition

$$\delta_{\omega_1} \mathbf{A}_{\omega_2}[g] - \delta_{\omega_2} \mathbf{A}_{\omega_1}[g] = 0. \tag{58.7}$$

Changing the renormalized source functional by a local metric counterterm $\mathcal{W}[g] \mapsto \mathcal{W}[g] + B[g]$ changes $\mathbf{A}_\omega[g]$ by $-\delta_\omega B[g]$. Therefore the intrinsic trace anomaly is the cohomology of the Weyl differential on local metric functionals: solutions of (58.7) modulo Weyl variations of local counterterms. This is the source-functional form of the abelian Weyl algebra. Apply two Weyl variations to the same renormalized functional $\mathcal{W}[g]$. Since local Weyl rescalings commute, $[\delta_{\omega_1}, \delta_{\omega_2}]\mathcal{W}[g] = 0$. Using Definition 58.4, this commutator is precisely $\delta_{\omega_1}\mathbf{A}_{\omega_2} - \delta_{\omega_2}\mathbf{A}_{\omega_1}$, giving (58.7). If $\mathcal{W}$ is shifted by a local counterterm $B[g]$, its anomaly shifts by the Weyl variation of that counterterm. Therefore only the cohomology class of $\mathbf{A}_\omega$ is intrinsic.

The classification below has two separate inputs. The QFT input has just been derived from the metric source functional: the anomaly is a cocycle for the abelian Weyl differential, and local counterterms add coboundaries. The geometric input is the local invariant-theory computation of that cohomology on the jet space of smooth metrics. The quoted theorem supplies this geometric classification. A particular CFT then supplies numerical coordinates on the listed cohomology classes through its stress-tensor correlators or through a regulated path integral.

Quoted Theorem 58.5 (Parity-even local Weyl anomaly classes)**.** *In the parity-even metric sector on a closed manifold without boundary, the bulk solutions in even dimension $D = 2n$ have the form*

$$\mathcal{A}_{2n}[g] = -a_{2n} E_{2n} + \sum_\alpha c_\alpha I_\alpha + \nabla_\mu J^\mu. \tag{58.8}$$

Here

$$E_{2n} = \frac{1}{2^n} \delta^{\mu_1\nu_1\cdots\mu_n\nu_n}_{\rho_1\sigma_1\cdots\rho_n\sigma_n} R^{\rho_1\sigma_1}{}_{\mu_1\nu_1} \cdots R^{\rho_n\sigma_n}{}_{\mu_n\nu_n} \tag{58.9}$$

is the Euler density in the curvature convention used in this chapter. The term E_{2n} is the type-A anomaly. Its integral is topological: $\int_M \sqrt{g}\, E_{2n}$ is proportional to the Euler characteristic on a closed $2n$-manifold. Consequently its Weyl variation is a total derivative, so it obeys (58.7). The scalar densities I_α are type-B anomalies: $\sqrt{g}\, I_\alpha$ is locally Weyl invariant in dimension $2n$. The divergence $\nabla_\mu J^\mu$ denotes type-D, or trivial, terms; these are Weyl variations of local metric counterterms and are scheme dependent.

This classification is local. It classifies the contact terms in stress-tensor Ward identities produced by varying a smooth background metric. Global terms, boundaries, defects, and parity-odd orientation-dependent candidates require additional data and are not part of the parity-even bulk list in (58.8). In odd dimension there is no parity-even local bulk trace anomaly of this type on a closed smooth manifold, although finite nonlocal data such as the sphere free energy can be important conformal data.

Cohomological mechanism. The representative $-a_{2n}E_{2n}+\sum_\alpha c_\alpha I_\alpha$ is a coordinate choice on the quotient of local Weyl cocycles by local Weyl coboundaries. The type-B terms are cocycles for the direct reason that $\sqrt{g}\,I_\alpha$ is Weyl invariant in dimension $2n$. The type-A term is a cocycle because the Euler form is obtained by Chern–Weil transgression from an invariant polynomial: the integrated Euler density is metric-independent on a closed manifold, and its local Weyl variation is therefore an exact divergence. Type-D terms are coboundaries by definition: if $B[g]$ is a local counterterm, then $-\delta_\omega B[g]=\int\sqrt{g}\,\omega\,\nabla_\mu J^\mu$ for the corresponding representative. The nontrivial content of the quoted theorem is the converse local statement: after imposing the algebraic and differential Bianchi identities and quotienting total derivatives, every parity-even bulk solution of the Wess–Zumino condition is represented by this type-A/type-B list plus a type-D coboundary. The chapter uses that converse as geometric cohomology infrastructure, not as a substitute for computing the coefficients of a given QFT.

In two dimensions, with the convention above, write

$$\mathcal{A}_2[g]=-\frac{c_{2d}}{24\pi}R. \tag{58.10}$$

This is purely type A: $E_2=R$, and there is no independent parity-even type-B scalar in two dimensions.

Four-dimensional parity-even Weyl anomaly. In four dimensions, define

$$E_4=R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}-4R_{\mu\nu}R^{\mu\nu}+R^2,\qquad W^2=W_{\mu\nu\rho\sigma}W^{\mu\nu\rho\sigma},$$

where $W_{\mu\nu\rho\sigma}$ is the Weyl tensor. A parity-even CFT has

$$\mathcal{A}_4[g]=\frac{1}{16\pi^2}\left(c_{\mathrm{W}}W^2-a_{\mathrm{W}}E_4+b_{\mathrm{D}}\nabla^2R\right). \tag{58.11}$$

The coefficient b_{D} is changed by adding a local R^2 counterterm to $\mathcal{W}[g]$. The coefficients a_{W} and c_{W} are unchanged by such counterterms at a conformal fixed point. E_4 is the type-A term, W^2 is the unique parity-even type-B scalar, and ∇^2R is type D. More explicitly,

$$\delta_\omega\int_M \mathrm{d}^4x\,\sqrt{g}\,R^2=-12\int_M \mathrm{d}^4x\,\sqrt{g}\,\omega\,\nabla^2R$$

on a closed four-manifold, so the coefficient of ∇^2R is shifted by a choice of local R^2 counterterm. The completeness of this parity-even four-dimensional list follows from the dimension-four curvature basis $R^2_{\mu\nu\rho\sigma}$, $R^2_{\mu\nu}$, R^2, and ∇^2R: the two nontrivial Wess–Zumino classes are the Euler combination E_4 and the Weyl-invariant combination W^2, while the remaining scalar can be changed by the R^2 counterterm just displayed. The local cohomological input is the four-dimensional specialization of Quoted Theorem 58.5: among the parity-even dimension-four curvature scalars modulo total derivatives and algebraic Bianchi identities, E_4 supplies the type-A class and W^2 supplies the type-B class. The displayed Weyl variation of $\int\sqrt{g}\,R^2$ gives the explicit representative of the type-D ambiguity.

Quoted Theorem 58.6 (Six-dimensional parity-even local Weyl cohomology)**.** *In six dimensions, modulo type-D total-derivative terms, the parity-even bulk classification has one type-A coefficient and three type-B coefficients:*

$$\mathcal{A}_6[g]=\frac{1}{(4\pi)^3}\left(-a_6E_6+c_1I_1+c_2I_2+c_3I_3+\nabla_\mu J^\mu\right). \tag{58.12}$$

A convenient representative of the three type-B invariants is

$$\begin{aligned}
I_1 &= W_{\mu\rho\sigma\nu} W^{\mu\alpha\beta\nu} W_\alpha{}^{\rho\sigma}{}_\beta, \\
I_2 &= W_{\mu\nu}{}^{\rho\sigma} W_{\rho\sigma}{}^{\alpha\beta} W_{\alpha\beta}{}^{\mu\nu}, \\
I_3 &\equiv W_{\mu\nu\rho\sigma} \left(\nabla^2 \delta^\mu{}_\alpha + 4R^\mu{}_\alpha - \frac{6}{5} R\, \delta^\mu{}_\alpha \right) W^{\alpha\nu\rho\sigma} \quad \mod \nabla_\mu J^\mu.
\end{aligned} \tag{58.13}$$

The equivalence sign in the definition of I_3 is essential: different representatives differ by type-D terms, while the coefficient c_3 of the cohomology class is invariant under local counterterm changes. In dimensions higher than six the same rule applies, but the number of independent Weyl invariants grows because more contractions of Weyl tensors and conformally covariant derivatives are available. For $D = 6$, dimension counting and the algebraic Bianchi identities leave two independent cubic Weyl contractions and one independent two-Weyl-tensor invariant with two derivatives; Ricci-dependent representatives either combine with these into the conformally covariant operator in I_3, enter the Euler density E_6, or are type-D counterterm variations.

The six-dimensional statement is used here as a basis theorem for local Weyl cohomology. The derivation of the Wess–Zumino cocycle condition and the counterterm quotient is the source-functional argument above; the enumeration of the three independent type-B representatives is the quoted invariant-theory input. Consequently a later computation of a six-dimensional theory is required to determine the four numbers (a_6, c_1, c_2, c_3) in a declared regularization scheme. The quoted theorem does not supply those numbers and does not assert that a particular six-dimensional QFT exists.

58.6 Anomaly Coefficients and Stress-Tensor Correlators

Convention 58.7 ($2D$ central charge and anomaly)**.** When a two-dimensional CFT is coupled to a curved metric and its flat holomorphic stress tensor is normalized by the same metric source functional, the symbol c_{2d} denotes both the coefficient in (58.10) and the Virasoro central charge in the holomorphic OPE normalization

$$\langle T(z)T(0)\rangle = \frac{c_{2d}}{2z^4}.$$

The identification is the contact Ward identity obtained by taking two metric variations of (58.10) around a flat metric and then rewriting the result in complex coordinates. The present chapter uses this identity as a normalization convention; it is not being introduced here as a separate theorem without proof.

Convention 58.8 (Four-dimensional C_T and c_{W})**.** Use the following local normalization of the separated flat-space stress-tensor two-point function:

$$\langle T_{\mu\nu}(x)T_{\rho\sigma}(0)\rangle = \frac{C_T}{|x|^{2D}} I_{\mu\nu,\rho\sigma}(x),$$

where

$$I_{\mu\nu,\rho\sigma}(x) = \frac{1}{2}\big(I_{\mu\rho}(x)I_{\nu\sigma}(x) + I_{\mu\sigma}(x)I_{\nu\rho}(x)\big) - \frac{1}{D}\delta_{\mu\nu}\delta_{\rho\sigma}.$$

The same two-point convention is developed systematically in Chapter 63. With this normalization, the symbol c_{W} in (58.11) is normalized so that the separated stress-tensor two-point coefficient is

$$C_T = \frac{40}{\pi^4}\, c_{\mathrm{W}}. \tag{58.14}$$

The relation is a normalization statement for the metric source. Its curvature-kernel verification is obtained by taking two metric variations of the W^2 term in (58.11), Fourier transforming the resulting quadratic curvature contact term, and matching the logarithmic scale dependence of the flat-space TT correlator to the displayed two-point normalization. The Euler term begins to contribute independent information at the next metric variation.

Remark 58.9 (Four-dimensional anomaly map from TTT data). Use the local convention in which the parity-even separated TTT correlator in $D = 4$ is expanded in three Osborn–Petkou structures,

$$\langle T_{\mu\nu}(x_1)T_{\rho\sigma}(x_2)T_{\alpha\beta}(x_3)\rangle_{\text{even}} = a_{\mathrm{OP}}\mathcal{I}^{(1)} + b_{\mathrm{OP}}\mathcal{I}^{(2)} + c_{\mathrm{OP}}\mathcal{I}^{(3)}.$$

Chapter 63 constructs these three separated tensor structures explicitly from conformal covariance, conservation, and permutation symmetry. The small-sphere stress-tensor Ward identity gives, in this normalization and at $D = 4$,

$$C_T = \frac{\pi^2}{3}\left(14a_{\mathrm{OP}} - 2b_{\mathrm{OP}} - 5c_{\mathrm{OP}}\right), \tag{58.15}$$

so c_{W} is this same linear combination through (58.14). The Euler coefficient a_{W} is a second, independent linear functional of $(a_{\mathrm{OP}}, b_{\mathrm{OP}}, c_{\mathrm{OP}})$, obtained by taking three metric variations of the E_4 term in (58.11) and projecting the resulting trace Ward identity onto the three separated tensor structures. Equivalently, one may use the free-field basis of four-dimensional stress-tensor structures:

$$\langle TTT\rangle = n_s\langle TTT\rangle_{\text{real scalar}} + n_f\langle TTT\rangle_{\text{Dirac fermion}} + n_v\langle TTT\rangle_{\text{Maxwell vector}}. \tag{58.16}$$

In that basis,

$$a_{\mathrm{W}} = \frac{n_s}{360} + \frac{11n_f}{360} + \frac{31n_v}{180}, \qquad c_{\mathrm{W}} = \frac{n_s}{120} + \frac{n_f}{20} + \frac{n_v}{10}. \tag{58.17}$$

Here n_f multiplies the Dirac-fermion stress-tensor structure; using a Weyl fermion instead halves the fermion entries. The third independent linear combination of $a_{\mathrm{OP}}, b_{\mathrm{OP}}, c_{\mathrm{OP}}$ is genuine TTT data not fixed by a_{W} and c_{W}. After C_T has fixed the overall stress-tensor normalization, Chapter 65 uses the conformal-collider coordinates t_2, t_4 as detector coordinates on the remaining separated TTT data.

58.7 Improvement of the Stress Tensor

Scalar improvement of the flat stress tensor. The stress tensor has improvement freedom. If $L(x)$ is a local scalar operator, then

$$T_{\mu\nu} \longmapsto T'_{\mu\nu} = T_{\mu\nu} + \left(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu\right) L \tag{58.18}$$

preserves conservation in flat space. More general improvements are possible, but (58.18) is the case needed for the free scalar and many scalar fixed points. Its trace is

$$T'^{\mu}{}_{\mu} = T^{\mu}{}_{\mu} + (D-1)\partial^2 L.$$

If $T^\mu{}_\mu$ is a total Laplacian of a local scalar, an improvement can make the trace vanish in flat space. The added tensor is identically conserved in flat space because

$$\partial^\mu(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu)L = \partial_\nu\partial^2 L - \partial^2\partial_\nu L = 0.$$

Taking its trace gives $(D-1)\partial^2 L$, which is the displayed trace shift.

The improvement can be represented by adding a curvature coupling to the background-metric action. For a scalar field ϕ, the term

$$\Delta S_\xi = \frac{\xi}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,R(g)\phi^2$$

vanishes in flat space when $R(g) = 0$, but its metric variation contributes to $T_{\mu\nu}$ at flat $g_{\mu\nu}$. Thus a term absent from the flat-space action can change the flat-space stress tensor.

58.8 The Conformally Coupled Free Scalar

Proposition 58.10 (Conformally coupled free scalar)**.** *For a real massless scalar field in $D > 2$ Euclidean dimensions, the curvature coupling*

$$\xi_* = \frac{D-2}{4(D-1)}$$

is the unique scalar-curvature improvement of the form $\frac{\xi}{2}\int\sqrt{g}\,R\phi^2$ for which the flat-space stress tensor has vanishing trace modulo the scalar equation of motion. The corresponding curved action is (58.21)*.*

Proof. Consider a real massless scalar field in Euclidean signature. The minimally coupled curved-space action is

$$S_0[\phi; g] = \frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,g^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi.$$

Its metric variation is

$$\delta_g S_0 = \frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,\delta g^{\mu\nu}\left(\partial_\mu\phi\,\partial_\nu\phi - \frac{1}{2}g_{\mu\nu}g^{\rho\sigma}\partial_\rho\phi\,\partial_\sigma\phi\right).$$

On the flat background this gives

$$T^{(0)}_{\mu\nu} = \partial_\mu\phi\,\partial_\nu\phi - \frac{1}{2}\delta_{\mu\nu}(\partial\phi)^2.$$

Its trace is

$$T^{(0)\mu}{}_\mu = \left(1 - \frac{D}{2}\right)(\partial\phi)^2.$$

For $D > 2$ this trace is a nonzero local operator before improvement. Using the equation of motion $\partial^2\phi = 0$, the identity

$$\partial^2\phi^2 = 2(\partial\phi)^2 + 2\phi\,\partial^2\phi$$

shows that the trace is a Laplacian modulo the equation of motion.

Now add the curvature functional

$$S_1[\phi; g] = \frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,R(g)\phi^2.$$

The scalar curvature variation with respect to $g^{\mu\nu}$ is

$$\delta R = R_{\mu\nu}\delta g^{\mu\nu} + \nabla_\rho\left(g^{\mu\nu}\delta\Gamma^\rho_{\mu\nu} - g^{\mu\rho}\delta\Gamma^\nu_{\mu\nu}\right),$$

where $\delta\Gamma^\rho_{\mu\nu}$ is the variation of the Levi-Civita connection. Integrating the total derivative by parts and then setting $g_{\mu\nu} = \delta_{\mu\nu}$ gives

$$\delta_g S_1\big|_{g=\delta} = \frac{1}{2}\int_{\mathbb{R}^D} \mathrm{d}^D x\,\delta g^{\mu\nu}\left(-\partial_\mu\partial_\nu\phi^2 + \delta_{\mu\nu}\partial^2\phi^2\right).$$

The remaining terms in the full curved-space variation are proportional to curvature and vanish after the metric is set to $\delta_{\mu\nu}$.

For

$$S[\phi; g] = S_0[\phi; g] + aS_1[\phi; g],$$

the flat-space stress tensor is

$$T_{\mu\nu} = \partial_\mu\phi\,\partial_\nu\phi - \frac{1}{2}\delta_{\mu\nu}(\partial\phi)^2 + a\left(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu\right)\phi^2, \tag{58.19}$$

The total translation generators $P^\nu = \int_\Sigma \mathrm{d}^{D-1}x\,T^{0\nu}$ are unchanged by the improvement term when spatial total derivatives integrate to zero on the constant-time slice. The trace changes:

$$T^\mu{}_\mu = \left(1 - \frac{D}{2}\right)(\partial\phi)^2 + a(D-1)\partial^2\phi^2$$

and therefore

$$T^\mu{}_\mu = \left(1 - \frac{D}{2} + 2(D-1)a\right)(\partial\phi)^2 + 2(D-1)a\,\phi\,\partial^2\phi.$$

The trace vanishes modulo the scalar equation of motion if and only if

$$a = \xi_* = \frac{D-2}{4(D-1)}. \tag{58.20}$$

The corresponding curved-space action is

$$S[\phi; g] = \frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,\left[g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi + \xi_* R(g)\phi^2\right]. \tag{58.21}$$

With the Weyl transformation

$$g_{\mu\nu} \mapsto \mathrm{e}^{2\omega}g_{\mu\nu}, \qquad \phi \mapsto \mathrm{e}^{-\frac{D-2}{2}\omega}\phi,$$

this action is Weyl invariant at the classical level by the conformal-Laplacian Weyl-covariance calculation below. In the corresponding free massless scalar QFT, the improved trace is

$$\widehat{T}^\mu{}_\mu(x) = 2(D-1)\xi_*\,\widehat{\phi}(x)\,\partial^2\widehat{\phi}(x).$$

It represents the zero class in the local-operator vector space modulo the free equation-of-motion ideal. Equivalently, for local insertions $\mathcal{O}_i(y_i)$ with $x \neq y_i$,

$$\left\langle \widehat{T}^\mu{}_\mu(x)\prod_i \mathcal{O}_i(y_i)\right\rangle = 0.$$

At coincident points the factor $\partial^2\widehat{\phi}$ generates the Schwinger–Dyson contact terms of the free Gaussian measure. $\square$

Weyl covariance of the conformal Laplacian. Let $D > 2$, set

$$\alpha = \frac{D-2}{2}, \qquad \xi_* = \frac{D-2}{4(D-1)},$$

and define the conformal Laplacian

$$P_g = -\nabla_g^2 + \xi_* R(g).$$

Under a Weyl transformation

$$g'_{\mu\nu} = \mathrm{e}^{2\omega} g_{\mu\nu}, \qquad \phi' = \mathrm{e}^{-\alpha\omega}\phi,$$

one has

$$P_{g'}\phi' = \mathrm{e}^{-\frac{D+2}{2}\omega} P_g \phi. \tag{58.22}$$

Consequently, on a closed manifold or with boundary conditions eliminating boundary terms,

$$\frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g}\,\phi\,P_g\phi = \frac{1}{2}\int_M \mathrm{d}^D x\,\sqrt{g'}\,\phi'\,P_{g'}\phi'.$$

This is precisely the Weyl invariance of (58.21). For a scalar f, the Laplacian transforms as

$$\nabla_{g'}^2 f = \mathrm{e}^{-2\omega}\left(\nabla_g^2 f + (D-2)\nabla^\mu\omega\,\nabla_\mu f\right),$$

where covariant derivatives and contractions on the right use g. Apply this to $f = \mathrm{e}^{-\alpha\omega}\phi$. Since $2\alpha = D-2$, the first derivative terms in ϕ cancel:

$$\nabla_{g'}^2(\mathrm{e}^{-\alpha\omega}\phi) = \mathrm{e}^{-(\alpha+2)\omega}\left(\nabla_g^2\phi - \alpha(\nabla_g^2\omega)\phi - \alpha^2(\nabla\omega)^2\phi\right).$$

The scalar curvature transforms by

$$R(g') = \mathrm{e}^{-2\omega}\left(R(g) - 2(D-1)\nabla_g^2\omega - (D-1)(D-2)(\nabla\omega)^2\right).$$

Therefore

$$\begin{aligned} P_{g'}(\mathrm{e}^{-\alpha\omega}\phi) = \mathrm{e}^{-(\alpha+2)\omega}\big[&-\nabla_g^2\phi + \xi_* R(g)\phi \\ &+ (\alpha - 2(D-1)\xi_*)(\nabla_g^2\omega)\phi \\ &+ (\alpha^2 - (D-1)(D-2)\xi_*)(\nabla\omega)^2\phi\big]. \end{aligned}$$

The two coefficients involving ω vanish exactly for $\xi_* = (D-2)/(4(D-1))$. Since $\alpha+2 = (D+2)/2$, this proves (58.22). Finally, $\sqrt{g'} = \mathrm{e}^{D\omega}\sqrt{g}$, and

$$D - \alpha - \frac{D+2}{2} = 0.$$

The integrated quadratic form is therefore invariant. Integrating $\phi(-\nabla_g^2)\phi$ by parts rewrites the quadratic form as (58.21).

Figure 58.1 records the dimension-dependent coefficient in the conformal Laplacian. The displayed values are a useful check on the normalization: in $D = 4$ the coefficient is $1/6$, while $D = 2$ is degenerate because the free scalar has $\Delta_\phi = 0$ and the curvature improvement coefficient vanishes.

D	$\Delta_\phi = (D-2)/2$	$\xi_* = (D-2)/[4(D-1)]$	conformal Laplacian P_g
2	0	0	$-\nabla_g^2$
3	1/2	1/8	$-\nabla_g^2 + \frac{1}{8}R(g)$
4	1	1/6	$-\nabla_g^2 + \frac{1}{6}R(g)$
5	3/2	3/16	$-\nabla_g^2 + \frac{3}{16}R(g)$
6	2	1/5	$-\nabla_g^2 + \frac{1}{5}R(g)$
10	4	2/9	$-\nabla_g^2 + \frac{2}{9}R(g)$

Figure 58.1: The conformal improvement coefficient is fixed by Weyl covariance of $P_g = -\nabla_g^2 + \xi_* R(g)$: $P_{e^{2\omega}g}(e^{-(D-2)\omega/2}\phi) = e^{-(D+2)\omega/2}P_g\phi$. Varying the metric-coupled action with this P_g, and only then setting $g_{\mu\nu} = \delta_{\mu\nu}$, gives the improved flat-space stress tensor.

58.9 Ward Identities with Stress-Tensor Insertions

Proposition 58.11 (Stress-tensor Ward identity with spinning insertions)**.** *Let*

$$X = \mathcal{O}_{A_1}(x_1)\cdots\mathcal{O}_{A_n}(x_n), \qquad X_i[B] = \mathcal{O}_{A_1}(x_1)\cdots B(x_i)\cdots\mathcal{O}_{A_n}(x_n),$$

where $B(x_i)$ replaces the i-th operator. Suppose first that each $\mathcal{O}_{A_i}$ belongs to a finite-dimensional source representation of linearized diffeomorphisms, with matrices $(\mathsf{R}^{\mu\nu}_{(i)})_{A_i}{}^{B_i}$ defined by the linear term

$$\delta_\xi\mathcal{O}_{A_i}(x_i) = \xi^\rho(x_i)\partial_\rho\mathcal{O}_{A_i}(x_i) + \partial_\mu\xi_\nu(x_i)(\mathsf{R}^{\mu\nu}_{(i)})_{A_i}{}^{B_i}\mathcal{O}_{B_i}(x_i).$$

For scalar operators the matrices $\mathsf{R}^{\mu\nu}_{(i)}$ vanish. For operators carrying only orthonormal-frame spin, the antisymmetric part of $\mathsf{R}^{\mu\nu}_{(i)}$ is the usual spin matrix $\mathsf{S}^{\mu\nu}_{(i)} = -\mathsf{S}^{\nu\mu}_{(i)}$, and the symmetric traceless part is absent. The source-functional identity (56.27), differentiated with respect to the corresponding sources and then evaluated at zero source, gives the smeared flat-space Ward identity

$$\int d^D x\, \partial_\mu\xi_\nu(x)\, \langle T^{\mu\nu}(x)X\rangle = \sum_{i=1}^n \xi^\nu(x_i)\partial_{x_i^\nu}\langle X\rangle + \sum_{i=1}^n \partial_\mu\xi_\nu(x_i)\left\langle X_i[(\mathsf{R}^{\mu\nu}_{(i)})_{A_i}{}^{B_i}\mathcal{O}_{B_i}]\right\rangle. \qquad (58.23)$$

Equivalently, as an identity of distributions in x,

$$\partial_\mu\langle T^{\mu\nu}(x)X\rangle = -\sum_{i=1}^n \delta(x-x_i)\partial_{x_i^\nu}\langle X\rangle + \sum_{i=1}^n \partial_\mu\left[\delta(x-x_i)\left\langle X_i[(\mathsf{R}^{\mu\nu}_{(i)})_{A_i}{}^{B_i}\mathcal{O}_{B_i}]\right\rangle\right]. \qquad (58.24)$$

There is no omitted spin term in (58.24). For scalar insertions $\mathsf{R}^{\mu\nu}_{(i)} = 0$, and the familiar translation Ward identity is obtained by deleting the second line. For spinning insertions that second line is part of the identity. To see its relation to the conformal Ward identities used later, let the i-th operator be a primary in an orthonormal-frame spin representation ρ_i, with infinitesimal spin matrices $S^{(i)}_{\mu\nu}$ in the convention of Chapter 61. If ϵ^μ is a conformal Killing vector and

$$J^\mu_\epsilon = T^\mu{}_\nu\epsilon^\nu, \qquad \sigma_\epsilon = \frac{1}{D}\partial_\rho\epsilon^\rho, \qquad \omega_{\epsilon,\mu\nu} = \frac{1}{2}(\partial_\nu\epsilon_\mu - \partial_\mu\epsilon_\nu),$$

then smearing (58.23) *with* $\xi = \epsilon$ *and adding the trace Ward identity gives*

$$\partial_\mu \langle J^\mu_\epsilon(x) X \rangle = \sum_{i=1}^{n} \delta^{(D)}(x - x_i) \left\langle X_i [\mathcal{D}^{(i)}_\epsilon \mathcal{O}_{A_i}] \right\rangle + \sigma_\epsilon(x) \mathcal{A}(x; X), \tag{58.25}$$

where

$$\mathcal{D}^{(i)}_\epsilon \mathcal{O}_{i,a_i}(x_i) = -\epsilon^\rho(x_i) \partial_{x_i^\rho} \mathcal{O}_{i,a_i}(x_i) - \Delta_i \sigma_\epsilon(x_i) \mathcal{O}_{i,a_i}(x_i) - \frac{\mathrm{i}}{2} \omega^{\mu\nu}_\epsilon(x_i) (S^{(i)}_{\mu\nu})_{a_i}{}^{b_i} \mathcal{O}_{i,b_i}(x_i). \tag{58.26}$$

Equations (58.25) *and* (58.26) *are the same source Ward identity as* (61.7)*; the derivative contact term in* (58.24) *is precisely what becomes the local rotation term proportional to* $\omega^{\mu\nu}_\epsilon S^{(i)}_{\mu\nu}$*. Thus one may use the scalar translation formula only after verifying that all insertions are scalars, or after the spin contact term has been carried along separately. For a basis of composite operators that mixes under the linearized diffeomorphism, the displayed representation matrix is replaced by the corresponding source-coordinate representation matrix. The trace Ward identity similarly records the response under Weyl transformations. At a flat-space conformal fixed point, the separated-point trace insertion vanishes, while contact terms encode scaling dimensions and conformal transformations of the inserted operators.*

The charge form of the Ward identity follows by integrating $T^\mu{}_\nu \epsilon^\nu$ *over a small sphere around each insertion. This is the bridge between the local stress-tensor equation and the conformal algebra acting on local operators.*

Chapter 59

Radial Quantization and the State-Operator Correspondence

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

59.1 Local Correlators as the Primary Data

Let $\widehat{\mathcal{O}}_I(x)$ denote a Lorentzian local operator-valued distribution on $\mathbb{R}^{1,D-1}$. The label I includes all internal and spin indices. Local commutativity means that for spacelike separated points

$$[\widehat{\mathcal{O}}_I(x), \widehat{\mathcal{O}}_J(y)]_\pm = 0, \qquad (x-y)^2 > 0,$$

where the graded commutator is used when fermionic operators are present. For a vacuum vector $|\Omega\rangle$, the unordered Lorentzian correlation functions are the Wightman distributions

$$W_{I_1\cdots I_n}(x_1, \dots, x_n) = \langle\Omega|\widehat{\mathcal{O}}_{I_1}(x_1)\cdots\widehat{\mathcal{O}}_{I_n}(x_n)|\Omega\rangle.$$

Time-ordered Green functions are

$$G^T_{I_1\cdots I_n}(x_1, \dots, x_n) = \langle\Omega|T\{\widehat{\mathcal{O}}_{I_1}(x_1)\cdots\widehat{\mathcal{O}}_{I_n}(x_n)\}|\Omega\rangle.$$

The corresponding Euclidean Schwinger functions are denoted by

$$S_{I_1\cdots I_n}(x_1^E, \dots, x_n^E) = \left\langle\mathcal{O}_{I_1}(x_1^E)\cdots\mathcal{O}_{I_n}(x_n^E)\right\rangle_E.$$

Hypothesis 59.1 (Radial reconstruction data)**.** The state–operator construction in this chapter is used for a Euclidean Schwinger hierarchy $S_{I_1\cdots I_n}$ satisfying the following conditions.

1. The S_n are distributional correlation functions of renormalized local operators on $\mathbb{R}^D$, with Euclidean covariance, graded permutation symmetry, and stated contact-term prescriptions at coincident points.

2. Let $\vartheta(x) = x/|x|^2$ be reflection through the unit sphere. The operator basis carries an antilinear reflection map Θ_{rad} that acts on a smeared insertion supported in the unit ball by applying ϑ, the appropriate Weyl factor, and the spin representation of the reflected orthonormal frame. For every finite linear combination F of such inside-supported insertions,
$$\langle F, F\rangle_{\mathrm{rad}} = \langle \Theta_{\mathrm{rad}} F\, F\rangle_E \geq 0.$$
The radial Hilbert space is the completion of this positive semidefinite form after quotienting by its null space.

3. The one-parameter group generated by dilatations acts on this Hilbert space by a nonnegative self-adjoint operator D_{rad}. Its spectrum on the finite-energy subspace is discrete, and for every $E < \infty$ the spectral subspace with $D_{\mathrm{rad}} \leq E$ is finite-dimensional. In particular every eigenspace has finite multiplicity, and the eigenvalue 0 subspace is spanned by the vacuum vector. Thus the conformally invariant vacuum in the radial Hilbert space is unique.

4. For each local operator $\mathcal{O}_I$ used below, the radial limit of the insertion at the origin defines a finite-energy vector. Descendant vectors are obtained by applying the translation generators, equivalently by derivatives of the insertion. The local operator basis is radially complete: after quotienting by the null radial two-point pairing, origin insertions of local operators and their descendants span precisely the finite-energy subspace
$$\mathcal{H}_{\mathrm{fin}} = \bigoplus_{\lambda<\infty} \ker(D_{\mathrm{rad}} - \lambda).$$
Equivalently, every finite-energy eigenvector is assumed to admit local radial boundary-value data of the kind specified in Definition 59.7 below. This is an existence assertion about distributional extensions at the origin; the theorem later in this chapter constructs the corresponding local-operator class from such data.

5. The Euclidean correlators are related to Lorentzian Wightman distributions by the standard tube-domain analytic continuation, with the Lorentzian distributions satisfying the spectrum condition and local commutativity. The flat-space vacuum correlators obey cluster decomposition: for two finite products of separated local insertions,
$$A(x_1, \ldots, x_m) = \mathcal{O}_{I_1}(x_1) \cdots \mathcal{O}_{I_m}(x_m), \qquad B(y_1, \ldots, y_n) = \mathcal{O}_{J_1}(y_1) \cdots \mathcal{O}_{J_n}(y_n),$$
and for a Euclidean vector a such that no coincident-point singularity is crossed along the translated configuration,
$$\lim_{\lambda\to+\infty} \langle A(x_1 + \lambda a, \ldots, x_m + \lambda a)\, B(y_1, \ldots, y_n)\rangle_E = \langle A(x_1, \ldots, x_m)\rangle_E\, \langle B(y_1, \ldots, y_n)\rangle_E.$$

Under Hypothesis 59.1, radial reflection positivity gives the inner product, D_{rad} gives the cylinder Hamiltonian, and local insertions at the origin give the complete finite-energy state space.

The completeness clause is the load-bearing part of the state–operator correspondence. Reflection positivity and the radial spectrum construct a Hilbert space and a Hamiltonian, but by themselves they only give an injection from local origin insertions into cylinder states. Surjectivity requires the additional local boundary-value assertion above: a finite-energy state must determine distributional correlators with an insertion at the origin whose contact terms, covariance, scaling law, and descendant Ward identities are those of a local operator. This condition is extra local distributional structure on top of the existence of a Hilbert-space vector.

The nonnegativity of D_{rad} in Hypothesis 59.1 is the radial spectrum condition for the vacuum representation. It is not the statement, proved later from descendant Gram positivity, that non-identity primary operators obey the unitarity lower bounds of Chapter 62. The same nonnegative self-adjoint operator D_{rad} is used in the radial OPE convergence theorem of Chapter 64.

These three versions are related by analytic continuation whenever the Lorentzian theory satisfies the spectral and locality hypotheses needed for the tube-domain construction. For an ordered Wightman product, continue

$$x_k^0 = -\mathrm{i}x_{E,k}^D$$

through a domain in which the imaginary parts remain ordered. With the convention $x^0 = -\mathrm{i}\tau_E$, the ordering

$$\operatorname{Im} x_1^0 < \operatorname{Im} x_2^0 < \cdots < \operatorname{Im} x_n^0$$

corresponds to

$$\tau_{E,1} > \tau_{E,2} > \cdots > \tau_{E,n}.$$

Here τ_E denotes Euclidean time inherited from Lorentzian analytic continuation. It is distinct from the cylinder coordinate $\tau = \log r$ introduced below. The Euclidean correlator is the boundary value obtained after this rotation. Time-ordered Green functions arise from a contour whose real-time projection places the insertions in chronological order.

Definition 59.2 (Status of the complex-time contour functional)**.** When a Lagrangian path-integral representative is available, the contour notation used for this analytic continuation is tied to the Lorentzian oscillatory convention of Definition 11.6 in Chapter 11. Choose a finite spatial regulator Λ and a finite subdivision P of the complex time contour C. Let $\mathcal{C}_{\Lambda,P}$ be the resulting finite-dimensional space of retained bosonic variables, together with the corresponding finite odd variables when fermions are present. The contour action is

$$S_{C,\Lambda,P}[\Phi] = \int_C \mathrm{d}x^0 \int \mathrm{d}^{D-1}\mathbf{x}\, \mathcal{L}_{\Lambda,P}(\Phi, \partial\Phi),$$

where the displayed integral is shorthand for the time-sliced finite regulator action along C. For $F = \prod_i \mathcal{O}_i(x_i)$, the finite-regulator contour functional is

$$I_{C,\Lambda,P}(F) = \int_{\mathcal{C}_{\Lambda,P}} d\nu_{\Lambda,P}(\Phi)\, \exp\{\mathrm{i}S_{C,\Lambda,P}[\Phi]\}\, F_{\Lambda,P}(\Phi). \tag{59.1}$$

For even variables $d\nu_{\Lambda,P}$ is an ordinary finite-dimensional reference measure. For odd variables it is a Berezin density. For gauge fields it is defined only after the finite-regulator gauge-fixing or BV data and boundary conditions have been supplied. If C contains Lorentzian segments, (59.1) is an oscillatory integral or oscillatory distribution, with Abel/Fourier boundary value or stationary-phase meaning as in Definition 11.6; Euclidean segments contribute the corresponding heat-kernel damping in the same time-sliced regulator.

The continuum symbol

$$\left\langle \prod_i \mathcal{O}_i(x_i) \right\rangle_C := \lim_{\Lambda,P} I_{C,\Lambda,P}\left(\prod_i \mathcal{O}_i(x_i)\right) \tag{59.2}$$

means the specified distributional boundary value in a construction where the limit exists. In a perturbative construction it denotes the corresponding formal asymptotic expansion obtained from the same regulator data. In an abstract CFT presentation the primary object is the Schwinger/Wightman hierarchy and its tube-domain analytic continuation; the contour functional is a representation of those boundary values.

Figure 59.1 records the boundary-value interpretation of complex-time contours used here: Euclidean, Lorentzian, and radially ordered correlators are different boundary presentations of the same analytic hierarchy once the relevant continuation exists.

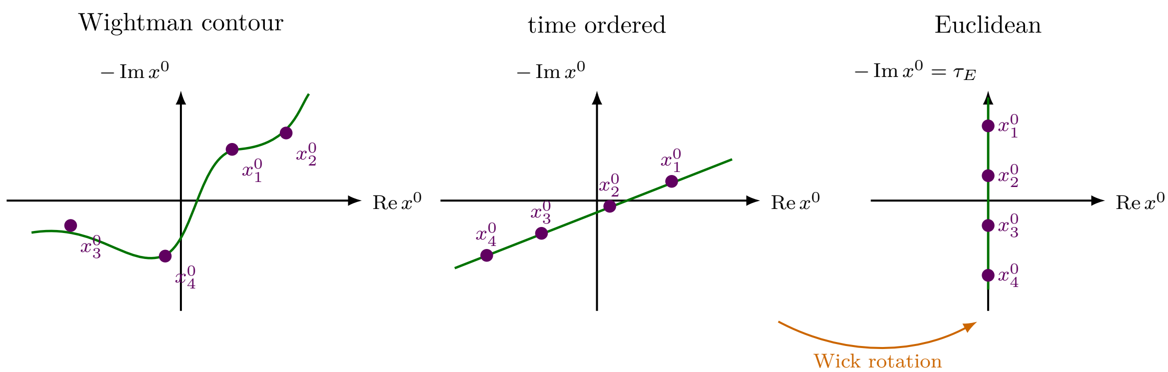

Figure 59.1: Different real-time orderings and Euclidean Schwinger functions are boundary values of the same analytic correlation functions, reached by deforming the complex-time contour without crossing singularities.

Remark 59.3 (Observables at a conformal fixed point). At a conformal fixed point, the data used in this volume are local operators, their correlation functions, and the Hilbert-space structure obtained from radial quantization. A separate scattering theory requires asymptotic particle states. Many conformal theories have no mass gap and no isolated massive particle sectors, so their intrinsic observable data are organized by local correlations rather than an S-matrix. Four-dimensional Yang–Mills theory illustrates a different situation: the classical action has no dimensionful coupling, but quantum renormalization produces Λ_{QCD} and a nonzero trace anomaly, so the quantum theory is not a conformal field theory.

59.2 The Weyl Map to the Cylinder

Let x^μ be Euclidean coordinates on $\mathbb{R}^D$, and write

$$r = |x|, \qquad x^\mu = r n^\mu, \qquad n^\mu n_\mu = 1.$$

The flat metric is

$$\mathrm{d}s^2 = \mathrm{d}r^2 + r^2 \mathrm{d}\Omega_{D-1}^2,$$

where $\mathrm{d}\Omega_{D-1}^2$ is the unit metric on S^{D-1}. Define

$$\tau = \log r.$$

Then

$$\frac{\mathrm{d}s^2}{r^2} = \mathrm{d}\tau^2 + \mathrm{d}\Omega_{D-1}^2. \tag{59.3}$$

Thus the punctured space $\mathbb{R}^D \setminus \{0\}$ is Weyl equivalent to the Euclidean cylinder

$$\mathbb{R}_\tau \times S^{D-1}.$$

The origin corresponds to $\tau = -\infty$, and infinity corresponds to $\tau = +\infty$.

The use of this Weyl map assumes that the flat-space conformal theory has been extended to background metrics with a specified Weyl transformation law for renormalized local operators. In even dimensions a Weyl anomaly may add local curvature terms to the generating functional. On the punctured flat space and cylinder comparison below, such terms affect contact and vacuum normalization data; the separated-point operator map is fixed after a choice of renormalized operator basis.

Figure 59.2 displays the Weyl map from punctured flat space to the cylinder, with radial distance becoming cylinder time $\tau = \log r$.

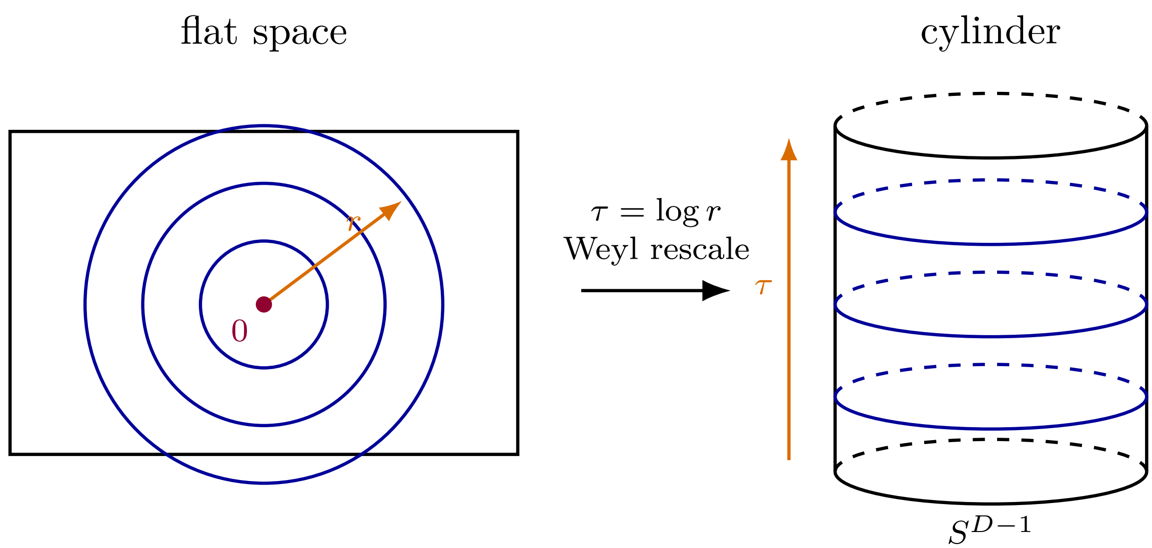

Figure 59.2: Radial quantization identifies dilatations on $\mathbb{R}^D$ with translations in cylinder time $\tau = \log r$.

59.3 Flat, Conformal, and Cylinder Vacua

Three vacuum vectors enter the radial construction, and their equality is a statement with hypotheses rather than a convention. The Lorentzian flat-space vacuum will be denoted by $|\Omega_\mathrm{P}\rangle$. It is the normalized Poincare-invariant vector in the Wightman Hilbert space on $\mathbb{R}^{1,D-1}$, with

$$P_\mu|\Omega_\mathrm{P}\rangle = 0, \qquad M_{\mu\nu}|\Omega_\mathrm{P}\rangle = 0,$$

where P_μ are the translation generators and $M_{\mu\nu}$ are the Lorentz generators. A conformal vacuum is a normalized vector $|\Omega_{\mathrm{conf}}\rangle$ invariant under the connected conformal group, or equivalently on a common invariant domain,

$$P_\mu|\Omega_{\mathrm{conf}}\rangle = M_{\mu\nu}|\Omega_{\mathrm{conf}}\rangle = D|\Omega_{\mathrm{conf}}\rangle = K_\mu|\Omega_{\mathrm{conf}}\rangle = 0.$$

The cylinder vacuum $|\Omega_0\rangle_{\mathrm{cyl}}$ is the normalized zero-eigenvalue state of the radial Hamiltonian D_{rad} in the Hilbert space on S^{D-1}:

$$D_{\mathrm{rad}}|\Omega_0\rangle_{\mathrm{cyl}} = 0.$$

It is represented by the empty Euclidean ball, or equivalently by insertion of the identity operator at the origin.

Proposition 59.4 (Identification of the flat and conformal vacua)**.** *Assume that the connected conformal group, or its universal cover, is implemented by strongly continuous unitaries on the Wightman Hilbert space on a common dense invariant domain containing $|\Omega_{\mathrm{P}}\rangle$. Assume also that the translation-invariant normalized vector is unique and that the generators obey the conformal Lie algebra on this domain. Then the flat Poincare vacuum is invariant under the connected conformal group. Thus $|\Omega_{\mathrm{conf}}\rangle = |\Omega_{\mathrm{P}}\rangle$, up to the irrelevant overall phase of a normalized vector.*

Proof. Let $U_D(s) = \exp(\mathrm{i}sD)$ be the unitary one-parameter group of dilatations. The relation

$$U_D(s)^{-1}P_\mu U_D(s) = \mathrm{e}^s P_\mu$$

implies that $U_D(s)|\Omega_{\mathrm{P}}\rangle$ is again annihilated by all translations. By uniqueness of the normalized translation-invariant vector,

$$U_D(s)|\Omega_{\mathrm{P}}\rangle = \mathrm{e}^{\mathrm{i}\alpha(s)}|\Omega_{\mathrm{P}}\rangle.$$

Strong continuity makes $\alpha(s)$ linear, so $D|\Omega_{\mathrm{P}}\rangle = d_0|\Omega_{\mathrm{P}}\rangle$ for some real number d_0. The number d_0 is forced to vanish by the conformal algebra: because $P_\nu|\Omega_{\mathrm{P}}\rangle = 0$ and P_ν is self-adjoint,

$$0 = \langle\Omega_{\mathrm{P}}|[P_\nu, K_\mu]|\Omega_{\mathrm{P}}\rangle = 2\eta_{\mu\nu}d_0.$$

Thus $D|\Omega_{\mathrm{P}}\rangle = 0$, which is the representation-theoretic normalization in which the identity operator has dimension zero.

Now use the conformal commutator

$$[P_\nu, K_\mu] = 2\eta_{\mu\nu}D + 2M_{\nu\mu}$$

with Lorentzian metric η. Since P_ν, D, and $M_{\nu\mu}$ annihilate $|\Omega_{\mathrm{P}}\rangle$,

$$P_\nu K_\mu|\Omega_{\mathrm{P}}\rangle = [P_\nu, K_\mu]|\Omega_{\mathrm{P}}\rangle = 0.$$

Therefore $K_\mu|\Omega_{\mathrm{P}}\rangle$ is translation-invariant. Uniqueness of the translation-invariant vector gives

$$K_\mu|\Omega_{\mathrm{P}}\rangle = c_\mu|\Omega_{\mathrm{P}}\rangle$$

for constants c_μ. Lorentz invariance of $|\Omega_{\mathrm{P}}\rangle$ and the vector transformation law of K_μ force c_μ to be a Lorentz invariant vector; hence $c_\mu = 0$. Thus the vacuum is annihilated by translations, Lorentz generators, dilatations, and special conformal generators, which are the infinitesimal generators of the connected conformal group. □

The relation between $|\Omega_{\mathrm{conf}}\rangle$ and $|\Omega_0\rangle_{\mathrm{cyl}}$ is supplied by the Weyl map $\mathbb{R}^D \setminus \{0\} \to \mathbb{R}_\tau \times S^{D-1}$. The Euclidean radial Hilbert space is constructed from the same flat-space vacuum correlators by cutting the Schwinger functions on spheres. Under this construction the identity operator at the origin creates the zero-energy state, so the common vacuum is identified as

$$|\Omega_{\mathrm{P}}\rangle = |\Omega_{\mathrm{conf}}\rangle \longleftrightarrow |\Omega_0\rangle_{\mathrm{cyl}}.$$

This identification fixes the notation used below: $|\Omega\rangle$ denotes this common vacuum whenever the flat or cylinder realization is clear from context.

The literal cutting-and-sewing meaning of radial quantization is a Kontsevich–Segal type Euclidean field-theoretic structure. In that language, a closed Euclidean hypersurface such as S^{D-1} is assigned a state space, a Euclidean bordism such as an annulus or punctured ball is assigned a linear amplitude between boundary state spaces, and gluing of bordisms is represented by composition of amplitudes. At this level the assigned state space should not be assumed to be a Hilbert space. In a general Euclidean field theory it is more naturally a locally convex topological vector space, often a Fréchet or nuclear space in analytic formulations, and the bordism amplitudes are continuous linear maps or distributional pairings.

Only for a unitary CFT does the radial cutting construction produce the Hilbert space used in the literal state–operator correspondence, and the extra ingredient is the inversion pairing. The map $x \mapsto x/|x|^2$ exchanges the inside and outside of a sphere, identifies the boundary sphere with its reflected copy up to the conformal Weyl factor, and turns reflection positivity of the doubled configuration into a positive semidefinite Hermitian form. Only after quotienting the null space and completing this form does one obtain the radial Hilbert space used below. Thus the hypotheses in this chapter use the part of the Kontsevich–Segal cutting/gluing structure needed for a CFT together with the inversion pairing: the state space on S^{D-1}, the positive radial inner product, the annular semigroup generated by D_{rad}, and the sewing identities for cylinder slabs. The complete Kontsevich–Segal axiom system and its construction status are developed in Chapter 13. The use here is the CFT specialization: literal radial quantization is first a hypersurface-cutting and bordism-gluing construction, and in a CFT the inversion pairing upgrades it to a Hilbert-space construction.

There remains a normalization convention. If a cylinder Hamiltonian is defined by integrating a chosen renormalized stress tensor on the curved cylinder, Weyl anomaly terms and local curvature counterterms can add a scalar Casimir energy to that operator. The radial Hamiltonian D_{rad} used in this chapter is the shifted generator whose identity state has eigenvalue zero. Equivalently the vacuum functional is normalized so that $\langle 1\rangle = 1$ on flat space and on the cylinder, with anomaly-dependent local curvature terms fixed once and for all. Separated-point operator correlators are then related by (59.9).

59.4 Operators Under the Cylinder Map

For a scalar primary $\mathcal{O}(x)$ of dimension Δ, define the cylinder operator

$$\widetilde{\mathcal{O}}(\tau, n) = \mathrm{e}^{\Delta\tau}\mathcal{O}(\mathrm{e}^{\tau} n). \tag{59.4}$$

This is the ordinary Weyl transformation of a scalar primary under $\mathrm{d}s^2 \mapsto r^{-2}\mathrm{d}s^2$.

The spin factor is the local orthonormal-frame rotation induced by the same map. Work on a coordinate patch $U \subset S^{D-1}$ with a smooth oriented orthonormal tangent frame

$$E_A^\mu(n), \qquad A = 1, \ldots, D-1, \qquad n_\mu E_A^\mu(n) = 0, \qquad E_A^\mu(n) E_{B\mu}(n) = \delta_{AB}.$$

The cylinder metric is $\widehat{g} = r^{-2}\delta_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu$. An orthonormal coframe for $\widehat{g}$, pulled back to the punctured flat space, is

$$\widehat{e}^{\hat{\tau}}{}_\mu(x) = r^{-1} n_\mu, \qquad \widehat{e}^{\hat{A}}{}_\mu(x) = r^{-1} E_{A\mu}(n). \tag{59.5}$$

Removing the common Weyl scale gives the $SO(D)$ rotation from the flat Cartesian orthonormal frame to the cylinder orthonormal frame,

$$R^{\hat{a}}{}_\mu(n) := r\,\widehat{e}^{\hat{a}}{}_\mu(x), \qquad R^{\hat{\tau}}{}_\mu(n) = n_\mu, \qquad R^{\hat{A}}{}_\mu(n) = E_{A\mu}(n), \tag{59.6}$$

so $R^{\hat{a}}{}_\mu R^{\hat{b}\mu} = \delta^{\hat{a}\hat{b}}$. On overlaps of two patches the frames E_A differ by an $SO(D-1)$ rotation; the formulas below transform by the corresponding tensor or spin representation.

For a covariant vector primary $V_\mu(x)$ of dimension Δ, the cylinder orthonormal-frame components are

$$\widetilde{V}_{\hat{a}}(\tau, n) = \mathrm{e}^{\Delta\tau} R_{\hat{a}}{}^\mu(n)\, V_\mu(\mathrm{e}^\tau n). \tag{59.7}$$

Equivalently,

$$V_\mu(\mathrm{e}^\tau n) = \mathrm{e}^{-\Delta\tau} R_\mu{}^{\hat{a}}(n)\, \widetilde{V}_{\hat{a}}(\tau, n).$$

The associated spin-one state map is obtained by inserting the flat operator at the origin:

$$|V_\mu\rangle := V_\mu(0)|\Omega\rangle, \qquad \lim_{\tau\to-\infty} \mathrm{e}^{-\Delta\tau}\, \widetilde{V}_{\hat{a}}(\tau, n)|\Omega\rangle = R_{\hat{a}}{}^\mu(n)|V_\mu\rangle. \tag{59.8}$$

The direction dependence in the last expression is exactly the rotation between the local cylinder frame at n and the fixed flat spin index at the origin. For a primary in a representation ρ of $SO(D)$, replace $R_{\hat{a}}{}^\mu$ in (59.7) by $\rho(R(n))$.

For a general renormalized local operator basis, the map can mix operators with the same quantum numbers when local counterterms are changed. The statement used in radial quantization is that, after fixing this basis, the correlation functions on the two Weyl-related backgrounds agree:

$$\langle \mathcal{O}_1(x_1) \cdots \mathcal{O}_n(x_n) \rangle_{\mathbb{R}^D} = \left\langle \widetilde{\mathcal{O}}_1(\tau_1, n_1) \cdots \widetilde{\mathcal{O}}_n(\tau_n, n_n) \right\rangle_{\mathbb{R}\times S^{D-1}}, \tag{59.9}$$

for separated points $x_i = \mathrm{e}^{\tau_i} n_i$, up to the specified local curvature and contact terms.

59.5 States from Local Operators

Let

$$B_R = \{x \in \mathbb{R}^D : |x| < R\}, \qquad \Sigma_R = \partial B_R = S_R^{D-1}.$$

The state prepared by a local operator at the origin is defined, in the radial reconstruction used in this chapter, by its radial pairings with the dense states prepared by insertions inside B_R. If A is a finite linear combination of renormalized local insertions supported in $B_R \setminus \{0\}$, and Θ_R denotes reflection through Σ_R,

$$\Theta_R(x) = \frac{R^2 x}{|x|^2},$$

then the vector $|\mathcal{O};R\rangle$ is characterized on the dense finite-energy domain by

$$\langle A,\mathcal{O};R\rangle_{\mathrm{rad}}=\langle\Theta_R A\,\mathcal{O}(0)\rangle_E\,. \tag{59.10}$$

Here $\Theta_R A$ includes the Weyl factors and spin-frame rotations of the reflected insertions. Equation (59.10) is the definition used for an abstract CFT supplied by Schwinger distributions. It uses the radial reflection-positive pairing and the null quotient of Hypothesis 59.1; it does not require a continuum field-configuration measure.

Definition 59.5 (Regulated ball preparation)**.** When a Lagrangian representative is used as a mnemonic or as an actual regularized construction, the ball preparation is the following finite regulator family. Map $B_R\setminus B_\rho$ to the cylinder slab $[\log\rho,\log R]\times S^{D-1}$. Choose a radial time spacing $a>0$, a finite angular spectral cutoff L for the eigenmodes of the relevant elliptic kinetic operator on S^{D-1}, and a renormalized operator representative $\mathcal{O}_{\rho,a,L}$ supported in the inner cap $|x|\le\rho$. The regulator parameter is

$$\varepsilon=(\rho,a,L),\qquad \rho\downarrow 0,\quad a\downarrow 0,\quad L\uparrow\infty. \tag{59.11}$$

At fixed ε, the boundary configuration space $\mathcal{B}_{\varepsilon,R}$ consists of the retained boundary modes on Σ_R. The finite-dimensional trace map

$$\mathrm{Tr}_{\varepsilon,R}:\mathcal{F}_{\varepsilon,R}\longrightarrow\mathcal{B}_{\varepsilon,R}$$

restricts a regulated bulk field configuration to those boundary modes. The finite-regulator measure or density on $\mathcal{F}_{\varepsilon,R}$ factors as

$$d\nu_{\varepsilon,R}(\Phi)=d\nu^{\mathrm{bulk}}_{\varepsilon,R}(\Phi\mid\varphi_\varepsilon)\,d\lambda^{\partial}_{\varepsilon,R}(\varphi_\varepsilon),\qquad \varphi_\varepsilon=\mathrm{Tr}_{\varepsilon,R}\,\Phi. \tag{59.12}$$

For even bosonic modes $d\lambda^{\partial}_{\varepsilon,R}$ is an ordinary finite-dimensional boundary measure. For odd variables it is the corresponding Berezin density, and in gauge theories it is supplied only after the finite-regulator gauge-fixing or BV data have been specified. The conditioned ball wavefunctional is

$$\Psi_{\mathcal{O},R,\varepsilon}(\varphi_\varepsilon)=\int_{\mathrm{Tr}_{\varepsilon,R}\,\Phi=\varphi_\varepsilon}d\nu^{\mathrm{bulk}}_{\varepsilon,R}(\Phi\mid\varphi_\varepsilon)\,\exp\{-S_{\varepsilon,R}[\Phi]\}\,\mathcal{O}_{\rho,a,L}. \tag{59.13}$$

The displayed conditioning is a finite-dimensional conditional integral over interior regulated variables. Gluing two regulated regions along Σ_R means pairing their boundary wavefunctionals by integration against $d\lambda^{\partial}_{\varepsilon,R}$, with the Berezin or gauge-fixed/BV analogue in the corresponding cases.

The continuum state represented by the regulated ball is the limit

$$|\mathcal{O};R\rangle=\lim_{\varepsilon\to 0}\mathfrak{R}_{\varepsilon,R}\Psi_{\mathcal{O},R,\varepsilon}, \tag{59.14}$$

whenever this limit exists in the radial Hilbert norm, or in the stated distribution topology before Hilbert completion. The map $\mathfrak{R}_{\varepsilon,R}$ embeds or identifies the finite-regulator boundary state with the regulated radial state space. In constructive positive-measure examples, (59.14) is compatible with disintegration of the constructed Euclidean field over the chosen boundary sigma-algebra or boundary Sobolev trace space. In the general CFT setting of this chapter, the mathematical state is the vector determined by (59.10), and (59.13) is a regulator-dependent representative of that vector when such a representative has been supplied.

After the Weyl map to the cylinder, changing R translates the state in τ. The state associated with $\mathcal{O}$, with the radius dependence absorbed into cylinder evolution, is denoted

$$|\mathcal{O}\rangle.$$

Definition 59.6 (Scaling operator classes and algebraic radial states)**.** A renormalized local operator class at the origin has definite scaling dimension Δ if, in all separated-point Euclidean correlators and with the stated contact-term convention, its infinitesimal dilatation Ward identity is

$$D_{\rm op}\mathcal{O}(0) = \Delta\,\mathcal{O}(0).$$

Equivalently, after the Weyl map to the cylinder, the corresponding origin-created state is an eigenvector of $D_{\rm rad}$ with eigenvalue Δ. Let $\mathcal{V}_{\rm loc}^{(\Delta)}$ be the quotient vector space of such local scaling operators, including all spin components and descendants of dimension Δ, modulo operators whose radial two-point pairing with every local operator vanishes.

The algebraic local-operator space is the direct sum over scaling dimensions,

$$\mathcal{V}_{\rm loc}^{\rm alg} = \bigoplus_{\Delta\in\mathrm{Spec}_{\rm pp}(D_{\rm rad})} \mathcal{V}_{\rm loc}^{(\Delta)}, \tag{59.15}$$

where the symbol $\oplus$ denotes finite linear combinations. The matching algebraic finite-energy subspace of the radial Hilbert space is

$$\mathcal{H}_{\rm alg} = \bigoplus_{\Delta\in\mathrm{Spec}_{\rm pp}(D_{\rm rad})} \ker(D_{\rm rad}-\Delta) \subset \mathcal{H}_{S^{D-1}}. \tag{59.16}$$

Here $\mathrm{Spec}_{\rm pp}$ denotes the point spectrum. Under Hypothesis 59.1 the eigenspaces appearing in (59.16) have finite multiplicity and $\mathcal{H}_{\rm alg}$ is dense in $\mathcal{H}_{S^{D-1}}$.

Definition 59.7 (Local radial boundary value of a state)**.** Let ψ_a, $a = 1,\dots,m$, be a finite rotation multiplet of vectors in $\ker(D_{\rm rad}-\Delta)$. The multiplet has local radial boundary-value data if the following distributions are specified.

For every ordered list of renormalized local operators $\mathcal{O}_{I_1},\dots,\mathcal{O}_{I_n}$, define on the configuration space $x_j \neq 0$, $x_i \neq x_j$, the punctured correlator

$$W^{\circ}_{\psi_a;I_1\dots I_n}(x_1,\dots,x_n) = \langle\Omega|\widetilde{\mathcal{O}}_{I_1}(\tau_1,n_1)\cdots\widetilde{\mathcal{O}}_{I_n}(\tau_n,n_n)|\psi_a\rangle_{\rm cyl}, \qquad x_j = \mathrm{e}^{\tau_j}n_j, \tag{59.17}$$

first in every radial ordering chamber, and in other chambers by the Euclidean permutation and contact prescriptions of the Schwinger hierarchy. The required data are extensions

$$W_{\psi_a;I_1\dots I_n} \in \mathcal{D}'\big((\mathbb{R}^D)^n\big) \tag{59.18}$$

of these punctured distributions such that:

1. their singular support is contained in the union of the ordinary partial diagonals $x_i = x_j$ and the origin diagonals $x_i = 0$;
2. their Euclidean covariance, spin transformation, and internal symmetry transformation laws are those of an additional insertion at the origin transforming in the same rotation and internal representation as the multiplet ψ_a;

3. their dilatation Ward identity has weight Δ at the origin, namely scaling all x_j by $\lambda > 0$ multiplies the origin insertion by $\lambda^{-\Delta}$, with the known anomalous-dimension matrix already diagonalized inside the finite-dimensional eigenspace;

4. translation of the origin insertion is represented by the descendant multiplets $P_{\mu_1} \cdots P_{\mu_k} \psi_a$, so differentiation with respect to the origin agrees, distributionally, with minus the sum of derivatives with respect to the exterior points;

5. for every radius R and every finite inside-supported insertion state $A \subset B_R \setminus \{0\}$, the exterior pairing obtained by reflecting A through Σ_R agrees with the Hilbert-space pairing,

$$W_{\psi_a;\Theta_R A} = \langle A, \psi_a \rangle_{\mathrm{rad}}. \tag{59.19}$$

The topology of the extension in (59.18) is the ordinary distribution topology on compact subsets after choosing the local contact-term convention.

Theorem 59.8 (Operator from a definite-energy radial state)**.** *Assume Hypothesis 59.1. Let $\psi_a \in \ker(D_{\mathrm{rad}} - \Delta)$ be a finite rotation multiplet with local radial boundary-value data in the sense of Definition 59.7. Then there is a unique class*

$$[\mathcal{O}_{\psi_a}] \in \mathcal{V}_{\mathrm{loc}}^{(\Delta)}$$

such that, for every exterior product of local operators, its Euclidean correlators are the distributions (59.18). Its radial state is precisely ψ_a:

$$|\mathcal{O}_{\psi_a}\rangle = \psi_a. \tag{59.20}$$

Two representatives that give the same radial state differ by a null local operator, namely by an element whose radial two-point pairing with every local operator vanishes.

Proof. The extensions (59.18) define the correlators of an additional distributional insertion supported at the origin. The singular support condition and the stated contact prescriptions give locality at all separated points and a prescribed extension across origin diagonals. The covariance and scaling Ward identities place this insertion in the Δ-eigenspace of the local dilatation action, with the specified spin and internal quantum numbers, and the translation condition identifies its descendants with the radial states $P_{\mu_1} \cdots P_{\mu_k} \psi_a$. Thus the data define a class $[\mathcal{O}_{\psi_a}] \in \mathcal{V}_{\mathrm{loc}}^{(\Delta)}$.

The radial state of this class is computed by pairing it with the dense set of inside-supported insertion states. For every such A, the defining pairing (59.10) and the boundary-value condition (59.19) give

$$\langle A, \mathcal{O}_{\psi_a}; R \rangle_{\mathrm{rad}} = \langle A, \psi_a \rangle_{\mathrm{rad}}.$$

Since these A's are dense after the radial null quotient, the two radial vectors agree. If two local insertions have the same radial state, their difference pairs to zero with every A, hence with every local operator by radial reflection and density; this is precisely the null equivalence used in the definition of $\mathcal{V}_{\mathrm{loc}}^{(\Delta)}$. □

Thus this theorem proves a conditional construction: local radial boundary-value data determine a local-operator class. The separate radial-completeness clause of Hypothesis 59.1 asserts that every finite-energy eigenspace vector has such data. Only after that clause is imposed can one conclude that the operator-from-state map is surjective on each eigenspace.

Construction 59.9 (cylinder sewing and Heisenberg operators)**.** Let

$$\Sigma_\tau = \{\tau\} \times S^{D-1}$$

be a constant-cylinder-time slice, and write

$$H_{\mathrm{cyl}} = D_{\mathrm{rad}}$$

for the nonnegative self-adjoint generator of translations in τ. For a cylinder local operator $X(n)$ placed on the slice Σ_0, its Euclidean Heisenberg translate is the operator on the common finite-energy domain

$$X(\tau, n) = \mathrm{e}^{\tau H_{\mathrm{cyl}}} X(0, n) \mathrm{e}^{-\tau H_{\mathrm{cyl}}}. \tag{59.21}$$

For separated insertions

$$\tau_+ > \tau_1 > \tau_2 > \cdots > \tau_n > \tau_-,$$

and boundary states v_- on Σ_{τ_-} and v_+ on Σ_{τ_+}, the cylinder amplitude obtained by cutting along all intermediate slices is

$$\begin{aligned}
&\mathcal{A}_{\tau_+,\tau_-}(v_+; X_1, \ldots, X_n; v_-) \\
&\quad = \left\langle v_+, \mathrm{e}^{-(\tau_+-\tau_1)H_{\mathrm{cyl}}} X_1(0, n_1) \mathrm{e}^{-(\tau_1-\tau_2)H_{\mathrm{cyl}}} \cdots X_n(0, n_n) \mathrm{e}^{-(\tau_n-\tau_-)H_{\mathrm{cyl}}} v_- \right\rangle.
\end{aligned} \tag{59.22}$$

Equation (59.22) is the Hilbert-space form of Euclidean sewing. In a functional-integral presentation it is obtained by integrating over the boundary field data on each cut Σ_{τ_j}; in the radial reconstruction presentation it is the composition law for the positive-time semigroup on the null quotient. The two descriptions give the same sesquilinear form because both are defined by the same Schwinger correlation hierarchy.

Taking $v_+ = \Omega$ and using

$$\langle \Omega | \mathrm{e}^{-sH_{\mathrm{cyl}}} = \langle \Omega |, \qquad s \geq 0,$$

turns (59.22) into the Euclidean Heisenberg matrix element

$$\langle \Omega | X_1(\tau_1, n_1) \cdots X_n(\tau_n, n_n) | v \rangle = \mathcal{A}_{\tau_+,\tau_-}\big(\Omega; X_1, \ldots, X_n; \mathrm{e}^{-\tau_- H_{\mathrm{cyl}}} v\big), \tag{59.23}$$

for every finite-energy vector v and every lower cut $\tau_- < \tau_n$. The right side is independent of the auxiliary cuts after the boundary state is transported as displayed. Thus the cylinder correlation function with a state prepared in the far past is computed by an ordered product of Heisenberg cylinder operators.

Theorem 59.10 (State–operator correspondence)**.** *Assume the radial reconstruction data of Hypothesis 59.1. For every $\Delta \in \mathrm{Spec}_{\mathrm{pp}}(D_{\mathrm{rad}})$, insertion at the origin defines an isometric linear isomorphism between local scaling operators of dimension Δ and cylinder energy eigenstates of energy Δ:*

$$\mathsf{S}_\Delta : \mathcal{V}_{\mathrm{loc}}^{(\Delta)} \xrightarrow{\sim} \ker(D_{\mathrm{rad}} - \Delta), \qquad \mathcal{O} \longmapsto |\mathcal{O}\rangle. \tag{59.24}$$

Consequently finite linear combinations of definite-dimension local operators give an isometric algebraic isomorphism

$$\mathsf{S}_{\mathrm{alg}} : \mathcal{V}_{\mathrm{loc}}^{\mathrm{alg}} \xrightarrow{\sim} \mathcal{H}_{\mathrm{alg}}.$$

The BPZ, or radial, completion of $\mathcal{V}_{\mathrm{loc}}^{\mathrm{alg}}$ is identified with $\mathcal{H}_{S^{D-1}}$, because $\mathcal{H}_{\mathrm{alg}}$ is dense. A generic vector in this completed Hilbert space is a state on the sphere; it is represented by a local *operator precisely when it lies in the algebraic finite-energy subspace with the local boundary-value property above. For a definite-dimension operator and for insertions ordered by cylinder time $\tau_1 > \tau_2 > \cdots > \tau_n$,*

$$\langle \mathcal{O}(0)\mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle_{\mathbb{R}^D} = \langle\Omega|\widetilde{\mathcal{O}}_1(\tau_1,n_1)\cdots\widetilde{\mathcal{O}}_n(\tau_n,n_n)|\mathcal{O}\rangle_{\mathrm{cyl}}. \tag{59.25}$$

Proof. Radial reflection positivity supplies the positive semidefinite inner product on local insertions inside a sphere. Quotienting its null space makes the map $\mathcal{O} \mapsto |\mathcal{O}\rangle$ injective, and the defining pairing (59.10) identifies its norm with the radial two-point pairing; hence the map is isometric. In a regulated Lagrangian representative this equality is the gluing identity obtained from (59.12), followed by the continuum limit (59.14). If $\mathcal{O} \in \mathcal{V}_{\mathrm{loc}}^{(\Delta)}$, the dilatation Ward identity for $\mathcal{O}(0)$ becomes the cylinder Hamiltonian equation

$$D_{\mathrm{rad}}|\mathcal{O}\rangle = \Delta|\mathcal{O}\rangle.$$

Thus S_Δ maps $\mathcal{V}_{\mathrm{loc}}^{(\Delta)}$ isometrically into $\ker(D_{\mathrm{rad}} - \Delta)$. Theorem 59.8, together with the radial-completeness clause of Hypothesis 59.1, gives the reverse inclusion: each vector in $\ker(D_{\mathrm{rad}} - \Delta)$ is represented by a local scaling operator of the same dimension, unique modulo null operators. This proves (59.24). Taking finite direct sums gives the algebraic isomorphism. Since D_{rad} is nonnegative self-adjoint, the spectral projections $P_{[0,E]}(D_{\mathrm{rad}})$ converge strongly to the identity as $E \to \infty$. Hence $\mathcal{H}_{\mathrm{alg}}$ is dense in $\mathcal{H}_{S^{D-1}}$, and the isometry extends by completion to the radial Hilbert space. This completion is a completion of states, not an assertion that every Hilbert-space vector is itself a local operator.

It remains to derive the correlation formula. Put

$$X_j(0,n_j) = \widetilde{\mathcal{O}}_j(0,n_j), \qquad X_j(\tau_j,n_j) = \widetilde{\mathcal{O}}_j(\tau_j,n_j),$$

where the second equality is the Heisenberg translation (59.21). Choose cuts $\tau_+ > \tau_1$ and $\tau_- < \tau_n$. By (59.23) with $v = |\mathcal{O}\rangle_{\mathrm{cyl}}$,

$$\langle\Omega|\widetilde{\mathcal{O}}_1(\tau_1,n_1)\cdots\widetilde{\mathcal{O}}_n(\tau_n,n_n)|\mathcal{O}\rangle_{\mathrm{cyl}}$$

is the cylinder Schwinger functional on the punctured cylinder with:

- the incoming boundary state prepared by the local insertion $\mathcal{O}(0)$, transported to the lower cut;
- insertions $X_n, \ldots, X_1$ placed in the slabs ordered by increasing cylinder time; and
- the outgoing boundary projected to the vacuum by the limit $\tau_+ \to +\infty$.

The vacuum projection exists because $H_{\mathrm{cyl}} \geq 0$ and the zero-energy subspace is $\mathbb{C}\Omega$. The sewing identity is unchanged if the auxiliary cuts are moved without crossing an insertion.

Finally apply the Weyl map $x_j = \mathrm{e}^{\tau_j} n_j$. The operator definition (59.4), with the corresponding spin-frame factor for spinning operators, identifies the cylinder Schwinger functional at separated points with the flat-space radially ordered correlator. Since $\tau_1 > \cdots > \tau_n$, radial ordering places $\mathcal{O}_1(x_1), \ldots, \mathcal{O}_n(x_n)$ outside the origin insertion in the displayed order. This gives (59.25).

□

The state $|\Omega\rangle$ is the ground state on S^{D-1}.

The vacuum state corresponds to the identity operator:

$$\mathbf{1} \longleftrightarrow |\Omega\rangle.$$

The algebraic local-operator space is dense in the BPZ/radial Hilbert norm but is not closed. Accordingly, the product of two separated local insertions inside a sphere defines a state on that sphere, not a new local operator at the origin. The operator product expansion is the statement that this state is the BPZ/radial-norm limit of finite sums of local scaling operators at the origin, organized by D_{rad}-eigenspaces. The density of $\mathcal{V}_{\mathrm{loc}}^{\mathrm{alg}}$ in this norm is the functional-analytic input that permits separated products to be represented by convergent local operator partial sums after radial ordering.

Figure 59.3 records the precise state-from-operator construction: inserting a local scaling operator at the origin gives an energy eigenstate on the sphere, and separated products give states approximated by local-operator partial sums.

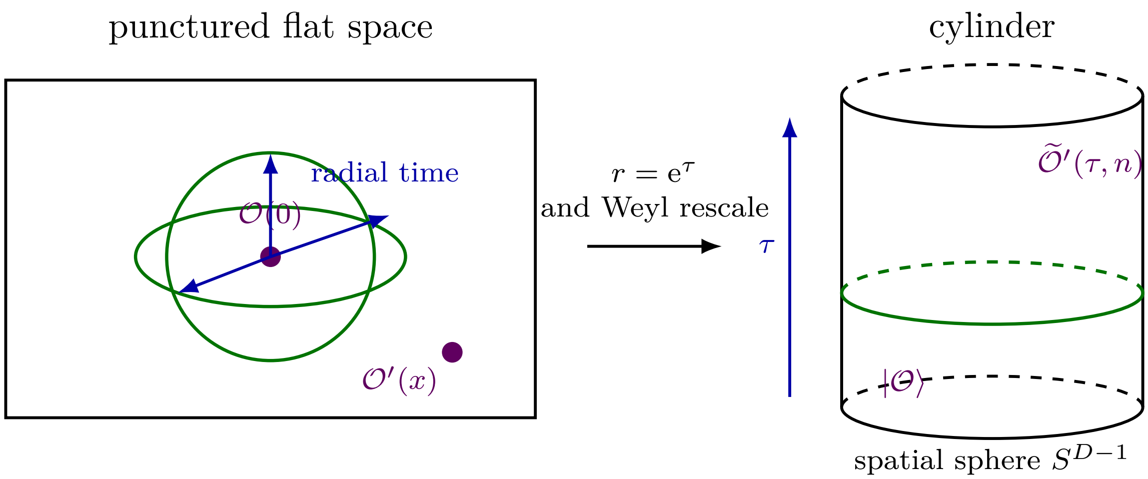

Figure 59.3: The singular endpoint $r = 0$ of the Weyl map becomes $\tau = -\infty$ on the cylinder. A local insertion at the origin therefore prepares a state on the spatial sphere.

59.6 Dilatation as the Cylinder Hamiltonian

The dilatation vector field on $\mathbb{R}^D$ is

$$x^\mu \partial_\mu = r\partial_r = \partial_\tau.$$

Therefore the dilatation charge maps to the Hamiltonian generating translations in cylinder time. Let $\widehat{H}_{\mathrm{cyl}}$ be defined by Euclidean evolution

$$|\psi(\tau + a)\rangle = \mathrm{e}^{-a\widehat{H}_{\mathrm{cyl}}}|\psi(\tau)\rangle.$$

In radial-quantization conventions the factors of i in the Lorentzian Hermitian conformal charges are absorbed, and

$$\widehat{H}_{\mathrm{cyl}} = \widehat{D}_{\mathrm{rad}}. \tag{59.26}$$

The eigenvalue of $\widehat{H}_{\rm cyl}$ is the scaling dimension.

The relation between the Hermitian Lorentzian convention and the radial Euclidean convention must be tracked at the level of the complexified conformal algebra. Let $\widehat{X}_{\rm L}$ denote the Hermitian Lorentzian charges in the convention of Chapter 57, so for example

$$[\widehat{D}_{\rm L},\widehat{P}^{\rm L}_\mu]={\rm i}\widehat{P}^{\rm L}_\mu,\qquad [\widehat{P}^{\rm L}_\mu,\widehat{K}^{\rm L}_\nu]=2{\rm i}(\delta_{\mu\nu}\widehat{D}_{\rm L}-\widehat{J}^{\rm L}_{\mu\nu}).$$

The radial descendant algebra is the real form adapted to the cylinder Hamiltonian and to the inversion pairing. With the subscript "rad" used only in this paragraph, the conversion is

$$\widehat{D}_{\rm rad}=-{\rm i}\widehat{D}_{\rm L},\qquad \widehat{J}^{\rm rad}_{\mu\nu}=-{\rm i}\widehat{J}^{\rm L}_{\mu\nu},\qquad \widehat{P}^{\rm rad}_\mu={\rm i}\widehat{P}^{\rm L}_\mu,\qquad \widehat{K}^{\rm rad}_\mu=-{\rm i}\widehat{K}^{\rm L}_\mu. \tag{59.27}$$

The opposite signs for $\widehat{P}_\mu$ and $\widehat{K}_\mu$ reflect their radial roles: translations create descendants and raise cylinder energy, while special conformal transformations annihilate primaries and lower cylinder energy. Applying (59.27) gives

$$[\widehat{D}_{\rm rad},\widehat{P}^{\rm rad}_\mu]=\widehat{P}^{\rm rad}_\mu,\qquad [\widehat{D}_{\rm rad},\widehat{K}^{\rm rad}_\mu]=-\widehat{K}^{\rm rad}_\mu,$$

and

$$[\widehat{P}^{\rm rad}_\mu,\widehat{K}^{\rm rad}_\nu]=-2(\delta_{\mu\nu}\widehat{D}_{\rm rad}-\widehat{J}^{\rm rad}_{\mu\nu}),\qquad [\widehat{K}^{\rm rad}_\mu,\widehat{P}^{\rm rad}_\nu]=2\delta_{\mu\nu}\widehat{D}_{\rm rad}-2\widehat{J}^{\rm rad}_{\nu\mu}. \tag{59.28}$$

The radial chapters suppress the subscript after this point. Thus the transition from Hermitian Lorentzian charges to the radial algebra is not a rule that deletes every visible factor of i; it is the complex change of real form displayed in (59.27). The sign in (59.28) is fixed against the conformal-Killing-vector realization: with the Hermitian charge convention $[Q_X,Q_Y]=-{\rm i}Q_{[X,Y]}$, the same vector-field brackets give the Lorentzian charge algebra, the Euclidean $SO(D+1,1)$ change of basis, and the radial real form above. The companion check `calculation-checks/conformal_algebra_sign_checks.py` verifies these three sign conversions from the vector fields rather than from mutually dependent displayed formulae. Positivity statements then use the Hilbert-space adjoint $\widehat{P}^\dagger_\mu=\widehat{K}_\mu$ supplied by radial reflection.

If $\mathcal{O}$ has scaling dimension Δ, then

$$\widehat{H}_{\rm cyl}|\mathcal{O}\rangle=\Delta|\mathcal{O}\rangle.$$

Thus the spectrum of scaling dimensions in flat space is the energy spectrum of the theory on the spatial sphere. Unitarity implies $\Delta\geq 0$ for states above the vacuum in a unitary CFT.

59.7 Primary and Descendant States

A local operator at the origin is called a conformal primary if the associated state is annihilated by all special conformal generators:

$$\widehat{K}_\mu|\mathcal{O}\rangle=0. \tag{59.29}$$

If $\mathcal{O}_\alpha$ transforms in a finite-dimensional spin representation with Hermitian matrices $(S_{\mu\nu})_\alpha{}^\beta$, so that a finite rotation near the identity is represented by $\exp(-\frac{\rm i}{2}\omega^{\mu\nu}S_{\mu\nu})$, then a primary state obeys

$$\widehat{D}_{\rm rad}|\mathcal{O}_\alpha\rangle=\Delta|\mathcal{O}_\alpha\rangle,\qquad \widehat{J}_{\mu\nu}|\mathcal{O}_\alpha\rangle=-(S_{\mu\nu})_\alpha{}^\beta|\mathcal{O}_\beta\rangle,\qquad \widehat{K}_\mu|\mathcal{O}_\alpha\rangle=0.$$

Translations generate descendants:

$$\widehat{P}_{\mu_1}\cdots\widehat{P}_{\mu_n}|\mathcal{O}\rangle\longleftrightarrow\partial_{\mu_1}\cdots\partial_{\mu_n}\mathcal{O}(0).$$

The commutator

$$[\widehat{D}_{\mathrm{rad}}, \widehat{P}_\mu] = \widehat{P}_\mu$$

shows that each derivative raises the scaling dimension by one. Before quotienting null relations, these descendant states form the conformal generalized Verma module generated by the primary datum (Δ, ρ); the algebraic definition is given in Definition 61.3. The Hilbert-space primary multiplet is the quotient by the radical of the radial inner product, and a shortening equation is precisely the vanishing of a descendant in this quotient.

Figure 59.4 displays the conformal multiplet structure used in this quotient: a primary state generates descendants by successive actions of $\widehat{P}_\mu$, with null descendants removed in the Hilbert completion.

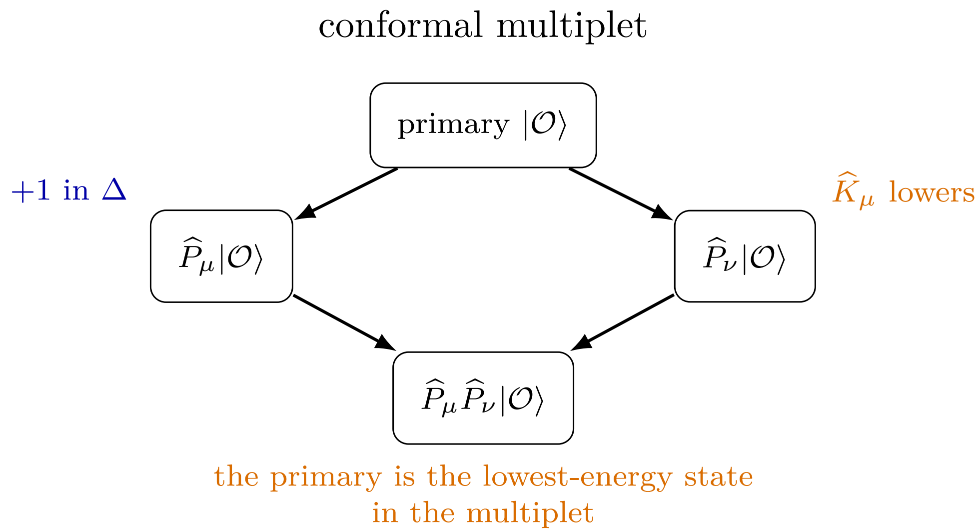

Figure 59.4: A conformal multiplet is generated from a primary by translations. On the cylinder, descendants have energies shifted upward by integers.

59.8 Reflection Positivity and Conjugation

Radial quantization gives a natural conjugation. In Euclidean flat space, reflection through the unit sphere is inversion:

$$x^\mu \mapsto \frac{x^\mu}{x^2}.$$

On the cylinder this is time reflection $\tau \mapsto -\tau$. For a scalar operator of dimension Δ, the conjugate insertion at infinity is

$$\mathcal{O}^\dagger(\infty) = \lim_{r\to\infty} r^{2\Delta}\mathcal{O}(rn)$$

when the limit is independent of n. The two-point function becomes the inner product

$$\langle \mathcal{O} \mid \mathcal{O}\rangle = \left\langle \mathcal{O}^\dagger(\infty)\mathcal{O}(0)\right\rangle.$$

For unitary theories this inner product is positive semidefinite and becomes positive definite after null states are quotiented. This positivity is the source of unitarity bounds, developed after primary transformation laws and two-point functions have been fixed.

59.9 Adjoints of the Conformal Generators

In radial quantization, Hermitian conjugation is a Hilbert-space statement in the reflection-positive completion of Hypothesis 59.1. Let $\mathcal{D}_{\text{loc}} \subset \mathcal{H}_{S^{D-1}}$ be the dense domain of finite linear combinations of local finite-energy states. For a scalar primary, the BPZ bra associated with the ket

$$|\mathcal{O}\rangle = \lim_{\tau\to-\infty} \mathrm{e}^{-\Delta\tau}\widetilde{\mathcal{O}}(\tau,n)|\Omega\rangle$$

is

$$\langle\!\langle\mathcal{O}| = \lim_{\tau\to+\infty} \mathrm{e}^{\Delta\tau}\langle\Omega|\widetilde{\mathcal{O}}^{\,\Theta_{\text{int}}}(\tau,n), \tag{59.30}$$

where Θ_{int} denotes the ordinary internal adjunction; for a spinning primary one also includes the spin-frame rotation specified by the radial reflection map in Hypothesis 59.1. Equivalently, in flat coordinates the bra is represented by the insertion obtained from $x \mapsto x/x^2$, together with the Weyl factor and spin transport. Formula (59.30) is the Hilbert-space version of the cylinder limit used later in (63.8).

The adjoint of an unbounded conformal generator is first defined on $\mathcal{D}_{\text{loc}}$. Let T_a be the finite translation of inside insertions by a small vector a, and let

$$C_a := \vartheta \circ T_a \circ \vartheta, \qquad \vartheta(x) = \frac{x}{|x|^2}, \tag{59.31}$$

be the corresponding finite special conformal transformation of the reflected insertions. The equality of Schwinger functions after applying the same conformal transformation to all separated insertions gives, for $A, B \in \mathcal{D}_{\text{loc}}$ and a small enough that no support crosses the reflection sphere,

$$\langle A, T_a B\rangle_{\text{rad}} = \langle C_a A, B\rangle_{\text{rad}}. \tag{59.32}$$

This is the step supplied by the BPZ bra construction: the transformation of the ket insertion is moved to the bra by radial reflection, and inversion turns the translated reflected insertion into a special-conformal one. With the radial generator convention in which translations create descendants,

$$\frac{\partial}{\partial a^\mu} T_a B\bigg|_{a=0} = \widehat{P}_\mu B, \qquad \frac{\partial}{\partial a^\mu} C_a A\bigg|_{a=0} = \widehat{K}_\mu A.$$

Differentiating (59.32) at $a = 0$ gives

$$\langle A, \widehat{P}_\mu B\rangle_{\text{rad}} = \langle \widehat{K}_\mu A, B\rangle_{\text{rad}}, \qquad A, B \in \mathcal{D}_{\text{loc}}. \tag{59.33}$$

Thus $\widehat{K}_\mu$ is the Hilbert-space adjoint of $\widehat{P}_\mu$ on the local finite-energy domain; after quotienting null states and taking the closure this is the adjoint relation used in the descendant Gram matrices.

Dilatations are translations in cylinder time, so

$$\widehat{D}^\dagger = \widehat{D}$$

in the cylinder Hilbert-space convention. Rotations are unitary symmetries of the spatial sphere:

$$\widehat{J}^\dagger_{\mu\nu} = \widehat{J}_{\mu\nu}.$$

Equation (59.33) is therefore summarized as

$$\widehat{P}^\dagger_\mu = \widehat{K}_\mu, \qquad \widehat{K}^\dagger_\mu = \widehat{P}_\mu. \tag{59.34}$$

Equation (59.34) is the algebraic input behind unitarity bounds. If $|\mathcal{O}\rangle$ is a primary state, then the norm of a first descendant is

$$\|\widehat{P}_\mu|\mathcal{O}\rangle\|^2 = \langle\mathcal{O}|\widehat{K}_\mu\widehat{P}_\mu|\mathcal{O}\rangle,$$

with summation over μ when a rotational scalar norm is taken. Commuting $\widehat{K}_\mu$ through $\widehat{P}_\nu$ and using $\widehat{K}_\mu|\mathcal{O}\rangle = 0$ expresses the result in terms of Δ and the spin representation of the primary. Positivity of all descendant norms is therefore a representation-theoretic constraint on allowed primary data.

59.10 The Free Scalar Check

Let ϕ be a free massless scalar primary with

$$\Delta_\phi = \frac{D-2}{2}.$$

The flat action is the $R = 0$ representative of the Weyl-covariant scalar action

$$S[\phi; g] = \frac{1}{2}\int \mathrm{d}^D x\,\sqrt{g}\,\left(g^{\mu\nu}\nabla_\mu\phi\nabla_\nu\phi + \xi_* R[g]\phi^2\right), \qquad \xi_* = \frac{D-2}{4(D-1)}. \tag{59.35}$$

Thus "massless in flat space" means that the curvature scalar vanishes in the flat representative; it does not mean that the Weyl-covariant representative lacks the curvature coupling. By the Weyl transformation already described in Chapter 58, the same theory on the cylinder has $R_{\mathrm{cyl}} > 0$, so the $\xi_* R\phi^2$ term is activated and becomes the cylinder mass term. If

$$\widetilde{\phi}(\tau, n) = \mathrm{e}^{\Delta_\phi \tau}\phi(\mathrm{e}^\tau n),$$

then

$$S_{\mathrm{cyl}}[\widetilde{\phi}] = \frac{1}{2}\int_{\mathbb{R}\times S^{D-1}} \mathrm{d}\tau\,\mathrm{d}\Omega_{D-1}\left[(\partial_\tau\widetilde{\phi})^2 + \nabla_{S^{D-1}}\widetilde{\phi}\cdot\nabla_{S^{D-1}}\widetilde{\phi} + \xi_* R_{\mathrm{cyl}}\widetilde{\phi}^2\right]. \tag{59.36}$$

The cylinder metric is

$$\mathrm{d}s^2_{\mathrm{cyl}} = \mathrm{d}\tau^2 + \mathrm{d}\Omega^2_{D-1},$$

where $\mathrm{d}\Omega^2_{D-1} = \gamma_{ab}\mathrm{d}\theta^a\mathrm{d}\theta^b$ is the unit round metric on S^{D-1}. The Levi-Civita connection of this product metric splits. Thus

$$R^{\mathrm{cyl}}_{\tau\tau} = 0, \qquad R^{\mathrm{cyl}}_{ab} = R^{S^{D-1}}_{ab} = (D-2)\gamma_{ab},$$

and contraction with $g^{\tau\tau}_{\mathrm{cyl}} = 1$ and $g^{ab}_{\mathrm{cyl}} = \gamma^{ab}$ gives

$$R_{\mathrm{cyl}} = g^{MN}_{\mathrm{cyl}} R^{\mathrm{cyl}}_{MN} = \gamma^{ab}(D-2)\gamma_{ab} = (D-1)(D-2).$$

The conformal mass term is

$$m^2_{\mathrm{cyl}} = \xi_* R_{\mathrm{cyl}} = \frac{(D-2)^2}{4}.$$

For a one-particle mode on S^{D-1} with angular momentum ℓ,

$$-\nabla^2_{S^{D-1}} Y_\ell = \ell(\ell + D - 2)Y_\ell.$$

The cylinder energy is

$$E_\ell = \sqrt{\ell(\ell + D - 2) + \frac{(D-2)^2}{4}} = \ell + \frac{D-2}{2}.$$

The $\ell = 0$ mode corresponds to the primary field ϕ, whose scaling dimension is

$$\Delta_\phi = \frac{D-2}{2}.$$

Modes with $\ell > 0$ correspond to derivative descendants of ϕ. This explicit spectrum realizes the state-operator correspondence in a theory where all local operators can be built from normal-ordered products of ϕ and its derivatives, modulo the equation of motion.

59.11 The Operator Partition Function of the Free Scalar

At a fixed point, it is often useful to count linearly independent local operators by their scaling dimension. This is a graded trace on the algebraic local-operator space, not a trace over the Hilbert completion. Let

$$Z_{\text{op}}(q) = \mathrm{Tr}_{\mathcal{V}_{\text{loc}}^{\text{alg}}} q^{\widehat{D}_{\text{rad}}}$$

be the formal character of the local-operator space. In the free scalar theory, the independent single-letter operators are the symmetric traceless derivatives

$$\partial_{(\mu_1} \cdots \partial_{\mu_\ell)}\phi \quad \text{with traces removed}, \qquad \ell = 0, 1, 2, \ldots.$$

The trace removal is the equation of motion $\partial^2\phi = 0$ and all of its derivatives. Counting all symmetric derivatives and subtracting the traces gives the single-letter character

$$f_\phi(q) = q^{\frac{D-2}{2}} \frac{1-q^2}{(1-q)^D}. \tag{59.37}$$

Proposition 59.11 (Free scalar letter character as a short-module character)**.** *The factor $1-q^2$ in (59.37) is the character subtraction of the null submodule generated by the level-two scalar descendant $\widehat{P}^2|\phi\rangle$, where $\widehat{P}^2 = \delta^{\mu\nu}\widehat{P}_\mu\widehat{P}_\nu$. Equivalently,*

$$f_\phi(q) = \chi\left(M\left(\frac{D-2}{2}, \mathbf{1}\right)\right) - q^2\,\chi\left(M\left(\frac{D-2}{2}, \mathbf{1}\right)\right),$$

where $M(\Delta, \mathbf{1})$ is the scalar conformal generalized Verma module defined in Chapter 61 and $\mathbf{1}$ is the trivial $SO(D)$ representation. This is the same null relation as the scalar unitarity-bound shortening proved in Theorem 62.1.

Proof. Before quotienting null states, the scalar generalized Verma module is freely generated by the commuting translations $\widehat{P}_\mu$. Hence its graded character is

$$\chi(M(\Delta, \mathbf{1})) = q^\Delta \sum_{n=0}^{\infty} \dim \mathrm{Sym}^n(\mathbb{C}^D)\, q^n = \frac{q^\Delta}{(1-q)^D}.$$

At $\Delta_\phi = (D-2)/2$, the level-two trace descendant is null by Theorem 62.1. It is also a singular vector. Indeed, using

$$[\widehat{K}_\nu, \widehat{P}_\mu] = 2\delta_{\nu\mu}\widehat{D}_{\text{rad}} - 2\widehat{J}_{\mu\nu}, \qquad [\widehat{J}_{\mu\nu}, \widehat{P}_\rho] = \delta_{\mu\rho}\widehat{P}_\nu - \delta_{\nu\rho}\widehat{P}_\mu,$$

and $\widehat{J}_{\mu\nu}|\phi\rangle = 0$, one obtains

$$\begin{aligned}
\widehat{K}_\nu \widehat{P}^2|\phi\rangle &= \left([\widehat{K}_\nu, \widehat{P}_\mu]\widehat{P}_\mu + \widehat{P}_\mu[\widehat{K}_\nu, \widehat{P}_\mu]\right)|\phi\rangle \\
&= \left(2(\Delta_\phi + 1)\widehat{P}_\nu - 2(D-1)\widehat{P}_\nu + 2\Delta_\phi \widehat{P}_\nu\right)|\phi\rangle \\
&= 4\left(\Delta_\phi + 1 - \frac{D}{2}\right)\widehat{P}_\nu|\phi\rangle = 0.
\end{aligned}$$

Therefore the null vector generates a conformal submodule. Its translation descendants have character

$$\frac{q^{\Delta_\phi+2}}{(1-q)^D}.$$

In polynomial notation $\widehat{P}_\mu \leftrightarrow p_\mu$, this quotient is the quotient of $\mathbb{C}[p_1, \ldots, p_D]$ by the ideal $p^2\mathbb{C}[p_1, \ldots, p_D]$, where $p^2 = \delta^{\mu\nu}p_\mu p_\nu$. At homogeneous degree ℓ, the Fischer decomposition gives

$$\mathrm{Sym}^\ell(\mathbb{C}^D) = \mathcal{H}_\ell \oplus p^2\,\mathrm{Sym}^{\ell-2}(\mathbb{C}^D),$$

where $\mathcal{H}_\ell$ is the space of harmonic homogeneous polynomials, equivalently the symmetric traceless rank-ℓ representation of $SO(D)$. Thus quotienting by the null submodule leaves exactly the symmetric traceless derivatives of ϕ, and the character is

$$\frac{q^{\Delta_\phi}}{(1-q)^D} - \frac{q^{\Delta_\phi+2}}{(1-q)^D} = q^{\frac{D-2}{2}}\frac{1-q^2}{(1-q)^D}.$$

□

Equivalently,

$$f_\phi(q) = q^{\frac{D-2}{2}}\sum_{\ell=0}^{\infty} d_{\ell,D}q^\ell, \qquad d_{\ell,D} = \binom{D+\ell-1}{\ell} - \binom{D+\ell-3}{\ell-2},$$

with the second binomial interpreted as zero for $\ell < 2$. These $d_{\ell,D}$ are the dimensions of scalar spherical harmonics of degree ℓ on S^{D-1}.

Normal-ordered products of the letters form the bosonic symmetric algebra of single-particle letters. If

$$f_\phi(q) = \sum_\Delta a_\Delta q^\Delta,$$

then the free scalar operator partition function is

$$Z^\phi_{\text{op}}(q) = \prod_\Delta \frac{1}{(1-q^\Delta)^{a_\Delta}} = \exp\left(\sum_{m=1}^{\infty}\frac{1}{m}f_\phi(q^m)\right). \tag{59.38}$$

For $D = 3$, $d_{\ell,3} = 2\ell + 1$, and therefore

$$f_\phi(q) = \sum_{\ell=0}^{\infty} (2\ell + 1) q^{\ell+\frac{1}{2}} = q^{1/2} \frac{1 - q^2}{(1 - q)^3}.$$

This is the same counting obtained from the one-particle spectrum of $\widehat{H}_{\text{cyl}} = \sqrt{-\nabla^2_{S^2} + 1/4}$ on S^2.

59.12 The Free Fermion Operator Partition Function

Let S be a complex spinor representation of $\mathrm{Spin}(D)$ with dimension $s_S = \dim S$. A free spinor primary ψ_α, $\alpha = 1, \ldots, s_S$, has scaling dimension

$$\Delta_\psi = \frac{D - 1}{2}.$$

The flat equation of motion is the Dirac equation

$$\gamma^\mu{}_\beta{}^\alpha \partial_\mu \psi_\alpha = 0, \tag{59.39}$$

where $\gamma^\mu : V \otimes S \to S'$ is Clifford multiplication from the vector representation $V \simeq \mathbb{C}^D$ and the chosen spinor module S to the target spinor module S'. In even D, for a chiral Weyl field, S' is the opposite chirality spinor; for a Dirac spinor, $S' = S$ after including both chiralities. The unrefined character only uses $\dim S' = \dim S = s_S$.

Before imposing (59.39), the translation descendants form

$$S \otimes \mathbb{C}[p_1, \ldots, p_D], \qquad p_\mu \leftrightarrow \widehat{P}_\mu,$$

with character $s_S q^{\Delta_\psi}/(1 - q)^D$. The Dirac equation is a level-one singular vector: the null descendant $\gamma^\mu \widehat{P}_\mu |\psi\rangle$ generates a submodule with character $s_S q^{\Delta_\psi+1}/(1 - q)^D$. Therefore the fermion single-letter character is

$$f_\psi(q) = s_S q^{\frac{D-1}{2}} \frac{1 - q}{(1 - q)^D} = \frac{s_S q^{\frac{D-1}{2}}}{(1 - q)^{D-1}}. \tag{59.40}$$

Free fermion letter character as a short-module character. The character (59.40) is the character of the free spinor conformal module obtained by quotienting the spinor generalized Verma module by the submodule generated by the Dirac descendant $\gamma^\mu \widehat{P}_\mu |\psi\rangle$. The generalized Verma module before shortening is freely generated by the commuting translations:

$$M(\Delta_\psi, S) = \mathbb{C}[\widehat{P}_1, \ldots, \widehat{P}_D] \otimes S, \qquad \chi(M(\Delta_\psi, S)) = \frac{s_S q^{\Delta_\psi}}{(1 - q)^D}.$$

At $\Delta_\psi = (D - 1)/2$, the Dirac descendant is primary. This follows from the radial commutator

$$[\widehat{K}_\nu, \widehat{P}_\mu] = 2\delta_{\nu\mu} \widehat{D}_{\text{rad}} - 2\widehat{J}_{\mu\nu}$$

and the spinor action

$$\widehat{J}_{\mu\nu}|\psi\rangle = \Sigma_{\mu\nu}|\psi\rangle, \qquad \Sigma_{\mu\nu} = \frac{1}{4}[\gamma_\mu, \gamma_\nu].$$

Using

$$\gamma^\mu \Sigma_{\mu\nu} = \frac{D-1}{2}\gamma_\nu$$

with the displayed $\Sigma_{\mu\nu}$ convention gives

$$\widehat{K}_\nu \gamma^\mu \widehat{P}_\mu |\psi\rangle = 2\left(\Delta_\psi - \frac{D-1}{2}\right)\gamma_\nu|\psi\rangle = 0.$$

Hence the Dirac descendant generates a conformal submodule. The submodule is again freely generated by translations, now starting one level higher and with spinor multiplicity s_S. Subtracting its character gives (59.40).

If $f_\psi(q) = \sum_\Delta a_\Delta q^\Delta$, the local-operator algebra generated by one free fermion field uses the exterior algebra of the odd letters:

$$Z^\psi_{\mathrm{op}}(q) = \prod_\Delta (1+q^\Delta)^{a_\Delta} = \exp\left(\sum_{m=1}^\infty \frac{(-1)^{m+1}}{m} f_\psi(q^m)\right). \tag{59.41}$$

This is the ordinary positive-counting trace over the fermionic Fock space; the insertion of $(-1)^F$ would replace $1+q^\Delta$ by $1-q^\Delta$.

In four dimensions, a Weyl fermion has $s_S = 2$ and

$$f_{\mathrm{Weyl}}(q) = \frac{2q^{3/2}}{(1-q)^3}.$$

A Dirac fermion, or a Weyl fermion together with its conjugate, has

$$f_{\mathrm{Dirac}}(q) = \frac{4q^{3/2}}{(1-q)^3}.$$

The coefficient of $q^{\ell+3/2}$ for a Weyl fermion is $(\ell+1)(\ell+2)$, the degeneracy of one chiral tower of spinor harmonics on S^3.

59.13 The Free Maxwell Operator Partition Function

The Maxwell field is conformal in four spacetime dimensions. The local gauge-invariant letters are the field-strength components $F_{\mu\nu}$. Work in Euclidean $D = 4$ with vector representation $V \simeq \mathbb{C}^4$. The primary $F_{\mu\nu} \in \wedge^2 V$ has $\Delta_F = 2$ and $\dim \wedge^2 V = 6$. Before imposing the equations, its translation descendants have character

$$\frac{6q^2}{(1-q)^4}.$$

The Bianchi identity and Maxwell equation are

$$\partial_{[\lambda}F_{\mu\nu]} = 0, \qquad \partial^\mu F_{\mu\nu} = 0. \tag{59.42}$$

At the level of polynomial jets, these are respectively a three-form constraint and a one-form constraint. Each has dimension 4, so together they subtract $8q^3/(1-q)^4$. The two constraints have one scalar reducibility identity each:

$$\partial_{[\rho}\partial_\lambda F_{\mu\nu]} = 0, \qquad \partial^\nu\partial^\mu F_{\mu\nu} = 0.$$

The first is $d^2F = 0$; the second follows from the antisymmetry of $F_{\mu\nu}$. They restore $2q^4/(1-q)^4$. Thus the Maxwell single-letter character is

$$f_{\mathrm{Max}}(q) = \frac{q^2(6-8q+2q^2)}{(1-q)^4} = \frac{6q^2-2q^3}{(1-q)^3}. \tag{59.43}$$

Equivalently, decompose

$$F = F^+ + F^-, \qquad F^+ \in (1,0), \qquad F^- \in (0,1)$$

under $\mathrm{Spin}(4) \simeq SU(2)_L \times SU(2)_R$. Each chiral field-strength module has character

$$f_{F^\pm}(q) = \frac{q^2(3-4q+q^2)}{(1-q)^4}, \qquad f_{\mathrm{Max}}(q) = f_{F^+}(q) + f_{F^-}(q).$$

This chiral expression makes the conformal shortening transparent: the level-one divergence descendant is removed, and the level-two scalar reducibility identity restores the over-subtraction.

If

$$f_{\mathrm{Max}}(q) = \sum_\Delta b_\Delta q^\Delta,$$

then the abelian Maxwell operator partition function generated by normal-ordered products of field-strength letters is the bosonic symmetric algebra

$$Z_{\mathrm{op}}^{\mathrm{Max}}(q) = \prod_\Delta \frac{1}{(1-q^\Delta)^{b_\Delta}} = \exp\left(\sum_{m=1}^\infty \frac{1}{m} f_{\mathrm{Max}}(q^m)\right). \tag{59.44}$$

Potential variables A_μ, gauge parameters, and ghosts belong to a gauge-fixed complex for path-integral determinants. The character (59.43) counts the BRST-invariant local field-strength cohomology in the free abelian theory.

59.14 High-Temperature Operator Entropy and the Cardy Limit

For a CFT satisfying Hypothesis 59.1, assume in addition that the spectral projection of D_{rad} onto $[0,\Delta]$ has finite trace for every finite Δ. The cylinder thermal trace is then

$$Z_{\mathrm{cyl}}(\beta) = \mathrm{Tr}_{\mathcal{H}_{S^{D-1}}}\, \mathrm{e}^{-\beta D_{\mathrm{rad}}} = \int_0^\infty \mathrm{e}^{-\beta E}\, dN(E), \qquad \beta > 0, \tag{59.45}$$

where

$$N(\Delta) = \mathrm{Tr}_{\mathcal{H}_{S^{D-1}}}\, \mathbf{1}_{[0,\Delta]}(D_{\mathrm{rad}}).$$

If the spectrum is pure point with finite degeneracies, this integral is $\sum_\Delta d(\Delta)\mathrm{e}^{-\beta\Delta}$, where $d(\Delta) = \dim\ker(D_{\mathrm{rad}} - \Delta)$. The operator partition function $Z_{\mathrm{op}}(q)$ is this same trace with $q = \mathrm{e}^{-\beta}$ when the local operator basis is complete and the trace converges. The large-Δ density should therefore be understood as the integrated spectral counting function $N(\Delta)$, or as a smoothed density obtained from it, rather than as an everywhere-defined ordinary function.

Assume that the high-temperature cylinder free energy has the leading form

$$\log Z_{\mathrm{cyl}}(\beta) = A\,\beta^{-(D-1)} + o(\beta^{-(D-1)}), \qquad A > 0. \tag{59.46}$$

This hypothesis is a thermodynamic input about the CFT on S^{D-1}: in $D > 2$ the constant A is not fixed by the stress-tensor two-point coefficient alone. It is the finite-volume version of the flat thermal pressure coefficient. The precise positivity input is the following Hardy–Littlewood Tauberian implication: if dN is a positive spectral measure on $[0, \infty)$ and $\log \int_0^\infty \mathrm{e}^{-\beta E} dN(E) = A\beta^{-\alpha} + o(\beta^{-\alpha})$ with $A, \alpha > 0$, then

$$\log N(E) = (\alpha+1)A^{1/(\alpha+1)} \left(\frac{E}{\alpha}\right)^{\alpha/(\alpha+1)} + o(E^{\alpha/(\alpha+1)}).$$

Applying this with $\alpha = D - 1$ gives the leading microcanonical entropy

$$\log N(\Delta) = D\,A^{1/D} \left(\frac{\Delta}{D-1}\right)^{\frac{D-1}{D}} + o(\Delta^{\frac{D-1}{D}}). \tag{59.47}$$

The saddle calculation is explicit. Extremize

$$\Phi(\beta) = \beta\Delta + A\beta^{-(D-1)}.$$

The stationary point satisfies

$$\Delta = (D-1)A\beta_*^{-D}, \qquad \beta_* = \left(\frac{(D-1)A}{\Delta}\right)^{1/D}.$$

Substitution gives (59.47). Thus the power $\Delta^{(D-1)/D}$ is fixed by extensivity of high-temperature thermal physics in $D-1$ spatial dimensions, while the coefficient records the specific CFT thermal free energy.

In $D = 2$ the torus supplies a stronger statement because modular invariance relates the high-temperature trace to the low-temperature vacuum. Let the spatial circle have circumference 2π, and let

$$H_{\mathrm{cyl}} = L_0 + \bar{L}_0 - \frac{c_L + c_R}{24}, \qquad \Delta = h + \bar{h}, \qquad J = h - \bar{h}.$$

For a compact unitary two-dimensional CFT with discrete finite-multiplicity spectrum, unique vacuum, and modular-invariant torus partition function, the thermal trace

$$Z(\beta) = \mathrm{Tr}\exp\left[-\beta\left(L_0 + \bar{L}_0 - \frac{c_L + c_R}{24}\right)\right]$$

obeys $Z(\beta) = Z(4\pi^2/\beta)$ for the rectangular torus. As $\beta \to 0^+$, the transformed trace is dominated by the vacuum, and

$$\log Z(\beta) = \frac{\pi^2(c_L + c_R)}{6\beta} + o(\beta^{-1}). \tag{59.48}$$

If $c_L = c_R = c$, then $A = \pi^2 c/3$ in (59.46). Equation (59.47) gives

$$\log N(\Delta) = 2\pi\sqrt{\frac{c\,\Delta}{3}} + o(\sqrt{\Delta}). \tag{59.49}$$

This is the Cardy entropy-dimension relation for total scaling dimension. Keeping left and right energies separately gives the spin-resolved form

$$\log \rho(h, \bar{h}) = 2\pi\sqrt{\frac{c_L h}{6}} + 2\pi\sqrt{\frac{c_R \bar{h}}{6}} + o(\sqrt{h} + \sqrt{\bar{h}}), \tag{59.50}$$

for $h, \bar{h} \to \infty$ with $h/\bar{h}$ remaining in a compact subinterval of $(0, \infty)$. If the lowest left or right conformal weight is not the vacuum value, the same derivation replaces c_L, c_R by the corresponding effective central charges $c_L - 24h_{\min}$ and $c_R - 24\bar{h}_{\min}$.

Chapter 60

Conformal Charges and Ward Identities

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

60.1 Charges as Surface Operators

Definition 60.1 (Conformal surface charge)**.** Let $\epsilon^\mu(x)\partial_\mu$ be a conformal Killing vector on flat Euclidean space, and let

$$J^\mu_\epsilon(x) = T^\mu{}_\nu(x)\epsilon^\nu(x)$$

be the corresponding conserved current at separated points. If $\Sigma \subset \mathbb{R}^D$ is an oriented smooth codimension-one surface with unit normal n_μ, define the charge supported on Σ by

$$Q_\epsilon(\Sigma) = \int_\Sigma \mathrm{d}\sigma\, n_\mu T^\mu{}_\nu(x)\epsilon^\nu(x). \tag{60.1}$$

Here $\mathrm{d}\sigma$ is the induced volume element.

Surface deformation of a conserved charge. Let Σ_0 and Σ_1 be homologous oriented smooth codimension-one surfaces in a region $U \subset \mathbb{R}^D$ that contains no operator insertions and no boundary. If $\partial_\mu J^\mu_\epsilon = 0$ as a separated-point distribution on U, then $Q_\epsilon(\Sigma_0) = Q_\epsilon(\Sigma_1)$ inside every correlation function whose other insertions lie outside the deformation region.

Let $V \subset U$ be the oriented region swept out by the deformation, with $\partial V = \Sigma_1 - \Sigma_0$. Smearing the distributional conservation law with a test function that is one on V and whose support avoids all insertions gives

$$0 = \int_V \mathrm{d}^D x \, \partial_\mu J^\mu_\epsilon(x) = \int_{\Sigma_1} \mathrm{d}\sigma \, n_\mu J^\mu_\epsilon - \int_{\Sigma_0} \mathrm{d}\sigma \, n_\mu J^\mu_\epsilon.$$

The last equality is Stokes' theorem for the smoothed distributional pairing; shrinking the transition region of the test function to zero gives the surface statement. No contact term appears because the support of the deformation avoids the insertion diagonals.

This deformation property is the local content of a conserved charge. A charge may be evaluated on a large sphere surrounding several insertions, or on a union of small spheres surrounding them separately. The equality of these two evaluations is the Ward identity.

Definition 60.2 (Lorentzian charge commutator across an insertion)**.** The Lorentzian operator meaning of the same construction is the following. Let $\widehat{Q}_\epsilon(\Sigma)$ be the flux of the conserved current through a spacelike Cauchy surface Σ, with future-directed unit normal. If a local operator $\widehat{\mathcal{O}}(0)$ is inserted between two nearby Cauchy surfaces Σ_- and Σ_+, then

$$[\widehat{Q}_\epsilon, \widehat{\mathcal{O}}(0)] = \widehat{Q}_\epsilon(\Sigma_+)\widehat{\mathcal{O}}(0) - \widehat{\mathcal{O}}(0)\widehat{Q}_\epsilon(\Sigma_-). \tag{60.2}$$

Here conservation identifies the charge on $\Sigma_\pm$ with the same abstract symmetry generator when no insertion lies between the two surfaces. Equation (60.2) is the definition of the commutator after the charge has been represented on the Hilbert spaces immediately to the future and past of the insertion. After Euclidean continuation, the two surfaces close into a small hypersurface surrounding the insertion, and the commutator becomes the small-surface action used below.

Figure 60.1 records this Lorentzian-to-Euclidean translation of a charge commutator: the difference between future and past charge slices becomes a closed surface surrounding the insertion.

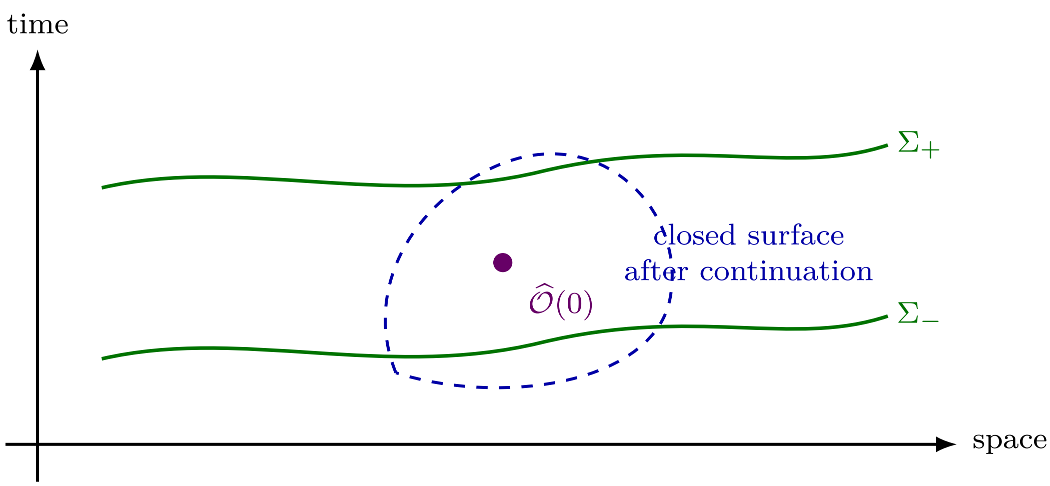

Figure 60.1: A Lorentzian commutator with a conserved charge is represented by the difference between charge insertions on slices immediately after and before the local operator. In Euclidean signature this difference is encoded by a closed surface enclosing the insertion.

Figure 60.2 displays the corresponding Euclidean Ward-identity deformation: a closed charge surface can be moved through regions free of insertions, and crossing an insertion gives the local symmetry action.

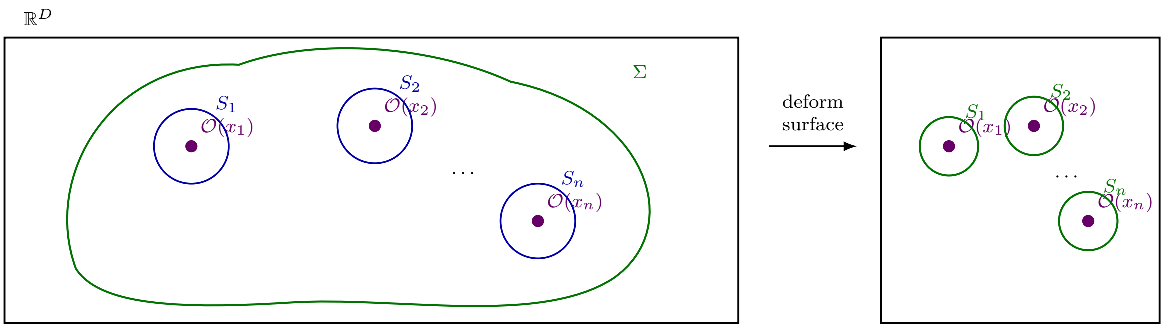

Figure 60.2: A conserved conformal charge can be moved from a large enclosing surface to small enclosing surfaces around the insertions. The Ward identity is this equality inside correlation functions.

60.2 Operator Variations from Small Spheres

Definition 60.3 (Small-surface action on a local operator)**.** Let S_x be a small sphere enclosing a single insertion at x, with orientation inherited from the boundary of a small ball removed from the correlation-function domain. The infinitesimal action of the symmetry on the operator $\mathcal{O}(x)$ is defined by

$$\delta_\epsilon \mathcal{O}(x) = \mathrm{i}\, Q_\epsilon(S_x)\mathcal{O}(x) \tag{60.3}$$

in Euclidean radial-ordering conventions. In Lorentzian operator language, this convention corresponds to

$$\delta_\epsilon \widehat{\mathcal{O}} = \mathrm{i}[\widehat{Q}_\epsilon, \widehat{\mathcal{O}}].$$

Changing the orientation convention changes both sides of (60.3) by the same sign; the Ward identity below is then unchanged.

Hypothesis 60.4 (Vacuum and large-boundary behavior)**.** For the conformal Killing vector $\epsilon^\mu \partial_\mu$ and the correlators under consideration, assume the following two properties.

(i) The vacuum is invariant under the corresponding charge. In Lorentzian notation this means

$$\widehat{Q}_\epsilon|\Omega\rangle = 0, \qquad \langle\Omega|\widehat{Q}_\epsilon = 0$$

on the common invariant domain on which the correlators are defined.

(ii) If Σ_R is a family of smooth enclosing surfaces whose distance from the insertions tends to infinity, then clustering makes the large boundary flux vanish:

$$\lim_{R\to\infty} \left\langle Q_\epsilon(\Sigma_R) \prod_{i=1}^{n} \mathcal{O}_i(x_i) \right\rangle = 0.$$

More explicitly, with

$$Q_\epsilon(\Sigma_R) = \int_{\Sigma_R} \mathrm{d}S_\mu\, \epsilon_\nu(x) T^{\mu\nu}(x),$$

the connected correlator

$$\left\langle T^{\mu\nu}(x) \prod_{i=1}^{n} \mathcal{O}_i(x_i) \right\rangle_c$$

must decay at large $|x|$ fast enough to overcome the area growth of Σ_R and the polynomial growth of the displayed conformal Killing vectors. This is the cluster-decomposition input in the deformation of the large surface to the small spheres S_i.

Global conformal Ward identity from surface deformation. Under Hypothesis 60.4, for separated insertions,

$$0 = \left\langle Q_\epsilon(\Sigma) \prod_{i=1}^{n} \mathcal{O}_i(x_i) \right\rangle = \sum_{i=1}^{n} \langle \mathcal{O}_1(x_1) \cdots Q_\epsilon(S_i)\mathcal{O}_i(x_i) \cdots \mathcal{O}_n(x_n) \rangle , \tag{60.4}$$

where Σ encloses all insertions and S_i is a small sphere enclosing x_i. Using (60.3), this becomes

$$\sum_{i=1}^{n} \langle \mathcal{O}_1(x_1) \cdots \delta_\epsilon \mathcal{O}_i(x_i) \cdots \mathcal{O}_n(x_n) \rangle = 0. \tag{60.5}$$

This is the global Ward identity associated with the conformal Killing vector ϵ^μ. It is a statement about distributions on the configuration space of distinct points, completed by contact terms on diagonals when operator products collide.

By vacuum invariance, the charge on a sufficiently large surface enclosing all insertions has zero expectation value after the large-boundary limit in Hypothesis 60.4. By the surface-deformation argument at the beginning of the chapter, that large surface can be deformed through the punctured configuration space to the union of small surfaces S_i surrounding the insertions. The induced orientation on the small boundaries is the one used in Definition 60.3, and hence each small surface gives

$$Q_\epsilon(S_i)\mathcal{O}_i(x_i) = -\mathrm{i}\, \delta_\epsilon \mathcal{O}_i(x_i).$$

Multiplying the equality of surface insertions by i gives (60.5). This derivation is carried out on the configuration space of distinct points; the extension to coincident configurations is a further source-convention statement about contact terms.

60.3 Source-Derived Local Ward Identities

The surface identity is the integral form of the source Ward identities introduced in Section 56.6. Let

$$X = \mathcal{O}_1(x_1) \cdots \mathcal{O}_n(x_n), \qquad x_i \neq x_j,$$

where the $\mathcal{O}_i$ are scalar local operators. In the source-coordinate system used for the stress tensor and the operators, the following distributional identities are the local form of the conformal Ward identity.

Proposition 60.5 (Local conformal-current Ward identity)**.** *Assume that the stress tensor is symmetric and that scalar primary sources are defined in the same source-coordinate system as the metric-source stress tensor. Let $\mathcal{O}_i$ have scaling dimensions Δ_i, and set*

$$\sigma_\epsilon = \frac{1}{D}\partial_\rho \epsilon^\rho, \qquad J^\mu_\epsilon = T^\mu{}_\nu \epsilon^\nu.$$

The translation Ward identity is

$$\partial_\mu \langle T^{\mu\nu}(x)X\rangle = -\sum_{i=1}^{n} \delta^{(D)}(x-x_i)\,\langle \mathcal{O}_1(x_1)\cdots \partial_i^\nu \mathcal{O}_i(x_i)\cdots \mathcal{O}_n(x_n)\rangle\,. \tag{60.6}$$

Here ∂_i^ν differentiates the ith insertion coordinate. A spin-carrying insertion adds the local representation term dictated by the diffeomorphism action on its source. Equation (60.6) is equivalent to the smeared identity (56.28); the displayed delta functions record the extension of the separated-point distribution across the diagonals $x = x_i$.

The flat-space trace Ward identity in the same source-coordinate system is

$$\langle T^\mu{}_\mu(x)X\rangle = -\sum_{i=1}^{n} \Delta_i\,\delta^{(D)}(x-x_i)\,\langle X\rangle + \mathcal{A}(x;X). \tag{60.7}$$

The distribution $\mathcal{A}(x;X)$ is the local anomaly or contact term obtained by differentiating the local source functional $\mathcal{A}_\sigma[X]$ in (56.29) with respect to the Weyl parameter $\sigma(x)$. It vanishes on the configuration space of distinct flat-space points; on collision diagonals or curved backgrounds it is part of the specified source convention.

If ϵ^μ is a conformal Killing vector, then

$$\partial_\mu \langle J^\mu_\epsilon(x)X\rangle = \sum_{i=1}^{n} \delta^{(D)}(x-x_i)\,\langle \mathcal{O}_1(x_1)\cdots \delta_\epsilon \mathcal{O}_i(x_i)\cdots \mathcal{O}_n(x_n)\rangle + \sigma_\epsilon(x)\mathcal{A}(x;X), \tag{60.8}$$

where for a scalar primary

$$\delta_\epsilon \mathcal{O}_i(x_i) = -\epsilon^\nu(x_i)\partial_{i,\nu}\mathcal{O}_i(x_i) - \Delta_i\sigma_\epsilon(x_i)\mathcal{O}_i(x_i).$$

For spin ρ_i, $\delta_\epsilon\mathcal{O}_i$ includes the local rotation term displayed later in (61.9).

Proof. The translation identity is the functional derivative of the metric-source diffeomorphism Ward identity with respect to the scalar sources, followed by setting all sources to their flat background values. The sign is fixed by the active variation $\delta_\epsilon\mathcal{O}_i = -\epsilon^\nu\partial_{i,\nu}\mathcal{O}_i$ for translations. The trace identity is the corresponding functional derivative of the Weyl Ward identity in the same source-coordinate system; the displayed Δ_i-term comes from the Weyl weight of the scalar source, while $\mathcal{A}(x;X)$ is the differentiated local Weyl anomaly functional.

For a conformal Killing vector,

$$\partial_\mu\epsilon_\nu + \partial_\nu\epsilon_\mu = 2\sigma_\epsilon\delta_{\mu\nu}.$$

Using symmetry of $T^{\mu\nu}$,

$$\partial_\mu\langle J^\mu_\epsilon(x)X\rangle = \epsilon_\nu(x)\partial_\mu\langle T^{\mu\nu}(x)X\rangle + \sigma_\epsilon(x)\langle T^\mu{}_\mu(x)X\rangle.$$

Substituting (60.6) and (60.7) gives (60.8), with the delta functions evaluating ϵ^μ and σ_ϵ at the insertion points. □

Integrating (60.8) over a region whose boundary is $\Sigma \cup_i (-S_i)$ gives the surface decomposition (60.4); if the large boundary contribution vanishes and the anomaly term integrates to zero in the chosen background, the global Ward identity (60.5) follows.

60.4 Conformal Charges on the Cylinder

Cylinder conformal charges and radial adjointness. Under the Weyl map

$$\mathbb{R}^D \setminus \{0\} \longrightarrow \mathbb{R}_\tau \times S^{D-1}, \qquad x^\mu = \mathrm{e}^\tau n^\mu, \qquad n^\mu n_\mu = 1,$$

closed spheres surrounding the origin become constant-τ slices. The dilatation charge becomes the cylinder Hamiltonian, rotations become the rotations of S^{D-1}, and the translation and special conformal charges become mutually adjoint raising and lowering operators:

$$\widehat{P}_\mu^\dagger = \widehat{K}_\mu. \tag{60.9}$$

This adjointness is a consequence of reflection positivity under $\tau \mapsto -\tau$, which is inversion in flat space. It is the positivity input used below to derive unitarity bounds. The map $x^\mu = \mathrm{e}^\tau n^\mu$ sends the flat metric on $\mathbb{R}^D \setminus \{0\}$ to $\mathrm{d}s^2 = \mathrm{e}^{2\tau}(\mathrm{d}\tau^2 + \mathrm{d}\Omega_{D-1}^2)$; after the Weyl rescaling by $\mathrm{e}^{-2\tau}$, spheres $|x| = \mathrm{e}^\tau$ are the constant cylinder-time slices. The conformal Killing vector $x^\mu \partial_\mu$ therefore becomes ∂_τ, so its charge is the generator of Euclidean cylinder translations. Reflection positivity pairs an insertion at τ with its reflected insertion at $-\tau$, and reflection in flat coordinates is inversion $x^\mu \mapsto x^\mu/x^2$. Inversion conjugates translations to special conformal transformations; hence the positive radial inner product identifies the adjoint of the translation charge with the special conformal charge, giving (60.9). Rotations commute with the Weyl factor and act as the ordinary isometries of S^{D-1}.

More explicitly, let

$$\Pi_{\mu\nu}(n) = \delta_{\mu\nu} - n_\mu n_\nu$$

be the projector onto the tangent space of S^{D-1} at n. Acting on functions on $\mathbb{R}_\tau \times S^{D-1}$, the flat-space conformal Killing vectors become

$$D_{\mathrm{rad}} = \partial_\tau, \tag{60.10}$$

$$P_\mu = \mathrm{e}^{-\tau}\left(n_\mu \partial_\tau + \Pi_{\mu\nu}(n)\frac{\partial}{\partial n_\nu}\right), \tag{60.11}$$

$$K_\mu = \mathrm{e}^{\tau}\left(-n_\mu \partial_\tau + \Pi_{\mu\nu}(n)\frac{\partial}{\partial n_\nu}\right), \tag{60.12}$$

with rotations acting as vector fields tangent to the sphere. Thus inversion $x^\mu \mapsto x^\mu/x^2$, which is $\tau \mapsto -\tau$, exchanges P_μ and K_μ. As vector fields their weights under $D_{\mathrm{rad}}^{\mathrm{vec}} = \partial_\tau$ are

$$[\partial_\tau, P_\mu^{\mathrm{vec}}] = -P_\mu^{\mathrm{vec}}, \qquad [\partial_\tau, K_\mu^{\mathrm{vec}}] = K_\mu^{\mathrm{vec}}.$$

The Hilbert-space grading has the opposite sign because the induced infinitesimal action on local operators contains the differential operator $-\mathcal{L}_\epsilon$, as in (60.8). In the radial Hilbert-space representation recalled in Chapter 59,

$$[\widehat{D}_{\mathrm{rad}}, \widehat{P}_\mu] = \widehat{P}_\mu.$$

Since $\widehat{D}_{\mathrm{rad}}$ is self-adjoint and $\widehat{P}_\mu^\dagger = \widehat{K}_\mu$ by (60.9), the adjoint commutator is $[\widehat{D}_{\mathrm{rad}}, \widehat{K}_\mu] = -\widehat{K}_\mu$. Consequently $\widehat{P}_\mu$ raises and $\widehat{K}_\mu$ lowers the cylinder energy by one unit.

The Hamiltonian identification is also visible directly from the stress tensor. On the sphere S_r^{D-1} of radius r, with $x^\mu = rn^\mu$,

$$\widehat{D}_{\mathrm{rad}} = \int_{S_r^{D-1}} \mathrm{d}\sigma\, n^\mu \widehat{T}_{\mu\nu}(x) x^\nu = r^D \int_{S^{D-1}} \mathrm{d}\Omega\, n^\mu n^\nu \widehat{T}_{\mu\nu}(rn). \tag{60.13}$$

Under the Weyl map this is the cylinder Hamiltonian

$$\widehat{H}_{\mathrm{cyl}} = \int_{S^{D-1}} \mathrm{d}\Omega\, \widehat{T}^{\mathrm{cyl}}_{\tau\tau}.$$

In Lorentzian cylinder time $t = -\mathrm{i}\tau$, the corresponding Hermitian generator differs from the Euclidean radial generator by the standard Wick-rotation factor described in Chapter 59. The monograph uses $\widehat{D}_{\mathrm{rad}}$ for the positive Euclidean cylinder Hamiltonian that grades local operators by their scaling dimensions; whenever Hermitian Lorentzian charges appear in Ward identities, the conversion to radial commutators is made by the same analytic continuation of the group parameter.

60.5 Two-Dimensional Chiral Stress-Tensor Charges

Two Euclidean dimensions require a refinement of the preceding finite conformal-charge construction. Let U be a coordinate chart on an oriented Euclidean surface with complex coordinate z. In a flat chart away from operator insertions, assume the separated-point stress-tensor Ward identities take the chiral form

$$\partial_{\bar z} T(z) = 0, \qquad \partial_z \bar{T}(\bar z) = 0 \tag{60.14}$$

inside correlation functions. Equation (60.14) has the separated distributional meaning that, for any product X of local insertions whose supports avoid z,

$$\partial_{\bar z}\langle T(z)X\rangle = 0, \qquad \partial_z\langle \bar{T}(\bar z)X\rangle = 0.$$

Contact terms at the insertions are part of the source convention discussed in Section 56.6.

Definition 60.6 (Chiral stress-tensor contour charge)**.** The chiral contour charge associated with a holomorphic vector field $v(z)\partial_z$ on an annulus A is the oriented contour operator

$$Q_v(C) = -\oint_C \frac{\mathrm{d}z}{2\pi\mathrm{i}}\, v(z)T(z), \tag{60.15}$$

where $C \subset A$ is positively oriented around the insertion on which the charge acts. The sign in (60.15) is the active-operator sign: the infinitesimal change generated by $z \mapsto z + \varepsilon v(z)$ is

$$\delta_v \mathcal{O} = \varepsilon Q_v(C)\mathcal{O}.$$

Suppose $\mathcal{O}(0)$ has holomorphic weight h, so that its response to translations and linear rescalings is finite and diagonal. Then the singular part of the stress-tensor OPE begins as

$$T(z)\mathcal{O}(0) = \cdots + \frac{h}{z^2}\mathcal{O}(0) + \frac{1}{z}\partial\mathcal{O}(0) + O(z^0), \tag{60.16}$$

where the omitted terms to the left of the displayed terms are possible poles of order z^{-3} and higher. These higher poles are the additional transformation data under nonlinear chiral vector fields.

Definition 60.7 (Virasoro primary and contour modes)**.** A Virasoro primary is a local operator ϕ whose stress-tensor singular part is exactly

$$T(z)\phi(0) = \frac{h}{z^2}\phi(0) + \frac{1}{z}\partial\phi(0) + O(z^0), \qquad \bar{T}(\bar{z})\phi(0) = \frac{\bar{h}}{\bar{z}^2}\phi(0) + \frac{1}{\bar{z}}\bar{\partial}\phi(0) + O(\bar{z}^0). \tag{60.17}$$

This is stronger than global conformal primarity: it is a statement about the whole local chiral stress-tensor representation, including the $\mathrm{PSL}(2,\mathbb{C})$ subalgebra.

On a punctured disc, the holomorphic modes are

$$L_n = \oint_0 \frac{\mathrm{d}z}{2\pi\mathrm{i}}\, z^{n+1} T(z), \qquad n \in \mathbb{Z}, \tag{60.18}$$

acting first on the common radial domain generated by finitely many local insertions and then, when reflection positivity and finite-energy decomposition are available, on the corresponding dense domain in the radial Hilbert space. With this convention,

$$L_0|\phi\rangle = h|\phi\rangle, \qquad L_{-1}|\phi\rangle = |\partial\phi\rangle$$

for a Virasoro primary ϕ. The antiholomorphic modes $\bar{L}_n$ are defined analogously from $\bar{T}(\bar{z})$.

Lemma 60.8 (Stress-tensor OPE and the Virasoro algebra)**.** *Assume that the singular part of the holomorphic stress-tensor OPE is*

$$T(z)T(w) \sim \frac{c}{2(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}. \tag{60.19}$$

Then the contour modes (60.18) *obey, on the radial finite-insertion domain,*

$$[L_n, L_m] = (n-m)L_{n+m} + \frac{c}{12}(n^3-n)\delta_{n+m,0}. \tag{60.20}$$

Proof. Let C_2 be a positively oriented contour around the origin and let C_1 be a positively oriented contour outside C_2. The ordered product L_nL_m is represented by

$$\oint_{C_1} \frac{\mathrm{d}z}{2\pi\mathrm{i}} \oint_{C_2} \frac{\mathrm{d}w}{2\pi\mathrm{i}}\, z^{n+1} w^{m+1} T(z)T(w).$$

The product L_mL_n is the same expression with the z-contour moved to a contour C_1' inside C_2. Hence the commutator is obtained by integrating z over $C_1 - C_1'$. Since $C_1 - C_1'$ encloses the point w but not the origin, it can be shrunk to a small positive contour around w. Only the singular part of (60.19) contributes:

$$[L_n, L_m] = \oint_{C_2} \frac{\mathrm{d}w}{2\pi\mathrm{i}} w^{m+1} \operatorname*{Res}_{z=w}\left[z^{n+1}\left(\frac{c}{2(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}\right)\right].$$

The residues are

$$\operatorname*{Res}_{z=w} \frac{z^{n+1}}{(z-w)^4} = \frac{(n+1)n(n-1)}{6}\, w^{n-2}, \qquad \operatorname*{Res}_{z=w} \frac{z^{n+1}}{(z-w)^2} = (n+1)w^n.$$

Thus

$$[L_n, L_m] = \oint_{C_2} \frac{\mathrm{d}w}{2\pi\mathrm{i}} \left[\frac{c}{12}(n^3-n)w^{m+n-1} + 2(n+1)w^{m+n+1}T(w) + w^{m+n+2}\partial T(w)\right].$$

The first term contributes precisely when $m+n=0$. For the last term, integrating by parts on the closed contour gives

$$\oint \frac{\mathrm{d}w}{2\pi\mathrm{i}}\, w^{m+n+2}\partial T(w) = -(m+n+2)\oint \frac{\mathrm{d}w}{2\pi\mathrm{i}}\, w^{m+n+1}T(w).$$

The coefficient of the remaining stress-tensor mode is therefore $2(n+1)-(m+n+2)=n-m$, giving (60.20). □

Remark 60.9 (Antiholomorphic sector and gravitational anomaly). The antiholomorphic modes satisfy the same algebra with c replaced by $\bar{c}$, and separated holomorphic and antiholomorphic contours commute up to possible contact terms that would be a gravitational anomaly. A reflection-positive parity-invariant two-dimensional CFT has $c=\bar{c}$. In a theory with a gravitational anomaly, the two chiral central charges are different and the spatial momentum on the cylinder acquires the corresponding vacuum shift.

Infinitesimal stress-tensor transformation. With the contour-charge convention (60.15) and the stress-tensor OPE (60.19), a holomorphic vector field $v(z)\partial_z$ acts on $T(w)$ by

$$\delta_v T(w) = -v(w)\partial T(w) - 2v'(w)T(w) - \frac{c}{12}v'''(w). \tag{60.21}$$

This is an equality of insertions on any annulus on which the contour for Q_v can be chosen without crossing other operators. The formula is therefore a separated-point Ward identity; contact extensions at collisions are fixed by the source convention for the stress tensor.

The contour calculation is local around w. By definition,

$$\delta_v T(w) = Q_v(C)T(w) = -\oint_C \frac{\mathrm{d}z}{2\pi\mathrm{i}}\, v(z)T(z)T(w),$$

where C is a small positive contour around w. Insert (60.19). The three required residues are

$$\operatorname*{Res}_{z=w}\frac{v(z)}{z-w} = v(w), \qquad \operatorname*{Res}_{z=w}\frac{v(z)}{(z-w)^2} = v'(w), \qquad \operatorname*{Res}_{z=w}\frac{v(z)}{(z-w)^4} = \frac{v'''(w)}{6}.$$

The overall minus sign in Q_v gives

$$-\left(v(w)\partial T(w) + 2v'(w)T(w) + \frac{c}{2}\,\frac{v'''(w)}{6}\right),$$

which is (60.21).

Schwarzian cocycle. For locally univalent holomorphic maps f and g, the Schwarzian derivative

$$\{f,z\} = \frac{f'''(z)}{f'(z)} - \frac{3}{2}\left(\frac{f''(z)}{f'(z)}\right)^2$$

satisfies

$$\{g\circ f, z\} = (f'(z))^2\{g, f(z)\} + \{f,z\}. \tag{60.22}$$

Moreover, if $f_s(z) = z + sv(z) + O(s^2)$, then

$$\left.\frac{\mathrm{d}}{\mathrm{d}s}\right|_{s=0} \{f_s, z\} = v'''(z). \tag{60.23}$$

Set

$$A_f(z) = \frac{f''(z)}{f'(z)} = \partial_z \log f'(z).$$

Then

$$\{f, z\} = A_f'(z) - \frac{1}{2}A_f(z)^2.$$

For a composition,

$$A_{g\circ f}(z) = A_f(z) + f'(z)A_g(f(z)).$$

Differentiate and subtract one half of the square:

$$\begin{aligned} A_{g\circ f}' - \frac{1}{2}A_{g\circ f}^2 = A_f' - \frac{1}{2}A_f^2 + (f')^2\left(A_g' - \frac{1}{2}A_g^2\right)\circ f \\ + f''A_g \circ f - A_f f' A_g \circ f. \end{aligned}$$

Since $A_f = f''/f'$, the last two terms cancel. This proves (60.22). Finally, for $f_s(z) = z + sv(z) + O(s^2)$,

$$f_s' = 1 + sv' + O(s^2), \qquad f_s'' = sv'' + O(s^2), \qquad f_s''' = sv''' + O(s^2).$$

Substitution into the definition of the Schwarzian gives $\{f_s, z\} = sv'''(z) + O(s^2)$, proving (60.23).

Proposition 60.10 (Schwarzian transformation and plane-cylinder shift)**.** *The stress tensor itself carries an affine chiral transformation law fixed by* (60.19)*. If $z' = f(z)$ is a holomorphic coordinate change, then*

$$T'(z') = \left(\frac{\mathrm{d}f}{\mathrm{d}z}\right)^{-2}\left[T(z) - \frac{c}{12}\{f, z\}\right], \qquad \{f, z\} = \frac{f'''(z)}{f'(z)} - \frac{3}{2}\left(\frac{f''(z)}{f'(z)}\right)^2. \tag{60.24}$$

The Schwarzian derivative satisfies the cocycle identity

$$\{g \circ f, z\} = (f'(z))^2\{g, f(z)\} + \{f, z\},$$

which is exactly the condition that successive coordinate changes act associatively on T.

For the cylinder coordinate $w = \sigma + \mathrm{i}\tau$, $\sigma \sim \sigma + 2\pi$, we use

$$z = \mathrm{e}^{-\mathrm{i}w}, \qquad w = \mathrm{i}\log z.$$

Applying (60.24) *to the coordinate change $z \mapsto w(z)$, for which $\{w, z\} = 1/(2z^2)$, gives*

$$T^{(w)}(w) = \left(\frac{\mathrm{d}z}{\mathrm{d}w}\right)^2 T^{(z)}(z) + \frac{c}{24} = -z^2 T^{(z)}(z) + \frac{c}{24}. \tag{60.25}$$

If

$$T^{(z)}(z) = \sum_{n\in\mathbb{Z}} \frac{L_n}{z^{n+2}}, \qquad \bar{T}^{(\bar{z})}(\bar{z}) = \sum_{n\in\mathbb{Z}} \frac{\bar{L}_n}{\bar{z}^{n+2}},$$

then

$$T^{(w)}(w) = -\sum_{n\in\mathbb{Z}} \mathrm{e}^{\mathrm{i}nw} L_n + \frac{c}{24}, \qquad \bar{T}^{(\bar{w})}(\bar{w}) = -\sum_{n\in\mathbb{Z}} \mathrm{e}^{-\mathrm{i}n\bar{w}} \bar{L}_n + \frac{\bar{c}}{24}.$$

In the cylinder normalization used in Chapter 59, the Hamiltonian and spatial momentum on the unit circle are therefore

$$H_{\mathrm{cyl}} = L_0 + \bar{L}_0 - \frac{c+\bar{c}}{24}, \qquad P_{\mathrm{cyl}} = L_0 - \bar{L}_0 - \frac{c-\bar{c}}{24}. \tag{60.26}$$

Thus the radial Hamiltonian differs from the naive dilatation eigenvalue by the Casimir term forced by the stress-tensor anomaly under the plane-cylinder coordinate change.

Proof. First prove the finite formula. For a local coordinate change f, define the right side of (60.24) by

$$\mathcal{T}_f(f(z)) = (f'(z))^{-2}\left[T(z) - \frac{c}{12}\{f,z\}\right].$$

If $f_s(z) = z + sv(z) + O(s^2)$, then

$$(f_s')^{-2} = 1 - 2sv' + O(s^2), \qquad T(z) = T(z_s - sv(z_s)) + O(s^2)$$

at the fixed final point $z_s = f_s(z)$. Together with (60.23),

$$\mathcal{T}_{f_s}(z_s) = T(z_s) - s\left(v\partial T + 2v'T + \frac{c}{12}v'''\right)(z_s) + O(s^2),$$

which is exactly the infinitesimal Ward action (60.21).

It remains to check compatibility with finite composition. Applying first f and then g gives

$$(g'(f)f')^{-2}\left[T - \frac{c}{12}\{f,z\} - \frac{c}{12}(f')^2\{g,f(z)\}\right],$$

which equals the transformation for $g\circ f$ precisely by (60.22). Thus the displayed formula is a projective cocycle for the connected local conformal group whose tangent action is the stress-tensor Ward action. On a simply connected neighborhood of the identity this characterizes the integrated action uniquely; analytic continuation along paths in the chosen coordinate-change group gives the stated finite law, with possible global monodromy recorded separately by the gravitational-anomaly data.

For $w = \mathrm{i}\log z$, direct differentiation gives

$$w' = \frac{\mathrm{i}}{z}, \qquad w'' = -\frac{\mathrm{i}}{z^2}, \qquad w''' = \frac{2\mathrm{i}}{z^3}, \qquad \{w,z\} = \frac{1}{2z^2}.$$

Using $z = \mathrm{e}^{-\mathrm{i}w}$ and $\mathrm{d}z/\mathrm{d}w = -\mathrm{i}z$ in (60.24) yields (60.25). Substituting the Laurent expansions of $T^{(z)}$ and $\bar{T}^{(\bar{z})}$ and taking the zero modes of cylinder translations and rotations gives (60.26). □

Remark 60.11 (Local operators and the radial Hilbert completion in $D=2$). The Virasoro mode construction refines the domain statement of Chapter 59. The local operators at the origin, including their Virasoro descendants, span an algebraic finite-energy subspace. After quotienting null vectors and completing in the BPZ/radial norm, this subspace is dense in the Hilbert space on the circle under the hypotheses of Hypothesis 59.1. The precise state–operator statement is therefore the correspondence between local scaling fields of definite $L_0, \bar{L}_0$ eigenvalues and the finite-energy radial eigenstates in this algebraic domain. The completed Hilbert space is the BPZ/radial completion of that dense domain. This density is the analytic input behind the radial OPE: the product of two nearby local insertions is represented by a convergent expansion in local scaling fields in the radial Hilbert norm.

Primary Operators and Finite Conformal Transformations

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

61.1 Spin Representations and Primary Data

Definition 61.1 (Spin primary datum)**.** Let ρ be a finite-dimensional representation of $SO(D)$ on a vector space V_ρ. A local operator valued in this representation is written

$$\mathcal{O}_a(x), \qquad a = 1, \dots, \dim V_\rho.$$

The infinitesimal spin matrices are denoted

$$(S_{\mu\nu})_a{}^b = -(S_{\nu\mu})_a{}^b.$$

They obey the $SO(D)$ Lie algebra in the representation ρ, in the convention in which a finite rotation R near the identity is represented as $\rho(R) = \exp(-\frac{\mathrm{i}}{2}\omega^{\mu\nu}S_{\mu\nu})$. Thus the $S_{\mu\nu}$ are Hermitian spin matrices in a unitary representation.

A conformal primary operator of spin ρ and scaling dimension Δ is an operator whose state at the origin obeys

$$\widehat{K}_\mu|\mathcal{O}_a\rangle = 0, \qquad \widehat{D}_{\mathrm{rad}}|\mathcal{O}_a\rangle = \Delta|\mathcal{O}_a\rangle, \qquad \widehat{J}_{\mu\nu}|\mathcal{O}_a\rangle = -(S_{\mu\nu})_a{}^b|\mathcal{O}_b\rangle. \tag{61.1}$$

Remark 61.2 (Global primaries, quasi-primaries, and Virasoro primaries). In $D \geq 3$ the conformal Killing equation on flat space has only the finite-dimensional conformal algebra. Therefore the state condition (61.1) is the intrinsic notion of a conformal primary used throughout this volume. In $D = 2$ there is an additional local conformal enhancement: on the plane the globally defined conformal group is $\mathrm{PSL}(2, \mathbb{C})$, generated by L_{-1}, L_0, L_1 and $\bar{L}_{-1}, \bar{L}_0, \bar{L}_1$, while the local holomorphic and antiholomorphic conformal transformations are represented quantum mechanically by the Virasoro algebras. A local operator whose state is annihilated by L_1 and $\bar{L}_1$ is often called a *quasi-primary*; it transforms covariantly under the global conformal group. A Virasoro primary is a stronger object: its state is annihilated by all $L_n, \bar{L}_n$ with $n > 0$, after choosing the stress-tensor and Virasoro representation. Thus, whenever this core volume uses the word primary in $D = 2$ without further qualification, it means global primary in the preceding sense, i.e. quasi-primary in much of the two-dimensional CFT literature. A later treatment that uses full Virasoro symmetry must state the stronger Virasoro-primary condition separately.

The translation generators create the descendant states:

$$\widehat{P}_{\mu_1} \cdots \widehat{P}_{\mu_k} |\mathcal{O}_a\rangle \longleftrightarrow \partial_{\mu_1} \cdots \partial_{\mu_k} \mathcal{O}_a(0).$$

Definition 61.3 (Conformal generalized Verma module)**.** Let

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{so}(D + 2, \mathbb{C})$$

be the complexified conformal Lie algebra, written in the radial triangular decomposition

$$\mathfrak{g}_{\mathbb{C}} = \mathfrak{n}_+ \oplus \mathfrak{l} \oplus \mathfrak{n}_-, \qquad \mathfrak{n}_+ = \mathrm{span}_{\mathbb{C}}\{\widehat{P}_\mu\}, \qquad \mathfrak{n}_- = \mathrm{span}_{\mathbb{C}}\{\widehat{K}_\mu\},$$

$$\mathfrak{l} = \mathfrak{so}(D, \mathbb{C}) \oplus \mathbb{C}\, \widehat{D}_{\mathrm{rad}}.$$

Let $V_{\Delta,\rho}$ be the finite-dimensional $\mathfrak{l} \oplus \mathfrak{n}_-$-module on which $\widehat{D}_{\mathrm{rad}}$ acts by Δ, $\mathfrak{so}(D)$ acts by ρ, and every $\widehat{K}_\mu$ acts by zero. The conformal generalized Verma module generated by this primary datum is the induced module

$$M(\Delta, \rho) = U(\mathfrak{g}_{\mathbb{C}}) \otimes_{U(\mathfrak{l} \oplus \mathfrak{n}_-)} V_{\Delta,\rho}. \tag{61.2}$$

By the Poincare–Birkhoff–Witt theorem and the commutativity of the translations, its level-n vector space is

$$M(\Delta, \rho)_n \simeq \mathrm{Sym}^n(\mathbb{C}^D) \otimes V_\rho, \qquad n \geq 0, \tag{61.3}$$

before equations of motion, conservation laws, and null relations are imposed.

Conformal multiplet generated by a primary datum. Under the state–operator correspondence, a positive-energy conformal module generated from a lowest-energy state is obtained by repeated action of $\widehat{P}_\mu$; algebraically this is the generalized Verma module $M(\Delta, \rho)$. A descendant vector annihilated by all $\widehat{K}_\mu$ is a singular vector and generates a submodule. In a reflection-positive theory the radial inner product has a radical consisting of null states, invariant under the conformal algebra because $\widehat{P}_\mu^\dagger = \widehat{K}_\mu$. The cyclic physical multiplet generated by the primary is obtained by quotienting $M(\Delta, \rho)$ by this null radical. When the radical is the maximal proper submodule, this quotient is the irreducible highest-weight module in the algebraic category.

The radial decomposition of the conformal algebra has $[\widehat{D}_{\mathrm{rad}}, \widehat{P}_\mu] = \widehat{P}_\mu$ and $[\widehat{D}_{\mathrm{rad}}, \widehat{K}_\mu] = -\widehat{K}_\mu$. A primary state is therefore a lowest-energy vector, and every algebraic descendant obtained from it by the enveloping algebra may be represented, by the Poincare–Birkhoff–Witt theorem, with all $\widehat{P}_\mu$'s to the left of the primary vector. Since the translations commute, the level-n space is the symmetric tensor space in (61.3). A descendant annihilated by all $\widehat{K}_\mu$ satisfies the same lowest-energy condition as a primary and therefore generates an invariant submodule. In a reflection-positive theory $\widehat{P}_\mu^\dagger = \widehat{K}_\mu$; hence the radical of the radial Gram form is invariant under both raising and lowering operators and may be quotiented. The quotient is the cyclic physical descendant module. It is irreducible once the radical has been identified with the maximal proper submodule, equivalently once no further invariant descendant subspace remains.

The determinant of the radial Gram form restricted to $M(\Delta, \rho)_n$, after decomposing into irreducible $SO(D)$ summands, is the finite conformal-algebra analogue of the Kac determinant. Its zeros as a function of Δ locate possible singular descendants. BGG embeddings and resolutions organize the pattern of nested singular submodules. Chapter 62 computes the low-level Gram factors needed for the unitarity bounds directly from the commutation relations, without invoking the full determinant formula.

Translation from the origin and descendant fields. An operator at a general point is obtained by translating the insertion from the origin, equivalently by its Taylor expansion in descendants:

$$\mathcal{O}_a(x) = \sum_{k=0}^{\infty} \frac{1}{k!} x^{\mu_1} \cdots x^{\mu_k} \partial_{\mu_1} \cdots \partial_{\mu_k} \mathcal{O}_a(0). \tag{61.4}$$

In the Hermitian translation convention $[\widehat{P}_\mu, \mathcal{O}(x)] = \mathrm{i}\partial_\mu \mathcal{O}(x)$, the corresponding state notation is

$$|\mathcal{O}(x)\rangle = \mathrm{e}^{-\mathrm{i}x^\mu \widehat{P}_\mu} |\mathcal{O}\rangle.$$

This is a convention-level consequence of the translation Ward identity. The local field is an operator-valued distribution, so the displayed Taylor series is a shorthand for equality after smearing with test functions in a neighborhood on which the expansion converges as a radial state. The translation commutator gives

$$\frac{\mathrm{d}}{\mathrm{d}s} \left(\mathrm{e}^{-\mathrm{i}sx\cdot \widehat{P}} \mathcal{O}(0) \mathrm{e}^{\mathrm{i}sx\cdot \widehat{P}} \right) = x^\mu \partial_\mu \mathcal{O}(sx), \qquad \mathcal{O}(0) \text{ at } s = 0.$$

Integrating this first-order equation gives the Taylor expansion (61.4). Passing to the radial state created by the insertion gives the state formula with the stated Hermitian translation convention.

61.2 Spin Sources and Contact Terms

Definition 61.4 (Spin source convention and contact operator)**.** The primary module data must agree with the source-defined Ward identities. Introduce a source $\eta^a(x)$ valued in the dual representation $V_\rho^\vee$ and couple it by

$$\int \mathrm{d}^D x\, \eta^a(x) \mathcal{O}_a(x).$$

For a primary of dimension Δ, the flat-space source convention associated with a conformal Killing vector ϵ^μ is

$$\delta_\epsilon^{\mathrm{src}}\eta^a = \epsilon^\mu\partial_\mu\eta^a + (\Delta - D)\sigma_\epsilon\eta^a + \frac{\mathrm{i}}{2}\omega_\epsilon^{\mu\nu}\eta^b(S_{\mu\nu})_b{}^a, \tag{61.5}$$

where

$$\sigma_\epsilon = \frac{1}{D}\partial_\mu\epsilon^\mu, \qquad \omega_{\epsilon,\mu\nu} = \frac{1}{2}(\partial_\nu\epsilon_\mu - \partial_\mu\epsilon_\nu).$$

The last term is the dual spin action. The sign convention in (61.5) is the source convention of Section 56.6; operator insertions then acquire the contact operator

$$\mathcal{D}_\epsilon\mathcal{O}_a(x) = -\epsilon^\mu(x)\partial_\mu\mathcal{O}_a(x) - \Delta\sigma_\epsilon(x)\mathcal{O}_a(x) - \frac{\mathrm{i}}{2}\omega_\epsilon^{\mu\nu}(x)(S_{\mu\nu})_a{}^b\mathcal{O}_b(x). \tag{61.6}$$

Spinful local conformal-current Ward identity. Differentiating the source Ward identity with respect to the sources and then setting the sources to zero gives, for

$$X = \mathcal{O}_{1,a_1}(x_1)\cdots\mathcal{O}_{n,a_n}(x_n), \qquad x_i \neq x_j,$$

the local current Ward identity

$$\partial_\mu\left\langle J_\epsilon^\mu(x)X\right\rangle = \sum_{i=1}^n \delta^{(D)}(x-x_i)\left\langle\mathcal{O}_{1,a_1}(x_1)\cdots\mathcal{D}_\epsilon^{(i)}\mathcal{O}_{i,a_i}(x_i)\cdots\mathcal{O}_{n,a_n}(x_n)\right\rangle + \sigma_\epsilon(x)\mathcal{A}(x;X). \tag{61.7}$$

Here $\mathcal{D}_\epsilon^{(i)}$ uses the spin representation and scaling dimension of the ith insertion. Equation (61.7) is the spinful version of (60.8). With the small-sphere orientation used in (60.3),

$$\mathrm{i}\,Q_\epsilon(S_x)\mathcal{O}_a(x) = \mathcal{D}_\epsilon\mathcal{O}_a(x). \tag{61.8}$$

To fix the contact signs, write the source coupling in the local chart as

$$\int \mathrm{d}^D x\,\eta^a(x)\mathcal{O}_a(x).$$

Under an infinitesimal conformal transformation generated by ϵ^μ, the integration measure changes by $(\partial_\mu\epsilon^\mu)\mathrm{d}^Dx = D\sigma_\epsilon\mathrm{d}^Dx$. The transport part of $\delta_\epsilon^{\mathrm{src}}\eta^a$ in (61.5) is $\epsilon^\mu\partial_\mu\eta^a$. Integrating it by parts in the source term, and keeping the measure variation, produces the contact action $-\epsilon^\mu\partial_\mu\mathcal{O}_a$ on the operator. The scalar source weight $(\Delta - D)\sigma_\epsilon\eta^a$ then combines with the measure variation $D\sigma_\epsilon$ to give $-\Delta\sigma_\epsilon\mathcal{O}_a$. Finally the source carries the dual spin representation, so moving the spin variation from the source to the operator gives the last term in (61.6). This proves the local insertion operator $\mathcal{D}_\epsilon$.

The source Ward identity has the distributional form that the divergence of the Noether current insertion is compensated by the variation of the source coupling, plus the possible Weyl anomaly. Differentiating it once with respect to each source that creates the insertions $\mathcal{O}_{i,a_i}(x_i)$, and then setting all sources to zero, produces a delta distribution whenever the source variation acts on the ith source factor. Because the insertion points are pairwise distinct, no additional coincident-operator contact terms occur in the displayed separated-point formula. This gives (61.7). Integrating the current identity over a small punctured ball around x, then shrinking the ball while keeping the orientation convention of Definition 60.3, leaves only the delta distribution at the insertion and gives (61.8).

61.3 Infinitesimal Action at a General Point

Infinitesimal conformal action on a spin primary. Let

$$\epsilon^\mu(x) = a^\mu + \omega^\mu{}_\nu x^\nu + \lambda x^\mu + c^\mu x^2 - 2(c\cdot x)x^\mu$$

be a conformal Killing vector in $D \geq 3$. Define

$$\sigma_\epsilon(x) = \frac{1}{D}\partial_\mu\epsilon^\mu(x), \qquad \omega_{\epsilon,\mu\nu}(x) = \frac{1}{2}(\partial_\nu\epsilon_\mu - \partial_\mu\epsilon_\nu).$$

For a primary operator, the infinitesimal variation generated by the charge is the contact operator $\mathcal{D}_\epsilon$:

$$\delta_\epsilon\mathcal{O}_a(x) = -\epsilon^\mu(x)\partial_\mu\mathcal{O}_a(x) - \Delta\sigma_\epsilon(x)\mathcal{O}_a(x) - \frac{\mathrm{i}}{2}\omega_\epsilon^{\mu\nu}(x)(S_{\mu\nu})_a{}^b\mathcal{O}_b(x). \tag{61.9}$$

The first term moves the insertion point. The second term is the local scale weight. The third term rotates the spin indices by the orthogonal part of the Jacobian. The formula is (61.6) written for a general conformal Killing vector. The special-conformal part is the only nonconstant point dependence not visible from translations, rotations, and dilatations, and it is checked explicitly below.

Elementary generator actions. For the four basic generators this gives

$$\delta_a\mathcal{O}(x) = -a^\mu\partial_\mu\mathcal{O}(x), \tag{61.10}$$
$$\delta_\lambda\mathcal{O}(x) = -\lambda(x^\mu\partial_\mu + \Delta)\mathcal{O}(x), \tag{61.11}$$

and

$$\delta_\omega\mathcal{O}_a(x) = -\omega^\mu{}_\nu x^\nu\partial_\mu\mathcal{O}_a(x) - \frac{\mathrm{i}}{2}\omega^{\mu\nu}(S_{\mu\nu})_a{}^b\mathcal{O}_b(x), \tag{61.12}$$
$$\begin{aligned}\delta_c\mathcal{O}_a(x) = &-\big(c^\mu x^2 - 2(c\cdot x)x^\mu\big)\partial_\mu\mathcal{O}_a(x) + 2\Delta(c\cdot x)\mathcal{O}_a(x)\\ &- 2\mathrm{i}c^\mu x^\nu(S_{\mu\nu})_a{}^b\mathcal{O}_b(x).\end{aligned} \tag{61.13}$$

The special-conformal line is obtained directly from (61.9). For

$$\epsilon_c^\mu(x) = c^\mu x^2 - 2(c\cdot x)x^\mu$$

one has

$$\partial_\mu\epsilon_c^\mu = -2D(c\cdot x), \qquad \sigma_{\epsilon_c} = -2(c\cdot x),$$

and

$$\omega_{\epsilon_c,\mu\nu} = \frac{1}{2}(\partial_\nu\epsilon_{c,\mu} - \partial_\mu\epsilon_{c,\nu}) = 2(c_\mu x_\nu - c_\nu x_\mu).$$

Substitution gives

$$-\Delta\sigma_{\epsilon_c}\mathcal{O}_a = 2\Delta(c\cdot x)\mathcal{O}_a,$$

and, using $S_{\mu\nu} = -S_{\nu\mu}$,

$$-\frac{\mathrm{i}}{2}\omega_{\epsilon_c}^{\mu\nu}(S_{\mu\nu})_a{}^b\mathcal{O}_b = -2\mathrm{i}c^\mu x^\nu(S_{\mu\nu})_a{}^b\mathcal{O}_b.$$

This proves (61.13) from the source-Ward contact operator. At $x = 0$, all three terms vanish for ϵ_c, so the same formula is consistent with $\widehat{K}_\mu|\mathcal{O}_a\rangle = 0$ in the state–operator correspondence.

61.4 Finite Transformation Law

Definition 61.5 (Conformal factor and local rotation)**.** Let

$$f : U \longrightarrow f(U)$$

be an orientation-preserving conformal map between open subsets of $\mathbb{R}^D$. Its Jacobian is

$$M_f(x)^\mu{}_\nu = \frac{\partial f^\mu}{\partial x^\nu}.$$

The conformal condition says that there is a positive function $\Omega_f(x)$ such that

$$M_f(x)^T M_f(x) = \Omega_f(x)^2 \mathbf{1}. \tag{61.14}$$

The orthogonal matrix

$$R_f(x) = \Omega_f(x)^{-1} M_f(x)$$

is the local rotation. Since f is orientation preserving, $\Omega_f(x)^D = \det M_f(x)$. The factors obey the cocycle identities

$$\Omega_{f\circ h}(x) = \Omega_f(h(x))\Omega_h(x), \qquad R_{f\circ h}(x) = R_f(h(x))R_h(x).$$

Theorem 61.6 (Finite transformation law for a primary operator)**.** *The finite primary transformation law is the integrated form of* (61.9) *on the connected conformal group:*

$$\mathcal{O}'_a(f(x)) = \Omega_f(x)^{-\Delta} \rho(R_f(x))_a{}^b \mathcal{O}_b(x). \tag{61.15}$$

Proof. Let f_s be the one-parameter flow of a conformal Killing vector,

$$\frac{\mathrm{d}}{\mathrm{d}s} f_s^\mu(x) = \epsilon^\mu(f_s(x)), \qquad f_0(x) = x,$$

and write $M_s = \partial f_s/\partial x = \Omega_s R_s$. At $s = 0$,

$$\left.\frac{\mathrm{d}}{\mathrm{d}s}\Omega_s(x)\right|_{s=0} = \sigma_\epsilon(x), \qquad \left.\frac{\mathrm{d}}{\mathrm{d}s}R_s(x)_\mu{}^\nu\right|_{s=0} = \omega_{\epsilon,\mu}{}^\nu(x), \tag{61.16}$$

because the conformal Killing equation decomposes $\partial_\nu\epsilon_\mu$ into its trace $\sigma_\epsilon\delta_{\mu\nu}$ and antisymmetric part $\omega_{\epsilon,\mu\nu}$. The transformed field at a fixed final point y is obtained from $x = f_s^{-1}(y)$:

$$\mathcal{O}'_{s,a}(y) = \Omega_s(f_s^{-1}y)^{-\Delta} \rho(R_s(f_s^{-1}y))_a{}^b \mathcal{O}_b(f_s^{-1}y).$$

Since $\frac{\mathrm{d}}{\mathrm{d}s} f_s^{-1}(y)\big|_{s=0} = -\epsilon(y)$ and

$$\left.\frac{\mathrm{d}}{\mathrm{d}s}\rho(R_s)_a{}^b\right|_{s=0} = -\frac{\mathrm{i}}{2}\omega_\epsilon^{\mu\nu}(S_{\mu\nu})_a{}^b,$$

differentiation at $s = 0$ gives exactly (61.9). Conversely, the vector fields close under the Lie bracket and the factors Ω_f, R_f obey the cocycle identities above; hence the finite law is the integrated representation of the infinitesimal contact action on every connected patch where the conformal map is defined. □

Elementary finite conformal transformations. The elementary generators make the signs transparent. A translation $f_a(x) = x + a$ has $\Omega = 1$, $R = 1$, and gives $\delta_a \mathcal{O} = -a^\mu \partial_\mu \mathcal{O}$ at fixed final coordinate. A dilatation $f_\lambda(x) = \mathrm{e}^\lambda x$ has $\Omega = \mathrm{e}^\lambda$, $R = 1$, and therefore

$$\mathcal{O}'(\mathrm{e}^\lambda x) = \mathrm{e}^{-\Delta\lambda}\mathcal{O}(x), \qquad \mathcal{O}'(y) = \mathrm{e}^{-\Delta\lambda}\mathcal{O}(\mathrm{e}^{-\lambda} y),$$

whose derivative is $-\lambda(y^\mu \partial_\mu + \Delta)\mathcal{O}(y)$. A rotation has $\Omega = 1$ and R equal to its orthogonal matrix, so exponentiating $\rho(R) = \exp[-\frac{\mathrm{i}}{2}\omega^{\mu\nu} S_{\mu\nu}]$ gives the spin term in (61.9). Finally the finite special conformal transformation is

$$f_c = I \circ T_c \circ I, \qquad f_c(x) = \frac{x + c\,x^2}{1 + 2c \cdot x + c^2 x^2};$$

expanding at $c = 0$ gives $\epsilon_c^\mu = c^\mu x^2 - 2(c \cdot x) x^\mu$, so the differentiated finite law reproduces (61.13).

Remark 61.7 (Tensor primary convention). For tensor representations this formula is the tensor transformation law with the Jacobian decomposed into the scale factor $\Omega_f(x)$ and the orthogonal rotation $R_f(x)$. At coincident points the corresponding statement is made at the level of the transformed source functional; the displayed formula is its restriction to noncoincident insertions.

Finite transformation of tensor primaries. For a covariant rank-s primary tensor $\mathcal{O}_{\mu_1 \cdots \mu_s}$, the same formula can be written without abstract representation notation as

$$\mathcal{O}'_{\mu_1 \cdots \mu_s}(f(x)) = \left(\det \frac{\partial f}{\partial x}\right)^{-(\Delta - s)/D} \frac{\partial x^{\nu_1}}{\partial f^{\mu_1}} \cdots \frac{\partial x^{\nu_s}}{\partial f^{\mu_s}}\, \mathcal{O}_{\nu_1 \cdots \nu_s}(x). \tag{61.17}$$

For a contravariant rank-s primary tensor,

$$\mathcal{O}'^{\mu_1 \cdots \mu_s}(f(x)) = \left(\det \frac{\partial f}{\partial x}\right)^{-(\Delta + s)/D} \frac{\partial f^{\mu_1}}{\partial x^{\nu_1}} \cdots \frac{\partial f^{\mu_s}}{\partial x^{\nu_s}}\, \mathcal{O}^{\nu_1 \cdots \nu_s}(x). \tag{61.18}$$

The different determinant powers in (61.17) and (61.18) follow from $M_f = \Omega_f R_f$. Each covariant index contributes one factor Ω_f^{-1} from M_f^{-1}, each contravariant index contributes one factor Ω_f from M_f, and the remaining determinant factor supplies the primary weight $\Omega_f^{-\Delta}$. For a conformal diffeomorphism f, the Jacobian matrix

$$M^\mu{}_\nu(x) = \frac{\partial f^\mu}{\partial x^\nu}$$

satisfies $M^T M = \Omega_f(x)^2 \mathbf{1}$. Hence

$$R^\mu{}_\nu(x) := \Omega_f(x)^{-1} M^\mu{}_\nu(x)$$

is orthogonal on the Euclidean tangent space, and

$$\det M = \Omega_f^D \det R.$$

On the connected orientation-preserving component, $\det R = 1$, so $\Omega_f = (\det M)^{1/D}$; on an orientation-reversing component the orientation sign is part of the $O(D)$ tensor representation and the positive scale is $\Omega_f = |\det M|^{1/D}$. The formulas above are written for the orientation-preserving component, which is the component used in the local conformal Ward identities.

The abstract primary law proved in Theorem 61.6 is

$$\mathcal{O}'_a(f(x)) = \Omega_f(x)^{-\Delta}\rho(R_f(x))_a{}^b\mathcal{O}_b(x).$$

For a covariant vector index, the orthogonal representation acts by

$$(R^{-1})^\nu{}_\mu = \Omega_f\frac{\partial x^\nu}{\partial f^\mu},$$

because $M^{-1} = \partial x/\partial f$. For a contravariant vector index it acts by

$$R^\mu{}_\nu = \Omega_f^{-1}\frac{\partial f^\mu}{\partial x^\nu}.$$

Tensor-product representations multiply these factors index by index. Thus a covariant rank-s tensor acquires

$$\Omega_f^{-\Delta}\Omega_f^s\frac{\partial x^{\nu_1}}{\partial f^{\mu_1}}\cdots\frac{\partial x^{\nu_s}}{\partial f^{\mu_s}} = (\det M)^{-(\Delta-s)/D}\frac{\partial x^{\nu_1}}{\partial f^{\mu_1}}\cdots\frac{\partial x^{\nu_s}}{\partial f^{\mu_s}},$$

which is (61.17). Similarly a contravariant rank-s tensor acquires

$$\Omega_f^{-\Delta}\Omega_f^{-s}\frac{\partial f^{\mu_1}}{\partial x^{\nu_1}}\cdots\frac{\partial f^{\mu_s}}{\partial x^{\nu_s}} = (\det M)^{-(\Delta+s)/D}\frac{\partial f^{\mu_1}}{\partial x^{\nu_1}}\cdots\frac{\partial f^{\mu_s}}{\partial x^{\nu_s}},$$

which is (61.18).

Remark 61.8 (Finite covariance of primary correlators). If the vacuum is invariant under the conformal transformation, correlation functions of primaries obey

$$\left\langle\prod_{i=1}^n\mathcal{O}_{i,a_i}(f(x_i))\right\rangle = \prod_{i=1}^n\Omega_f(x_i)^{-\Delta_i}\rho_i(R_f(x_i))_{a_i}{}^{b_i}\left\langle\prod_{i=1}^n\mathcal{O}_{i,b_i}(x_i)\right\rangle. \tag{61.19}$$

Equation (61.19) is the finite form of the global Ward identities on the configuration space of distinct insertion points, with contact extensions fixed by the same source convention as in (61.7). Let U_f denote the Hilbert-space or Euclidean functional action of the connected conformal transformation on the common domain of separated insertions. Vacuum invariance means that inserting $U_f^{-1}U_f$ in the expectation value does not change it:

$$\left\langle\prod_i\mathcal{O}_{i,a_i}(f(x_i))\right\rangle = \left\langle U_f^{-1}\left(\prod_i\mathcal{O}_{i,a_i}(f(x_i))\right)U_f\right\rangle.$$

On the configuration space $x_i \neq x_j$, the conjugated product is the ordinary product of the individually transformed fields, because no two insertions collide while the transformation is applied. Substituting (61.15) for each primary therefore produces one factor $\Omega_f(x_i)^{-\Delta_i}\rho_i(R_f(x_i))$ for each insertion and gives (61.19). Extensions to collision diagonals are not determined by this separated-point argument; they are fixed by the source Ward identity (61.7).

61.5 Inversion

Inversion of scalar and spin primaries. The inversion map

$$I(x)^\mu = \frac{x^\mu}{x^2}$$

has

$$\Omega_I(x) = \frac{1}{x^2}, \qquad R_I(x)^\mu{}_\nu = \delta^\mu{}_\nu - 2\frac{x^\mu x_\nu}{x^2}.$$

For a scalar primary,

$$\mathcal{O}'(I(x)) = |x|^{2\Delta}\mathcal{O}(x). \tag{61.20}$$

This formula, together with translations, rotations, and dilatations, determines the separated-point covariance constraints used below. The matrix $R_I(x)$ lies in $O(D)$ and has determinant -1. For operators with spin, inversion therefore requires a specified extension of the spin action from $SO(D)$ to the relevant disconnected orthogonal or pin action; once that choice is made, $R_I(x)$ acts on each spin index through that representation.

Differentiating $I^\mu = x^\mu/x^2$ gives

$$\frac{\partial I^\mu}{\partial x^\nu} = \frac{1}{x^2}\left(\delta^\mu{}_\nu - 2\frac{x^\mu x_\nu}{x^2}\right).$$

The matrix in parentheses squares to the identity and has determinant -1, since it reflects the component parallel to x^μ and fixes the orthogonal hyperplane. Thus $\Omega_I = 1/x^2$ and $R_I = \delta - 2xx/x^2$. Substituting these factors into (61.15) gives (61.20) for scalar primaries and the stated orthogonal or pin action for spin primaries.

61.6 Descendants

Descendant transformation laws from primary data. The descendants of a primary are obtained by applying derivatives. Their transformation laws are obtained by differentiating (61.15) and by decomposing the result into irreducible $SO(D)$ representations. Once the primary dimension, spin representation, and normalization are fixed, the action of the whole conformal algebra on the generated multiplet is fixed. Concretely, every descendant at level n is represented algebraically by an element of $\mathrm{Sym}^n(\mathbb{C}^D)\otimes V_\rho$ in (61.3), modulo any null or equation-of-motion relations. The conformal generators act on this space by the commutation relations of $\mathfrak{so}(D+2,\mathbb{C})$. Equivalently, at separated points, differentiating (61.15) with respect to the insertion coordinate gives the finite transformation of derivatives of $\mathcal{O}$. Decomposing the resulting tensor products into irreducible $SO(D)$ summands changes the basis of descendants while preserving the representation generated by the primary datum.

Chapter 62

Unitarity Bounds and Short Multiplets

Conventions in this chapter.

- **Signature.** Lorentzian local-operator data and Euclidean radial or conformal geometry where stated.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the Lorentzian or radial-quantization vacuum.
- **Generator convention.** Poincare translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$; represented conformal charges use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$ when a unitary Hilbert-space action is present.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

62.1 Positivity in Radial Quantization

Assume the conformal theory is unitary after analytic continuation to Lorentzian signature and satisfies reflection positivity in Euclidean radial quantization. Then the Hilbert space on S^{D-1} has a positive semidefinite inner product, and null states are quotiented to obtain the physical Hilbert space. The adjoint relation

$$\widehat{P}_\mu^\dagger = \widehat{K}_\mu$$

implies that every Gram matrix of descendant states must be positive semidefinite. This adjoint relation is the BPZ Hilbert-space adjoint on the dense local finite-energy domain, derived in (59.33); it is not a separate formal rule about flat-space vector fields. For example, for every complex vector a^μ and every state created by a local operator $\mathcal{O}(0)$,

$$\left\| a^\mu \widehat{P}_\mu |\mathcal{O}\rangle \right\|^2 = \overline{a}^\mu a^\nu \langle \mathcal{O}| \widehat{K}_\mu \widehat{P}_\nu |\mathcal{O}\rangle \geq 0. \tag{62.1}$$

Thus $\langle \mathcal{O}|\widehat{K}_\mu \widehat{P}_\nu|\mathcal{O}\rangle$ is a positive semidefinite Hermitian matrix in the vector indices and in any additional spin or degeneracy labels. The unitarity bounds are obtained by computing such matrices from the conformal algebra.

In this chapter the generators are the radial-quantization generators, with the conventional factors of i absorbed relative to Lorentzian Hermitian charges. The commutator used below is

$$[\widehat{K}_\mu, \widehat{P}_\nu] = 2\delta_{\mu\nu}\widehat{D}_{\mathrm{rad}} - 2\widehat{J}_{\nu\mu}, \tag{62.2}$$

where $\widehat{J}_{\mu\nu}$ acts on the spin indices of the operator multiplet. This convention makes the descendant Gram matrices real Euclidean inner products. Its sign is the radial sign derived from the Hermitian Lorentzian charge algebra in (59.27)–(59.28); it is not obtained by simply deleting the factors of i in the Lorentzian commutators.

Let $|\mathcal{O}_a\rangle$ be a primary of dimension Δ and spin representation ρ, normalized so that

$$\widehat{D}_{\mathrm{rad}}|\mathcal{O}_a\rangle = \Delta|\mathcal{O}_a\rangle, \qquad \widehat{K}_\mu|\mathcal{O}_a\rangle = 0.$$

Level-one descendant Gram calculation. Assume reflection positivity in radial quantization, the adjoint relation $\widehat{P}_\mu^\dagger = \widehat{K}_\mu$, and a primary multiplet $V_\rho = \mathrm{span}\{|\mathcal{O}_a\rangle\}$ of dimension Δ. The level-one descendant Gram matrix

$$G^{(1)}_{\mu a,\nu b} = \langle\mathcal{O}_a|\widehat{K}_\mu\widehat{P}_\nu|\mathcal{O}_b\rangle. \tag{62.3}$$

is positive semidefinite and is given by

$$G^{(1)}_{\mu a,\nu b} = 2\langle\mathcal{O}_a|(\delta_{\mu\nu}\widehat{D}_{\mathrm{rad}} - \widehat{J}_{\nu\mu})|\mathcal{O}_b\rangle. \tag{62.4}$$

For any finite array $c^{\mu a}$,

$$\bar{c}^{\mu a}G^{(1)}_{\mu a,\nu b}c^{\nu b} = \left\| c^{\nu b}\widehat{P}_\nu|\mathcal{O}_b\rangle \right\|^2 \geq 0,$$

which is the positivity assertion. Since $\widehat{K}_\mu|\mathcal{O}_b\rangle = 0$, the Gram matrix is

$$\langle\mathcal{O}_a|[\widehat{K}_\mu, \widehat{P}_\nu]|\mathcal{O}_b\rangle.$$

Substituting (62.2) gives the displayed formula.

This equation is a representation-theoretic constraint. Positivity of $G^{(1)}$ gives lower bounds on Δ once the $SO(D)$ representation ρ is specified.

The Hilbert-space convention is the following. A primary multiplet is a finite-dimensional subspace $V_\rho \subset \mathcal{H}_{\mathrm{rad}}$ on which $\widehat{D}_{\mathrm{rad}}$ acts by the scalar Δ, and the rotation generators act as a unitary $SO(D)$ representation. Descendants are obtained by applying the closed operators $\widehat{P}_\mu$ on their common finite-energy invariant domain. Positivity is imposed on every finite Gram matrix of descendants in this domain; null vectors are then quotiented. Thus each shortening equation below is an operator equation in the quotient of the local-operator space by null operators.

Equivalently, the calculation is the restriction of the Shapovalov form on the conformal generalized Verma module $M(\Delta, \rho)$ of Definition 61.3 to finite descendant levels, with the real radial adjoint $P_\mu^\dagger = K_\mu$. At each level the determinant of this form factorizes into irreducible $SO(D)$ channels; this finite conformal-algebra determinant is the Kac-determinant framework used to locate singular vectors. The proofs below compute the channels needed here explicitly, so every stated bound follows from the displayed Gram matrix rather than from an unstated determinant formula.

62.2 Scalar Primaries

For a scalar primary ϕ, the spin matrices vanish. The level-one Gram matrix reduces to

$$\langle\phi|\widehat{K}_\mu \widehat{P}_\nu|\phi\rangle = 2\Delta_\phi \delta_{\mu\nu} \langle\phi \mid \phi\rangle.$$

Thus

$$\Delta_\phi \geq 0.$$

If $\Delta_\phi = 0$, all first descendants have zero norm. After quotienting null states, this gives

$$\widehat{P}_\mu|\phi\rangle = 0.$$

Since $\widehat{P}_\mu$ represents the derivative of the local insertion at the origin, the corresponding local field obeys $\partial_\mu\phi(x) = 0$. If the theory has a unique conformally invariant vacuum and cluster decomposition for local correlators, as specified in Hypothesis 59.1, a spacetime-constant scalar local field is proportional to the identity operator, so the primary belongs to the identity representation. These hypotheses are stated because a direct sum with a decoupled topological or superselection sector can otherwise contain additional zero-energy central operators.

The sharper scalar bound comes from level two. Define

$$M^{(2)}_{\alpha\beta,\mu\nu} = \langle\phi|\widehat{K}_\alpha \widehat{K}_\beta \widehat{P}_\mu \widehat{P}_\nu|\phi\rangle.$$

Repeated use of the conformal commutation relations gives, for a scalar primary,

$$M^{(2)}_{\alpha\beta,\mu\nu} = 4\left[(\delta_{\alpha\mu}\delta_{\beta\nu} + \delta_{\alpha\nu}\delta_{\beta\mu})\Delta_\phi(\Delta_\phi + 1) - \delta_{\alpha\beta}\delta_{\mu\nu}\Delta_\phi\right]\langle\phi \mid \phi\rangle. \tag{62.5}$$

This formula is obtained by commuting the two $\widehat{K}$'s to the right until they annihilate the primary. No dynamical equation has been assumed; the only inputs are (62.2), the scalar action of $\widehat{D}_{\mathrm{rad}}$, and the vanishing spin action on $|\phi\rangle$. Contracting with $\delta^{\alpha\beta}\delta^{\mu\nu}$ computes the norm of $\widehat{P}^2|\phi\rangle$:

$$\delta^{\alpha\beta}\delta^{\mu\nu} M^{(2)}_{\alpha\beta,\mu\nu} = \left\|\widehat{P}^2|\phi\rangle\right\|^2 = 4\left[2D\,\Delta_\phi(\Delta_\phi + 1) - D^2\Delta_\phi\right]\langle\phi \mid \phi\rangle = 4D\,\Delta_\phi\big(2\Delta_\phi + 2 - D\big)\langle\phi \mid \phi\rangle. \tag{62.6}$$

Theorem 62.1 (Scalar unitarity bound and scalar shortening)**.** *Assume a positive-norm scalar primary ϕ in a reflection-positive radial-quantized CFT in $D > 2$. Then either $\Delta_\phi = 0$ and $\widehat{P}_\mu|\phi\rangle = 0$, or*

$$\Delta_\phi \geq \frac{D-2}{2}. \tag{62.7}$$

If $\Delta_\phi = (D-2)/2$, the scalar trace descendant is null and the quotient local-operator space obeys

$$\partial^2\phi(x) = 0. \tag{62.8}$$

Proof. In radial quantization $\widehat{K}_\mu = \widehat{P}^\dagger_\mu$. The level-one descendant Gram matrix is therefore

$$\langle\phi|\widehat{K}_\mu \widehat{P}_\nu|\phi\rangle = 2\Delta_\phi \delta_{\mu\nu}\langle\phi \mid \phi\rangle,$$

using the scalar-primary condition $\widehat{K}_\mu|\phi\rangle = 0$ and the commutator (62.2). Positivity gives $\Delta_\phi \geq 0$. If $\Delta_\phi = 0$, every first descendant has zero norm. After quotienting the radical of the reflection-positive form this means $\widehat{P}_\mu|\phi\rangle = 0$, so the state is translation-invariant and belongs to the identity branch under the vacuum assumptions stated in the preceding section.

Assume now $\Delta_\phi > 0$. The scalar trace descendant $\widehat{P}^2|\phi\rangle = \delta^{\mu\nu}\widehat{P}_\mu\widehat{P}_\nu|\phi\rangle$ is a vector in the level-two descendant space, hence its norm is nonnegative. The explicit Gram computation in (62.6) gives

$$0 \le 4D\,\Delta_\phi(2\Delta_\phi + 2 - D)\langle\phi \mid \phi\rangle.$$

Because $D > 2$, $\Delta_\phi > 0$, and $\langle\phi \mid \phi\rangle > 0$, this is equivalent to $2\Delta_\phi + 2 - D \ge 0$, namely (62.7). At equality the trace descendant is a null vector. In the Hilbert-space quotient by null descendants, the local state-field map sends that null relation to the operator equation $\partial^2\phi(x) = 0$ inside separated-point correlators; contact terms at coincident insertions are separate local-extension data. □

The $\Delta_\phi = 0$ branch was identified above as the identity representation under the stated vacuum assumptions. The second branch is the scalar unitarity bound for non-identity scalar primaries. At the level of conformal representation theory, the resulting shortened multiplet is the massless scalar multiplet.

62.3 Level-One Decomposition for Spin

Let $\mathcal{H}_\ell$ denote the $SO(D)$ representation of rank-ℓ symmetric traceless tensors, with $D \ge 3$. For a primary in $\mathcal{H}_\ell$, the level-one descendants transform in

$$\mathcal{H}_1 \otimes \mathcal{H}_\ell.$$

The $SO(D)$-orthogonal decomposition is

$$\mathcal{H}_1 \otimes \mathcal{H}_\ell = \mathcal{H}_{\ell+1} \oplus \mathcal{H}_{\ell,1} \oplus \mathcal{H}_{\ell-1},$$

where $\mathcal{H}_{\ell,1}$ is the traceless mixed-symmetry representation with two-row Young shape $(\ell, 1)$, and absent summands are omitted. For $\ell = 0$ the decomposition reduces to the vector descendant of a scalar. For $\ell \ge 1$, the last summand is the divergence channel.

The level-one Gram operator is $SO(D)$-equivariant. Because the above decomposition is multiplicity free, Schur's lemma implies that the Gram operator is scalar on each summand. The scalar is computed from quadratic Casimirs. Write

$$C_\ell = \ell(\ell + D - 2), \qquad C_1 = D - 1$$

for the $SO(D)$ Casimirs of $\mathcal{H}_\ell$ and the vector representation. In the descendant space, the spin-coupling operator appearing in (62.3) has eigenvalue

$$L_Q = -\frac{1}{2}\left(C_Q - C_1 - C_\ell\right) \tag{62.9}$$

on an irreducible summand $Q \subset \mathcal{H}_1 \otimes \mathcal{H}_\ell$. The minus sign is fixed by the radial commutator (62.2). The relevant Casimirs are

$$C_{\ell+1} = (\ell + 1)(\ell + D - 1), \tag{62.10}$$
$$C_{\ell,1} = \ell(\ell + D - 2) + D - 3, \tag{62.11}$$
$$C_{\ell-1} = (\ell - 1)(\ell + D - 3). \tag{62.12}$$

Substitution in (62.9) gives

$$L_{\ell+1} = -\ell, \qquad L_{\ell,1} = 1, \qquad L_{\ell-1} = \ell + D - 2.$$

Since $G^{(1)} = 2(\Delta - L_Q)$ on the summand Q, positivity gives

$$\Delta + \ell \geq 0, \qquad \Delta - 1 \geq 0, \qquad \Delta - \ell - D + 2 \geq 0. \tag{62.13}$$

For $\ell \geq 1$, the last inequality is the strongest one. Its null channel is the $\mathcal{H}_{\ell-1}$ projection of $P_\mu\mathcal{O}$, namely the divergence of the symmetric traceless tensor. Thus conservation at the unitarity bound is the null-state equation forced by positivity of the conformal representation.

The same first-level test applies to any irreducible $SO(D)$ representation ρ. If Q runs over the irreducible summands in $\mathcal{H}_1 \otimes \rho$, then positivity of the level-one Gram form requires

$$\Delta + \frac{1}{2}\left(C_Q - C_1 - C_\rho\right) \geq 0 \qquad \text{for every } Q \subset \mathcal{H}_1 \otimes \rho. \tag{62.14}$$

When equality holds for one summand, the corresponding projected first descendant is a null operator. Higher-level Gram matrices can impose further conditions in special cases, as the scalar trace descendant did above.

62.4 Two-Row Mixed-Symmetry Tensor Primaries

The first non-symmetric tensor case already displays the mechanism for mixed-symmetry shortening. Let $\mathcal{H}_{a,b}$ be the traceless $SO(D)$ tensor representation with Young row lengths (a, b), where $a \geq b \geq 1$. Work first in the stable tensor range in which the Young diagrams displayed below are distinct irreducible tensor representations; in lower dimensions Hodge duality may split or identify summands, and the same Gram-matrix test is then applied to the resulting irreducible $\mathrm{Spin}(D)$ summands.

With the normalization $C_1 = D - 1$ for the vector representation, the quadratic Casimir of a traceless tensor representation with row lengths $\lambda = (\lambda_1, \lambda_2, \ldots)$ is

$$C_\lambda = \sum_{i\geq 1} \lambda_i(\lambda_i + D - 2i). \tag{62.15}$$

To derive this formula, let $r = \lfloor D/2 \rfloor$ and choose the orthonormal basis e_i for the weight space of $\mathfrak{so}(D)_{\mathbb{C}}$ in which the vector representation has highest weight e_1. In the stable tensor range the highest weight of the tensor representation is $\Lambda = \sum_i \lambda_i e_i$, while the Weyl vector ϱ obeys $2\varrho_i = D - 2i$. The quadratic Casimir eigenvalue is $(\Lambda, \Lambda + 2\varrho)$, normalized so that the vector highest weight e_1 has $C_1 = (e_1, e_1 + 2\varrho) = D - 1$, and this gives (62.15). Thus

$$C_{a,b} = a(a + D - 2) + b(b + D - 4).$$

The level-one descendant space decomposes by adding or removing one box from the Young diagram. The derivative vector index may be projected into an added first, second, or third row, or it may be contracted with an index in the first or second row and then projected back to the traceless Young symmetry. This gives

$$\mathcal{H}_1 \otimes \mathcal{H}_{a,b} = \mathcal{H}_{a+1,b} \oplus \mathcal{H}_{a,b+1} \oplus \mathcal{H}_{a,b,1} \oplus \mathcal{H}_{a-1,b} \oplus \mathcal{H}_{a,b-1}. \tag{62.16}$$

Invalid summands are omitted: for example $\mathcal{H}_{a,b+1}$ and $\mathcal{H}_{a-1,b}$ are absent when $a = b$, and $\mathcal{H}_{a,b-1}$ becomes $\mathcal{H}_a$ when $b = 1$. The $\mathcal{H}_{a,b,1}$ channel is present only when the corresponding three-row tensor representation is not removed by a low-dimensional duality. Each displayed summand has multiplicity one in the stable range, so the level-one Gram operator is diagonal on these channels.

Substituting the Casimirs in (62.14) gives the following table:

$$\begin{array}{c|c|c} Q & \frac{1}{2}(C_Q - C_1 - C_{a,b}) & \text{level-one positivity condition} \\ \hline \mathcal{H}_{a+1,b} & a & \Delta + a \geq 0 \\ \mathcal{H}_{a,b+1} & b-1 & \Delta + b - 1 \geq 0 \\ \mathcal{H}_{a,b,1} & -2 & \Delta - 2 \geq 0 \\ \mathcal{H}_{a-1,b} & -(a+D-2) & \Delta - a - D + 2 \geq 0 \\ \mathcal{H}_{a,b-1} & -(b+D-3) & \Delta - b - D + 3 \geq 0. \end{array} \tag{62.17}$$

For instance,

$$\frac{1}{2}(C_{a-1,b} - C_1 - C_{a,b}) = -a - D + 2,$$

because replacing a by $a-1$ changes the first-row contribution to the Casimir by $-2a-D+3$, and the vector Casimir subtracts another $D-1$. The other entries follow from the same row-by-row subtraction in (62.15).

Proposition 62.2 (Two-row tensor unitarity bound at first level)**.** *Let $\mathcal{O}$ be a primary whose rotation representation is $\mathcal{H}_{a,b}$, $a \geq b \geq 1$, in the stable tensor range described above. If $a > b$, positivity of the first descendant Gram matrix implies*

$$\Delta_{\mathcal{O}} \geq a + D - 2. \tag{62.18}$$

At equality the $\mathcal{H}_{a-1,b}$ projection of $P_\mu|\mathcal{O}\rangle$ is null. In local-operator notation this is

$$\Pi_{a-1,b}\, \partial\mathcal{O} = 0, \tag{62.19}$$

where $\Pi_{a-1,b} : \mathcal{H}_1 \otimes \mathcal{H}_{a,b} \to \mathcal{H}_{a-1,b}$ is the $SO(D)$-equivariant traceless Young projector. If $a = b$, the channel $\mathcal{H}_{a-1,b}$ is not an allowed Young shape, and the leading first-level condition is instead

$$\Delta_{\mathcal{O}} \geq a + D - 3. \tag{62.20}$$

At equality the $\mathcal{H}_{a,a-1}$ projection of the first descendant is null:

$$\Pi_{a,a-1}\, \partial\mathcal{O} = 0. \tag{62.21}$$

Proof. The inequalities in (62.17) are precisely the eigenvalue inequalities for the positive semidefinite level-one Gram form. When $a > b$, the removal channel $\mathcal{H}_{a-1,b}$ is present, and its condition $\Delta \geq a + D - 2$ is stronger than $\Delta \geq b + D - 3$ because $a - b + 1 > 0$; it is also stronger than the add-a-box conditions for a positive-energy representation. If equality holds, the Gram norm on that irreducible summand is zero, hence the corresponding state is in the null subspace and becomes the operator equation (62.19) in the quotient by null operators.

When $a = b$, the Young diagram $(a-1, a)$ is not allowed, so the $\mathcal{H}_{a-1,b}$ row in the table is absent. The strongest remaining condition is $\Delta \geq a + D - 3$, coming from $\mathcal{H}_{a,a-1}$. Equality makes the $\mathcal{H}_{a,a-1}$ component of $P_\mu|\mathcal{O}\rangle$ null, giving (62.21). The special case $(a, b) = (1, 1)$ is the antisymmetric two-tensor primary: the shortening equation is the projected divergence $\partial^\mu J_{\mu\nu} = 0$, after traces are removed according to the representation. □

62.5 Spinor Primaries

For spinor primaries the rotation representation is a representation of $\mathrm{Spin}(D)$, the double cover of $SO(D)$. Let $D \geq 3$, and let S be an irreducible complex spinor representation. In even D, S may be one of the two chiral spinor representations; Clifford multiplication by a vector then maps S to the opposite chirality. Denote the spinor representation reached by Clifford multiplication by S_γ. Thus $S_\gamma \simeq S$ in odd dimension, while S_γ is the opposite chiral spinor in even dimension. Choose Euclidean Clifford maps

$$\Gamma_\mu : S \longrightarrow S_\gamma, \qquad \Gamma_\mu^\dagger : S_\gamma \longrightarrow S, \qquad \Gamma_\mu^\dagger \Gamma_\nu + \Gamma_\nu^\dagger \Gamma_\mu = 2\delta_{\mu\nu} \mathrm{id}_S.$$

These maps are intertwiners for the $\mathrm{Spin}(D)$ action and therefore identify the gamma-trace summand in the level-one descendant space.

Theorem 62.3 (Spinor unitarity bound and Dirac shortening)**.** *Let ψ be a spinor primary of scaling dimension Δ_ψ whose radial-quantization primary space carries the unitary spin representation S. Then*

$$\Delta_\psi \geq \frac{D-1}{2}. \tag{62.22}$$

If equality holds, the gamma-trace first descendant is null. In local-operator notation the shortening equation is

$$\Gamma^\mu \partial_\mu \psi(x) = 0. \tag{62.23}$$

Proof. The relevant $SO(D)$ Casimir eigenvalues, in the normalization used in (62.9), are

$$C_S = C_{S_\gamma} = \frac{D(D-1)}{8}, \qquad C_1 = D - 1.$$

The tensor product of the vector representation with S decomposes as

$$\mathcal{H}_1 \otimes S = S_\gamma \oplus S_{3/2},$$

where $S_{3/2}$ is the gamma-traceless vector-spinor representation. The orthogonal projection onto the first summand is the gamma-trace projection: for $A_\mu \in \mathcal{H}_1 \otimes S$,

$$(\Pi_\gamma A)_\mu = \frac{1}{D} \Gamma_\mu^\dagger \Gamma^\nu A_\nu, \qquad \Gamma^\mu (A_\mu - \Pi_\gamma A_\mu) = 0.$$

Equivalently, after normalizing the primary state so that $\| |\psi(s)\rangle \|^2 = \|s\|_S^2$ for $s \in S$, the gamma-trace descendant has Gram norm

$$\left\| \frac{1}{\sqrt{D}} \Gamma^\mu \widehat{P}_\mu |\psi(s)\rangle \right\|^2 = 2 \left(\Delta_\psi - \frac{D-1}{2} \right) \|s\|_S^2. \tag{62.24}$$

This is precisely (62.3) restricted to the $Q = S_\gamma$ irreducible summand, because

$$\Delta_\psi + \frac{1}{2}(C_{S_\gamma} - C_1 - C_S) = \Delta_\psi - \frac{D-1}{2}.$$

Reflection positivity of radial quantization requires the left-hand side of (62.24) to be nonnegative for every s, giving (62.22). If equality holds, the gamma-trace descendant is a null state and therefore vanishes in the quotient local-operator space, which gives (62.23).

For completeness, the complementary vector-spinor summand has

$$C_{S_{3/2}} = C_S + D.$$

Its level-one inequality is

$$\Delta_\psi + \frac{1}{2}(C_{S_{3/2}} - C_1 - C_S) = \Delta_\psi + \frac{1}{2} \geq 0,$$

so it gives no stronger lower bound for a positive-energy spinor primary. □

62.6 Symmetric Traceless Tensor Primaries

Let

$$\mathcal{O}_{\mu_1\cdots\mu_\ell}(x)$$

be a primary transforming as a rank-ℓ symmetric traceless tensor of $SO(D)$, with $\ell \geq 1$. Thus the indices are symmetric and

$$\delta^{\mu_1\mu_2}\mathcal{O}_{\mu_1\mu_2\cdots\mu_\ell} = 0.$$

Theorem 62.4 (Symmetric-traceless unitarity bound)**.** *Assume a positive-norm primary $\mathcal{O}_{\mu_1\cdots\mu_\ell}$, $\ell \geq 1$, transforming in the rank-ℓ symmetric traceless representation of $SO(D)$, with $D \geq 3$. Then*

$$\Delta_{\mathcal{O}} \geq \ell + D - 2. \tag{62.25}$$

At equality, the divergence descendant is null and therefore

$$\partial^{\mu_1}\mathcal{O}_{\mu_1\mu_2\cdots\mu_\ell}(x) = 0. \tag{62.26}$$

Proof. The level-one descendant space decomposes as

$$\mathcal{H}_1 \otimes \mathcal{H}_\ell = \mathcal{H}_{\ell+1} \oplus \mathcal{H}_{\ell,1} \oplus \mathcal{H}_{\ell-1}.$$

This is an orthogonal decomposition for the $SO(D)$-invariant radial Gram form, because the Gram operator commutes with rotations. On each irreducible summand, Schur's lemma makes the level-one Gram operator a scalar. Formula (62.3) identifies that scalar as

$$2\left[\Delta_{\mathcal{O}} + \frac{1}{2}(C_Q - C_1 - C_\ell)\right],$$

where Q is the corresponding irreducible summand. The Casimir computation above gives the three inequalities in (62.13); for $\ell \geq 1$, the strongest is

$$\Delta_{\mathcal{O}} - \ell - D + 2 \geq 0.$$

The representation that carries this eigenvalue is $\mathcal{H}_{\ell-1}$. At the level of tensor fields this projection is the trace-free part of the divergence $\partial^{\mu_1}\mathcal{O}_{\mu_1\mu_2\cdots\mu_\ell}$; because the original operator is symmetric traceless, the displayed divergence is already the relevant $\mathcal{H}_{\ell-1}$ descendant. At saturation the entire $\mathcal{H}_{\ell-1}$ descendant subspace is null. Passing to the quotient by the null radical gives the separated-point local-operator equation (62.26); contact terms in Ward identities are additional coincident-point extension data. □

For $\ell = 1$ this is current conservation and $\Delta_J = D - 1$. For $\ell = 2$ it is stress-tensor conservation and $\Delta_T = D$.

62.7 Short Multiplets as Operator Equations

The scalar, spinor, and symmetric-traceless calculations above give the following collected reference list. The proof of each entry is the corresponding descendant Gram-matrix computation: Theorem 62.1 for scalars, Theorem 62.3 for spinors, and Theorem 62.4 for rank-ℓ symmetric traceless tensors.

1. A scalar primary ϕ either lies in the $\Delta_\phi = 0$ identity branch described in Theorem 62.1, or obeys
$$\Delta_\phi \geq \frac{D-2}{2}.$$
At $\Delta_\phi = (D-2)/2$, the level-two trace descendant is null and
$$\partial^2\phi = 0$$
in the quotient local-operator space.
2. A spinor primary ψ obeys
$$\Delta_\psi \geq \frac{D-1}{2}.$$
At equality, the gamma-trace first descendant is null and
$$\Gamma^\mu \partial_\mu \psi = 0.$$
3. A rank-ℓ symmetric traceless tensor primary $\mathcal{O}_{\mu_1\cdots\mu_\ell}$, $\ell \geq 1$, obeys
$$\Delta_{\mathcal{O}} \geq \ell + D - 2.$$
At equality, the divergence first descendant is null and
$$\partial^{\mu_1}\mathcal{O}_{\mu_1\mu_2\cdots\mu_\ell} = 0.$$

A short conformal multiplet is a primary multiplet for which a descendant has zero norm and is set to zero in the physical Hilbert space. In local-operator language, the null descendant is an operator equation. The equations

$$\partial^2\phi = 0, \qquad \partial^\mu J_\mu = 0, \qquad \partial^\mu T_{\mu\nu} = 0$$

are therefore representation-theoretic statements in a unitary conformal theory. They also carry dynamical information: a conserved current generates a global symmetry, the stress tensor generates spacetime symmetries, and a scalar saturating the scalar bound obeys the scalar Laplace shortening equation.

The unitarity bounds thus convert positivity of the Hilbert-space inner product into exact restrictions on the allowed local operator spectrum.

Correlation Functions and Conformal Frames

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

63.1 Ward Identities for Correlators

Throughout this chapter, correlators are Euclidean vacuum correlators at separated insertion points. The symbol $|\Omega\rangle$ denotes the common vacuum identified in Section 59.3: the Poincare vacuum of the flat Wightman theory, the conformally invariant vacuum under the hypotheses of Proposition 59.4, and the zero-energy cylinder ground state after the Weyl-map normalization of radial quantization. With this identification, and with the special-conformal vacuum invariance derived in Lemma 63.2, the global Ward identity of Chapter 60 applies. If $\epsilon^\mu(x)\partial_\mu$ is a conformal Killing vector and $\delta_\epsilon \mathcal{O}_i$ is the corresponding infinitesimal variation of the ith local operator, then

$$\sum_{i=1}^{n} \langle \mathcal{O}_1(x_1) \cdots \delta_\epsilon \mathcal{O}_i(x_i) \cdots \mathcal{O}_n(x_n)\rangle = 0 \tag{63.1}$$

as a distribution on the configuration space $x_i \neq x_j$. Contact terms on coincident-point diagonals are part of the local Ward identities and are not used in the kinematic classification below.

Definition 63.1 (Separated Euclidean CFT correlator)**.** For an ordered n-tuple of local operators $\mathcal{O}_1, \ldots, \mathcal{O}_n$, the separated configuration space is

$$\mathrm{Conf}_n(\mathbb{R}^D) = \{(x_1, \ldots, x_n) \in (\mathbb{R}^D)^n \mid x_i \neq x_j \text{ for } i \neq j\}.$$

The separated correlator is the restriction of the corresponding Schwinger distribution to this open set,

$$G_{\mathcal{O}_1\cdots\mathcal{O}_n}(x_1,\dots,x_n)=\langle\mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle\,,$$

with values in the dual tensor product of the spin representation spaces when the insertions carry indices. A scalar primary tuple $(\mathcal{O}_i,\Delta_i)$ is separated conformally covariant if, for every finite conformal transformation f whose image avoids coincidences,

$$G_{\mathcal{O}_1\cdots\mathcal{O}_n}(f(x_1),\dots,f(x_n))=\prod_{i=1}^{n}\Omega_f(x_i)^{-\Delta_i}\,G_{\mathcal{O}_1\cdots\mathcal{O}_n}(x_1,\dots,x_n),\tag{63.2}$$

where $f^*\delta=\Omega_f^2\delta$. This definition contains no extension across the collision diagonals. Such extensions are local renormalization data and can differ by contact terms supported on partial diagonals.

Lemma 63.2 (Special-conformal invariance from radial spectrum positivity)**.** *Let $|\Omega\rangle$ be the common vacuum of Section 59.3. Assume that $\widehat{D}_{\mathrm{rad}}$ is a nonnegative self-adjoint generator of cylinder time translations, that*

$$\widehat{D}_{\mathrm{rad}}|\Omega\rangle=0,$$

and that the special conformal generators are defined on the vacuum and obey, on the relevant common domain,

$$[\widehat{D}_{\mathrm{rad}},\widehat{K}_\mu]=-\widehat{K}_\mu.\tag{63.3}$$

Then

$$\widehat{K}_\mu|\Omega\rangle=0.$$

Thus the special-conformal part of the vacuum Ward identity follows from radial spectral positivity and the conformal commutation relation; it is not an extra invariance assumption.

Proof. Let $\psi_\mu=\widehat{K}_\mu|\Omega\rangle$. The domain hypothesis is included so that both $\widehat{K}_\mu|\Omega\rangle$ and $\widehat{D}_{\mathrm{rad}}\widehat{K}_\mu|\Omega\rangle$ are honest Hilbert-space vectors. On this common domain, (63.3) gives

$$\widehat{D}_{\mathrm{rad}}\psi_\mu=\widehat{D}_{\mathrm{rad}}\widehat{K}_\mu|\Omega\rangle=\widehat{K}_\mu\widehat{D}_{\mathrm{rad}}|\Omega\rangle-\widehat{K}_\mu|\Omega\rangle=-\psi_\mu.$$

Thus, if $\psi_\mu\neq 0$, the spectral measure of ψ_μ for the nonnegative self-adjoint operator $\widehat{D}_{\mathrm{rad}}$ would be supported at the single point -1. The spectral theorem gives $\langle\psi_\mu,\widehat{D}_{\mathrm{rad}}\psi_\mu\rangle\geq 0$ for every vector in the quadratic-form domain, while the displayed eigenvalue equation gives the same expectation value as $-\|\psi_\mu\|^2$. Hence $\|\psi_\mu\|=0$, and $\widehat{K}_\mu|\Omega\rangle=0$. □

Equivalently, for a finite conformal transformation $f:x\mapsto\widetilde{x}$ implemented by a unitary operator U_f, invariance of the vacuum gives

$$\langle\mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle=\left\langle(U_f\mathcal{O}_1U_f^{-1})(x_1)\cdots(U_f\mathcal{O}_nU_f^{-1})(x_n)\right\rangle.$$

The operators on the right are written at the same coordinate labels as before; their transformation laws supply the Jacobian and spin factors. For a scalar primary ϕ of dimension Δ_ϕ,

$$\widetilde{\phi}(\widetilde{x})=\left|\det\frac{\partial\widetilde{x}}{\partial x}\right|^{-\Delta_\phi/D}\phi(x).\tag{63.4}$$

63.2 One- and Two-Point Functions

Let $\mathcal{O}_i$ be scalar primary operators of dimensions Δ_i. If the separated Ward identities and the finite scalar primary covariance law hold, then

$$\langle \mathcal{O}_i(x) \rangle = 0 \qquad \text{unless} \qquad \Delta_i = 0.$$

In a reflection-positive CFT whose $\Delta = 0$ scalar primary sector is the vacuum representation, the only nonzero scalar-primary one-point function is the identity expectation value, after choosing the identity normalization. Translation invariance makes a one-point function constant:

$$\langle \mathcal{O}_i(x) \rangle = c_i.$$

Scale covariance gives

$$c_i = \lambda^{-\Delta_i} c_i \qquad \text{for all } \lambda > 0.$$

If $\Delta_i \neq 0$, choosing any $\lambda \neq 1$ forces $c_i = 0$. The final statement uses the $\Delta = 0$ branch of the scalar unitarity analysis in Chapter 62: the local field has vanishing translation descendants and hence acts as a multiple of the identity on the cyclic vacuum representation.

Scalar two-point selection rule. Assume the separated-point global conformal Ward identities (63.1) and scalar primary transformation law (63.4). If $\mathcal{O}_i, \mathcal{O}_j$ are scalar primaries of dimensions Δ_i, Δ_j, then

$$\langle \mathcal{O}_i(x)\mathcal{O}_j(y) \rangle = \begin{cases} \dfrac{C_{ij}}{|x-y|^{2\Delta_i}}, & \Delta_i = \Delta_j, \\ 0, & \Delta_i \neq \Delta_j. \end{cases} \tag{63.5}$$

Translation and rotation invariance imply

$$\langle \mathcal{O}_i(x)\mathcal{O}_j(y) \rangle = F_{ij}(|x-y|).$$

Scale covariance gives

$$F_{ij}(r) = \frac{C_{ij}}{r^{\Delta_i+\Delta_j}}.$$

The condition $\Delta_i = \Delta_j$ for a nonzero coefficient follows from a conformal transformation that fixes both points but has different local scale factors at the two points. Put the two points at 0 and e_1, where e_1 is a fixed unit vector, and define

$$f_\lambda(x)^\mu = \lambda \frac{x^\mu + a^\mu x^2}{1 + 2a\cdot x + a^2 x^2}, \qquad a^\mu = (\lambda - 1)e_1^\mu, \qquad \lambda > 0.$$

Then $f_\lambda(0) = 0$, $f_\lambda(e_1) = e_1$,

$$\left.\frac{\partial f_\lambda^\mu}{\partial x^\nu}\right|_{x=0} = \lambda\, \delta^\mu{}_\nu, \qquad \left.\frac{\partial f_\lambda^\mu}{\partial x^\nu}\right|_{x=e_1} = \lambda^{-1} \delta^\mu{}_\nu.$$

Applying (63.4) to $\langle \mathcal{O}_i(e_1)\mathcal{O}_j(0) \rangle$ gives

$$C_{ij} = \lambda^{\Delta_i - \Delta_j} C_{ij} \qquad \text{for all } \lambda > 0,$$

so $C_{ij} = 0$ unless $\Delta_i = \Delta_j$. Substituting this condition in the scale-covariant form gives (63.5). Within a finite-dimensional space of primaries with the same dimension and the same spin, one may choose a basis that diagonalizes the Hermitian matrix C_{ij}.

63.3 Radial Inner Product and BPZ Conjugation

Let $x = rn$, $r > 0$, $n \in S^{D-1}$, and set $\tau = \log r$. The Weyl map from $\mathbb{R}^D \setminus \{0\}$ to $\mathbb{R}_\tau \times S^{D-1}$ relates a scalar primary on flat space to the cylinder operator by

$$\mathcal{O}(x) = r^{-\Delta}\widetilde{\mathcal{O}}(\tau, n). \tag{63.6}$$

The state created by insertion at the origin is

$$|\mathcal{O}\rangle = \lim_{\tau \to -\infty} \mathrm{e}^{-\Delta\tau}\widetilde{\mathcal{O}}(\tau, n)|\Omega\rangle, \tag{63.7}$$

where $|\Omega\rangle$ is the common vacuum specified above. For a primary the limit is independent of n. The conjugate bra is obtained by the opposite cylinder-time limit,

$$\langle\!\langle \mathcal{O}| = \lim_{\tau \to +\infty} \mathrm{e}^{\Delta\tau}\langle\Omega|\widetilde{\mathcal{O}}(\tau, n). \tag{63.8}$$

This radial conjugation is often called BPZ conjugation. In a reflection-positive theory, after including the ordinary internal adjoint of the local operator, it is the Hilbert-space adjoint of the state. Consequently the two-point coefficient has the inner-product interpretation

$$\langle\!\langle \mathcal{O}_i|\mathcal{O}_j\rangle = \lim_{\tau_i \to +\infty,\ \tau_j \to -\infty} \mathrm{e}^{\Delta_i\tau_i - \Delta_j\tau_j}\left\langle \widetilde{\mathcal{O}}_i(\tau_i, n_i)\widetilde{\mathcal{O}}_j(\tau_j, n_j)\right\rangle = C_{ij}, \tag{63.9}$$

for primaries with equal dimension. Positivity of this matrix is the same positivity used in the unitarity-bound derivation.

Figure 63.1 records the two-point cylinder inner product used in radial quantization: one insertion is reflected to the opposite cylinder end, and the coefficient matrix C_{ij} is the BPZ inner product for equal dimensions.

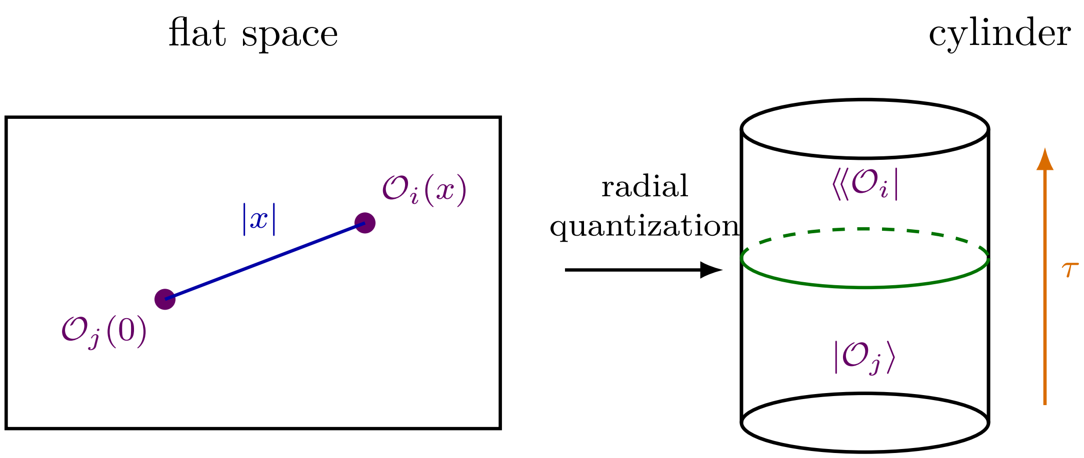

Figure 63.1: The scalar two-point coefficient is the radial-quantization inner product between the state created at the origin and the BPZ-conjugate insertion at future cylinder time.

63.4 Spin Structures

Definition 63.3 (Inversion tensor and symmetric-traceless transport)**.** The inversion tensor

$$I_{\mu\nu}(x) = \delta_{\mu\nu} - 2\frac{x_\mu x_\nu}{x^2} \tag{63.10}$$

is the orthogonal part of the inversion Jacobian. It is the basic building block for two-point functions with vector or tensor indices. Its action on the line spanned by x^μ is multiplication by -1, while its action on the orthogonal complement of x^μ is the identity. Hence $\det I(x) = -1$: inversion lies in $O(D)\backslash SO(D)$. Every use of $I_{\mu\nu}(x)$ in a spin tensor structure therefore presupposes the extension of the $SO(D)$ spin action to the disconnected orthogonal, or pin, action specified in Chapter 61.

For a rank-s symmetric traceless tensor representation, define

$$\mathcal{I}^{(s)}_{\mu_1\cdots\mu_s,\nu_1\cdots\nu_s}(x) = \Pi_{\mathrm{STT}}\left[I_{\mu_1\nu_1}(x)\cdots I_{\mu_s\nu_s}(x)\right],$$

where Π_{STT} symmetrizes separately in the μ-indices and the ν-indices and removes all traces with respect to $\delta_{\mu\nu}$.

Spinning two-point structures. Let V_μ be a vector primary of dimension Δ_V. After diagonalizing degeneracy labels within the same primary type,

$$\langle V_\mu(x)V_\nu(0)\rangle = \frac{C_V}{|x|^{2\Delta_V}} I_{\mu\nu}(x). \tag{63.11}$$

More generally, if $\mathcal{O}_{\mu_1\cdots\mu_s}$ is a rank-s symmetric traceless tensor primary of dimension $\Delta_{\mathcal{O}}$, then

$$\langle \mathcal{O}_{\mu_1\cdots\mu_s}(x)\mathcal{O}_{\nu_1\cdots\nu_s}(0)\rangle = \frac{C_{\mathcal{O}}}{|x|^{2\Delta_{\mathcal{O}}}}\mathcal{I}^{(s)}_{\mu_1\cdots\mu_s,\nu_1\cdots\nu_s}(x), \tag{63.12}$$

up to the same positive Hermitian coefficient matrix in possible degeneracy labels. Two-point functions between inequivalent $SO(D)$ representations vanish by rotational covariance. Translation covariance puts one insertion at the origin, and dilatation covariance gives the overall power $|x|^{-2\Delta}$ once the two dimensions have been matched by the scalar selection rule generalized to the chosen spin type. The remaining tensor must intertwine the spin representation at the origin with the spin representation transported to the point x. Applying inversion sends x to x/x^2, fixes the origin as the point at infinity in radial quantization, and contributes the orthogonal Jacobian $I_{\mu\nu}(x)$ on vector indices. Hence the unique vector intertwiner is $I_{\mu\nu}(x)$. For symmetric traceless rank s, the tensor product of s vector intertwiners must be projected to the symmetric-traceless irreducible component at both ends, giving $\mathcal{I}^{(s)}$. Schur's lemma on each irreducible $SO(D)$ type gives vanishing between inequivalent representations and a Hermitian degeneracy matrix within equivalent representations. Reflection positivity makes that matrix positive semidefinite before quotienting null states and positive definite on the Hilbert quotient.

For the stress tensor, $s = 2$, $\Delta_T = D$, and conservation gives a canonical normalization convention through the Ward identity. Its two-point function is

$$\langle T_{\mu\nu}(x)T_{\rho\sigma}(0)\rangle = \frac{C_T}{|x|^{2D}} I_{\mu\nu,\rho\sigma}(x), \tag{63.13}$$

where

$$I_{\mu\nu,\rho\sigma}(x) = \frac{1}{2}\big(I_{\mu\rho}(x)I_{\nu\sigma}(x) + I_{\mu\sigma}(x)I_{\nu\rho}(x)\big) - \frac{1}{D}\delta_{\mu\nu}\delta_{\rho\sigma}.$$

The coefficient C_T is part of the intrinsic CFT data because the normalization of $T_{\mu\nu}$ is fixed by the translation Ward identity.

63.5 Three-Point Functions

Lemma 63.4 (Scalar three-point kinematics)**.** *Let $\mathcal{O}_i$ be scalar primaries of dimensions Δ_i. On the configuration space of three distinct points, separated conformal covariance fixes the three-point function to the form*

$$\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\rangle = \frac{C_{123}}{|x_{12}|^{\Delta_1+\Delta_2-\Delta_3}|x_{23}|^{\Delta_2+\Delta_3-\Delta_1}|x_{13}|^{\Delta_1+\Delta_3-\Delta_2}}, \tag{63.14}$$

where

$$x_{ij} = x_i - x_j.$$

Proof. The connected Euclidean conformal group acts transitively on ordered triples of distinct points. Indeed, translate x_3 to the origin, use an inversion composed with a translation to send one of the remaining points to infinity, and then rotate and dilate the last finite point to a fixed unit vector. Thus there is no conformal cross-ratio for three separated points; the correlator is determined by one coefficient once its local weights at the three insertions are fixed.

It remains to determine the powers of the pairwise distances. Write the unique possible separated scalar form as

$$C_{123}|x_{12}|^{-\alpha_{12}}|x_{23}|^{-\alpha_{23}}|x_{13}|^{-\alpha_{13}}.$$

Under inversion $x \mapsto x/x^2$,

$$|x_{ij}| \longmapsto \frac{|x_{ij}|}{|x_i|\,|x_j|}, \qquad \Omega(x_i) = |x_i|^{-2}.$$

Comparison with (63.2) gives the three local weight equations

$$\alpha_{12}+\alpha_{13} = 2\Delta_1, \qquad \alpha_{12}+\alpha_{23} = 2\Delta_2, \qquad \alpha_{13}+\alpha_{23} = 2\Delta_3.$$

Solving this linear system gives

$$\alpha_{12} = \Delta_1+\Delta_2-\Delta_3, \quad \alpha_{23} = \Delta_2+\Delta_3-\Delta_1, \quad \alpha_{13} = \Delta_1+\Delta_3-\Delta_2,$$

which is precisely (63.14). Uniform dilatation covariance is then automatic because the sum of the three powers is $\Delta_1+\Delta_2+\Delta_3$. □

The constants C_{123}, after fixing the two-point normalization of primaries, are the scalar three-point OPE coefficients. If the primaries carry spin, let a_i denote indices in the corresponding finite-dimensional $SO(D)$ representations. Conformal covariance says that

$$\langle \mathcal{O}_{1,a_1}(x_1)\mathcal{O}_{2,a_2}(x_2)\mathcal{O}_{3,a_3}(x_3)\rangle = \sum_{r=1}^{n_{123}} C_{123}^{(r)}\mathcal{I}^{(r)}_{a_1a_2a_3}(x_{12},x_{13}), \tag{63.15}$$

where the tensors $\mathcal{I}^{(r)}$ form a basis of conformally covariant three-point tensor structures, including the required homogeneity in the separations. The finite integer n_{123} is representation-theoretic; the numbers $C_{123}^{(r)}$ are dynamical data after a convention for two-point normalization has been fixed.

The stress tensor illustrates why some three-point coefficients are constrained but not removed from the data. In a parity-even CFT in $D \geq 4$, the separated three-point function of a symmetric conserved traceless stress tensor is classified by the following Osborn–Petkou basis.[1] Set

$$X \equiv X_{12,3} = \frac{x_{13}}{x_{13}^2} - \frac{x_{23}}{x_{23}^2}, \qquad \widehat{X}_\mu = \frac{X_\mu}{(X^2)^{1/2}},$$

and, for a dimensionless tensor $t_{\mu\nu,\rho\sigma,\alpha\beta}(\widehat{X})$, define

$$\mathfrak{C}[t]_{\mu\nu,\rho\sigma,\alpha\beta} = \frac{I_{\mu\nu,\mu'\nu'}(x_{13}) I_{\rho\sigma,\rho'\sigma'}(x_{23}) t_{\mu'\nu',\rho'\sigma',\alpha\beta}(\widehat{X})}{|x_{12}|^D |x_{13}|^D |x_{23}|^D}. \tag{63.16}$$

Let $\mathrm{Sym}_{\mu\nu}$ denote the unnormalized symmetrization obtained by adding the expression with μ and ν interchanged. The following symmetric-traceless tensors are

$$\begin{aligned}
h^1_{\mu\nu} &= \widehat{X}_\mu \widehat{X}_\nu - \frac{1}{D}\delta_{\mu\nu}, \\
h^2_{\mu\nu,\rho\sigma} &= \widehat{X}_\mu \widehat{X}_\rho \delta_{\nu\sigma} + \widehat{X}_\nu \widehat{X}_\rho \delta_{\mu\sigma} + \widehat{X}_\mu \widehat{X}_\sigma \delta_{\nu\rho} + \widehat{X}_\nu \widehat{X}_\sigma \delta_{\mu\rho} \\
&\quad - \frac{4}{D}\left(\widehat{X}_\mu \widehat{X}_\nu \delta_{\rho\sigma} + \widehat{X}_\rho \widehat{X}_\sigma \delta_{\mu\nu}\right) + \frac{4}{D^2}\delta_{\mu\nu}\delta_{\rho\sigma}, \\
h^3_{\mu\nu,\rho\sigma} &= \delta_{\mu\rho}\delta_{\nu\sigma} + \delta_{\mu\sigma}\delta_{\nu\rho} - \frac{2}{D}\delta_{\mu\nu}\delta_{\rho\sigma}, \\
h^4_{\mu\nu,\rho\sigma,\alpha\beta} &= \mathrm{Sym}_{\rho\sigma}\,\mathrm{Sym}_{\alpha\beta}\left[h^3_{\mu\nu,\rho\alpha}\widehat{X}_\sigma \widehat{X}_\beta\right] - \frac{2}{D}\delta_{\rho\sigma} h^2_{\mu\nu,\alpha\beta} \\
&\quad - \frac{2}{D}\delta_{\alpha\beta} h^2_{\mu\nu,\rho\sigma} - \frac{8}{D^2}\delta_{\rho\sigma}\delta_{\alpha\beta} h^1_{\mu\nu}, \\
h^5_{\mu\nu,\rho\sigma,\alpha\beta} &= \mathrm{Sym}_{\mu\nu}\,\mathrm{Sym}_{\rho\sigma}\,\mathrm{Sym}_{\alpha\beta}\left[\delta_{\mu\rho}\delta_{\nu\alpha}\delta_{\sigma\beta}\right] \\
&\quad - \frac{4}{D}\left(\delta_{\mu\nu} h^3_{\rho\sigma,\alpha\beta} + \delta_{\rho\sigma} h^3_{\mu\nu,\alpha\beta} + \delta_{\alpha\beta} h^3_{\mu\nu,\rho\sigma}\right) - \frac{8}{D^2}\delta_{\mu\nu}\delta_{\rho\sigma}\delta_{\alpha\beta}.
\end{aligned} \tag{63.17}$$

Each h^r is symmetric and traceless in every displayed index pair. The most general parity-even separated-point structure satisfying stress-tensor conservation is the three-parameter tensor

$$\begin{aligned}
t[a,b,c]_{\mu\nu,\rho\sigma,\alpha\beta} &= a\, h^5_{\mu\nu,\rho\sigma,\alpha\beta} + b\, h^4_{\alpha\beta,\mu\nu,\rho\sigma} - (2a+b)\left(h^4_{\mu\nu,\rho\sigma,\alpha\beta} + h^4_{\rho\sigma,\mu\nu,\alpha\beta}\right) \\
&\quad + c\, h^3_{\mu\nu,\rho\sigma} h^1_{\alpha\beta} + c\left(h^3_{\rho\sigma,\alpha\beta} h^1_{\mu\nu} + h^3_{\mu\nu,\alpha\beta} h^1_{\rho\sigma}\right) \\
&\quad + e\, h^2_{\mu\nu,\rho\sigma} h^1_{\alpha\beta} + e'\left(h^2_{\rho\sigma,\alpha\beta} h^1_{\mu\nu} + h^2_{\mu\nu,\alpha\beta} h^1_{\rho\sigma}\right) \\
&\quad + f\, h^1_{\mu\nu} h^1_{\rho\sigma} h^1_{\alpha\beta},
\end{aligned} \tag{63.18}$$

where conservation fixes the auxiliary coefficients to be

$$\begin{aligned}
e = (D+2)(Da+b-c), \qquad e' &= -(D+4)(D-2)a - (D-2)b + Dc, \\
f &= (D+4)(D-2)(4a+2b-c).
\end{aligned} \tag{63.19}$$

The three tensor structures in (63.20) are therefore

$$\mathcal{I}^{(1)} = \mathfrak{C}[t[1,0,0]], \qquad \mathcal{I}^{(2)} = \mathfrak{C}[t[0,1,0]], \qquad \mathcal{I}^{(3)} = \mathfrak{C}[t[0,0,1]].$$

[1] This is the position-space basis of H. Osborn and A. C. Petkou, *Implications of Conformal Invariance in Field Theories for General Dimensions*, Ann. Phys. 231 (1994), 311–362, arXiv:hep-th/9307010, specialized here to the separated-point, parity-even stress-tensor three-point function and rewritten in the conventions of this chapter.

Equivalently,

$$\langle T_{\mu\nu}(x_1)T_{\rho\sigma}(x_2)T_{\alpha\beta}(x_3)\rangle = a\,\mathcal{I}^{(1)}_{\mu\nu,\rho\sigma,\alpha\beta} + b\,\mathcal{I}^{(2)}_{\mu\nu,\rho\sigma,\alpha\beta} + c\,\mathcal{I}^{(3)}_{\mu\nu,\rho\sigma,\alpha\beta} = \mathfrak{C}[t[a,b,c]]_{\mu\nu,\rho\sigma,\alpha\beta}, \tag{63.20}$$

with three independent coefficients a, b, c when $D \geq 4$. The independence statement is not a counting by inspection. Before imposing conservation, conformal covariance, tracelessness, and the exchange symmetries of the three stress tensors reduce the parity-even separated-point ansatz to the five coefficients a, b, c, e, f; the coefficient e' appearing in (63.18) is then fixed by

$$e + e' = 8a + 4b - 2c.$$

The conservation equation

$$\left(\partial_\mu - D\frac{X_\mu}{X^2}\right) t_{\mu\nu,\rho\sigma,\alpha\beta}(X) = 0$$

imposes two independent linear equations. In the parametrization above these equations are exactly the formulae (63.19), which determine e, e', and f in terms of a, b, c. To see that no further relation is hidden for $D \geq 4$, put the three insertion points in a collinear frame by a conformal transformation. The residual group is $O(D-1)$. The completely transverse part of the conserved tensor is then parametrized by three $O(D-1)$-invariant tensors with coefficients r, s, u, and the Osborn–Petkou comparison gives

$$D^2 r = 16a - 2Db + (D+4)c, \qquad Ds = -4a - c, \qquad u = a. \tag{63.21}$$

For $D \geq 4$, the transverse space has dimension at least three, and these three invariant tensors are linearly independent. Hence $(a, b, c) \mapsto (r, s, u)$ has no universal null direction in the space of separated-point parity-even TTT structures.

For $D = 3$, the transverse space in the collinear frame is two-dimensional. [2] The three transverse invariant tensors obey one Schouten identity, and the collinear tensor depends only on

$$r - 4u, \qquad s + 2u. \tag{63.22}$$

Using (63.21) at $D = 3$, the null direction is

$$(a, b, c) = (1, -1, 2).$$

Thus, as separated parity-even three-dimensional structures,

$$\mathcal{I}^{(1)}_{D=3} - \mathcal{I}^{(2)}_{D=3} + 2\mathcal{I}^{(3)}_{D=3} = 0, \qquad \mathcal{I}^{(3)}_{D=3} = \frac{1}{2}\left(\mathcal{I}^{(2)}_{D=3} - \mathcal{I}^{(1)}_{D=3}\right). \tag{63.23}$$

Consequently a parity-even three-dimensional stress-tensor three-point function has two separated structures, for instance

$$\langle TTT\rangle^{\text{even}}_{D=3} = A\,\mathcal{I}^{(1)}_{D=3} + B\,\mathcal{I}^{(2)}_{D=3}. \tag{63.24}$$

If parity is not imposed in $D = 3$, there is a further parity-odd separated structure; it is not part of the parity-even Osborn–Petkou basis displayed here.

[2] For the three-dimensional stress-tensor/current structure count see J. Maldacena and A. Zhiboedov, *A Note on CFT Correlators in Three Dimensions*, arXiv:1104.4317. For the general spinning-correlator counting technology and its later conformal-block implementation, see M. S. Costa, J. Penedones, D. Poland, and S. Rychkov, *Spinning Conformal Correlators*, arXiv:1107.3554, and M. S. Costa, T. Hansen, J. Penedones, and E. Trevisani, *Radial Expansion for Spinning Conformal Blocks*, arXiv:1603.05552.

The Ward identity fixes one linear combination of these coefficients in terms of the two-point coefficient C_T. Let

$$S_D = \frac{2\pi^{D/2}}{\Gamma(D/2)}$$

be the area of the unit $(D-1)$-sphere. The small-sphere Ward identity uses the angular averages

$$\int_{S^{D-1}} \mathrm{d}\Omega\, \widehat{n}_\mu \widehat{n}_\nu = \frac{S_D}{D}\delta_{\mu\nu}, \qquad \int_{S^{D-1}} \mathrm{d}\Omega\, \widehat{n}_\mu \widehat{n}_\nu \widehat{n}_\rho \widehat{n}_\sigma = \frac{S_D}{D(D+2)}\left(\delta_{\mu\nu}\delta_{\rho\sigma} + \delta_{\mu\rho}\delta_{\nu\sigma} + \delta_{\mu\sigma}\delta_{\nu\rho}\right).$$

Substituting (63.18) into the flux $\int_{\partial B_\epsilon(x_3)} \mathrm{d}S\, n_\lambda T^{\lambda\tau}\epsilon_\tau$, taking $\epsilon \to 0$, and comparing with the conformal variation of the two remaining stress tensors in (63.13) gives

$$4S_D\, \frac{(D-2)(D+3)a - 2b - (D+1)c}{D(D+2)} = C_T. \tag{63.25}$$

The remaining two independent combinations are genuine CFT data. In lower dimensions or in parity-violating theories the list of admissible structures changes; the statement above is tied to the stated assumptions.

Figure 63.2 shows the surface Ward-identity argument fixing one linear combination of the three stress-tensor three-point structures in terms of C_T.

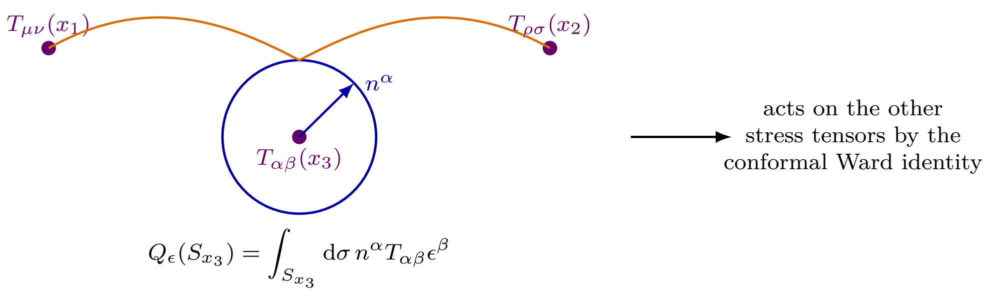

Figure 63.2: The Ward identity relates a small-sphere stress-tensor flux inside $\langle TTT\rangle$ to the conformal variation of the remaining insertions. This fixes the Ward-normalized part of the TTT data in terms of C_T.

As an important mixed example, the Ward identity fixes the coefficient of the stress-tensor three-point function with two identical scalar primaries. For $\Delta_1 = \Delta_2 = \Delta$,

$$\langle \mathcal{O}(x_1)\mathcal{O}(x_2)T_{\mu\nu}(x_3)\rangle = \frac{C_{\mathcal{O}\mathcal{O}T}}{|x_{13}|^D |x_{23}|^D |x_{12}|^{2\Delta - D}}\left(\frac{X_\mu X_\nu}{X^2} - \frac{1}{D}\delta_{\mu\nu}\right), \tag{63.26}$$

with

$$X^\mu = \frac{x_{13}^\mu}{x_{13}^2} - \frac{x_{23}^\mu}{x_{23}^2}.$$

More generally, for two scalar primaries $\mathcal{O}_1, \mathcal{O}_2$ of the same dimension Δ with

$$\langle \mathcal{O}_1(x)\mathcal{O}_2(0)\rangle = \frac{N_{12}}{|x|^{2\Delta}},$$

the same tensor structure appears with coefficient

$$C_{12T} = -\frac{D\Delta}{(D-1)A_{D-1}} N_{12}, \qquad A_{D-1} = \mathrm{vol}(S^{D-1}) = \frac{2\pi^{D/2}}{\Gamma(D/2)}. \tag{63.27}$$

Here the sign is the sign of the stress-tensor convention in (60.1) and (60.3). The derivation is a small-sphere Ward identity for the dilatation vector $\epsilon^\nu = x^\nu$. Put $x_1 = x$, $x_2 = 0$, $x_3 = y = rn$, where $|n| = 1$, and send $r \to 0$ with x fixed. Then

$$X^\mu = \frac{(x-y)^\mu}{|x-y|^2} - \frac{(-y)^\mu}{|y|^2} = \frac{n^\mu}{r} + \frac{x^\mu}{|x|^2} + O\left(\frac{r}{|x|^2}\right),$$

and therefore

$$\frac{X_\mu X_\nu}{X^2} - \frac{1}{D}\delta_{\mu\nu} = n_\mu n_\nu - \frac{1}{D}\delta_{\mu\nu} + O\left(\frac{r}{|x|}\right), \qquad \frac{1}{|x_{13}|^D |x_{23}|^D |x_{12}|^{2\Delta-D}} = \frac{r^{-D}}{|x|^{2\Delta}}\left(1 + O\left(\frac{r}{|x|}\right)\right).$$

The sphere S_2 is oriented as the boundary of the punctured integration domain, hence $\mathrm{d}S_\mu = -r^{D-1} n_\mu \mathrm{d}\Omega$, while $\epsilon_\nu(y) = rn_\nu$. The leading flux is consequently

$$\langle \mathcal{O}_1(x) Q_\epsilon(S_2) \mathcal{O}_2(0)\rangle = -\frac{C_{12T}}{|x|^{2\Delta}} \int_{S^{D-1}} \mathrm{d}\Omega\, n^\mu n^\nu \left(n_\mu n_\nu - \frac{1}{D}\delta_{\mu\nu}\right),$$

up to terms that vanish as $r \to 0$. The angular projection is

$$\begin{aligned}\int_{S^{D-1}} \mathrm{d}\Omega\, n^\mu n^\nu \left(n_\mu n_\nu - \frac{1}{D}\delta_{\mu\nu}\right) &= \int_{S^{D-1}} \mathrm{d}\Omega \left[(n^\mu n_\mu)(n^\nu n_\nu) - \frac{1}{D} n^\mu n_\mu\right] \\ &= \int_{S^{D-1}} \mathrm{d}\Omega \left[1 - \frac{1}{D}\right] = A_{D-1}\left(1 - \frac{1}{D}\right).\end{aligned} \tag{63.28}$$

In the second line we used $n^\mu n_\mu = 1$ pointwise on the unit sphere; this is the entire reduction of the fourth-order angular expression in this particular contraction. so the flux equals

$$-\frac{D-1}{D} A_{D-1} \frac{C_{12T}}{|x|^{2\Delta}}.$$

The same orientation convention converts the local dilatation Ward identity $\delta_\epsilon \mathcal{O}_2(0) = -\Delta \mathcal{O}_2(0)$ into

$$\langle \mathcal{O}_1(x) Q_\epsilon(S_2) \mathcal{O}_2(0)\rangle = \frac{\Delta N_{12}}{|x|^{2\Delta}}.$$

Matching the two expressions gives (63.27). If $\Delta_1 \neq \Delta_2$, the two-point coefficient N_{12} vanishes by dilatation covariance, and the corresponding stress-tensor three-point function vanishes.

63.6 Four-Point Functions and Cross Ratios

Definition 63.5 (Ordered four-point conformal frame)**.** For $D \geq 2$, let

$$x = (x_1, x_2, x_3, x_4) \in \mathrm{Conf}_4(\mathbb{R}^D).$$

A four-point conformal frame for x is a conformal transformation, possibly followed by the one-point compactification of $\mathbb{R}^D$, that sends the quadruple to

$$z_1 = 0, \qquad z_2 = z, \qquad z_3 = 1, \qquad z_4 = \infty$$

inside an oriented two-plane. The associated scalar cross ratios are

$$u = \frac{x_{12}^2 x_{34}^2}{x_{13}^2 x_{24}^2}, \qquad v = \frac{x_{14}^2 x_{23}^2}{x_{13}^2 x_{24}^2}. \tag{63.29}$$

In the frame they obey

$$z = \frac{z_{12} z_{34}}{z_{13} z_{24}}, \qquad u = z\bar{z}, \qquad v = (1-z)(1-\bar{z}).$$

Proposition 63.6 (Completeness of four-point cross ratios)**.** *For a generic ordered quadruple of distinct Euclidean points in $D \geq 2$, an oriented four-point frame is labelled by z. The pair (u, v) is equivalent to z modulo complex conjugation. For $D \geq 3$, this pair separates connected conformal orbits. For $D = 2$, it separates orbits only after adjoining the orientation-reversing conformal transformation $z \mapsto \bar{z}$; the connected orientation-preserving group distinguishes z from $\bar{z}$. Thus scalar four-point correlators invariant under the relevant Euclidean parity operation can have nontrivial position dependence only through two independent real conformal invariants.*

Proof. We give the explicit frame construction. Translate so that $x_1 = 0$. The special conformal map

$$y \longmapsto \frac{y - b\,y^2}{1 - 2b \cdot y + b^2 y^2}, \qquad b = \frac{x_4}{x_4^2},$$

fixes the origin and sends x_4 to the point at infinity, because the denominator vanishes at $y = x_4$. For a generic quadruple, the image of x_3 is finite and nonzero; a rotation and a dilatation send it to the unit vector e_1. The stabilizer of 0, e_1, and ∞ is the orthogonal group acting on the $(D-1)$-dimensional subspace orthogonal to e_1. This stabilizer rotates the image of x_2 into the (e_1, e_2)-plane, leaving a complex coordinate z. In this frame the Euclidean distances give exactly

$$u = z\bar{z}, \qquad v = (1-z)(1-\bar{z}).$$

Conversely, two framed quadruples with the same z are equal, and replacing the orientation of the two-plane sends z to $\bar{z}$ without changing (u, v). When $D \geq 3$, this orientation reversal of the chosen two-plane is implemented by a rotation in the orthogonal complement, for instance by flipping one in-plane basis vector and one transverse basis vector. When $D = 2$, it is not in the connected orientation-preserving conformal group and must be added as a separate parity operation. The dimension count is consistent:

$$4D - \frac{(D+1)(D+2)}{2} + \frac{(D-2)(D-3)}{2} = 2,$$

where the last term is the dimension of the residual rotation group fixing a generic two-plane frame. $\square$

Figure 63.3 displays the conformal frame used for four scalar insertions: the four positions are reduced to the two cross ratios (u, v), with a residual rotation group fixing the chosen two-plane.

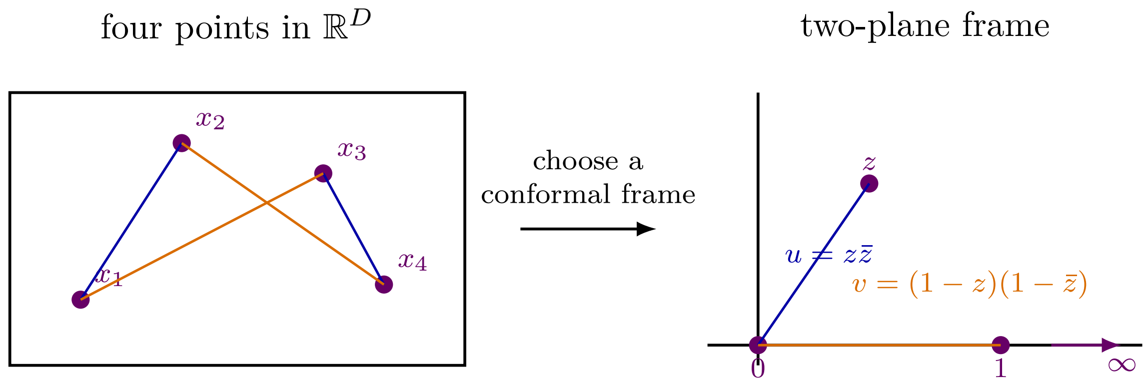

Figure 63.3: A scalar four-point function has two conformal invariants. A conformal frame places the points at $0, z, 1, \infty$ in a two-plane.

Scalar four-point prefactor covariance. Let $\mathcal{O}_i$ be scalar primaries of dimensions Δ_i. Every separated conformally covariant four-point function can be written uniquely in the form

$$\begin{aligned}&\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_3(x_3)\mathcal{O}_4(x_4)\rangle \\ &\quad = \frac{\mathcal{G}(u,v)}{|x_{12}|^{\Delta_1+\Delta_2}|x_{34}|^{\Delta_3+\Delta_4}} \left(\frac{|x_{24}|}{|x_{14}|}\right)^{\Delta_1-\Delta_2} \left(\frac{|x_{14}|}{|x_{13}|}\right)^{\Delta_3-\Delta_4}.\end{aligned} \tag{63.30}$$

For identical scalar primaries of dimension Δ, this simplifies to

$$\langle \mathcal{O}(x_1)\mathcal{O}(x_2)\mathcal{O}(x_3)\mathcal{O}(x_4)\rangle = \frac{\mathcal{G}(u,v)}{|x_{12}|^{2\Delta}|x_{34}|^{2\Delta}}. \tag{63.31}$$

The quotient of a scalar four-point function by the displayed prefactor is invariant under translations and rotations because it is built from distances. Under a uniform dilatation, the prefactor has degree $-(\Delta_1+\Delta_2+\Delta_3+\Delta_4)$, the required total degree. It remains to check the local weights under inversion. Since

$$|x_{ij}| \longmapsto \frac{|x_{ij}|}{|x_i|\,|x_j|},$$

write the prefactor as $\prod_{i<j} |x_{ij}|^{a_{ij}}$, with

$$\begin{gathered} a_{12} = -(\Delta_1+\Delta_2), \qquad a_{34} = -(\Delta_3+\Delta_4), \qquad a_{24} = \Delta_1-\Delta_2, \\ a_{14} = -(\Delta_1-\Delta_2)+(\Delta_3-\Delta_4), \qquad a_{13} = -(\Delta_3-\Delta_4), \qquad a_{23} = 0. \end{gathered}$$

The inversion power at x_i is $-\sum_{j\neq i} a_{ij}$. Direct substitution gives $2\Delta_i$ for each $i = 1, \dots, 4$. This is exactly the inversion weight of four scalar primaries because $\Omega_I(x_i) = |x_i|^{-2}$. Therefore the remaining factor is a dimensionless conformal invariant and hence a function of u, v on the generic configuration space by Proposition 63.6. Uniqueness follows because the prefactor is nonzero on $\mathrm{Conf}_4(\mathbb{R}^D)$. The identical-scalar formula is the specialization $\Delta_1 = \cdots = \Delta_4 = \Delta$.

The function $\mathcal{G}(u,v)$ is dynamical CFT data. The next stage is to determine how the operator product expansion encodes local multiplication of operators and how associativity constrains the allowed spectrum and OPE coefficients. Detailed computational machinery for solving crossing equations is deferred from the core monograph until conformal theory is rebuilt as a separate systematic development.

Chapter 64

The Operator Product Expansion

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$, with radial quantization invoked where stated.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for the radial-quantization vacuum when a Hilbert space is used.
- **Generator convention.** represented symmetry transformations use $\exp(\mathrm{i}\epsilon^A \widehat{Q}_A)$; differential conformal generators are defined with the sign displayed in the relevant formula.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

64.1 Local Expansion in Radial Quantization

Let $\mathcal{O}_i(x)$ and $\mathcal{O}_j(0)$ be local operators inserted inside a sphere of radius R, and let all other insertions lie outside that sphere. Radial quantization turns the separated pair

$$\Psi_{ij}(x) := \mathcal{O}_i(x)\mathcal{O}_j(0)|\Omega\rangle, \qquad |x| < R,$$

into a state on S_R^{D-1}. This state is not, as an object, a local operator at the origin, and there is no operation in the local-operator space which sends the ordered pair $(\mathcal{O}_i(x), \mathcal{O}_j(0))$, with $x \neq 0$, to a new local operator at 0. The local-operator states of definite scaling dimension form an algebraic dense subspace of the BPZ/radial Hilbert space, and the finite-energy spectral projections of the separated-pair state are finite linear combinations of those local-operator states. If $P_{\leq E}$ denotes the spectral projection of D_{rad} onto scaling dimensions at most E, the OPE is the Hilbert-norm convergence

$$\lim_{E\to\infty} P_{\leq E}\Psi_{ij}(x) = \Psi_{ij}(x).$$

Written in local-operator coordinates on the dense finite-energy subspace, the same statement is conventionally abbreviated as

$$\Psi_{ij}(x) \sim_{\mathrm{BPZ}} \sum_{\mathcal{O}} C_{ij\mathcal{O}}(x, \partial)\, \mathcal{O}(0). \tag{64.1}$$

The sum runs over primary operators $\mathcal{O}$ and the differential operator $C_{ij\mathcal{O}}(x,\partial)$ generates the descendants of $\mathcal{O}$. The symbol $\sim_{\mathrm{BPZ}}$ does not denote equality in a pointwise algebra of local operators. It denotes that the finite partial sums over dimensions $\Delta \le \Delta_*$ define local-operator states at the origin whose sequence converges to $\Psi_{ij}(x)$ in the BPZ/radial Hilbert norm on the separating sphere, and hence inside correlation functions with all other insertions farther from the origin than $|x|$.

Equivalently, write $x = \mathrm{e}^{\tau} n_x$ under the Weyl map $\mathbb{R}^D \setminus \{0\} \simeq \mathbb{R}_\tau \times S^{D-1}$. For scalar primaries, $\mathcal{O}_i(x) = |x|^{-\Delta_i} \widetilde{\mathcal{O}}_i(\tau, n_x)$, so the product creates the cylinder state

$$\widetilde{\mathcal{O}}_i(\tau, n_x)|\mathcal{O}_j\rangle \in \mathcal{H}_{S^{D-1}}.$$

The OPE is the statement that this state is represented, in every exterior correlation function, by a convergent limit of local operators at the origin, organized into primary states and their descendants. Thus the expansion is not a formal Taylor series in elementary fields and not a multiplication law closing the local-operator space. It is the spectral expansion of the Hilbert-space state created by separated local insertions by a sequence in the dense algebraic subspace of local-operator states.

The convergence parameter is radial separation. If the nearest outside insertion is at radial distance R, the expansion is organized by powers of $|x|/R$, with larger scaling dimensions contributing at higher radial energy. The OPE is therefore a convergent spectral expansion controlled by the local operator spectrum and the conformal representation theory of descendants.

Definition 64.1 (Radial OPE inputs from radial reconstruction)**.** The Euclidean radial OPE theorem below is stated for a Schwinger hierarchy satisfying the radial reconstruction data of Hypothesis 59.1. The following list is not an independent set of assumptions; it records which clauses of that single radial-reconstruction hypothesis enter the Euclidean convergence proof:

1. distributional Euclidean correlators of renormalized local operators, with covariance, graded permutation symmetry, and contact-term prescriptions;
2. radial reflection positivity and the corresponding null quotient and Hilbert completion;
3. a nonnegative self-adjoint radial Hamiltonian D_{rad} with discrete point spectrum and finite-dimensional spectral subspaces below every finite energy;
4. radial local completeness, so the algebraic direct sum of local scaling-operator states is dense and its homogeneous components identify with the D_{rad}-eigenspaces as in Theorem 59.10.

The Lorentzian continuation statements in this chapter additionally use the tube-domain analytic continuation, spectrum condition, and local commutativity part of the same hypothesis. Thus the phrase "radial OPE convergence under reflection positivity" denotes this listed Hilbert-space and spectral package.

Theorem 64.2 (Euclidean radial OPE convergence)**.** *Assume Hypothesis 59.1, including its spectral clause that D_{rad} is a nonnegative self-adjoint operator with discrete point spectrum, finite-dimensional spectral subspaces $\mathbf{1}_{[0,E]}(D_{\mathrm{rad}})\mathcal{H}_{\mathrm{rad}}$ for every $E < \infty$, and dense algebraic span by local scaling-operator states and their descendants. Let $\mathcal{O}_i(x_E)\mathcal{O}_j(0)\Omega$ be inserted at Euclidean points inside a sphere of radius r in $\mathbb{R}^D_E$, and let all remaining Euclidean insertions lie outside radius $R > r$. Then the expansion of this state in eigenspaces of D_{rad} converges in Hilbert norm for $r < R$, and the resulting OPE converges inside the corresponding Euclidean correlation functions.*

If the expansion is truncated to states of scaling dimension at most Δ_*, the remainder is bounded by the spectral tail above Δ_*, with the damping factor determined by $(r/R)^{D_{\mathrm{rad}}}$.

Proof. The proof is the spectral theorem applied to Euclidean radial quantization. Radial time is $\tau = \log|x_E|$, and the dilatation operator is the nonnegative self-adjoint radial Hamiltonian D_{rad} of Hypothesis 59.1. A separating sphere at radius R inserts the damping factor

$$\exp[-(\log(R/r))D_{\mathrm{rad}}].$$

Set $q = r/R \in (0,1)$, and write $\Psi_{ij}(x_E) = \mathcal{O}_i(x_E)\mathcal{O}_j(0)\Omega$ for the radial Hilbert-space vector defined by the inside insertions. For a spectral cutoff Δ_*, let

$$P_{\le\Delta_*} := \mathbf{1}_{[0,\Delta_*]}(D_{\mathrm{rad}}), \qquad P_{>\Delta_*} := 1 - P_{\le\Delta_*}.$$

The finite-dimensionality of $\mathbf{1}_{[0,\Delta_*]}(D_{\mathrm{rad}})\mathcal{H}_{\mathrm{rad}}$ gives an orthonormal basis $\{|A\rangle\}$ of local scaling-operator states in this subspace, and hence

$$P_{\le\Delta_*}\Psi_{ij}(x_E) = \sum_{\Delta_A\le\Delta_*} |A\rangle\,\langle A, \Psi_{ij}(x_E)\rangle_{\mathrm{rad}}.$$

This is the finite radial OPE partial sum, with the coefficients read as the radial matrix elements of the product insertion. Strong convergence of the spectral projections gives

$$\lim_{\Delta_*\to\infty} \|P_{>\Delta_*}\Psi_{ij}(x_E)\|_{\mathrm{rad}} = 0,$$

so the partial sums converge in Hilbert norm.

Pairing the inside vector with an outside vector Ξ whose support begins at radius R inserts $q^{D_{\mathrm{rad}}}$. Therefore

$$\left|\langle \Xi, q^{D_{\mathrm{rad}}} P_{>\Delta_*}\Psi_{ij}(x_E)\rangle_{\mathrm{rad}}\right| \le q^{\Delta_*}\,\|\Xi\|_{\mathrm{rad}}\,\|P_{>\Delta_*}\Psi_{ij}(x_E)\|_{\mathrm{rad}},$$

and sharper bounds follow by replacing q^{Δ_*} with the exact spectral tail of $q^{D_{\mathrm{rad}}}$ on the omitted dimensions. Since local operator states are dense in the finite-energy subspace, the Hilbert-space partial sums are precisely finite sums of local scaling operators and their descendants. For a radial Hamiltonian with continuous spectrum, the same spectral theorem produces a spectral integral; the displayed discrete OPE requires the finite-multiplicity point-spectrum hypothesis stated in the theorem. □

The preceding theorem is a statement in the Euclidean radial Hilbert space. It does not by itself assert pointwise convergence at arbitrary real Lorentzian configurations. Lorentzian OPE convergence is obtained by applying the Euclidean expansion inside a common holomorphic domain and then taking the appropriate Wightman boundary value.

Proposition 64.3 (Lorentzian continuation of the radial OPE)**.** *Assume the tube-domain part of Hypothesis 59.1. Work with a fixed Wightman ordering π and write $V_+ \subset \mathbb{R}^{1,D-1}$ for the open future light cone in the mostly-plus metric. Let $\mathcal{W}_\pi(z_1,\ldots,z_n)$ be the holomorphic continuation in the tube component*

$$z_{\pi(a)} - z_{\pi(a+1)} = \xi_a - \mathrm{i}\eta_a, \qquad \eta_a \in V_+.$$

For a chosen OPE channel, let $\rho, \bar\rho$ denote the radial cross-ratios of that channel. On every compact subset of the tube component on which

$$|\rho| \le q, \qquad |\bar\rho| \le q, \qquad q < 1, \tag{64.2}$$

the channel OPE converges locally uniformly as a holomorphic function. Its boundary value is the Lorentzian Wightman OPE in that ordering. Strictly timelike configurations in which the fused pair lies in each other's future or past light cone are included when the specified $i\epsilon$ approach remains in such a compact radial domain. Null separation, coincident points, and crossings of external light cones are boundary strata and require the distributional boundary-value interpretation.

Proof. The Euclidean radial theorem gives a convergent expansion in the open polydisc of radial variables. On a compact set satisfying (64.2), the same spectral estimate supplies a summable majorant: each level-Δ descendant contribution is multiplied by a factor bounded by q^{Δ}, while finite multiplicity below each level and radial Hilbert convergence control the corresponding coefficient norm. Therefore the OPE partial sums converge uniformly on compact subsets of the radial polydisc after analytic continuation of $\rho, \bar{\rho}$.

Each finite partial sum is a finite linear combination of Wightman matrix elements of local operators at the origin with the remaining insertions. By the spectrum condition, these matrix elements are boundary values of functions holomorphic in the tube component displayed above. Local uniform convergence of holomorphic partial sums gives a holomorphic limit by the Weierstrass theorem. On the Euclidean subdomain this limit equals $\mathcal{W}_\pi$, because both sides are the Euclidean radial OPE. The identity theorem then identifies the holomorphic limit with $\mathcal{W}_\pi$ throughout the connected tube component reached without crossing singular hypersurfaces. Taking ordered $i\epsilon$ boundary values gives the stated Lorentzian distributional convergence. ☐

Remark 64.4 (Status of Lorentzian OPE convergence)*.* The criterion above separates the Euclidean Hilbert-space theorem from its Lorentzian continuation. The tube condition fixes the operator ordering, and the radial inequality $|\rho|, |\bar{\rho}| < 1$ fixes the OPE channel. For scalar four-point functions in unitary Euclidean CFT, Kravchuk, Qiao, and Rychkov prove the needed forward-tube radial bound and distributional Minkowski OPE convergence; Qiao gives a channel-by-channel classification of real Lorentzian four-point configurations.[1]

Figure 64.1 records the radial OPE geometry: the smaller sphere encloses the approaching operator pair, and convergence is controlled by the ratio of radii in the radial Hilbert norm.

Rychkov, "Distributions in CFT II. Minkowski Space," JHEP **08** (2021) 094, arXiv:2104.02090; and J. Qiao, "Classification of Convergent OPE Channels for Lorentzian CFT Four-Point Functions," SciPost Phys. **13** (2022) 093, arXiv:2005.09105.

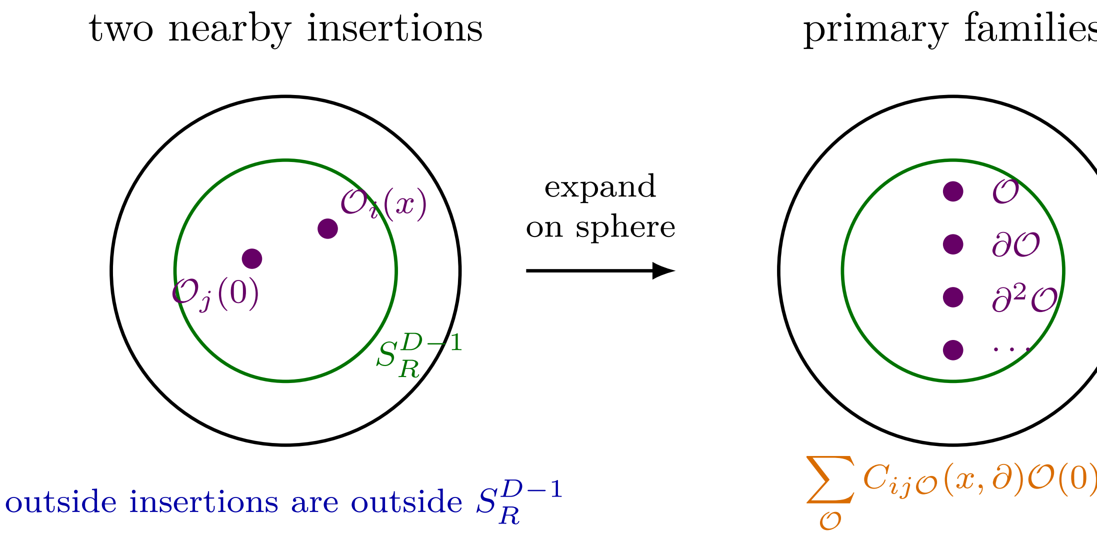

Figure 64.1: The OPE is the expansion of the state created by nearby insertions in the basis of primary conformal multiplets on a separating sphere.

64.2 Scalar-Scalar OPE

Let ϕ_1 and ϕ_2 be scalar primaries of dimensions Δ_1 and Δ_2. Let $\mathcal{O}_{\mu_1\cdots\mu_\ell}$ be a symmetric traceless primary of spin ℓ and dimension Δ. Its leading contribution to the $\phi_1 \times \phi_2$ OPE has the following state-valued asymptotic coordinate in the BPZ/radial expansion:

$$\phi_1(x)\phi_2(0) \supset \lambda_{12\mathcal{O}} \frac{x^{\mu_1}\cdots x^{\mu_\ell}}{|x|^{\Delta_1+\Delta_2-\Delta+\ell}} \mathcal{O}_{\mu_1\cdots\mu_\ell}(0) + \text{descendants}. \tag{64.3}$$

The tensor $x^{\mu_1}\cdots x^{\mu_\ell}$ selects the symmetric traceless part of the spin-ℓ representation. Antisymmetric components do not appear in the product of powers of a single vector, and trace parts are absorbed into descendants or lower-spin structures.

For an exchanged scalar primary $\mathcal{O}$, the first descendant term is fixed by conformal symmetry:

$$\phi_1(x)\phi_2(0) \supset \lambda_{12\mathcal{O}}|x|^{\Delta-\Delta_1-\Delta_2}\left(1 + \frac{\Delta+\Delta_1-\Delta_2}{2\Delta} x^\mu \partial_\mu + \cdots\right)\mathcal{O}(0). \tag{64.4}$$

The coefficient of the derivative is determined by requiring the OPE to reproduce the conformally fixed three-point function $\langle \phi_1\phi_2\mathcal{O}\rangle$. To see the coefficient, place the third operator at z with $|x| \ll |z|$ and normalize $\langle \mathcal{O}(y)\mathcal{O}(z)\rangle = |y-z|^{-2\Delta}$. The three-point function gives

$$\langle \phi_1(x)\phi_2(0)\mathcal{O}(z)\rangle = \lambda_{12\mathcal{O}}|x|^{\Delta-\Delta_1-\Delta_2}|z|^{-2\Delta}\left[1 + (\Delta+\Delta_1-\Delta_2)\frac{x\cdot z}{z^2} + O(x^2)\right].$$

The OPE ansatz

$$\lambda_{12\mathcal{O}}|x|^{\Delta-\Delta_1-\Delta_2}\big(1 + a\, x^\mu \partial_\mu + \cdots\big)\mathcal{O}(0)$$

gives instead

$$\lambda_{12\mathcal{O}}|x|^{\Delta-\Delta_1-\Delta_2}|z|^{-2\Delta}\left[1 + 2a\Delta\frac{x\cdot z}{z^2} + O(x^2)\right],$$

because $\partial_{y^\mu}|y-z|^{-2\Delta}|_{y=0} = 2\Delta z_\mu |z|^{-2\Delta-2}$. Matching the two expansions gives

$$a = \frac{\Delta + \Delta_1 - \Delta_2}{2\Delta}.$$

Higher descendants are fixed in the same way by matching higher orders, or equivalently by the conformal algebra.

For identical scalar primaries this reduces to the especially important normalization

$$\phi(x)\phi(0) \supset \lambda_{\phi\phi\mathcal{O}} |x|^{\Delta_{\mathcal{O}}-2\Delta_\phi} \left(1 + \frac{1}{2}x^\mu \partial_\mu + \cdots\right) \mathcal{O}(0) \tag{64.5}$$

for scalar exchange. The coefficient 1/2 is not an extra convention; it is the specialization of the conformal Ward constraints to two equal external dimensions.

64.3 OPE Data

Choose a basis of primaries with diagonal two-point functions. The local CFT data are then

$$\left\{\Delta_{\mathcal{O}},\ \rho_{\mathcal{O}},\ \lambda^{(a)}_{ij\mathcal{O}}\right\}. \tag{64.6}$$

Here $\rho_{\mathcal{O}}$ is the spin representation, and the label a enumerates independent three-point tensor structures when more than one structure exists. Once this data is specified, all descendant coefficients in the OPE are representation-theoretic consequences of the conformal algebra.

In representation language, if V_i is the conformal multiplet generated by a primary $\mathcal{O}_i$, the OPE map is a conformally covariant state-valued intertwining map from the tensor product of two local-state multiplets, together with a nonzero radial separation, to the Hilbert space on the separating sphere. On the decomposition into irreducible conformal multiplets its finite-energy projections have the form

$$V_i \otimes V_j \longrightarrow \bigoplus_{\mathcal{O}} m^{\mathcal{O}}_{ij} V_{\mathcal{O}} \subset \mathcal{H}_{S^{D-1}}.$$

The multiplicity $m^{\mathcal{O}}_{ij}$ equals the number of independent three-point structures connecting i, j, and $\mathcal{O}$. When $\mathcal{O}_i$ and $\mathcal{O}_j$ are both scalars, rotational covariance permits only symmetric traceless tensor primaries in the leading term, and the multiplicity for each such representation is one. For spinning external operators, several independent tensor structures may couple the same three representations, and the OPE coefficients must then carry the corresponding structure label.

Repeated OPEs determine every separated Euclidean correlation function from the primary spectrum, the two-point pairing, and the three-point coefficients, provided the radial convergence assumptions stated above hold. The data are therefore local in a strong sense: higher-point functions do not bring in independent local constants. Their nontrivial content is the compatibility of the same OPE data in different channels.

64.4 Reconstruction from OPE Data

The preceding paragraph has a converse direction only after the word "data" is given a precise mathematical meaning. A complete primary OPE table $\{\Delta_{\mathcal{O}}, \rho_{\mathcal{O}}, \lambda^{(a)}_{ij\mathcal{O}}\}$, with all primary labels, degeneracies, tensor structures, and operator-basis conventions resolved, is the table of radial expansion coefficients for separated-pair states in the dense local-operator subspace. It is therefore a candidate for an inverse determination of the theory, in the same sense that a sufficiently rich exact set of low-energy observables can in principle determine the parameters and operator content of an effective theory. If a smaller set of local operators generates the finite-energy local-operator subspace under iterated radial OPE limits, the complete OPE spectrum and coefficients visible in suitable four-point functions of those generators may likewise determine the rest of the local theory. Turning such rigidity into a reconstruction statement requires the Hilbert topology, positivity, radial convergence, channel compatibility, and distributional interpretation of separated correlators. The following formulation starts after those inputs have been supplied: it is a radial construction from a fully specified OPE system, rather than a derivation of that system from finite lists of four-point data.

Definition 64.5 (Abstract radial OPE system)**.** An abstract radial OPE system in dimension $D \geq 2$ consists of the following objects.

(i) A countable set $\mathcal{P}$ of primary labels, including the identity label $\mathbf{1}$. Each $a \in \mathcal{P}$ carries a scaling dimension $\Delta_a \in \mathbb{R}_{\geq 0}$ and a finite-dimensional unitary representation ρ_a of $\mathrm{Spin}(D)$. For every $E < \infty$, only finitely many descendant states in the modules below have dimension at most E.

(ii) For each a, a positive-energy conformal module V_a generated by a primary vector $|a\rangle$, with null descendants quotiented. The direct sum

$$\mathcal{H}_{\mathrm{fin}}^{\mathrm{abs}} = \bigoplus_{a \in \mathcal{P}} V_a$$

is equipped with a positive Hermitian inner product for which the conformal generators obey the radial adjointness relations $D^\dagger = D$, $M_{\mu\nu}^\dagger = -M_{\mu\nu}$, and $P_\mu^\dagger = K_\mu$.

(iii) A conjugation $a \mapsto a^\dagger$ and a nondegenerate two-point pairing between V_a and $V_{a^\dagger}$, normalized so that $V_{\mathbf{1}}$ is the one-dimensional vacuum module.

(iv) For every ordered pair a, b and every $c \in \mathcal{P}$, a finite list of conformally covariant three-point tensor structures $\mathcal{T}_{ab}^{c,\alpha}$, $\alpha = 1, \ldots, m_{ab}^c$, and complex coefficients $\lambda_{ab}^{c,\alpha}$. The descendant OPE coefficients are the coefficients obtained by applying the conformal algebra and the quotient Gram matrices inside V_c.

(v) For every finite ordered list of primary or descendant labels and every rooted binary OPE tree T, an iterated OPE series

$$S_T(x_1, \ldots, x_n)$$

on the radial configuration domain of T. This series is required to converge in the radial Hilbert norm for state-valued partial products and locally uniformly, after pairing with exterior finite-energy states, on compact subsets of the separated-point domain of T.

(vi) Channel compatibility: if two trees T and T' have overlapping radial domains, the functions S_T and $S_{T'}$ agree on the common domain after the canonical permutation and tensor-index identifications. For four-point functions this condition is crossing, namely equality of two binary radial-expansion limits tested between exterior states. For higher-point functions it is the equality of all iterated OPE parenthesizations on their common radial domains. A separate coherence theorem may allow the higher-point identities to be derived from a smaller list of associativity identities; absent such a theorem, the all-tree compatibility is part of the system.

(vii) Euclidean covariance under the conformal group, graded permutation symmetry at separated points, and radial reflection positivity for every finite linear combination of inside-supported products.

(viii) A prescription for extending the separated-point functions to distributions with contact terms on diagonals, whenever coincident-point Ward identities or deformations are part of the theory.

The finite-multiplicity condition in item (i) is part of the system because the radial OPE theorem uses spectral projections onto finite-dimensional energy windows. The compatibility condition in item (vi) is also part of the system. A single four-point crossing equation is one instance of this condition and is normally far from determining even that four-point function uniquely. Complete all-primary four-point associativity constraints are a different object: once the OPE table is known, they constrain the whole system of binary radial-expansion limits. The construction below therefore does not hide this analytic and higher-coherence substance in a theorem statement. The hard input is Definition 64.5; the construction records how such input is assembled into a hierarchy.

Construction 64.6 (Separated correlators from an abstract radial OPE system)**.** Let $\mathfrak{D}$ be an abstract radial OPE system in the sense of Definition 64.5. It determines a separated-point Euclidean conformal correlation hierarchy

$$S^{\mathfrak{D}}_{I_1\cdots I_n}(x_1,\ldots,x_n), \qquad x_i \neq x_j,$$

unique up to unitary equivalence of the radial Hilbert space and invertible changes of local operator basis preserving the two-point pairing. This hierarchy satisfies Euclidean conformal covariance, graded permutation symmetry, radial reflection positivity, the spectral discreteness and finite-multiplicity conditions of radial quantization, and the OPE with the prescribed primary dimensions, spin representations, and three-point coefficients. If the system also includes tube-domain analytic continuation, the spectrum condition, and local commutativity for the boundary values, then the reconstructed Euclidean hierarchy gives a Lorentzian Wightman CFT satisfying the radial reconstruction hypotheses used in this volume.

Verification of the construction. First construct the dense finite-energy vector space $\mathcal{H}^{\mathrm{abs}}_{\mathrm{fin}} = \bigoplus_a V_a$ with the positive inner product specified in Definition 64.5. Its Hilbert completion is the radial Hilbert space. The conformal generators act on each V_a, and the adjointness relations make the representation unitary on the finite-energy domain. The identity module supplies the vacuum vector.

For a separated Euclidean configuration, choose a rooted binary OPE tree whose radial inequalities are satisfied by the insertion points. Apply the intertwining OPE maps at the internal vertices of the tree and sum over intermediate primary modules and descendants. Item (v) gives a convergent state-valued expansion at each internal radial step and locally uniform convergence after pairing with the remaining exterior states. Hence the tree defines a correlation function $S_T(x_1,\ldots,x_n)$ on its radial domain.

If two admissible trees describe the same configuration on an overlap, item (vi) identifies the two sums there. The separated Euclidean configuration space is covered by such radial domains. Patching the locally defined functions through their overlaps gives a single separated-point hierarchy $S^{\mathfrak{D}}$. Conformal covariance and graded permutation symmetry are inherited from the covariance of the three-point tensor structures and from item (vii). Reflection positivity follows from the assumed positivity of all inside-supported products; quotienting by zero-norm vectors gives the physical radial Hilbert space.

The OPE of the reconstructed fields is built into the construction. When a subset of insertions is separated from the rest by a sphere, using an OPE tree that first fuses that subset gives precisely the convergent expansion with coefficients $\lambda_{ab}^{c;\alpha}$ and conformally determined descendant coefficients. Since compatible trees give the same patched correlator, the same OPE holds independently of the auxiliary tree used to compute the correlator. The stated uniqueness follows because any Euclidean hierarchy with the same system has the same convergent OPE sums on every radial tree domain, and those domains cover separated configurations.

Finally, if tube-domain analytic continuation, the Lorentzian spectrum condition, and local commutativity are included, the usual Wightman boundary value construction applied to the reconstructed Euclidean hierarchy gives the corresponding Lorentzian distributions. These are precisely the additional analytic hypotheses listed in Hypothesis 59.1.

Open Problem 64.7 (Completeness of four-point OPE data). The useful reconstruction problem is not the claim that a bare crossing equation for a single correlator produces a CFT, or even uniquely determines that correlator. The crossing equation is a functional constraint on an unknown function or distribution with unknown spectral decomposition; without additional input it has many formal solutions and many possible completions. A single correlator probes only the sector generated by its external operators, and even there one must resolve degeneracies, tensor structures, normalizations, and null states. The natural problem is sharper. Suppose one is given a complete all-primary OPE table

$$\{\Delta_a, \rho_a, \lambda_{ab}^{c;\alpha}\}$$

or, in a generated theory, the complete OPE data appearing in the four-point functions of a set of generators, with enough information to recover every primary and every independent three-point tensor structure. Suppose further that this table obeys the unitary representation-theoretic bounds, reflection-positivity inequalities, and the four-point associativity equations for all relevant choices of external operators. This is an exact infinite-data problem, analogous to determining a theory from a sufficiently complete set of precision observables; it is not the problem of solving a single bootstrap equation. Under what additional analytic hypotheses does it extend to an abstract radial OPE system satisfying Definition 64.5?

In dimension $D > 2$, complete such data are expected to determine at most one CFT up to unitary equivalence and changes of operator basis, once the generator or all-primary hypothesis is made. The existence part still requires theorem-level control of radial convergence, spectral finiteness, coherence of higher iterated OPEs, distributional extensions and contact-term prescriptions, and Lorentzian boundary-value properties. Those requirements are precisely why Construction 64.6 is formulated from an abstract radial OPE system rather than from a single informal crossing statement.

64.5 Conformal Blocks as Multiplet Contributions

The representation-theoretic object underlying a conformal block is a channel projector, or more generally a pair of intertwiners through a multiplicity space. Work in a radial Hilbert space satisfying Hypothesis 59.1, and use the positive-energy $\widetilde{G}_{\mathrm{conf}}^{\mathrm{Lor}}$-module conventions of Section 57.8.

For a primary label $\mathfrak{m} = (\Delta, \rho)$, let

$$L_{\mathfrak{m}} = M(\Delta, \rho)/\operatorname{Rad} M(\Delta, \rho)$$

be the irreducible null-quotient conformal multiplet, with its radial Hilbert globalization. In a fixed OPE channel, the finite-energy part of the separated-pair state generated by $\mathcal{O}_i$ and $\mathcal{O}_j$ has a spectral decomposition of the form

$$\mathcal{H}_{ij}^{\mathrm{ch}} \simeq \widehat{\bigoplus_{\mathfrak{m}}} \mathcal{M}_{ij}^{\mathfrak{m}} \otimes L_{\mathfrak{m}}, \tag{64.7}$$

where $\mathcal{M}_{ij}^{\mathfrak{m}}$ is a finite-dimensional multiplicity space when the finite-multiplicity radial hypotheses hold. The hat records Hilbert completion after the algebraic finite-energy direct sum is formed. For finite energy cutoffs this is an ordinary finite direct sum.

Let

$$\iota_{ij}^{\mathfrak{m},a} : L_{\mathfrak{m}} \longrightarrow \mathcal{H}_{ij}^{\mathrm{ch}}, \qquad a = 1, \ldots, \dim \mathcal{M}_{ij}^{\mathfrak{m}},$$

be a basis of conformal intertwiners for the ij channel, and let $\iota_{kl}^{\mathfrak{m},b}$ be the corresponding basis for the opposite pairing. The block contribution of $L_{\mathfrak{m}}$ is the matrix element of the finite-energy channel projector

$$\Pi_{\mathfrak{m}} : \mathcal{H}_{\mathrm{rad}} \longrightarrow \mathcal{M}^{\mathfrak{m}} \otimes L_{\mathfrak{m}}$$

between the two separated-pair states. Equivalently, after choosing the two-point pairing on $L_{\mathfrak{m}}$ and the basis of multiplicity spaces,

$$\mathcal{B}_{\mathfrak{m}}^{ab}(x_i) = \left\langle \Psi_{34}^{b}(x_3, x_4), \Pi_{\mathfrak{m}} \Psi_{12}^{a}(x_1, x_2) \right\rangle_{\mathrm{rad}}. \tag{64.8}$$

This equation is the definition of the conformal block as a Hilbert-space object. The differential-equation, shadow-integral, Mellin, and radial-series formulae below are coordinate descriptions of (64.8) under additional analytic hypotheses. If $L_{\mathfrak{m}}$ is short, the projector is formed after quotienting the generalized Verma module by its null radical; Gram matrices are inverted only on the quotient spaces.

For a scalar four-point function, this channel-projector definition separates the contribution of each primary conformal multiplet. For the general scalar four-point function (63.30), the $12 \to 34$ OPE gives

$$\mathcal{G}(u, v) = \sum_{\mathcal{O},a,b} \lambda_{12\mathcal{O}}^{(a)} N_{\mathcal{O}}^{ab} \lambda_{34\mathcal{O}}^{(b)} G_{\Delta,\ell}^{(a,b;12|34)}(u, v). \tag{64.9}$$

Here $\mathcal{O}$ runs over primary multiplets of dimension Δ and spin ℓ, a, b label possible tensor structures in the $\mathcal{O}_1\mathcal{O}_2\mathcal{O}$ and $\mathcal{O}_3\mathcal{O}_4\mathcal{O}$ three-point functions, and $N_{\mathcal{O}}^{ab}$ is the inverse two-point pairing on the corresponding degeneracy space. In an orthonormal basis and for scalar external operators with a single structure, this reduces to

$$\mathcal{G}(u, v) = \sum_{\mathcal{O}} \lambda_{12\mathcal{O}} \lambda_{34\mathcal{O}}\, G_{\Delta,\ell}^{(12|34)}(u, v).$$

The function $G_{\Delta,\ell}^{(12|34)}$ is the conformal block: it is the sum of the primary $\mathcal{O}$ and all of its descendants, with descendant coefficients fixed by the conformal algebra.

Figure 64.2 displays the two OPE association patterns for a four-point function; equality of the corresponding expansions is the crossing equation in the common convergence domain.

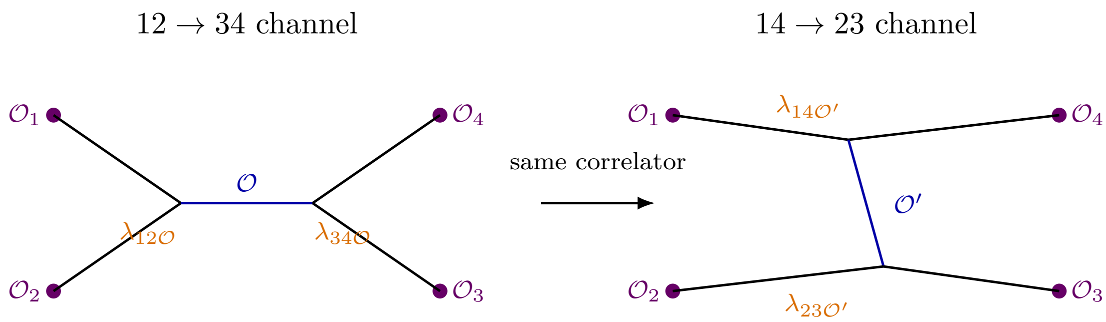

Figure 64.2: A four-point function may be expanded in different OPE trees. The equality of these decompositions is the four-point form of OPE associativity.

The block is characterized representation-theoretically by the quadratic Casimir, together with an OPE boundary condition. Put

$$u = z\bar{z}, \qquad v = (1-z)(1-\bar{z}), \qquad a = \frac{\Delta_2 - \Delta_1}{2}, \qquad b = \frac{\Delta_3 - \Delta_4}{2}, \qquad \varepsilon_D = \frac{D}{2} - 1.$$

After the external scalar prefactor in (63.30) has been removed, the 12-channel quadratic Casimir acts on the reduced function by

$$\mathcal{C}_{12}^{(u,v)} = 2\mathcal{D}_{a,b}, \tag{64.10}$$

where

$$\begin{aligned} \mathcal{D}_{a,b} = {} & u^2(1-u+v)\partial_u^2 - 2uv(1+u-v)\partial_u\partial_v + v\big((1-v)^2 - u(1+v)\big)\partial_v^2 \\ & - u\big((a+b+1)(1+u-v) + 2\varepsilon_D\big)\partial_u + (a+b+1)\big((1-v)^2 - u(1+v)\big)\partial_v \\ & - ab(1+u-v). \end{aligned} \tag{64.11}$$

Equivalently, in the algebraic coordinates $z, \bar{z}$,

$$\begin{aligned} \mathcal{D}_{a,b} &= D_z + D_{\bar{z}} + 2\varepsilon_D \frac{z\bar{z}}{z-\bar{z}}\big((1-z)\partial_z - (1-\bar{z})\partial_{\bar{z}}\big), \\ D_z &= z^2(1-z)\partial_z^2 - (a+b+1)z^2\partial_z - abz, \qquad D_{\bar{z}} = D_z\big|_{z\mapsto\bar{z}}. \end{aligned} \tag{64.12}$$

The conversion from (64.12) to (64.11) is the chain rule together with

$$z + \bar{z} = 1 + u - v, \qquad \partial_z = \bar{z}\,\partial_u - (1-\bar{z})\partial_v, \qquad \partial_{\bar{z}} = z\,\partial_u - (1-z)\partial_v.$$

The apparently singular term in (64.12) is regular on symmetric functions of $z, \bar{z}$, since

$$(1-z)\partial_z - (1-\bar{z})\partial_{\bar{z}} = (\bar{z} - z)\partial_u.$$

The factor 2 in (64.10) fixes the normalization of the conformal-algebra quadratic Casimir used in this chapter:

$$\mathcal{C}_{12}^{(u,v)} G_{\Delta,\ell}^{(12|34)}(u,v) = C_{\Delta,\ell} G_{\Delta,\ell}^{(12|34)}(u,v), \qquad C_{\Delta,\ell} = \Delta(\Delta - D) + \ell(\ell + D - 2). \tag{64.13}$$

The equality $C_{\Delta,\ell} = C_{D-\Delta,\ell}$ already shows that the differential equation alone does not select an OPE block. In the radial frame of (64.33), the two local Frobenius branches at the 12 OPE boundary are

$$G^{(12|34)}_{\Delta,\ell}(u,v) = r^{\Delta} C^{(D/2-1)}_{\ell}(\cos\alpha) + O(r^{\Delta+1}), \tag{64.14}$$

$$G^{(12|34)}_{D-\Delta,\ell}(u,v) = r^{D-\Delta} C^{(D/2-1)}_{\ell}(\cos\alpha) + O(r^{D-\Delta+1}). \tag{64.15}$$

The conformal block in the OPE sum is the solution with the first leading coefficient normalized as in (64.14) and with zero coefficient multiplying the shadow branch (64.15).

Short multiplets require a levelwise quotient, not a single informal deletion of dependent vectors. Section 62.7 explains how saturation of a unitarity bound produces a null descendant at a definite level: for example the scalar Laplace descendant $\widehat{P}^2|\phi\rangle$ at level 2, the divergence of a conserved symmetric-traceless tensor at level 1, or the spinor gamma-trace descendant at level 1. If N_α denotes such a singular null descendant at level r_α, then every

$$\widehat{P}_{\mu_1} \cdots \widehat{P}_{\mu_k} N_\alpha \qquad (k \geq 0)$$

is null at level $r_\alpha + k$. The descendant space used in the block at level n is therefore the raw level-n descendant space modulo the span of all null descendants whose total level is n. This is the same null submodule subtraction that produces the short-module characters in Chapter 59; it is performed before any Gram matrix is inverted.

Theorem 64.8 (Local existence and uniqueness of the OPE block)**.** *Assume the radial reconstruction hypotheses of Hypothesis 59.1, finite multiplicity of descendant states at each level, and the levelwise null-submodule quotient just described. For scalar external operators and one exchanged symmetric-traceless primary of dimension Δ and spin ℓ, there is a unique* 12*-channel block with the OPE normalization* (64.14)*. It is a convergent radial series for $r < 1$, satisfies the Casimir equation* (64.13)*, and contains no shadow branch.*

Proof. Let $V_{\Delta,\ell}$ be the conformal multiplet generated from the exchanged primary. Let

$$W_n \simeq \mathrm{Sym}^n(\mathbb{C}^D) \otimes V_{\Delta,\ell}$$

be the raw level-n descendant space before equations of motion, conservation laws, or other shortening relations are imposed. Its null radical for the radial Gram form is

$$\mathcal{N}_n = \{v \in W_n : \langle v, w\rangle = 0 \text{ for all } w \in W_n\}.$$

When the exchanged multiplet is short, $\mathcal{N}_n$ is generated level-by-level by the singular null descendants fixed by the saturated unitarity bounds and by all of their translation descendants at total level n. Reflection positivity implies that every vector in $\mathcal{N}_n$ has zero matrix element against every physical exterior state, so replacing W_n by

$$Q_n = W_n / \mathcal{N}_n$$

does not change any physical four-point function. Choose a basis $\{|A,n\rangle\}_A$ of Q_n and let

$$M^{(n)}_{AB} = \langle A,n|B,n\rangle$$

be the quotient Gram matrix. The quotient has no null radical, hence $M^{(n)}$ is invertible on this finite-dimensional space. The contribution of this level to the four-point function is

$$r^{\Delta+n} \sum_{A,B} \langle \mathcal{O}_4\mathcal{O}_3|A,n\rangle \, (M^{(n)})^{-1}_{AB} \, \langle B,n|\mathcal{O}_1\mathcal{O}_2\rangle, \tag{64.16}$$

with the angular dependence carried by the cylinder wavefunctions of the descendants. The three-point Ward identities fix the two vectors of matrix elements in (64.16) recursively from the primary three-point structures, because moving a conformal generator from a descendant state onto the external primaries is governed by the conformal algebra and by the scalar transformation law. Summing over all $n \geq 0$ therefore constructs a radial series whose leading term is the primary matrix element

$$r^{\Delta} C_{\ell}^{(D/2-1)}(\cos\alpha).$$

The convergence for $r < 1$ is the radial OPE convergence theorem applied after projecting the inside state to the multiplet $V_{\Delta,\ell}$.

The same construction gives the Casimir equation. The operator $\mathcal{C}_{12}$ is the square of the total conformal generator acting on the pair $(1, 2)$. On the projected intermediate multiplet it acts by the scalar $C_{\Delta,\ell}$, while the external scalar prefactor converts this action on the four-point function into the differential operator $\mathcal{C}_{12}^{(u,v)}$ displayed in (64.11). Hence the constructed radial series satisfies (64.13).

For uniqueness, let $H(r, \alpha)$ be the difference of two local solutions with the OPE normalization (64.14) and no shadow branch. Its first nonzero radial coefficient, if present, has some level $n > 0$ and lies in the finite descendant space at that level. The Casimir equation and the Ward identities impose the same finite linear system as in (64.16). Since $M^{(n)}$ is invertible on the quotient by null states and all lower-level coefficients of H vanish, that coefficient must vanish. This contradicts the choice of the first nonzero level. Therefore $H = 0$, proving uniqueness. □

Thus the spectrum and OPE coefficients are the dynamical data, while the blocks are kinematic functions determined by conformal representation theory and by the OPE branch condition.

64.5.1 Blocks, Shadows, and Partial Waves

The object just defined is an OPE-channel conformal block. Its normalization in this chapter is the OPE normalization: in the $12 \to 34$ channel the leading term as $x_1 \to x_2$ is the contribution of a primary of dimension Δ and spin ℓ, with no contribution from the shadow dimension. This is the normalization used in the discrete OPE sum (64.9).

A *conformal partial wave* is a different, although closely related, object. It is the harmonic-analysis kernel obtained from the conformal projector onto an irreducible principal-series representation. Let $\widetilde{\Delta} = D - \Delta$ be the shadow dimension of Δ. For scalar external operators and a single exchanged symmetric-traceless tensor structure, the shadow-projector normalization may be represented, with the symmetric-traceless spin-index contraction suppressed from the notation, by

$$\Psi_{\Delta,\ell}^{(12|34)}(x_i) = \frac{1}{\mathcal{N}_{\Delta,\ell}} \int_{\mathbb{R}^D} \mathrm{d}^D x_0 \, \big\langle \mathcal{O}_1(x_1)\mathcal{O}_2(x_2)\mathcal{O}_{\Delta,\ell}(x_0)\big\rangle \big\langle \widetilde{\mathcal{O}}_{\widetilde{\Delta},\ell}(x_0)\mathcal{O}_3(x_3)\mathcal{O}_4(x_4)\big\rangle. \tag{64.17}$$

The spin indices of $\mathcal{O}_{\Delta,\ell}$ and $\widetilde{\mathcal{O}}_{\widetilde{\Delta},\ell}$ are contracted with the invariant two-point pairing. The constant $\mathcal{N}_{\Delta,\ell}$ is fixed once the two-point functions and the shadow transform are normalized; the convention is that the resulting projector is idempotent on the irreducible representation and that the Plancherel formula below has no additional scalar normalization. With spinning external operators or multiple three-point tensor structures, $\Psi_{\Delta,\ell}$ becomes a matrix in the corresponding structure labels.

After the same external kinematic prefactor has been factored out as in the four-point decomposition, the partial wave gives a function $\Psi^{(12|34)}_{\Delta,\ell}(u,v)$. It satisfies the same quadratic Casimir equation as the block with eigenvalue $C_{\Delta,\ell}$, but it has different analytic boundary data. In the 12 OPE limit it is a fixed linear combination

$$\Psi^{(12|34)}_{\Delta,\ell}(u,v) = A^{(12|34)}_{\Delta,\ell} G^{(12|34)}_{\Delta,\ell}(u,v) + A^{(12|34)}_{\widetilde{\Delta},\ell} G^{(12|34)}_{\widetilde{\Delta},\ell}(u,v), \qquad \widetilde{\Delta} = D - \Delta, \tag{64.18}$$

where the coefficients $A_{\Delta,\ell}$ are determined by the chosen shadow-transform normalization. Thus a partial wave is not the same object as the conformal block appearing in a physical Euclidean OPE sum. The block selects one OPE boundary condition; the partial wave is a single-valued Euclidean conformal harmonic, containing both the block and the shadow block.

For functions of cross-ratios satisfying the hypotheses of conformal harmonic analysis, the partial waves on the principal series $\Delta = D/2 + \mathrm{i}\nu$, $\nu \in \mathbb{R}$, form the continuous basis

$$\mathcal{F}(u,v) = \sum_{\ell=0}^{\infty} \int_{-\infty}^{\infty} \frac{\mathrm{d}\nu}{2\pi}\, \mu(\nu,\ell)\, a(\nu,\ell)\, \Psi_{D/2+\mathrm{i}\nu,\ell}(u,v). \tag{64.19}$$

Here $\mu(\nu,\ell)$ is the Plancherel density associated with the normalization in (64.17), and $a(\nu,\ell)$ is the partial-wave transform of $\mathcal{F}$. Physical OPE data are recovered, when the required analyticity and growth hypotheses hold, by moving the ν-contour and taking residues at poles in Δ. This is why one must distinguish the two objects: conformal blocks organize the discrete OPE in a channel, whereas conformal partial waves provide the representation-theoretic resolution of identity used in integral inversion formulae.

64.5.2 Mellin Representation and OPE Poles

Mellin space is a transform representation of scalar separated-point correlators. Its use requires an existence and growth hypothesis parallel to the partial-wave transform above: a meromorphic Mellin amplitude belongs to a specific Mellin-Barnes representation of the correlator. When the representation exists with suitable vertical-contour decay, it turns the 12-channel OPE expansion into a residue expansion in a complex variable conjugate to the cross-ratio u.

Let $X_{ij} = x_{ij}^2$ for Euclidean separated points and let $\mathcal{O}_i$ be scalar primaries of dimensions Δ_i. Define the affine Mellin constraint space

$$\mathfrak{A}_\Delta = \left\{ \delta_{ij} = \delta_{ji} \in \mathbb{C}, \quad \delta_{ii} = 0, \quad \sum_{j\neq i} \delta_{ij} = \Delta_i \text{ for } i = 1,\ldots,n \right\}. \tag{64.20}$$

The constraints are exactly the conditions that make $\prod_{i<j} X_{ij}^{-\delta_{ij}}$ transform like an n-point function of scalar primaries under independent local scale factors at the insertion points.

Definition 64.9 (Scalar Mellin representation)**.** An n-point scalar Euclidean correlator is Mellin representable on a configuration-space domain U if there are vertical cycles $\mathcal{C} \subset \mathfrak{A}_\Delta$, a meromorphic or distributional function $M(\delta_{ij})$, and a choice of logarithm for each X_{ij} on U, such that

$$\langle \mathcal{O}_1(x_1)\cdots\mathcal{O}_n(x_n)\rangle = \int_{\mathcal{C}} [\mathrm{d}\delta]\, M(\delta_{ij}) \prod_{1\le i<j\le n} \Gamma(\delta_{ij})\, X_{ij}^{-\delta_{ij}}. \tag{64.21}$$

The measure $[\mathrm{d}\delta]$ is the product of $\mathrm{d}\delta/(2\pi\mathrm{i})$ over a basis of independent affine coordinates on $\mathfrak{A}_\Delta$. The contour is chosen so that the pole families whose residues give the desired OPE expansions lie on the side prescribed by the corresponding radial domain. The gamma factors in (64.21) are part of the normalization of M; moving any universal gamma factor between M and the kernel gives a different Mellin amplitude representing the same correlator.

For four points it is useful to replace the constrained variables by three Mellin-channel variables

$$\mathfrak{s}+\mathfrak{t}+\mathfrak{u}=\Delta_\Sigma, \qquad \Delta_\Sigma=\Delta_1+\Delta_2+\Delta_3+\Delta_4,$$

where

$$\begin{aligned} \delta_{12} &= \frac{\Delta_1+\Delta_2-\mathfrak{s}}{2}, & \delta_{34} &= \frac{\Delta_3+\Delta_4-\mathfrak{s}}{2}, \\ \delta_{14} &= \frac{\Delta_1+\Delta_4-\mathfrak{t}}{2}, & \delta_{23} &= \frac{\Delta_2+\Delta_3-\mathfrak{t}}{2}, \\ \delta_{13} &= \frac{\Delta_1+\Delta_3-\mathfrak{u}}{2}, & \delta_{24} &= \frac{\Delta_2+\Delta_4-\mathfrak{u}}{2}. \end{aligned} \tag{64.22}$$

The letters $\mathfrak{s},\mathfrak{t},\mathfrak{u}$ are Mellin variables; they are not scattering Mandelstam invariants. They are named by the OPE channel whose twist poles they expose.

With the four-point prefactor of (63.30), Definition 64.9 becomes

$$\mathcal{G}(u,v)=\int_{\mathcal{C}_{\mathfrak{s},\mathfrak{t}}} \frac{\mathrm{d}\mathfrak{s}\,\mathrm{d}\mathfrak{t}}{(4\pi\mathrm{i})^2}\, u^{\mathfrak{s}/2}v^{(\mathfrak{t}-\Delta_2-\Delta_3)/2}\Gamma_\Delta(\mathfrak{s},\mathfrak{t})\, M(\mathfrak{s},\mathfrak{t}), \tag{64.23}$$

where $\mathfrak{u}=\Delta_\Sigma-\mathfrak{s}-\mathfrak{t}$ and

$$\begin{aligned} \Gamma_\Delta(\mathfrak{s},\mathfrak{t}) = {}& \Gamma\!\left(\frac{\Delta_1+\Delta_2-\mathfrak{s}}{2}\right)\Gamma\!\left(\frac{\Delta_3+\Delta_4-\mathfrak{s}}{2}\right)\Gamma\!\left(\frac{\Delta_1+\Delta_4-\mathfrak{t}}{2}\right)\Gamma\!\left(\frac{\Delta_2+\Delta_3-\mathfrak{t}}{2}\right) \\ & \times\Gamma\!\left(\frac{\Delta_1+\Delta_3-\mathfrak{u}}{2}\right)\Gamma\!\left(\frac{\Delta_2+\Delta_4-\mathfrak{u}}{2}\right). \end{aligned} \tag{64.24}$$

The normalization $(4\pi\mathrm{i})^{-2}$ comes from $\mathrm{d}\delta_{12}\mathrm{d}\delta_{14}=\mathrm{d}\mathfrak{s}\,\mathrm{d}\mathfrak{t}/4$.

Compatibility with the four-point prefactor. The representation (64.23) is exactly the $n=4$ constrained Mellin representation (64.21) after factoring out the kinematic prefactor in (63.30). The Mellin product has exponent $-\delta_{ij}$ on X_{ij}. Subtract the exponents of the prefactor in (63.30). For X_{12} and X_{34} the remaining exponent is

$$-\delta_{12}+\frac{\Delta_1+\Delta_2}{2}=-\delta_{34}+\frac{\Delta_3+\Delta_4}{2}=\frac{\mathfrak{s}}{2}.$$

For X_{14} and X_{23} the remaining exponent is

$$\frac{\mathfrak{t}-\Delta_2-\Delta_3}{2}.$$

For X_{13} and X_{24} the remaining exponent is the negative of the sum of these two numbers, because $\mathfrak{u}=\Delta_\Sigma-\mathfrak{s}-\mathfrak{t}$. These are precisely the exponents of

$$u^{\mathfrak{s}/2}v^{(\mathfrak{t}-\Delta_2-\Delta_3)/2}=\left(\frac{X_{12}X_{34}}{X_{13}X_{24}}\right)^{\mathfrak{s}/2}\left(\frac{X_{14}X_{23}}{X_{13}X_{24}}\right)^{(\mathfrak{t}-\Delta_2-\Delta_3)/2}.$$

The six gamma factors are those in (64.21) with (64.22) substituted.

The pole interpretation is a contour-shift statement. Write

$$\mathcal{I}(\mathfrak{s}, \mathfrak{t}) = \Gamma_{\Delta}(\mathfrak{s}, \mathfrak{t}) M(\mathfrak{s}, \mathfrak{t})$$

for the full Mellin integrand without the cross-ratio powers. Suppose the $\mathfrak{s}$-contour is a vertical line, $0 < u < 1$, the integrand is meromorphic in the strip swept by moving the contour to the right, and the horizontal contour arcs vanish in that strip. If $\mathcal{I}$ has a simple pole at $\mathfrak{s} = \sigma$ with residue $R_\sigma(\mathfrak{t})$, then that pole contributes

$$u^{\sigma/2} \int_{\mathcal{C}_{\mathfrak{t}}} \frac{\mathrm{d}\mathfrak{t}}{2\pi \mathrm{i}}\, v^{(\mathfrak{t}-\Delta_2-\Delta_3)/2} R_\sigma(\mathfrak{t}) \tag{64.25}$$

to $\mathcal{G}(u, v)$. A pole of order $r+1$ gives a polynomial of degree r in $\log u$ multiplying $u^{\sigma/2}$. Conversely, under the same vertical-growth hypothesis, a term $u^\alpha H(v)$ in the asymptotic expansion at fixed v is represented in the Mellin transform by a pole at $\mathfrak{s} = 2\alpha$, with residue equal to the one-dimensional Mellin transform of $H(v)$ in the $\mathfrak{t}$ variable.

Now apply this to the radial OPE. An exchanged primary of dimension Δ and spin ℓ has twist

$$\tau = \Delta - \ell.$$

In the $12 \to 34$ OPE channel, the corresponding conformal block has a radial expansion of the form

$$G^{(12|34)}_{\Delta,\ell}(u, v) = u^{\tau/2} \sum_{m=0}^{\infty} u^m\, H_m^{(\Delta,\ell)}(v), \tag{64.26}$$

inside the radial convergence domain, after the spin-dependent angular dependence is expressed through v in the chosen conformal frame. Therefore the full Mellin integrand has poles at

$$\mathfrak{s} = \tau + 2m, \qquad m = 0, 1, 2, \ldots. \tag{64.27}$$

If the gamma-stripped amplitude M is meromorphic and the pole does not coincide with a gamma-kernel pole, the same family appears in M. With the OPE normalization of the block fixed in (64.14), its local form is

$$M(\mathfrak{s}, \mathfrak{t}) = \sum_{m=0}^{\infty} \frac{\lambda_{12\mathcal{O}} \lambda_{34\mathcal{O}}\, Q^{(12|34)}_{m,\ell}(\mathfrak{t})}{\mathfrak{s} - \tau - 2m} + M_{\mathrm{hol}}(\mathfrak{s}, \mathfrak{t}), \tag{64.28}$$

in a neighborhood of the displayed pole family. The residue $Q^{(12|34)}_{m,\ell}$ is the Mack polynomial in this normalization. It is characterized intrinsically as the unique polynomial residue which, after substitution in (64.23), produces the level-m term of the Casimir eigenfunction with OPE boundary condition (64.14). Its degree in $\mathfrak{t}$ is ℓ; the descendant label m changes the coefficients and the gamma kernel, not the spin degree.

Proposition 64.10 (OPE poles in Mellin space). *Assume the radial OPE theorem of Theorem 64.2, the four-point Mellin representation* (64.23)*, meromorphic continuation of M in the relevant $\mathfrak{s}$-strip, and the vertical growth needed for the contour shift above. Then every exchanged symmetric-traceless primary $\mathcal{O}$ in the $12 \to 34$ scalar OPE whose twist-pole family does not coincide with a gamma-kernel pole contributes the pole family* (64.28)*. The residue is proportional to the product $\lambda_{12\mathcal{O}}\lambda_{34\mathcal{O}}$, and the proportionality function is fixed by conformal representation theory.*

Proof. The radial OPE theorem gives an absolutely convergent sum of conformal families in the channel domain. Project to a single exchanged conformal multiplet and use the block construction in Theorem 64.8. Its radial series has the form (64.26): the primary supplies the exponent $\tau/2$, and the descendant contribution can be grouped into integer powers of u after the remaining angular dependence is kept in the functions $H_m(v)$. The coefficient multiplying the block in the four-point function is $\lambda_{12\mathcal{O}}\lambda_{34\mathcal{O}}$ in the orthonormal single-structure case, or the corresponding contraction with the inverse two-point pairing in the notation of (64.9).

The contour-shift identity (64.25) identifies every term $u^{\tau/2+m}H_m(v)$ with a pole at $\mathfrak{s} = \tau + 2m$ in the full Mellin integrand. When this pole is not a pole already forced by Γ_Δ, it is represented by a pole of M. The v-dependence of the residue is converted to a polynomial in $\mathfrak{t}$ by the one-dimensional Mellin transform with the fixed gamma kernel in (64.24). The Casimir equation (64.13) and the OPE boundary condition (64.14) fix this residue uniquely. The highest power of $\mathfrak{t}$ is fixed by the spin-ℓ leading angular structure of the primary three-point functions, hence the residue has degree ℓ. This proves the stated pole family and normalization. □

Crossing acts linearly on Mellin space. A permutation $\sigma \in S_4$ sends δ_{ij} to $\delta_{\sigma(i)\sigma(j)}$, and the induced action on $(\mathfrak{s}, \mathfrak{t}, \mathfrak{u})$ permutes the channel variables with $\mathfrak{s} + \mathfrak{t} + \mathfrak{u} = \Delta_\Sigma$ preserved. For identical scalar primaries, crossing of the separated-point correlator is equivalent, in a common Mellin domain, to the corresponding invariance of the Mellin integrand up to contour deformation across the pole families. Thus the Mellin form expresses the same OPE-associativity constraints as the block expansion, but in a language where exchanged twists are pole locations and spins are polynomial degrees of residues.

64.5.3 Lorentzian Inversion as a Boundary Theorem

The Euclidean OPE sum determines correlators by summing over the discrete operator spectrum. Lorentzian inversion goes in the opposite direction: under additional Lorentzian analyticity and boundedness hypotheses, it reconstructs the spin-analytic OPE coefficient function from a double discontinuity of the four-point function. For identical scalar primaries, define the t-channel double discontinuity across the branch cut $\bar{z} \in [1, \infty)$ by

$$\mathrm{dDisc}_t[\mathcal{G}](z, \bar{z}) = \mathcal{G}(z, \bar{z}) - \frac{1}{2}\,\mathcal{G}^{\circlearrowleft}(z, \bar{z}) - \frac{1}{2}\,\mathcal{G}^{\circlearrowright}(z, \bar{z}), \tag{64.29}$$

where the arrows denote the two analytic continuations of $\bar{z}$ around $\bar{z} = 1$. For unequal external dimensions the two continued terms are multiplied by the corresponding monodromy phases fixed by the external weights.

In the scalar normalization compatible with the partial-wave convention above, the t-channel contribution to the Caron-Huot Lorentzian inversion formula has the form

$$c^t(\Delta, J) = \frac{\kappa_{\Delta+J}}{4} \int_0^1 \mathrm{d}z \int_0^1 \mathrm{d}\bar{z}\, \frac{|z-\bar{z}|^{D-2}}{(z\bar{z})^D}\, G^{(12|34)}_{J+D-1,\,\Delta-D+1}(z, \bar{z})\, \mathrm{dDisc}_t[\mathcal{G}](z, \bar{z}), \tag{64.30}$$

with

$$\kappa_\beta = \frac{\Gamma(\beta/2)^4}{2\pi^2\,\Gamma(\beta-1)\Gamma(\beta)} \qquad \text{for identical external scalars.} \tag{64.31}$$

The full identical-scalar coefficient includes the crossed u-channel contribution

$$c(\Delta, J) = c^t(\Delta, J) + (-1)^J c^u(\Delta, J),$$

with the same kernel after the corresponding interchange of points. The block appearing in the kernel has analytically continued labels: its first label is $J+D-1$, and its second label is $\Delta-D+1$. This is the same block/partial-wave duality already visible in (64.18); the inversion integral pairs the Lorentzian double discontinuity with the shadow-side harmonic kernel.

The coefficient function $c(\Delta, J)$ is meromorphic in Δ for the spins covered by the Regge boundedness hypothesis. If a primary of spin J and dimension $\Delta_{\mathcal{O}}$ appears in the $\phi \times \phi$ OPE, then near the pole

$$c(\Delta, J) = \frac{\lambda^2_{\phi\phi\mathcal{O}}}{\Delta - \Delta_{\mathcal{O}}} + \text{holomorphic near } \Delta_{\mathcal{O}}. \tag{64.32}$$

Thus the formula extracts OPE data from Lorentzian branch-cut data rather than from Euclidean projection onto a discrete radial spectrum.

Remark 64.11 (Hypotheses and scope). Equation (64.30) is not an additional axiom of CFT data. It is a theorem under hypotheses: unitarity or reflection positivity sufficient for the Lorentzian continuation, Euclidean OPE convergence in the required domains, analyticity in the relevant tube domains, and Regge boundedness strong enough to suppress the arcs used in the contour deformation. The spin range begins above the Regge intercept; in many unitary CFT applications this gives $J > 1$, with possible lower-spin terms requiring separate subtractions. Later analytic-bootstrap and light-ray discussions use the inversion formula only at this theorem boundary.[2]

64.5.4 Radial Expansion of a Block

For identical Hermitian scalar primaries ϕ, there is a particularly transparent block expansion in the Hogervorst–Rychkov radial variable ρ. Put the four points in a plane at

$$x_1 = \rho, \qquad x_2 = -\rho, \qquad x_3 = -1, \qquad x_4 = 1, \qquad \rho = r e^{i\alpha}, \quad 0 \le r < 1.$$

With the cross-ratio convention of (63.29), this frame gives

$$z = \frac{4\rho}{(1+\rho)^2}, \qquad \rho = \frac{z}{(1+\sqrt{1-z})^2}. \tag{64.33}$$

The Weyl map to the cylinder places the two inner insertions at radial time $\tau = \log r$ and angular positions separated by π, while the two outer insertions lie at $\tau = 0$. The map (64.33) is chosen so that $|\rho| < 1$ is precisely the radial ordering domain for the $12 \to 34$ OPE channel; the descendant expansion below is the radial-coordinate expansion introduced by Hogervorst and Rychkov.[3]

Theorem 64.12 (Hogervorst–Rychkov radial block convergence)**.** *Assume the radial reconstruction hypotheses of Hypothesis 59.1, finite multiplicity of radial energy eigenspaces, and reflection positivity in the channel under consideration. For each exchanged conformal family in a scalar four-point function, the radial block expansion constructed below converges absolutely, with convergence uniform on every closed subdisk $|\rho| \le q < 1$, in the Euclidean radial configuration where*

$\bar\rho = \rho^*$. Equivalently, after analytic continuation of z with the square-root branch $\operatorname{Re}\sqrt{1-z} > 0$,

$$\rho(z) = \frac{z}{(1+\sqrt{1-z})^2} = \frac{1-\sqrt{1-z}}{1+\sqrt{1-z}}$$

maps the cut z-plane $\mathbb{C} \setminus [1,\infty)$ to the unit disk, and every compact subset of the cut plane maps into $|\rho| \le q$ for some $q < 1$. The radial series therefore gives the analytic continuation of the block throughout that regularity domain.

Proof. The geometric part is elementary. Put $w = \sqrt{1-z}$ with $\operatorname{Re} w > 0$. Then

$$\rho = \frac{1-w}{1+w}.$$

The Cayley transform sends the right half-plane to the unit disk because

$$|\rho|^2 = \frac{|1-w|^2}{|1+w|^2} = 1 - \frac{4\operatorname{Re} w}{|1+w|^2} < 1.$$

Its inverse is $z = 4\rho/(1+\rho)^2$. Hence the unit disk in ρ is not only the old $|z| < 1$ power-series domain in disguise; it is the uniformizing radial disk for the whole z-plane cut along the crossed channel singular locus.

The analytic convergence is the radial Hilbert-space argument in the symmetric cylinder frame. After the standard external kinematic factors have been removed, the contribution of one exchanged conformal family is obtained by inserting the orthogonal projection to that family between the two states created by the two operator pairs. Denote these states by A and B. Let P_E be the spectral projection of the cylinder Hamiltonian D_{rad} onto the finite-dimensional eigenspace of radial energy E inside the chosen family. Rotations of S^{D-1} commute with D_{rad}, so the level expansion is a matrix element of

$$r^{D_{\mathrm{rad}}} U(\alpha), \qquad \rho = r e^{\mathrm{i}\alpha},$$

where $U(\alpha)$ is the unitary rotation relating the angular positions of the two pairs. For $r \le q < 1$, Cauchy–Schwarz gives

$$\sum_E r^E \,|\langle A, P_E U(\alpha) B\rangle| \le \left(\sum_E q^E \|P_E A\|^2\right)^{1/2} \left(\sum_E q^E \|P_E B\|^2\right)^{1/2}.$$

The two sums on the right are

$$\|q^{D_{\mathrm{rad}}/2} A\|^2, \qquad \|q^{D_{\mathrm{rad}}/2} B\|^2.$$

By reflection positivity these norms are Euclidean correlation functions in which the two operator pairs are separated by an annulus of radial modulus q. The radial reconstruction hypothesis asserts exactly that such separated Euclidean configurations define finite Hilbert-space vectors. Hence the displayed bound is finite and independent of the partial-sum cutoff and of α. This proves absolute convergence uniformly for $r \le q$.

Finite multiplicity makes each energy-level contribution a finite matrix element in the corresponding space of spherical harmonics; for scalar external operators it is a finite linear combination of

Gegenbauer polynomials in the angular variable. The same majorant therefore controls every compact subdisk $|\rho| \le q$, and the Weierstrass test gives local uniform convergence of the radial series. The identity with the conformal block follows on the real radial domain from the complete-set construction; the locally uniform limit is analytic in the radial variable, so the identity theorem continues the equality to the ρ-disk and, through the inverse map $z = 4\rho/(1+\rho)^2$, to the cut z-plane. $\square$

At the crossing-symmetric Euclidean point $z = \bar{z} = 1/2$,

$$\rho(1/2) = \frac{1-\sqrt{1/2}}{1+\sqrt{1/2}} = 3 - 2\sqrt{2} \approx 0.1716. \tag{64.34}$$

This small value, and for identical external scalars the additional even-level selection discussed below, is the convergence mechanism behind efficient radial-block evaluation near the bootstrap crossing point.

Figure 64.3 shows the ρ-coordinate cylinder frame used for radial-block convergence, including the small value $\rho(1/2) = 3 - 2\sqrt{2}$ at the crossing-symmetric Euclidean point.

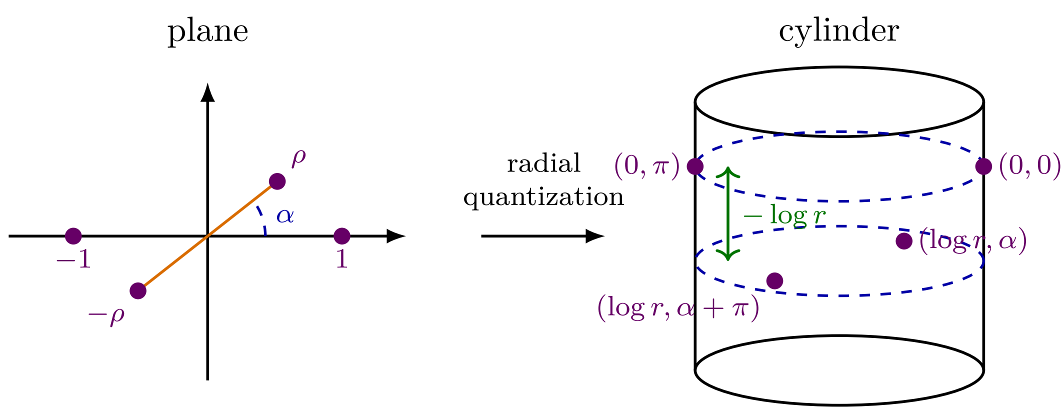

Figure 64.3: The radial variable $\rho = r\mathrm{e}^{\mathrm{i}\alpha}$ puts the $12 \to 34$ OPE channel into a cylinder frame. Inserting a complete set of cylinder energy eigenstates gives a convergent expansion in powers of r.

Assume ϕ is normalized by $\langle\langle\phi|\phi\rangle\rangle = 1$. In the cylinder frame, inserting a complete basis of states gives

$$\begin{aligned} 2^{-4\Delta_\phi}\mathcal{G}(u,v) &= \langle\Omega|\widetilde{\phi}(0,0)\widetilde{\phi}(0,\pi)\widetilde{\phi}(\log r,\alpha)\widetilde{\phi}(\log r,\alpha+\pi)|\Omega\rangle \\ &= \sum_n r^{E_n}\langle\Omega|\widetilde{\phi}(0,0)\widetilde{\phi}(0,\pi)|n\rangle\langle n|\widetilde{\phi}(0,\alpha)\widetilde{\phi}(0,\alpha+\pi)|\Omega\rangle. \end{aligned} \tag{64.35}$$

For a primary Φ_i of spin s_i and dimension Δ_i, its level-n descendants have energy $\Delta_i + n$. If $a = (\beta; N_1, \ldots, N_D)$, with $\sum_\mu N_\mu = n$, labels a raw descendant

$$|\Phi_i, a\rangle = \prod_{\mu=1}^{D} \widehat{P}_\mu^{N_\mu}|\Phi_i,\beta\rangle,$$

let

$$G^{\mathrm{raw}}_{ab} = \langle \Phi_i, a \,|\, \Phi_i, b\rangle$$

be the level-n Gram form. This raw Gram form is finite-dimensional at fixed n, but it can be singular. Its null subspace is

$$\mathcal{N}_{i,n} = \{v \in W_{i,n} : \langle v|w\rangle = 0 \text{ for every } w \in W_{i,n}\},$$

where $W_{i,n}$ is the raw level-n descendant space. Reflection positivity implies that every $v \in \mathcal{N}_{i,n}$ has zero matrix element against every physical state, by the Cauchy–Schwarz inequality. Hence null descendants are first quotiented:

$$Q_{i,n} = W_{i,n}/\mathcal{N}_{i,n}.$$

Choose any basis $\{|e^{(n)}_A\rangle\}_A$ of $Q_{i,n}$, represented by raw descendants, and define the nonsingular quotient Gram matrix

$$M^{(n)}_{AB} = \langle e^{(n)}_A|e^{(n)}_B\rangle.$$

The level-n projector onto the exchanged conformal family is

$$\Pi_{i,n} = \sum_{A,B} |e^{(n)}_A\rangle \left(M^{(n)}\right)^{-1}_{AB} \langle e^{(n)}_B|. \tag{64.36}$$

This expression is independent of the chosen quotient basis: under $|e_A\rangle \mapsto S_A{}^B|e_B\rangle$, the Gram matrix and its inverse transform contragrediently. The complete-set term at level n is therefore

$$r^{\Delta_i+n} \sum_{A,B} \langle\Omega|\widetilde{\phi}(0,0)\widetilde{\phi}(0,\pi)|e^{(n)}_A\rangle \left(M^{(n)}\right)^{-1}_{AB} \langle e^{(n)}_B|\widetilde{\phi}(0,\alpha)\widetilde{\phi}(0,\alpha+\pi)|\Omega\rangle. \tag{64.37}$$

The block is obtained by applying (64.37) to each finite level and then summing over levels. Thus no inverse of an infinite descendant Gram matrix is being assumed; the inverse is taken after quotienting null states at each energy level. Conservation laws and other shortening conditions enter exactly through the null subspaces $\mathcal{N}_{i,n}$. Consequently a block has a radial expansion

$$2^{-4\Delta_\phi} G_{\Delta_i,s_i}(u,v) = \sum_{n=0}^{\infty} A_{\Delta_i,s_i,n}(\alpha)\, r^{\Delta_i+n}, \tag{64.38}$$

where each coefficient is fixed by conformal representation theory.

The leading coefficient is especially simple. At level zero the only angular dependence is the contraction of two symmetric traceless spin-s tensors made from the two unit vectors separated by angle α. Hence, with a standard normalization of the block,

$$G_{\Delta,s}(u,v) = r^{\Delta} C^{(D/2-1)}_s(\cos\alpha) + O(r^{\Delta+1}), \tag{64.39}$$

where $C^{(\lambda)}_s$ is the standard Gegenbauer polynomial. Thus $C^{(1/2)}_s(\cos\alpha) = P_s(\cos\alpha)$ in $D = 3$, while

$$C^{(1)}_s(\cos\alpha) = \frac{\sin((s+1)\alpha)}{\sin\alpha}$$

in $D = 4$. The $D = 2$ angular functions are the separate limiting harmonic $\cos(s\alpha)$, since the Gegenbauer parameter $\lambda = D/2 - 1$ vanishes.

64.6 Reflection Positivity and OPE Coefficients

Reflection positivity constrains the numerical OPE data. Choose Hermitian scalar primaries with two-point normalization

$$\langle \mathcal{O}_A(x)\mathcal{O}_B(0)\rangle = \frac{\delta_{AB}}{|x|^{2\Delta_A}}.$$

With this normalization, phases of nondegenerate Hermitian primaries can be chosen so that three-point coefficients of Hermitian scalar operators are real. If ϕ is a Hermitian scalar primary, the contribution of a primary family $\mathcal{O}$ to the $\phi\phi\phi\phi$ four-point function has coefficient

$$\lambda^2_{\phi\phi\mathcal{O}} \geq 0$$

in the channel where the first pair of operators is radially inside the second pair. This nonnegative number is the squared norm of the projection of the state $\phi(x)\phi(0)\Omega$ onto the conformal multiplet of $\mathcal{O}$.

When several operators with the same quantum numbers mix, the statement is matrix-valued. Let P_Δ be the spectral projection onto a finite degenerate subspace of fixed spin and scaling dimension. For any coefficients α_i,

$$\left\| P_\Delta \sum_i \alpha_i \, \mathcal{O}_i(x_i)\Omega \right\|^2 \geq 0.$$

The corresponding OPE coefficients form a positive semidefinite matrix in that degenerate subspace. Positivity of OPE data is therefore a direct Hilbert-space consequence of radial quantization, not a separate dynamical assumption.

64.7 Associativity

Consider a Euclidean correlation function with three operators inside a sphere that separates them from all other insertions. If the insertion points admit nested separating spheres, there are two ways to apply the OPE:

$$(\mathcal{O}_1\mathcal{O}_2)\mathcal{O}_3, \qquad \mathcal{O}_1(\mathcal{O}_2\mathcal{O}_3).$$

Let S_{out} be the outer separating sphere. The product of the three separated insertions defines a vector in the radial Hilbert space on S_{out}, not a local operator. The two nested OPE procedures are two ways of inserting complete spectral resolutions of the same vector. On a common nested radial domain the two partial sums converge in Hilbert norm to that vector, hence have the same matrix elements against exterior states. Away from the common domain, the statement becomes an analytic-continuation statement: each nested expansion defines a holomorphic function in its own channel domain, and both are restrictions of the same separated-point correlation function on the connected component of complexified configuration space reached without crossing coincident-point or light-cone singular hypersurfaces.

For identical scalar primaries ϕ of dimension Δ_ϕ, write the four-point function in the form

$$\langle \phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\rangle = \frac{\mathcal{G}(u,v)}{|x_{12}|^{2\Delta_\phi}|x_{34}|^{2\Delta_\phi}},$$

where $x_{ij} = x_i - x_j$ and the conformal cross-ratios are

$$u = \frac{x_{12}^2 x_{34}^2}{x_{13}^2 x_{24}^2}, \qquad v = \frac{x_{14}^2 x_{23}^2}{x_{13}^2 x_{24}^2}.$$

Introduce $z, \bar{z}$ by $u = z\bar{z}$ and $v = (1-z)(1-\bar{z})$. The $12 \to 34$ channel is controlled by

$$\rho_s = \frac{z}{(1+\sqrt{1-z})^2}, \qquad \bar{\rho}_s = \frac{\bar{z}}{(1+\sqrt{1-\bar{z}})^2},$$

and its Euclidean radial block expansion converges on compact subsets of

$$\mathcal{D}_s = \{(z, \bar{z}) : |\rho_s| < 1,\ |\bar{\rho}_s| < 1\}. \tag{64.40}$$

The $14 \to 23$ channel uses the crossed variables

$$\rho_t = \frac{1-z}{(1+\sqrt{z})^2}, \qquad \bar{\rho}_t = \frac{1-\bar{z}}{(1+\sqrt{\bar{z}})^2},$$

and converges on compact subsets of

$$\mathcal{D}_t = \{(z, \bar{z}) : |\rho_t| < 1,\ |\bar{\rho}_t| < 1\}. \tag{64.41}$$

These domains are channel domains, not identical power-series neighborhoods: $\mathcal{D}_s$ contains the $u \to 0$ OPE boundary, while $\mathcal{D}_t$ contains the $v \to 0$ OPE boundary. Their Euclidean intersection is nonempty; for example $0 < z = \bar{z} < 1$ lies in both domains. On that intersection the two convergent Hilbert-space expansions compute the same four-point function. The identity theorem then identifies their holomorphic continuations on every connected component where both continuations are defined.

The crossing equation itself follows from the permutation symmetry of the identical Euclidean scalar correlator. Exchanging x_2 and x_4 sends (u, v) to (v, u). The same separated-point function may therefore be written as

$$\frac{\mathcal{G}(u,v)}{|x_{12}|^{2\Delta_\phi} |x_{34}|^{2\Delta_\phi}} = \frac{\mathcal{G}(v,u)}{|x_{14}|^{2\Delta_\phi} |x_{23}|^{2\Delta_\phi}}.$$

Since

$$\frac{u}{v} = \frac{x_{12}^2 x_{34}^2}{x_{14}^2 x_{23}^2},$$

this equality is equivalent to

$$v^{\Delta_\phi} \mathcal{G}(u,v) = u^{\Delta_\phi} \mathcal{G}(v,u). \tag{64.42}$$

If ϕ is Hermitian and the exchanged primaries are orthonormal, the $12 \to 34$ expansion takes the form

$$\mathcal{G}(u,v) = 1 + \sum_{\mathcal{O} \neq \mathbf{1}} \lambda_{\phi\phi\mathcal{O}}^2 G_{\Delta_\mathcal{O}, s_\mathcal{O}}(u,v), \qquad \lambda_{\phi\phi\mathcal{O}}^2 \geq 0. \tag{64.43}$$

The identity block gives the constant 1. The $14 \to 23$ expansion gives the same formula with $(u, v) \mapsto (v, u)$, valid in the channel domain $\mathcal{D}_t$. Equation (64.42) is therefore the equality of two OPE-defined holomorphic functions after both have been identified with the analytic continuation of one Euclidean separated-point correlator. It is not obtained by comparing two unrelated power series at their distinct expansion corners.

64.8 Worked Example: Generalized-Free Scalar Crossing

The preceding discussion becomes completely concrete for a scalar generalized-free datum. Assume $D > 2$ and $\Delta_\phi \geq (D-2)/2$, or $D = 2$ and $\Delta_\phi \geq 0$ for a spin-zero global conformal scalar. Normalize

$$\langle \phi(x)\phi(y)\rangle_{\mathrm{GFF}} = |x-y|^{-2\Delta_\phi}.$$

The separated-point $2m$-point functions are defined by Wick pairings,

$$\langle \phi(x_1)\cdots\phi(x_{2m})\rangle_{\mathrm{GFF}} = \sum_{\pi\in\mathrm{Pair}(2m)} \prod_{\{i,j\}\in\pi} |x_i - x_j|^{-2\Delta_\phi}, \qquad \langle \phi(x_1)\cdots\phi(x_{2m+1})\rangle_{\mathrm{GFF}} = 0. \tag{64.44}$$

Here $\mathrm{Pair}(2m)$ denotes the set of partitions of $\{1,\ldots,2m\}$ into unordered two-element subsets. In the special case $D > 2$ and $\Delta_\phi = (D-2)/2$, the quotient by the null descendant $\partial^2\phi$ gives the ordinary massless free scalar CFT. For larger Δ_ϕ the same formula defines a generalized-free scalar sector. The statements below use the scalar module generated by ϕ, the Wick pairing rule, and radial reflection positivity.

In radial quantization, $\phi(0)|\Omega\rangle$ generates the scalar lowest-weight conformal module V_{Δ_ϕ}, quotienting null vectors when the unitarity bound is saturated. Equation (64.44) makes the m-particle Gram matrix the permanent Gram matrix on $\mathrm{Sym}^m V_{\Delta_\phi}$, meaning that its entries are sums over pairings with no sign character. Thus the reconstructed radial Hilbert space of this sector is the symmetric Fock space over V_{Δ_ϕ}, before Hilbert completion and after the same null-vector quotient. This finite Gram-matrix statement is the reason the OPE below has nonnegative squared coefficients.

For four points Wick factorization gives the three pairings

$$\begin{aligned}\langle \phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)\rangle_{\mathrm{GFF}} = \frac{1}{|x_{12}|^{2\Delta_\phi}|x_{34}|^{2\Delta_\phi}} + \frac{1}{|x_{13}|^{2\Delta_\phi}|x_{24}|^{2\Delta_\phi}} \\ + \frac{1}{|x_{14}|^{2\Delta_\phi}|x_{23}|^{2\Delta_\phi}}.\end{aligned} \tag{64.45}$$

With the four-point prefactor and cross-ratios used in (64.42), the reduced correlator is therefore
