Volume Dependency Guide

This monograph is organized by logical dependency rather than by historical order or course sequence. A topic first appears where its primitive objects are needed, but full development is placed where the required mathematical machinery is available. The list below is a reader-facing map for such deferrals.

Scattering before perturbative amplitudes
: Particles, Haag–Ruelle wave operators, LSZ, and analytic scattering theory are developed in Volume II. Perturbative Feynman rules for S-matrix elements are to be read only after that nonperturbative construction.

Gauge theory and effective actions
: Gauge-fixed perturbation theory, BRST, BV, lattice gauge regulators, anomalies, QCD, jets, energy correlators, and the hybrid Standard Model framework are developed in Volume IV. Wilsonian or 1PI claims for gauge theories in Volume III are therefore conditional on either finite-cutoff BV data or a lattice gauge-theory construction.

Conformal fixed points
: The core CFT volume is Volume V. Volume III discusses RG fixed points and critical phenomena only to the extent needed for renormalization and scaling limits. Representation theory, radial quantization, OPE convergence, crossing, conformal blocks, and light-ray observables belong to Volume V.

Two-dimensional exact QFT
: Factorized scattering, Yang–Baxter consistency, form factors, thermodynamic Bethe ansatz, exact finite-volume data, sine–Gordon, Gross–Neveu, sigma-model families, and bridges to nonintegrable two-dimensional theories are developed in Volume VI.

Supersymmetry
: Supersymmetry algebras, particle versus field multiplets, superspace, supersymmetric gauge theories, holomorphy, Wilsonian scheme questions, Seiberg–Witten theory, localization caveats, and supersymmetric examples in various dimensions are developed in Volume VII.

Topological and cohomological theories
: Metric independence, bordism functoriality, extended TQFT, BF theory, Chern–Simons theory, cohomological field theory, topological sigma models, twists of supersymmetric theories, and Donaldson–Seiberg–Witten comparison problems are developed in Volume VIII.

Global structure and generalized symmetry
: Global forms of gauge groups, higher-form symmetries, line and surface operators, con-

finement diagnostics, discrete theta terms, anomaly inflow, defects, categorical symmetry, noninvertible defects, gauging, and SymTFT viewpoints are developed in Volume IX.

Thermal and hydrodynamic QFT
KMS states, finite-temperature path integrals, Schwinger–Keldysh theory, spectral functions, Kubo formulae, hydrodynamic constitutive relations, thermal gauge theory, kinetic theory, anomalous transport, nonequilibrium states, and long-time tails are developed in Volume X.

Constructive, lattice, and numerical routes
Constructive scalar models, lattice reflection positivity, continuum scaling windows, Wilson lattice gauge theory, Monte Carlo, sign problems, rigorous RG, lattice-to-continuum local QFT, stochastic quantization, Hamiltonian truncation, DLCQ, and lattice fermion/chiral-symmetry questions are developed in Volume XI.

Curved backgrounds
Locally covariant QFT, Hadamard states, point-splitting stress tensors, trace anomalies, Unruh and Hawking effects, index-theoretic anomalies, eta-invariants, cosmological spacetimes, microlocal spectrum conditions, perturbative algebraic QFT on curved backgrounds, and semiclassical backreaction are developed in Volume XII.

When a chapter uses a result from a later volume, the local statement should identify the object being imported and its theorem status. This guide only locates the development; it does not prove a claim by itself.

Source Assembly Map

The source directory names still contain traces of earlier drafting stages. They are therefore not authoritative indicators of the printed order. The printed parts are assembled by the following files, in the order shown in `main.tex`.

Part I	`volumes/volume_i/volume_i_current.tex`
Part II	`volumes/volume_ii/volume_ii_current.tex`
Part III	`volumes/volume_iii/volume_iii_current.tex`
Part IV	`volumes/volume_iv/volume_iv_current.tex`
Part V	`volumes/volume_v/volume_v_current.tex`
Part VI	`volumes/volume_vi/volume_vi_current.tex`
Part VII	`volumes/volume_vii/volume_vii_current.tex`
Part VIII	`volumes/volume_viii/volume_viii_current.tex`
Part IX	`volumes/volume_ix/volume_ix_current.tex`
Part X	`volumes/volume_x/volume_x_current.tex`
Part XI	`volumes/volume_xi/volume_xi_current.tex`
Part XII	`volumes/volume_xii/volume_xii_current.tex`

For chapters not listed below, the chapter source file lies in the same source-volume directory as the printed part. The table records every current exception. A row marked “section input” means that the source file is inserted into the preceding printed chapter and does not increment the chapter counter.

Part I

Foundations of Local Quantum Field Theory

Chapter 1

Starting Data for Local Quantum Field Theory

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

1.1 Spacetime And Operator Conventions

Throughout the opening volume, D denotes the spacetime dimension. The symbol $\mathbb{M}^D$ denotes D-dimensional Minkowski affine space. After a choice of inertial coordinates, $\mathbb{M}^D$ is identified with $\mathbb{R}^D$. The metric tensor has components

$$\eta_{\mu\nu} = \mathrm{diag}(-1, 1, \ldots, 1),$$

and units are chosen so that $\hbar = c = 1$. In the quantum-mechanical path-integral derivations $\hbar$ is displayed until the semiclassical weighting and Wick rotation have been derived; after that point $\hbar = 1$ is restored unless a dimensional check explicitly reintroduces it. The vacuum vector is denoted by Ω; the same printed letter may occur with subscripts for reconstructed cyclic vectors, but unsubscripted Ω always denotes the vacuum of the theory under discussion. A vector $x \in \mathbb{M}^D$ is spacelike when

$$x^2 := \eta_{\mu\nu} x^\mu x^\nu > 0.$$

A test function is a smooth compactly supported complex-valued function on $\mathbb{M}^D$, an element of $C_c^\infty(\mathbb{M}^D)$, unless another test-function space is explicitly declared. A pointlike quantum field

$\widehat{\Phi}_A(x)$ is an operator-valued distribution: its primary operator expression is the smeared field

$$\widehat{\Phi}_A(f) = \int_{\mathbb{M}^D} \mathrm{d}^D x\, f(x)\widehat{\Phi}_A(x), \qquad f \in C_c^\infty(\mathbb{M}^D).$$

The integral sign is distributional notation for evaluating the field on the test function f. When $\widehat{\Phi}_A(f)$ is unbounded, its common dense domain is part of the field framework being used. The symbol $\mathcal{B}(\mathcal{H})$ denotes the algebra of bounded linear operators on a Hilbert space $\mathcal{H}$, and $\mathcal{U}(\mathcal{H})$ denotes its unitary group. The label A denotes a component in a finite-dimensional representation space for Lorentz and internal indices, or a composite-operator label, as specified in the chapter where the field is introduced.

This notation distinguishes mathematical object classes. In Hilbert-space formulas a hat on a field symbol denotes an operator-valued distribution: $\widehat{\phi}$ for a scalar field and $\widehat{\Phi}_A$ for a multiplet. Unhatted fields such as ϕ, φ, or Φ_E denote classical variables, path-integral variables, or Euclidean Schwinger/random fields unless a chapter explicitly declares a different use. Fourier transforms of such variables are written with a tilde, for example $\widetilde{\phi}(k)$.

The test-function space is part of the framework data. Locality statements use C_c^∞ because support controls localization in bounded spacetime regions. Spectral, Wightman, and Euclidean reconstruction statements often use the Schwartz space $\mathcal{S}$, because temperedness and Fourier analysis are then built into the topology. A chapter may use either declared nuclear test-function space, provided all field and correlation distributions are continuous for that topology. A tempered field on $\mathcal{S}$ restricts to compactly supported test functions for local statements; a compactly supported-test distribution is treated as tempered only after a stated growth or continuity hypothesis supplies a continuous extension to $\mathcal{S}$.

Euclidean correlation distributions are called Schwinger functions when they are being used as reconstruction data and are then denoted S_n. In path-integral perturbation chapters the notation $G_{E,n}$ denotes the same kind of Euclidean n-point distribution before the OS reconstruction hypotheses have been imposed; G_E without an n-index is reserved for a two-point kernel or its Fourier transform.

The connected proper orthochronous Lorentz group is denoted $SO^+(1, D-1)$, and the connected Poincare group is

$$\mathcal{P}_+^\uparrow = \mathbb{R}^D \rtimes SO^+(1, D-1).$$

Two subsets $\mathcal{O}_1, \mathcal{O}_2 \subset \mathbb{M}^D$ are spacelike separated when $(x-y)^2 > 0$ for every $x \in \mathcal{O}_1$ and $y \in \mathcal{O}_2$.

1.2 Local Continuum Theories And Effective Presentations

The organizing structure of quantum field theory is quantum dynamics together with spacetime localization. The word "localization" has a precise content: observables, or field coordinates for observables, are attached to spacetime regions or test functions; spacetime symmetries move these localized objects covariantly; and observables localized in spacelike separated regions obey the appropriate commutativity law. The exact algebraic, field-theoretic, or Euclidean form of this structure must always be specified.

Two different mathematical statuses will appear throughout the monograph. They share locality, but they are not the same assertion.

Definition 1.1 (Continuum local quantum field theory)**.** A continuum local quantum field theory is a local quantum theory whose declared correlation functions, local algebras, or Hilbert-space operators exist after the ultraviolet regulator has been removed, in a stated topology and within a stated spacetime and state-sector framework. In a Minkowski vacuum presentation this includes Poincare symmetry, a spectrum condition, local observables or local field distributions, and microcausality. The phrase "infinitely many degrees of freedom" will be used in the operational sense that the local data are indexed by infinite-dimensional test-function or region data and are not specified by a finite list of canonical coordinates.

Definition 1.2 (Effective field theory presentation)**.** An effective field theory presentation is a regulated or renormalized local prescription for computing observables in a specified range of length, energy, and external-state scales. Its defining data include the fields or local variables, the symmetries, the regulator or renormalization prescription, the expansion parameters, and the class of observables for which the expansion is claimed. When it is perturbative, it defines an asymptotic expansion of Green functions, and of scattering quantities only after the nonperturbative scattering framework and LSZ interpretation have been supplied.

Power-counting renormalizability is a property of an effective presentation near a chosen fixed point or scaling regime: only finitely many local operators are needed as independent counterterms at a fixed order in the declared expansion. Existence of an ultraviolet continuum theory is a separate question, requiring constructive Wilsonian, lattice, or comparable nonperturbative input. Power-counting nonrenormalizable presentations are also local effective theories when the infinitely many allowed operators are organized by scale and symmetry.

Remark 1.3 (Conformal perturbation as a controlled construction method)*.* A deformation of a conformal field theory is a precise construction problem only after the conformal theory has already been supplied as local QFT data. The input consists of a stress tensor, a Hilbert space or Euclidean reconstruction datum, local operators O_A with specified normalization and contact-term convention, and a regulator or subtraction prescription for insertions of

$$\exp\left(-\sum_A g^A \int \mathrm{d}^D x\, O_A(x)\right).$$

When these data exist and the deformation parameters are controlled, conformal perturbation theory produces a local expansion of deformed correlation functions and beta functions. Its hypotheses are therefore:

1. an already constructed or otherwise supplied fixed point;
2. identified operator insertions, including their coincident-point renormalization;
3. a domain in coupling space where the expansion or nonperturbative deformation is defined;
4. a reconstruction or regulator argument connecting the deformed correlators to local QFT data.

Without these inputs, the phrase "perturb a UV CFT" is only a description of a possible route. Asymptotically free gauge theories, constructive scalar models, lattice scaling limits, stochastic-quantization constructions, and effective presentations of the Standard Model may each possess local QFT content in their own frameworks; none is thereby defined by conformal perturbation theory. This monograph uses CFT perturbations when their operator-algebra and regulator hypotheses are declared, for example in Wilson–Fisher and two-dimensional integrable-flow problems, and does not use them as the definition of quantum field theory.

The opening chapter will use two mathematical statuses: continuum local QFT data after regulator removal, and effective presentations valid in a declared scale window. Definitions 1.1 and 1.2 are the operative definitions; comparison maps among Wightman, OS, local-net, and regulated presentations are registered below only after their hypotheses have been stated.

1.3 Opening Framework

The first construction takes place in a flat-spacetime vacuum sector. The following definition gives the data used in the opening volume.

Definition 1.4 (Vacuum Minkowski local quantum theory)**.** In the opening framework, a vacuum Minkowski local quantum theory consists of:

1. a complex Hilbert space $\mathcal{H}$;
2. a spacetime symmetry convention. Let G_{Lor} be $SO^+(1, D-1)$, or the appropriate double cover when spinor fields are included, and let $\pi : G_{\mathrm{Lor}} \to SO^+(1, D-1)$ be the covering projection. The connected Poincare group used here is
$$\mathcal{P} = \mathbb{R}^D \rtimes G_{\mathrm{Lor}}, \qquad (a, \Lambda)(b, \Gamma) = (a + \pi(\Lambda)b, \Lambda\Gamma).$$
It acts on $\mathbb{M}^D$ from the left by
$$gx = \pi(\Lambda)x + a, \qquad g = (a, \Lambda) \in \mathcal{P},$$
and $g\mathcal{O} := \{gx : x \in \mathcal{O}\}$ for a region $\mathcal{O} \subset \mathbb{M}^D$;
3. a strongly continuous unitary representation
$$U : \mathcal{P} \to \mathcal{U}(\mathcal{H}), \qquad g \mapsto U(g),$$
as a left representation, $U(g_1 g_2) = U(g_1)U(g_2)$, where $\mathcal{U}(\mathcal{H})$ is the unitary group of $\mathcal{H}$;
4. self-adjoint translation generators P^μ, equivalently $P_\mu = \eta_{\mu\nu}P^\nu$, defined by
$$U(a, 1) = \exp(\mathrm{i}a_\mu P^\mu) = \exp(\mathrm{i}a^\mu P_\mu).$$
Thus a positive time translation gives $\exp(-\mathrm{i}a^0 P^0)$, with P^0 the Hamiltonian. Let E_P be the joint projection-valued spectral measure of the contravariant energy-momentum $P = (P^0, \ldots, P^{D-1})$. The spectrum condition is
$$\operatorname{supp} E_P \subset \overline{V}_+ = \{p \in \mathbb{R}^D : p^0 \geq 0,\ \eta_{\mu\nu}p^\mu p^\nu \leq 0\};$$
5. a Poincare-invariant unit vector $\Omega \in \mathcal{H}$,
$$U(g)\Omega = \Omega, \qquad g \in \mathcal{P}.$$
In this pure-vacuum-sector framework, vacuum uniqueness is part of the datum: the zero-momentum spectral projection is one-dimensional,
$$E_P(\{0\})\mathcal{H} = \mathbb{C}\Omega;$$

6. an assignment
$$\mathcal{O} \longmapsto \mathcal{A}(\mathcal{O}) \subset \mathcal{B}(\mathcal{H})$$
from bounded open regions $\mathcal{O} \subset \mathbb{M}^D$ to unital concrete $*$-subalgebras of the bounded operators on $\mathcal{H}$, satisfying covariance, isotony, and locality:
$$U(g)^{-1}\mathcal{A}(\mathcal{O})U(g) = \mathcal{A}(g\mathcal{O}), \qquad g \in \mathcal{P},$$
$$\mathcal{O}_1 \subset \mathcal{O}_2 \quad \Longrightarrow \quad \mathcal{A}(\mathcal{O}_1) \subset \mathcal{A}(\mathcal{O}_2),$$
and
$$[A, B] = 0 \quad \text{for } A \in \mathcal{A}(\mathcal{O}_1),\ B \in \mathcal{A}(\mathcal{O}_2)$$
whenever $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated, with the graded commutator
$$[A, B]_{\mathrm{gr}} = AB - (-1)^{|A||B|}BA$$
used for homogeneous odd operators after a fermion parity grading and the parities $|A|, |B| \in \mathbb{Z}/2\mathbb{Z}$ have been specified;

7. vacuum cyclicity for the bounded local observable content. Let $\mathcal{A}_{\mathrm{loc}}^{\mathrm{alg}}$ denote the unital $*$-algebra generated in $\mathcal{B}(\mathcal{H})$ by $\bigcup_{\mathcal{O}} \mathcal{A}(\mathcal{O})$, where the union is over bounded open regions. Then
$$\overline{\mathcal{A}_{\mathrm{loc}}^{\mathrm{alg}}\Omega}^{\|\cdot\|_{\mathcal{H}}} = \mathcal{H};$$

8. when unbounded field coordinates are part of the presentation, a specified field-domain datum
$$(\mathcal{D}_\Phi, \{\widehat{\Phi}_A\}_{A \in I}).$$
Here I is the field-label set, $\mathcal{D}_\Phi \subset \mathcal{H}$ is a dense linear subspace with $\Omega \in \mathcal{D}_\Phi$, $U(g)\mathcal{D}_\Phi \subset \mathcal{D}_\Phi$ for all $g \in \mathcal{P}$, and each smeared field is a linear operator
$$\widehat{\Phi}_A(f) : \mathcal{D}_\Phi \to \mathcal{D}_\Phi, \qquad f \in \mathcal{T}_A,$$
where $\mathcal{T}_A$ is the declared test-function space for that field component. Finite products of such smeared fields are defined on $\mathcal{D}_\Phi$. If adjoints are used, then $\mathcal{D}_\Phi \subset \mathrm{Dom}(\widehat{\Phi}_A(f)^*)$ and the adjoint fields preserve $\mathcal{D}_\Phi$. For every $\psi, \chi \in \mathcal{D}_\Phi$, the matrix elements of finite smeared products are continuous multilinear functionals of their test functions. Field covariance, field locality, and any relation between $\widehat{\Phi}_A(f)$ with $\operatorname{supp} f \subset \mathcal{O}$ and $\mathcal{A}(\mathcal{O})$ are imposed on this same domain or by a specified affiliation to the chosen local observable algebra.

The uniqueness clause is a spectral assumption on the chosen representation. It identifies the projection onto translation-invariant vectors with the rank-one projection $|\Omega\rangle\langle\Omega|$. Consequently, after subtracting the vacuum expectation value of a scalar local field, the vector $\widehat{\phi}(f)\Omega$ has no residual $p = 0$ component. This is the assumption used in the Källén–Lehmann analysis when the $(\Omega, \cdot)$ projection removes the vacuum atom before the invariant-mass decomposition is formed. If a theory has several infinite-volume vacua or a mixed representation of phases, one must first choose a pure vacuum sector or else keep the additional $p = 0$ spectral summands explicitly; they sit at $\mu^2 = 0$ as zero-momentum atoms, distinct from massless one-particle states whose momenta lie on the nonzero light cone.

The covariance convention has the following infinitesimal form. With $U(a,1) = \exp(\mathrm{i}a^\mu P_\mu) = \exp(\mathrm{i}a_\mu P^\mu)$, a coordinate-labelled scalar field obeys

$$U(a,1)^{-1}\widehat{\phi}(x)U(a,1) = \widehat{\phi}(x+a), \qquad [P_\mu, \widehat{\phi}(x)] = \mathrm{i}\,\partial_\mu \widehat{\phi}(x)$$

as an identity of distributions on a common invariant domain. Equivalently, conjugation by $U(a,1)$ shifts the coordinate label by $-a$. The local-net covariance law above uses the same passive coordinate convention: conjugating an observable by $U(g)^{-1}$, with $g = (a, \Lambda)$, sends its localization region to $g\mathcal{O} = \pi(\Lambda)\mathcal{O} + a$.

Vacuum projection and translation convention. The vacuum-uniqueness clause in Definition 1.4 says $E_P(\{0\})\mathcal{H} = \mathbb{C}\Omega$, with $\|\Omega\| = 1$. Hence the projection onto translation-invariant vectors is $|\Omega\rangle\langle\Omega|$. If a scalar field satisfies

$$U(a,1)^{-1}\widehat{\phi}(x)U(a,1) = \widehat{\phi}(x+a),$$

then differentiating $e^{-\mathrm{i}a^\mu P_\mu}\widehat{\phi}(x)e^{\mathrm{i}a^\mu P_\mu} = \widehat{\phi}(x+a)$ at $a = 0$, as an identity of smeared distributions on the common invariant domain, gives

$$[P_\mu, \widehat{\phi}(x)] = \mathrm{i}\,\partial_\mu \widehat{\phi}(x).$$

In this opening convention $\mathcal{A}(\mathcal{O})$ is a concrete algebra of bounded observables on the chosen Hilbert space and is not assumed to be norm closed or weakly closed unless this is stated. If a C^*-algebra or von Neumann algebra is needed, the relevant closure or bicommutant is included in the datum or constructed explicitly. This convention is sufficient for the first dependency layer: localization, covariance, the spectrum condition, vacuum matrix elements, and comparison with field coordinates.

This framework describes a vacuum representation on flat spacetime. Thermal states, boundary conditions, curved spacetimes, and non-vacuum superselection sectors are introduced by changing the stated data: the state space, spacetime category, covariance group, region assignment, or representation sector. Existing Wightman, Euclidean, algebraic, constructive, perturbative, and factorization frameworks will be introduced as precise frameworks with their own domains, beginning with the Wightman and algebraic formulations.

Open Problem 1.5 (Four-dimensional constructive local QFT). A constructive solution of a four-dimensional local quantum field theory is a construction of the correlation functions, Hilbert space, local fields or observable net, symmetry representation, and positivity structure in a topology strong enough to verify the stated framework. In a Wightman presentation this means tempered vacuum distributions satisfying covariance, the spectrum condition, locality, positivity, and a reconstruction theorem. In an Osterwalder–Schrader presentation it means Euclidean Schwinger distributions with reflection positivity, Euclidean covariance, symmetry, clustering or the declared vacuum-sector condition, and the regularity hypotheses needed for OS reconstruction. In either presentation, an interacting model means that the truncated correlation functions and local operator content are not those of a Gaussian or generalized-free field alone, and that the local stress-tensor, charge, or gauge-invariant observables required in the later physical discussion are part of the constructed data.

Completed constructive examples occupy special regimes: $P(\phi)_2$ models, including ϕ^4_2, and massive ϕ^4_3 give non-Gaussian scalar models after their model-specific Wick ordering and local renormalizations; other superrenormalizable low-dimensional scalar–fermion models are constructed under similarly explicit hypotheses; and two-dimensional Yang–Mills has rigorous gauge-theory constructions through holonomy and heat-kernel measures. Four-dimensional physics presents a different constructive problem. Free and generalized-free Wightman fields are available, but the usual interacting scalar and gauge theories require separate continuum-limit theorems. Standard positive $\lambda\phi^4_D$ scaling-limit families in $D \geq 4$ are constrained by triviality theorems, with the four-dimensional marginal case governed by the Aizenman–Duminil-Copin triviality theorem for the nearest-neighbor Ising/ϕ^4_4 scaling problem. Four-dimensional pure Yang–Mills, QCD, and other asymptotically free gauge theories still require a construction of the continuum gauge-invariant Schwinger functions or Wightman theory with the desired spectral properties. Perturbative renormalizability and asymptotic freedom are mechanisms inside a specified expansion; they are not by themselves constructive existence theorems for the nonperturbative continuum theory.

1.4 Framework Presentations And Comparison Maps

The opening data admit several mathematically precise presentations. Each presentation emphasizes a different class of objects, and each comparison map carries hypotheses.

Definition 1.6 (Wightman field presentation)**.** A Wightman field presentation consists of Hilbert-space data

$$(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_A\}_{A\in I})$$

where I is an index set for fields, $\mathcal{D} \subset \mathcal{H}$ is a dense common invariant domain containing Ω, and each $\widehat{\Phi}_A$ is an operator-valued distribution on a declared invariant test-function space $\mathcal{T}$, with common domain $\mathcal{D}$. In the classical Wightman case $\mathcal{T} = \mathcal{S}(\mathbb{M}^D)$, so the vacuum distributions below are tempered. The domain assumptions are

$$\Omega \in \mathcal{D}, \qquad U(g)\mathcal{D} \subset \mathcal{D} \quad (g \in \mathcal{P}), \qquad \widehat{\Phi}_A(f)\mathcal{D} \subset \mathcal{D} \quad (A \in I,\ f \in \mathcal{T}),$$

and, for every $n \geq 1$,

$$\widehat{\Phi}_{A_1}(f_1) \cdots \widehat{\Phi}_{A_n}(f_n)\mathcal{D} \subset \mathcal{D}, \qquad A_i \in I, \quad f_i \in \mathcal{T}.$$

Matrix elements of finite products are required to be continuous multilinear functionals of the test functions:

$$(f_1, \dots, f_n) \longmapsto \left\langle \psi, \widehat{\Phi}_{A_1}(f_1) \cdots \widehat{\Phi}_{A_n}(f_n)\chi \right\rangle \in \mathbb{C}, \qquad \psi, \chi \in \mathcal{D}.$$

Let $g = (a, \Lambda) \in \mathcal{P}$, $gx = \pi(\Lambda)x + a$, and $f_g(y) = f(g^{-1}y)$. If the fields carry a finite-dimensional Lorentz representation R of G_{Lor}, covariance is the smeared identity

$$U(g)^{-1}\widehat{\Phi}_A(f)U(g) = R(\Lambda)_A{}^B\, \widehat{\Phi}_B(f_g),$$

with summation over repeated component labels. In point-field notation this is

$$U(g)^{-1}\widehat{\Phi}_A(x)U(g) = R(\Lambda)_A{}^B\widehat{\Phi}_B(gx).$$

The representation U satisfies the spectrum condition of Definition 1.4: if E_P is the joint spectral measure of the translation generators, then

$$\operatorname{supp} E_P \subset \overline{V}_+.$$

Locality is imposed after smearing:

$$[\widehat{\Phi}_A(f), \widehat{\Phi}_B(h)]_{\mathrm{gr}} = 0$$

whenever $\operatorname{supp} f$ and $\operatorname{supp} h$ are spacelike separated, with the ordinary commutator in the purely bosonic case.

Its primary correlation data are the vacuum distributions whose distribution kernels are written

$$W_{A_1\cdots A_n}(x_1,\ldots,x_n) = \langle\Omega|\widehat{\Phi}_{A_1}(x_1)\cdots\widehat{\Phi}_{A_n}(x_n)|\Omega\rangle.$$

Equivalently,

$$W_{A_1\cdots A_n}(f_1,\ldots,f_n) = \left\langle\Omega, \widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)\Omega\right\rangle.$$

Translation invariance gives a distribution in difference variables. With

$$\xi_j = x_{j+1} - x_j, \qquad \mathcal{W}_{A_1\cdots A_n}(\xi_1,\ldots,\xi_{n-1}) = W_{A_1\cdots A_n}(0,\xi_1,\xi_1+\xi_2,\ldots,\xi_1+\cdots+\xi_{n-1}),$$

the Wightman spectral condition is the support equation

$$\operatorname{supp}\widehat{\mathcal{W}}_{A_1\cdots A_n} \subset \overline{V}_+^{\,n-1}.$$

Positivity of the hierarchy means the following. For every finite sequence of test tensors in the declared test-function space

$$F = \{F^{(n)}_{A_1\cdots A_n}\}_{0\le n\le N}, \qquad F^{(0)} \in \mathbb{C},$$

define

$$\Psi_F = F^{(0)}\Omega + \sum_{n=1}^{N}\sum_{A_1,\ldots,A_n}\int F^{(n)}_{A_1\cdots A_n}(x_1,\ldots,x_n)\widehat{\Phi}_{A_1}(x_1)\cdots\widehat{\Phi}_{A_n}(x_n)\Omega\,\mathrm{d}^D x_1\cdots\mathrm{d}^D x_n.$$

The condition is $\langle\Psi_F,\Psi_F\rangle \ge 0$, with the inner product evaluated by the distributions W_n:

$$\langle\Psi_F,\Psi_F\rangle \ge 0.$$

Vacuum cyclicity is the density equation

$$\overline{\operatorname{span}\{\widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)\Omega : n\ge 0,\ f_i\in\mathcal{T},\ A_i\in I\}}^{\|\cdot\|_{\mathcal{H}}} = \mathcal{H}.$$

Definition 1.7 (Local-net presentation)**.** A local-net presentation consists of a specified class $\mathcal{K}(\mathbb{M}^D)$ of open spacetime regions, a quasilocal $*$-algebra or C^*-algebra $\mathcal{A}_{\mathrm{qloc}}$, and an assignment

$$\mathcal{O} \longmapsto \mathcal{A}(\mathcal{O}) \subset \mathcal{A}_{\mathrm{qloc}}$$

for $\mathcal{O}\in\mathcal{K}(\mathbb{M}^D)$. The assignment satisfies isotony, locality, covariance under the declared spacetime symmetry group, and any additional structural conditions imposed in the problem under study, such as additivity, Haag duality, or the time-slice property. A state is a normalized positive linear functional $\omega : \mathcal{A}_{\mathrm{qloc}} \to \mathbb{C}$; it gives a Hilbert-space representation by the GNS construction.

Definition 1.8 (Euclidean correlation presentation)**.** Let $E = \mathbb{R}^D$ be Euclidean space and let V be the finite-dimensional complex field-label space, with homogeneous basis labels a and parity $|a| \in \mathbb{Z}/2\mathbb{Z}$ when a grading is present. A Euclidean correlation presentation consists of a test-function space $\mathcal{T}_E$, usually $\mathcal{S}(E)$ in the tempered OS framework, an adjoint antilinear involution $a \mapsto a^\dagger$ on labels, a Euclidean rotation representation R_E on V, and a hierarchy

$$S_n \in \mathcal{T}'_{E,\circ}(E^n; (V^*)^{\otimes n}), \qquad n \geq 0, \qquad S_0 = 1.$$

Here $\mathcal{T}_{E,\circ}(E^n; V^{\otimes n})$ denotes the corresponding $V^{\otimes n}$-valued zero-diagonal test-function space on E^n: test functions vanish with all derivatives on every partial diagonal $x_i = x_j$. The prime denotes its continuous dual, and $S_n(F)$ denotes the distributional pairing. A contact-term extension of S_n from $\mathcal{T}_{E,\circ}$ to the full $\mathcal{T}_E$ is additional renormalization data and is not required for OS reconstruction. The component notation

$$S_{a_1 \cdots a_n}(x_1, \ldots, x_n)$$

is kernel notation for the distributional pairing of S_n with $V^{\otimes n}$-valued test functions. If $g = (b, r) \in \mathbb{R}^D \rtimes O(D)$, $gx = rx + b$, define the action on test tensors by

$$(gF)^{a_1 \cdots a_n}(x_1, \ldots, x_n) = R_E(r)^{a_1}{}_{b_1} \cdots R_E(r)^{a_n}{}_{b_n} \, F^{b_1 \cdots b_n}(g^{-1}x_1, \ldots, g^{-1}x_n).$$

Euclidean covariance is the distributional identity

$$S_n(gF) = S_n(F), \qquad g \in \mathbb{R}^D \rtimes O(D).$$

For a permutation $\sigma \in \mathfrak{S}_n$, graded permutation symmetry is

$$S_{a_{\sigma(1)} \cdots a_{\sigma(n)}}(x_{\sigma(1)}, \ldots, x_{\sigma(n)}) = \epsilon(\sigma; a_1, \ldots, a_n) \, S_{a_1 \cdots a_n}(x_1, \ldots, x_n),$$

as an equality of distributions, where

$$\epsilon(\sigma; a_1, \ldots, a_n) = \prod_{\substack{i<j \\ \sigma(i)>\sigma(j)}} (-1)^{|a_i||a_j|}.$$

In the ungraded case all parities are zero. Hermiticity is

$$\overline{S_{a_1 \cdots a_n}(x_1, \ldots, x_n)} = S_{a_n^\dagger \cdots a_1^\dagger}(x_n, \ldots, x_1),$$

again as a distributional statement.

Choose Euclidean coordinates $x = (\tau, \mathbf{x})$ and let

$$\theta(\tau, \mathbf{x}) = (-\tau, \mathbf{x})$$

be time reflection. Set $E_+ = \{(\tau, \mathbf{x}) \in E : \tau > 0\}$. Reflection positivity is the requirement that for every finite sequence of test tensors

$$F = \{F^{(n)}_{a_1 \cdots a_n}\}_{0 \leq n \leq N}, \qquad F^{(n)} \in \mathcal{T}_E(E^n; V^{\otimes n}), \qquad \operatorname{supp} F^{(n)} \subset E^n_+,$$

the quadratic form

$$\langle F,F\rangle_{\mathrm{OS}} = \sum_{m,n=0}^{N} \sum_{\substack{a_1,\ldots,a_m\\ b_1,\ldots,b_n}} \int \overline{F^{(m)}_{a_1\cdots a_m}(x_1,\ldots,x_m)} F^{(n)}_{b_1\cdots b_n}(y_1,\ldots,y_n)$$
$$\times S_{a_m^\dagger\cdots a_1^\dagger b_1\cdots b_n}(\theta x_m,\ldots,\theta x_1,y_1,\ldots,y_n) \prod_{i=1}^{m} \mathrm{d}^D x_i \prod_{j=1}^{n} \mathrm{d}^D y_j$$

is nonnegative. The convention $S_0 = 1$ is used in the terms with $m = 0$ or $n = 0$.

The regularity and growth condition is also part of the data. The corrected OS-II reconstruction theorem requires more than ordinary temperedness at each fixed n: one needs uniform control on the growth of the distributional order with n. In a full-Schwartz presentation this includes constants $A, B, \gamma > 0$ and a seminorm order $N(n)$ growing at most linearly in n, such that every $F \in \mathcal{S}_\circ(E^n; V^{\otimes n})$ obeys a Schwartz-seminorm bound, where $\mathcal{S}_\circ$ denotes the Schwartz subspace of functions flat on the partial diagonals, using any fixed norm on the finite-dimensional space $V^{\otimes n}$:

$$|S_n(F)| \le A\,B^n (n!)^\gamma \sum_{|\alpha|,|\beta|\le N(n)} \sup_{X\in E^n} \left| X^\beta \partial^\alpha F(X) \right|.$$

If a different nuclear test-function space is chosen, the corresponding continuity seminorms and the growth assumptions needed for OS reconstruction must be stated with the presentation.

Under the full Osterwalder–Schrader hypotheses, quotienting by the null space of this form and completing reconstructs the Lorentzian Hilbert space; analytic continuation then gives Wightman boundary values.

The comparison from fields to a local net is obtained, when the needed operator-domain and affiliation statements hold, by assigning to a region $\mathcal{O}$ the von Neumann algebra generated by bounded functions, resolvents, or other bounded functional-calculus representatives of smeared fields $\widehat{\Phi}_A(f)$ with $\operatorname{supp} f \subset \mathcal{O}$. The comparison from a local net to a Hilbert-space theory is the GNS construction applied to a state, followed by the representation of the local algebras on the GNS Hilbert space. Recovering point-field coordinates from a represented net requires additional phase-space, regularity, or affiliated-field hypotheses; it is not a formal consequence of the net axioms alone. The comparison from Euclidean correlations to Lorentzian fields is the corrected OS-II reconstruction theorem followed by analytic continuation to Wightman boundary values. Conversely, Wightman fields give Euclidean Schwinger functions by tube analyticity and restriction to noncoincident imaginary-time configurations.

The theorem-level comparison register is the actual content of the comparison. Each entry names the source presentation, the target presentation, and the hypotheses that are not automatic from notation alone:

- **Wightman hierarchy to Wightman fields.** Theorem 2.4 reconstructs the cyclic field presentation from a positive Wightman hierarchy with covariance, spectrum, Hermiticity, locality, and tempered continuity.
- **Wightman fields to AQFT.** Theorem 3.10 constructs a represented local net once the relevant smeared Hermitian fields have essentially self-adjoint closures and strong locality of their spectral projections. The comparison is an observable-net identification only after the

additional datum of Definition 3.13 is supplied: the generated coordinate net must be additive in bounded functional calculus, and it must equal the represented observable net, either directly or through a specified fixed-point or gauge-invariant subnet operation.

- **AQFT to Wightman fields.** Remark 3.16 records the converse comparison: a represented positive-energy local net gives Wightman field coordinates only after affiliated operator-valued tempered distributions on a common invariant domain have been supplied.
- **OS data to Wightman fields.** Theorem 12.16 reconstructs a Lorentzian presentation from OS-admissible Euclidean data. Its analytic input is the OS-II positive-time semigroup and linear-growth package, not reflection positivity alone.
- **Path integral to Wightman fields.** The path-integral-to-Wightman paragraph after OS reconstruction records the composition: a regulated path integral determines a Wightman presentation only after its continuum Schwinger limits exist and satisfy the OS hypotheses.
- **Wightman fields to OS data.** Tube analyticity from the Wightman spectrum condition gives Euclidean Schwinger functions by restriction to noncoincident imaginary-time configurations; this is the reverse Wick-rotation direction discussed in Chapter 2.

These definitions make the foundational objects explicit. A later calculation may use fields, path integrals, local algebras, or Euclidean correlators; the framework in which the calculation lives and the comparison maps needed to interpret it must be stated.

1.5 Status of Axiom Systems and Constructive Examples

The presentations above have a precise logical role. They are theorem-bearing frameworks for local quantum field theory: each one specifies objects, topologies, positivity conditions, covariance conditions, and reconstruction or comparison theorems. A result proved in one framework has the hypotheses of that framework as part of its statement. Thus a theorem proved for Wightman fields is a theorem for theories admitting the declared Wightman presentation; a theorem proved for a represented local net is a theorem under the local-net hypotheses and any additional phase-space or modular hypotheses used in the proof; and a theorem proved from OS data is a theorem after the OS-II regularity and analytic-continuation input has been verified.

The physical expectation is broader and more constructive. A Poincare-invariant ultraviolet-complete local QFT in a vacuum sector is expected, when it has point-field coordinates of the appropriate regularity, to produce Wightman distributions; when it has Euclidean reflection-positive correlators with the required growth, to produce OS data; and when it is organized by bounded localized observables, to produce a Haag–Kastler type net. These are expected properties of a completed local quantum theory in the corresponding sector. Comparisons among the frameworks require explicit hypotheses: charged superselection sectors, gauge-invariant observable algebras, fermionic field variables in path integrals, curved-background formulations, and functorial or extended geometric structures may be primary in one presentation and derived or hidden in another.

The path-integral aspiration can be stated as a gluing problem. One seeks an assignment of amplitudes and correlation distributions to a declared category of backgrounds with sources,

$$(M, g, \text{bundles}, J, \dots) \longmapsto Z[M, g, \text{bundles}, J, \dots],$$

compatible with cutting and gluing, locality of source variation, reflection or unitarity, and covariance under background isomorphisms. The Kontsevich–Segal formulation makes this aspiration mathematically sharper: it asks for a functorial or multilinear assignment on admissible complex Riemannian bordisms, with Lorentzian metrics appearing as boundary values and reflection positivity/unitarity represented by structure on the target spaces. It is the most promising current framework for the path-integral and OPE aspects of the subject, precisely because sewing is a primitive operation. Chapter 13 develops the axioms, the finite-dimensional allowability condition, and the current construction status. In the opening construction we still use Wightman, OS, and local-net frameworks because they give the spectral theory, Källén–Lehmann representation, Haag–Ruelle scattering theory, LSZ comparison, and analytic continuation theorems in the form needed for the later chapters.

Constructive results calibrate these frameworks. Table 136.1 in Chapter 136 records representative examples and open problems. The completed non-Gaussian constructions are concentrated in special low-dimensional regimes, such as $P(\phi)_2$, massive ϕ^4_3, selected two-dimensional scalar–fermion models, massive Gross–Neveu type models, and two-dimensional Yang–Mills in holonomy or heat-kernel formulations. The reflection-positive Ising/$\lambda\phi^4$ route in $D \geq 4$ is constrained by triviality theorems, with the four-dimensional marginal case requiring the precise qualification stated in Table 136.1. A four-dimensional UV-complete interacting QFT agreeing with formal ϕ^4_4 perturbation theory to all orders is not ruled out by the positive-lattice triviality theorem as a purely logical matter; it is a distinct open construction problem. Four-dimensional Yang–Mills with mass gap remains the central constructive gauge-theory problem.

Open Problem 1.9 (Axiomatic comparison and physical examples). Give sharp hypotheses, and prove the resulting comparison theorems, relating the principal nonperturbative frameworks for local QFT:

$$\begin{array}{cc} \text{Wightman fields,} & \text{Osterwalder–Schrader data,} \\ \text{Haag–Kastler local nets,} & \text{functorial/path-integral data.} \end{array}$$

Some directions are established under substantial hypotheses: OS-II reconstruction gives Wightman boundary values from OS-admissible Schwinger data; Wightman fields give local nets after the relevant self-adjointness, bounded-functional-calculus, and strong-locality conditions are imposed; and positive states on local algebras give Hilbert-space representations by GNS. The converse directions, the precise functorial completion, and the verification of all required hypotheses in physically central interacting four-dimensional theories remain open. The problem has two parts: prove the comparison maps with minimal usable assumptions, and construct substantial examples for which the assumptions are actually verified.

1.6 Analytic Status of the Basic Objects

The opening framework deliberately separates several levels of mathematical status. This separation is part of the subject, because the same formula may denote different objects in different constructions.

Definition 1.10 (Regulated theory)**.** A regulated theory is a finite-dimensional or cutoff-defined construction with a specified state space or configuration space, algebra of variables, covariance or symmetry action, and expectation functional $\langle\cdot\rangle_\Lambda$, where Λ denotes the regulator data. Examples include a finite lattice, a finite spatial volume with momentum cutoff, or a finite-dimensional time-sliced integral. All integrals and operator products in a regulated theory are ordinary objects in the regulator-dependent category.

Definition 1.11 (Continuum correlation theory)**.** A continuum correlation theory is a hierarchy of distributions, Schwinger functions, Wightman functions, or time-ordered distributions obtained as a limit of regulated theories or specified directly by axioms. The topology of convergence is part of the datum: distributional convergence of correlators, convergence of moments, weak convergence of measures, or another declared topology.

Definition 1.12 (Contact terms and local source-coordinate systems)**.** Let M be the spacetime manifold and let

$$\Delta_n = \bigcup_{1\le i<j\le n} \{(x_1,\dots,x_n)\in M^n \mid x_i = x_j\}$$

be the collision locus. A separated-point n-point distribution is a distribution $T^\circ \in \mathcal{D}'(M^n\setminus\Delta_n)$, with values in the appropriate tensor product of operator-label bundles. A contact-term extension of T° is a distribution $T\in\mathcal{D}'(M^n)$ whose restriction to $M^n\setminus\Delta_n$ equals T°. A contact term is a distribution supported on Δ_n, or on one of its partial collision diagonals. Locally near a smooth partial diagonal, with coordinates z on the diagonal and normal coordinates y, such a distribution has finite normal order,

$$C = \sum_{|\alpha|\le N} \partial_y^\alpha \delta(y)\, c_\alpha(z), \qquad c_\alpha \in \mathcal{D}'(\Delta),$$

after choosing local coordinates and a density convention. Thus contact terms are ordinary distributional data on collision strata.

A local source-coordinate system consists of source fields $J^A \in C_c^\infty(M, E_A)$, a source functional $W[J]$ in the chosen category, and distributional source derivatives

$$G_{A_1\cdots A_n}(x_1,\dots,x_n) = \left.\frac{\delta^n W[J]}{\delta J^{A_1}(x_1)\cdots\delta J^{A_n}(x_n)}\right|_{J=0}.$$

Changing the chart by a local functional $\int_M \mathcal{L}(x, j_x^k J)\mathrm{d}^D x$, or by a local source-coordinate change whose nonlinear part is supported through jets at the same point, changes these derivatives by finite sums of distributions supported on collision diagonals. With the linear source normalization fixed, the restriction of $G_{A_1\cdots A_n}$ to $M^n\setminus\Delta_n$ is unchanged by such purely local finite choices, while the contact-term extension changes.

The source-coordinate system is bookkeeping for a concrete operation: differentiate a specified generating functional with respect to specified compactly supported backgrounds. It is not an additional invariant structure on the QFT. Its invariant content is the separated-point distribution together with the declared equivalence relation on local counterterms and local redefinitions of the sources. Whenever the monograph says that a contact term depends on this choice, the statement means exactly that two coordinate systems agree away from collision diagonals and differ on the diagonals by local distributions of the form displayed above.

Local source-coordinate changes. Fix the linear source normalization in Definition 1.12. If the source functional is changed by a local functional of a finite jet of the source,

$$W[J] \longmapsto W[J] + \int_M \mathcal{L}(x, j_x^k J)\mathrm{d}^D x,$$

then the induced change in each n-fold source derivative at $J = 0$ is a finite sum of distributions supported on collision diagonals in M^n. Consequently the separated-point distribution on $M^n \setminus \Delta_n$ is unchanged.

Every dependence of the added functional on the sources occurs through $\partial^\alpha J^A(x)$ at one integration point x, with $|\alpha| \leq k$. A functional derivative with respect to $J^A(y)$ therefore produces a finite linear combination of derivatives of $\delta(x - y)$. After n source derivatives, the x-integration leaves finite sums of products of delta functions and their derivatives imposing $y_i = y_j$ along partial or total diagonals. These distributions have support contained in Δ_n, hence vanish after restriction to $M^n \setminus \Delta_n$.

The Wightman and Osterwalder–Schrader frameworks assign distributional correlators to the selected basic or named fields. This assignment gives the distributions specified by those frameworks, including their declared domains and positivity properties. It does not canonically choose composite fields, time-ordered products, nonlinear source couplings, or the response of correlators to repeated local source differentiation on collision diagonals. Those choices are additional local source or operator-product data. Ward identities, current algebra, stress-tensor products, anomaly formulae, and deformations of a theory therefore carry contact-term conventions in addition to their separated-point correlation functions.

Renormalization is one construction in which these local extension choices are produced and compared. The concept is broader: a contact term is coincident-point/source-response data, while a counterterm is a local term in a chosen regulated or perturbative action functional. Perturbative Epstein–Glaser constructions, perturbative algebraic QFT, microlocal extension methods, Hollands–Wald local Wick-polynomial and time-ordered product constructions, and Costello–Gwilliam factorization algebras give precise comparison frameworks for such extensions under their stated hypotheses. They will be used as technical models where their hypotheses match the problem under discussion, without being treated as a complete nonperturbative axiom system for all QFTs.

Definition 1.13 (Hilbert-space or algebraic completion)**.** A Hilbert-space or algebraic completion is a reconstruction of operators, states, local algebras, and symmetries from correlation data or from an abstract local net. Positivity is the bridge: Hilbert spaces arise from positive inner products, while local observable algebras arise from positive states and their GNS representations.

Perturbation theory has its own status. A perturbative statement is an asymptotic expansion in a specified parameter, with coefficients computed from regulated distributions and then renormalized. The existence of the perturbative coefficients and the existence of a nonperturbative continuum object are distinct assertions. A perturbative assertion is specified when the observable being expanded, the expansion parameter, the renormalization prescription, and the error class or asymptotic meaning have been stated.

These levels of status will be tracked separately in later chapters. Spectral measures, scattering states, renormalization-group flows, anomalies, conformal data, and gauge-invariant observables are different constructions related by theorems, controlled approximations, or comparison problems.

1.7 Fields As Local Distributional Data

A field presentation assigns localized distributional operators to test functions. For a test function $f \in C_c^\infty(\mathbb{M}^D)$ with $\operatorname{supp} f \subset \mathcal{O}$,

$$\widehat{\Phi}_A(f) = \int_{\mathbb{M}^D} \mathrm{d}^D x \, f(x) \widehat{\Phi}_A(x)$$

is localized in $\mathcal{O}$, in the sense that the smeared operator is affiliated with the local algebra $\mathcal{A}(\mathcal{O})$ or belongs to a common dense invariant field domain associated with that algebra. The precise operator-domain statement will be made in the field framework of the next chapter.

The field presentation is used in two constructions. First, it gives concrete generators or affiliated operators for examples. Second, it gives correlation functions:

$$W_{A_1 \cdots A_n}(x_1, \ldots, x_n) = \langle \Omega | \widehat{\Phi}_{A_1}(x_1) \cdots \widehat{\Phi}_{A_n}(x_n) | \Omega \rangle,$$

again as distributions. Under suitable positivity, covariance, spectral, and domain assumptions, such correlation functions can reconstruct the Hilbert space and fields. Reconstruction theorems will be used later as comparison results with stated hypotheses.

1.8 Additional Constructions And Hypotheses

Several familiar objects are constructed from the framework after adding further hypotheses.

Definition 1.14 (First derived objects and their extra hypotheses)**.** A stable one-particle sector is a spectral subspace of the translation generators associated with an isolated positive-energy mass hyperboloid $p^2 = -m^2$, $p^0 > 0$, possibly with finite internal or spin multiplicity. An S-matrix is constructed from incoming and outgoing asymptotic multiparticle states and wave operators comparing asymptotic Hilbert spaces with the interacting Hilbert space. Surjectivity of those wave operators onto the physical sector is the stronger asymptotic-completeness property and must be supplied as a separate theorem or hypothesis. LSZ reduction is a theorem relating already-defined S-matrix elements to residues or pole parts of time-ordered correlation functions, after the relevant asymptotic states and field-particle overlaps have been identified.

A path-integral presentation is a construction or computational scheme for correlation functions after a regulator, contour, measure, or perturbative prescription has been specified. The symbol $\int D\phi \, \mathrm{e}^{\mathrm{i}S[\phi]}$ receives its meaning from that additional specification.

This dependency order is part of the construction. Perturbative Feynman graphs may be introduced as an expansion for Green functions before scattering is discussed. Diagrams for S-matrix elements acquire that interpretation after asymptotic states and LSZ reduction have been established.

1.9 The First Spectral Question

Translation invariance permits simultaneous spectral analysis of the energy-momentum generators P^μ. Let $E_P(\Delta)$ denote the joint spectral projection of $P = (P^0, \ldots, P^{D-1})$ associated with a Borel set $\Delta \subset \mathbb{R}^D$. The joint spectrum $\mathrm{Spec}(P)$ is the support of this projection-valued measure. The spectrum condition is

$$\mathrm{Spec}(P) \subset \overline{V}_+ = \{p \in \mathbb{R}^D : p^0 \geq 0,\ p^2 \leq 0\}.$$

For $\mu^2 \geq 0$, write $\Delta_F(x;\mu^2)$ for the free scalar Feynman distribution with mass parameter μ:

$$\Delta_F(x;\mu^2) = -\mathrm{i} \lim_{\epsilon \downarrow 0} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k\cdot x}}{k^2 + \mu^2 - \mathrm{i}\epsilon},$$

where the limit is taken in the sense of tempered distributions. The prefactor $-\mathrm{i}$ and the denominator $k^2 + \mu^2 - \mathrm{i}\epsilon$ are part of the mostly-plus Lorentzian Feynman convention used throughout this opening volume, with Fourier factor $\mathrm{e}^{\mathrm{i}k\cdot x}$. With these conventions Δ_F is the vacuum time-ordered two-point distribution of a free scalar field. This is only a notation-setting definition at this point; its relation to spectral measures is derived in Chapter 14. For a scalar Wightman field in the vacuum Hilbert-space framework, positivity of the Hilbert-space inner product, translation invariance, and the spectrum condition imply that the two-point function admits a positive spectral measure on invariant mass. Let $\mathrm{d}\rho(\mu^2)$ denote this positive Borel measure on $[0,\infty)$. For two scalar fields at separated times, $T\{\widehat{\phi}(x)\widehat{\phi}(y)\}$ means

$$\theta(x^0 - y^0)\widehat{\phi}(x)\widehat{\phi}(y) + \theta(y^0 - x^0)\widehat{\phi}(y)\widehat{\phi}(x),$$

with the extension across equal-time coincidences fixed by the distributional Feynman prescription. The time-ordered two-point function has the form

$$\langle \Omega | T\{\widehat{\phi}(x)\widehat{\phi}(0)\} | \Omega \rangle = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2)\, \Delta_F(x;\mu^2).$$

When this measure is absolutely continuous with respect to Lebesgue measure, one may write

$$\mathrm{d}\rho(\mu^2) = \rho_{\mathrm{ac}}(\mu^2)\,\mathrm{d}\mu^2, \qquad \rho_{\mathrm{ac}}(\mu^2) \geq 0 \quad \text{for almost every } \mu^2.$$

This formula will be derived from the stated Hilbert-space assumptions in Chapter 14. It is the first result in the text that relates local two-point data to particle content: isolated atoms of the spectral measure correspond to stable one-particle states, while continuous spectral support corresponds to multi-particle and other continuum contributions.

1.10 Logical Order Of The Opening Construction

The opening construction will proceed as follows:

Hilbert space, symmetry, spectrum, vacuum, locality
$\longrightarrow$ local fields and Wightman functions $\longrightarrow$ path-integral constructions of Green functions
$\longrightarrow$ Källén–Lehmann spectral representation $\longrightarrow$ perturbative Green functions
$\longrightarrow$ Haag–Ruelle asymptotic states $\longrightarrow$ LSZ $\longrightarrow$ perturbative scattering amplitudes.

Each arrow indicates an added construction or theorem. The construction will use each arrow only after its assumptions have been stated.

The first detailed computations follow three dependency bands. First, finite and regulated Lagrangian quantum mechanics supplies path integrals, regularization, perturbation theory for correlation functions, diagrammatics, and local counterterms. Second, relativistic scalar fields supply the first local field examples, Green functions, spectral representations, asymptotic states, the nonperturbative scattering operator, and LSZ. Third, spin and gauge fields require representation theory, fermionic and gauge-field quantization, gauge fixing, ghosts, BRST cohomology, and applications such as QED precision observables. Perturbative Feynman rules for scattering amplitudes belong after the second band has supplied their interpretation.

Chapter 2

Wightman Fields and Reconstruction

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The first four chapters of this volume separate four ways of presenting the same physical theory, but they are not interchangeable levels of structure. This chapter starts from Lorentzian Wightman field data and reconstructs the cyclic field presentation carried by its vacuum n-point distributions. Chapter 12 starts instead from Euclidean Schwinger data and proves, under the corrected OS hypotheses, that such Wightman data are obtained as boundary values of analytic continuations. Chapter 3 then treats bounded local algebras as the invariant observable object: a Wightman field family may coordinatize a represented local net only after closure, affiliation, spectral-projection locality, additivity, and observable-subnet identification have been supplied. Finally Chapter 4 uses that bounded net as the input for DHR sectors, Doplicher–Roberts reconstruction, Tomita–Takesaki theory, split inclusions, and Bisognano–Wichmann modular structure.

Thus the foundational route is a chain of theorem boundaries rather than a single dictionary:

(a) Wightman distributions reconstruct a cyclic unbounded-field presentation;

(b) OS-positive Euclidean data reconstruct such Wightman distributions away from the contact-term choices on diagonals;

(c) passage from fields to an observable net requires additional bounded operator and localization input;

(d) sector, modular, split, and type-theoretic conclusions require their own AQFT hypotheses after the net has been constructed.

Statements later in the volume are meant to name which link is being used, not to slide silently from one presentation to another.

2.1 Field-Theoretic Data

Let $M = \mathbb{M}^D$ be D-dimensional Minkowski space with translation coordinates x^μ and metric $\eta = \mathrm{diag}(-1, 1, \ldots, 1)$. The proper orthochronous Poincare group is denoted by

$$\mathcal{P}_+^\uparrow = \mathbb{R}^D \rtimes SO^+(1, D-1).$$

With $p^2 = \eta_{\mu\nu} p^\mu p^\nu$, define the open and closed forward cones by

$$V_+ = \{p \in \mathbb{R}^D \mid p^0 > 0,\ p^2 < 0\}, \qquad \overline{V}_+ = \{p \in \mathbb{R}^D \mid p^0 \geq 0,\ p^2 \leq 0\}.$$

The framework-level definition in Definition 1.6 records the same object as one possible presentation of a QFT. The present chapter refines that entry by fixing the cyclic domain, field-label, adjunction, and reconstruction conventions needed for theorem-level work.

Definition 2.1 (cyclic Wightman field presentation)**.** A cyclic Wightman field presentation on M consists of

$$\mathfrak{W} = (\mathcal{H}, \Omega, U, \mathcal{D}, E_I, J, |\cdot|, \{\widehat{\Phi}_\alpha\}_{\alpha \in I})$$

with the following properties.

(i) $\mathcal{H}$ is a complex Hilbert space, $\Omega \in \mathcal{H}$ is a unit vector, and $U : \mathcal{P}_+^\uparrow \to \mathcal{U}(\mathcal{H})$ is a strongly continuous unitary representation with

$$U(g)\Omega = \Omega, \qquad g \in \mathcal{P}_+^\uparrow.$$

(ii) $\mathcal{D} \subset \mathcal{H}$ is a dense common invariant domain:

$$\Omega \in \mathcal{D}, \qquad U(g)\mathcal{D} = \mathcal{D}, \qquad \widehat{\Phi}_{\alpha_1}(f_1) \cdots \widehat{\Phi}_{\alpha_n}(f_n)\mathcal{D} \subset \mathcal{D}$$

for all $g \in \mathcal{P}_+^\uparrow$, all $n \geq 1$, all labels α_j, and all test functions f_j in the declared local test-function space. In this chapter the test-function space is the Schwartz space $\mathcal{S}(M)$; compactly supported local smearings are obtained by restriction.

(iii) For each finite multiplet under discussion,

$$E_I = \bigoplus_{\alpha \in I} \mathbb{C} e_\alpha$$

is the finite field-label space, $J : E_I \to E_I$ is an antilinear involution, and $|\cdot| : I \to \mathbb{Z}/2\mathbb{Z}$ is the parity assignment. We write

$$J e_\alpha = e_{\alpha^\dagger}, \qquad J^2 = 1,$$

allowing J to contain the finite-dimensional conjugation matrix when the chosen basis is not closed under componentwise conjugation.

(iv) Each $\widehat{\Phi}_\alpha$ is an operator-valued tempered distribution with common domain $\mathcal{D}$. Thus, for $f \in \mathcal{S}(M)$,

$$\widehat{\Phi}_\alpha(f) = \int_M \mathrm{d}^D x\, f(x)\widehat{\Phi}_\alpha(x)$$

means distributional pairing, and $\widehat{\Phi}_\alpha(f) : \mathcal{D} \to \mathcal{D}$. Matrix elements of finite products between vectors in $\mathcal{D}$ are continuous multilinear functionals of the test functions.

(v) For an E_I-valued test function $h = \sum_\alpha h^\alpha e_\alpha$, set

$$\widehat{\Phi}(h) = \sum_\alpha \widehat{\Phi}_\alpha(h^\alpha), \qquad h^\dagger(x) = Jh(x) = \sum_\alpha \overline{h^\alpha(x)}\, e_{\alpha^\dagger}.$$

The field adjunction is the domain inclusion

$$\widehat{\Phi}(h)^* \supset \widehat{\Phi}(h^\dagger). \tag{2.1}$$

Equivalently,

$$\widehat{\Phi}_\alpha(f)^* \supset \widehat{\Phi}_{\alpha^\dagger}(\overline{f}).$$

Here $\widehat{\Phi}(h)^*$ is the Hilbert-space adjoint of the densely defined operator $\widehat{\Phi}(h) : \mathcal{D} \to \mathcal{D}$; the inclusion means that $\mathcal{D} \subset \mathrm{Dom}(\widehat{\Phi}(h)^*)$ and that the two operators agree on $\mathcal{D}$.

(vi) If the field multiplet transforms in a finite-dimensional Lorentz representation R, covariance is the smeared identity

$$U(a,\Lambda)^{-1}\widehat{\Phi}_\alpha(f)U(a,\Lambda) = R(\Lambda)_\alpha{}^\beta\, \widehat{\Phi}_\beta(f_{a,\Lambda}), \qquad f_{a,\Lambda}(x) = f\big(\Lambda^{-1}(x-a)\big).$$

For pure translations we write $U(a) := U(a,1)$, and with the convention of Chapter 1,

$$U(a) = \exp(\mathrm{i}a_\mu P^\mu) = \exp(\mathrm{i}a^\mu P_\mu).$$

In particular $U(a^0, \vec{0}) = \exp(-\mathrm{i}a^0 P^0)$.

(vii) If E_P is the joint spectral measure of the translation generators $P = (P^0, \ldots, P^{D-1})$, then the spectrum condition is

$$\mathrm{Spec}(P) \subset \overline{V}_+.$$

(viii) If the supports of f and g are spacelike separated, then

$$[\widehat{\Phi}_\alpha(f), \widehat{\Phi}_\beta(g)]_{\mathrm{gr}} = 0$$

on $\mathcal{D}$, where for homogeneous fields

$$[A,B]_{\mathrm{gr}} = AB - (-1)^{|A||B|}BA.$$

For purely bosonic fields this is the ordinary commutator; when both fields are odd it is the anticommutator.

(ix) The vacuum is cyclic for the polynomial field algebra:

$$\mathrm{span}\{\widehat{\Phi}_{\alpha_1}(f_1)\cdots\widehat{\Phi}_{\alpha_n}(f_n)\Omega \mid n \geq 0\} \quad \text{is dense in } \mathcal{H}.$$

Definition 2.1 is the Wightman object used throughout this chapter. It is the cyclic, tempered, Minkowski-space specialization of the framework-level Wightman presentation introduced in Definition 1.6: the present chapter fixes the Schwartz test space, the mostly-plus Poincare convention, the field-label adjunction J, the parity grading, the spectrum cone, and the cyclicity condition needed for reconstruction. A Hermitian field smeared with a real test function is symmetric on $\mathcal{D}$, but essential self-adjointness of its closure is an additional analytic assertion. The spectral, covariance, locality, Hermiticity, and cyclicity requirements are independent conditions on the same field presentation. The reconstruction theorem below is the construction step that builds a cyclic field presentation from a Wightman distribution hierarchy.

A pure vacuum Wightman sector is a cyclic Wightman field presentation for which, writing E_P for the joint spectral measure of the translation generators, the zero-momentum spectral projection satisfies

$$E_P(\{0\})\mathcal{H} = \mathbb{C}\Omega.$$

This chapter does not build that purity condition into the base definition: Theorem 2.3 proves that it is equivalent, under the Wightman locality and spectrum assumptions, to the weak cluster property for polynomial local fields.

2.2 Fields and Local Observable Content

The objects $\widehat{\Phi}_\alpha(f)$ in Definition 2.1 are generally unbounded operators. Their algebraic products are defined first on the common invariant domain $\mathcal{D}$, and their locality statement is a statement about graded commutators on that domain. A local algebra of bounded observables is a further object constructed from, or compared with, these field coordinatizations.

For an open region $\mathcal{O} \subset M$, let

$$\mathfrak{P}_\Phi(\mathcal{O})$$

denote the unital $*$-algebra on $\mathcal{D}$ generated by smeared fields $\widehat{\Phi}_\alpha(f)$ with $\operatorname{supp} f \subset \mathcal{O}$, together with their adjoints on $\mathcal{D}$. The subscript Φ names the chosen field family; the individual Hilbert-space fields in the family remain the hatted operator-valued distributions $\widehat{\Phi}_\alpha$. This is an algebra of generally unbounded operators on a common domain, not a C^*-algebra. If the relevant smeared Hermitian fields are essentially self-adjoint and if the closures and bounded Borel functions have the required localization properties, one can form a represented local von Neumann algebra

$$\mathcal{R}_\Phi(\mathcal{O}) = \{\text{bounded functions of closures of fields localized in } \mathcal{O}\}'', \tag{2.2}$$

or, more invariantly, require the unbounded fields to be affiliated with a local algebra $\mathcal{R}(\mathcal{O})$. The double prime denotes weak operator closure. The affiliation formulation is often the correct one: spectral projections of a self-adjoint operator affiliated with $\mathcal{R}(\mathcal{O})$ belong to $\mathcal{R}(\mathcal{O})$.

Figure 2.1 compares two logically different routes to local observable algebras. The upper route starts from unbounded Wightman field coordinates and needs closure, functional-calculus, or affiliation hypotheses. The lower route starts from a local-net datum. The two right-hand algebras are identified only after a comparison theorem is proved; equality is not a notation convention.

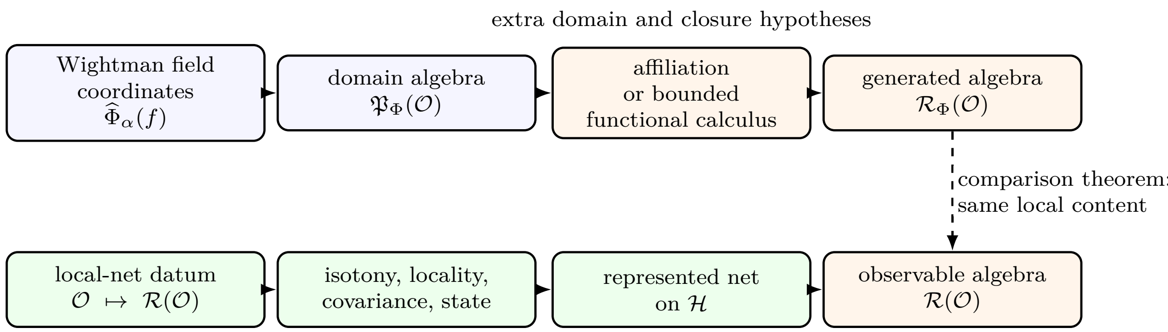

Figure 2.1: Two routes to local observable algebras. Field coordinates generate a local algebra only after closure and affiliation input; a local net may instead be supplied directly, and equivalence of the two descriptions is an additional theorem.

Several different field families may coordinatize the same local observable content. In this monograph a field coordinatization is treated as part of the presentation, while the local observable net, when it has been constructed, is the invariant local object. Thus the Wightman hierarchy for a chosen field family is complete for reconstructing that chosen field presentation, whereas comparisons between different field presentations require an additional equivalence statement: one must show that they generate the same represented local algebras, or a specified subtheory, in the relevant vacuum sector.

2.3 Wightman Functions

The vacuum n-point distributions are

$$W_{\alpha_1\cdots\alpha_n}(x_1,\ldots,x_n) = \langle\Omega|\widehat{\Phi}_{\alpha_1}(x_1)\cdots\widehat{\Phi}_{\alpha_n}(x_n)|\Omega\rangle. \tag{2.3}$$

They are tempered distributions on M^n. Translation invariance allows one to pass to difference variables

$$\xi_j = x_{j+1} - x_j, \qquad j = 1,\ldots,n-1.$$

The spectral condition implies that the Fourier transform in the difference variables has support in $\overline{V}_+^{\,n-1}$. This is the same positive spectral input that will lead in Chapter 14 to the Källén–Lehmann representation of two-point functions.

The Wightman hierarchy also records the adjunction operation on fields. On one-field test functions the adjunction is the map $h \mapsto h^\dagger$ fixed in (2.1). On test functions valued in field-label tensor powers, one must also reverse the order of insertions because the Hilbert-space adjoint reverses products. For $f_n \in \mathcal{S}(M^n, E_I^{\otimes n})$, define the antilinear tensor reversal $R_n : E_I^{\otimes n} \to E_I^{\otimes n}$ by

$$R_n(v_1 \otimes \cdots \otimes v_n) = Jv_n \otimes \cdots \otimes Jv_1$$

and set

$$f_n^\dagger(x_1,\ldots,x_n) = R_n\big(f_n(x_n,\ldots,x_1)\big).$$

Thus $f_n^\dagger$ simultaneously reverses the order of insertions, complex conjugates the coefficient functions, and applies the field-label adjunction to each tensor factor.

The Wightman hierarchy satisfies five structural conditions that are directly read from the Hilbert-space data:

Covariance. The distribution W_n transforms under $\mathcal{P}_+^\uparrow$ by the n-fold field representation on its labels and test functions.

Spectrum. In translation-difference variables,

$$\operatorname{supp} \widehat{W}_n \subset \overline{V}_+^{\,n-1}.$$

Hermiticity. For all labels and test functions,

$$\overline{W_{\alpha_1\cdots\alpha_n}(f_1 \otimes \cdots \otimes f_n)} = W_{\alpha_n^\dagger\cdots\alpha_1^\dagger}(\overline{f}_n \otimes \cdots \otimes \overline{f}_1).$$

This is the vacuum distribution form of the operator-domain adjoint condition $\widehat{\Phi}(h)^* \supset \widehat{\Phi}(h^\dagger)$, with product order reversed after taking adjoints.

Locality. W_n has the graded permutation property when adjacent field insertions are smeared with spacelike separated test functions.

Positivity. For every finite sequence $F = (f_0, f_1, f_2, \ldots)$ of test functions,

$$\sum_{m,n} W_{m+n}(f_m^\dagger \otimes f_n) \geq 0.$$

In the positivity condition, f_n denotes a compactly supported or Schwartz test function valued in the appropriate finite direct sum of field labels. Hermiticity is the compatibility condition that makes the reconstructed left-multiplication fields have the intended adjoints on the common domain.

2.4 Clustering and the Vacuum Sector

The vacuum vector should represent one pure infinite-volume phase. In the Wightman setting this is expressed by a cluster property. For two polynomial local operators A and B, formed from fields smeared in bounded regions, define

$$B(a) = U(a)BU(a)^{-1}.$$

The weak cluster property in the vacuum sector is

$$\lim_{\lambda\to+\infty} \langle \Omega, A\, B(\lambda a)\Omega\rangle = \langle \Omega, A\Omega\rangle\langle \Omega, B\Omega\rangle \tag{2.4}$$

for every spacelike vector a. In terms of Wightman functions, this says that widely spacelike-separated groups of insertions factorize.

The spectral argument is as follows. Insert the spectral resolution of translations between A and $B(a)$. The vacuum atom at $p = 0$ gives the product on the right side of (2.4). If the vacuum is the only translation-invariant vector, then no other atom at $p = 0$ contributes. The remaining continuous spectral part has oscillatory phase $\exp(\mathrm{i}\lambda a \cdot p)$; after smearing, its contribution vanishes in the large-spacelike-separation limit because locality and the spectrum condition make the relevant one-parameter spectral measure a Rajchman measure on every spacelike translation line. The analytic mechanism is the lemma below. With a mass gap and suitable regularity, the same argument gives stronger decay estimates. Selecting a pure vacuum sector is the condition that the zero-momentum projection is the one-dimensional projection onto $\mathbb{C}\Omega$.

Lemma 2.2 (Jost cluster step for local vectors)**.** *Let A and B be homogeneous polynomial field operators obtained by smearing fields in bounded regions $\mathcal{O}_A$ and $\mathcal{O}_B$, and let*

$$\psi = A^{\dagger}\Omega, \qquad \chi = (1 - P_0)B\Omega.$$

For every spacelike vector a,

$$\lim_{\lambda\to+\infty} \langle \psi, U(\lambda a)\chi \rangle = 0. \tag{2.5}$$

Proof. Set

$$F_+(x) = \langle \Omega, A\, B(x)\Omega \rangle - \langle \Omega, A\Omega \rangle\langle \Omega, B\Omega \rangle, \qquad B(x) = U(x)BU(x)^{-1}.$$

Equivalently,

$$F_+(x) = \langle A^{\dagger}\Omega, U(x)(1 - P_0)B\Omega \rangle. \tag{2.6}$$

The joint spectral theorem gives a finite complex measure

$$\mathrm{d}\mu_{\psi,\chi}(p) = \langle \psi, E_P(\mathrm{d}p)\chi \rangle, \qquad \operatorname{supp} \mu_{\psi,\chi} \subset \overline{V}_+,$$

and F_+ is its Fourier transform in the translation variable, with the Fourier sign convention fixed by $U(x) = \exp(\mathrm{i}x \cdot P)$. The subtraction by P_0 is exactly the assertion

$$\mu_{\psi,\chi}(\{0\}) = 0. \tag{2.7}$$

Let

$$\mathcal{C}_{A,B} = \{x \in M \mid \mathcal{O}_A \text{ is spacelike separated from } \mathcal{O}_B + x\}.$$

This is an open real set, and for every spacelike a there is λ_0 such that $\lambda a \in \mathcal{C}_{A,B}$ for $\lambda > \lambda_0$. On $\mathcal{C}_{A,B}$, locality gives

$$F_+(x) = \varepsilon_{AB}F_-(x), \qquad F_-(x) = \langle \Omega, B(x)A\Omega \rangle - \langle \Omega, B\Omega \rangle\langle \Omega, A\Omega \rangle, \tag{2.8}$$

where $\varepsilon_{AB} = (-1)^{|A||B|}$. The spectral condition gives a holomorphic function $\mathcal{F}_+$ in the forward tube whose boundary value is F_+. The same condition applied to the reversed matrix element gives a holomorphic function $\mathcal{F}_-$ in the backward tube whose boundary value is F_-. Equation (2.8) identifies the two boundary values on the real edge $\mathcal{C}_{A,B}$. The edge-of-the-wedge theorem therefore gives a single holomorphic continuation through a complex neighborhood of $\mathcal{C}_{A,B}$.

It remains to spell out the spectral consequence of this continuation along the line $\mathbb{R}a$. Let $H_a = a \cdot P$, and let E_a be its spectral measure. Suppose first that $E_a(\{q\})\chi$ contributes to the local matrix coefficient for some real q. Replacing χ by this spectral component in (2.6) gives a boundary value whose restriction to the a-line has the factor $\exp(\mathrm{i}\lambda q)$. The reversed boundary value has the opposite one-parameter spectral support. Since the two boundary values are restrictions of the same holomorphic function across the Jost edge, the Fourier support of the isolated component must lie simultaneously in the forward and backward translation spectra. Hence its full energy-momentum support is contained in

$$\overline{V}_+ \cap (-\overline{V}_+) = \{0\}.$$

For $q = 0$ this is precisely the removed projection $P_0\chi = 0$; for $q \neq 0$ it is impossible. Thus the one-parameter spectral measure of χ, tested against every local vector $\psi = A^\dagger\Omega$, has no point mass.

The continuous part is controlled by the same Jost-domain theorem in its one-parameter form. In the present notation, the theorem says that a tempered local matrix coefficient F_+ satisfying:

(a) forward-tube spectral support for F_+;

(b) backward-tube spectral support for the reversed ordering F_-;

(c) equality of the two boundary values on a nonempty Jost edge; and

(d) absence of the zero-momentum spectral atom after vacuum subtraction

has the following Rajchman property on every spacelike ray:

$$\lim_{\lambda \to +\infty} \int_{\mathbb{R}} e^{i\lambda q}\, d\nu_a(q) = 0, \qquad d\nu_a = (a \cdot p)_* d\mu_{\psi,\chi}. \tag{2.9}$$

The proof of this one-parameter theorem is a carrier-cone argument. Localize the edge to a compact set of spacelike points and apply the edge-of-the-wedge continuation to the forward and backward tubes. The Paley–Wiener–Schwartz carrier theorem then identifies the part of $\mu_{\psi,\chi}$ that could fail to have the decay (2.9) with a spectral component carried by a proper real hyperplane and invariant under the corresponding spacelike translations. Applying the preceding atom argument to that component puts its full energy-momentum carrier in $\overline{V}_+ \cap (-\overline{V}_+) = \{0\}$. Equation (2.7) removes this last possibility. Hence the push-forward measure is Rajchman, and (2.5) follows. □

Theorem 2.3 (Cluster decomposition and vacuum uniqueness)**.** *Let $(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_\alpha\})$ be the Hilbert-space and field part of a cyclic Wightman field presentation in the sense of Definition 2.1, with joint translation spectral measure E_P, and let*

$$P_0 = E_P(\{0\})$$

be the joint spectral projection of the translation generators onto zero momentum. The following conditions are equivalent.

(i) *The zero-momentum subspace is one-dimensional:*

$$P_0\mathcal{H} = \mathbb{C}\Omega.$$

(ii) *The vacuum is the unique translation-invariant vector up to scalar multiple.*

(iii) *The weak cluster property (2.4) holds for all polynomial field insertions A and B and for every spacelike translation direction a.*

Proof. The equivalence of (i) and (ii) is the joint spectral theorem for the translation representation: translation-invariant vectors are precisely the vectors in $\operatorname{Ran} P_0$. For (i) $\Rightarrow$ (iii), write

$$\langle \Omega, A\, B(\lambda a)\Omega\rangle = \langle A^\dagger\Omega, U(\lambda a)B\Omega\rangle,$$

first for polynomial fields whose domain adjoints are defined on $\mathcal{D}$, and then by linearity. The Wightman spectral condition and temperedness make this matrix element the Fourier transform, in the weak large-spacelike-separation sense, of the spectral distribution between $A^\dagger\Omega$ and $B\Omega$. Its zero-momentum atom contributes

$$\langle A^\dagger\Omega, P_0 B\Omega\rangle = \langle \Omega, A\Omega\rangle\,\langle \Omega, B\Omega\rangle,$$

because $P_0 = |\Omega\rangle\langle\Omega|$. The remaining spectral part has no zero-momentum atom. Lemma 2.2, applied to $(1 - P_0)B\Omega$, gives the required weak large-separation limit.

Conversely, assume the weak cluster property. The same spectral decomposition shows that the large-separation limit of the non-oscillatory part is $\langle A^\dagger\Omega, P_0 B\Omega\rangle$. Comparing with (2.4) gives

$$\langle A^\dagger\Omega, P_0 B\Omega\rangle = \langle A^\dagger\Omega, \Omega\rangle\,\langle \Omega, B\Omega\rangle$$

for all polynomial A, B. Since the polynomial field orbit of Ω is dense, this identity implies

$$P_0 B\Omega = \Omega\,\langle \Omega, B\Omega\rangle$$

on a dense set of vectors $B\Omega$. Hence $P_0 = |\Omega\rangle\langle\Omega|$, which is (i). ☐

The finite algebra in this proof is worth isolating. Let $\mathcal{E}$ be the linear span of polynomial vectors $B\Omega$. The weak cluster identity tests the sesquilinear form

$$(X, Y) \longmapsto \langle X, P_0 Y\rangle$$

on the dense subspace $\mathcal{E}$. If the identity

$$\langle X, P_0 Y\rangle = \langle X, \Omega\rangle\langle \Omega, Y\rangle, \qquad X, Y \in \mathcal{E},$$

holds, continuity of P_0 extends it to $\overline{\mathcal{E}} = \mathcal{H}$, so P_0 is the rank-one projection onto $\mathbb{C}\Omega$. Conversely, when $P_0 = |\Omega\rangle\langle\Omega|$, the zero-momentum atom in the spectral decomposition is exactly the product term. Thus the analytic content of the cluster theorem is not this projection algebra; it is Lemma 2.2, which proves that no other spectral piece survives along a spacelike ray after the vacuum atom is removed.

2.5 Reconstruction From Correlation Functions

The Wightman reconstruction theorem says that the correlation hierarchy is itself a complete encoding of a chosen Wightman field presentation, provided the hierarchy satisfies the Wightman conditions with the required regularity. The source trace for the reconstruction theorem in this form is Wightman's vacuum-expectation-value formulation and the Streater–Wightman presentation [1, 2]; the proof below is included because the null-space quotient, common domain, and uniqueness statements are load-bearing for the later comparison with local nets.

Theorem 2.4 (Wightman reconstruction). *Let $\{W_n\}_{n\geq 0}$ be a hierarchy with $W_0 = 1$, where W_n is a continuous linear functional on $\mathcal{S}(M^n, E_I^{\otimes n})$, and where E_I carries the label adjunction and parity data used in Hermiticity and locality. Equivalently, on every finite field-label subspace, each component distribution is bounded by finitely many Schwartz seminorms: after choosing scalar components F_j of a test function F, there are $C, N < \infty$ such that*

$$|W_n(F)| \leq C \sum_j \sum_{|a|,|b|\leq N} \sup_{x\in M^n} |x^a \partial^b F_j(x)|.$$

Suppose the hierarchy satisfies Poincare covariance, the spectral support condition, Hermiticity, locality, and positivity. Then there exists a cyclic Wightman field presentation in the sense of Definition 2.1,

$$(\mathcal{H}, \Omega, U, \mathcal{D}, E_I, J, |\cdot|, \{\widehat{\Phi}_\alpha\}_{\alpha\in I}),$$

with the following properties:

(i) *Its vacuum correlation functions are exactly $\{W_n\}$.*

(ii) *The dense domain is the polynomial field orbit of the vacuum,*

$$\mathcal{D} = \operatorname{span}\{\widehat{\Phi}_{\alpha_1}(f_1)\cdots\widehat{\Phi}_{\alpha_n}(f_n)\Omega \mid n \geq 0,\ \alpha_j \in I,\ f_j \in \mathcal{S}(M)\}.$$

In particular, Ω is cyclic for the reconstructed polynomial field algebra.

(iii) *U is a strongly continuous unitary representation of $\mathcal{P}_+^\uparrow$, the fields are covariant operator-valued tempered distributions on the common domain $\mathcal{D}$, and the spectrum, adjoint, and locality properties specified above hold on $\mathcal{D}$.*

The cyclic reconstruction satisfying these properties is unique up to the canonical unitary induced by identifying finite test-function sequences with the same Wightman inner products.

Proof. The construction begins with formal vectors

$$[\alpha_1, f_1; \ldots; \alpha_n, f_n]$$

and defines an inner product by the Wightman distributions. Positivity makes this a positive semidefinite form. Dividing by zero-norm vectors and completing gives $\mathcal{H}$. Fields act by left multiplication on the dense subspace of finite sequences, and the Poincare action is induced by covariance of the hierarchy.

More explicitly, let $\mathcal{V}$ be the vector space of finite sequences

$$F = (f_0, f_1, f_2, \ldots),$$

where f_n is a Schwartz test function on M^n valued in the n-fold field-label space and only finitely many components are nonzero. Define

$$\langle F, G\rangle_W = \sum_{m,n} W_{m+n}(f_m^\dagger \otimes g_n). \tag{2.10}$$

Let

$$\mathcal{N}_W = \{F \in \mathcal{V} \mid \langle F, F\rangle_W = 0\}.$$

The dense domain $\mathcal{D}$ is the image of $\mathcal{V}/\mathcal{N}_W$ inside its Hilbert-space completion. For an E_I-valued one-field test function h, the reconstructed smeared field is

$$\widehat{\Phi}(h)[F] = [h \otimes F],$$

where $h \otimes F$ means left insertion of the one-field test function before the sequence F. In components, $\widehat{\Phi}_\alpha(k)[F] = [(ke_\alpha) \otimes F]$. Positivity and the Wightman identities ensure that this action is well defined on the null quotient and that the vacuum vector is the class of $(1, 0, 0, \ldots)$. The Poincare representation acts by transforming all test functions; covariance of $\{W_n\}$ makes this action unitary.

The same finite-sequence construction gives cyclicity. Starting with the vacuum class $\Omega = [(1, 0, 0, \ldots)]$, repeated left insertion gives

$$\widehat{\Phi}(h_1) \cdots \widehat{\Phi}(h_n)\Omega = [h_1 \otimes \cdots \otimes h_n],$$

and finite sums of such vectors are precisely the image of $\mathcal{V}$ in the quotient. Since $\mathcal{D}$ is defined as this image, $\mathcal{D}$ is the polynomial field orbit of Ω, and its Hilbert-space closure is all of $\mathcal{H}$.

The same formula verifies the adjoint inclusion on the reconstructed common domain. For an E_I-valued one-field test function h and finite sequences F, G,

$$\langle \widehat{\Phi}(h)F, G\rangle_W = \langle F, \widehat{\Phi}(h^\dagger)G\rangle_W.$$

Indeed, inserting h on the left of F and then applying the dagger in (2.10) moves h to the right place with the label adjunction and complex conjugation fixed above. After quotienting by $\mathcal{N}_W$, this identity says precisely that

$$\widehat{\Phi}(h)^* \supset \widehat{\Phi}(h^\dagger)$$

on the dense finite-sequence domain.

Covariance of $\{W_n\}$ makes the induced Poincare action on $\mathcal{V}/\mathcal{N}_W$ isometric. Its completion gives the strongly continuous unitary representation U. Strong continuity follows because the Poincare action is strongly continuous on Schwartz test functions and the finite-sequence vectors are dense. The spectral condition for U follows from the stated support condition on the Fourier transforms of the Wightman distributions: if F, G are finite sequences, the distribution $a \mapsto \langle F, U(a)G\rangle_W$ has Fourier support in the closed forward cone after passing to translation-difference variables, hence the joint spectral measure of U is supported in $\overline{V}_+$.

Locality is also inherited at the finite-sequence level. If the supports of two one-field test functions are spacelike separated, the locality axiom for the hierarchy equates the corresponding Wightman functionals after graded interchange. Therefore the difference between the two graded-ordered field products has zero matrix element against every finite sequence. Positivity then puts that difference in the null subspace, so the graded commutator vanishes as an operator on $\mathcal{D}$. The same argument applies to polynomial products by iterating the adjacent interchange.

Finally, if two cyclic reconstructions are built from the same hierarchy, the map sending a finite test-function sequence in the first reconstruction to the class of the same sequence in the second preserves all inner products by (2.10). It descends through the same null quotient, has dense range, intertwines the fields and the Poincare action on finite sequences, and therefore extends uniquely to the canonical unitary equivalence. □

For a hierarchy satisfying the reconstruction hypotheses, the reconstructed translation representation has a zero-momentum projection P_0. Adding the weak cluster condition (2.4) selects exactly the case $P_0\mathcal{H} = \mathbb{C}\Omega$ by Theorem 2.3. Thus clustering is the correlation-function condition for reconstructing a pure vacuum sector.

The uniqueness statement is internal to the specified hierarchy and its field labels. It says that two cyclic reconstructions of the same $\{W_n\}$ have the same pre-Hilbert space of finite test-function sequences modulo null vectors, hence the same vacuum matrix elements for every finite product of field insertions. This is a uniqueness statement about the Wightman hierarchy and the cyclic field presentation it generates. It does not identify different choices of field coordinatization whose local observable algebras may agree only after additional closure, affiliation, or quotient constructions. Those comparisons belong to the relation between Wightman fields and local nets described above and in Chapter 3.

Figure 2.2 organizes the reconstruction proof: finite test-function sequences are quotiented by null vectors, completed to $\mathcal{H}_W$, and the fields act by left insertion on the common dense domain.

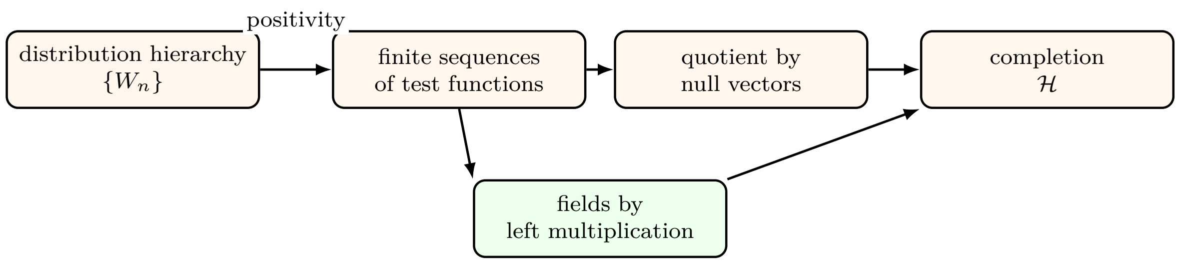

Figure 2.2: Wightman reconstruction builds the Hilbert space and fields from the positive correlation hierarchy.

2.6 Analytic Continuation From Spectral Positivity

For scalar fields, write the Wightman function in difference variables as

$$W_n(\xi_1, \ldots, \xi_{n-1}).$$

The support condition for the Fourier transform implies that W_n is the boundary value of a holomorphic function on the forward tube

$$T_{n-1} = \{z_j = \xi_j - \mathrm{i}\eta_j \in \mathbb{C}^D \mid \eta_j \in V_+,\ j = 1, \ldots, n-1\}.$$

Lorentz covariance enlarges the domain to the extended tube obtained by the complex Lorentz group. Locality then identifies the analytic continuations associated with permutations at Jost configurations, where all relevant real linear combinations are spacelike.

Proposition 2.5 (Wightman tube boundary-value package)**.** *Fix a component of an n-point Wightman distribution in a cyclic Wightman field presentation, and write it in difference variables $\xi = (\xi_1, \ldots, \xi_{n-1})$ as*

$$w_n(\xi) \in \mathcal{S}'(M^{n-1}).$$

Use the Fourier convention

$$w_n(\xi) = \int \frac{\mathrm{d}^{D(n-1)}p}{(2\pi)^{D(n-1)}} \exp\left(\mathrm{i}\sum_{j=1}^{n-1} p_j \cdot \xi_j\right) \widetilde{w}_n(p)$$

in distribution notation. The spectrum condition gives

$$\operatorname{supp} \widetilde{w}_n \subset \overline{V}_+^{\,n-1}.$$

For $z_j = \xi_j - \mathrm{i}\eta_j$, $\eta_j \in V_+$, the Fourier–Laplace transform

$$\mathcal{W}_n(z) = \frac{1}{(2\pi)^{D(n-1)}} \left\langle \widetilde{w}_n(p), \exp\left(\mathrm{i}\sum_{j=1}^{n-1} p_j \cdot z_j\right)\right\rangle$$

is holomorphic in T_{n-1} and has w_n as its distributional boundary value. If the fields transform in finite-dimensional Lorentz representations that extend holomorphically to the complexified spin group, Lorentz covariance continues $\mathcal{W}_n$ to the extended tube. Finally, if two adjacent orderings differ only by exchanging homogeneous fields whose coordinates are spacelike separated on a Jost real edge, their tube boundary values agree there up to the Koszul sign, and the distributional edge-of-the-wedge theorem gives a common holomorphic continuation across that edge.

Proof. Insert the joint spectral resolution of translations between successive fields. In the relative-coordinate matrix element, the Fourier variables are the momenta transported by the intermediate states between adjacent field insertions. The Wightman spectrum condition places every such momentum in $\overline{V}_+$, giving the displayed support inclusion for $\widetilde{w}_n$.

For $p \in \overline{V}_+$ and $\eta \in V_+$, the mostly-plus metric gives $p \cdot \eta \leq 0$. Hence

$$\exp\bigl(\mathrm{i}p \cdot (\xi - \mathrm{i}\eta)\bigr) = \exp(\mathrm{i}p \cdot \xi + p \cdot \eta)$$

is exponentially damped on closed subcones inside the tube direction. For a tempered distribution carried by $\overline{V}_+^{\,n-1}$, multiplication by the damping factor is defined by inserting a smooth conic cutoff equal to one near the support; independence of the cutoff follows because two such cutoffs differ away from the support. Differentiating with respect to any z_j only inserts polynomial factors in p_j, still controlled by the same damping on proper subtubes. This proves holomorphy of $\mathcal{W}_n$. The same finite-order Schwartz seminorm bound for $\widetilde{w}_n$, applied after the conic cutoff and differentiated finitely many times, gives the standard polynomial normal-growth estimate on each proper subtube; this is the growth hypothesis needed for distributional boundary values and for the edge-of-the-wedge step below.

To identify the boundary value, pair $\mathcal{W}_n(\xi - \mathrm{i}\eta)$ with a Schwartz test function $f(\xi)$. In Fourier variables this is the pairing of $\widetilde{w}_n$ with the Schwartz function $\check{f}(p)$ multiplied by $\exp(\sum_j p_j \cdot \eta_j)$ and by the same harmless conic cutoff. As $\eta \to 0$ within V_+^{n-1}, these multipliers converge to one in the C^∞ multiplier topology on every conic neighborhood of the support after the cutoff. Continuity of the tempered distribution therefore gives the limit $\langle w_n, f\rangle$.

For the covariance enlargement, first take real proper orthochronous Lorentz transformations. Covariance of the fields identifies the transformed boundary distributions with the original distribution acted on by the finite field-label matrices. Both sides have holomorphic tube continuations.

Since the finite-dimensional spin/tensor representation matrices are polynomial or holomorphic functions of the complexified Lorentz parameters, the identity extends by the identity theorem along the connected complexified Lorentz orbit as long as the transformed point remains in the holomorphy envelope. This is the extended-tube construction.

It remains to identify where locality enters. Let O be a real open set of noncoincident configurations on which the exchanged adjacent coordinates are spacelike separated. A test function supported in O can be written, by a partition of unity, as a finite sum of product-smearing pieces whose two exchanged one-field supports are spacelike separated. Microcausality on the common Wightman domain gives equality of the two smeared matrix elements, with sign $(-1)^{|a||b|}$ for homogeneous odd/even labels. Thus the two permuted tube functions have equal distributional boundary values on the Jost edge. The analytic theorem used at this last step is the distributional edge-of-the-wedge theorem stated and proved in Theorem 16.6: polynomial tube bounds come from the preceding Fourier–Laplace construction, and the boundary equality is the microcausality statement just verified. Therefore the permuted holomorphic functions glue across the edge. □

Figure 2.3 sketches a two-dimensional slice of the complexified difference variable. The real edge carries the boundary values, the forward tube is obtained by writing the difference variables as $z = \xi - \mathrm{i}\eta$ with $\eta \in V_+$, and the Jost configurations are real spacelike boundary points at which locality identifies different permutation-ordered boundary values.

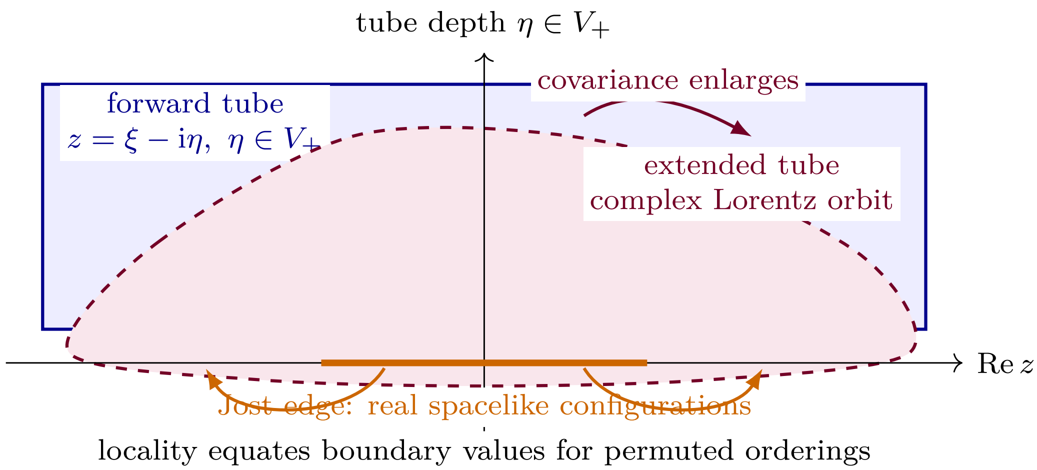

Figure 2.3: A slice of Wightman tube analyticity. Spectral support gives the mostly-plus forward tube $z = \xi - \mathrm{i}\eta$, $\eta \in V_+$, covariance enlarges it to the extended tube, and locality identifies the boundary values reached at real Jost configurations.

The Euclidean Schwinger functions are restrictions of these analytic functions to noncoincident imaginary-time configurations. The converse passage from Euclidean data to Lorentzian Wightman data requires reflection positivity and growth hypotheses. That converse is the subject of the next chapter.

2.7 The PCT Theorem

The theorem usually called CPT in particle language is most naturally a PCT theorem in the Wightman setting: it is an antiunitary implementation of the total spacetime inversion $x \mapsto -x$, together with the corresponding conjugation of field labels. Charge conjugation is not assumed as a separate unitary symmetry. It appears because the field adjunction sends a charged field to the field carrying the conjugate charge.

Let $D = 4$ in this section, and let the finite field-label space be closed under the adjoint operation fixed in (2.1). For each covariant field multiplet, the finite-dimensional representation of $\mathrm{Spin}^+(1,3)$ and the adjoint label map determine, after a choice of basis, an antilinear test-function operation

$$h \longmapsto h^\Theta, \qquad h^\Theta(x) = C_{\mathrm{PCT}}\,\overline{h(-x)}.$$

Here C_{PCT} is a finite matrix on field labels. It contains the Lorentz spinor/tensor matrix required by the representation and the internal conjugation sending a field to its adjoint charged multiplet. The displayed formula is a definition of notation: if the original field list is not closed under this operation, one first enlarges it by adjoining the conjugate fields.

Theorem 2.6 (Wightman PCT theorem)**.** Proof references.[1] *Let*

$$(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_\alpha\})$$

be the Hilbert-space and field part of a four-dimensional cyclic Wightman field presentation satisfying Definition 2.1. Assume also that the field-label family is stable under the PCT test-function operation $h \mapsto h^\Theta$ just described. Then there exists an antiunitary operator

$$\Theta_{\mathrm{PCT}} : \mathcal{H} \to \mathcal{H}$$

with the following properties.

(i) *Vacuum invariance:*

$$\Theta_{\mathrm{PCT}}\Omega = \Omega.$$

(ii) *Poincare covariance extended by spacetime inversion:*

$$\Theta_{\mathrm{PCT}}\, U(a,\Lambda)\, \Theta_{\mathrm{PCT}}^{-1} = U(-a,\Lambda), \qquad (a,\Lambda) \in \mathbb{R}^4 \rtimes SO^+(1,3). \tag{2.11}$$

Equivalently, $\Theta_{\mathrm{PCT}} P_\mu \Theta_{\mathrm{PCT}}^{-1} = P_\mu$, while the antiunitarity of Θ_{PCT} sends $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ to $U(-a)$.

(iii) *Distributional field covariance:*

$$\Theta_{\mathrm{PCT}}\, \widehat{\Phi}(h)\, \Theta_{\mathrm{PCT}}^{-1} = \widehat{\Phi}(h^\Theta) \tag{2.12}$$

as an identity of operators on the transformed common domain. In point-field notation this says, distributionally,

$$\Theta_{\mathrm{PCT}}\, \widehat{\Phi}_\alpha(x)\, \Theta_{\mathrm{PCT}}^{-1} = C_{\mathrm{PCT},\alpha}{}^{\beta}\widehat{\Phi}^\dagger_\beta(-x),$$

with the finite spin and charge-conjugation matrix appropriate to the field multiplet.

[1]The theorem is due to Jost and to Pauli–Luders in the Wightman framework. Standard mathematical proofs are given in R. F. Streater and A. S. Wightman, *PCT, Spin and Statistics, and All That*, Benjamin, 1964, and in R. Jost, *The General Theory of Quantized Fields*, American Mathematical Society, 1965 [2, 3].

(iv) *Vacuum correlation PCT identity. For*

$$W_n(h_1,\dots,h_n)=\langle\Omega,\widehat{\Phi}(h_1)\cdots\widehat{\Phi}(h_n)\Omega\rangle,$$

one has

$$W_n(h_1,\dots,h_n)=\overline{W_n(h_1^\Theta,\dots,h_n^\Theta)}=W_n((h_n^\Theta)^\dagger,\dots,(h_1^\Theta)^\dagger). \tag{2.13}$$

The second equality is the adjoint reversal already present in the Wightman Hermiticity condition.

No mass gap is required for this theorem. A mass gap is an additional hypothesis for particle sectors, Haag–Ruelle scattering, and many DHR superselection statements, but not for the PCT antiunitary itself.

Proof. The proof has two logically distinct parts: first a distributional identity for the Wightman functions, and then the construction of the antiunitary operator from that identity.

Write the n-point functions in translation-difference variables. The spectrum condition makes them boundary values of holomorphic functions in the forward tube. Proper Lorentz covariance extends these functions to the extended tube, obtained by acting with the complex Lorentz group. In four dimensions the complex Lorentz group contains a path which implements the total spacetime inversion on Jost configurations, with the corresponding finite spin matrix acting on the field labels. A Jost configuration is a real configuration for which all relevant convex linear combinations of differences are spacelike; in such a configuration the fields may be reordered by graded locality. Applying locality to reverse the order at the Jost edge, and then using the edge-of-the-wedge theorem, gives the analytic identity whose boundary value is precisely (2.13). This is the Jost form of the PCT theorem: weak local commutativity at Jost points and the PCT identity are equivalent under the remaining Wightman analyticity hypotheses.

Now pass from the identity of distributions to Hilbert space. On the dense finite-sequence domain used in the reconstruction proof, define an antilinear map by

$$\Theta_0\,[h_1;\dots;h_n]=[h_1^\Theta;\dots;h_n^\Theta],\qquad \Theta_0[(1,0,0,\dots)]=(1,0,0,\dots),$$

and extend by antilinearity to finite sums. Equation (2.13), together with the Wightman inner product (2.10), implies

$$\langle\Theta_0F,\Theta_0G\rangle_W=\overline{\langle F,G\rangle_W}.$$

Thus Θ_0 maps null vectors to null vectors and descends to an anti-isometry of the quotient pre-Hilbert space. Its range contains the same finite polynomial domain because $h\mapsto h^\Theta$ is an involutive operation on the enlarged field-label space. Hence it extends uniquely to an antiunitary Θ_{PCT} on $\mathcal{H}$.

The vacuum vector is the class of the empty sequence, so it is fixed. The field identity (2.12) follows from left insertion:

$$\Theta_0\,\widehat{\Phi}(h)[F]=\Theta_0[h;F]=[h^\Theta;\Theta_0F]=\widehat{\Phi}(h^\Theta)\Theta_0[F].$$

The translation identity follows from $(U(a)h)^\Theta=U(-a)h^\Theta$ on test functions, with antiunitarity accounting for complex conjugation of the phase. The proper Lorentz identity follows in the same way from the covariance of C_{PCT} with the finite-dimensional spin representation. These identities extend from the dense domain to the Hilbert-space operators wherever the latter are bounded, and as domain identities for the unbounded field operators. □

2.8 Observable Subpresentations in Gauge Theories

A gauge construction enters the positive Hilbert-space Wightman framework through a specified observable sector. The object to verify is the following positive local field presentation.

Definition 2.7 (observable Wightman subpresentation)**.** Suppose a gauge construction supplies a positive physical Hilbert space $\mathcal{H}_{\mathrm{phys}}$, a vacuum vector Ω_{phys}, a unitary Poincare representation U_{phys}, a common dense domain $\mathcal{D}_{\mathrm{phys}}$, and a local net of physical von Neumann algebras $\mathcal{R}_{\mathrm{phys}}(\mathcal{O})$. A family of gauge-invariant local distributions $\{O_\gamma\}_{\gamma\in J}$ is an observable Wightman subpresentation if:

(i) each $O_\gamma(f)$, $f \in \mathcal{S}(M)$, is an operator on $\mathcal{D}_{\mathrm{phys}}$ and the map $f \mapsto O_\gamma(f)$ is a tempered operator-valued distribution;

(ii) the data $(\mathcal{H}_{\mathrm{phys}}, \Omega_{\mathrm{phys}}, U_{\mathrm{phys}}, \mathcal{D}_{\mathrm{phys}}, \{O_\gamma\})$, with its observable label adjunction and parities, satisfy Definition 2.1 on $\mathcal{H}_{\mathrm{phys}}$;

(iii) for every open region $\mathcal{O}$, all $O_\gamma(f)$ with $\operatorname{supp} f \subset \mathcal{O}$ are affiliated with $\mathcal{R}_{\mathrm{phys}}(\mathcal{O})$, and the local von Neumann algebra generated by their bounded functional calculi is the specified observable subnet under discussion.

In a BRST realization, the auxiliary space $\mathcal{K}$ carries an odd nilpotent operator Q and the physical Hilbert space is obtained, after the required completion and quotient by null vectors, from

$$\mathcal{H}_{\mathrm{phys}} = \ker Q \,/\, \overline{\operatorname{im} Q}.$$

A local auxiliary operator B descends to a physical local observable when it preserves $\ker Q$ and $\overline{\operatorname{im} Q}$; a sufficient algebraic condition on a common invariant domain is

$$[Q, B]_{\mathrm{gr}} = 0.$$

Operators differing by a graded commutator $[Q, C]_{\mathrm{gr}}$ induce the same operator on BRST cohomology, provided the same domain and closure hypotheses hold. The Wightman functions to which the reconstruction theorem applies are therefore the vacuum matrix elements of the descended observable fields $\{O_\gamma\}$ on $\mathcal{H}_{\mathrm{phys}}$; auxiliary representatives enter through their cohomology classes.

Thus the Wightman framework supplies precise theorems for local observable fields, spectral positivity, analytic continuation, and reconstruction. Its output is Hilbert-space QFT data with operator-valued distributions and a distinguished vacuum representation; comparison between gauges is a comparison of the resulting observable nets or observable Wightman subpresentations.

Chapter 3

Algebraic QFT: Local Nets and States

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter uses local nets as the invariant operator-algebraic object and treats fields, Euclidean measures, perturbative functionals, and gauge variables as different ways of presenting or constructing that object. The logical order matters. First one specifies an abstract C^*-net, before a state has selected a Hilbert-space representation and before weak operator closure has any meaning. A state then gives a represented von Neumann net by the GNS construction. Only after that represented bounded net is in place can one compare it with unbounded Wightman coordinates, field nets, gauge fixed-points, or constructive model estimates. Thus the chapter does not use "field" and "local algebra" as interchangeable words: the former is a coordinate presentation, while the latter is the bounded localization datum whose equality, duality, split, and sector properties have to be proved.

The proof obligations are staged accordingly. The free Weyl net is a direct bounded-algebra benchmark: locality, additivity, and the time-slice property are verified inside the C^*-net itself. The Wightman comparison is conditional: self-adjoint closures, spectral-projection locality, and operator-theoretic additivity are additional inputs needed to promote domain-level field relations into a represented local net. Gauge or charged coordinates introduce a second comparison, from a field net to the observable fixed-point or gauge-invariant subnet, where fixed points and additivity must be checked rather than inferred from the presence of neutral expressions. Constructive examples such as $P(\phi)_2$ and the Schwinger model are used as estimate-to-property checkpoints: they show which analytic estimates or exact bosonizations actually supply the bounded local net, and which stronger AQFT properties, such as nuclearity, split inclusions, Haag duality, and DHR reconstruction, remain separate theorem boundaries.

3.1 Local Observable Nets

Let $M = \mathbb{M}^D$ be Minkowski spacetime, and let $\mathcal{K}(M)$ be a chosen class of open spacetime regions, for example double cones or bounded causally complete regions. The connected Poincare group is denoted

$$\mathcal{P}_+^\uparrow = \mathbb{R}^D \rtimes SO^+(1, D-1).$$

If $\mathcal{O}_1, \mathcal{O}_2 \in \mathcal{K}(M)$, the notation $\mathcal{O}_1 \perp \mathcal{O}_2$ means that every point of $\mathcal{O}_1$ is spacelike separated from every point of $\mathcal{O}_2$. If $N \subset M$, $D(N)$ denotes its domain of dependence.

Definition 3.1 (Haag–Kastler C^*-net)**.** A Haag–Kastler C^*-net on M, indexed by $\mathcal{K}(M)$, consists of the following data.

(i) For each $\mathcal{O} \in \mathcal{K}(M)$, a unital C^*-algebra $\mathcal{A}(\mathcal{O})$.

(ii) For every inclusion $\mathcal{O}_1 \subset \mathcal{O}_2$, an injective unital $*$-homomorphism $\iota_{\mathcal{O}_2\mathcal{O}_1} : \mathcal{A}(\mathcal{O}_1) \to \mathcal{A}(\mathcal{O}_2)$ compatible with composition. After using these embeddings, we write $\mathcal{A}(\mathcal{O}_1) \subset \mathcal{A}(\mathcal{O}_2)$.

(iii) A strongly continuous action $g \mapsto \alpha_g$ of $\mathcal{P}_+^\uparrow$ by $*$-automorphisms of the quasilocal algebra

$$\mathcal{A}_{\mathrm{qloc}} = \overline{\bigcup_{\mathcal{O} \in \mathcal{K}(M)} \mathcal{A}(\mathcal{O})}^{\|\cdot\|}.$$

The data obey:

(HK1) *Isotony:* the inclusions are the embeddings in (ii).

(HK2) *Einstein causality:* if $\mathcal{O}_1 \perp \mathcal{O}_2$, then

$$[A, B] = 0, \qquad A \in \mathcal{A}(\mathcal{O}_1), \quad B \in \mathcal{A}(\mathcal{O}_2).$$

(HK3) *Poincare covariance:*

$$\alpha_g(\mathcal{A}(\mathcal{O})) = \mathcal{A}(g\mathcal{O}), \qquad g \in \mathcal{P}_+^\uparrow.$$

(HK4) *Time-slice property:* whenever $N \in \mathcal{K}(M)$ contains a Cauchy surface for $D(N)$ and $D(N) \in \mathcal{K}(M)$, the inclusion

$$\mathcal{A}(N) \longrightarrow \mathcal{A}(D(N))$$

is an isomorphism.

(HK5) *Additivity:* if $\mathcal{O} = \bigcup_i \mathcal{O}_i$ with $\mathcal{O}_i, \mathcal{O} \in \mathcal{K}(M)$, then $\mathcal{A}(\mathcal{O})$ is the C^*-subalgebra generated by the images of the $\mathcal{A}(\mathcal{O}_i)$.

The definition is the C^*-algebraic form of the Haag–Kastler locality framework [18]. Its axioms are stated here as data, not as a consequence of a field presentation; the relation to Wightman fields is a separate conditional construction below.

Throughout this chapter $\mathcal{A}(\mathcal{O})$ denotes the abstract C^*-local algebra generated by observables localized inside $\mathcal{O}$, before a Hilbert-space representation has been chosen. The norm closure in $\mathcal{A}_{\mathrm{qloc}}$ is part of the abstract C^*-algebraic presentation. Weak operator closures belong to represented von Neumann algebras and are introduced only after a state has selected a representation.

Figure 3.1 records the distinction made in this definition: the abstract local net assigns C^*-algebras to regions before any Hilbert-space state or weak operator closure has been chosen.

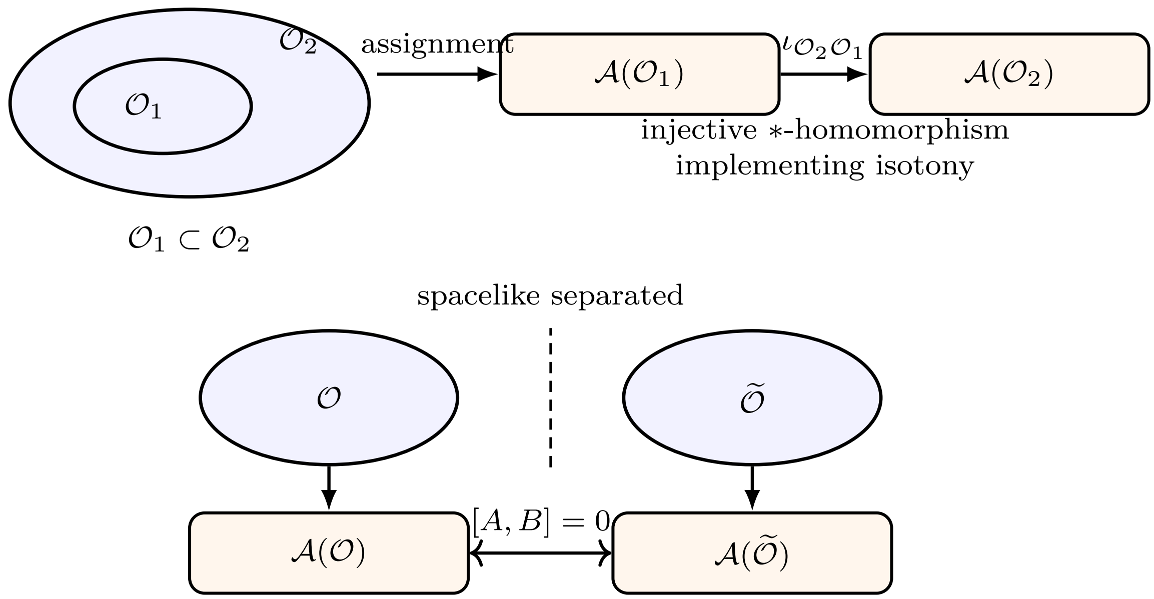

Figure 3.1: The local net is an isotone assignment from suitable spacetime regions to abstract C^*-algebras. Inclusion of regions is represented by the isotony morphism $\iota_{\mathcal{O}_2\mathcal{O}_1}$, while spacelike separation is represented algebraically by commutation of the corresponding observable algebras.

Benchmark model: the massive scalar Weyl net. Before entering perturbative or constructive interacting examples, it is useful to have one completely explicit local net in view. Let

$$P_m = \partial^\mu \partial_\mu - m^2$$

be the mostly-plus Klein–Gordon operator on $M = \mathbb{M}^D$, with $m > 0$, and let

$$\Delta_m^{\mathrm{ret}}, \qquad \Delta_m^{\mathrm{adv}}$$

be the retarded and advanced fundamental solutions:

$$P_m \Delta_m^{\mathrm{ret/adv}} f = f, \qquad \Delta_m^{\mathrm{ret/adv}} P_m f = f, \qquad \operatorname{supp} \Delta_m^{\mathrm{ret/adv}} f \subset J^\pm(\operatorname{supp} f)$$

for every $f \in C_c^\infty(M;\mathbb{R})$. The causal propagator is

$$\Delta_m = \Delta_m^{\mathrm{ret}} - \Delta_m^{\mathrm{adv}}.$$

Green hyperbolicity gives the exact sequence

$$C_c^\infty(M;\mathbb{R}) \xrightarrow{P_m} C_c^\infty(M;\mathbb{R}) \xrightarrow{\Delta_m} C_{\mathrm{sc}}^\infty(M;\mathbb{R}),$$

where C^∞_{sc} denotes smooth solutions with spatially compact support. Exactness at the middle term says

$$\ker \Delta_m = P_m C^\infty_c(M;\mathbb{R}).$$

Thus the real vector space

$$\mathsf{V}_m := C^\infty_c(M;\mathbb{R})\big/P_m C^\infty_c(M;\mathbb{R}) \tag{3.1}$$

is the test-function coordinatization of the classical solution space. For $[f],[g] \in \mathsf{V}_m$ define

$$\sigma_m([f],[g]) = \int_M f(x)\,(\Delta_m g)(x)\,\mathrm{d}^D x. \tag{3.2}$$

This is well defined because P_m is formally self-adjoint and $P_m\Delta_m = \Delta_m P_m = 0$ on test functions. It is antisymmetric since $\Delta_m(x,y) = -\Delta_m(y,x)$. It is nondegenerate on the quotient: if $\sigma_m([f],[g]) = 0$ for all g, then the distribution $\Delta_m f$ pairs trivially with all compactly supported test functions, so $\Delta_m f = 0$, hence $f \in P_m C^\infty_c(M;\mathbb{R})$ by exactness.

The Weyl C^*-algebra

$$\mathfrak{W}(\mathsf{V}_m, \sigma_m)$$

is the universal C^*-algebra generated by symbols $W(u)$, $u \in \mathsf{V}_m$, subject to

$$W(0) = 1, \qquad W(u)^* = W(-u), \qquad W(u)W(v) = \mathrm{e}^{-\frac{\mathrm{i}}{2}\sigma_m(u,v)}W(u+v). \tag{3.3}$$

The sign in (3.3) matches the field normalization of Volume I: if $W([f]) = \exp(\mathrm{i}\widehat{\phi}(f))$ in the Fock representation, then

$$[\widehat{\phi}(f), \widehat{\phi}(g)] = \mathrm{i}\sigma_m([f],[g])\,1,$$

and the Baker–Campbell–Hausdorff formula gives the displayed Weyl relation. For an open region $\mathcal{O}$, let

$$\mathsf{V}_m(\mathcal{O}) = \mathrm{image}\big(C^\infty_c(\mathcal{O};\mathbb{R}) \longrightarrow \mathsf{V}_m\big),$$

and define

$$\mathcal{A}_m(\mathcal{O}) = C^*\big(W(u) \mid u \in \mathsf{V}_m(\mathcal{O})\big) \subset \mathfrak{W}(\mathsf{V}_m, \sigma_m). \tag{3.4}$$

The Haag–Kastler properties can now be checked without appealing to unbounded fields. Isotony follows immediately from $C^\infty_c(\mathcal{O}_1) \subset C^\infty_c(\mathcal{O}_2)$. If $\mathcal{O}_1 \perp \mathcal{O}_2$, then $\operatorname{supp}\Delta_m g \subset J(\operatorname{supp} g)$ is disjoint from $\operatorname{supp} f$ for $f \in C^\infty_c(\mathcal{O}_1)$, $g \in C^\infty_c(\mathcal{O}_2)$. Hence $\sigma_m([f],[g]) = 0$, and the Weyl relations give

$$W([f])W([g]) = W([g])W([f]).$$

Since the local algebras are C^*-closures of the algebras generated by such Weyl elements, spacelike separated local algebras commute. Poincare covariance is induced by

$$\alpha_g\big(W([f])\big) = W([f \circ g^{-1}]), \qquad g \in \mathcal{P}^\uparrow_+,$$

where g acts on test functions by pullback. The covariance of P_m, $\Delta_m^{\mathrm{ret/adv}}$, and the volume form preserves the quotient and the symplectic form.

Additivity follows from compact support. Suppose $\mathcal{O} = \bigcup_i \mathcal{O}_i$, and let $f \in C^\infty_c(\mathcal{O};\mathbb{R})$. The compact set $\operatorname{supp} f$ is covered by finitely many $\mathcal{O}_i$'s. Choose a smooth partition of unity $\{\rho_j\}_{j=1}^r$ subordinate to this finite cover on a neighborhood of $\operatorname{supp} f$. Then

$$f = \sum_{j=1}^r f_j, \qquad f_j = \rho_j f, \qquad \operatorname{supp} f_j \subset \mathcal{O}_{i_j}.$$

In $\mathsf{V}_m(\mathcal{O})$ this gives $[f] = \sum_j [f_j]$. Iterating the Weyl relation (3.3) expresses $W([f])$, up to an explicit phase determined by the pairings $\sigma_m([f_j],[f_k])$, as a product of the $W([f_j])$'s. Hence every generator of $\mathcal{A}_m(\mathcal{O})$ belongs to the C^*-algebra generated by the $\mathcal{A}_m(\mathcal{O}_i)$'s, and the opposite inclusion is isotony. The phase just mentioned is not an additional analytic hypothesis. In any finite-dimensional symplectic vector space $(V_{\mathrm{fin}}, \sigma)$ with Weyl relations

$$W(u)W(v) = \exp\left(-\frac{\mathrm{i}}{2}\sigma(u,v)\right) W(u+v),$$

one has

$$W(u)W(v) = \exp[-\mathrm{i}\sigma(u,v)]\, W(v)W(u), \qquad W(u)W(v)W(u)^*W(v)^* = \exp[-\mathrm{i}\sigma(u,v)]\, 1.$$

Thus vanishing of the symplectic pairing is exactly the finite algebraic mechanism behind local commutation. Likewise, for a finite decomposition $u = \sum_{j=1}^r u_j$,

$$W(u) = \exp\left(\frac{\mathrm{i}}{2} \sum_{1\le j<k\le r} \sigma(u_j, u_k)\right) W(u_1)\cdots W(u_r).$$

The continuum additivity proof above supplies the support-theoretic decomposition $[f] = \sum_j [f_j]$ in the Green-hyperbolic quotient; the displayed finite cocycle identity is the bounded-algebra step that converts that decomposition into containment of local C^*-algebras.

The time-slice property is the only axiom in this model that uses a real hyperbolic argument. Let $U = D(N)$, and assume the chosen region class is regular enough that $N \subset U$ contains a Cauchy-surface collar: there is a smooth Cauchy time function τ on U and numbers $\tau_- < \tau_+$ for which $\tau^{-1}([\tau_-,\tau_+]) \subset N$. Choose $\chi \in C^\infty(U)$ with $\chi = 0$ for $\tau < \tau_-$ and $\chi = 1$ for $\tau > \tau_+$. For $f \in C_c^\infty(U;\mathbb{R})$, set

$$\varphi = \Delta_m f, \qquad f_N = P_m(\chi\varphi).$$

Because $P_m\varphi = 0$, the support of f_N lies where derivatives of χ are nonzero, hence in N. To compare the quotient classes, note that $\chi\varphi$ vanishes in the far past and solves

$$P_m(\chi\varphi) = f_N;$$

by uniqueness of the retarded solution it is $\Delta_m^{\mathrm{ret}} f_N$. Likewise $(\chi - 1)\varphi$ vanishes in the far future and solves

$$P_m\big((\chi-1)\varphi\big) = f_N;$$

by uniqueness of the advanced solution it is $\Delta_m^{\mathrm{adv}} f_N$. Therefore

$$\Delta_m f_N = \Delta_m^{\mathrm{ret}} f_N - \Delta_m^{\mathrm{adv}} f_N = \chi\varphi - (\chi-1)\varphi = \varphi = \Delta_m f.$$

Exactness of the Green-hyperbolic sequence then gives $[f] = [f_N]$ in the quotient associated with U. Since $\mathsf{V}_m(N)$ and $\mathsf{V}_m(U)$ were defined as image subspaces of the global quotient, this proves equality of image subspaces,

$$\mathsf{V}_m(N) = \mathsf{V}_m(U).$$

The generated Weyl algebras are therefore identical:

$$\mathcal{A}_m(N) = \mathcal{A}_m(D(N)).$$

The usual vacuum representation is a state on this abstract net, not part of the net definition. The positive-frequency two-point distribution Δ_+ defines a real covariance

$$\mu_m([f],[g]) = \mathrm{Re}\int_{M\times M} f(x)\Delta_+(x-y)g(y)\,\mathrm{d}^D x\,\mathrm{d}^D y$$

satisfying

$$|\sigma_m(u,v)|^2 \le 4\,\mu_m(u,u)\mu_m(v,v).$$

Consequently

$$\omega_0(W(u)) = \exp\left[-\frac{1}{2}\mu_m(u,u)\right]$$

is a regular quasi-free state, and its GNS representation is the scalar Fock representation. This final step illustrates the structural separation: $\mathcal{O} \mapsto \mathcal{A}_m(\mathcal{O})$ is the abstract observable net, while $(\mathcal{H}_{\omega_0}, \pi_{\omega_0}, \Omega_{\omega_0})$ is selected only after a state is chosen.

3.2 Perturbative Algebraic QFT and Interacting Examples

Perturbative algebraic QFT is the framework in which Epstein–Glaser causal renormalization, local time-ordered products, and algebraic locality are put in the same language. Its algebras are formal power series in the interaction and in $\hbar$; at every fixed formal order the locality and renormalization statements are statements about distributions and their extensions.

Definition 3.2 (Microcausal functionals and the BDF star product)**.** For a scalar field on a globally hyperbolic spacetime M, let $\mathcal{E} = C^\infty(M)$ be the classical configuration space. A smooth functional $F : \mathcal{E} \to \mathbb{C}$ belongs to $\mathcal{F}_{\mu c}$, the space of microcausal functionals, if every functional derivative $F^{(n)}(\varphi)$ is a compactly supported distribution on M^n and

$$\mathrm{WF}\big(F^{(n)}(\varphi)\big) \cap \big(\overline{V}^n_+ \cup \overline{V}^n_-\big) = \emptyset. \tag{3.5}$$

Here $\overline{V}^n_\pm$ is the set of n-tuples of nonzero covectors all lying in the closed future or all lying in the closed past light cone. If $H(x,y)$ is a Hadamard bidistribution for the free theory, the Brunetti–Duetsch–Fredenhagen product is

$$F \star_H G = m \circ \exp\left[\hbar \int_{M^2} H(x,y)\frac{\delta}{\delta\varphi(x)} \otimes \frac{\delta}{\delta\varphi(y)}\,\mathrm{d}x\,\mathrm{d}y\right](F\otimes G), \tag{3.6}$$

where $m(F\otimes G)(\varphi) = F(\varphi)G(\varphi)$. The exponential is expanded as a formal power series and every term is defined by the Hörmander wavefront-set product criterion applied to (3.5) and the Hadamard wavefront set of H.

Peierls bracket from the pAQFT star commutator. Assume that the antisymmetric part of H is $(\mathrm{i}/2)\Delta$, where Δ is the causal propagator of the free equation of motion. For regular functionals, and then by the microcausal extension wherever the products are defined,

$$[F,G]_{\star_H} = \mathrm{i}\hbar\,\{F,G\}_{\text{Peierls}} + O(\hbar^2). \tag{3.7}$$

The order-$\hbar$ part of (3.6) is

$$\hbar \int_{M^2} H(x,y)\frac{\delta F}{\delta\varphi(x)}\frac{\delta G}{\delta\varphi(y)}\,\mathrm{d}x\,\mathrm{d}y.$$

Subtracting the same expression with F and G interchanged replaces $H(x,y)$ by $H(x,y) - H(y,x) = \mathrm{i}\Delta(x,y)$. The resulting bilinear form is exactly $\mathrm{i}\hbar\{F,G\}_{\mathrm{Peierls}}$ in the free theory. Higher terms in the exponential contribute $O(\hbar^2)$.

Proposition 3.3 (Perturbative interacting local net)**.** *Let $T_n : \mathcal{F}_{\mathrm{loc}}^{\otimes n} \to \mathcal{F}_{\mu c}$ be Epstein–Glaser time-ordered products satisfying symmetry, covariance, microlocal spectrum bounds, unitarity, field independence, and causal factorization. Define*

$$\mathcal{S}(F) = 1 + \sum_{n\geq 1} \frac{\mathrm{i}^n}{\hbar^n n!} T_n(F^{\otimes n}).$$

Causal factorization is the identity

$$\mathcal{S}(F+G) = \mathcal{S}(F) \star_H \mathcal{S}(G) \quad \textit{if} \quad \operatorname{supp} F \cap J^-(\operatorname{supp} G) = \emptyset. \tag{3.8}$$

We shall also use its three-functional form

$$\mathcal{S}(F+G+H) = \mathcal{S}(F+G) \star_H \mathcal{S}(G)^{-1}_{\star_H} \star_H \mathcal{S}(G+H), \qquad \operatorname{supp} F \cap J^-(\operatorname{supp} H) = \emptyset, \tag{3.9}$$

which is part of the causal-factorization axiom for the formal S-matrix. For an interaction functional V, set

$$\mathcal{S}_V(F) := \mathcal{S}(V)^{-1}_{\star_H} \star_H \mathcal{S}(V+F), \tag{3.10}$$

where the inverse is taken in the completed formal $\star_H$-algebra. Let $\mathfrak{A}_V^{\mathrm{pert}}(\mathcal{O})$ be the formal $*$-algebra generated by $\mathcal{S}_V(F)$ with $\operatorname{supp} F \subset \mathcal{O}$, modulo the causal-factorization relations and the time-slice ideal. Then

$$\mathcal{O} \longmapsto \mathfrak{A}_V^{\mathrm{pert}}(\mathcal{O})$$

is an isotonic, time-slice local net of formal algebras. Covariance has the following precise form: a spacetime symmetry g sends $\mathfrak{A}_V^{\mathrm{pert}}(\mathcal{O})$ to $\mathfrak{A}_{gV}^{\mathrm{pert}}(g\mathcal{O})$; if V is invariant under the symmetry, this is covariance of a single net. Locality means that generators with spacelike separated supports commute.

Proof. The formal inverse in (3.10) exists because $\mathcal{S}(V) = 1 + O(V)$ in the completed formal algebra. The net maps for inclusions are the homomorphisms induced by the identity on generators: if $\mathcal{O}_1 \subset \mathcal{O}_2$, every generator with support in $\mathcal{O}_1$ is also one with support in $\mathcal{O}_2$, and the relations imposed in the smaller algebra are restrictions of the relations imposed in the larger algebra. This proves isotony. The time-slice property is exactly the quotient by the time-slice ideal: if $\mathcal{N} \subset \mathcal{O}$ contains a Cauchy surface for $\mathcal{O}$, the ideal identifies the generators in $\mathcal{O}$ with the algebra generated by representatives supported in $\mathcal{N}$, using the free equation of motion and causal propagation in the Epstein–Glaser construction.

For covariance, let g be a spacetime symmetry preserving the background data used in H. Covariance of the time-ordered products gives

$$\alpha_g(\mathcal{S}(F)) = \mathcal{S}(gF), \qquad \alpha_g(A \star_H B) = \alpha_g(A) \star_H \alpha_g(B),$$

where gF is the pushforward of the local functional. Applying this to (3.10) gives

$$\alpha_g\big(\mathcal{S}_V(F)\big) = \mathcal{S}_{gV}(gF), \qquad \operatorname{supp}(gF) = g(\operatorname{supp} F).$$

Thus g sends the algebra of $\mathcal{O}$ for V to the algebra of $g\mathcal{O}$ for the transformed interaction gV. If $gV = V$, this is a covariance automorphism of the same net.

It remains to prove locality. We first record the relative causal factorization identity. If

$$\operatorname{supp} F \cap J^-(\operatorname{supp} G) = \emptyset,$$

then (3.9), applied with the interaction V as the middle functional, gives

$$\mathcal{S}(V + F + G) = \mathcal{S}(V + F) \star_H \mathcal{S}(V)^{-1}_{\star_H} \star_H \mathcal{S}(V + G).$$

Multiplying on the left by $\mathcal{S}(V)^{-1}_{\star_H}$ yields

$$\mathcal{S}_V(F + G) = \mathcal{S}_V(F) \star_H \mathcal{S}_V(G). \tag{3.11}$$

For spacelike separated supports both causal orderings are allowed:

$$\operatorname{supp} F \cap J^-(\operatorname{supp} G) = \emptyset, \qquad \operatorname{supp} G \cap J^-(\operatorname{supp} F) = \emptyset.$$

Using (3.11) in the two orders and using symmetry of the time-ordered products, $\mathcal{S}_V(F + G) = \mathcal{S}_V(G + F)$, gives

$$\mathcal{S}_V(F) \star_H \mathcal{S}_V(G) = \mathcal{S}_V(G) \star_H \mathcal{S}_V(F).$$

Since the generators of $\mathfrak{A}^{\mathrm{pert}}_V(\mathcal{O}_1)$ and $\mathfrak{A}^{\mathrm{pert}}_V(\mathcal{O}_2)$ are of this form, and the quotient relations are compatible with $\star_H$, this proves the locality relation for spacelike separated regions. $\square$

Renormalization in this framework is the freedom in extending T_n to the diagonals. The ambiguity is local: two choices are related by a Stueckelberg–Petermann redefinition of the interaction by local functionals and their derivatives. For gauge theory the same construction must be combined with the BV complex and the quantum master equation; the physical perturbative algebra is then the BRST/BV cohomology of the interacting algebra. These facts make perturbative AQFT a natural mathematical home for local counterterms, contact terms, and gauge-theoretic Ward identities. It will not be treated only as a dictionary between path integrals and local nets. Later chapters must develop the perturbative algebra itself: the classification of time-ordered-product extensions, the renormalization group as the Stueckelberg–Petermann group, interacting fields by Bogoliubov's formula, the time-slice axiom in perturbation theory, BV cohomology for gauge theories, and the relation between these constructions and the 1PI and Wilsonian effective actions.

The algebraic formulation must also be developed through substantial interacting examples. A persistent weakness of much abstract AQFT literature is that the axioms, sector theory, and local-algebra technology are developed with too few nontrivial models in view. In this monograph, whenever an interacting construction is available or partially available, the associated algebraic questions should be asked explicitly: what are the local algebras or formal local algebras, what is the state space, which sectors are present, how does scattering or infraparticle structure appear, how are scaling limits and operator product structures represented, and which steps are theorem-level rather than expected structure? Constructive scalar models, perturbatively constructed Epstein–Glaser/pAQFT models, factorizing two-dimensional models, lattice-continuum scaling limits, conformal nets, and gauge theories with BRST/BV control are therefore not examples after the axioms; they are part of the theory development and tests of whether the algebraic formulation captures the physics it is meant to organize.

The purpose of including this material is not only to collect known constructions. The comparison among Wightman, Euclidean, Wilsonian, perturbative algebraic, BV, and operator-algebraic formulations exposes genuine gaps: gauge-theory local nets beyond perturbation theory, charged sectors requiring nonlocal dressing, infraparticle scattering, contact-term control in deformations, and the passage from constructive or lattice scaling limits to detailed algebraic data. These gaps should be formulated as precise mathematical and physical problems and, where feasible, developed within the monograph itself. Existing results supply boundary conditions for this development; they are not the endpoint of the project. No axiomatic framework is taken here as sacred or final. A framework earns its place by clarifying nontrivial physics and the mathematics behind it: which observables are defined, which limits exist, which locality and positivity statements are actually proven, how sectors and scattering are encoded, and where the formulation fails to see structures that are physically present. The comparison of frameworks is therefore part of the subject matter, not a preliminary choice of doctrine.

3.3 States and GNS Representations

Definition 3.4 (State on a C^*-algebra)**.** A state on a unital C^*-algebra $\mathcal{A}$ is a linear functional

$$\omega : \mathcal{A} \to \mathbb{C}$$

such that

$$\omega(A^*A) \geq 0, \qquad \omega(1) = 1.$$

The source trace for the operator-algebra form of the construction used here is the Gelfand–Naimark representation theorem together with Segal's state-to-representation construction [20, 21]; Takesaki's account is the modular-theory reference used later in this volume [26].

Theorem 3.5 (Gelfand–Naimark–Segal construction)**.** *Let ω be a state on a unital C^*-algebra $\mathcal{A}$. There are a Hilbert space $\mathcal{H}_\omega$, a unital $*$-representation $\pi_\omega : \mathcal{A} \to B(\mathcal{H}_\omega)$, and a cyclic unit vector $\Omega_\omega \in \mathcal{H}_\omega$ such that*

$$\omega(A) = \langle \Omega_\omega, \pi_\omega(A)\Omega_\omega \rangle_\omega, \qquad A \in \mathcal{A}. \tag{3.12}$$

If $(\mathcal{H}', \pi', \Omega')$ is another cyclic representation satisfying (3.12), there is a unique unitary $W : \mathcal{H}_\omega \to \mathcal{H}'$ with

$$W\Omega_\omega = \Omega', \qquad W\pi_\omega(A) = \pi'(A)W.$$

Proof. Let

$$\mathcal{N}_\omega = \{A \in \mathcal{A} \mid \omega(A^*A) = 0\}.$$

The positivity of ω gives the Cauchy–Schwarz inequality

$$|\omega(C^*D)|^2 \leq \omega(C^*C)\,\omega(D^*D), \qquad C, D \in \mathcal{A}.$$

Hence $C \in \mathcal{N}_\omega$ implies $\omega(C^*D) = \omega(D^*C) = 0$ for all $D \in \mathcal{A}$, so $\mathcal{N}_\omega$ is a linear subspace. It is also a left ideal. If $C \in \mathcal{N}_\omega$ and $A \in \mathcal{A}$, then the C^*-algebra order inequality $0 \leq A^*A \leq \|A\|^2 1$ gives

$$0 \leq \omega((AC)^*(AC)) = \omega(C^*A^*AC) \leq \|A\|^2 \omega(C^*C) = 0.$$

Thus $AC \in \mathcal{N}_\omega$. The quotient $\mathcal{A}/\mathcal{N}_\omega$ therefore has the well-defined inner product

$$\langle [A], [B] \rangle_\omega = \omega(A^* B).$$

Let $\mathcal{H}_\omega$ be its completion. Define

$$\pi_\omega(A)[B] = [AB], \qquad \Omega_\omega = [1].$$

The representation is well-defined because $\mathcal{N}_\omega$ is a left ideal, and

$$\|\pi_\omega(A)[B]\|_\omega^2 = \omega(B^* A^* AB) \le \|A\|^2 \omega(B^* B),$$

so $\pi_\omega(A)$ extends to a bounded operator on $\mathcal{H}_\omega$. Equation (3.12) follows from the definition of the inner product, and Ω_ω is cyclic because $\pi_\omega(\mathcal{A})\Omega_\omega$ contains all quotient classes $[A]$.

For uniqueness, define W on the dense subspace $\pi_\omega(\mathcal{A})\Omega_\omega$ by

$$W \pi_\omega(A)\Omega_\omega = \pi'(A)\Omega'.$$

This is well-defined and isometric because both cyclic vector states equal ω:

$$\langle \pi_\omega(A)\Omega_\omega, \pi_\omega(B)\Omega_\omega \rangle = \omega(A^* B) = \langle \pi'(A)\Omega', \pi'(B)\Omega' \rangle.$$

Cyclicity of Ω' makes the range dense, hence W extends to a unitary. The intertwining identity and $W\Omega_\omega = \Omega'$ follow on the dense cyclic subspace. $\square$

Figure 3.2 summarizes the GNS construction: a state defines the null ideal, the quotient pre-Hilbert space, the cyclic vector, and the represented algebra, uniquely up to unitary equivalence.

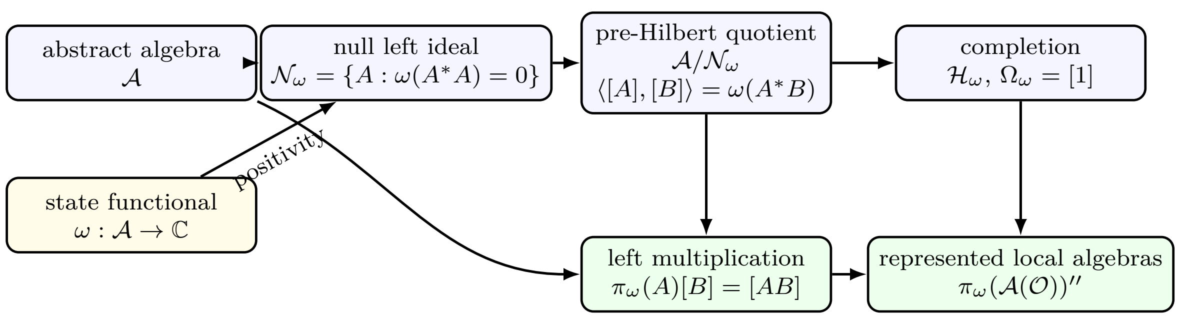

Figure 3.2: The GNS representation is obtained by quotienting the abstract algebra by the null ideal determined by the state, completing the resulting inner-product space, and representing the algebra by left multiplication. Local C^*-algebras become represented von Neumann algebras only after this state-dependent Hilbert space has been constructed.

3.4 Vacuum Representations

Definition 3.6 (Vacuum state and represented vacuum net)**.** Let $\mathcal{O} \mapsto \mathcal{A}(\mathcal{O})$ be a Poincare-covariant Haag–Kastler C^*-net. A state ω_0 on $\mathcal{A}_{\text{qloc}}$ is a vacuum state when:

(i) ω_0 is Poincare invariant:

$$\omega_0(\alpha_g(A)) = \omega_0(A), \qquad A \in \mathcal{A}_{\mathrm{qloc}}, \quad g \in \mathcal{P}_+^{\uparrow};$$

(ii) in the GNS representation $(\mathcal{H}_{\omega_0}, \pi_{\omega_0}, \Omega_{\omega_0})$, translations are implemented by a strongly continuous unitary representation whose joint spectrum lies in $\overline{V}_+$;

(iii) Ω_{ω_0} is the unique invariant vector up to phase.

The represented von Neumann local algebra of a region is

$$\mathcal{R}_{\omega_0}(\mathcal{O}) = \pi_{\omega_0}(\mathcal{A}(\mathcal{O}))''.$$

The double commutant indicates weak operator closure.

Proposition 3.7 (Unitary implementation of an invariant state)**.** *Let ω_0 be invariant under $\mathcal{P}_+^{\uparrow}$. In its GNS representation there is a unique strongly continuous unitary representation U_{ω_0} of $\mathcal{P}_+^{\uparrow}$ satisfying*

$$U_{\omega_0}(g)\pi_{\omega_0}(A)U_{\omega_0}(g)^{-1} = \pi_{\omega_0}(\alpha_g(A)), \qquad U_{\omega_0}(g)\Omega_{\omega_0} = \Omega_{\omega_0}. \tag{3.13}$$

Proof. On the algebraic cyclic subspace $\mathcal{D}_0 = \pi_{\omega_0}(\mathcal{A}_{\mathrm{qloc}})\Omega_{\omega_0}$, define

$$U_{\omega_0}(g)\pi_{\omega_0}(A)\Omega_{\omega_0} = \pi_{\omega_0}(\alpha_g(A))\Omega_{\omega_0}.$$

This is well defined on the GNS quotient. If $\pi_{\omega_0}(A)\Omega_{\omega_0} = 0$, then $\omega_0(A^*A) = 0$; invariance gives

$$\omega_0(\alpha_g(A)^*\alpha_g(A)) = \omega_0(\alpha_g(A^*A)) = \omega_0(A^*A) = 0,$$

so $\pi_{\omega_0}(\alpha_g(A))\Omega_{\omega_0} = 0$. The same calculation shows preservation of inner products:

$$\langle \pi_{\omega_0}(\alpha_g(A))\Omega_{\omega_0}, \pi_{\omega_0}(\alpha_g(B))\Omega_{\omega_0}\rangle = \omega_0(\alpha_g(A^*B)) = \omega_0(A^*B).$$

Thus $U_{\omega_0}(g)$ extends from $\mathcal{D}_0$ to an isometry on $\mathcal{H}_{\omega_0}$. Applying the same construction to g^{-1} gives the inverse isometry, so $U_{\omega_0}(g)$ is unitary. The group law holds on $\mathcal{D}_0$:

$$U_{\omega_0}(g)U_{\omega_0}(h)\pi_{\omega_0}(A)\Omega_{\omega_0} = \pi_{\omega_0}(\alpha_{gh}(A))\Omega_{\omega_0},$$

and hence holds on the Hilbert-space completion. The covariance relation in (3.13) is checked on $\mathcal{D}_0$ and extended by boundedness.

For strong continuity, it is enough to test vectors in the dense $\mathcal{D}_0$, uniformly boundedness then extends the result to all vectors. For $A \in \mathcal{A}_{\mathrm{qloc}}$,

$$\|U_{\omega_0}(g)\pi_{\omega_0}(A)\Omega_{\omega_0} - \pi_{\omega_0}(A)\Omega_{\omega_0}\|^2 = \omega_0\left((\alpha_g(A) - A)^*(\alpha_g(A) - A)\right),$$

which tends to zero by the assumed strong continuity of the automorphic action in the GNS norm. Finally, if a unitary representation satisfying (3.13) and fixing Ω_{ω_0} exists, its value on every vector $\pi_{\omega_0}(A)\Omega_{\omega_0}$ is forced by the covariance relation; density gives uniqueness. $\square$

When the vacuum representation is fixed, we write $\mathcal{R}(\mathcal{O})$ for $\mathcal{R}_{\omega_0}(\mathcal{O})$. Thus, in the remainder of this chapter, $\mathcal{A}(\mathcal{O})$ denotes the abstract local C^*-algebra, whereas $\mathcal{R}(\mathcal{O})$ denotes its vacuum-representation von Neumann completion $\pi_{\omega_0}(\mathcal{A}(\mathcal{O}))''$. These are related by the chosen representation and are distinct mathematical objects.

3.5 Correlation Functions in a Representation

The algebraic presentation produces correlation functions once a state and a representation have been chosen. If

$$A_j \in \mathcal{A}(\mathcal{O}_j), \qquad j = 1, \ldots, n,$$

are bounded local observables, their vacuum correlation function is

$$\omega_0(A_1 \cdots A_n) = \langle \Omega_{\omega_0}, \pi_{\omega_0}(A_1) \cdots \pi_{\omega_0}(A_n)\Omega_{\omega_0} \rangle.$$

Covariance gives spacetime dependence by translating the local observables:

$$A_j(x_j) = \alpha_{x_j}(A_j).$$

Thus bounded local observables give well-defined functions or distributions after smearing in the spacetime parameters x_j, depending on the continuity and phase-space properties imposed on the net.

Point fields require additional structure. A field $\Phi(f)$ localized in $\mathcal{O}$ should be affiliated with the represented algebra $\mathcal{R}(\mathcal{O})$, or should arise as a limit of bounded local observables in a topology specified by the construction. When this is available, the Wightman distributions are recovered as vacuum matrix elements of these affiliated unbounded operators. The algebraic net therefore supplies the local observable content, while field coordinatizations specify distributional generators for that content.

3.6 Haag Duality and the Dual Net

Definition 3.8 (Causal complement and Haag duality)**.** For a represented net, the causal complement of a region $\mathcal{O}$ is

$$\mathcal{O}^\perp = \{x \in M : \ (x-y)^2 > 0 \text{ for all } y \in \mathcal{O}\}.$$

The net satisfies Haag duality for $\mathcal{O}$ if

$$\mathcal{R}(\mathcal{O}) = \mathcal{R}(\mathcal{O}^\perp)'. \tag{3.14}$$

It says that every bounded operator commuting with all observables localized outside $\mathcal{O}$ is already generated by observables localized in $\mathcal{O}$.

Let $\mathcal{R}$ be a local represented net indexed by causally complete regions, so $\mathcal{O} = \mathcal{O}^{\perp\perp}$. Define

$$\mathcal{R}^d(\mathcal{O}) := \mathcal{R}(\mathcal{O}^\perp)'.$$

Then $\mathcal{R}^d$ is isotonic and

$$\mathcal{R}(\mathcal{O}) \subset \mathcal{R}^d(\mathcal{O}).$$

The equality $\mathcal{R} = \mathcal{R}^d$ is precisely Haag duality. The locality of $\mathcal{R}^d$ is an additional property, often called essential duality. Einstein causality gives

$$\mathcal{R}(\mathcal{O}) \subset \mathcal{R}(\mathcal{O}^\perp)' = \mathcal{R}^d(\mathcal{O}).$$

If $\mathcal{O}_1 \subset \mathcal{O}_2$, then $\mathcal{O}_2^\perp \subset \mathcal{O}_1^\perp$, hence $\mathcal{R}(\mathcal{O}_2^\perp) \subset \mathcal{R}(\mathcal{O}_1^\perp)$. Taking commutants reverses the inclusion and gives $\mathcal{R}^d(\mathcal{O}_1) \subset \mathcal{R}^d(\mathcal{O}_2)$. This is isotony.

The inclusion $\mathcal{R} \subset \mathcal{R}^d$ measures the possible gap between the chosen local observable generators and the maximal algebra determined by causal commutation. In superselection theory, Haag duality is the condition that permits localized representations to be represented cleanly by localized endomorphisms of the observable algebra.

Dual-net algebra. The algebra $\mathcal{R}^d(\mathcal{O})$ is the algebra detected by all causal-commutation tests outside $\mathcal{O}$. Thus an operator $T \in B(\mathcal{H})$ belongs to $\mathcal{R}^d(\mathcal{O})$ precisely when

$$[T, B] = 0, \qquad B \in \mathcal{R}(\mathcal{O}^\perp).$$

This criterion is intrinsic to the represented net, but it is weaker than membership in the originally assigned algebra $\mathcal{R}(\mathcal{O})$ unless Haag duality has been established. The dual net is therefore not a decorative reformulation of locality. It records the maximal bounded operator algebra which the exterior observables cannot distinguish from a local operator in $\mathcal{O}$.

Two elementary consequences are used repeatedly later. First, if $\mathcal{O}_1 \subset \mathcal{O}_2$, then

$$\mathcal{R}^d(\mathcal{O}_1) = \mathcal{R}(\mathcal{O}_1^\perp)' \subset \mathcal{R}(\mathcal{O}_2^\perp)' = \mathcal{R}^d(\mathcal{O}_2),$$

so the dual assignment is isotonic. Second, if $A \in \mathcal{R}(\mathcal{O})$ then locality gives

$$[A, B] = 0, \qquad B \in \mathcal{R}(\mathcal{O}^\perp),$$

hence $A \in \mathcal{R}^d(\mathcal{O})$. Haag duality is exactly the assertion that these two tests are equivalent for the chosen represented net.

Load-bearing use in localized sectors. Let ρ be a normal endomorphism of the represented quasilocal von Neumann algebra which is localized in a causally complete region $\mathcal{O}_0$, in the sense that

$$\rho(B) = B, \qquad B \in \mathcal{R}(\mathcal{O}_0^\perp).$$

Let $\mathcal{O}_1$ be causally complete with $\mathcal{O}_0 \subset \mathcal{O}_1$. For $A \in \mathcal{R}(\mathcal{O}_1)$ and $B \in \mathcal{R}(\mathcal{O}_1^\perp)$, one has $\mathcal{O}_1^\perp \subset \mathcal{O}_0^\perp$, so $\rho(B) = B$. Since A and B commute,

$$\rho(A)B = \rho(A)\rho(B) = \rho(AB) = \rho(BA) = \rho(B)\rho(A) = B\rho(A).$$

Therefore

$$\rho(A) \in \mathcal{R}(\mathcal{O}_1^\perp)' = \mathcal{R}^d(\mathcal{O}_1).$$

If Haag duality holds for $\mathcal{O}_1$, this improves to

$$\rho(\mathcal{R}(\mathcal{O}_1)) \subset \mathcal{R}(\mathcal{O}_1).$$

This is the concrete algebraic step behind the DHR passage from a sector that is indistinguishable from the vacuum outside $\mathcal{O}_0$ to an endomorphism of the local observable net. Without the equality $\mathcal{R} = \mathcal{R}^d$, the same calculation gives an endomorphism into the dual net; additional input is then required to identify that image with the originally specified observable algebra.

The same point controls intertwiners. If ρ and σ are localized in $\mathcal{O}$ and T satisfies

$$T\rho(A) = \sigma(A)T$$

for all quasilocal A, then for every $B \in \mathcal{R}(\mathcal{O}^\perp)$,

$$TB = T\rho(B) = \sigma(B)T = BT.$$

Thus $T \in \mathcal{R}^d(\mathcal{O})$, and Haag duality is precisely what places the intertwiner in the local algebra $\mathcal{R}(\mathcal{O})$. The tensor-category construction of bounded localized charges therefore uses Haag duality as a structural hypothesis, not as a terminology choice.

3.7 Point Fields as Coordinatizations

If a Wightman field $\Phi(f)$ is available, bounded functions of smeared fields can generate local algebras. Conversely, in many algebraic settings point fields arise as operator-valued distributions affiliated with the local algebras. The invariant object is the local observable content:

$$\mathcal{O} \mapsto \mathcal{A}(\mathcal{O}) \quad \text{or} \quad \mathcal{O} \mapsto \mathcal{R}(\mathcal{O}).$$

Fields are then coordinatizations of local observables, organized by symmetry, scaling, and the operator product expansion when those structures are available.

The comparison in this section has four distinct layers. The Wightman layer contains vacuum matrix elements and unbounded smeared fields on a common domain. The closure layer asks whether the Hermitian smearings have self-adjoint closures whose spectral projections satisfy spacelike strong commutation. The bounded-net layer asks whether those spectral projections generate an additive represented von Neumann net. The observable layer asks whether that coordinate-generated net is the actual observable net, or instead only a field net whose fixed points, gauge-invariant subalgebra, or BRST/BV observable sector must still be identified. Confusing any two adjacent layers is the usual source of false shortcuts: cyclic Wightman data do not identify von Neumann algebras, affiliation does not imply generation, and a fixed-point formula does not by itself prove Haag–Kastler additivity.

The passage from unbounded Wightman fields to a Haag–Kastler net is not a formal consequence of the Wightman axioms in their bare domain formulation. For real test functions the smeared fields are symmetric operators on a common invariant domain, but this alone neither supplies self-adjoint closures nor implies strong commutativity of the spectral measures of spacelike separated closures. The construction below records the standard route under the extra closure and strong-locality hypotheses needed to make it a theorem. The source traces for the two sides of this comparison are the Wightman and Haag–Kastler frameworks [1, 2, 18]; the theorem below isolates the extra functional-analytic hypotheses rather than folding them into either named framework.

Definition 3.9 (Affiliation of an unbounded operator)**.** For a self-adjoint operator T on $\mathcal{H}$, affiliation with a von Neumann algebra $\mathcal{M} \subset B(\mathcal{H})$ means that the spectral projections $E_T(\Delta)$ of T belong to $\mathcal{M}$ for every Borel set $\Delta \subset \mathbb{R}$. Equivalently, every unitary in the commutant $\mathcal{M}'$ preserves the graph of T and commutes with T on its domain.

Affiliation is the precise way in which an unbounded field can be localized in a bounded local algebra.

The equivalence in Definition 3.9 is often the practical test for locality of unbounded field coordinates, so we spell it out. Let E_T be the spectral measure of T. If $E_T(\Delta) \in \mathcal{M}$ for every Borel Δ, then every $B \in \mathcal{M}'$ commutes with every bounded Borel function of T. In particular,

$$B(1+T^2)^{-1/2} = (1+T^2)^{-1/2}B, \qquad BT(1+T^2)^{-1/2} = T(1+T^2)^{-1/2}B.$$

The first identity implies that $B \operatorname{Dom} T \subset \operatorname{Dom} T$: indeed

$$\operatorname{Dom} T = (1+T^2)^{-1/2}\mathcal{H}.$$

The second identity then gives $BT\xi = TB\xi$ for $\xi \in \operatorname{Dom} T$, by applying it to $\xi = (1+T^2)^{-1/2}\eta$. Thus commutant operators preserve the graph and commute with T on the graph domain.

Conversely, suppose every unitary $V \in \mathcal{M}'$ preserves $\operatorname{Dom} T$ and satisfies $VT\xi = TV\xi$ for $\xi \in \operatorname{Dom} T$. Then $VTV^{-1} = T$ as self-adjoint operators, so uniqueness in the spectral theorem gives

$$VE_T(\Delta)V^{-1} = E_T(\Delta)$$

for every Borel Δ. Hence $E_T(\Delta)$ commutes with all unitaries of $\mathcal{M}'$. The unitary group of a von Neumann algebra generates it ultraweakly, and the bicommutant theorem gives

$$(\mathcal{M}')' = \mathcal{M}.$$

Therefore $E_T(\Delta) \in \mathcal{M}$. This argument is the bounded operator-algebra content behind the phrase "the unbounded field is localized in $\mathcal{M}$"; the difficult QFT input is proving that the closed field operators in question have such spectral projections.

Theorem 3.10 (Wightman fields generate a represented local net under strong closure hypotheses)**.** *Let*

$$(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_\alpha\}_{\alpha \in I})$$

be a Wightman field presentation on M. Enlarge the field-label space, if needed, so that the smeared generators used below are Hermitian on $\mathcal{D}$. Suppose that for every real Hermitian labelled test function h the symmetric operator $\widehat{\Phi}(h)$ is essentially self-adjoint on $\mathcal{D}$; write $X(h)$ for its self-adjoint closure and

$$E_h(\Delta)$$

for the spectral projection of $X(h)$ associated with the Borel set $\Delta \subset \mathbb{R}$. Define, for every region $\mathcal{O} \in \mathcal{K}(M)$,

$$\mathcal{R}_\Phi(\mathcal{O}) := \{E_h(\Delta) \mid \operatorname{supp} h \subset \mathcal{O}, \quad h = h^\dagger, \quad \Delta \subset \mathbb{R} \text{ Borel}\}''. \tag{3.15}$$

Equivalently, by the spectral theorem,

$$\mathcal{R}_\Phi(\mathcal{O}) = \{\exp(\mathrm{i}tX(h)) \mid \operatorname{supp} h \subset \mathcal{O}, \quad h = h^\dagger, \quad t \in \mathbb{R}\}''. \tag{3.16}$$

Since t may be absorbed into h, this is the standard displayed construction

$$\mathcal{R}_\Phi(\mathcal{O}) = \{\exp(\mathrm{i}X(h)) \mid \operatorname{supp} h \subset \mathcal{O}, \quad h = h^\dagger\}''.$$

For every such h, the closed operator $X(h)$ is affiliated with $\mathcal{R}_\Phi(\mathcal{O})$. If $\mathcal{O}_1 \subset \mathcal{O}_2$, the same $X(h)$ is also affiliated with $\mathcal{R}_\Phi(\mathcal{O}_2)$. Assume strong locality of these closures: if $\mathcal{O}_1 \perp \mathcal{O}_2$, then every spectral projection entering $\mathcal{R}_\Phi(\mathcal{O}_1)$ commutes with every spectral projection entering $\mathcal{R}_\Phi(\mathcal{O}_2)$. Then

$$\mathcal{O} \longmapsto \mathcal{R}_\Phi(\mathcal{O})$$

is an isotonic, Poincare-covariant represented local net of von Neumann algebras on $\mathcal{H}$. The vector state

$$A \longmapsto \langle \Omega, A\Omega \rangle$$

is invariant under the represented Poincare action.

Proof. For a fixed h, the spectral theorem identifies the von Neumann algebra generated by the projection-valued measure E_h with the von Neumann algebra generated by the one-parameter unitary group $\{\exp(\mathrm{i}tX(h))\}_{t\in\mathbb{R}}$. Indeed $\exp(\mathrm{i}tX(h)) = \int \exp(\mathrm{i}t\lambda)\,\mathrm{d}E_h(\lambda)$, so the unitaries lie in $\{E_h(\Delta) \mid \Delta \subset \mathbb{R} \text{ Borel}\}''$; conversely, the spectral projections are bounded Borel functions of $X(h)$, hence lie in the von Neumann algebra generated by the unitary group by the Borel functional calculus for a self-adjoint operator. This proves the equivalence of (3.15) and (3.16), and also proves the affiliation statement because all spectral projections of $X(h)$ are generators of $\mathcal{R}_\Phi(\mathcal{O})$.

If $\mathcal{O}_1 \subset \mathcal{O}_2$, then the test functions with support in $\mathcal{O}_1$ are among those with support in $\mathcal{O}_2$, hence the generating spectral projections for $\mathcal{R}_\Phi(\mathcal{O}_1)$ are contained in $\mathcal{R}_\Phi(\mathcal{O}_2)$. This proves isotony. Wightman covariance gives

$$U(g)X(h)U(g)^{-1} = X(gh),$$

where gh is the transformed labelled test function. The spectral theorem then gives

$$U(g)E_h(\Delta)U(g)^{-1} = E_{gh}(\Delta),$$

so

$$U(g)\mathcal{R}_\Phi(\mathcal{O})U(g)^{-1} = \mathcal{R}_\Phi(g\mathcal{O}).$$

Strong locality is exactly the commutation of the spectral-projection generators for spacelike separated regions; taking double commutants preserves commutation of von Neumann algebras. The vacuum invariance follows from $U(g)\Omega = \Omega$. □

The constructive checkpoint below records a useful sufficient mechanism for the strong-locality hypothesis: Lemma 3.15 shows how joint analytic-vector estimates upgrade domain-level Wightman commutators to commutation of spectral projections. This is an additional functional-analytic input beyond the abstract Wightman distributional axioms.

Domain commutation and spectral locality. The word "strong" in the preceding hypothesis records a real operator-theoretic passage. Wightman locality gives an identity $[X,Y]\xi = 0$ on a common invariant field domain. The represented local algebra, however, is generated by the bounded Borel functional calculi of the self-adjoint closures. The needed implication is therefore

$$[X,Y]\mathcal{D} = 0 \quad \Longrightarrow \quad \exp(\mathrm{i}t\overline{X})\exp(\mathrm{i}s\overline{Y}) = \exp(\mathrm{i}s\overline{Y})\exp(\mathrm{i}t\overline{X}) \quad \text{for all } s,t \in \mathbb{R}, \tag{3.17}$$

or, equivalently, commutation of the two projection-valued spectral measures. Equation (3.17) is supplied by extra hypotheses such as the joint analytic-vector estimate in Lemma 3.15, by a direct resolvent commutation theorem, or by a constructive finite-regulator limit proving strong convergence of the relevant spectral windows. The finite companion check `calculation-checks/wightman_net_bridge_checks.py` includes a rational three-dimensional witness for the algebraic failure mode: a commutator can vanish on a stable test sector while the spectral projection of one self-adjoint generator fails to commute with a spectral projection of the other. The continuum theorem has a denser domain and hence requires stronger analysis, but the bounded-algebra target is the same spectral projection statement.

There is an analogous point for additivity. The formula (3.15) is isotonic by inclusion of its generating spectral projections, but Haag–Kastler additivity for a cover is not a formal consequence of writing a test function as a sum of smaller test functions. Suppose $\mathcal{O} \subset \bigcup_{j=1}^{r} \mathcal{O}_j$ and h is Hermitian with $\operatorname{supp} h \subset \mathcal{O}$. A partition of unity gives

$$h = h_1 + \cdots + h_r, \qquad \operatorname{supp} h_j \subset \mathcal{O}_j.$$

On the Wightman domain one has $\widehat{\Phi}(h) = \sum_j \widehat{\Phi}(h_j)$, but the bounded local algebra requires the spectral projections of the self-adjoint closure $X(h)$. A sufficient additivity condition is therefore the closure/Trotter statement

$$X(h) = \overline{X(h_1) + \cdots + X(h_r)}$$

on a common core, together with the strong Trotter product formula

$$\exp(\mathrm{i}tX(h)) = \operatorname*{s-lim}_{n\to\infty} \left(\exp\left(\frac{\mathrm{i}t}{n} X(h_1)\right) \cdots \exp\left(\frac{\mathrm{i}t}{n} X(h_r)\right)\right)^{n}. \tag{3.18}$$

The right side belongs to $\bigvee_j \mathcal{R}_\Phi(\mathcal{O}_j)$. The spectral projections of $X(h)$, being bounded Borel functions of the unitary group $\{\exp(\mathrm{i}tX(h))\}_{t\in\mathbb{R}}$, then belong to the same generated von Neumann algebra. Thus additivity of a Wightman-generated bounded net is a closure and functional-calculus statement about the self-adjoint field coordinates; it should not be imported from the distributional linearity of the fields alone. The finite check `calculation-checks/wightman_net_bridge_checks.py` contains the corresponding matrix-algebra shadow: the spectral projection of a sum of two noncommuting local self-adjoint generators lies in the von Neumann algebra generated by the two smaller algebras only after the sum has been specified as an operator in that generated algebra.

Remark 3.11 (Status of the Wightman-to-net direction). The theorem is conditional. Wightman commutativity is initially a statement about commutators of unbounded smeared fields on a common dense domain; it does not automatically imply commutativity of the spectral projections of self-adjoint closures. Thus the displayed Weyl-unitary formula should not be read as saying that arbitrary Wightman fields automatically span a local Haag–Kastler algebra. In constructive scalar models obtained from Euclidean measures, the route is model-specific: one proves the Schwinger functions, OS reconstruction, Wightman properties, and the required local-net properties with estimates particular to the construction. That is a proof of the Haag–Kastler axioms for those models, not a general implication from the abstract Wightman axioms alone.

Bounded orbit criterion for equality of local algebras. The equality condition in a complete Wightman coordinatization is an equality of represented von Neumann algebras. Cyclic correlator formulae belong to the earlier field-reconstruction layer; the following bounded criterion is often the operator-algebraic step that one needs after the local fields, closures, and functional calculi have already been constructed. Let $\mathcal{M}, \mathcal{N} \subset B(\mathcal{H})$ be von Neumann algebras and let $\Omega \in \mathcal{H}$ be separating for the generated von Neumann algebra $\mathcal{M} \vee \mathcal{N}$. Suppose that for every $A \in \mathcal{M}$ there is a uniformly bounded net $\{B_i\} \subset \mathcal{N}$ such that

$$B_i\Omega \longrightarrow A\Omega \qquad \text{in } \mathcal{H}.$$

Then $A \in \mathcal{N}$, and hence $\mathcal{M} \subset \mathcal{N}$. Indeed, after replacing B_i by a subnet, weak operator compactness of bounded balls in a von Neumann algebra gives a weak-operator limit $B \in \mathcal{N}$. The vector convergence above implies $B\Omega = A\Omega$. Since $A - B \in \mathcal{M} \vee \mathcal{N}$ and Ω is separating for $\mathcal{M} \vee \mathcal{N}$, one obtains $A = B$. Applying the same criterion in both directions gives $\mathcal{M} = \mathcal{N}$.

The hypotheses in this criterion are not decorative. Without separatingness, orbit agreement at a vector can be blind to operators that vanish on that vector. Without uniformly bounded approximants, equality of Hilbert-space orbit closures does not specify a bounded element of the candidate von Neumann algebra. Thus equality of Wightman polynomial matrix elements, or even equality of a dense set of cyclic vectors, does not by itself identify local algebras. One must first construct the bounded algebras and then prove a bounded orbit or strong-operator density statement of the type above. In QFT, the separating input is usually obtained from a Reeh–Schlieder theorem for an appropriate complementary region together with locality, as in Corollary 3.20; it is not a formal consequence of polynomial field cyclicity alone.

Definition 3.12 (Wightman-to-net comparison structure)**.** Let $(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_\alpha\}_{\alpha\in I})$ be a Wightman field presentation. A Wightman-to-net comparison structure for a chosen region class $\mathcal{K}(M)$ consists of the following additional objects and hypotheses.

(i) For every $\mathcal{O} \in \mathcal{K}(M)$, a real vector space

$$\mathcal{H}_\Phi(\mathcal{O}) \subset \mathrm{span}_{\mathbb{R}}\{\text{Hermitian labelled test functions supported in } \mathcal{O}\}$$

such that $\mathcal{O}_1 \subset \mathcal{O}_2$ implies $\mathcal{H}_\Phi(\mathcal{O}_1) \subset \mathcal{H}_\Phi(\mathcal{O}_2)$, and

$$U(g)\widehat{\Phi}(h)U(g)^{-1} = \widehat{\Phi}(gh), \qquad gh \in \mathcal{H}_\Phi(g\mathcal{O})$$

whenever $h \in \mathcal{H}_\Phi(\mathcal{O})$.

(ii) A self-adjoint closure $X(h) = \overline{\widehat{\Phi}(h)}$ for every $h \in \mathcal{H}_\Phi(\mathcal{O})$, with the covariance identity

$$U(g)X(h)U(g)^{-1} = X(gh)$$

understood as equality of self-adjoint operators on their closed graph domains.

(iii) Strong spacelike locality: if $\mathcal{O}_1 \perp \mathcal{O}_2$, $h_i \in \mathcal{H}_\Phi(\mathcal{O}_i)$, and E_{h_i} is the spectral measure of $X(h_i)$, then

$$E_{h_1}(\Delta_1)E_{h_2}(\Delta_2) = E_{h_2}(\Delta_2)E_{h_1}(\Delta_1) \tag{3.19}$$

for all Borel sets $\Delta_1, \Delta_2 \subset \mathbb{R}$.

(iv) An observable-subnet prescription. If the fields include charged, gauge-variant, or otherwise non-observable coordinates, the field-generated net

$$\mathcal{F}_\Phi(\mathcal{O}) = \{E_h(\Delta) \mid h \in \mathcal{H}_\Phi(\mathcal{O})\}''$$

is distinct from the neutral observable net. One must specify an observable subnet, for example a fixed-point net

$$\mathcal{R}_\Phi(\mathcal{O}) = \mathcal{F}_\Phi(\mathcal{O})^G$$

for an implemented compact internal group G, or a separately constructed gauge-invariant subnet.

This comparison structure is deliberately stronger than the Wightman distributional axioms. The Wightman hierarchy determines the cyclic field representation and its vacuum matrix elements. The comparison structure adds the bounded functional-calculus and observable-identification data needed to speak about a Haag–Kastler net. The resulting field-generated net is the represented von Neumann net

$$\mathcal{F}_\Phi(\mathcal{O}) = \{E_h(\Delta) \mid h \in \mathcal{H}_\Phi(\mathcal{O}), \quad \Delta \subset \mathbb{R} \text{ Borel}\}'',$$

or, when only observable coordinates are present, the same formula with $\mathcal{R}_\Phi$ in place of $\mathcal{F}_\Phi$. The remaining datum is whether this coordinate net exhausts the local observable content.

Definition 3.13 (Complete observable Wightman coordinatization)**.** Let

$$\mathcal{O} \longmapsto \mathcal{R}(\mathcal{O}) \subset B(\mathcal{H})$$

be a represented observable net on the same Hilbert space and with the same vacuum vector and spacetime symmetry representation as the Wightman field presentation. A Wightman-to-net comparison structure is a complete observable coordinatization of $\mathcal{R}$ on the region class $\mathcal{K}(M)$ if the following additional conditions hold.

(i) The covariance and vacuum actions agree:

$$U(g)\mathcal{R}(\mathcal{O})U(g)^{-1} = \mathcal{R}(g\mathcal{O}), \qquad U(g)\Omega = \Omega,$$

and the Wightman covariance in Definition 3.12 uses this same unitary representation U.

(ii) The bounded coordinate net is additive in the operator-theoretic sense appropriate to the chosen field coordinates. For every finite cover $\mathcal{O} \subset \bigcup_{j=1}^{r} \mathcal{O}_j$, every $h \in \mathcal{H}_\Phi(\mathcal{O})$, and every decomposition

$$h = h_1 + \cdots + h_r, \qquad h_j \in \mathcal{H}_\Phi(\mathcal{O}_j),$$

used to prove additivity, the closure and functional-calculus data satisfy

$$X(h) = \overline{X(h_1) + \cdots + X(h_r)}$$

on a common core and the unitary group of $X(h)$ is obtained from the unitary groups of the $X(h_j)$ by the strong Trotter limit (3.18). Equivalently, the spectral projections of $X(h)$ lie in $\bigvee_j \mathcal{F}_\Phi(\mathcal{O}_j)$, with $\mathcal{F}_\Phi$ replaced by the observable coordinate net when no charged field net is used.

(iii) The observable prescription is part of the comparison. If all chosen coordinates are observable, then the generated net itself exhausts the represented observable net:

$$\mathcal{R}_\Phi(\mathcal{O}) = \mathcal{R}(\mathcal{O}) \qquad \text{for all } \mathcal{O} \in \mathcal{K}(M).$$

If the chosen coordinates generate a charged or field net $\mathcal{F}_\Phi$, then an observable operation must be specified and must recover the represented observable net. For an implemented compact internal group G, this condition is

$$\mathcal{F}_\Phi(\mathcal{O})^G = \mathcal{R}(\mathcal{O}) \qquad \text{for all } \mathcal{O} \in \mathcal{K}(M),$$

with the fixed-point additivity and charged-intertwiner generation issues verified in the model rather than inferred from the equality of vector-space test functions.

(iv) The equality in the preceding item is equality of von Neumann algebras in the given representation. It requires equality of bounded operator closures, with the strong or weak operator topology built into the represented local algebra. Thus every bounded local observable in $\mathcal{R}(\mathcal{O})$ is obtained as a strong-operator limit of bounded functions of the specified local field coordinates, after applying the stated observable-subnet operation.

With this definition the statement that exponentials of smeared Wightman fields generate the local algebra has a precise meaning: it asserts Definition 3.13 for a specified region class, field-coordinate space, closure choice, strong locality statement, additivity mechanism, and observable-subnet prescription. In scalar theories with a complete neutral field system this may reduce to $\mathcal{R}_\Phi(\mathcal{O}) = \mathcal{R}(\mathcal{O})$. In a theory with charged fields, gauge variables, or a global internal symmetry, the same bounded functions first generate a field or coordinate net, and the observable net is obtained only after the fixed-point, gauge-invariant, BRST/BV, lattice physical-Hilbert-space, or other explicitly specified observable operation has been applied. Conversely, affiliated fields inside a given represented net provide local coordinates for a subnet unless the generation equality in Definition 3.13 is separately proved.

The finite algebra behind the last point is simple but important. Let $\Gamma = \mathbb{Z}/2\mathbb{Z}$ act on a two-dimensional Hilbert space by the parity unitary $P = \mathrm{diag}(1, -1)$. The self-adjoint operator $X = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ is odd: $PXP^{-1} = -X$. Its spectral projections generate bounded field coordinates, but they are exchanged by Γ and therefore are not observables of the fixed-point algebra. The invariant subalgebra is the diagonal algebra generated by 1 and P, while adding the spectral projections of X generates the full matrix algebra. This toy model is a bounded-algebra diagnostic; it supplies no spacetime localization, domain, or spectrum theorem. Its role is to check the field-net versus observable-net distinction that the Wightman-to-net comparison structure must retain in every genuine model.

Affiliation is not generation. The converse comparison is equally important. Suppose a represented observable net $\mathcal{R}(\mathcal{O})$ is already given, and suppose one has a family of self-adjoint field coordinates $T_i(f)$ affiliated with $\mathcal{R}(\mathcal{O})$ whenever $\operatorname{supp} f \subset \mathcal{O}$. Affiliation means that all spectral projections of these coordinates are bounded local observables. It gives a canonical inclusion

$$\mathcal{R}_{\mathrm{coord}}(\mathcal{O}) := \{E_{T_i(f)}(\Delta) \mid \operatorname{supp} f \subset \mathcal{O}, \Delta \subset \mathbb{R} \text{ Borel}\}'' \subset \mathcal{R}(\mathcal{O}), \tag{3.20}$$

not an equality. Equality is a separate generation, or coordinatization completeness, hypothesis:

$$\mathcal{R}_{\mathrm{coord}}(\mathcal{O}) = \mathcal{R}(\mathcal{O}) \qquad \text{for every region } \mathcal{O}$$

in the region class under consideration. This hypothesis may hold for a chosen generating field system, may fail for a distinguished but incomplete field such as a current or stress tensor, and may be inappropriate when the physical observable net is a fixed-point or gauge-invariant subnet of a larger field net. Thus the statement that local fields are affiliated with local algebras is weaker than the statement that their bounded functional calculus generates all local observables.

The finite diagonal model makes the distinction visible without domains. In the algebra $D_3 \subset M_3(\mathbb{C})$ of diagonal matrices, the self-adjoint coordinate

$$T = \mathrm{diag}(0, 0, 1)$$

is affiliated with D_3, because its spectral projections $\mathrm{diag}(1,1,0)$ and $\mathrm{diag}(0,0,1)$ lie in D_3. They generate only the two-dimensional subalgebra $\mathbb{C}\,\mathrm{diag}(1,1,0)\oplus\mathbb{C}\,\mathrm{diag}(0,0,1)$, not the full diagonal algebra. A second coordinate $S=\mathrm{diag}(0,1,0)$ refines the spectral partition and, together with T, generates all three minimal diagonal projections. The finite check `calculation-checks/wightman_net_bridge_checks.py` verifies exactly this coarse-spectral-generation obstruction. In QFT the analogous issue is not finite-dimensional degeneracy but whether the chosen local fields separate the local bounded observable content with the topology relevant to the represented net.

Fixed points and additivity. Suppose the comparison structure has produced a represented field net $\mathcal{F}(\mathcal{O})$, and suppose a compact internal group G is implemented by strongly continuous unitaries $V(g)$ such that

$$V(g)\Omega=\Omega,\qquad V(g)U(a,\Lambda)=U(a,\Lambda)V(g),\qquad V(g)\mathcal{F}(\mathcal{O})V(g)^{-1}=\mathcal{F}(\mathcal{O}).$$

The fixed-point candidate for the observable net is

$$\mathcal{R}(\mathcal{O})=\mathcal{F}(\mathcal{O})^G=\{A\in\mathcal{F}(\mathcal{O})\mid V(g)AV(g)^{-1}=A\text{ for all }g\in G\}.\tag{3.21}$$

The Haar integral gives a normal conditional expectation

$$E_{\mathcal{O}}(A)=\int_G V(g)AV(g)^{-1}\,\mathrm{d}g,\qquad A\in\mathcal{F}(\mathcal{O}),\tag{3.22}$$

where the integral is taken in the ultraweak topology. It satisfies

$$E_{\mathcal{O}}^2=E_{\mathcal{O}},\qquad E_{\mathcal{O}}(B_1AB_2)=B_1E_{\mathcal{O}}(A)B_2,\quad B_1,B_2\in\mathcal{R}(\mathcal{O}),$$

and its range is $\mathcal{R}(\mathcal{O})$. Hence each $\mathcal{R}(\mathcal{O})$ is a von Neumann algebra, isotony and Poincare covariance are inherited from $\mathcal{F}$, and locality follows because $\mathcal{R}(\mathcal{O})\subset\mathcal{F}(\mathcal{O})$.

The previous paragraph is only the bounded fixed-point mechanism. It does not by itself prove all Haag–Kastler properties for the observable net. Additivity is the point where the distinction is visible. For two regions with field algebras carrying charged coordinates X_1 and X_2, a neutral composite such as X_1X_2 may be invariant under the diagonal action of G on the algebra generated by the two field algebras, while neither X_1 nor X_2 belongs to the separate fixed-point algebras. Thus

$$\bigvee_i\mathcal{F}(\mathcal{O}_i)^G\subset\left(\bigvee_i\mathcal{F}(\mathcal{O}_i)\right)^G$$

can be a proper inclusion. An observable-net additivity theorem must explain which neutral composites are generated locally, often using field-algebra reconstruction, charged intertwiners, split inclusions, or a model-specific constructive argument. The formula (3.21) supplies the bounded fixed-point algebras; DHR/DR reconstruction or a constructive model proof supplies the additional charged-sector and generation information needed for the full observable Haag–Kastler axioms.

Constructive interacting checkpoint: massive $P(\phi)_2$. The massive $P(\phi)_2$ models developed constructively in Chapter 137 give a useful test of the previous theorem because every word in the local-net construction has to be earned from estimates. Start with the infinite-volume

Schwinger hierarchy of Quoted Theorem 137.8, in a clustering single-vacuum phase. OS reconstruction gives a Hilbert space $\mathcal{H}_P$, vacuum Ω_P, translation representation U_P, and a scalar Wightman field $\Phi_P(f)$ on the reconstructed polynomial domain $\mathcal{D}_P$. The polynomial domain is generated by positive-time Euclidean fields modulo the OS null space; after analytic continuation it is the common domain for finite products of smeared Lorentzian fields.

The associated bounded local field net is obtained from the spectral projections of real smeared fields,

$$\mathcal{F}_P(\mathcal{O}) = \{E_{\overline{\Phi_P(f)}}(\Delta) \mid f \in C_c^\infty(\mathcal{O}, \mathbb{R}),\ \Delta \subset \mathbb{R} \text{ Borel}\}'', \tag{3.23}$$

where $\overline{\Phi_P(f)}$ denotes the self-adjoint closure obtained in the constructive Hilbert-space realization. This displayed formula is a definition of the net only after three analytic inputs have been supplied. First, the Hamiltonian or Euclidean construction must prove essential self-adjointness of the real smeared fields on a common invariant core. Second, spacelike separated closures must commute strongly, meaning that their spectral projections commute; the finite-cutoff equal-time tensor-factor locality and the thermodynamic/ultraviolet limiting estimates are the model mechanism for this statement. Third, the limiting bounded functions must be compatible with Poincare covariance and the time-slice dynamics. With these inputs, isotony follows from support inclusion, covariance from the reconstructed U_P, and locality from strong commutation of the spectral projections.

Lemma 3.14 (Strong-limit route from regulated locality to bounded locality)**.** *Let $\{A_\lambda\}_{\lambda\in\Lambda}$ and $\{B_\lambda\}_{\lambda\in\Lambda}$ be two nets of bounded operators on a Hilbert space, indexed by a directed set. Assume that*

$$\sup_\lambda \|A_\lambda\| < \infty, \qquad \sup_\lambda \|B_\lambda\| < \infty, \qquad A_\lambda B_\lambda = B_\lambda A_\lambda,$$

and that $A_\lambda \to A$, $B_\lambda \to B$ strongly. Then

$$AB = BA.$$

Consequently, suppose a constructive regulator supplies self-adjoint regulated local fields $\Phi_\lambda(f)$ whose spectral projections $E_{\Phi_\lambda(f)}(\Delta)$ converge strongly to $E_{\overline{\Phi(f)}}(\Delta)$ for every interval Δ in the chosen spectral-window class. If the finite-regulator projections commute whenever $\operatorname{supp} f$ *and* $\operatorname{supp} g$ *are spacelike separated, then the limiting spectral projections commute for the same windows.*

Proof. For $\xi \in \mathcal{H}$,

$$\|(A_\lambda B_\lambda - AB)\xi\| \le \|A_\lambda\|\,\|(B_\lambda - B)\xi\| + \|(A_\lambda - A)B\xi\|.$$

The first term tends to zero by strong convergence of B_λ and the uniform bound on A_λ. The second tends to zero by strong convergence of A_λ, applied to the fixed vector $B\xi$. Hence $A_\lambda B_\lambda \to AB$ strongly. The same argument gives $B_\lambda A_\lambda \to BA$ strongly. Since $A_\lambda B_\lambda = B_\lambda A_\lambda$ for every λ, their strong limits are equal.

Apply this bounded statement to

$$A_\lambda = E_{\Phi_\lambda(f)}(\Delta), \qquad B_\lambda = E_{\Phi_\lambda(g)}(\Delta')$$

for spacelike separated supports. Spectral projections have norm at most one, so the uniform boundedness hypothesis is automatic once the strong spectral-window convergence is supplied. The conclusion is the commutation of the limiting spectral projections. This proves bounded locality of the local von Neumann algebras generated by those projections on the declared spectral windows. ∎

This lemma is not a replacement for constructive estimates. It identifies the bounded convergence statement those estimates must produce. A convergence result only for vacuum expectation values of unbounded smeared fields, or only for formal commutators on a polynomial domain, does not by itself imply commutation of the spectral projections that define $\mathcal{F}_P(\mathcal{O})$. A model proof may use the strong-limit route above, the analytic-vector route of Lemma 3.15, or another functional calculus argument; it must supply one of them before the Wightman polynomial field presentation has become a bounded Haag–Kastler net.

If the polynomial P has a finite internal symmetry group Γ, for example $\Gamma = \mathbb{Z}_2$ when P is even and the chosen phase is $\mathbb{Z}_2$-invariant, the observable net is the fixed-point net

$$\mathcal{R}_P(\mathcal{O}) = \mathcal{F}_P(\mathcal{O})^{\Gamma}. \tag{3.24}$$

Thus the same constructive model distinguishes the field net, the observable net, and possible sector questions. In broken phases, kink sectors are localized by asymptotic boundary conditions and therefore sit at the boundary between ordinary local endomorphism sectors and more global charge data. Massive clustering gives a spectral gap through the argument in Chapter 137; nuclearity, split inclusions, Haag duality, and DHR sector reconstruction require separate model estimates. The example is therefore an interacting AQFT object: it supplies concrete local von Neumann algebras and also identifies which algebraic properties require additional theorems beyond the OS axioms.

Gauge-theory checkpoint: the local Schwinger-model observable net. The massless Schwinger model of Chapter 52 supplies a different test: the starting variables are a gauge potential and a charged Dirac field, but the physical local algebra is generated by gauge-invariant fields. Let $e > 0$ be the dynamical charge, let $m_{\mathrm{Sch}}^2 = e^2/\pi$, and fix a local electric-flux branch and a value of the theta parameter as in Lemma 52.5. The exact local bosonization result gives the operator identity

$$E = -\frac{e}{\sqrt{\pi}}\left(\varphi + \frac{\theta}{2\sqrt{\pi}}\right), \qquad (\partial^\mu\partial_\mu - m_{\mathrm{Sch}}^2)E = 0, \tag{3.25}$$

on the gauge-invariant local sector. The additive constant in (3.25) shifts smeared fields by a scalar multiple of the identity and therefore does not change the von Neumann algebras generated by their spectral projections. Consequently the local electric-field net is the massive scalar Weyl net of the benchmark model above at mass m_{Sch}:

$$\mathcal{R}_{\mathrm{Sch}}(\mathcal{O}) = \left\{E_{\overline{E(f)}}(\Delta) \mid f \in C_c^\infty(\mathcal{O},\mathbb{R}),\ \Delta \subset \mathbb{R} \text{ Borel}\right\}'' \cong \mathcal{A}_{m_{\mathrm{Sch}}}(\mathcal{O}). \tag{3.26}$$

This is an equality of represented local nets after the local bosonization map has been fixed; it is not a statement that the gauge representative a_μ or the charged fermion ψ is an observable field. The mechanism behind (3.26) is concrete. For $f \in C_c^\infty(\mathcal{O};\mathbb{R})$,

$$E(f) = -\frac{e}{\sqrt{\pi}}\,\varphi(f) - \frac{e\theta}{2\pi}\int f\,\mathrm{d}^2x. \tag{3.27}$$

Thus, for every Borel set $\Delta \subset \mathbb{R}$,

$$E_{\overline{E(f)}}(\Delta) = E_{\overline{\varphi(f)}}\left(-\frac{\sqrt{\pi}}{e}\left(\Delta + \frac{e\theta}{2\pi}\int f\,\mathrm{d}^2x\right)\right),$$

where the right side means the spectral projection of $\overline{\varphi(f)}$ for the indicated affine image of Δ. Since $-e/\sqrt{\pi} \neq 0$, the spectral projections generated by $E(f)$ and by $\varphi(f)$ are the same. Gauge-invariant currents do not add an independent local coordinate. If $h = h_\mu \mathrm{d}x^\mu$ is compactly supported in $\mathcal{O}$, then the bosonization formula (52.8) and integration by parts give

$$J(h) := \int h_\mu J^\mu \, \mathrm{d}^2 x = -\frac{1}{\sqrt{\pi}} \, \varphi(\partial_\nu(\epsilon^{\mu\nu} h_\mu)) \,, \tag{3.28}$$

with the same support control. The Gauss-law relation $\partial_x E + eJ^0 = 0$ is then an identity among these scalar coordinates, not a second local generator. Closed Wilson loops whose support bounds a compact region reduce, by Stokes' theorem and the chosen local flux branch, to bounded functions of smeared E. Open Wilson lines, line-dressed charged fields, external fractional probes, and flux-changing operators are different data: they carry endpoint, path, or asymptotic flux information and are therefore not elements of $\mathcal{R}_{\mathrm{Sch}}(\mathcal{O})$ for a bounded region unless an additional construction supplies a gauge-invariant local composite.

There is also a global boundary. On a spatial circle, or on a line after imposing boundary conditions at infinity, the electric field may have a harmonic or asymptotic flux coordinate. That coordinate is not produced by compactly supported smearings inside a bounded region. In a fixed flux branch it is a number in the representation, and (3.26) describes the local observable net in that branch. If several flux branches are represented at once, the spectral projections of the global flux are central operators for the represented global algebra; they commute with every bounded local algebra but are not elements of any proper bounded-region algebra. Thus flux-sector projections belong to the superselection or boundary datum of the representation, not to the local Schwinger-model net generated by $E(f)$ with $\operatorname{supp} f \Subset \mathcal{O}$. The finite check `calculation-checks/wightman_net_bridge_checks.py` includes the bounded shadow of this distinction: a flux-sector projection in an auxiliary tensor factor commutes with all local electric coordinates while remaining outside the local electric-coordinate algebra.

This example isolates the AQFT bridge in a solvable gauge theory. The Haag–Kastler properties of $\mathcal{R}_{\mathrm{Sch}}$ follow from the massive scalar Weyl net once the Schwinger-model derivation has proved the local bosonization identity and the Gauss-law constraint on physical states. External fractional probes, compact zero modes on a circle, and flux sectors are not defects of the local net; they are additional sector data attached to the same observable algebra. Thus the example separates three notions that are often conflated: the gauge representative used in a Lagrangian calculation, the gauge-invariant local observable net, and the charged or line-dressed sectors on which nonlocal probes act.

Lemma 3.15 (Analytic-vector route to strong locality)**.** *Let X and Y be symmetric operators on a Hilbert space $\mathcal{H}$, with a common dense invariant domain $\mathcal{D}$. Assume:*

(i) *X and Y are essentially self-adjoint on $\mathcal{D}$;*

(ii) *every vector in $\mathcal{D}$ is jointly entire analytic for the ordered pair (X, Y), meaning that, for every $\xi \in \mathcal{D}$ and every $r, s \geq 0$,*

$$\sum_{m,n \geq 0} \frac{r^m s^n}{m! \, n!} \, \|X^m Y^n \xi\| < \infty;$$

(iii) *$[X, Y]\xi = 0$ for every $\xi \in \mathcal{D}$.*

Then the self-adjoint closures $\overline{X}$ and $\overline{Y}$ strongly commute, equivalently all spectral projections of $\overline{X}$ commute with all spectral projections of $\overline{Y}$.

Proof. Because $\mathcal{D}$ is invariant under X and Y, the commutator assumption implies $X^mY^n\xi = Y^nX^m\xi$ for all $m, n \geq 0$ and $\xi \in \mathcal{D}$, by induction. The joint analyticity assumption implies separate analyticity for X and Y, and also gives absolute convergence of the double series below. Let $U(t) = \exp(\mathrm{i}t\overline{X})$ and $V(s) = \exp(\mathrm{i}s\overline{Y})$. For $\xi \in \mathcal{D}$, the joint analytic-vector hypothesis gives norm-convergent power series

$$U(t)\xi = \sum_{m\geq 0} \frac{(\mathrm{i}t)^m}{m!} X^m\xi, \qquad V(s)\xi = \sum_{n\geq 0} \frac{(\mathrm{i}s)^n}{n!} Y^n\xi.$$

The Cauchy product is legitimate because

$$\sum_{m,n\geq 0} \frac{|t|^m|s|^n}{m!\,n!} \|X^mY^n\xi\| < \infty,$$

and gives

$$U(t)V(s)\xi = \sum_{m,n\geq 0} \frac{(\mathrm{i}t)^m(\mathrm{i}s)^n}{m!\,n!} X^mY^n\xi = \sum_{m,n\geq 0} \frac{(\mathrm{i}t)^m(\mathrm{i}s)^n}{m!\,n!} Y^nX^m\xi = V(s)U(t)\xi.$$

Since $\mathcal{D}$ is dense and $U(t), V(s)$ are bounded unitaries, the equality holds on all of $\mathcal{H}$. The spectral theorem then implies commutation of the projection-valued measures of $\overline{X}$ and $\overline{Y}$. □

For the constructive net $\mathcal{O} \mapsto \mathcal{F}_P(\mathcal{O})$, this lemma states exactly which analytic estimate must accompany Wightman locality. If $f, g \in C_c^\infty(M, \mathbb{R})$ have spacelike separated supports, Wightman locality gives

$$[\Phi_P(f), \Phi_P(g)]\xi = 0, \qquad \xi \in \mathcal{D}_P.$$

The bounded local algebras in (3.23) are local only after the specific construction supplies a common core on which the smeared fields are essentially self-adjoint and analytic-vector estimates hold. In Hamiltonian constructions these estimates usually come from comparison of smeared fields with powers of the finite-volume Hamiltonian, followed by uniform bounds in the infinite-volume and ultraviolet limits. In Euclidean constructions the same information is encoded in hypercontractive or Nelson-type bounds for polynomial fields on the OS Hilbert space. The resulting strong commutation is a bounded-algebra statement; it is stronger than the formal vanishing of a commutator on the polynomial domain.

The structural information obtained from the model should therefore be read in the following order. The OS hierarchy first gives the Hilbert space, vacuum, translation representation, Wightman distributions, and polynomial field domain. Essential self-adjointness and analytic-vector estimates then turn real smeared fields into spectral projection generators. Strong commutation of these generators gives locality of $\mathcal{F}_P$. Internal fixed points give the observable net $\mathcal{R}_P = \mathcal{F}_P^\Gamma$. Further AQFT properties are separate: nuclearity is an estimate on

$$\Theta_{\beta,\mathcal{O}} \colon \mathcal{F}_P(\mathcal{O}) \to \mathcal{H}_P, \qquad A \longmapsto \exp(-\beta H_P)A\Omega_P,$$

split inclusions follow only after such maps are trace-class or nuclear with the appropriate local bounds, Haag duality is a statement about equality of a local algebra with a commutant of an exterior algebra, and DHR reconstruction requires a tensor category of transportable localized endomorphisms. None of these conclusions is contained in the symbol $P(\phi)_2$ itself. The constructive example is valuable precisely because each assertion can be attached to a named estimate or representation-theoretic construction.

For later use it is helpful to make this estimate-to-property map explicit. Let $\mathcal{O}$ be a double cone and let

$$\Theta_{\beta,\mathcal{O}} \colon \mathcal{F}_P(\mathcal{O})_1 \longrightarrow \mathcal{H}_P, \qquad A \longmapsto \mathrm{e}^{-\beta H_P} A \Omega_P$$

denote the energy-damped image of the unit ball of the local field algebra. Buchholz–Wichmann nuclearity is a uniform approximation statement for this entire image. For each $\beta > 0$ and each fixed local region one must produce vectors $\xi_j \in \mathcal{H}_P$ and bounded linear functionals $\ell_j \in \mathcal{F}_P(\mathcal{O})^*$ such that

$$\mathrm{e}^{-\beta H_P} A \Omega_P = \sum_{j \geq 1} \ell_j(A) \xi_j, \qquad \sum_{j \geq 1} \|\ell_j\| \, \|\xi_j\| < \infty, \qquad A \in \mathcal{F}_P(\mathcal{O})_1,$$

with a bound on the infimum of the last sum that is stable under the thermodynamic and ultraviolet limits. A typical useful form is

$$\|\Theta_{\beta,\mathcal{O}}\|_1 \leq \exp\big(C_{\mathcal{O}} \beta^{-s}\big)$$

for small β, with $C_{\mathcal{O}}$ controlled by the size of the region and with s below the phase-space exponent allowed by the split criterion used in Chapter 4. Only after such a nuclearity estimate has been proved may one invoke the split theorem for a positive collar $\mathcal{O}_1 \Subset \mathcal{O}_2$. The output is then a type-I factor $\mathcal{N}$ satisfying

$$\mathcal{F}_P(\mathcal{O}_1) \subset \mathcal{N} \subset \mathcal{F}_P(\mathcal{O}_2).$$

Mass-gap information and finite low-energy counting may help organize the estimate, but the nuclearity statement itself concerns the full local unit ball after energy damping. The type-I factor is a positive-collar interpolant; sharp-algebra type classification requires the separate modular-spectrum and factoriality analysis discussed in Chapter 4.

Haag duality and sector reconstruction require different information. Haag duality for a double cone is the equality

$$\mathcal{R}_P(\mathcal{O}) = \bigcap_{\widetilde{\mathcal{O}} \perp \mathcal{O}} \mathcal{R}_P(\widetilde{\mathcal{O}})',$$

so a constructive proof must control operators commuting with every exterior algebra and show that no boundary-condition or disorder operator has been left in the dual algebra. This is a duality statement about the continuum net, independent of the nuclear decomposition of $\Theta_{\beta,\mathcal{O}}$. DHR reconstruction is still another layer: one must construct transportable endomorphisms localized in bounded regions, prove conjugates and finite statistics, and check the symmetric exchange structure before the Doplicher–Roberts compact group theorem can be applied. In massive $P(\phi)_2$ these are concrete model questions. In a symmetric phase they ask whether charged fields in the field net generate all finite observable sectors; in a broken phase they ask whether kink Hilbert spaces with different spatial boundary conditions can be represented by bounded local endomorphisms of the vacuum observable net. The model name specifies the arena; the estimates and category constructions above supply the content.

This separation is also the right language for phase structure. In an unbroken finite-symmetry phase the fixed-point observable net has sectors created by localized charged fields in the larger field net, when such fields are available. In a broken phase the natural kink Hilbert spaces are built with different asymptotic boundary conditions at spatial infinity. A kink cannot be treated as an ordinary DHR charge in the vacuum representation unless one proves an additional localization/transportability statement that turns the boundary-condition sector into an endomorphism localized in bounded regions. Thus the example exhibits both the power and the limitations of the standard local-endomorphism formulation of superselection theory.

Remark 3.16 (Field coordinates as a Wightman presentation). Let

$$\mathcal{O} \longmapsto \mathcal{R}(\mathcal{O})$$

be a Poincare-covariant represented local net on a Hilbert space $\mathcal{H}$, with unitary implementation U and invariant unit vector Ω. Assume the translation spectrum of U is contained in $\overline{V}_+$. Suppose there are a dense subspace $\mathcal{D} \subset \mathcal{H}$, a label set I, and operators $\widehat{\Phi}_\alpha(f)$ such that:

(i) $\Omega \in \mathcal{D}$, $U(g)\mathcal{D} \subset \mathcal{D}$, and $\widehat{\Phi}_\alpha(f)\mathcal{D} \subset \mathcal{D}$;

(ii) for each α, the map $f \mapsto \widehat{\Phi}_\alpha(f)$ is an operator-valued tempered distribution on the common domain $\mathcal{D}$;

(iii) if $\operatorname{supp} f \subset \mathcal{O}$, then $\widehat{\Phi}_\alpha(f)$ is affiliated with $\mathcal{R}(\mathcal{O})$;

(iv) the fields satisfy the Wightman covariance and adjunction identities on $\mathcal{D}$;

(v) fields affiliated with spacelike separated regions have vanishing graded commutator on $\mathcal{D}$;

(vi) the polynomial field orbit of Ω is dense in $\mathcal{H}$.

Then

$$(\mathcal{H}, \Omega, U, \mathcal{D}, \{\widehat{\Phi}_\alpha\}_{\alpha \in I})$$

is a Wightman field presentation, and its vacuum distributions are the matrix elements

$$W_{\alpha_1 \cdots \alpha_n}(f_1, \ldots, f_n) = \langle \Omega, \widehat{\Phi}_{\alpha_1}(f_1) \cdots \widehat{\Phi}_{\alpha_n}(f_n)\Omega \rangle.$$

Indeed, the Hilbert space, invariant vacuum vector, unitary Poincare representation, dense common domain, and operator-valued tempered distributions are the data just listed. The spectral condition is the assumed joint spectrum condition for translations; covariance, adjunction, locality, and cyclicity are items (iv), (v), and (vi). Continuity of the vacuum matrix elements is part of the operator-valued tempered-distribution hypothesis on the common invariant domain. Thus the listed AQFT-plus-field-coordinate data are exactly a Wightman field presentation in the sense used in Chapter 2.

This relation is important for gauge theories. The algebraic observable net can be defined from gauge-invariant observables without choosing gauge potentials as physical operators. If charged fields are introduced, they belong to additional data: an enlarged field algebra, charged representations, or sector endomorphisms. They are not elements of the neutral observable algebra unless the construction explicitly identifies them as observables.

3.8 Reeh–Schlieder and Local Cyclicity

Definition 3.17 (Weak additivity in a vacuum representation)**.** Let Ω be the vacuum vector in a Poincare-covariant representation, and let

$$\mathcal{R}_{\mathrm{glob}} := \bigvee_{\mathcal{O} \in \mathcal{K}(M)} \mathcal{R}(\mathcal{O}).$$

Here $\bigvee$ denotes the von Neumann algebra generated by the displayed family. The represented net is weakly additive when, for every nonempty open region $\mathcal{U}$ with nontrivial causal completion,

$$\bigvee_{a \in \mathbb{R}^D} \mathcal{R}(\mathcal{U} + a) = \mathcal{R}_{\mathrm{glob}}.$$

Weak additivity is the translated-generation condition used in the proof below. Finite-cover additivity identifies the algebra of one region with the algebra generated by a cover of that same region; weak additivity is a global condition on translates of one fixed local algebra.

Lemma 3.18 (Positive-energy tube uniqueness for translation matrix coefficients)**.** *Let $M = \mathbb{R}^{1,D-1}$ carry the mostly-plus metric, and let μ be a finite complex Borel measure on momentum space with*

$$\operatorname{supp}\mu \subset \overline{V}_+.$$

Define, for $a \in M$,

$$F_0(a) = \int_{\overline{V}_+} \mathrm{e}^{\mathrm{i}a\cdot p}\,\mathrm{d}\mu(p).$$

For $b \in V_+$, set

$$F(a - \mathrm{i}b) = \int_{\overline{V}_+} \mathrm{e}^{\mathrm{i}(a-\mathrm{i}b)\cdot p}\,\mathrm{d}\mu(p).$$

Then F is holomorphic in the tube $M - \mathrm{i}V_+$ and has continuous boundary value F_0 as $b \downarrow 0$. If F_0 vanishes on a nonempty open subset of the real edge M, then F_0 vanishes on all of M.

Proof. For each compact subcone $K \Subset V_+$ there is a constant $c_K > 0$ such that

$$b \cdot p \le -c_K|p|, \qquad b \in K, \quad p \in \overline{V}_+.$$

Here $|p|$ is any fixed Euclidean norm after choosing inertial coordinates; changing this norm only changes c_K. Consequently

$$\left|\mathrm{e}^{\mathrm{i}(a-\mathrm{i}b)\cdot p}\right| = \mathrm{e}^{b\cdot p} \le \mathrm{e}^{-c_K|p|},$$

and the same exponential bound, multiplied by any fixed polynomial in p, dominates the derivatives obtained by differentiating under the integral. This proves holomorphy in $M - \mathrm{i}V_+$. Since μ is finite and $\mathrm{e}^{b\cdot p} \le 1$, dominated convergence gives the continuous boundary value F_0 as $b \downarrow 0$.

Let $O \subset M$ be a nonempty open set on which $F_0 = 0$. On the opposite tube $M + \mathrm{i}V_+$ take the holomorphic function 0. The boundary values of F and 0 agree on O. Applying the distributional edge-of-the-wedge theorem, Theorem 16.6, with cones $-V_+$ and V_+, gives a connected complex neighborhood $\mathcal{N}$ of a smaller open ball $B \Subset O$ and a holomorphic function on $\mathcal{N}$ agreeing with F on $\mathcal{N} \cap (M - \mathrm{i}V_+)$ and with 0 on $\mathcal{N} \cap (M + \mathrm{i}V_+)$. The latter set is open in $\mathcal{N}$, so the identity theorem makes the glued holomorphic function identically zero on $\mathcal{N}$. Hence F vanishes on the nonempty open set $\mathcal{N} \cap (M - \mathrm{i}V_+)$. Since the tube $M - \mathrm{i}V_+$ is connected, the identity theorem again gives $F = 0$ on the whole tube. Taking the continuous boundary value proves $F_0(a) = 0$ for every real translation a. □

The source trace for Reeh–Schlieder local cyclicity is [19, 2]. The proof is included in the represented-net form because the spectral condition and weak additivity are the inputs needed later in modular and scattering arguments.

Theorem 3.19 (Reeh–Schlieder theorem for a weakly additive vacuum net)**.** *Let $\mathcal{R}$ be a Poincare-covariant represented local net on $\mathcal{H}$. Assume:*

(i) *the vacuum vector Ω is translation invariant;*

(ii) *the joint translation spectrum lies in $\overline{V}_+$;*

(iii) Ω *is cyclic for* $\mathcal{R}_{\mathrm{glob}}$*;*

(iv) *the represented net is weakly additive in the sense of Definition 3.17.*

Then for every nonempty open region $\mathcal{O}$ *containing the closure of some nonempty open* $\mathcal{U} \in \mathcal{K}(M)$*,*

$$\overline{\mathcal{R}(\mathcal{O})\Omega} = \mathcal{H}.$$

Proof. Let ψ be orthogonal to $\mathcal{R}(\mathcal{O})\Omega$. Choose a nonempty open region $\mathcal{U}$ whose closure is contained in $\mathcal{O}$, and choose $A \in \mathcal{R}(\mathcal{U})$. For translations a in a neighborhood of 0, the inclusion $\mathcal{U} + a \subset \mathcal{O}$ and covariance give $U(a)AU(a)^{-1} \in \mathcal{R}(\mathcal{O})$, hence

$$\langle \psi,\, U(a)A\Omega \rangle = 0$$

there. Let E be the joint spectral measure of the translation generators, so that $U(a) = \int e^{ia\cdot p}\, dE(p)$ and $\operatorname{supp} E \subset \overline{V}_+$. The finite complex measure

$$\mu_{\psi,A}(\Delta) := \langle \psi, E(\Delta)A\Omega \rangle$$

gives, for real a,

$$F_A(a) := \langle \psi, U(a)A\Omega \rangle = \int_{\overline{V}_+} e^{ia\cdot p}\, d\mu_{\psi,A}(p).$$

For $z = a - ib$ with $b \in V_+$, the same spectral integral

$$F_A(z) = \int_{\overline{V}_+} e^{iz\cdot p}\, d\mu_{\psi,A}(p)$$

is holomorphic in z by Lemma 3.18. The same lemma applies because $F_A(a)$ vanishes for a in a neighborhood of 0. Hence

$$\langle \psi, U(a)A\Omega \rangle = 0$$

for every real translation a. Since A was arbitrary in $\mathcal{R}(\mathcal{U})$, weak additivity says that ψ is orthogonal to $\mathcal{R}_{\mathrm{glob}}\Omega$. Global cyclicity then gives $\psi = 0$. The orthogonal complement of $\mathcal{R}(\mathcal{O})\Omega$ is zero, which proves the density. □

Corollary 3.20 (Separatingness from Reeh–Schlieder and locality)**.** *Under the hypotheses of Theorem 3.19, let* $\mathcal{O}$ *be a nonempty open region to which the theorem applies. If* $B \in \mathcal{B}(\mathcal{H})$ *commutes with* $\mathcal{R}(\mathcal{O})$ *and* $B\Omega = 0$*, then* $B = 0$*. Consequently* Ω *is separating for every von Neumann algebra* $\mathcal{M} \subset \mathcal{R}(\mathcal{O})'$*.*

In particular, let W *be a wedge and define* $\mathcal{R}(W)$ *as the von Neumann algebra generated by double-cone algebras contained in* W*. If the causal complement* W' *contains a nonempty open region* $\mathcal{O}$ *to which Theorem 3.19 applies, then* Ω *is separating for* $\mathcal{R}(W)$*.*

Proof. Let B commute with $\mathcal{R}(\mathcal{O})$ and satisfy $B\Omega = 0$. For every $A \in \mathcal{R}(\mathcal{O})$,

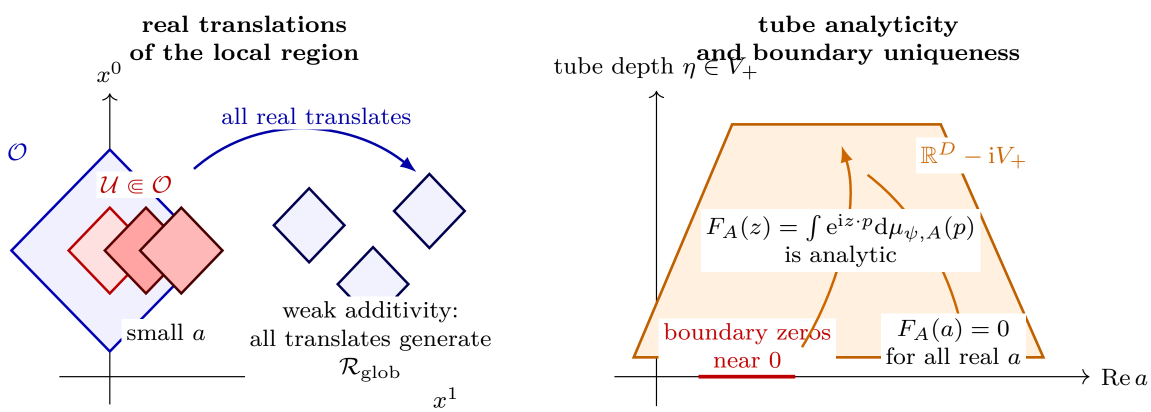
$$BA\Omega = AB\Omega = 0.$$

Theorem 3.19 says that $\mathcal{R}(\mathcal{O})\Omega$ is dense in $\mathcal{H}$. Since B is bounded, B vanishes on all of $\mathcal{H}$. If $\mathcal{M} \subset \mathcal{R}(\mathcal{O})'$, the same argument applies to each $B \in \mathcal{M}$ with $B\Omega = 0$, which is precisely separatingness of Ω for $\mathcal{M}$.

For the wedge statement, locality gives $\mathcal{R}(W) \subset \mathcal{R}(\mathcal{O})'$ whenever $\mathcal{O} \subset W'$. The preceding paragraph then applies with $\mathcal{M} = \mathcal{R}(W)$. No Haag duality is used here; Haag duality would identify a larger commutant with an algebra assigned to the causal complement, whereas the separatingness conclusion only needs the inclusion forced by locality. $\square$

The theorem and its separatingness corollary are used as inputs for modular theory, superselection analysis, and scattering theory in algebraic form.

Figure 3.3 emphasizes the strong content of the theorem. Operators localized in a fixed small region $\mathcal{O}$ generate, from the vacuum alone, a set of vectors dense in the whole vacuum Hilbert space. The conclusion is a Hilbert-space density statement controlled by positive-energy analytic continuation: weak additivity and analyticity leave no nonzero vector orthogonal to all vectors $A\Omega$ with $A \in \mathcal{R}(\mathcal{O})$.



$$\boxed{\psi \perp \mathcal{R}(\mathcal{O})\Omega \Rightarrow F_A(a) = 0 \text{ near } 0 \Rightarrow F_A(a) = 0 \text{ for all } a \Rightarrow \psi \perp \mathcal{R}_{\mathrm{glob}}\Omega \Rightarrow \psi = 0}$$

Figure 3.3: Reeh–Schlieder local cyclicity. The geometric input is the existence of $\mathcal{U} \Subset \mathcal{O}$, so that small real translations of $\mathcal{U}$ remain inside $\mathcal{O}$. If $\psi \perp \mathcal{R}(\mathcal{O})\Omega$, then $F_A(a) = \langle \psi, U(a)A\Omega\rangle$ vanishes on a real neighborhood of 0 for every $A \in \mathcal{R}(\mathcal{U})$. The spectral condition analytically continues F_A to the forward spectral tube $M - \mathrm{i}V_+$; the boundary-value uniqueness lemma for such tube-holomorphic functions propagates this vanishing to all real translations. Weak additivity then turns the translated local algebras into $\mathcal{R}_{\mathrm{glob}}$, and global cyclicity forces $\psi = 0$.

3.9 Locally Covariant Form

Definition 3.21 (Locally covariant C^*-algebraic QFT functor)**.** Let **Loc** be the category whose objects are oriented, time-oriented globally hyperbolic Lorentzian spacetimes X, and whose morphisms $\chi : X \to Y$ are isometric embeddings preserving orientation and time orientation, with causally convex image. Let $\mathbf{C^*Alg}_{\mathrm{inj}}$ be the category of unital C^*-algebras and injective unital $*$-homomorphisms. A locally covariant C^*-algebraic QFT is a functor

$$\mathfrak{A} : \mathbf{Loc} \longrightarrow \mathbf{C^*Alg}_{\mathrm{inj}}.$$

For a morphism $\chi : X \to Y$, write

$$\alpha_\chi := \mathfrak{A}(\chi) : \mathfrak{A}(X) \to \mathfrak{A}(Y).$$

The functor satisfies the time-slice property when α_χ is an isomorphism for every Cauchy morphism, meaning every χ whose image contains a Cauchy surface of Y. It satisfies Einstein causality when, for two morphisms $\chi_i : X_i \to Y$ with causally disjoint images,

$$[\alpha_{\chi_1}(A_1), \alpha_{\chi_2}(A_2)] = 0, \qquad A_i \in \mathfrak{A}(X_i).$$

This formulation preserves the local content of QFT in spacetimes where symmetry selects no distinguished global vacuum. On Minkowski spacetime, restricting $\mathfrak{A}$ to embeddings of suitable regions into M recovers a Haag–Kastler-type net.

For the present monograph, the algebraic framework supplies a precise language for local observables, states, sectors, and structural locality theorems. Its connection with path integrals, perturbative expansions, and point-field descriptions is a comparison problem to be tracked explicitly case by case.

4.1 Representations as Sectors

Let $M = \mathbb{M}^D$ be Minkowski spacetime, let $\mathcal{O} \mapsto \mathcal{A}(\mathcal{O})$ be a local observable net, and let $\mathcal{A}_{\mathrm{qloc}}$ be its quasilocal algebra. Let

$$\pi_0 : \mathcal{A}_{\mathrm{qloc}} \to \mathcal{B}(\mathcal{H}_0)$$

be a vacuum representation. A representation

$$\pi : \mathcal{A}_{\mathrm{qloc}} \to \mathcal{B}(\mathcal{H}_\pi)$$

defines a representation sector. Two representations belong to the same sector when they are unitarily equivalent:

$$\pi_1 \simeq \pi_2 \quad \iff \quad \exists\, V : \mathcal{H}_{\pi_1} \to \mathcal{H}_{\pi_2} \text{ unitary with } V\pi_1(A) = \pi_2(A)V.$$

For irreducible representations, inequivalent sectors have no nonzero observable intertwiner between them. More generally, disjoint representations have no unitarily equivalent nonzero subrepresentations; this is the representation-theoretic content of superselection by the observable algebra.

In massive relativistic theories, the sectors relevant for ordinary charges are often captured by the Doplicher–Haag–Roberts localization criterion. A representation π is localized in a bounded region $\mathcal{O}$ relative to the vacuum if

$$\pi|_{\mathcal{A}(\mathcal{O}^\perp)} \simeq \pi_0|_{\mathcal{A}(\mathcal{O}^\perp)}, \tag{4.1}$$

where $\mathcal{O}^\perp$ denotes the spacelike complement and $\mathcal{A}(\mathcal{O}^\perp)$ is the algebra generated by local algebras $\mathcal{A}(\mathcal{U})$ with $\mathcal{U} \subset \mathcal{O}^\perp$. It is transportable if an equivalent representation can be localized in any other suitable bounded region. A transportable localized sector is a charge class whose localization region may be changed without changing its sector.

Figure 4.1 records the geometric content of the DHR localization condition in a $1+1$-dimensional slice. The relevant exterior region is the spacelike complement $\mathcal{O}^\perp$, not the set-theoretic complement of $\mathcal{O}$: observables supported there have no causal contact with the bounded localization region, and the sector representation restricts to the vacuum representation on the algebra generated by those observables.

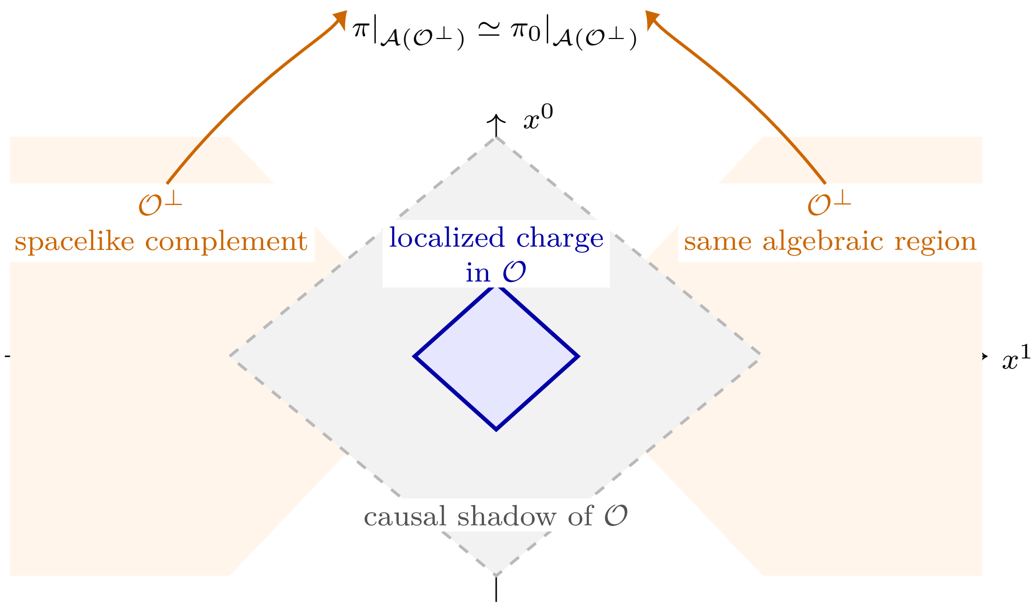

Figure 4.1: DHR localization in a spacetime slice. The sector may differ from the vacuum inside a bounded localization region $\mathcal{O}$, while on the algebra generated by observables in the spacelike complement $\mathcal{O}^\perp$ its representation is unitarily equivalent to the vacuum representation.

4.2 Endomorphisms, Fusion, and Intertwiners

Assume Haag duality in the vacuum representation,

$$\mathcal{R}(\mathcal{O}) = \mathcal{R}(\mathcal{O}^\perp)',$$

and assume the representation π satisfies the localization and transportability condition above. After identifying $\pi|_{\mathcal{A}(\mathcal{O}^\perp)}$ with $\pi_0|_{\mathcal{A}(\mathcal{O}^\perp)}$, and after replacing $\mathcal{A}_{\mathrm{qloc}}$ by its image in the vacuum representation, the action of π may be represented by an endomorphism

$$\rho : \mathcal{A}_{\mathrm{qloc}} \to \mathcal{A}_{\mathrm{qloc}}$$

localized in $\mathcal{O}$, meaning that

$$\rho(A) = A, \qquad A \in \mathcal{A}(\mathcal{O}^\perp).$$

The reason Haag duality appears in this sentence is the containment argument of Chapter 3. If $\mathcal{O}_0$ localizes ρ and $\mathcal{O}_0 \subset \mathcal{O}_1$, then for $A \in \mathcal{R}(\mathcal{O}_1)$ and $B \in \mathcal{R}(\mathcal{O}_1^\perp)$,

$$\rho(A)B = \rho(A)\rho(B) = \rho(AB) = \rho(BA) = B\rho(A).$$

Hence $\rho(A) \in \mathcal{R}(\mathcal{O}_1^\perp)'$. Haag duality turns this exterior-commutation conclusion into $\rho(A) \in \mathcal{R}(\mathcal{O}_1)$. Similarly, an intertwiner $T\rho(\,\cdot\,) = \sigma(\,\cdot\,)T$ between endomorphisms localized in $\mathcal{O}$ commutes with $\mathcal{R}(\mathcal{O}^\perp)$, and Haag duality places T in $\mathcal{R}(\mathcal{O})$. Without this step the same construction naturally lands in the dual net $\mathcal{R}^d(\mathcal{O}) = \mathcal{R}(\mathcal{O}^\perp)'$. Composition of localized endomorphisms defines fusion:

$$\rho_1 \otimes \rho_2 = \rho_1 \circ \rho_2.$$

We use ordinary function-composition order:

$$(\rho_1 \circ \rho_2)(A) = \rho_1(\rho_2(A)), \qquad A \in \mathcal{A}_{\mathrm{qloc}}.$$

Thus ρ_2 acts first and ρ_1 acts second. An intertwiner from ρ to σ is an observable $T \in \mathcal{A}_{\mathrm{qloc}}$ such that

$$T\rho(A) = \sigma(A)T, \qquad A \in \mathcal{A}_{\mathrm{qloc}}.$$

The intertwiners are morphisms between charge sectors. With direct sums, subobjects, conjugates, and a tensor product, transportable localized endomorphisms form a tensor category. Locality gives the exchange isomorphism

$$\varepsilon_{\rho,\sigma} : \rho \circ \sigma \to \sigma \circ \rho$$

when the localization regions are spacelike separated and then transported back to common reference regions. In spacetime dimension at least three, this exchange is symmetric when the DHR hypotheses used above are supplemented by transportability, Haag duality for the vacuum net, finite statistics, and the path-connectedness of the relevant spacelike localization configurations. The last condition is the topological input that makes the two exchanges ρ around σ homotopic. In two dimensions and for lower-codimension extended sectors, the corresponding configuration spaces need not have this symmetry; the exchange maps are then represented by braid group actions rather than by the symmetric group.

4.3 Statistics Operators and Conjugates

The exchange isomorphism contains the statistics of the sector. For a localized endomorphism ρ, choose a transported copy ρ' localized spacelike to ρ. Locality gives an intertwiner

$$\varepsilon_{\rho,\rho} : \rho \circ \rho \to \rho \circ \rho$$

after transporting ρ' back to the reference region. In spacetime dimension at least three, the DHR exchange operators satisfy symmetric tensor category identities, so irreducible sectors have Bose, Fermi, or more general parastatistics encoded by finite-dimensional permutation-group representations.

For objects η, θ, the morphism space $\mathrm{Hom}(\eta, \theta)$ is the space of intertwiners from η to θ. The symbol 1_η denotes the identity morphism in $\mathrm{Hom}(\eta, \eta)$; in the endomorphism realization it is the unit observable viewed as an intertwiner $\eta \to \eta$. A sector ρ has a conjugate $\bar{\rho}$ when there are intertwiners

$$R : \mathrm{id} \to \bar{\rho} \circ \rho, \qquad \bar{R} : \mathrm{id} \to \rho \circ \bar{\rho}$$

satisfying the conjugate equations

$$\bar{R}^* \rho(R) = 1_\rho, \qquad R^* \bar{\rho}(\bar{R}) = 1_{\bar{\rho}}.$$

The minimal value of $\|R\| \, \|\bar{R}\|$ defines the statistical dimension

$$d(\rho).$$

In the Doplicher–Haag–Roberts setting, saying that a sector has finite statistics is shorthand for a categorical finiteness package, not only for a choice of exchange sign. In the form used below it means that the sector lies in a C^*-tensor category with finite-dimensional intertwiner spaces, admits a conjugate satisfying the conjugate equations, and has finite statistical dimension $d(\rho) < \infty$. For reducible sectors, the statement is applied after decomposing into irreducible subobjects and requiring only finitely many irreducible summands in each object under consideration. For sectors reconstructed from a compact internal group, $d(\rho)$ is the ordinary dimension of the corresponding irreducible group representation. Thus charge conjugation, fusion multiplicities, and statistics are encoded in the tensor category of localized endomorphisms before any charged field coordinates are chosen.

4.4 Observable Algebra, Field Algebra, and Compact Internal Group

The observable algebra $\mathcal{A}_{\mathrm{qloc}}$ contains neutral operators. Charged fields, when they are introduced as operators, can be organized in an enlarged algebra

$$\mathcal{F}$$

with a compact internal group G acting by automorphisms. The observable algebra is the fixed-point algebra

$$\mathcal{A}_{\mathrm{qloc}} = \mathcal{F}^G.$$

Quoted Theorem 4.1 (Doplicher–Roberts reconstruction)**.** Proof references.[1] *Let $D \geq 3$. Let the vacuum representation of the observable net be irreducible and satisfy Haag duality for double cones. Let $\mathcal{C}$ be the category of DHR sectors represented by transportable localized endomorphisms of $\mathcal{A}_{\mathrm{qloc}}$. Equivalently, their associated representations satisfy the localization criterion* (4.1) *in some bounded double cone and are transportable to every other such double cone; in the endomorphism realization they act trivially on the algebra of the spacelike complement. Assume that $\mathcal{C}$ has the following structure:*

[1] The DHR sector analysis is developed in S. Doplicher, R. Haag, and J. E. Roberts, "Local observables and particle statistics I," *Communications in Mathematical Physics* **23** (1971), 199–230, and "Local observables and particle statistics II," *Communications in Mathematical Physics* **35** (1974), 49–85. The categorical compact-group duality is proved in S. Doplicher and J. E. Roberts, "A new duality theory for compact groups," *Inventiones Mathematicae* **98** (1989), 157–218. The field-algebra reconstruction in the AQFT setting is proved in S. Doplicher and J. E. Roberts, "Why there is a field algebra with a compact gauge group describing the superselection structure in particle physics," *Communications in Mathematical Physics* **131** (1990), 51–107 [22, 23, 24, 25].

(i) *it is a symmetric C^*-tensor category with simple tensor unit;*

(ii) *each intertwiner space* $\mathrm{Hom}(\rho, \sigma)$ *is finite-dimensional;*

(iii) *the category is closed under finite direct sums and subobjects;*

(iv) *every irreducible object has a conjugate object satisfying the conjugate equations and has finite statistical dimension $d(\rho) < \infty$;*

(v) *every object of $\mathcal{C}$ is a finite direct sum of irreducible subobjects of the preceding kind.*

Then there is a compact group

$$G = \mathrm{Aut}^{\otimes,*}(\omega_{\mathrm{fib}})$$

for a faithful symmetric tensor $*$-functor $\omega_{\mathrm{fib}} : \mathcal{C} \to \mathrm{Hilb}_{\mathrm{fd}}$, where $\mathrm{Hilb}_{\mathrm{fd}}$ *denotes finite-dimensional Hilbert spaces, and*

$$\mathcal{C} \simeq \mathrm{Rep}_{\mathrm{fd}}(G)$$

as symmetric C^*-tensor categories. Moreover, after the standard Doplicher–Roberts field-algebra reconstruction, there is a C^*-algebra $\mathcal{F}$ carrying a continuous action of G by automorphisms such that

$$\mathcal{A}_{\mathrm{qloc}} \simeq \mathcal{F}^G.$$

The irreducible DHR sectors correspond to irreducible finite-dimensional unitary representations of G, and charged field multiplets in $\mathcal{F}$ transform according to these representations.

In this quoted theorem, the word gauge means a reconstruction of charged field coordinates from the neutral observable category; physical observables remain the G-invariant elements. The compact group description is therefore not an input at this stage. It is a conclusion from locality, transportability, Haag duality, symmetric exchange, and finite statistics.

Reconstruction logic and theorem boundary. The reconstruction has two logically separate components. The first is the QFT-specific passage from localized representations to a rigid symmetric C^*-tensor category. Haag duality is the step that permits a DHR representation localized in $\mathcal{O}$ to be represented by an endomorphism ρ of the vacuum quasilocal algebra acting trivially on $\mathcal{A}(\mathcal{O}^\perp)$. Transportability makes the localization region a choice of representative rather than part of the sector. Locality and the path-connectedness of spacelike configurations in $D \geq 3$ give a symmetric exchange isomorphism, while finite statistics supplies conjugates and finite statistical dimension. These are the hypotheses that must be verified in a model before the theorem applies.

The second component is categorical duality. Once the category $\mathcal{C}$ has the properties listed in Theorem 4.1, the compact group

$$G = \mathrm{Aut}^{\otimes,*}(\omega_{\mathrm{fib}})$$

is obtained as the group of unitary tensor automorphisms of a faithful fiber functor ω_{fib}. Its topology is the compact topology inherited from the product of the unitary groups $\prod_{\rho \in \mathrm{Obj}(\mathcal{C})} U(\omega_{\mathrm{fib}}(\rho))$, with the closed conditions expressing naturality and tensor compatibility. The equivalence $\mathcal{C} \simeq \mathrm{Rep}_{\mathrm{fd}}(G)$ is therefore a Tannakian output of the observable sector category.

The field algebra reconstructed from $\mathcal{C}$ can be recognized locally by its charged multiplets. For an irreducible sector ρ with statistical dimension $d(\rho)$, which is the dimension of the corresponding irreducible representation after the Doplicher–Roberts equivalence, the reconstructed algebra contains a finite-dimensional Hilbert space of charged operators

$$\mathcal{H}_\rho^{\mathrm{ch}} = \mathrm{span}\{\psi_{\rho,1}, \ldots, \psi_{\rho,d(\rho)}\} \subset \mathcal{F}$$

whose elements satisfy the intertwining relation

$$\rho(A)\psi_{\rho,i} = \psi_{\rho,i}A, \qquad A \in \mathcal{A}_{\mathrm{qloc}}. \tag{4.2}$$

After choosing an orthonormal multiplet, one has the Cuntz-type normalization

$$\psi_{\rho,i}^*\psi_{\rho,j} = \delta_{ij}\mathbf{1}, \qquad \sum_{i=1}^{d(\rho)} \psi_{\rho,i}\psi_{\rho,i}^* = \mathbf{1}, \tag{4.3}$$

in the finite-statistics case, and the observable endomorphism is recovered from the charged fields by

$$\rho(A) = \sum_{i=1}^{d(\rho)} \psi_{\rho,i}A\psi_{\rho,i}^*. \tag{4.4}$$

The G-action rotates the multiplet by the representation corresponding to ρ:

$$\alpha_g(\psi_{\rho,i}) = \sum_{j=1}^{d(\rho)} \psi_{\rho,j}\, D_\rho(g)_{ji}, \qquad g \in G. \tag{4.5}$$

Equations (4.2)–(4.5) are not additional assumptions on observables; they are the operator form of the reconstructed charged coordinates. The observable algebra remains the fixed algebra $\mathcal{F}^G$, and the physical sector information is already present in $\mathcal{C}$.

Local charged-field core. The preceding formulae become a local field net only after the localization regions of the DHR endomorphisms are used. Fix a double cone $\mathcal{O}$ and choose, for each irreducible DHR sector ρ localizable in $\mathcal{O}$, a charged multiplet

$$\mathcal{H}_\rho^{\mathrm{ch}}(\mathcal{O}) = \mathrm{span}\{\psi_{\rho,1}^{\mathcal{O}}, \ldots, \psi_{\rho,d(\rho)}^{\mathcal{O}}\}$$

satisfying (4.2) with ρ localized in $\mathcal{O}$. The algebraic local core is the finite linear span

$$\mathcal{F}_{\mathrm{alg}}(\mathcal{O}) = \mathrm{span}\{A\psi_{\rho,i}^{\mathcal{O}} : A \in \mathcal{R}(\mathcal{O}),\ \rho \in \mathrm{Irr}(\mathcal{C}),\ 1 \le i \le d(\rho)\}. \tag{4.6}$$

This is a core, not yet a completed local C^*-algebra. Its multiplication is forced by the intertwining relation. If $A, B \in \mathcal{R}(\mathcal{O})$, then

$$(A\psi_{\rho,i}^{\mathcal{O}})(B\psi_{\sigma,j}^{\mathcal{O}}) = A\,\rho(B)\,\psi_{\rho,i}^{\mathcal{O}}\psi_{\sigma,j}^{\mathcal{O}}. \tag{4.7}$$

Haag duality and the containment calculation above are used here in a load-bearing way: since ρ is localized in $\mathcal{O}$, $\rho(B) \in \mathcal{R}(\mathcal{O})$. The product $\psi_{\rho,i}^{\mathcal{O}}\psi_{\sigma,j}^{\mathcal{O}}$ transforms in the sector $\rho \circ \sigma$, because

$$(\rho \circ \sigma)(A)\psi_{\rho,i}^{\mathcal{O}}\psi_{\sigma,j}^{\mathcal{O}} = \psi_{\rho,i}^{\mathcal{O}}\sigma(A)\psi_{\sigma,j}^{\mathcal{O}} = \psi_{\rho,i}^{\mathcal{O}}\psi_{\sigma,j}^{\mathcal{O}}A.$$

After decomposing $\rho\circ\sigma$ into irreducible sectors, the Clebsch–Gordan intertwiners in $\mathrm{Hom}(\tau, \rho\circ\sigma)$ rewrite the right side of (4.7) as a finite sum of generators of the form (4.6). Thus fusion in the DHR category is the multiplication law of local charged coordinates.

The involution uses the conjugate sector. Finite statistics supplies standard conjugate data

$$R : \mathrm{id} \to \bar{\rho} \circ \rho, \qquad \bar{R} : \mathrm{id} \to \rho \circ \bar{\rho},$$

and the adjoint of a ρ-charged generator is expanded, through this conjugate data and local intertwiners, as a finite linear combination of $\bar{\rho}$-charged generators with coefficients in $\mathcal{R}(\mathcal{O})$. Finite statistics therefore supplies the adjoint-closing structure required by the field-algebra theorem, in addition to the exchange data.

The reconstructed compact group acts on the local core by

$$\alpha_g(A) = A, \qquad \alpha_g(\psi^{\mathcal{O}}_{\rho,i}) = \sum_j \psi^{\mathcal{O}}_{\rho,j} D_\rho(g)_{ji}.$$

The Haar conditional expectation on the local core is

$$E_{\mathcal{O}}(F) = \int_G \alpha_g(F)\,\mathrm{d}g. \tag{4.8}$$

By Schur orthogonality it kills every nontrivial irreducible charged block and keeps the trivial block. Consequently

$$E_{\mathcal{O}}(\mathcal{F}_{\mathrm{alg}}(\mathcal{O})) = \mathcal{R}(\mathcal{O}), \qquad \mathcal{F}_{\mathrm{alg}}(\mathcal{O})^G = \mathcal{R}(\mathcal{O})$$

at the algebraic core level. The Doplicher–Roberts field-algebra theorem is the statement that this core can be completed, with compatible choices as $\mathcal{O}$ varies, to a local charged-field net whose G-fixed subnet is the original observable net. The nontrivial analytic work is not the formal multiplication above; it is the proof that the transported charged multiplets, exchange operators, adjoints, C^*-norm, and locality relations can be chosen coherently across all regions.

The word conditional in $E_{\mathcal{O}}$ is also load-bearing. On the algebraic core, Haar invariance gives

$$E_{\mathcal{O}}^2 = E_{\mathcal{O}}, \qquad E_{\mathcal{O}}(\alpha_g(F)) = E_{\mathcal{O}}(F), \qquad E_{\mathcal{O}}(A_1 F A_2) = A_1 E_{\mathcal{O}}(F) A_2$$

for $A_1, A_2 \in \mathcal{R}(\mathcal{O})$. Positivity is inherited from averaging $*$-automorphisms. Thus the fixed-point statement has the algebraic form of a faithful expectation from charged coordinates back to neutral observables, with charge-zero projection as its representation-ring shadow. The theorem-level completion must preserve this expectation in the local C^*-norms.

Charged locality and observable locality. For spacelike separated double cones, the charged field generators need not commute as ordinary neutral observables. Their exchange is controlled by the DHR symmetry

$$\varepsilon_{\rho,\sigma} : \rho \circ \sigma \to \sigma \circ \rho.$$

In dimension $D \geq 3$, under the symmetric finite-statistics hypotheses of Theorem 4.1, this exchange reduces to the Bose/Fermi/parastatistical symmetry encoded by the reconstructed compact group and its central grading. The invariant subnet is local because the exchange factors cancel in the trivial representation channel. Thus the locality statement for observables is recovered as the invariant part of the charged-field exchange mechanism.

Neutral-channel locality in the reconstructed core. The preceding cancellation is a categorical statement before it is an operator-closure theorem. Let V_ρ and V_σ be the finite charged multiplet spaces carrying the compact-group representations D_ρ and D_σ. The projection onto the neutral component of the product multiplet is

$$P_{\mathbf{1}}^{\rho,\sigma} = \int_G D_\rho(g) \otimes D_\sigma(g)\,\mathrm{d}g \in \mathrm{End}(V_\rho \otimes V_\sigma). \tag{4.9}$$

For irreducible ρ, σ, Schur orthogonality says that $P_{\mathbf{1}}^{\rho,\sigma} = 0$ unless $\sigma \simeq \bar{\rho}$; in the conjugate case its image is the one-dimensional tensor-unit summand

$$\mathrm{Hom}_G(\mathbb{C}, V_\rho \otimes V_{\bar{\rho}}).$$

Applying $E_{\mathcal{O}}$ in (4.8) to a product of charged local generators is exactly the insertion of these projectors on the charged indices after the fusion decomposition. Thus an observable local element is not an arbitrary product of charged fields; it is the tensor-unit component of such a product, with all nontrivial charged blocks removed by Haar projection.

Now take $F_1 \in \mathcal{F}_{\mathrm{alg}}(\mathcal{O}_1)^G$ and $F_2 \in \mathcal{F}_{\mathrm{alg}}(\mathcal{O}_2)^G$ with $\mathcal{O}_1 \perp \mathcal{O}_2$. The charged-field exchange operation first transports the charged tensor factors by $\varepsilon_{\rho,\sigma}$. But F_1 and F_2 lie in tensor-unit subobjects after the projections (4.9). Naturality of the symmetric braiding and simplicity of the tensor unit give

$$\varepsilon_{\mathbf{1},\mathbf{1}} = \mathrm{id}_{\mathbf{1}}\,.$$

Hence no charge matrix remains on the invariant channel: the categorical exchange reduces to the ordinary equality required for observable locality. This proves only the algebraic neutral-channel mechanism in the DR core. The hard local-QFT theorem remains the coherent C^*-completion and regionwise choice of charged multiplets for which the charged exchange relations and the invariant local observable net survive completion.

Finite pointed check of the compact group output. A useful local model of the categorical part is the following pointed symmetric C^*-tensor category. Fix an integer $N \geq 2$. Let the simple objects be X_q, $q \in \mathbb{Z}/N\mathbb{Z}$, with

$$X_q \otimes X_r \simeq X_{q+r}, \qquad X_0 = \mathbf{1}, \qquad \mathrm{Hom}(X_q, X_r) = \begin{cases} \mathbb{C}, & q = r, \\ 0, & q \neq r. \end{cases}$$

Take the fiber functor $\omega_{\mathrm{fib}}(X_q) = \mathbb{C}$. A unitary tensor automorphism $u \in \mathrm{Aut}^{\otimes,*}(\omega_{\mathrm{fib}})$ is then a choice of phases $u_q \in U(1)$ satisfying

$$u_0 = 1, \qquad u_{q+r} = u_q u_r.$$

Thus $u_q = u_1^q$ and $u_1^N = 1$. The reconstructed compact group is

$$G \simeq \mu_N = \{\zeta \in U(1) : \zeta^N = 1\}, \tag{4.10}$$

and X_q is the one-dimensional representation

$$\zeta \longmapsto \zeta^q.$$

If the corresponding algebraic charged-field core is written as a finite grading

$$\mathcal{F}_{\mathrm{alg}} = \bigoplus_{q \in \mathbb{Z}/N\mathbb{Z}} \mathcal{F}_q, \qquad \mathcal{F}_q \mathcal{F}_r \subset \mathcal{F}_{q+r}, \qquad \alpha_\zeta(F_q) = \zeta^q F_q, \quad F_q \in \mathcal{F}_q, \tag{4.11}$$

then the fixed algebra is exactly the degree-zero summand:

$$\mathcal{F}_{\mathrm{alg}}^{\mu_N} = \mathcal{F}_0. \tag{4.12}$$

Indeed, averaging F_q over G multiplies it by

$$\frac{1}{N} \sum_{\zeta^N = 1} \zeta^q = \delta_{q,0}.$$

This computation functions as a finite-dimensional diagnostic for the theorem's output: the compact group is recovered from the tensor compatibility of the sector fiber functor, and invariants project precisely onto neutral degree.

Finite nonabelian check of the fiber functor. The compact-group output also has genuinely nonabelian content. Take the finite nonabelian group S_3. Its irreducible representations are the trivial representation $\mathbf{1}$, the sign representation ϵ, and the two-dimensional standard representation V. With conjugacy classes ordered as

$$(e), \qquad (12), \qquad (123),$$

their characters are

	e	(12)	(123)
$\mathbf{1}$	1	1	1
ϵ	1	-1	1
V	2	0	-1.

The inner product

$$\langle \chi, \psi \rangle_{S_3} = \frac{1}{6} \sum_{g \in S_3} \chi(g) \overline{\psi(g)}$$

gives the tensor-product rules

$$\epsilon \otimes \epsilon \simeq \mathbf{1}, \qquad \epsilon \otimes V \simeq V, \qquad V \otimes V \simeq \mathbf{1} \oplus \epsilon \oplus V. \tag{4.13}$$

For each group element g, evaluation gives a unitary tensor automorphism of the forgetful fiber functor

$$\omega_{\mathrm{fib}} : \mathrm{Rep}_{\mathrm{fd}}(S_3) \to \mathrm{Hilb}_{\mathrm{fd}}, \qquad \eta_g(W) = D_W(g).$$

Tensor compatibility is the identity

$$D_{W_1 \otimes W_2}(g) = D_{W_1}(g) \otimes D_{W_2}(g),$$

and naturality says that every intertwiner, in particular the projection maps realizing (4.13), commutes with η_g. The standard representation is faithful, so the six automorphisms η_g are distinct. The converse statement, that every unitary tensor natural automorphism of the forgetful functor is evaluation at a unique $g \in S_3$, is the finite Tannakian part of the Doplicher–Roberts theorem in this example. The calculation above makes visible what the theorem reconstructs: a nonabelian group is encoded by the compatibility of the multiplet transformations with all fusion and intertwiner maps, not by an externally assigned charge label.

The fixed-point projection is likewise representation-theoretic rather than degree-theoretic. If a finite charged-field core decomposes into matrix coefficient spaces for irreducible S_3-representations, Haar averaging is

$$E_{S_3}(F) = \frac{1}{6}\sum_{g\in S_3} \alpha_g(F).$$

For a nontrivial irreducible representation W, Schur orthogonality gives

$$\frac{1}{6}\sum_{g\in S_3} D_W(g)_{ab} = 0,$$

whereas the trivial representation is fixed. Thus averaging projects onto the $\mathbf{1}$-isotypic, observable part. In the pointed $\mathbb{Z}/N\mathbb{Z}$ model this projection is the elementary root-of-unity sum; in the nonabelian S_3 model it is the vanishing of nontrivial matrix coefficients.

Finite nonabelian charged-coordinate core. The preceding S_3 calculation can be made into a finite field-core model, with the observable algebra suppressed to $\mathbb{C}$, by taking

$$\mathcal{F}_{\mathrm{ch}} = \mathrm{Fun}(S_3)$$

with pointwise multiplication. The reconstructed compact group acts on the right:

$$(\alpha_h f)(g) = f(gh), \qquad f \in \mathrm{Fun}(S_3), \quad g, h \in S_3. \tag{4.14}$$

The fixed algebra is the constants, since right translations act transitively on S_3. For an irreducible finite-dimensional representation W, its matrix coefficients

$$f^W_{ab}(g) = D_W(g)_{ab}$$

span a right S_3-multiplet:

$$\alpha_h(f^W_{ab}) = \sum_c f^W_{ac}\, D_W(h)_{cb}. \tag{4.15}$$

Thus the column index is the charged multiplet index, while the row index records the multiplicity with which W appears in the finite regular field-core model. Haar projection is the finite conditional expectation

$$E_{S_3}(f) = \frac{1}{6}\sum_{h\in S_3} \alpha_h(f), \qquad E_{S_3}(f^W_{ab}) = \begin{cases} 1, & W = \mathbf{1}, \\ 0, & W \neq \mathbf{1}, \end{cases} \tag{4.16}$$

with the second line understood after choosing the constant matrix coefficient for $W = \mathbf{1}$. Multiplication of charged coordinates is the matrix-coefficient form of tensor product:

$$f^U_{ab}(g) f^V_{cd}(g) = D_{U\otimes V}(g)_{(a,c),(b,d)}. \tag{4.17}$$

Decomposing $U \otimes V$ by intertwiners gives the fusion rules such as (4.13). This finite model is not a local QFT field algebra; its observable part is only $\mathbb{C}$. Its purpose is to show, without the analytic burden of DHR localization, how nonabelian charged coordinates, Haar expectation, and fusion multiplication are the same data that the Doplicher–Roberts theorem reconstructs from a symmetric finite-statistics sector category.

Finite Tannakian converse through the regular algebra. The finite regular algebra also makes the converse direction of the Tannakian reconstruction visible. Let G be a finite group and let

$$\mathcal{R} = \mathrm{Fun}(G)$$

with point idempotents δ_x, $x \in G$. The left regular action is

$$(L_a f)(g) = f(a^{-1}g), \qquad L_a\delta_x = \delta_{ax}. \tag{4.18}$$

Every unital $*$-automorphism T of the commutative finite-dimensional algebra $\mathcal{R}$ permutes the minimal projections:

$$T\delta_x = \delta_{\phi(x)}$$

for a unique permutation ϕ of G. If T commutes with every left translation, then

$$\delta_{\phi(ax)} = TL_a\delta_x = L_aT\delta_x = \delta_{a\phi(x)}.$$

Hence $\phi(ax) = a\phi(x)$. Setting $x = e$ gives

$$\phi(a) = ah, \qquad h = \phi(e),$$

and therefore $\phi(x) = xh$ for all $x \in G$. Thus every left-equivariant algebra automorphism of $\mathrm{Fun}(G)$ is a right translation:

$$(T_h f)(g) = f(gh^{-1}). \tag{4.19}$$

For a matrix coefficient $f^W_{\alpha i}(g) = D_W(g)_{\alpha i}$, (4.19) gives

$$T_h f^W_{\alpha i}(g) = D_W(gh^{-1})_{\alpha i} = \sum_j f^W_{\alpha j}(g)\, D_W(h^{-1})_{ji}. \tag{4.20}$$

Thus the corresponding tensor natural automorphism of the forgetful fiber functor is

$$u_W = D_W(h^{-1})$$

on every finite-dimensional representation W. Conversely, a unitary tensor natural automorphism u_W acts on matrix coefficients by the right side of (4.20); tensor compatibility makes this action multiplicative under (4.17), naturality makes it commute with the intertwiners that decompose tensor products, and the Peter–Weyl decomposition of $\mathrm{Fun}(G)$ gives a left-equivariant $*$-automorphism of $\mathcal{R}$. The preceding paragraph then supplies a unique $h \in G$. For finite groups this proves

$$\mathrm{Aut}^{\otimes,*}(\omega_{\mathrm{fib}}) \simeq G$$

in the convention $u_W = D_W(h^{-1})$. The compact-group Doplicher–Roberts theorem uses the same Peter–Weyl mechanism with the dense Hopf $*$-algebra of representative functions and the C^*-norm closure; the local-QFT burden remains the DHR construction of the symmetric finite-statistics sector category and the field-algebra realization of this categorical duality.

Compact Peter–Weyl coordinate algebra. The compact version of the preceding finite calculation is the representative-function Hopf $*$-algebra. Let G be a compact group and let W range over finite-dimensional continuous unitary representations. For $v \in W$ and $\ell \in W^*$, write

$$f^W_{\ell,v}(g) = \ell(D_W(g)v).$$

The algebra

$$\mathrm{Pol}(G) = \mathrm{span}\{f^W_{\ell,v}\} \subset C(G)$$

is closed under multiplication because

$$f^{W_1}_{\ell_1,v_1}(g)\, f^{W_2}_{\ell_2,v_2}(g) = f^{W_1\otimes W_2}_{\ell_1\otimes\ell_2,\, v_1\otimes v_2}(g), \tag{4.21}$$

and it is closed under $*$ because complex conjugation is the matrix coefficient of the conjugate representation. The Hopf operations are the group-law operations written on functions; in this paragraph write Δ_{H} for the coproduct, to avoid confusing it with the modular operator Δ used elsewhere in the chapter:

$$(\Delta_{\mathrm{H}} f)(g,h) = f(gh), \quad \epsilon(f) = f(e), \quad (Sf)(g) = f(g^{-1}). \tag{4.22}$$

Associativity of group multiplication gives coassociativity of Δ_{H}; the identity element gives the counit identities; inversion gives the antipode identities

$$m(S\otimes \mathrm{id})\Delta_{\mathrm{H}} f = m(\mathrm{id}\otimes S)\Delta_{\mathrm{H}} f = \epsilon(f)\mathbf{1}.$$

Peter–Weyl says that $\mathrm{Pol}(G)$ is uniformly dense in $C(G)$, and Schur orthogonality decomposes it as the algebraic direct sum of matrix coefficient spaces

$$\mathrm{Pol}(G) \simeq \bigoplus_{\widehat{G}} W^* \otimes W.$$

Haar integration is the unique bi-invariant positive normalized functional

$$h_G(f) = \int_G f(g)\,\mathrm{d}g,$$

and it kills every nontrivial irreducible matrix-coefficient block while keeping the trivial block.

This compact Peter–Weyl algebra is the coordinate side of the compact group appearing in Doplicher–Roberts reconstruction. The tensor category supplies the representations W, tensor products supply multiplication in (4.21), and tensor natural automorphisms of the fiber functor are evaluated by the same matrices $D_W(g)$. The representative functions separate points of G, so the compact group is recoverable from how all charged multiplets transform; equivalently, after the C^*-completion $C(G)$ is supplied, the character space recovers G with its compact topology. None of this proves that a given observable net has the required DHR category; it identifies the compact-group algebra that appears after those local-QFT hypotheses have already been established.

Compact abelian completion: the $U(1)$ charge lattice. The finite pointed example also has a compact limit that contains no finite-group artifact. Let $\mathrm{Rep}_{\mathrm{fd}}(U(1))$ denote the category of finite-dimensional continuous unitary representations of $U(1)$. Its simple objects are the one-dimensional characters L_n, $n \in \mathbb{Z}$, with

$$L_m \otimes L_n \simeq L_{m+n}, \qquad L_0 = \mathbf{1}, \qquad \mathrm{Hom}(L_m, L_n) = \begin{cases} \mathbb{C}, & m = n, \\ 0, & m \neq n. \end{cases}$$

For the forgetful fiber functor $\omega_{\mathrm{fib}} : \mathrm{Rep}_{\mathrm{fd}}(U(1)) \to \mathrm{Hilb}_{\mathrm{fd}}$, a unitary tensor natural automorphism is a family of phases

$$u_n \in U(1), \qquad n \in \mathbb{Z},$$

satisfying

$$u_0 = 1, \qquad u_{m+n} = u_m u_n, \qquad u_{-n} = \overline{u_n}.$$

The first two equations give $u_n = u_1^n$ for $n > 0$ and then, by unitarity, for all $n \in \mathbb{Z}$. Conversely every $\lambda \in U(1)$ gives such a family by $u_n = \lambda^n$. With the topology of pointwise convergence on objects, the evaluation map

$$U(1) \longrightarrow \mathrm{Aut}^{\otimes,*}(\omega_{\mathrm{fib}}), \qquad \lambda \longmapsto (u_n = \lambda^n)_{n \in \mathbb{Z}},$$

is therefore a homeomorphism: continuity is pointwise continuity of λ^n, and the inverse reads off u_1.

The corresponding representative-function algebra is the Laurent polynomial $*$-algebra

$$\mathbb{C}[z, z^{-1}], \qquad z^m z^n = z^{m+n}, \qquad (z^n)^* = z^{-n}.$$

Its C^*-completion in the supremum norm on the unit circle is

$$C(U(1)),$$

because Laurent polynomials are a unital self-adjoint subalgebra separating points of $U(1)$. Haar expectation is the projection onto the trivial isotypic component:

$$E_{U(1)}(z^n) = \int_{U(1)} z^n \, \mathrm{d}z = \delta_{n0}. \tag{4.23}$$

Thus a $U(1)$-graded charged algebraic core

$$\mathcal{F}_{\mathrm{alg}} = \bigoplus_{n \in \mathbb{Z}} \mathcal{F}_n, \qquad \mathcal{F}_m \mathcal{F}_n \subset \mathcal{F}_{m+n}, \qquad \alpha_\lambda(F_n) = \lambda^n F_n$$

has invariant part

$$\mathcal{F}_{\mathrm{alg}}^{U(1)} = \mathcal{F}_0$$

on every finite Laurent-polynomial subspace. This compact abelian calculation is the charge-lattice version of the finite $\mathbb{Z}/N\mathbb{Z}$ diagnostic above. It supplies the categorical and representative-function completion, not the local-QFT theorem: a concrete QFT still has to produce the localized symmetric finite-statistics category, the field algebra, and the action whose fixed points are the observable net.

Example 4.2 (Pointed field algebra as a crossed product)**.** The same pointed category has an explicit charged-field algebra when the sector X_1 is represented by an order-N localized automorphism

$$\rho \in \mathrm{Aut}(\mathcal{A}), \qquad \rho^N = \mathrm{id}_{\mathcal{A}},$$

of a neutral algebra $\mathcal{A}$. Introduce a unitary charged generator u with

$$u^N = 1, \qquad uAu^* = \rho(A), \quad A \in \mathcal{A},$$

and define the algebraic field core

$$\mathcal{F}_{\mathrm{alg}} = \bigoplus_{q \in \mathbb{Z}/N\mathbb{Z}} \mathcal{A}u^q. \tag{4.24}$$

The multiplication and involution are

$$(Au^q)(Bu^r) = A\,\rho^q(B)\,u^{q+r}, \qquad (Au^q)^* = \rho^{-q}(A^*)u^{-q}. \tag{4.25}$$

Associativity follows from the group law $\rho^{q+r} = \rho^q\rho^r$:

$$\begin{aligned}((Au^q)(Bu^r))(Cu^s) &= A\rho^q(B)\rho^{q+r}(C)u^{q+r+s},\\ (Au^q)((Bu^r)(Cu^s)) &= A\rho^q\big(B\rho^r(C)\big)u^{q+r+s}.\end{aligned}$$

The two expressions agree because ρ^q is an algebra automorphism. The involution is anti-multiplicative because

$$\begin{aligned}\big((Au^q)(Bu^r)\big)^* &= \rho^{-q-r}\big(\rho^q(B^*)A^*\big)u^{-q-r}\\ &= \rho^{-r}(B^*)\,\rho^{-q-r}(A^*)u^{-q-r} = (Bu^r)^*(Au^q)^*.\end{aligned}$$

The reconstructed compact group $\mu_N = \{\zeta \in U(1) : \zeta^N = 1\}$ acts by

$$\alpha_\zeta(Au^q) = \zeta^q Au^q. \tag{4.26}$$

Its fixed algebra is exactly the neutral algebra:

$$\mathcal{F}_{\mathrm{alg}}^{\mu_N} = \mathcal{A}.$$

Indeed, the Haar average over the finite group is

$$E_{\mu_N}\left(\sum_q A_q u^q\right) = \frac{1}{N}\sum_{\zeta^N=1}\sum_q \zeta^q A_q u^q = A_0.$$

Thus the charge creator u implements the localized sector by

$$\rho(A) = uAu^*,$$

while the observable algebra is recovered as the invariant subalgebra. This example is the DR field-algebra output in the invertible pointed case. It is an algebraic output construction. To interpret it as a local charged-field net, the QFT must first supply the DHR input package: locality, transportability, Haag duality, and finite statistics for the sector endomorphisms.

This theorem therefore applies to charges whose sector representatives are localized in bounded regions and satisfy the finite-statistics DHR hypotheses. Charged sectors controlled by long-range Gauss laws, by Wilson-line or spacelike-cone localization, by infraparticle clouds, or by confining dynamics require different localization categories and additional analytic input. Such sectors are not failures of the reconstruction theorem; they lie outside the DHR category to which the theorem is attached. For them one must first define the relevant charged operators and localization structure before asking for an analogue of field-algebra reconstruction or of Haag–Ruelle scattering.

Constructive kink-sector diagnostic. The boundary of the DHR category is visible in broken two-dimensional constructive scalar models. Suppose a massive model has pure phases indexed by σ, vacuum representations π_σ, and a bounded local order-parameter observable B with distinct phase values m_σ. More precisely, choose spatial averaging functions supported in the far left and far right tails and let $B_L(R)$, $B_R(R)$ denote the corresponding bounded observables, with supports moving to $x^1 < -R$ and $x^1 > R$. A solitonic representation

$$\pi_{\sigma_-,\sigma_+}$$

interpolating from phase σ_- at $x^1 = -\infty$ to phase σ_+ at $x^1 = +\infty$ is characterized, when the constructive limits have been proved, by weak-operator tail limits

$$\operatorname*{w-lim}_{R\to\infty} \pi_{\sigma_-,\sigma_+}(B_L(R)) = m_{\sigma_-}\mathbf{1}, \qquad \operatorname*{w-lim}_{R\to\infty} \pi_{\sigma_-,\sigma_+}(B_R(R)) = m_{\sigma_+}\mathbf{1}. \tag{4.27}$$

These limits are macroscopic phase data, not local charged-field data. If π_{σ_-,σ_+} were DHR-localized in a bounded double cone $\mathcal{O}$ relative to a vacuum phase π_{σ_0}, then for sufficiently large R both $B_L(R)$ and $B_R(R)$ would belong to $\mathcal{A}(\mathcal{O}^\perp)$. The DHR equivalence

$$\pi_{\sigma_-,\sigma_+}|_{\mathcal{A}(\mathcal{O}^\perp)} \simeq \pi_{\sigma_0}|_{\mathcal{A}(\mathcal{O}^\perp)}$$

would therefore carry the weak limits of the two tails to the corresponding tail limits in the phase σ_0, namely $m_{\sigma_0}\mathbf{1}$ on both sides. Hence bounded-region DHR localization forces

$$m_{\sigma_-} = m_{\sigma_0} = m_{\sigma_+}.$$

Whenever the left and right asymptotic phases differ, the soliton sector is therefore not a DHR sector relative to a single vacuum representation. It is a sector controlled by asymptotic boundary conditions, equivalently by morphisms between phase representations or by half-line/spacelike-cone localization data. The diagnostic does not assert the existence of such soliton Hilbert spaces; that is a model theorem. It shows which representation-theoretic statement must be proved before a constructive kink can be brought into the DHR local-endomorphism framework, and why the Doplicher–Roberts theorem above is a bounded-charge theorem rather than a classification of all superselection sectors in low-dimensional models.

4.5 Split Property and Local Tensor Factorization

Let $\mathcal{O}_1 \Subset \mathcal{O}_2$ mean that the closure of $\mathcal{O}_1$ is contained in $\mathcal{O}_2$ with a positive spacetime collar. The split property is the existence of a type I factor $\mathcal{N}$ satisfying

$$\mathcal{R}(\mathcal{O}_1) \subset \mathcal{N} \subset \mathcal{R}(\mathcal{O}_2). \tag{4.28}$$

A type I factor is isomorphic to $\mathcal{B}(\mathcal{K})$ for some Hilbert space $\mathcal{K}$. The split inclusion gives a controlled tensor-product separation between observables well inside $\mathcal{O}_1$ and observables outside $\mathcal{O}_2$. It is a precise algebraic substitute for a finite-dimensional subsystem factorization at nonzero separation.

Figure 4.2 records the split inclusion $\mathcal{R}(\mathcal{O}_1) \subset \mathcal{N} \subset \mathcal{R}(\mathcal{O}_2)$ and its role as a type-I tensor-product separation at positive distance.

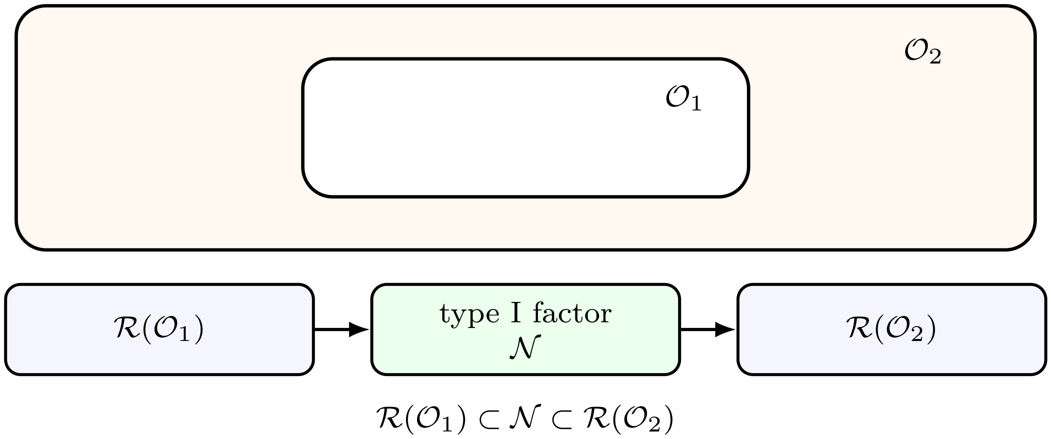

Figure 4.2: The split property inserts a type I factor between nested local algebras separated by a collar.

The split property is tied to phase-space and nuclearity conditions. Such conditions control the number of local degrees of freedom below a given energy scale and make local thermodynamic behavior mathematically tractable.

The operational meaning of the type-I interpolant is normal statistical independence at positive separation. If $\mathcal{M}_1 = \mathcal{R}(\mathcal{O}_1)$, $\mathcal{M}_2 = \mathcal{R}(\mathcal{O}_2)$, and $\mathcal{M}_1 \subset \mathcal{N} \subset \mathcal{M}_2$ is split, choose a spatial representation

$$U\mathcal{N}U^* = \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}, \qquad U\mathcal{N}'U^* = \mathbf{1} \otimes \mathcal{B}(\mathcal{L}).$$

Then $U\mathcal{M}_1U^* \subset \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}$ and $U\mathcal{M}_2'U^* \subset \mathbf{1} \otimes \mathcal{B}(\mathcal{L})$. Hence normal states φ_1 on $\mathcal{M}_1$ and φ_2 on $\mathcal{M}_2'$ extend to normal states $\widetilde{\varphi}_1$ on $\mathcal{B}(\mathcal{K})$ and $\widetilde{\varphi}_2$ on $\mathcal{B}(\mathcal{L})$. The normal product state $\widetilde{\varphi}_1 \bar{\otimes} \widetilde{\varphi}_2$ restricts to a normal state on the von Neumann algebra generated by the two commuting algebras, and on products it satisfies

$$\Phi(AB') = \varphi_1(A)\varphi_2(B'), \qquad A \in \mathcal{M}_1, \quad B' \in \mathcal{M}_2'.$$

The construction uses the ordinary tensor product after conjugating by U; the positive collar is what permits this tensor product to be represented normally inside the vacuum Hilbert space. As the collar is removed, the interpolating type-I factor is no longer part of the sharp local-algebra data, which is why split limits and relative entropy are the intrinsic continuum objects used later.

4.6 Modular Data and Locality

Let $\mathcal{R}$ be a von Neumann algebra on a Hilbert space with a vector Ω that is cyclic and separating for $\mathcal{R}$. Tomita–Takesaki theory defines an antilinear operator S by

$$SA\Omega = A^*\Omega, \qquad A \in \mathcal{R},$$

and its polar decomposition

$$S = J\Delta^{1/2}.$$

Here J is antiunitary and Δ is positive self-adjoint. The operator Δ and its square root may be unbounded, but the Borel functional calculus for positive self-adjoint operators gives Δ^{it} as a bounded unitary operator for every $t \in \mathbb{R}$, forming a strongly continuous one-parameter unitary group. The modular automorphism group is

$$\sigma_t(A) = \Delta^{\mathrm{i}t} A \Delta^{-\mathrm{i}t}.$$

Quoted Theorem 4.3 (Tomita–Takesaki modular automorphisms)**.** Proof references.[2] *For a cyclic and separating vector Ω for $\mathcal{R}$, the modular operators constructed above satisfy, for every $t \in \mathbb{R}$,*

$$\Delta^{\mathrm{i}t} \mathcal{R} \Delta^{-\mathrm{i}t} = \mathcal{R}.$$

Consequently

$$\sigma_t = \mathrm{Ad}_{\Delta^{\mathrm{i}t}}\big|_{\mathcal{R}}$$

is a one-parameter group of $*$-automorphisms of $\mathcal{R}$. Moreover, the modular conjugation identifies the algebra with its commutant:

$$J\mathcal{R}J = \mathcal{R}',$$

where $\mathcal{R}'$ denotes the commutant of $\mathcal{R}$ in $\mathcal{B}(\mathcal{H})$.

Example 4.4 (Finite standard form of a faithful matrix state)**.** Let $K \simeq \mathbb{C}^n$, let $\mathcal{R} = \mathcal{B}(K)$, and let $\rho \in \mathcal{B}(K)$ be a positive definite matrix with $\mathrm{Tr}_K \rho = 1$. Put

$$\mathcal{H}_{\mathrm{HS}} = \mathcal{B}(K), \qquad \langle X, Y \rangle_{\mathrm{HS}} = \mathrm{Tr}_K(X^* Y), \qquad \pi(A)X = AX, \qquad \Omega = \rho^{1/2}.$$

Then Ω is cyclic and separating for $\pi(\mathcal{R})$. The Tomita operator, modular conjugation, and modular operator are

$$S(X) = \rho^{-1/2} X^* \rho^{1/2}, \qquad J(X) = X^*, \qquad \Delta(X) = \rho X \rho^{-1}. \tag{4.29}$$

Consequently

$$J\pi(\mathcal{R})J = \pi(\mathcal{R})', \qquad \sigma_t(A) = \rho^{\mathrm{i}t} A \rho^{-\mathrm{i}t}.$$

With the boundary-value convention used below for KMS states, $F(t) = \omega(A\alpha_t(B))$ and $F(t+\mathrm{i}) = \omega(\alpha_t(B)A)$, the vector state

$$\omega(A) = \langle \Omega, \pi(A)\Omega \rangle_{\mathrm{HS}} = \mathrm{Tr}_K(\rho A)$$

is a 1-KMS state for $\alpha_t = \sigma_{-t}$.

Verification of the finite model. Every $X \in \mathcal{H}_{\mathrm{HS}}$ has the form

$$X = (X\rho^{-1/2})\Omega,$$

so Ω is cyclic. If $A\Omega = 0$, then $A\rho^{1/2} = 0$, and invertibility of $\rho^{1/2}$ gives $A = 0$; hence Ω is separating. For $X = A\Omega$,

$$S(X) = S(A\rho^{1/2}) = A^* \rho^{1/2} = \rho^{-1/2} X^* \rho^{1/2}.$$

[2] A complete proof of Tomita's theorem and the modular automorphism theorem is given in M. Takesaki, *Tomita's Theory of Modular Hilbert Algebras and Its Applications*, Lecture Notes in Mathematics **128**, Springer, 1970. See also M. Takesaki, *Theory of Operator Algebras I*, Springer, 1979, Chapter VI, for the von Neumann algebra formulation used here [26].

The Hilbert-Schmidt basis of matrix units diagonalizing ρ shows that

$$(J\Delta^{1/2})(X) = J(\rho^{1/2}X\rho^{-1/2}) = \rho^{-1/2}X^*\rho^{1/2} = S(X),$$

with $J(X) = X^*$ and $\Delta = L_\rho R_{\rho^{-1}}$, where L and R denote left and right multiplication. The commutant of all left multiplications is the algebra of right multiplications, and

$$J\pi(A)J(X) = J(AX^*) = XA^*,$$

so $J\pi(\mathcal{R})J = \pi(\mathcal{R})'$. Conjugating a left multiplication by $\Delta^{\mathrm{i}t}$ gives

$$\Delta^{\mathrm{i}t}\pi(A)\Delta^{-\mathrm{i}t}X = \rho^{\mathrm{i}t}A\rho^{-\mathrm{i}t}X,$$

which is the displayed modular automorphism.

For this boundary-value convention, define

$$F_{A,B}(z) = \mathrm{Tr}_K\left(\rho A\rho^{-\mathrm{i}z}B\rho^{\mathrm{i}z}\right), \qquad 0 \le \operatorname{Im} z \le 1.$$

This is an entire finite sum after diagonalizing ρ. The lower boundary is $F_{A,B}(t) = \omega(A\alpha_t(B))$. At the upper boundary, using $\alpha_t(B) = \rho^{-\mathrm{i}t}B\rho^{\mathrm{i}t}$ and cyclicity of the finite trace,

$$\begin{aligned} F_{A,B}(t+\mathrm{i}) &= \mathrm{Tr}_K\left(\rho A\rho^{-\mathrm{i}t+1}B\rho^{\mathrm{i}t-1}\right) \\ &= \mathrm{Tr}_K\left(A\rho\rho^{-\mathrm{i}t}B\rho^{\mathrm{i}t}\right) = \mathrm{Tr}_K(\rho\alpha_t(B)A) = \omega(\alpha_t(B)A). \end{aligned}$$

Thus ω satisfies the 1-KMS boundary condition for $\alpha_t = \sigma_{-t}$.

Proof mechanism and local role. The theorem is a statement about a standard von Neumann algebra $(\mathcal{R}, \mathcal{H}, \Omega)$, where standard means that Ω is cyclic and separating for $\mathcal{R}$. The proof begins with the second antilinear operator

$$F_0(B\Omega) = B^*\Omega, \qquad B \in \mathcal{R}'.$$

The commutation of $\mathcal{R}$ and $\mathcal{R}'$ gives the adjoint identity for antilinear operators on the two algebraic cores,

$$\langle S_0(A\Omega), B\Omega\rangle = \langle A^*\Omega, B\Omega\rangle = \langle B^*\Omega, A\Omega\rangle = \langle F_0(B\Omega), A\Omega\rangle, \qquad A \in \mathcal{R},\ B \in \mathcal{R}',$$

using $AB = BA$. Hence $S_0 \subset F_0^*$ and $F_0 \subset S_0^*$. Cyclicity of Ω for $\mathcal{R}$ and $\mathcal{R}'$ supplies dense domains, and the two inclusions imply closability. Denote the closures by S and F. The same adjoint identity upgrades to

$$S^* = F, \qquad F^* = S.$$

The polar decomposition of the closed antilinear operator S gives

$$S = J\Delta^{1/2}, \qquad F = J\Delta^{-1/2}, \qquad J\Delta J = \Delta^{-1}.$$

The substantive step is the Tomita invariance theorem for the left Hilbert algebra $\mathfrak{A} = \mathcal{R}\Omega$. The product and involution on the core are

$$(A\Omega)(B\Omega) = AB\Omega, \qquad (A\Omega)^\# = A^*\Omega.$$

Left multiplication by $A \in \mathcal{R}$ is bounded on the Hilbert-space completion. The closure of the involution is precisely S. Tomita's analytic argument shows that the closed left Hilbert algebra is stable under the modular unitaries $\Delta^{\mathrm{i}t}$, and therefore $\Delta^{\mathrm{i}t} A \Delta^{-\mathrm{i}t}$ is again a bounded left multiplier of $\mathfrak{A}$. Bounded left multipliers of the closed algebra are exactly the elements of $\mathcal{R}$. This proves

$$\Delta^{\mathrm{i}t} \mathcal{R} \Delta^{-\mathrm{i}t} \subset \mathcal{R}.$$

Applying the same argument at time $-t$ gives equality. The commutant identity follows from the polar part of the same closed involution: JAJ acts as right multiplication by A^* on the core and hence commutes with all left multipliers, while the symmetric argument starting from $\mathcal{R}'$ gives the reverse inclusion.

For the QFT applications in this chapter the theorem supplies an abstract modular flow for any local algebra whose vacuum vector is standard. The QFT work begins after this theorem: one must prove Reeh–Schlieder or another standardness criterion for the local algebra, and one must separately identify the abstract modular flow with a geometric flow when such an identification is claimed. The Bisognano–Wichmann theorem boundary below is precisely that additional QFT input for wedges.

4.7 KMS States and Modular Equilibrium

The modular group is not only an algebraic automorphism group. It is the canonical source of the operator-algebraic equilibrium condition. We first state the condition for an arbitrary time evolution, because this is the form used in finite-temperature QFT and in infinite-volume statistical mechanics.

Definition 4.5 (KMS state)**.** Let $\mathfrak{A}$ be a C^*-algebra or a von Neumann algebra, let $\alpha : \mathbb{R} \to \mathrm{Aut}(\mathfrak{A})$ be a strongly continuous one-parameter automorphism group, and let ω be a state on $\mathfrak{A}$. For $\beta > 0$, ω is a β-KMS state for α when, for every pair $A, B \in \mathfrak{A}$, there is a function

$$F_{A,B} : \{z \in \mathbb{C} : 0 \leq \operatorname{Im} z \leq \beta\} \to \mathbb{C}$$

which is bounded and continuous on the closed strip, holomorphic in its interior, and satisfies the boundary conditions

$$F_{A,B}(t) = \omega(A\, \alpha_t(B))\,, \qquad F_{A,B}(t + \mathrm{i}\beta) = \omega(\alpha_t(B)\, A)\,, \qquad t \in \mathbb{R}. \tag{4.30}$$

The order of the two boundary values is the content of the condition. It is not periodicity of an ordinary function of real time; it is an analytic continuation statement whose upper boundary has the operators cyclically permuted. This distinction is essential in infinite volume, where the trace of $\mathrm{e}^{-\beta H}$ usually does not exist but the local state may still satisfy (4.30).

Example 4.6 (Gibbs traces satisfy KMS)**.** Let H be self-adjoint and suppose that $\mathrm{e}^{-\beta H}$ is trace class. On the algebra of bounded operators for which the following expressions are defined by trace-class products, set

$$\omega_\beta(A) = Z_\beta^{-1} \operatorname{Tr}\left(\mathrm{e}^{-\beta H} A\right), \qquad Z_\beta = \operatorname{Tr} \mathrm{e}^{-\beta H}, \qquad \alpha_t(A) = \mathrm{e}^{\mathrm{i}tH} A \mathrm{e}^{-\mathrm{i}tH}.$$

Then ω_β is a β-KMS state for α.

Verification of the trace-class KMS strip. For bounded A, B, define

$$F_{A,B}(z) = Z_\beta^{-1} \operatorname{Tr}\left(\mathrm{e}^{-\beta H} A \mathrm{e}^{\mathrm{i}zH} B \mathrm{e}^{-\mathrm{i}zH}\right).$$

In finite dimension this is entire. Under the stated trace-class hypothesis the same formula is holomorphic in the open strip and bounded on the closed strip by the standard trace-norm estimates for products with e^{-sH}, $0 \le s \le \beta$; finite-dimensional spectral truncations give the same identity and converge in trace norm. At the lower boundary,

$$F_{A,B}(t) = \omega_\beta(A\alpha_t(B)).$$

At the upper boundary,

$$\begin{aligned} F_{A,B}(t+\mathrm{i}\beta) &= Z_\beta^{-1} \operatorname{Tr}\left(\mathrm{e}^{-\beta H} A \mathrm{e}^{\mathrm{i}tH} \mathrm{e}^{-\beta H} B \mathrm{e}^{-\mathrm{i}tH} \mathrm{e}^{\beta H}\right) \\ &= Z_\beta^{-1} \operatorname{Tr}\left(A \mathrm{e}^{\mathrm{i}tH} \mathrm{e}^{-\beta H} B \mathrm{e}^{-\mathrm{i}tH}\right) \\ &= Z_\beta^{-1} \operatorname{Tr}\left(\mathrm{e}^{-\beta H} \mathrm{e}^{\mathrm{i}tH} B \mathrm{e}^{-\mathrm{i}tH} A\right) = \omega_\beta(\alpha_t(B)A). \end{aligned}$$

The first equality is the analytic continuation. The second uses cyclicity of the trace to move the final $\mathrm{e}^{\beta H}$ to the front, where it cancels one $\mathrm{e}^{-\beta H}$. The third uses cyclicity again and the commutation of $\mathrm{e}^{-\beta H}$ with $\mathrm{e}^{\mathrm{i}tH}$. These two trace-cyclicity moves are precisely what the KMS boundary condition retains after the literal Gibbs trace ceases to exist.

Theorem 4.7 (Modular KMS property)**.** *Let $\mathcal{R}$ be a von Neumann algebra and let Ω be cyclic and separating for $\mathcal{R}$. Let*

$$\omega(A) = \langle \Omega, A\Omega \rangle, \qquad \sigma_t(A) = \Delta^{\mathrm{i}t} A \Delta^{-\mathrm{i}t}$$

be the vector state and the Tomita–Takesaki modular automorphism group. Then ω satisfies the unit-width strip KMS condition for the modular flow. Equivalently, for every $A, B \in \mathcal{R}$ there is a bounded strip function $G_{A,B}$, analytic for $0 < \operatorname{Im} z < 1$, such that

$$G_{A,B}(t) = \omega(\sigma_t(A)B), \qquad G_{A,B}(t+\mathrm{i}) = \omega(B\sigma_t(A)). \tag{4.31}$$

In the convention of Definition 4.5, this says that ω is a 1-KMS state for the reversed modular dynamics $\alpha_t = \sigma_{-t}$.

Proof. The nontrivial input is Tomita–Takesaki theory: the closable antilinear operator $S_0 A\Omega = A^*\Omega$ has polar decomposition $S = J\Delta^{1/2}$, the unitary group $\Delta^{\mathrm{i}t}$ implements automorphisms of $\mathcal{R}$, and the analytic vectors for this unitary group form a strong-operator dense $*$-subalgebra of $\mathcal{R}$. For analytic A, the vector-valued function $z \mapsto \sigma_z(A)\Omega$ is analytic in the strip. Pairing it with $B^*\Omega$ gives the candidate $G_{A,B}(z)$. The lower boundary is the definition of σ_t. The upper boundary follows from

$$S\,\sigma_t(A)\Omega = \sigma_t(A)^*\Omega, \qquad S = J\Delta^{1/2},$$

or, equivalently, from moving a vector through the closed graph of S: the operation that is trace cyclicity in Example 4.6 is replaced by the Tomita relation between $\mathcal{R}$ and $\mathcal{R}'$. Thus

$$\langle \Omega, \sigma_{t+\mathrm{i}}(A)B\Omega \rangle = \langle \Omega, B\sigma_t(A)\Omega \rangle$$

for analytic A. The general case follows by Gaussian smearing in modular time,

$$A_\epsilon = \frac{1}{\sqrt{\pi\epsilon}} \int_{\mathbb{R}} \mathrm{e}^{-s^2/\epsilon} \sigma_s(A)\, \mathrm{d}s,$$

which produces entire analytic elements converging strongly to A and uniformly controls the strip functions by $\|A\|\,\|B\|$. Taking the limit gives (4.31). $\square$

The theorem is the precise sense in which a cyclic separating vector is an equilibrium state for its own modular time. The modular Hamiltonian

$$K_{\mathrm{mod}} := -\log \Delta$$

is generally not the physical Hamiltonian and need not be an integral of a local density. When a geometric theorem identifies modular flow with a spacetime symmetry, the abstract KMS condition becomes a physical thermal statement for the corresponding observer or subregion.

4.8 Relative Modular Operators and Connes Cocycles

The modular data of a single pair $(\mathcal{R}, \Omega)$ compare an algebra with its commutant. The modular data of two states compare two normal statistical preparations on the same algebra. This relative form is the operator-algebraic replacement for density-matrix quotients in local QFT, where local algebras are typically type III and no local density matrix exists.

Definition 4.8 (Relative Tomita operator)**.** Let $\mathcal{R} \subset \mathcal{B}(\mathcal{H})$ be a von Neumann algebra, and let $\Psi, \Omega \in \mathcal{H}$ be cyclic and separating for $\mathcal{R}$. Define the antilinear operator $S^{(0)}_{\Psi|\Omega}$ on the dense domain $\mathcal{R}\Omega$ by

$$S^{(0)}_{\Psi|\Omega} A\Omega = A^*\Psi, \qquad A \in \mathcal{R}.$$

It is closable. Its closure is denoted $S_{\Psi|\Omega}$, and

$$\Delta_{\Psi|\Omega} := S^*_{\Psi|\Omega} S_{\Psi|\Omega}$$

is the relative modular operator. The polar decomposition is

$$S_{\Psi|\Omega} = J_{\Psi|\Omega} \Delta^{1/2}_{\Psi|\Omega},$$

where $J_{\Psi|\Omega}$ is a partial antiunitary with initial and final closures determined by the supports of the two normal vector states. Under the cyclic-and-separating hypothesis the supports are 1, so $J_{\Psi|\Omega}$ is antiunitary.

The order in the subscript is part of the convention. The operator $\Delta_{\Psi|\Omega}$ has the state represented by Ψ on the left and the state represented by Ω on the right. In a finite type-I algebra this statement becomes literal. Let $\mathcal{R} = \mathcal{B}(\mathcal{K})$ act by left multiplication on the Hilbert–Schmidt space

$$\mathcal{H}_{\mathrm{st}} = \{X : \mathcal{K} \to \mathcal{K} : \mathrm{Tr}(X^*X) < \infty\}, \qquad \langle X, Y\rangle_{\mathrm{st}} = \mathrm{Tr}(X^*Y).$$

A faithful normal state with density matrix $\rho > 0$ is represented by $\Omega_\rho = \rho^{1/2}$. For faithful density matrices ρ_ψ, ρ_ω,

$$\Delta_{\psi|\omega}(X) = \rho_\psi X \rho_\omega^{-1}. \tag{4.32}$$

Indeed, for $X = A\rho_\omega^{1/2}$,

$$S_{\psi|\omega}X = A^*\rho_\psi^{1/2}.$$

The adjoint relation in the Hilbert–Schmidt inner product gives

$$S^*_{\psi|\omega}S_{\psi|\omega}(A\rho_\omega^{1/2}) = \rho_\psi A\rho_\omega^{-1/2} = \rho_\psi(A\rho_\omega^{1/2})\rho_\omega^{-1},$$

which is (4.32) on a dense set and hence by closure. This calculation fixes the convention used below.

Definition 4.9 (Araki relative entropy)**.** Let ψ, ω be faithful normal states represented by cyclic separating vectors Ψ, Ω. The Araki relative entropy of ψ with respect to ω is

$$S_{\mathcal{R}}(\psi\|\omega) = -\langle\Psi, \log\Delta_{\Omega|\Psi}\Psi\rangle, \tag{4.33}$$

with the value $+\infty$ if the logarithmic quadratic form is not finite or if the support of ψ is not dominated by the support of ω.

In the finite type-I model, (4.32) turns (4.33) into the ordinary Umegaki formula:

$$\begin{aligned} S_{\mathcal{B}(\mathcal{K})}(\psi\|\omega) &= -\operatorname{Tr}\Big[\rho_\psi^{1/2}\big(\log\rho_\omega - \log\rho_\psi\big)\rho_\psi^{1/2}\Big] \\ &= \operatorname{Tr}\rho_\psi(\log\rho_\psi - \log\rho_\omega). \end{aligned}$$

The algebraic definition is therefore not a new thermodynamic convention; it is the continuation of the density-matrix expression to algebras for which no density matrix exists.

Quoted Theorem 4.10 (Connes cocycle derivative)**.** Proof references.[3] *Let ω and ψ be faithful normal states on a von Neumann algebra $\mathcal{R}$. In a standard representation, define*

$$u_t = [D\psi : D\omega]_t = \Delta^{\mathrm{i}t}_{\psi|\omega}\Delta^{-\mathrm{i}t}_\omega, \qquad t \in \mathbb{R},$$

where $\Delta_\omega = \Delta_{\Omega|\Omega}$. Then $u_t \in \mathcal{R}$, u_t is unitary, and

$$u_{t+s} = u_t\,\sigma_t^\omega(u_s), \qquad t, s \in \mathbb{R}. \tag{4.34}$$

Moreover the modular flows of the two states are related by

$$\sigma_t^\psi(A) = u_t\,\sigma_t^\omega(A)\,u_t^*, \qquad A \in \mathcal{R}. \tag{4.35}$$

Proof mechanism and local role. The cocycle theorem is the Radon–Nikodym theorem for faithful normal states in standard form. The standard-form data are

$$(\mathcal{R}, \mathcal{H}, J, \mathcal{P}),$$

where J is the modular conjugation and $\mathcal{P}$ is the natural positive cone. Each faithful normal state has a unique vector representative in $\mathcal{P}$; write these representatives as Ω for ω and Ψ for ψ. The relative Tomita operator is initially defined on the dense core $\mathcal{R}\Omega$ by

$$S_{\Psi|\Omega}(A\Omega) = A^*\Psi, \qquad A \in \mathcal{R}.$$

[3] The cocycle derivative and Radon–Nikodym theorem for faithful normal weights are proved in A. Connes, "Une classification des facteurs de type III," *Annales scientifiques de l'Ecole Normale Superieure* **6** (1973), 133–252, and in Takesaki, *Theory of Operator Algebras II*, Chapter VIII [27].

Its closure has polar data

$$S_{\Psi|\Omega} = J_{\Psi|\Omega}\Delta^{1/2}_{\psi|\omega}.$$

The positive operator $\Delta_{\psi|\omega}$ is the noncommutative Radon–Nikodym derivative at the modular level. The crucial assertion is that the relative modular unitaries differ from the reference modular unitaries by a unitary belonging to the algebra:

$$\Delta^{\mathrm{i}t}_{\psi|\omega}\Delta^{-\mathrm{i}t}_{\omega} \in \mathcal{R}.$$

One proves this by testing the product against $\mathcal{R}'\Omega$, using the relative Tomita adjoint relation to show that it commutes with the commutant, and then applying $(\mathcal{R}')' = \mathcal{R}$. The same relative-modular calculation gives

$$\Delta^{\mathrm{i}(t+s)}_{\psi|\omega}\Delta^{-\mathrm{i}(t+s)}_{\omega} = \big(\Delta^{\mathrm{i}t}_{\psi|\omega}\Delta^{-\mathrm{i}t}_{\omega}\big)\Delta^{\mathrm{i}t}_{\omega}\big(\Delta^{\mathrm{i}s}_{\psi|\omega}\Delta^{-\mathrm{i}s}_{\omega}\big)\Delta^{-\mathrm{i}t}_{\omega},$$

which is exactly the cocycle relation (4.34). Conjugating $A \in \mathcal{R}$ by the relative modular unitary and inserting the preceding factorization gives (4.35).

The theorem's role in QFT is to compare modular Hamiltonians associated with different states while staying inside the same local algebra. Relative entropy, modular energy, and the algebraic proof of monotonicity use this cocycle as the replacement for a density-matrix quotient in type-III local algebras. The finite type-I calculation below is a normalization check; the operator-algebraic theorem supplies the type-III object used by local QFT.

Example 4.11 (Finite standard-form Connes cocycle)**.** Let ρ_ω, ρ_ψ be positive definite density matrices on $\mathcal{K}$, and represent $\mathcal{R} = \mathcal{B}(\mathcal{K})$ on the Hilbert–Schmidt standard space by left multiplication. With the convention (4.32), the operator

$$\Delta^{\mathrm{i}t}_{\psi|\omega}\Delta^{-\mathrm{i}t}_{\omega}$$

is left multiplication by

$$u_t = \rho^{\mathrm{i}t}_{\psi}\rho^{-\mathrm{i}t}_{\omega} \in \mathcal{B}(\mathcal{K}). \tag{4.36}$$

The family u_t is unitary in $\mathcal{R}$, satisfies the Connes cocycle identity

$$u_{t+s} = u_t\,\sigma^{\omega}_t(u_s), \qquad \sigma^{\omega}_t(A) = \rho^{\mathrm{i}t}_{\omega}A\rho^{-\mathrm{i}t}_{\omega},$$

and implements the change of modular flow,

$$\sigma^{\psi}_t(A) = u_t\sigma^{\omega}_t(A)u^*_t, \qquad \sigma^{\psi}_t(A) = \rho^{\mathrm{i}t}_{\psi}A\rho^{-\mathrm{i}t}_{\psi}.$$

Verification of the finite cocycle. On the Hilbert–Schmidt space, the relative and reference modular unitaries act by

$$\Delta^{\mathrm{i}t}_{\psi|\omega}X = \rho^{\mathrm{i}t}_{\psi}X\rho^{-\mathrm{i}t}_{\omega}, \qquad \Delta^{-\mathrm{i}t}_{\omega}X = \rho^{-\mathrm{i}t}_{\omega}X\rho^{\mathrm{i}t}_{\omega}.$$

Their product is therefore

$$\Delta^{\mathrm{i}t}_{\psi|\omega}\Delta^{-\mathrm{i}t}_{\omega}X = \rho^{\mathrm{i}t}_{\psi}\rho^{-\mathrm{i}t}_{\omega}X = u_tX,$$

which is left multiplication by the matrix in (4.36). Since the factors $\rho^{\mathrm{i}t}_{\psi}$ and $\rho^{-\mathrm{i}t}_{\omega}$ are unitary, u_t is a unitary element of $\mathcal{R}$.

The cocycle law keeps the density matrices in their noncommuting order:

$$\begin{aligned} u_t\sigma_t^\omega(u_s) &= \rho_\psi^{\mathrm{i}t}\rho_\omega^{-\mathrm{i}t}\rho_\omega^{\mathrm{i}t}(\rho_\psi^{\mathrm{i}s}\rho_\omega^{-\mathrm{i}s})\rho_\omega^{-\mathrm{i}t} \\ &= \rho_\psi^{\mathrm{i}(t+s)}\rho_\omega^{-\mathrm{i}(t+s)} = u_{t+s}. \end{aligned}$$

Likewise,

$$u_t\sigma_t^\omega(A)u_t^* = \rho_\psi^{\mathrm{i}t}\rho_\omega^{-\mathrm{i}t}\rho_\omega^{\mathrm{i}t}A\rho_\omega^{-\mathrm{i}t}\rho_\omega^{\mathrm{i}t}\rho_\psi^{-\mathrm{i}t} = \rho_\psi^{\mathrm{i}t}A\rho_\psi^{-\mathrm{i}t}.$$

This is exactly $\sigma_t^\psi(A)$. The finite calculation shows the algebraic object that the general theorem constructs: an algebra unitary whose cocycle law records the change of state and keeps the implementer inside $\mathcal{R}$.

For local QFT this quoted theorem is a calculational device. Changing the state in a bounded region is encoded not by dividing density matrices, but by a unitary cocycle inside the local algebra. In perturbative algebraic QFT this is the operator-algebraic structure behind relative Cauchy evolution and local source deformations; in constructive models it is the object on which monotonicity, convexity, and energy inequalities are formulated.

4.9 Type III Local Algebras and Phase-Space Bounds

The split property introduced above is an inclusion $\mathcal{R}(\mathcal{O}_1) \subset N \subset \mathcal{R}(\mathcal{O}_2)$ through a type-I factor for separated regions, while sharply localized tensor factorization would be a stronger and generally unavailable structure. For a proper bounded region $\mathcal{O}$, the physically expected local algebra $\mathcal{R}(\mathcal{O})$ is not a type-I factor. Under the standard structural hypotheses satisfied by known relativistic models, it is a type III_1 factor: it has no nonzero finite projections and no faithful normal trace. The absence of a trace is why local thermal and entanglement quantities must be formulated with modular theory rather than with local density matrices.

Definition 4.12 (Buchholz–Wichmann nuclearity map)**.** Let $U(t) = \mathrm{e}^{\mathrm{i}tH}$ be the vacuum time-translation group with $H \geq 0$, and let $\mathcal{R}(\mathcal{O})$ be a bounded-region algebra. For $\beta > 0$, define

$$\Theta_{\beta,\mathcal{O}} : \mathcal{R}(\mathcal{O}) \to \mathcal{H}, \qquad \Theta_{\beta,\mathcal{O}}(A) = \mathrm{e}^{-\beta H}A\Omega.$$

The net satisfies the Buchholz–Wichmann nuclearity condition on $\mathcal{O}$ if $\Theta_{\beta,\mathcal{O}}$ is a nuclear map for every $\beta > 0$ and its nuclear norm obeys a local phase-space growth estimate, for example

$$\|\Theta_{\beta,\mathcal{O}}\|_1 \leq \exp\bigl(C_{\mathcal{O}}\beta^{-s_{\mathcal{O}}}\bigr) \quad \text{as } \beta \downarrow 0$$

for some finite constants $C_{\mathcal{O}}, s_{\mathcal{O}}$.

Here nuclear means that

$$\Theta_{\beta,\mathcal{O}}(A) = \sum_{n=1}^{\infty} \ell_n(A)\xi_n, \qquad \sum_n \|\ell_n\|\,\|\xi_n\| < \infty,$$

for bounded linear functionals ℓ_n on $\mathcal{R}(\mathcal{O})$ and vectors $\xi_n \in \mathcal{H}$. The condition is an infinite-dimensional replacement for saying that only finitely many independent localized states are visible below energy scale $1/\beta$. It is not an ultraviolet cutoff: it is a phase-space compactness estimate in the continuum theory.

Free Fock phase-space benchmark. The growth form in Definition 4.12 is visible already in the free bosonic Fock counting problem. Let the spatial dimension be $s = D-1 \geq 1$, put a scalar field of mass $m > 0$ in a spatial torus of side length L, and write the one-particle energies as

$$\epsilon_n = \sqrt{\left(\frac{2\pi}{L}\right)^2 |n|_2^2 + m^2}, \qquad n \in \mathbb{Z}^s.$$

On the bosonic Fock space the finite-volume Hamiltonian is $H_L = d\Gamma(h_L)$. For finitely many one-particle modes with energies $\epsilon_1, \ldots, \epsilon_M$, the occupation-number basis gives

$$\begin{aligned}\operatorname{Tr}_{\mathcal{F}_B} \exp[-\beta\, d\Gamma(h_M)] &= \sum_{k_1,\ldots,k_M \geq 0} \exp\left[-\beta \sum_{j=1}^{M} k_j \epsilon_j\right] \\ &= \prod_{j=1}^{M} \frac{1}{1 - \mathrm{e}^{-\beta\epsilon_j}}.\end{aligned}$$

Passing to all torus modes is justified for $\beta > 0$ by convergence of

$$\log Z_B(\beta, L) = \sum_{n \in \mathbb{Z}^s} f(\beta\epsilon_n), \qquad f(x) := -\log(1 - \mathrm{e}^{-x}).$$

Indeed $f(x) \leq C\mathrm{e}^{-x/2}$ for large x, while the number of lattice points with $|n|_\infty = k$ is

$$N_s(k) = (2k+1)^s - (2k-1)^s \leq 2s(2k+1)^{s-1}.$$

For $n \neq 0$,

$$\epsilon_n \geq \frac{2\pi}{L}|n|_\infty.$$

Set $\tau = 2\pi\beta/L$. The remaining estimate is elementary but it is important to separate the logarithmic singularity of f near the origin from its exponential decay at infinity. For $0 < x \leq 1$,

$$f(x) \leq C(1 + |\log x|),$$

while for $x \geq 1$,

$$f(x) \leq C\mathrm{e}^{-x/2}.$$

Therefore, for $0 < \tau \leq 1$,

$$\sum_{1 \leq k \leq \tau^{-1}} (1+k)^{s-1} f(\tau k) \leq C_s \tau^{-s} \int_0^1 u^{s-1}(1 + |\log u|)\, \mathrm{d}u,$$

and

$$\sum_{k > \tau^{-1}} (1+k)^{s-1} f(\tau k) \leq C_s \sum_{k > \tau^{-1}} k^{s-1} \mathrm{e}^{-\tau k/2} \leq C_s' \tau^{-s} \int_1^\infty u^{s-1} \mathrm{e}^{-u/2}\, \mathrm{d}u.$$

The two integrals are finite, so the nonzero-mode sum is bounded by $C_s\tau^{-s}$. Hence

$$\log Z_B(\beta, L) \leq f(\beta m) + C_s \left(\frac{L}{2\pi\beta}\right)^s.$$

Since $s \geq 1$, the zero-mode term $f(\beta m) \sim \log(\beta^{-1})$ is absorbed into $C_{s,m,L}\beta^{-s}$ on $0 < \beta \leq 1$. Thus

$$\log Z_B(\beta, L) \leq C_{s,m,L}\,\beta^{-s}, \qquad 0 < \beta \leq 1. \tag{4.37}$$

Equivalently,

$$Z_B(\beta, L) \leq \exp(C_{s,m,L}\beta^{-s}).$$

The local nuclearity map replaces the global box trace by the localized map $A \mapsto \mathrm{e}^{-\beta H}A\Omega$. The theorem below is precisely the operator-algebraic statement that a comparable phase-space estimate for localized vectors is strong enough to create a split inclusion between separated local algebras. The free Fock calculation supplies the basic mode-counting scale; the local theorem requires the sharper localization and normality arguments described after the quoted theorem.

Quoted Theorem 4.13 (Buchholz–Wichmann nuclearity implies split inclusions)**.** Proof references.[4] *Let a vacuum local net satisfy isotony, locality, covariance, positivity of energy, uniqueness of the vacuum, Reeh–Schlieder for double cones, and the Buchholz–Wichmann nuclearity condition. Then every pair of double cones $\mathcal{O}_1 \Subset \mathcal{O}_2$ is split:*

$$\mathcal{R}(\mathcal{O}_1) \subset \mathcal{N} \subset \mathcal{R}(\mathcal{O}_2)$$

for some type-I factor $\mathcal{N}$. In the Doplicher–Longo split criterion, this conclusion is equivalent to normal extendability of the multiplication representation

$$\mathcal{R}(\mathcal{O}_1) \odot \mathcal{R}(\mathcal{O}_2)' \longrightarrow \mathcal{B}(\mathcal{H}), \qquad A \otimes B' \longmapsto AB',$$

to the spatial von Neumann tensor product.

Functional-analytic mechanism of the split conclusion. The split part of the theorem converts an energy-damped compactness estimate into a spatial tensor-product representation for separated algebras. Let

$$\mathcal{M}_1 = \mathcal{R}(\mathcal{O}_1), \qquad \mathcal{M}_2 = \mathcal{R}(\mathcal{O}_2), \qquad \mathcal{O}_1 \Subset \mathcal{O}_2.$$

Because $\mathcal{M}_1$ and $\mathcal{M}_2'$ commute, there is an algebraic multiplication representation

$$m : \mathcal{M}_1 \odot \mathcal{M}_2' \longrightarrow \mathcal{B}(\mathcal{H}), \qquad m(A \otimes B') = AB'.$$

If the inclusion is split, the normal tensor-product representation can be seen directly. A type-I factor $\mathcal{N}$ with $\mathcal{M}_1 \subset \mathcal{N} \subset \mathcal{M}_2$ is spatial: there are Hilbert spaces $\mathcal{K}, \mathcal{L}$ and a unitary $U : \mathcal{H} \to \mathcal{K} \otimes \mathcal{L}$ such that

$$U\mathcal{N}U^* = \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}.$$

Then

$$U\mathcal{M}_1U^* \subset \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}, \qquad U\mathcal{M}_2'U^* \subset U\mathcal{N}'U^* = \mathbf{1} \otimes \mathcal{B}(\mathcal{L}).$$

Therefore the product map is the restriction of the spatial normal representation

$$\mathcal{M}_1\bar{\otimes}\mathcal{M}_2' \longrightarrow \mathcal{B}(\mathcal{K} \otimes \mathcal{L}), \qquad A \otimes B' \longmapsto UAU^*\,UB'U^*. \tag{4.38}$$

[4]The phase-space condition and split property are developed in D. Buchholz and E. H. Wichmann, "Causal independence and the energy-level density of states in local quantum field theory," *Communications in Mathematical Physics* **106** (1986), 321–344, and in C. D'Antoni and R. Longo, "Interpolation by type I factors and the flip automorphism," *Journal of Functional Analysis* **51** (1983), 361–371 [29, 28].

The converse implication, from normal extendability of the multiplication representation to the existence of an interpolating type-I factor, is the Doplicher–Longo split criterion. It is part of the operator-algebraic input in Quoted Theorem 4.13, not a consequence of algebraic commutativity alone. When the criterion applies, the unitary identification can be chosen so that the two commuting algebras act as

$$\mathcal{M}_1 \subset \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}, \qquad \mathcal{M}_2' \subset \mathbf{1} \otimes \mathcal{B}(\mathcal{L}),$$

and the interpolating type-I factor is

$$\mathcal{N} = U^{-1}(\mathcal{B}(\mathcal{K}) \otimes \mathbf{1})\, U.$$

This criterion is the functional-analytic content behind the phrase "approximate tensor factorization": it is a normal tensor-product representation for algebras separated by a positive collar.

Split states are positive-collar states. The split inclusion also produces a precise replacement for the informal operation of assigning independent states to a region and its exterior. Fix a spatial implementation

$$U : \mathcal{H} \to \mathcal{K} \otimes \mathcal{L}, \qquad U\mathcal{N}U^* = \mathcal{B}(\mathcal{K}) \otimes \mathbf{1},$$

so that $U\mathcal{M}_1U^* \subset \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}$ and $U\mathcal{M}_2'U^* \subset \mathbf{1} \otimes \mathcal{B}(\mathcal{L})$. Let $\varphi_1 \in (\mathcal{M}_1)_*^+$ and $\varphi_2 \in (\mathcal{M}_2')_*^+$ be normal positive functionals. Choose normal positive extensions $\widetilde{\varphi}_1$ and $\widetilde{\varphi}_2$ to $\mathcal{B}(\mathcal{K})$ and $\mathcal{B}(\mathcal{L})$. This is a pure von Neumann algebra extension step: a normal positive functional on a von Neumann subalgebra of $\mathcal{B}(\mathcal{K})$ has a normal positive extension to $\mathcal{B}(\mathcal{K})$, with the same norm. Their product normal functional on $\mathcal{B}(\mathcal{K})\bar{\otimes}\mathcal{B}(\mathcal{L})$ restricts to a normal positive functional on the von Neumann algebra generated by $\mathcal{M}_1$ and $\mathcal{M}_2'$:

$$\omega^{\mathcal{O}_1 \Subset \mathcal{O}_2}_{\varphi_1,\varphi_2}(AB') = \varphi_1(A)\varphi_2(B'), \qquad A \in \mathcal{M}_1, \quad B' \in \mathcal{M}_2'. \tag{4.39}$$

The right side shows independence of the chosen normal extensions on the algebraic products AB', and normality gives the extension to the generated von Neumann algebra. Equation (4.39) is the exact mathematical meaning of statistical independence at a positive separation. The superscript $\mathcal{O}_1 \Subset \mathcal{O}_2$ is part of the datum: the collar and the interpolating type-I factor are not discarded. If the collar is shrunk, the theorem supplies no canonical limiting product state on $\mathcal{R}(\mathcal{O}) \vee \mathcal{R}(\mathcal{O}^\perp)$. In a type-III sharp local algebra there is no density matrix for $\mathcal{R}(\mathcal{O})$ and no literal Hilbert-space tensor factor $\mathcal{H}_\mathcal{O} \otimes \mathcal{H}_{\mathcal{O}^\perp}$ from which such a state could be obtained. Split states are therefore regulator-independent local QFT objects only after the positive collar has been specified.

The nuclearity hypothesis supplies the normality in (4.38). A nuclear decomposition of $\Theta_{\beta,\mathcal{O}}$ has the form

$$\mathrm{e}^{-\beta H} A\Omega = \sum_{n \geq 1} \ell_n(A)\xi_n, \qquad \sum_n \|\ell_n\|\,\|\xi_n\| < \infty.$$

Thus the set of vectors obtained by acting with the local unit ball and then damping energy by $\mathrm{e}^{-\beta H}$ is contained in the absolutely convex hull of a summable family. This Banach-space statement is only the first ingredient. Since $\mathcal{M}_1$ and $\mathcal{M}_2'$ are von Neumann algebras, the split criterion asks for normality, not only norm convergence. Equivalently, for every vector pair $\eta, \zeta \in \mathcal{H}$, the functional

$$A \otimes B' \longmapsto \langle \eta, AB'\zeta \rangle \qquad (A \in \mathcal{M}_1,\ B' \in \mathcal{M}_2')$$

must be represented, after the required limiting argument, by a normal functional on $\mathcal{M}_1 \bar{\otimes} \mathcal{M}_2'$. Finite sums of separated normal functionals,

$$\sum_{j=1}^{N} \varphi_j(A)\psi_j(B'), \qquad \varphi_j \in (\mathcal{M}_1)_*, \quad \psi_j \in (\mathcal{M}_2')_*,$$

are the elementary normal functionals on the spatial tensor product; a summable infinite version is the analytic form in which the split proof detects normal extendability of the multiplication representation.

The nuclear decomposition is used to produce such summable separated forms. For a fixed B' and a fixed vector η, the energy-damped matrix coefficient

$$A \longmapsto \langle \eta, B' \mathrm{e}^{-\beta H} A\Omega \rangle$$

has the absolutely convergent expansion

$$\sum_{n \geq 1} \ell_n(A) \, \langle B'^* \eta, \xi_n \rangle.$$

The displayed formula by itself does not prove splitness: the coefficient functionals ℓ_n in an arbitrary Banach-space nuclear decomposition need not be normal, and the undamped vector functional $(A, B') \mapsto \langle \eta, AB'\zeta \rangle$ is not obtained by algebraically removing $\mathrm{e}^{-\beta H}$. These two points are precisely where the local QFT hypotheses enter. The collar $\mathcal{O}_1 \Subset \mathcal{O}_2$ permits small imaginary time translations whose tube domains do not cross the spacelike complement of $\mathcal{O}_2$. Locality then moves operators in $\mathcal{M}_2'$ past the translated $\mathcal{M}_1$-operators, and the spectral condition supplies the energy damping that makes the nuclear expansion summable. The remaining analytic estimates identify the resulting bilinear vector functionals with limits, in the predual $(\mathcal{M}_1 \bar{\otimes} \mathcal{M}_2')_*$, of separated normal sums. This is the functional-analytic content hidden behind the short phrase "nuclearity implies the split property."

The finite-dimensional shadow is simple but useful for keeping the objects straight. If $\mathcal{M}_1 \subset \mathcal{B}(\mathcal{K}) \otimes \mathbf{1}$ and $\mathcal{M}_2' \subset \mathbf{1} \otimes \mathcal{B}(\mathcal{L})$, then any density matrices r_1 on $\mathcal{K}$ and r_2 on $\mathcal{L}$ give a normal product functional

$$A \otimes B' \longmapsto \mathrm{Tr}_{\mathcal{K}}(r_1 A) \ \mathrm{Tr}_{\mathcal{L}}(r_2 B') = \mathrm{Tr}_{\mathcal{K}\otimes\mathcal{L}}\big[(r_1 \otimes r_2)(A \otimes B')\big] \, .$$

For a finite-rank map $\Theta(A) = \sum_j \ell_j(A)\xi_j$, every coefficient $\langle \eta, B'\Theta(A) \rangle$ is correspondingly a finite separated sum. The infinite theorem is the statement that, under relativistic phase-space and collar hypotheses, this finite separated normality survives the continuum limit for the actual local multiplication representation.

This proof mechanism also explains the status of the constants in the phase-space bound. The exponential estimate

$$\|\Theta_{\beta,\mathcal{O}}\|_1 \leq \exp(C_{\mathcal{O}} \beta^{-s_{\mathcal{O}}})$$

is stronger than mere nuclearity and is used to make the construction stable as the collar, region, or thermodynamic comparison is varied. The existence of a single nuclear map for a fixed $(\beta, \mathcal{O})$ gives compactness at one scale; the uniform small-β bound is the continuum phase-space statement needed in applications.

Type classification is a separate sharp-region theorem. The split theorem and the type-classification theorem concern different objects. Let $\mathcal{M}$ be a von Neumann algebra. Its center is

$$Z(\mathcal{M}) = \mathcal{M} \cap \mathcal{M}',$$

and $\mathcal{M}$ is a factor when $Z(\mathcal{M}) = \mathbb{C}\mathbf{1}$. A projection $p \in \mathcal{M}$ is minimal when

$$p\mathcal{M}p = \mathbb{C}p.$$

A type-I factor has minimal projections and is isomorphic to $\mathcal{B}(\mathcal{K})$ for a Hilbert space $\mathcal{K}$. A factor is type III when it has no nonzero finite projections, equivalently when it has no nonzero normal semifinite trace. For a type-III factor the finer Connes invariant may be described by

$$S(\mathcal{M}) = \bigcap_{\varphi} \mathrm{Spec}(\Delta_\varphi),$$

where the intersection is over faithful normal semifinite weights φ and Δ_φ is the corresponding modular operator in the standard form. The type III_1 case is characterized by

$$S(\mathcal{M}) = \mathbb{R}_{\geq 0}.$$

These definitions show exactly why the type statement cannot be read off from the split inclusion alone. The split inclusion supplies, for $\mathcal{O}_1 \Subset \mathcal{O}_2$, an auxiliary type-I factor $\mathcal{N}$ between $\mathcal{R}(\mathcal{O}_1)$ and $\mathcal{R}(\mathcal{O}_2)$. It does not say that either endpoint algebra is type I. Conversely, a finite-regulator lattice system has type-I local algebras and may satisfy an exact tensor factorization at positive lattice separation; that finite statement is not the continuum sharp-region conclusion. The theorem-boundary problem for local QFT is to prove, in the continuum representation, the factor property, absence of finite local projections, and the modular spectrum needed for type-III_1. Those inputs use locality, covariance, the spectrum condition, Reeh–Schlieder standardness, additivity or scaling regularity, and phase-space control in a way that is not captured by the existence of a positive-collar type-I interpolant.

The quoted theorem just stated has one local-QFT message: a positive collar between regions, together with a nuclear phase-space estimate strong enough to make the multiplication representation normal, allows a type-I interpolant and hence a collar-dependent tensor-product representation. It does not classify the sharp endpoint algebras. The type-III statement is a different sharp-region theorem boundary. It says, under additional factoriality, additivity or scaling-regularity, and modular-spectrum hypotheses, that the collar cannot be shrunk to zero while retaining a type-I description. In particular, a formal notation such as

$$\mathcal{H} \overset{\text{formal}}{\neq} \mathcal{H}_{\mathcal{O}} \otimes \mathcal{H}_{\mathcal{O}^\perp}$$

is not a technical inconvenience; it is the local algebraic structure of a continuum relativistic QFT. Local entropy therefore has to be understood through split limits, relative entropy, or other regulator-dependent procedures whose limiting content is stated explicitly.

The type-III_1 identification is a further sharp-local-algebra statement. Its input is not the split property alone but the combination of relativistic locality, vacuum cyclicity and separatingness, additivity or scaling regularity, and the absence of finite-dimensional local summands. Under those hypotheses the local algebra has no minimal projections, no faithful normal trace, and no type-I density-matrix description. The split property supplies type-I factors only at positive separation; the sharp region algebra belongs to the type-III class.

4.10 Modular Hamiltonians and Energy Bounds

Let ω be a faithful normal state on $\mathcal{R}$, represented by a cyclic separating vector Ω. The modular Hamiltonian of the pair $(\mathcal{R}, \omega)$ is

$$K_\omega = -\log \Delta_\omega.$$

It is an operator on the GNS Hilbert space of the algebra-state pair. When $\mathcal{R} = \mathcal{B}(\mathcal{K}_A) \otimes 1$ in a finite bipartite system and ω has reduced density matrix ρ_A^ω, the restriction of K_ω to the left standard representation is $-\log \rho_A^\omega$ up to the right-action term that cancels in left expectation differences. Thus the finite-dimensional identity

$$S(\rho_A^\psi \| \rho_A^\omega) = \operatorname{Tr} \rho_A^\psi (\log \rho_A^\psi - \log \rho_A^\omega)$$

can be rewritten as

$$S(\rho_A^\psi \| \rho_A^\omega) = \Delta_\psi \langle K_A^\omega \rangle - \Delta_\psi S_A, \qquad K_A^\omega = -\log \rho_A^\omega. \tag{4.40}$$

Here

$$\Delta_\psi \langle K_A^\omega \rangle = \operatorname{Tr}(\rho_A^\psi - \rho_A^\omega) K_A^\omega, \qquad \Delta_\psi S_A = -\operatorname{Tr} \rho_A^\psi \log \rho_A^\psi + \operatorname{Tr} \rho_A^\omega \log \rho_A^\omega.$$

Equation (4.40) is often called the entropy–modular-energy identity. In a type-III local algebra the two terms on the right are not separately defined without a chosen split inclusion or regulator, but the left side is the Araki relative entropy (4.33). The mathematically primary object is therefore

$$S_{\mathcal{R}}(\psi \| \omega),$$

not an unqualified local von Neumann entropy.

Finite-dimensional first variation of relative entropy. Let $\rho_\lambda = \rho_0 + \lambda \dot\rho + O(\lambda^2)$ be a differentiable family of faithful density matrices with $\operatorname{Tr} \dot\rho = 0$. Let $K_0 = -\log \rho_0$. Then

$$\left.\frac{\mathrm{d}}{\mathrm{d}\lambda}\right|_{\lambda=0} S(\rho_\lambda \| \rho_0) = 0$$

is equivalent to

$$\left.\frac{\mathrm{d}}{\mathrm{d}\lambda}\right|_{\lambda=0} S_{\mathrm{vN}}(\rho_\lambda) = \operatorname{Tr}(\dot\rho K_0). \tag{4.41}$$

The calculation uses

$$S(\rho_\lambda \| \rho_0) = \operatorname{Tr} \rho_\lambda \log \rho_\lambda - \operatorname{Tr} \rho_\lambda \log \rho_0.$$

The Fréchet derivative of $X \mapsto \operatorname{Tr} X \log X$ at a faithful matrix ρ_0 is

$$\operatorname{Tr} \dot\rho (\log \rho_0 + 1).$$

The 1-term vanishes because $\operatorname{Tr} \dot\rho = 0$. Therefore

$$\left.\frac{\mathrm{d}}{\mathrm{d}\lambda}\right|_0 S(\rho_\lambda \| \rho_0) = \operatorname{Tr} \dot\rho \log \rho_0 - \operatorname{Tr} \dot\rho \log \rho_0 = 0.$$

On the other hand,

$$\left.\frac{\mathrm{d}}{\mathrm{d}\lambda}\right|_0 S_{\mathrm{vN}}(\rho_\lambda) = -\operatorname{Tr} \dot\rho \log \rho_0 = \operatorname{Tr} \dot\rho K_0,$$

which proves (4.41). The same identity in local QFT is obtained by applying this finite calculation to split inclusions and then passing only those quantities with regulator-independent limits to the sharp algebra.

The inequality

$$S_{\mathcal{R}}(\psi\|\omega) \geq 0$$

is the modular-theoretic source of many energy bounds. In a regulated type-I approximation it gives

$$\Delta_\psi S_A \leq \Delta_\psi \langle K_A^\omega \rangle.$$

When $\mathcal{R}$ is a wedge algebra and ω is the vacuum, Bisognano–Wichmann identifies

$$K_{W_R,\omega} = 2\pi K_R, \qquad U(\Lambda_R(s)) = \mathrm{e}^{\mathrm{i}sK_R},$$

because $\Delta_{W_R}^{\mathrm{i}t} = U(\Lambda_R(-2\pi t))$. If the theory has a stress tensor normalized so that K_R is the boost charge, then formally on the $x^0 = 0$ Cauchy surface

$$K_{W_R,\omega} = 2\pi \int_{x^1>0} x^1\, T_{00}(0, \mathbf{x})\, \mathrm{d}^{D-1}\mathbf{x}. \tag{4.42}$$

Equation (4.42) is not a definition of the local algebra; it is the consequence of the geometric modular-flow theorem plus the independently normalized stress tensor. The standard derivations of the Bekenstein-type bound for half-spaces and of the averaged null energy condition use three inputs: positivity of Araki relative entropy, monotonicity of relative entropy under inclusion of von Neumann algebras, and the geometric form of the vacuum modular Hamiltonian for wedges or balls. Whenever one of these inputs is absent, the claimed bound must be restated as a hypothesis or as a regulated theorem.

4.11 Half-Sided Modular Inclusions

Modular theory can also generate spacetime symmetry from inclusions of algebras. This is the mechanism behind the use of modular inclusions in chiral CFT, wedge-local constructions, and several reconstruction theorems.

Definition 4.14 (Half-sided modular inclusion)**.** Let $\mathcal{N} \subset \mathcal{M}$ be von Neumann algebras on $\mathcal{H}$, and let Ω be cyclic and separating for both. Let $\sigma_t^{\mathcal{M}}$ be the modular automorphism group of $(\mathcal{M}, \Omega)$. The inclusion is right half-sided modular if

$$\sigma_t^{\mathcal{M}}(\mathcal{N}) \subset \mathcal{N}, \qquad t \geq 0,$$

and left half-sided modular if the same inclusion holds for $t \leq 0$.

Quoted Theorem 4.15 (Borchers–Wiesbrock structure)**.** Proof references.[5] *Let $\mathcal{N} \subset \mathcal{M}$ be a standard right half-sided modular inclusion, meaning here that Ω is cyclic and separating for $\mathcal{M}$, for $\mathcal{N}$, and for the relative commutant $\mathcal{N}' \cap \mathcal{M}$, and that*

$$\sigma_t^{\mathcal{M}}(\mathcal{N}) \subset \mathcal{N}, \qquad t \geq 0.$$

[5]Borchers' commutation relations and Wiesbrock's reconstruction theorem are proved in H.-J. Borchers, "The CPT theorem in two-dimensional theories of local observables," *Communications in Mathematical Physics* **143** (1992), 315–332, and H.-W. Wiesbrock, "Half-sided modular inclusions of von Neumann algebras," *Communications in Mathematical Physics* **157** (1993), 83–92. See also Guido–Longo–Wiesbrock for the connection with conformal nets [30, 32, 31].

Then there is a strongly continuous one-parameter unitary group. With the Stone sign convention used below for physical inward light-ray translations, write it as

$$T(a) = \mathrm{e}^{-\mathrm{i}aP}, \qquad P \geq 0,$$

such that $T(a)\Omega = \Omega$, $T(a)\mathcal{M}T(a)^* \subset \mathcal{M}$ *for* $a \geq 0$, *and the modular group of* $\mathcal{M}$ *acts by dilations:*

$$\Delta_{\mathcal{M}}^{\mathrm{i}t} T(a) \Delta_{\mathcal{M}}^{-\mathrm{i}t} = T(\mathrm{e}^{+2\pi t} a). \tag{4.43}$$

Equivalently, with $K_{\mathcal{M}} = -\log \Delta_{\mathcal{M}}$,

$$\Delta_{\mathcal{M}}^{\mathrm{i}t} = \mathrm{e}^{-\mathrm{i}tK_{\mathcal{M}}}, \qquad [K_{\mathcal{M}}, P] = +2\pi\mathrm{i}P$$

on the common invariant core of analytic vectors. For a left half-sided modular inclusion the same statement is obtained after reversing the modular parameter; equivalently the dilation factor in (4.43) *is replaced by* $\mathrm{e}^{-2\pi t}a$, *and the infinitesimal commutator has the opposite sign.*

The modular-inclusion mechanism. The theorem is not the differentiated commutator below. Its content is the construction of the translation unitary $T(a)$ and the positivity of its generator from inclusion data alone. The standardness assumption provides three standard pairs:

$$(\mathcal{M}, \Omega), \qquad (\mathcal{N}, \Omega), \qquad (\mathcal{N}' \cap \mathcal{M}, \Omega).$$

Equivalently, in standard-subspace language, the closed real subspaces

$$H_{\mathcal{M}} = \overline{\{A\Omega : \ A = A^* \in \mathcal{M}\}}^{\mathcal{H}}, \qquad H_{\mathcal{N}} = \overline{\{A\Omega : \ A = A^* \in \mathcal{N}\}}^{\mathcal{H}}$$

are standard real subspaces: $H \cap \mathrm{i}H = \{0\}$ and $H + \mathrm{i}H$ is dense. Their Tomita operators

$$s_{\mathcal{M}}(h + \mathrm{i}k) = h - \mathrm{i}k, \qquad h, k \in H_{\mathcal{M}},$$

and similarly for $H_{\mathcal{N}}$, have polar decompositions with the same modular objects as the von Neumann algebras. The half-sided condition $\Delta_{\mathcal{M}}^{\mathrm{i}t} H_{\mathcal{N}} \subset H_{\mathcal{N}}$ for $t \geq 0$ is therefore a geometric statement about the position of two standard real subspaces under the modular dilations of the larger one.

The finite-dimensional comparison is rigid. Suppose, for comparison, that $\mathcal{M}$ is finite dimensional and that $\sigma_t^{\mathcal{M}}(\mathcal{N}) \subset \mathcal{N}$ for all $t \geq 0$. The automorphism $\sigma_t^{\mathcal{M}}$ is a linear isomorphism of the finite-dimensional vector space $\mathcal{M}$. Its restriction maps the finite-dimensional subspace $\mathcal{N}$ injectively into itself, and hence onto itself:

$$\sigma_t^{\mathcal{M}}(\mathcal{N}) = \mathcal{N}, \qquad t \geq 0.$$

Applying the same equality to $-t$ by the group law gives invariance for all $t \in \mathbb{R}$. Thus the half-sided condition becomes ordinary modular invariance in finite dimension. The strict inclusion phenomenon in Quoted Theorem 4.15 depends on the infinite-dimensional standard-subspace geometry of local algebras: an injective continuous motion can move a closed real subspace properly inside itself without contradicting finite-dimensional rank.

Borchers–Wiesbrock theory proves that such a pair of standard real subspaces carries a positive-energy representation of the affine group of the line. In the Stone sign convention of the theorem statement, this representation is generated by the modular dilation group of $\mathcal{M}$ and a translation group $T(a) = \mathrm{e}^{-\mathrm{i}aP}$, $P \geq 0$, satisfying

$$\Delta_{\mathcal{M}}^{\mathrm{i}t} T(a) \Delta_{\mathcal{M}}^{-\mathrm{i}t} = T(\mathrm{e}^{+2\pi t} a).$$

The positivity $P \geq 0$ is the analytic half-sidedness input: it is the operator-algebraic analogue of the spectrum condition for the translation reconstructed from the inclusion. Once the unitary group has been obtained on the standard subspaces, standardness of the relative commutant lifts the standard-subspace inclusion back to the von Neumann algebra inclusion and gives

$$T(a)\mathcal{M}T(a)^* \subset \mathcal{M}, \qquad a \geq 0.$$

Thus the theorem reconstructs a translation-dilation semigroup from modular data; the Lie-algebra commutator is only the infinitesimal shadow of this stronger statement.

Derivation of the displayed commutator. The existence of $T(a)$ and the positivity $P \geq 0$ require the full half-sided modular inclusion result, Quoted Theorem 4.15. Once (4.43) is known, the commutator follows by differentiating twice. For the right half-sided convention displayed in (4.43), first differentiate in a at $a = 0$:

$$\Delta_{\mathcal{M}}^{\mathrm{i}t} P \Delta_{\mathcal{M}}^{-\mathrm{i}t} = \mathrm{e}^{+2\pi t} P.$$

Since $\Delta_{\mathcal{M}}^{\mathrm{i}t} = \mathrm{e}^{-\mathrm{i}tK_{\mathcal{M}}}$, the derivative at $t = 0$ gives

$$-\mathrm{i}[K_{\mathcal{M}}, P] = +2\pi P,$$

and hence $[K_{\mathcal{M}}, P] = +2\pi \mathrm{i} P$. In the opposite half-sided convention the Borchers relation has $\mathrm{e}^{-2\pi t} a$ in place of $\mathrm{e}^{+2\pi t} a$, so the differentiated commutator carries the opposite sign.

For the standard right wedge, take $\mathcal{M} = \mathcal{R}(W_R)$ and let $\mathcal{N}$ be the algebra of the wedge translated inward along a lightlike direction. The inclusion is half-sided because the Lorentz boost rescales that lightlike translation without leaving the wedge family. The sign is convention-sensitive, and the convention used in this chapter is the following one.

Example 4.16 (Right-wedge light-ray inclusion and the half-sided sign)**.** Let

$$e_+ = (1, 1, 0, \dots, 0), \qquad W_R(a) = W_R + ae_+, \qquad a > 0.$$

Then $W_R(a) \subset W_R$. Indeed, if $(x^0, x^1) \in W_R$ and $y = x + ae_+$, then

$$y^1 - y^0 = x^1 - x^0 > 0, \qquad y^1 + y^0 = x^1 + x^0 + 2a > 0,$$

so $y^1 > |y^0|$. Moreover

$$b \geq a \quad \Longrightarrow \quad W_R(b) \subset W_R(a), \tag{4.44}$$

because translating farther along e_+ moves the wedge deeper inside itself. Assume the Bisognano–Wichmann identification in the sign convention used below,

$$\sigma_t^{W_R} = \operatorname{Ad} \Delta_{W_R}^{\mathrm{i}t} = \operatorname{Ad} U(\Lambda_R(-2\pi t)).$$

Since $\Lambda_R(s)e_+ = \mathrm{e}^s e_+$, isotony and covariance give

$$\sigma_t^{W_R}\big(\mathcal{R}(W_R(a))\big) = \mathcal{R}\big(W_R(\mathrm{e}^{-2\pi t} a)\big). \tag{4.45}$$

Combining (4.44) and (4.45), this translated-wedge inclusion is left half-sided in Definition 4.14:

$$\sigma_t^{W_R}\big(\mathcal{R}(W_R(a))\big) \subset \mathcal{R}(W_R(a)) \quad \Longleftrightarrow \quad t \leq 0.$$

Changing the modular-flow sign convention, or using the corresponding oppositely directed light-ray inclusion, changes the word "left" to "right". The calculation verifies only the geometric hypothesis in this example. The Borchers–Wiesbrock theorem supplies the converse structural content: from the half-sided modular inclusion it reconstructs the translation unitary and its positive generator.

Physical light-ray translations in a covariant net. If the net already carries a Poincare representation, the abstract affine translation in the preceding paragraph has a visible candidate. With the translation convention of Definition 5.7,

$$U(x, \mathbf{1}) = \int_{\overline{V}_+} \mathrm{e}^{\mathrm{i}x^\mu p_\mu}\, \mathrm{d}E(p), \qquad p_\mu = \eta_{\mu\nu} p^\nu,$$

define the positive light-ray momentum

$$P_+^{\mathrm{phys}} := P^0 - P^1 = \int_{\overline{V}_+} (p^0 - p^1)\, \mathrm{d}E(p).$$

The spectrum condition gives $P_+^{\mathrm{phys}} \geq 0$, since $p^0 \geq |p^1|$ on $\overline{V}_+$. For $e_+ = (1, 1, 0, \ldots, 0)$, however,

$$e_+^\mu p_\mu = -p^0 + p^1 = -(p^0 - p^1),$$

so the physical inward light-ray translation is

$$U(ae_+, \mathbf{1}) = \mathrm{e}^{-\mathrm{i}aP_+^{\mathrm{phys}}}, \qquad a \geq 0.$$

This is the reason for the Stone sign convention in Quoted Theorem 4.15. Isotony and covariance give

$$U(ae_+, \mathbf{1})\mathcal{R}(W_R)U(ae_+, \mathbf{1})^* = \mathcal{R}(W_R(a)) \subset \mathcal{R}(W_R), \qquad a \geq 0,$$

and the Bisognano–Wichmann modular action gives the affine covariance

$$\Delta_{W_R}^{\mathrm{i}t} U(ae_+, \mathbf{1}) \Delta_{W_R}^{-\mathrm{i}t} = U(\Lambda_R(-2\pi t)ae_+, \mathbf{1}) = U(\mathrm{e}^{-2\pi t} ae_+, \mathbf{1}).$$

Thus, in a Poincare-covariant net satisfying Bisognano–Wichmann, the physical light-ray translations realize the left half-sided version of the positive-energy affine representation reconstructed by the Borchers–Wiesbrock theorem. The theorem's converse content is not this sign calculation: it is that a standard half-sided modular inclusion by itself already forces such a positive translation-dilation representation.

Thus the algebraic inclusion knows the translation-dilation subgroup before one has written down a point field. This is one reason modular theory is not only a structural theorem: it reconstructs geometric motion from the order structure of local algebras.

Let

$$W_R = \{x \in \mathbb{M}^D : \; x^1 > |x^0|\}$$

be the standard right wedge, and let $\Lambda_R(s)$ be the boost in the (x^0, x^1)-plane,

$$\Lambda_R(s) : \begin{pmatrix} x^0 \\ x^1 \end{pmatrix} \longmapsto \begin{pmatrix} \cosh s & \sinh s \\ \sinh s & \cosh s \end{pmatrix} \begin{pmatrix} x^0 \\ x^1 \end{pmatrix}.$$

Remark 4.17 (Bisognano–Wichmann theorem boundary for wedges). Let a Poincare-covariant quantum field theory on Minkowski space be generated by Wightman fields satisfying the Wightman domain, covariance, locality, vacuum, and spectrum hypotheses. Let

$$\mathcal{R}(W)$$

be the von Neumann algebra generated by fields smeared in a wedge W, and let Ω be the unique invariant vacuum. Then Ω is cyclic and separating for every wedge algebra. For the standard right wedge W_R, let (J_{W_R}, Δ_{W_R}) be the Tomita–Takesaki modular data of $(\mathcal{R}(W_R), \Omega)$. Then

$$\Delta_{W_R}^{\mathrm{i}t} = U(\Lambda_R(-2\pi t)), \qquad t \in \mathbb{R}.$$

If $W = gW_R$, then the modular group of $(\mathcal{R}(W), \Omega)$ is

$$\Delta_W^{\mathrm{i}t} = U\big(g\Lambda_R(-2\pi t)g^{-1}\big), \qquad t \in \mathbb{R}.$$

Moreover the modular conjugation implements the corresponding wedge reflection j_W on the local net:

$$J_W \mathcal{R}(\mathcal{O}) J_W = \mathcal{R}(j_W \mathcal{O})$$

for every local region $\mathcal{O}$ in the indexing class. On a charged field algebra reconstructed from the observable net, the same antiunitary operation includes the charge-conjugation action on charged field coordinates. This is a theorem boundary in the present monograph, with its scope recorded explicitly. The proof in the Wightman setting has two logically separate components. The first component is the polynomial-core KMS strip proved in Theorem 4.18 below from the spectrum condition, complex boosts, and wedge locality. The second component is the operator-domain closure theorem that identifies the closed Tomita operator of $(\mathcal{R}(W_R), \Omega)$, including the modular conjugation and the passage from field-polynomial boundary values to the full wedge von Neumann algebra. That closure theorem is the part supplied by the original Bisognano–Wichmann work and by the AQFT treatments of modular covariance.

Theorem 4.18 (Wightman polynomial-core wedge KMS mechanism)**.** *Let Φ_a be Wightman fields on the common invariant domain $\mathcal{D}$, transforming covariantly under the proper orthochronous Poincare group and satisfying the spectrum condition and graded locality. Let $\mathfrak{P}(W_R)$ be the unital $*$-algebra generated on $\mathcal{D}$ by smeared fields $\Phi_a(f)$ with $\operatorname{supp} f \subset W_R$, and let*

$$\alpha_s^R(A) = U(\Lambda_R(s)) A U(\Lambda_R(s))^{-1}.$$

For

$$A = \Phi_{a_1}(f_1) \cdots \Phi_{a_m}(f_m), \qquad B = \Phi_{b_1}(g_1) \cdots \Phi_{b_n}(g_n), \qquad \operatorname{supp} f_i, \operatorname{supp} g_j \subset W_R.$$

there is a function $F_{A,B}$, holomorphic for $0 < \operatorname{Im} z < 2\pi$ and with tempered boundary values on the two horizontal edges, such that

$$F_{A,B}(s) = \langle \Omega, A\alpha_s^R(B)\Omega \rangle, \qquad F_{A,B}(s + 2\pi\mathrm{i}) = \langle \Omega, \alpha_s^R(B) A\Omega \rangle. \tag{4.46}$$

Thus the vacuum functional satisfies the boost 2π-KMS boundary relation on the Wightman polynomial core of the wedge. For a fermionic field algebra the statement is the graded KMS relation on field coordinates; after restriction to the observable algebra the grading signs cancel.

Proof. The theorem is an analytic-domain statement: the boost generator supplies the real flow, while the KMS boundary relation requires holomorphic continuation and locality. The initial Tomita operator on polynomial wedge vectors is

$$S_{W_R,0}A\Omega = A^*\Omega, \qquad A \in \mathfrak{P}(W_R).$$

Reeh–Schlieder gives density of $\mathfrak{P}(W_R)\Omega$, and Corollary 3.20 supplies separatingness of Ω for $\mathcal{R}(W_R)$ from locality and cyclicity in the opposite wedge. These are the standardness inputs that make the initial Tomita operator closable in the full Bisognano–Wichmann theorem. The polynomial KMS strip itself is obtained directly from Wightman analyticity. Suppressing finite spin matrices in the covariance law, define the smeared boundary value

$$\begin{aligned} F_{A,B}(z) = \int \prod_i \mathrm{d}x_i\, f_i(x_i) \prod_j \mathrm{d}y_j\, g_j(y_j) \\ \times W_{a_1\ldots a_m b_1\ldots b_n}\big(x_1,\ldots,x_m,\Lambda_R(z)y_1,\ldots,\Lambda_R(z)y_n\big), \end{aligned} \tag{4.47}$$

with the usual component matrices inserted for non-scalar fields. The spectrum condition supplies the tube holomorphy as follows. After rewriting an ordered Wightman distribution in relative variables, its Fourier transform is supported where every partial momentum sum lies in the closed future cone. If a relative coordinate is shifted as $\xi \mapsto \xi - \mathrm{i}\eta$ with $\eta \in V_+$, the Fourier factor $\exp(-\mathrm{i}p\cdot(\xi - \mathrm{i}\eta))$ contains $\exp(p\cdot\eta)$; in the mostly-plus convention $p\cdot\eta \le 0$ for $p,\eta \in \overline{V}_+$. Thus the spectral support gives exponential damping in the tube selected by the ordering, and the Wightman distribution is recovered as a boundary value. For $z = s + \mathrm{i}u$ and $0 < u < \pi$, the imaginary part of $\Lambda_R(z)y$, $y \in W_R$, lies in the future timelike cone in the mostly-plus convention. Therefore the differences between each earlier real argument x_i and each complex-boosted later argument have imaginary part in the past tube, so the ordered distribution in (4.47) is holomorphic in the first half-strip and has tempered boundary values.

At $u = \pi$, $\Lambda_R(s + \mathrm{i}\pi)W_R = W_L$, the left wedge. Points of W_L are spacelike to points of W_R. Graded locality therefore permits the boosted fields in B to pass through the fields in A, with the sign determined by the field grading. On the observable subalgebra this sign is one. After this reordering, the same tube analyticity gives the continuation through the second half-strip $\pi < u < 2\pi$. The lower and upper boundary values are consequently

$$F_{A,B}(s + 2\pi\mathrm{i}) = \omega\big(\alpha_s^R(B)A\big), \qquad F_{A,B}(s) = \omega\big(A\alpha_s^R(B)\big), \tag{4.48}$$

where $\omega(C) = \langle \Omega, C\Omega\rangle$. This is (4.46). The full modular theorem adds the closure statement

$$\overline{S_{W_R,0}} = J_{W_R}\Delta_{W_R}^{1/2}.$$

The operator $\Delta_{W_R}^{1/2}$ is then obtained by analytic continuation of boosts to imaginary value $\mathrm{i}\pi$, and the remaining antiunitary maps the wedge to its geometric reflection. That closed-operator identification is the additional domain theorem named in Remark 4.17. □

Corollary 4.19 (PCT from wedge modular covariance)**.** *Let $D = 4$. Let a vacuum representation of a local observable net satisfy isotony, locality, Poincare covariance, the spectrum condition, uniqueness of the invariant vacuum, wedge cyclicity and separatingness, wedge duality, and the Bisognano–Wichmann modular-covariance conclusion*

$$\Delta_{W_R}^{\mathrm{i}t} = U(\Lambda_R(-2\pi t)), \qquad J_{W_R}\mathcal{R}(\mathcal{O})J_{W_R} = \mathcal{R}(j_R\mathcal{O})$$

for the standard right wedge. Let $R_\perp(\pi)$ be the spatial rotation by π in the (x^2, x^3)-plane, so that

$$R_\perp(\pi) j_R x = -x.$$

Then

$$\Theta_{\mathrm{PCT}} := U(R_\perp(\pi)) J_{W_R} \tag{4.49}$$

is an antiunitary operator satisfying

$$\Theta_{\mathrm{PCT}}\Omega = \Omega, \qquad \Theta_{\mathrm{PCT}} U(a,\Lambda)\Theta_{\mathrm{PCT}}^{-1} = U(-a,\Lambda),$$

and

$$\Theta_{\mathrm{PCT}}\mathcal{R}(\mathcal{O})\Theta_{\mathrm{PCT}}^{-1} = \mathcal{R}(-\mathcal{O}). \tag{4.50}$$

For a Doplicher–Roberts charged field algebra reconstructed from the observable category, the induced antiunitary sends each charged field multiplet to the conjugate charged multiplet, in agreement with the Wightman PCT theorem of Theorem 2.6.

Proof. The antiunitarity of Θ_{PCT} follows from antiunitarity of the modular conjugation J_{W_R} and unitarity of $U(R_\perp(\pi))$. The displayed hypotheses identify J_{W_R} with the geometric wedge reflection j_R on the net. Conjugating afterward by the proper spatial rotation $R_\perp(\pi)$ changes the geometric action from j_R to the total inversion $x \mapsto -x$, proving (4.50). Both J_{W_R} and the rotation preserve the vacuum, so $\Theta_{\mathrm{PCT}}\Omega = \Omega$.

The covariance identity follows by applying the same geometric conjugation to translations and proper Lorentz transformations. Since the total inversion commutes with every proper Lorentz transformation and sends a to $-a$, the automorphism of the Poincare group is

$$(a,\Lambda) \longmapsto (-a,\Lambda).$$

Antiunitarity then gives the same translation-generator convention as in (2.11). Finally, in the Doplicher–Roberts reconstruction the modular conjugation maps a localized endomorphism to its conjugate localized endomorphism; on the reconstructed field algebra this is exactly the passage from a charged multiplet to the conjugate charged multiplet. □

The cyclic and separating hypotheses needed for the modular data of wedge algebras are supplied in the Wightman setting by Theorem 3.19 and Corollary 3.20: cyclicity is the positive-energy local-density theorem, while separatingness for a wedge uses locality with the opposite wedge. In a purely algebraic formulation not assumed to arise from Wightman fields, the conclusion of Remark 4.17 is an explicit modular-covariance hypothesis on the vacuum net unless it has been proved from the chosen AQFT assumptions. Under that theorem or hypothesis, modular flow is geometric Lorentz boost flow. The result connects locality, positivity of energy, the KMS structure of Definition 4.5 for accelerated observers, and the PCT antiunitary stated in Corollary 4.19.

Indeed, define the boost automorphism of the standard wedge algebra by

$$\alpha_s^R(A) = U(\Lambda_R(s)) A U(\Lambda_R(s))^{-1}, \qquad A \in \mathcal{R}(W_R).$$

Bisognano–Wichmann says $\sigma_t = \alpha^R_{-2\pi t}$, so the modular KMS property implies that $\omega(A) = \langle \Omega, A\Omega\rangle$, restricted to $\mathcal{R}(W_R)$, is a 2π-KMS state for the boost dynamics α_s^R:

$$F_{A,B}(s) = \omega(A\alpha_s^R(B)), \qquad F_{A,B}(s+2\pi\mathrm{i}) = \omega(\alpha_s^R(B)A).$$

Thus the vacuum is thermal with respect to the boost generator, even though it is a pure state on the global algebra. Along a uniformly accelerated orbit whose proper time is related to boost parameter by $s = a\tau$, this becomes the Unruh inverse temperature $2\pi/a$ in units $\hbar = c = k_B = 1$.

Figure 4.3 shows the Bisognano–Wichmann wedge geometry: modular flow is Lorentz boost flow, and its KMS period becomes the Unruh temperature along an accelerated orbit.

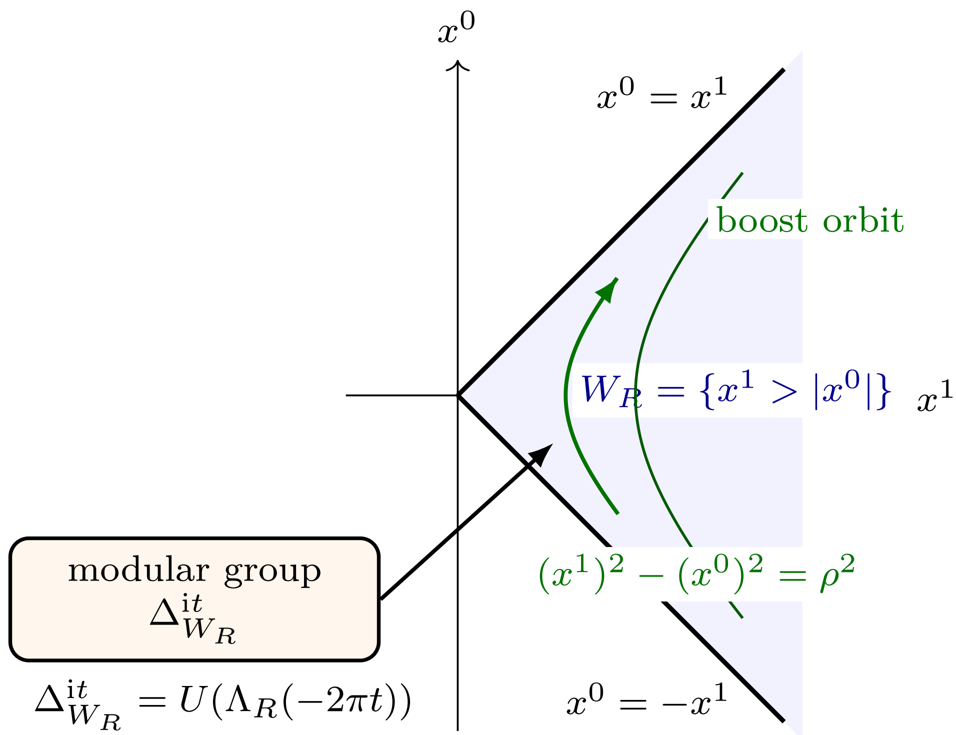

Figure 4.3: By the Bisognano–Wichmann theorem, or by the corresponding explicit modular-covariance hypothesis in an AQFT net, wedge modular flow is geometric Lorentz boost flow; its flow lines inside the right wedge are hyperbolae $(x^1)^2 - (x^0)^2 = \rho^2$.

4.12 Status of the Structural Inputs Used Above

The preceding sections use several deep operator-algebraic and local-QFT results. Their logical statuses differ. The distinction matters because an abstract von Neumann algebra theorem may be used after standardness and normality have been verified, whereas a local-QFT theorem usually requires covariance, spectrum, locality, additivity, phase-space control, or wedge-domain estimates in the concrete representation.

Doplicher–Roberts reconstruction. The purely categorical part says that a rigid symmetric C^*-tensor category with simple unit, finite-dimensional morphism spaces, conjugates, and finite statistical dimensions is equivalent to $\mathrm{Rep}_{\mathrm{fd}}(G)$ for a compact group G, after choosing a faithful symmetric tensor fiber functor. The local-QFT part is earlier: one must first prove that the sectors are transportable bounded-region DHR endomorphisms, that Haag duality places localized images and intertwiners in the assigned local observable algebra rather than only in the dual net, and that locality gives a symmetric exchange structure. The local charged-field core (4.6)–(4.8) proves the algebraic form of multiplication, fusion, conjugation, and fixed-point projection once those hypotheses are present. Charged fields for Gauss-law sectors, spacelike-cone sectors, infraparticles, or confining theories require different localization categories before a field-algebra theorem can even be formulated.

Tomita–Takesaki theory. This is pure operator-algebra infrastructure. Its input is a standard pair $(\mathcal{R}, \Omega)$, meaning Ω is cyclic and separating for $\mathcal{R}$. The chapter displays the S_0/F_0 adjoint-core argument, the closed Tomita operator, and the left-Hilbert-algebra mechanism leading to $\Delta^{it}\mathcal{R}\Delta^{-it} = \mathcal{R}$ and $J\mathcal{R}J = \mathcal{R}'$. In QFT applications, the theorem may be used only after standardness of the relevant local or wedge algebra has been proved, typically through Reeh–Schlieder and locality. It supplies an abstract modular flow. Identification of that flow with a spacetime symmetry is an additional local-QFT theorem.

Connes cocycle and Araki relative entropy. This is also operator-algebraic infrastructure, formulated for faithful normal states or weights in a common standard representation. The relative Tomita operator and the product $[D\psi : D\omega]_t = \Delta^{it}_{\psi|\omega}\Delta^{-it}_{\omega}$ give an algebra unitary implementing the change of modular flow. The finite standard-form calculation fixes the density-matrix normalization. In local QFT the required work is to specify the von Neumann algebra, the normal states on it, and the faithfulness/support condition. Those data provide the intrinsic type-III replacement for a formal density-matrix quotient.

Nuclearity, split inclusions, and type classification. Buchholz–Wichmann nuclearity is a local phase-space hypothesis on $\Theta_{\beta,\mathcal{O}} : A \mapsto e^{-\beta H}A\Omega$. The operator-algebraic split criterion asks for normal extendability of the multiplication representation $\mathcal{M}_1 \odot \mathcal{M}_2' \to \mathcal{B}(\mathcal{H})$ to $\mathcal{M}_1 \bar{\otimes} \mathcal{M}_2'$. The text above explains how summable separated normal functionals arise from energy damping, locality, and the positive collar $\mathcal{O}_1 \Subset \mathcal{O}_2$. The type III or type III_1 classification of sharp local algebras is a separate theorem boundary: a type-I interpolant at positive separation describes collar-separated independence, while type-III behavior concerns the sharp zero-collar algebra. Concrete models require their own phase-space estimates, factoriality input, and modular-spectrum control.

Borchers–Wiesbrock half-sided inclusions. The abstract theorem starts from a standard inclusion $\mathcal{N} \subset \mathcal{M}$ and a one-sided modular invariance condition. Its content is the construction of a positive-generator translation group with affine modular covariance. The finite-dimensional rank argument above isolates the content as infinite-dimensional standard-subspace geometry. In a Poincare-covariant QFT net, an inward translated wedge gives the geometric half-sided inclusion only after wedge standardness, isotony, covariance, and the relevant Bisognano–Wichmann modular identification are available. The light-ray calculation then matches the abstract generator to the positive physical momentum $P^0 - P^1$, while the converse reconstruction remains the Borchers–Wiesbrock theorem itself.

Bisognano–Wichmann and modular PCT. The Wightman polynomial-core theorem proved above establishes the boost KMS strip from tube analyticity and locality. The full wedge-modular theorem additionally identifies the closure of the wedge Tomita operator with geometric Lorentz boosts and the wedge reflection. That closed-operator/domain statement is the Bisognano–Wichmann QFT theorem boundary unless the net is assumed to satisfy modular covariance. Corollary 4.19 is therefore conditional on the explicit modular-covariance hypotheses stated there.

Thus each structural conclusion in this chapter is tied to a visible input: DHR localization and duality for charge reconstruction; standardness for modular theory; normal state data for relative entropy; phase-space bounds and collars for split inclusions; half-sided standardness for Borchers–Wiesbrock; and wedge-domain control for Bisognano–Wichmann.

4.13 Algebraic Scattering Interface

The Haag–Ruelle construction can be formulated in the algebraic setting using almost-local operators whose energy-momentum transfer is concentrated near an isolated mass shell. Acting on the vacuum, such operators create single-particle states. Time-dependent translated operators with separated velocity supports have limits that define incoming and outgoing scattering states:

$$|\psi_1, \ldots, \psi_n\rangle_{\mathrm{in/out}} = \lim_{t \to \mp\infty} A_1(t) \cdots A_n(t)\Omega.$$

This gives the same conceptual order established earlier: first the nonperturbative asymptotic states, then the scattering operator, and only afterward any perturbative representation of matrix elements.

The algebraic language records the dependence of scattering on local observables, spectral isolation, and phase-space properties. Infraparticle theories, gauge theories with long-range fields, and theories without a mass gap require modified asymptotic constructions whose hypotheses must be stated separately.

Relativistic Quantum Mechanics and Local Operator Structure

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

5.1 Hilbert-Space Quantum Data

Definition 5.1 (Hilbert-space quantum datum)**.** Let $\mathcal{H}$ be a complex Hilbert space. A pure state is a ray in $\mathcal{H}$. A mixed state is a positive trace-class operator ρ on $\mathcal{H}$ satisfying

$$\rho \geq 0, \qquad \mathrm{Tr}_{\mathcal{H}}\, \rho = 1.$$

For a bounded operator $A \in \mathcal{B}(\mathcal{H})$, the expectation value in the state ρ is

$$\langle A \rangle_\rho = \mathrm{Tr}_{\mathcal{H}}(\rho A).$$

For an unbounded operator, the operator domain and the domain of every product appearing in a matrix element are part of the data.

Definition 5.2 (Hamiltonian time evolution)**.** A Hamiltonian time evolution is specified by a self-adjoint operator H and the unitary one-parameter group

$$U(t) = \mathrm{e}^{-\mathrm{i}tH}, \qquad A(t) = U(t)^{-1} A U(t).$$

Stone's theorem gives the converse: every strongly continuous unitary one-parameter group has a unique self-adjoint generator. When H is first given as a formal differential expression, choosing its self-adjoint realization is part of the definition of the quantum system. In a stable sector H is bounded below. Spacetime localization is additional structure: a local relativistic theory assigns operators or algebras to spacetime regions.

5.2 Rigged Hilbert Spaces and Continuous Spectra

The Hilbert space contains the normalizable states. The momentum kets, energy kets, position kets, and plane-wave scattering states used throughout the monograph are generalized vectors. Their precise home is a rigged Hilbert space, also called a Gelfand triple.

Definition 5.3 (Rigged Hilbert space)**.** A rigged Hilbert space consists of a dense subspace $\Phi \subset \mathcal{H}$, equipped with a locally convex topology finer than the Hilbert norm topology, together with the continuous inclusions

$$\Phi \subset \mathcal{H} \subset \Phi^{\times}.$$

Here $\Phi^{\times}$ is the continuous antilinear dual of Φ. The second inclusion sends $h \in \mathcal{H}$ to the functional

$$\phi \longmapsto \langle \phi, h\rangle_{\mathcal{H}}, \qquad \phi \in \Phi.$$

Thus every Hilbert vector defines a generalized vector, but $\Phi^{\times}$ is larger than $\mathcal{H}$. Distributional eigenvectors live in $\Phi^{\times}$.

The basic model is

$$\mathcal{S}(\mathbb{R}^d) \subset L^2(\mathbb{R}^d, \mathrm{d}^d x) \subset \mathcal{S}'(\mathbb{R}^d),$$

where $\mathcal{S}$ is the Schwartz space and $\mathcal{S}'$ is the space of tempered distributions. The position and momentum kets are the tempered distributions defined by

$$\langle x|\psi\rangle = \psi(x), \qquad \langle p|\psi\rangle = \widetilde{\psi}(p), \qquad \psi \in \mathcal{S}(\mathbb{R}^d),$$

with the Fourier convention chosen in the relevant chapter. The identities

$$\langle x|x'\rangle = \delta^{(d)}(x-x'), \qquad \langle p|p'\rangle = (2\pi)^d \delta^{(d)}(p-p'),$$

and

$$\int \mathrm{d}^d x\, |x\rangle\langle x| = \mathbf{1}, \qquad \int \frac{\mathrm{d}^d p}{(2\pi)^d}\, |p\rangle\langle p| = \mathbf{1}$$

are weak identities: after pairing with test vectors in Φ on the left and right, they become ordinary identities for functions or distributions. Point evaluation and Fourier evaluation are continuous linear functionals on $\mathcal{S}(\mathbb{R}^d)$, hence define elements of $\mathcal{S}'(\mathbb{R}^d)$. Pairing the displayed resolution of the identity with $\varphi, \psi \in \mathcal{S}(\mathbb{R}^d)$ gives respectively $\int \overline{\varphi(x)}\psi(x)\mathrm{d}^d x$ and the same inner product written after Fourier inversion. The delta distributions are precisely the kernels which reproduce these pairings, so the displayed bra-ket identities are kernel statements, not equalities between Hilbert vectors.

Definition 5.4 (Generalized eigenvector in a rigged Hilbert space)**.** For a self-adjoint operator A with spectral measure E_A, a number λ is an eigenvalue in the Hilbert-space sense precisely when

$$E_A(\{\lambda\})\mathcal{H} \neq 0.$$

If $E_A(\{\lambda\}) = 0$ but λ lies in the continuous spectrum, there is no normalizable eigenvector with that eigenvalue. A generalized eigenvector at λ is instead a functional

$$F_\lambda \in \Phi^\times$$

such that, on a common invariant test domain,

$$F_\lambda(A\phi) = \lambda F_\lambda(\phi), \qquad \phi \in \Phi.$$

This is the mathematical meaning of a plane wave of sharp momentum or an energy eigenstate in a continuous spectrum. It is a distributional object used to write kernels. Physical Hilbert vectors are obtained by smearing such kernels with square-integrable wave packets.

Definition 5.5 (Direct-integral coordinate ket)**.** Equivalently, the spectral theorem may be written as a direct integral

$$\mathcal{H} \simeq \int_X^\oplus \mathcal{H}_\lambda \, \mathrm{d}\nu(\lambda), \qquad A = \int_X^\oplus \lambda \, \mathbf{1}_{\mathcal{H}_\lambda} \, \mathrm{d}\nu(\lambda).$$

The label λ indexes fibers over the spectrum. A generalized ket $|\lambda, a\rangle$ is not an element of $\mathcal{H}$. It denotes the distributional coordinate functional that extracts the a-component in the fiber $\mathcal{H}_\lambda$ of the direct integral. Delta-normalization records the kernel of the identity relative to the measure $\mathrm{d}\nu$. Changing $\mathrm{d}\nu$ rescales these generalized kets and therefore changes the displayed delta factors; the Hilbert-space vector obtained after smearing is unchanged.

Definition 5.6 (Relativistic one-particle rigging)**.** For a relativistic one-particle mass shell this gives, for example,

$$\Phi_1 = C_c^\infty(\Sigma_m^+; V) \subset \mathcal{H}_1 = L^2(\Sigma_m^+, \mathrm{d}\mu_m; V) \subset \Phi_1^\times,$$

where V is the finite-dimensional little-group representation space. The little-group label convention is fixed by choosing an orthonormal basis $\{e_\sigma\}$ of V and writing

$$\langle e_\tau, e_\sigma \rangle_V = \delta_{\tau\sigma}.$$

Thus, in a bra-ket expression, the first Kronecker index is the label carried by the bra and the second is the label carried by the ket; since the Kronecker delta is symmetric, $\delta_{\tau\sigma} = \delta_{\sigma\tau}$. The symbol $|p, \sigma\rangle$ is an element of $\Phi_1^\times$, and

$$\langle p, \tau | p', \sigma \rangle = (2\pi)^{D-1} 2p^0 \, \delta^{(D-1)}(\vec{p} - \vec{p}')\delta_{\tau\sigma}$$

is the distribution kernel for the identity in the covariant mass-shell measure. All scattering kernels written later with sharp external momenta are to be read in this sense. The wave-packet formulation is the primary Hilbert-space statement; the plane-wave formula is the corresponding distributional kernel.

5.3 Poincare Symmetry

Definition 5.7 (Poincare-covariant vacuum Hilbert datum)**.** Let

$$\mathcal{P}_+^\uparrow = \mathbb{R}^D \rtimes SO^+(1, D-1)$$

be the connected Poincare group of $\mathbb{M}^D$. A relativistic quantum theory in the opening framework carries a strongly continuous unitary representation

$$U : \mathcal{P}_+^\uparrow \to \mathcal{U}(\mathcal{H}), \qquad (a, \Lambda) \mapsto U(a, \Lambda),$$

or the corresponding representation of the double cover when spinorial representations are present. The group law is

$$(a', \Lambda')(a, \Lambda) = (a' + \Lambda' a, \Lambda'\Lambda),$$

so a genuine unitary representation satisfies

$$U(a', \Lambda')U(a, \Lambda) = U(a' + \Lambda' a, \Lambda'\Lambda).$$

Infinitesimally,

$$U(a, \Lambda) = 1 + \mathrm{i} a_\mu P^\mu + \frac{\mathrm{i}}{2}\omega_{\mu\nu} J^{\mu\nu} + O(a^2, \omega^2, a\omega),$$

where P^μ are the self-adjoint energy-momentum generators, $P_\mu = \eta_{\mu\nu} P^\nu$, and $J^{\mu\nu} = -J^{\nu\mu}$ are the Lorentz generators on a common invariant domain. The commutation relations are

$$[P^\mu, P^\nu] = 0,$$

$$[P^\mu, J^{\rho\sigma}] = -\mathrm{i}(\eta^{\mu\rho} P^\sigma - \eta^{\mu\sigma} P^\rho),$$

and

$$[J^{\mu\nu}, J^{\rho\sigma}] = -\mathrm{i}\left(\eta^{\nu\rho} J^{\mu\sigma} - \eta^{\mu\rho} J^{\nu\sigma} - \eta^{\nu\sigma} J^{\mu\rho} + \eta^{\mu\sigma} J^{\nu\rho}\right).$$

Equivalently, $[J^{\rho\sigma}, P^\mu] = \mathrm{i}(\eta^{\mu\rho} P^\sigma - \eta^{\mu\sigma} P^\rho)$. This is the Lorentzian Poincare subalgebra convention used again in the conformal chapters. There the Hermitian charge Q_X associated to a conformal Killing field X obeys $[Q_X, Q_Y] = -\mathrm{i} Q_{[X,Y]}$; see Chapter 57, (57.10). Taking $X = M^{\rho\sigma}$ and $Y = P^\mu$, then raising indices with η, gives the displayed $[J^{\rho\sigma}, P^\mu]$ bracket. The radial-quantization real form is obtained later by the explicit generator map (59.27). The spectrum condition is

$$\mathrm{Spec}(P) \subset \overline{V}_+.$$

In a vacuum sector there is a unit vector $\Omega \in \mathcal{H}$ satisfying

$$U(a, \Lambda)\Omega = \Omega.$$

5.4 Translation Spectrum and Mass Sectors

Proposition 5.8 (Joint translation spectrum)**.** *The restriction of the Poincare representation to translations has a unique joint spectral measure*

$$E : \{\textit{Borel subsets of } \mathbb{R}^D\} \longrightarrow \{\textit{orthogonal projections on } \mathcal{H}\}$$

such that

$$P^\mu = \int_{\mathbb{R}^D} p^\mu \, \mathrm{d}E(p), \qquad U(a, \mathbf{1}) = \int_{\mathbb{R}^D} \mathrm{e}^{\mathrm{i} a^\mu p_\mu} \, \mathrm{d}E(p).$$

The one-parameter Stone generators P^μ are therefore the coordinate operators of this single joint spectral measure. In particular the translation generators are strongly commuting self-adjoint *operators: their spectral projections $E(\Delta)$ commute. For a vector $\psi \in \mathcal{H}$, its energy-momentum spectral measure is*

$$\mu_\psi(\Delta) = \|E(\Delta)\psi\|^2, \qquad \Delta \subset \mathbb{R}^D \text{ Borel.}$$

The spectral support of ψ is the closed support of this measure. The spectrum condition in the preceding section is the statement that

$$E(\mathbb{R}^D \setminus \overline{V}_+) = 0.$$

Proof. Restrict U in Definition 5.7 to the translation subgroup. The subgroup is abelian and locally compact, and the restriction is strongly continuous and unitary. The Stone–Naimark spectral theorem therefore gives the single projection-valued measure E displayed above. Explicitly, the equality

$$U(a, \mathbf{1}) = \int_{\mathbb{R}^D} \mathrm{e}^{\mathrm{i}a^\mu p_\mu} \, \mathrm{d}E(p)$$

is an equality of bounded operators for every $a \in \mathbb{R}^D$, and uniqueness follows because Fourier transforms of finite complex Borel measures on $\mathbb{R}^D$ determine those measures. Differentiating the one-parameter subgroup $s \mapsto U(se_\mu, \mathbf{1})$ in Stone's sense gives the coordinate multiplication operator p^μ in this joint spectral representation, namely

$$P^\mu \psi = \int_{\mathbb{R}^D} p^\mu \, \mathrm{d}E(p) \, \psi$$

on its natural domain

$$\{\psi \in \mathcal{H} : \int_{\mathbb{R}^D} |p^\mu|^2 \, \mathrm{d}\|E(p)\psi\|^2 < \infty\}.$$

All spectral projections obtained from E commute because they are projections in the same countably additive projection-valued measure. This strong commutativity is stronger than the formal infinitesimal relation $[P^\mu, P^\nu] = 0$ on a common invariant domain: for unbounded operators, commutation on a core does not by itself imply that the spectral projections commute. The displayed Lie-algebra commutator is therefore the differential shadow of the joint functional calculus. Finally, the operator-valued support statement $E(\mathbb{R}^D \setminus \overline{V}_+) = 0$ is equivalent to saying that every scalar spectral measure $\mu_\psi(\Delta) = \|E(\Delta)\psi\|^2$ is supported in $\overline{V}_+$; this is the precise spectral-measure form of the spectrum condition. □

Definition 5.9 (Invariant mass spectral measure)**.** The invariant mass operator is defined by functional calculus:

$$M^2 = -P_\mu P^\mu = \int_{\mathbb{R}^D} (-p_\mu p^\mu) \, \mathrm{d}E(p).$$

For a Borel set $I \subset [0, \infty)$, the projection onto the corresponding mass range is

$$E_M(I) = E\big(\{p \in \overline{V}_+ : -p_\mu p^\mu \in I\}\big).$$

The vacuum subspace is the zero-momentum subspace

$$E(\{0\})\mathcal{H}.$$

In a pure vacuum sector this subspace is one-dimensional and is spanned by Ω.

Definition 5.10 (Mass sector and particle shell)**.** A mass sector of mass $m \geq 0$ is the spectral subspace of M^2 at the value m^2, namely $E_M(\{m^2\})\mathcal{H}$. For $m > 0$, the corresponding positive-energy mass shell is the smooth hyperboloid

$$\Sigma_m^+ = \{p \in \mathbb{R}^D : p^0 = \sqrt{\vec{p}^2 + m^2},\ p_\mu p^\mu = -m^2\}.$$

For $m = 0$, the nonzero massless particle shell is the punctured future light cone

$$\Sigma_0^+ = \{p \in \mathbb{R}^D : p^0 = |\vec{p}|,\ p_\mu p^\mu = 0,\ p \neq 0\}.$$

It is isolated when there is an open neighborhood $N \subset \mathbb{R}^D$ of the shell under discussion such that

$$\operatorname{Spec}(P) \cap N = \Sigma_m^+$$

in the massive case, and analogously with Σ_0^+ in a massless sector when such a global isolation statement is true. In a vacuum representation the massless cone usually accumulates at the vacuum point $p = 0$, so the global isolation condition is a genuine additional spectral hypothesis beyond the invariant-mass equation $M^2 = 0$.

Isolated shell as a one-particle subrepresentation. An isolated massive particle in a local quantum theory is the closed spectral subspace

$$\mathcal{H}_1 = E(\Sigma_m^+)\mathcal{H}$$

inside the physical Hilbert space. Its Wigner representation is the restriction of the Poincare representation to this subspace. Later, the Källén–Lehmann representation detects the same object as an atom in a two-point spectral measure, and Haag–Ruelle theory uses the isolation hypothesis to construct asymptotic multi-particle states. The set Σ_m^+ is Borel, so $E(\Sigma_m^+)$ is an orthogonal projection. The spectral covariance relation $U(a,\Lambda)E(\Delta)U(a,\Lambda)^{-1} = E(\Lambda\Delta)$ follows from conjugating the translation representation by $U(a,\Lambda)$. Since Σ_m^+ is a positive-energy Lorentz orbit, the range of $E(\Sigma_m^+)$ is invariant under the Poincare representation. Restricting the representation to this closed range gives the one-particle Wigner subrepresentation.

Remark 5.11 (Infraparticle sectors)*.* The word "isolated" is a spectral hypothesis in addition to the mass equation $M^2 = m^2$. A theory with a massless long-range gauge field can have charged sectors whose charged threshold is the lower edge of continuous energy-momentum support. In four-dimensional QED, Gauss's law ties nonzero electric charge to an electromagnetic field at spatial infinity; charged sector states are therefore represented by operators carrying noncompact dressing data. A charged dressing carries a Coulomb tail and admits arbitrarily soft photon excitations. The resulting charged particle is an infraparticle: its spectral support accumulates at the charged threshold in place of an isolated shell with a nonzero projection $E(\Sigma_m^+)$. The Haag–Ruelle and LSZ constructions below apply to sectors satisfying the isolated-shell hypothesis; the infrared replacement in QED is treated in Chapters 42 and 44.

Figure 5.1 displays the spectral separation assumed in the one-particle subrepresentation construction: an isolated positive mass shell inside the future cone, separated from the multiparticle continuum.

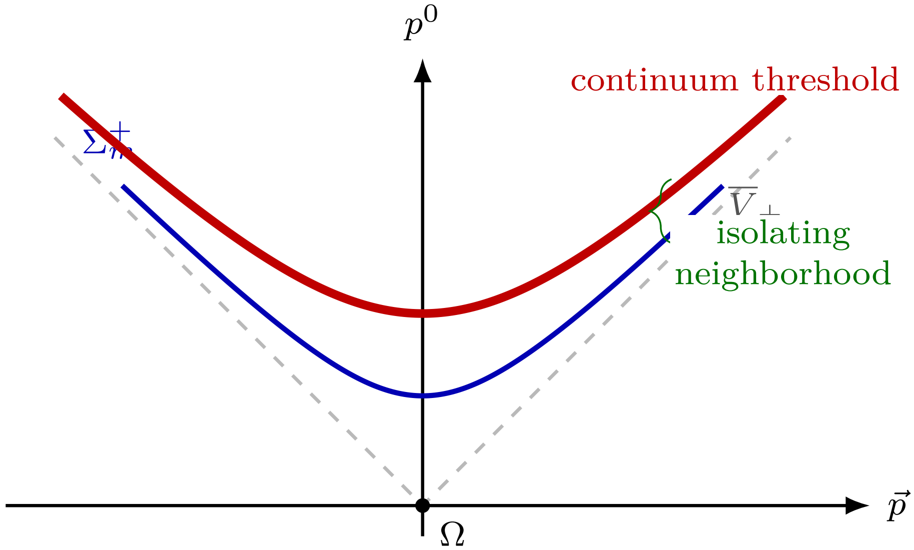

Figure 5.1: The translation spectrum lies in the closed future cone. A stable massive particle corresponds to an isolated positive-energy mass shell, separated from the continuum in a neighborhood of the shell.

5.5 One-Particle Representations

Definition 5.12 (Massive scalar Wigner one-particle space)**.** The spectral subspace $E(\Sigma_m^+)\mathcal{H}$ carries a unitary representation of the Poincare group. The corresponding abstract one-particle representation is described by Wigner's little-group construction. For a massive spinless particle, the one-particle Hilbert space is realized as

$$\mathcal{H}_1 = L^2\left(\Sigma_m^+, \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}2E_{\vec{p}}}\right), \qquad E_{\vec{p}} = \sqrt{\vec{p}^2 + m^2}.$$

The measure displayed here is the Lorentz-invariant measure on Σ_m^+ in the chosen normalization. General massive particles carry a finite-dimensional unitary representation of the double cover of the massive little group $SO(D-1)$. Massless finite-helicity particles in four spacetime dimensions are classified by helicity representations of the massless little group.

Definition 5.13 (Four-dimensional Wigner orbit datum)**.** For later reference we record the corresponding four-dimensional Wigner classification in one place. Let

$$\widetilde{\mathcal{P}_+^\uparrow} = \mathbb{R}^{1,3} \rtimes SL(2,\mathbb{C})$$

be the universal-cover version of the connected Poincare group. An irreducible unitary representation whose translation spectrum is supported on a single Lorentz orbit is obtained by choosing a representative momentum $\bar{p}$, an irreducible unitary representation of its stabilizer

$$G_{\bar{p}} = \{\Lambda \in SL(2,\mathbb{C}) : \Lambda\bar{p} = \bar{p}\},$$

and inducing to $\widetilde{\mathcal{P}_+^\uparrow}$. The spectrum condition keeps only orbits contained in the closed future cone, but the representation-theoretic list is useful because it makes explicit which cases are being assumed away.

Orbit type	Representative and invariant	Little group	Irreducible little-group data	Role in this monograph
Vacuum orbit	$\bar{p} = 0$	$SL(2, \mathbb{C})$	The pure vacuum sector uses the trivial representation.	This is the zero-momentum state, not a particle shell.
Massive positive-energy orbit	$\bar{p} = (m, 0, 0, 0)$, $m > 0$, $\bar{p}^2 = -m^2$	$SU(2)$	Spin $j = 0, \frac{1}{2}, 1, \frac{3}{2}, \ldots$, with $\dim V_j = 2j + 1$.	Isolated massive particles and their higher-spin tower; developed in Chapters 20 and 40.
Massless finite-helicity orbit	$\bar{p} = (\kappa, 0, 0, \kappa)$, $\kappa > 0$, $\bar{p}^2 = 0$	double cover of $ISO(2)$	The two null-translation generators act trivially; the rotation generator has helicity $h \in \frac{1}{2}\mathbb{Z}$.	Photons, gravitons, and finite-helicity external states; developed in Chapters 21 and 41.
Massless continuous-spin orbit	Same lightlike orbit, $\bar{p}^2 = 0$, with nontrivial little-group translations	double cover of $ISO(2)$	Nonzero transverse-translation orbit $N_1^2 + N_2^2 = \rho^2 > 0$, giving an infinite helicity tower mixed by boosts.	A legitimate positive-energy Wigner class, but not generated by point-local covariant fields under the usual locality assumptions; see Remark 21.3.
Spacelike, or tachyonic, orbit	$\bar{p} = (0, \mu, 0, 0)$, $\mu > 0$, $\bar{p}^2 = \mu^2$	double cover of $SO^+(1, 2)$	Unitary little-group representations are representations of a noncompact group, typically infinite-dimensional.	Excluded here by the spectrum condition: the full Lorentz orbit is not contained in $\overline{V}_+$ and has no invariant lower energy bound.

Table 5.1: Four-dimensional Wigner orbit classes for irreducible one-particle representations of the universal cover of the connected Poincare group. A general Hilbert space representation may contain direct sums or direct integrals of such irreducibles; a stable particle species is an isolated copy of one of the particle orbits satisfying the spectral and localization hypotheses used later.

This construction supplies one-particle state spaces and their Poincare transformation law. A local quantum theory also supplies a localization assignment for observables.

5.6 Free Fock Space From One-Particle Data

Definition 5.14 (Free bosonic and fermionic Fock spaces)**.** From a one-particle Hilbert space $\mathcal{H}_1$, define the bosonic Fock space

$$\mathcal{F}_s(\mathcal{H}_1) = \bigoplus_{n=0}^{\infty} \operatorname{Sym}^n \mathcal{H}_1$$

and the fermionic Fock space

$$\mathcal{F}_a(\mathcal{H}_1) = \bigoplus_{n=0}^{\infty} \wedge^n \mathcal{H}_1.$$

Definition 5.15 (Bosonic creation-operator tensor normalization)**.** The symmetric tensor powers use the creation-operator normalization. Let

$$\Pi_{s,n} = \frac{1}{n!} \sum_{\sigma \in S_n} U_\sigma$$

be the orthogonal projection from $\mathcal{H}_1^{\otimes n}$ to its symmetric subspace, where

$$U_\sigma(\psi_1 \otimes \cdots \otimes \psi_n) = \psi_{\sigma^{-1}(1)} \otimes \cdots \otimes \psi_{\sigma^{-1}(n)}.$$

For $\psi_1, \dots, \psi_n \in \mathcal{H}_1$ define

$$\psi_1 \odot \cdots \odot \psi_n := \sqrt{n!}\, \Pi_{s,n}(\psi_1 \otimes \cdots \otimes \psi_n) \in \mathrm{Sym}^n \mathcal{H}_1. \tag{5.1}$$

Bosonic Fock inner product in creation-operator normalization. With this convention

$$\big\langle \psi_1 \odot \cdots \odot \psi_n,\, \chi_1 \odot \cdots \odot \chi_m \big\rangle = \delta_{mn} \sum_{\sigma \in S_n} \prod_{j=1}^{n} \langle \psi_j, \chi_{\sigma(j)} \rangle_{\mathcal{H}_1}. \tag{5.2}$$

Different tensor powers in the direct sum defining $\mathcal{F}_s(\mathcal{H}_1)$ are orthogonal, giving the factor δ_{mn}. For $m = n$, Definition 5.15 gives

$$\psi_1 \odot \cdots \odot \psi_n = \frac{1}{\sqrt{n!}} \sum_{\sigma \in S_n} \psi_{\sigma^{-1}(1)} \otimes \cdots \otimes \psi_{\sigma^{-1}(n)}$$

and the analogous formula for the χ's. Hence

$$\big\langle \psi_1 \odot \cdots \odot \psi_n,\, \chi_1 \odot \cdots \odot \chi_n \big\rangle = \frac{1}{n!} \sum_{\sigma, \tau \in S_n} \prod_{i=1}^{n} \langle \psi_{\sigma^{-1}(i)}, \chi_{\tau^{-1}(i)} \rangle_{\mathcal{H}_1}.$$

For each fixed σ, set $j = \sigma^{-1}(i)$ and $\rho = \tau^{-1}\sigma$. The product becomes $\prod_{j=1}^{n} \langle \psi_j, \chi_{\rho(j)} \rangle_{\mathcal{H}_1}$, and as τ runs over S_n, so does ρ. The sum over σ cancels the prefactor $1/n!$, leaving the displayed permutation sum.

Definition 5.16 (Mass-shell Fock test domain and kernels)**.** For the massive scalar one-particle space $\mathcal{H}_1 = L^2(\Sigma_m^+, \mathrm{d}\mu_m)$, identify the mass shell with $\mathbb{R}^{D-1}$ by

$$\vec{p} \longmapsto (E_{\vec{p}}, \vec{p}), \qquad E_{\vec{p}} = \sqrt{\vec{p}^{\,2} + m^2},$$

and define

$$\mathcal{S}_m = \mathcal{S}(\Sigma_m^+)$$

to be the wave packets whose pullback to the $\vec{p}$-chart is a Schwartz function. The space $\mathcal{S}_m$ is dense in $\mathcal{H}_1$, is contained in the domain of every polynomial in the one-particle energy-momentum operators, and is invariant under the one-particle Poincare representation. The common algebraic Fock domain used below is

$$\mathcal{D}_0 = \mathrm{span}\{a^\dagger(\psi_1) \cdots a^\dagger(\psi_n)\Omega \mid n \geq 0,\ \psi_1, \dots, \psi_n \in \mathcal{S}_m\}.$$

It is dense in $\mathcal{F}_s(\mathcal{H}_1)$ and invariant under creation and annihilation operators smeared by elements of $\mathcal{S}_m$. For a free scalar species, the momentum-space annihilation and creation operators $a(\vec{p})$ and $a^\dagger(\vec{p})$ are operator-valued distributions characterized by

$$[a(\vec{p}), a^\dagger(\vec{q})] = (2\pi)^{D-1} 2E_{\vec{p}}\, \delta^{(D-1)}(\vec{p} - \vec{q}),$$

with all other commutators vanishing. The free Hamiltonian is

$$H_0 = \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}2E_{\vec{p}}}\, E_{\vec{p}}\, a^\dagger(\vec{p})a(\vec{p}),$$

after the vacuum energy has been normalized. The spatial momentum is

$$\vec{P}_0 = \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}2E_{\vec{p}}}\, \vec{p}\, a^\dagger(\vec{p})a(\vec{p}).$$

Write

$$\mathrm{d}\mu_m(\vec{p}) = \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}2E_{\vec{p}}}.$$

For a one-particle test wave packet $\psi \in \mathcal{S}_m$, the smeared creation and annihilation operators on $\mathcal{D}_0$ are

$$a^\dagger(\psi) = \int \mathrm{d}\mu_m(\vec{p})\, \psi(\vec{p})a^\dagger(\vec{p}), \qquad a(\psi) = \int \mathrm{d}\mu_m(\vec{p})\, \overline{\psi(\vec{p})}a(\vec{p}).$$

The closed Fock operators can be defined for all $\psi \in \mathcal{H}_1$. The operator-valued distribution notation and the common-domain commutator calculation use the dense test class $\mathcal{S}_m$. For $\psi, \chi \in \mathcal{S}_m$, the operators on $\mathcal{D}_0$ satisfy

$$[a(\psi), a^\dagger(\chi)] = \int \mathrm{d}\mu_m(\vec{p})\, \overline{\psi(\vec{p})}\chi(\vec{p}) = \langle \psi, \chi\rangle_{\mathcal{H}_1}.$$

Definition 5.17 (Noncovariant creation and momentum-ket normalization)**.** There is a second common normalization, useful for displaying the elementary Fock construction. Define operator-valued distributions $\mathfrak{a}_{\vec{p}}$ by

$$a(\vec{p}) = \sqrt{(2\pi)^{D-1}2E_{\vec{p}}}\, \mathfrak{a}_{\vec{p}}.$$

Then

$$[\mathfrak{a}_{\vec{p}}, \mathfrak{a}^\dagger_{\vec{q}}] = \delta^{(D-1)}(\vec{p}-\vec{q}), \qquad [\mathfrak{a}_{\vec{p}}, \mathfrak{a}_{\vec{q}}] = [\mathfrak{a}^\dagger_{\vec{p}}, \mathfrak{a}^\dagger_{\vec{q}}] = 0.$$

The corresponding sharp-momentum kets are distributional vectors,

$$|\vec{p}\rangle = \mathfrak{a}^\dagger_{\vec{p}}\Omega, \qquad |\vec{p}_1, \ldots, \vec{p}_n\rangle = \mathfrak{a}^\dagger_{\vec{p}_1} \cdots \mathfrak{a}^\dagger_{\vec{p}_n}\Omega,$$

and

$$\langle \vec{p}|\vec{q}\rangle = \delta^{(D-1)}(\vec{p}-\vec{q}).$$

In this normalization

$$H_0 = \int \mathrm{d}^{D-1}\vec{p}\, E_{\vec{p}}\, \mathfrak{a}^\dagger_{\vec{p}}\mathfrak{a}_{\vec{p}}, \qquad \vec{P}_0 = \int \mathrm{d}^{D-1}\vec{p}\, \vec{p}\, \mathfrak{a}^\dagger_{\vec{p}}\mathfrak{a}_{\vec{p}}.$$

Definition 5.18 (Free multi-species Fock representation)**.** For a finite collection of free stable species, let B be the set of bosonic species and F the set of fermionic species, with one-particle spaces $\mathcal{H}_{1,b}$ and $\mathcal{H}_{1,f}$. The free multi-species Hilbert space is the completed tensor product

$$\mathcal{H}_{\mathrm{Fock}} = \bigotimes_{b\in B} \mathcal{F}_s(\mathcal{H}_{1,b}) \otimes \bigotimes_{f\in F} \mathcal{F}_a(\mathcal{H}_{1,f}).$$

The vacuum is the tensor product of the factor vacua, and the free Poincare representation is the tensor product of the corresponding second-quantized one-particle representations. Equivalently, $\bigotimes_{b\in B} \mathcal{F}_s(\mathcal{H}_{1,b}) \simeq \mathcal{F}_s(\bigoplus_{b\in B} \mathcal{H}_{1,b})$, and similarly for fermions with $\mathcal{F}_a$. The operator algebra on the fermionic factors uses the graded tensor-product convention, so homogeneous odd creation or annihilation operators associated with distinct fermion species anticommute.

The Fock construction gives a free multi-particle representation. A local QFT also specifies which operators are localized in each bounded spacetime region.

5.7 Locality As A Constraint On Interacting Particle Dynamics

At a cutoff or algebraic bookkeeping level, an interaction written in free Fock variables has the form

$$H = H_0 + H_{\text{int}},$$

where H_{int} is a sum of normally ordered monomials such as

$$\int K_{2,1}\, a^\dagger a^\dagger a + \int K_{1,2}\, a^\dagger a a + \cdots ,$$

with kernels $K_{r,s}$ and the mass-shell measures suppressed in the displayed shorthand. This expression is not yet a definition of a relativistic local theory. A local-theory datum also includes translation generators P_μ, Lorentz generators $J^{\mu\nu}$, a Poincare-invariant vacuum, and local observables or fields satisfying covariance and microcausality. In an interacting theory the boost generators, the Hamiltonian, and the local field operators are tied together by the Poincare algebra and locality.

The causal input is spacetime-local operation. A local operation near a point or region can influence only its causal future. The algebraic expression of this statement is locality for spacelike separated regions.

Figure 5.2 fixes the light-cone convention used here: the local operation sits at the vertex, the allowed influence lies in the causal future, and spacelike separated regions remain outside this causal domain.

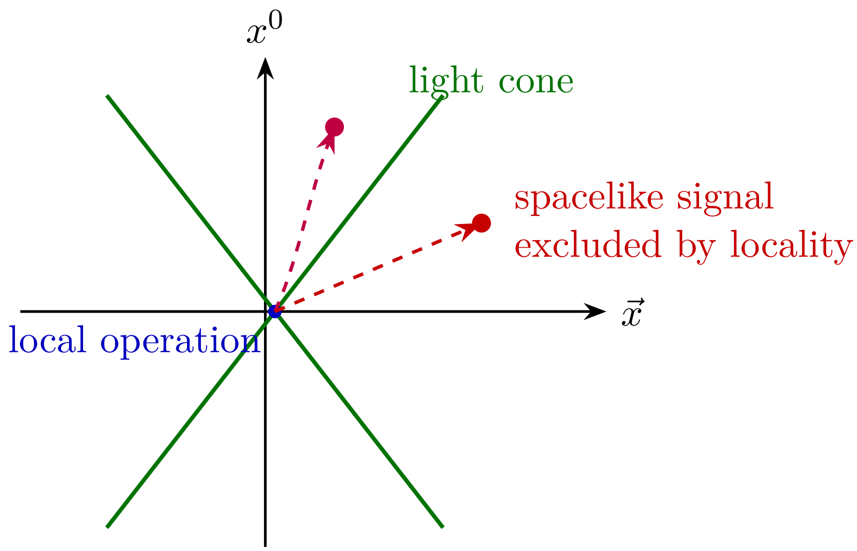

Figure 5.2: Causal localization in Minkowski space. The field-theoretic condition corresponding to the exclusion of spacelike signaling is commutativity, or graded commutativity, of observables localized in spacelike separated regions.

5.8 Locality Data

Definition 5.19 (Local observable assignment)**.** For bounded open regions $\mathcal{O} \subset \mathbb{M}^D$, the opening framework assigns algebras $\mathcal{A}(\mathcal{O}) \subset \mathcal{B}(\mathcal{H})$. If $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated, locality is

$$[A, B] = 0, \qquad A \in \mathcal{A}(\mathcal{O}_1), \quad B \in \mathcal{A}(\mathcal{O}_2),$$

with the graded commutator after a fermion parity grading has been specified.

This condition states compatibility of spacelike separated local observables: their order gives the same matrix elements in every vector for which the matrix elements are defined.

5.9 Free Scalar Field As A Derived Example

Definition 5.20 (Free scalar field from mass-shell creation kernels)**.** Use the dense domain $\mathcal{D}_0 \subset \mathcal{F}_s(\mathcal{H}_1)$ generated from the mass-shell Schwartz test space $\mathcal{S}_m$. On $\mathcal{D}_0$, define the free scalar field as the operator-valued distribution

$$\widehat{\phi}(x) = \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2E_{\vec{p}}} \left(a(\vec{p}) \mathrm{e}^{\mathrm{i}p\cdot x} + a^\dagger(\vec{p}) \mathrm{e}^{-\mathrm{i}p\cdot x} \right),$$

where $p^0 = E_{\vec{p}}$ and

$$p \cdot x = \eta_{\mu\nu} p^\mu x^\nu.$$

For $f \in C_c^\infty(\mathbb{M}^D)$, the smeared field is

$$\widehat{\phi}(f) = \int \mathrm{d}^D x\, f(x) \widehat{\phi}(x).$$

In the noncovariant normalization this is equivalently

$$\widehat{\phi}(x) = \int \frac{\mathrm{d}^{D-1}\vec{p}}{\sqrt{(2\pi)^{D-1} 2E_{\vec{p}}}} \left(\mathfrak{a}_{\vec{p}} \mathrm{e}^{\mathrm{i}p\cdot x} + \mathfrak{a}^\dagger_{\vec{p}} \mathrm{e}^{-\mathrm{i}p\cdot x} \right).$$

Covariance of the free scalar field. The free scalar field is covariant. Let $g = (b, \Lambda) \in \mathcal{P}_+^\uparrow$, and let $U_1(g)$ be the one-particle scalar representation on $\mathcal{H}_1$. The free Fock representation is its second quantization $U_0(g) = \Gamma(U_1(g))$, so

$$U_0(g) a^\dagger(\psi) U_0(g)^{-1} = a^\dagger(U_1(g)\psi)$$

for $\psi \in \mathcal{S}_m$ on $\mathcal{D}_0$. Since $U_1(g)\mathcal{S}_m \subset \mathcal{S}_m$, this identity preserves the common test domain; the closed operators give the corresponding Hilbert-space identity for arbitrary $\psi \in \mathcal{H}_1$. The adjoint identity gives the annihilation part. Applying these identities to the distributional creation and annihilation kernels in Definition 5.20, followed by the invariant change of variables on Σ_m^+, gives

$$U_0(b, \Lambda) \widehat{\phi}(x) U_0(b, \Lambda)^{-1} = \widehat{\phi}(\Lambda x + b).$$

Thus the calculation checks compatibility of the free kernel definition with the chosen one-particle representation.

Proposition 5.21 (Free scalar microcausality)**.** *The commutator is*

$$[\widehat{\phi}(x), \widehat{\phi}(y)] = \mathrm{i}\Delta(x-y),$$

where the Pauli–Jordan distribution is

$$\Delta(x) = \frac{1}{\mathrm{i}} \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2E_{\vec{p}}} \left(\mathrm{e}^{\mathrm{i}p\cdot x} - \mathrm{e}^{-\mathrm{i}p\cdot x}\right).$$

The distribution Δ is Lorentz invariant and its restriction to the spacelike region vanishes. Consequently

$$[\widehat{\phi}(f), \widehat{\phi}(g)] = 0$$

when the supports of f and g are spacelike separated.

Proof. The canonical commutation relation in Definition 5.16 gives the displayed Pauli–Jordan commutator on the common domain $\mathcal{D}_0$. In smeared form, for $f, g \in C_c^\infty(\mathbb{M}^D)$,

$$[\widehat{\phi}(f), \widehat{\phi}(g)] = \mathrm{i} \int \mathrm{d}^D x\, \mathrm{d}^D y\, f(x) g(y) \Delta(x-y)$$

as a scalar multiple of the identity on $\mathcal{D}_0$. The mass-shell measure and the two exponentials are invariant under the connected Lorentz group, so $\Delta(\Lambda x) = \Delta(x)$ as a distribution. On the open spacelike region $x^2 > 0$, the mass-shell Fourier integral defines a smooth solution of the Klein–Gordon equation. For each spacelike x choose a proper orthochronous Lorentz transformation sending it to $(0, \vec{r})$. At equal time the two exponentials in the defining integral are exchanged by the measure-preserving map $\vec{p} \mapsto -\vec{p}$, hence the smooth restriction of Δ to that point is zero. Since the spacelike region is open and every point in it is covered by this argument, Δ vanishes there as a distribution. If the supports of f and g are spacelike separated, then $x - y$ remains in this open spacelike region on $\operatorname{supp} f \times \operatorname{supp} g$; the displayed smeared commutator therefore vanishes. □

Remark 5.22. The cancellation above uses the antisymmetric combination $\Delta_+(x-y) - \Delta_+(y-x)$, equivalently the ordinary commutator for an even scalar field. If the same scalar two-point function were assigned odd locality, the vacuum matrix element of the required anticommutator would contain

$$\Delta_+(x-y) + \Delta_+(y-x).$$

At equal time and spacelike separation this becomes

$$2 \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2E_{\vec{p}}} \cos(\vec{p}\cdot\vec{r}),$$

which has spacelike support. Thus the sign in the Pauli–Jordan distribution is already the local free-field manifestation of the spin-statistics connection. The theorem-level statement, with its positivity, covariance, and domain hypotheses, is discussed in Chapter 40.

This calculation establishes locality for the free scalar field from the stated data: the free scalar Fock representation, the Lorentz-invariant mass-shell measure, the distributional field definition, and smearing by test functions.

5.10 Constructed Structures

The chapter has constructed five distinct structures. Hilbert-space quantum mechanics supplies states and operators. Translation spectral theory supplies energy-momentum support, invariant mass, and particle subspaces inside the physical Hilbert space. Poincare representation theory supplies the transformation law of one-particle state spaces. Fock space supplies free multi-particle state spaces. A local quantum theory supplies local observable assignments satisfying covariance and microcausality. The free scalar field realizes these structures explicitly and will serve as the first model for the general field framework.

Chapter 6

Local Fields, Covariance, and Microcausality

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

This chapter works in the Wightman field presentation introduced in Chapter 2: local fields are operator-valued distributions on a common invariant dense domain, and every point-field formula is shorthand for a continuous smeared matrix element.

6.1 Field Multiplets As Operator-Valued Distributions

Definition 6.1 (Field multiplet as an operator-valued distribution)**.** Let $\mathcal{D} \subset \mathcal{H}$ be a dense linear subspace. In this chapter $\mathrm{End}(\mathcal{D})$ denotes the algebra of linear maps $\mathcal{D} \to \mathcal{D}$. A field multiplet is a collection $\widehat{\Phi}_A$, with A in a finite index set, such that each component defines a continuous linear map

$$\widehat{\Phi}_A : C_c^\infty(\mathbb{M}^D) \to \mathrm{End}(\mathcal{D}), \qquad f \mapsto \widehat{\Phi}_A(f).$$

Continuity is meant in the usual locally convex LF topology on $C_c^\infty(\mathbb{M}^D)$. This is the localization version of the test-function convention in Chapter 1; when a later spectral statement uses $\mathcal{S}(\mathbb{M}^D)$, the additional tempered-continuity hypothesis is part of that statement. The notation

$$\widehat{\Phi}_A(f) = \int_{\mathbb{M}^D} \mathrm{d}^D x\, f(x) \widehat{\Phi}_A(x)$$

is the distributional notation for this linear map. The symbol x in $\widehat{\Phi}_A(x)$ is a spacetime label, not an operator on $\mathcal{H}$. The operator is obtained only after smearing the distributional field against a test function. This convention separates spacetime localization data from the Hilbert-space operators that act on states.

Definition 6.2 (Localization of a smeared field)**.** The support of the smeared field $\widehat{\Phi}_A(f)$ is controlled by $\operatorname{supp} f$. If $\operatorname{supp} f \subset \mathcal{O}$, where $\mathcal{O} \subset \mathbb{M}^D$ is a bounded open region, the field is localized in $\mathcal{O}$. In the local-algebra framework of Chapter 1, this means that $\widehat{\Phi}_A(f)$ is affiliated with $\mathcal{A}(\mathcal{O})$ or belongs to the unbounded field algebra whose bounded functions generate observables localized in $\mathcal{O}$.

Definition 6.3 (Common invariant field domain)**.** A common invariant field domain for a family of fields is a dense subspace $\mathcal{D} \subset \mathcal{H}$ such that every smeared field $\widehat{\Phi}_A(f)$ maps $\mathcal{D}$ into itself, every finite product of smeared fields is defined on $\mathcal{D}$, the vacuum vector belongs to $\mathcal{D}$, and the Poincare representation maps $\mathcal{D}$ into itself. If adjoints are used, the adjoint field is required to preserve the same domain.

The domain condition is what makes a product such as $\widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)\Omega$ an actual vector before any distributional limit is taken. Matrix elements

$$(f_1,\dots,f_n) \longmapsto \left\langle \psi, \widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)\chi \right\rangle$$

are required to be continuous multilinear functionals of the test functions for ψ, χ in a stated dense domain. This continuity is the analytic content behind point-field notation.

Remark 6.4 (Distributional matrix elements). Suppose the smeared products above are defined on a common invariant field domain and the displayed matrix elements are continuous multilinear functionals on $C_c^\infty(\mathbb{M}^D)^n$. The Schwartz kernel theorem identifies the completed projective tensor product $C_c^\infty(\mathbb{M}^D)^{\widehat{\otimes} n}$ with $C_c^\infty((\mathbb{M}^D)^n)$. Thus the displayed matrix element is equivalently a distribution $W_{\psi,\chi}^{A_1\cdots A_n} \in \mathcal{D}'((\mathbb{M}^D)^n)$ satisfying

$$W_{\psi,\chi}^{A_1\cdots A_n}(f_1\otimes\cdots\otimes f_n) = \left\langle \psi, \widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)\chi \right\rangle.$$

This is the functional-analytic meaning of the stated continuity hypothesis.

Remark 6.5 (Direction of point-field notation). The preceding remark fixes the direction of logic: point-dependent expressions are compact notation for continuous smeared matrix elements. Later analytic continuation, spectral representation, and LSZ extraction all act on these distributions or on their Fourier transforms.

6.2 Poincare Covariance Of Fields

Let

$$g = (a, \Lambda) \in \mathcal{P}_+^\uparrow$$

act on spacetime by $gx = \Lambda x + a$. Let S be a finite-dimensional representation of $SO^+(1, D-1)$, or of its double cover for spinor fields, acting on the field components:

$$S(\Lambda)_A{}^B.$$

Definition 6.6 (Poincare pullback on test functions)**.** For $f \in C_c^\infty(\mathbb{M}^D)$, define the transformed test function

$$f_g(y) = f(g^{-1}y) = f(\Lambda^{-1}(y-a)).$$

The assignment $f \mapsto f_g$ is the pullback by g^{-1}. With the group law $hg : x \mapsto h(gx)$, it satisfies

$$(f_g)_h = f_{hg}.$$

Definition 6.7 (Covariant field multiplet)**.** A field multiplet $\widehat{\Phi}_A$ is Poincare covariant with component representation S when

$$U(g)^{-1}\widehat{\Phi}_A(f)U(g) = S(\Lambda)_A{}^B\,\widehat{\Phi}_B(f_g)$$

for every $g = (a, \Lambda)$, every test function f, and every component index A, with summation over repeated component indices.

In point-field notation this covariance law is written

$$U(a,\Lambda)^{-1}\widehat{\Phi}_A(x)U(a,\Lambda) = S(\Lambda)_A{}^B\,\widehat{\Phi}_B(\Lambda x + a).$$

The smeared equation is the definition; the point-field equation is its compact distributional form. With $U(a,\mathbf{1}) = \exp(\mathrm{i}a_\mu P^\mu) = \exp(\mathrm{i}a^\mu P_\mu)$, conjugation with U^{-1} on the left is the convention in which the coordinate label is translated by $+a$.

For a scalar field $S(\Lambda) = 1$. The infinitesimal translation law is

$$[P_\mu, \widehat{\Phi}(f)] = -\mathrm{i}\,\widehat{\Phi}(\partial_\mu f),$$

equivalently

$$[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\,\partial_\mu\widehat{\Phi}(x)$$

in distributional notation. The two signs are the same distributional statement: for compactly supported f,

$$\int \mathrm{d}^D x\, f(x)\,\partial_\mu\widehat{\Phi}(x) = -\int \mathrm{d}^D x\,(\partial_\mu f)(x)\widehat{\Phi}(x),$$

so moving the derivative from the field distribution to the test function produces the minus sign in the smeared commutator. Lorentz generators act by an orbital term on the spacetime argument and a spin term on the component index.

Infinitesimal translation covariance. Let $\widehat{\Phi}$ be a scalar covariant field and assume that $a \mapsto U(a,\mathbf{1})$ is generated on the common domain by $U(a,\mathbf{1}) = \exp(\mathrm{i}a^\mu P_\mu)$. Then, as an identity of smeared operators on $\mathcal{D}$,

$$[P_\mu, \widehat{\Phi}(f)] = -\mathrm{i}\,\widehat{\Phi}(\partial_\mu f).$$

Equivalently, in distributional point notation,

$$[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\,\partial_\mu\widehat{\Phi}(x).$$

For a pure translation $g = (a,\mathbf{1})$, Definition 6.7 gives

$$U(a)^{-1}\widehat{\Phi}(f)U(a) = \widehat{\Phi}(f_a), \qquad f_a(y) = f(y-a).$$

Differentiate at $a = 0$ in the μ-direction. The left side gives

$$\frac{d}{dt}\Big|_{t=0} e^{-\mathrm{i}tP_\mu}\widehat{\Phi}(f)e^{\mathrm{i}tP_\mu} = -\mathrm{i}[P_\mu, \widehat{\Phi}(f)],$$

while the right side gives

$$\frac{d}{dt}\Big|_{t=0} \widehat{\Phi}(f(\,\cdot - te_\mu)) = -\widehat{\Phi}(\partial_\mu f).$$

Equating the two derivatives gives the smeared formula. Pairing the point-field identity with f and integrating by parts gives the distributional version.

This is the infinitesimal form of the covariance definition; the displayed signs are part of the convention fixed by putting $U(a)^{-1}$ on the left in the finite transformation law.

Covariance of localization regions. If $\operatorname{supp} f \subset \mathcal{O}$, then $\operatorname{supp} f_g \subset g\mathcal{O}$. Therefore the covariant transform $U(g)^{-1}\widehat{\Phi}_A(f)U(g)$ is localized in $g\mathcal{O}$ whenever $\widehat{\Phi}_A(f)$ is localized in $\mathcal{O}$. The support identity $\operatorname{supp} f_g = g \operatorname{supp} f$ follows from $f_g(y) = f(g^{-1}y)$ and continuity of the homeomorphism g. The covariance law then rewrites the transformed operator as a linear combination of fields smeared with test functions supported in $g\mathcal{O}$.

Covariance of Wightman distributions. Assume that $\widehat{\Phi}_A$ is a covariant field multiplet on the common invariant domain of Definition 6.3, and that the vacuum is Poincare invariant:

$$U(g)\Omega = \Omega, \qquad g \in \mathcal{P}_+^\uparrow.$$

Then the n-point Wightman distributions satisfy

$$\begin{aligned} W_{A_1\cdots A_n}(f_1, \dots, f_n) = {} & S(\Lambda)_{A_1}{}^{B_1} \cdots S(\Lambda)_{A_n}{}^{B_n} \\ & \times W_{B_1\cdots B_n}\big((f_1)_g, \dots, (f_n)_g\big), \qquad g = (a, \Lambda), \end{aligned}$$

where $(f_i)_g(y) = f_i(g^{-1}y)$. In point-field notation this is

$$W_{A_1\cdots A_n}(x_1, \dots, x_n) = S(\Lambda)_{A_1}{}^{B_1} \cdots S(\Lambda)_{A_n}{}^{B_n} W_{B_1\cdots B_n}(gx_1, \dots, gx_n),$$

with the same distributional meaning as the smeared formula. The derivation uses only the stated field covariance and vacuum invariance. By vacuum invariance and unitarity,

$$\langle\Omega|\widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)|\Omega\rangle = \langle\Omega|U(g)^{-1}\widehat{\Phi}_{A_1}(f_1)\cdots\widehat{\Phi}_{A_n}(f_n)U(g)|\Omega\rangle.$$

Since $U(g)\mathcal{D} \subset \mathcal{D}$, conjugation by $U(g)$ may be applied to each factor on the common domain. Using Definition 6.7 for every field gives

$$U(g)^{-1}\widehat{\Phi}_{A_i}(f_i)U(g) = S(\Lambda)_{A_i}{}^{B_i}\widehat{\Phi}_{B_i}((f_i)_g).$$

Multiplying these identities in the given operator order yields the smeared covariance formula. The point-field formula is exactly the same identity paired with tensor-product test functions.

6.3 Spacelike Separation Of Supports

Definition 6.8 (Spacelike separated supports)**.** Two subsets $K_1, K_2 \subset \mathbb{M}^D$ are spacelike separated when

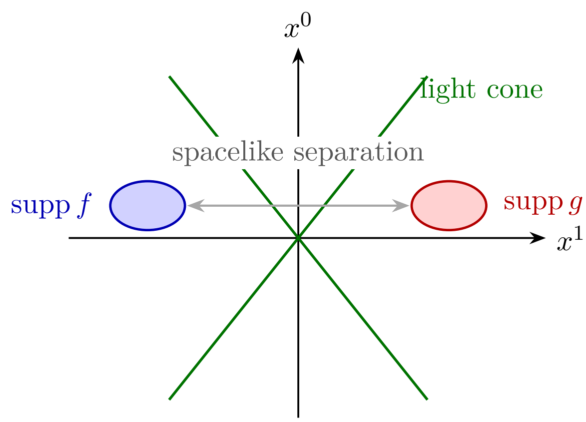
$$(x-y)^2 > 0 \qquad \text{for every } x \in K_1,\ y \in K_2.$$

Thus two test functions $f, g \in C_c^\infty(\mathbb{M}^D)$ have spacelike separated supports when $K_1 = \operatorname{supp} f$ and $K_2 = \operatorname{supp} g$ satisfy this condition.

Poincare invariance of spacelike support separation. Let $g = (a, \Lambda) \in \mathcal{P}_+^\uparrow$. If $K_1, K_2 \subset \mathbb{M}^D$ are spacelike separated, then gK_1 and gK_2 are spacelike separated: for $x \in K_1$ and $y \in K_2$,

$$(gx - gy)^2 = (\Lambda(x-y))^2 = (x-y)^2 > 0,$$

because translations cancel in differences and Λ preserves the Minkowski quadratic form. For test functions, $\operatorname{supp}(f_g) = g \operatorname{supp} f$: indeed $f_g(y) = f(g^{-1}y)$ can be nonzero only when $g^{-1}y \in \operatorname{supp} f$, equivalently $y \in g \operatorname{supp} f$, and the reverse inclusion follows after taking closures. Therefore Poincare transformation preserves spacelike separation of supports.



The figure displays one spatial dimension. The condition is the set-theoretic one written above: every pair of points, one from each support, has spacelike separation.

6.4 Microcausality

Definition 6.9 (Homogeneous parity and graded commutator)**.** Suppose the field multiplets carry a fermion parity $|\widehat{\Phi}_A| \in \{0, 1\}$. For homogeneous operators X, Y, define the graded commutator by

$$[X, Y]_{\text{gr}} = XY - (-1)^{|X||Y|} YX.$$

For bosonic fields both parities are zero, so this is the ordinary commutator.

Definition 6.10 (Microcausality for smeared fields)**.** The field multiplets satisfy microcausality on $\mathcal{D}$ when

$$[\widehat{\Phi}_A(f), \widehat{\Psi}_B(g)]_{\text{gr}} \psi = 0$$

for every $\psi \in \mathcal{D}$, whenever $\operatorname{supp} f$ and $\operatorname{supp} g$ are spacelike separated.

In point-field notation the bosonic case is written

$$[\widehat{\Phi}_A(x), \widehat{\Psi}_B(y)] = 0 \qquad (x-y)^2 > 0.$$

The smeared statement is the definition. It is the local compatibility condition for spacelike separated field insertions.

Adjacent spacelike exchange in Wightman functions. Assume microcausality in the sense of Definition 6.10. Let $\widehat{\Phi}_A$ and $\widehat{\Psi}_B$ be homogeneous fields of parities $|A|$ and $|B|$. If f and g have spacelike separated supports, then for any fields placed to the left and right whose products are defined on the common domain,

$$\begin{aligned}&\langle\Omega|\widehat{X}\,\widehat{\Phi}_A(f)\widehat{\Psi}_B(g)\,\widehat{Y}|\Omega\rangle\\ &\qquad = (-1)^{|A||B|}\langle\Omega|\widehat{X}\,\widehat{\Psi}_B(g)\widehat{\Phi}_A(f)\,\widehat{Y}|\Omega\rangle.\end{aligned}$$

Equivalently, adjacent entries of a Wightman distribution may be exchanged across a spacelike support separation with the Koszul sign $(-1)^{|A||B|}$.

Microcausality gives, on $\mathcal{D}$,

$$\widehat{\Phi}_A(f)\widehat{\Psi}_B(g) - (-1)^{|A||B|}\widehat{\Psi}_B(g)\widehat{\Phi}_A(f) = 0.$$

Let $\widehat{Y}|\Omega\rangle \in \mathcal{D}$; this is part of the common-domain assumption for finite products of smeared fields. Applying the displayed operator identity to this vector and then pairing with $\langle\Omega|\widehat{X}$ gives the stated matrix-element identity. Since Wightman distributions are the continuous multilinear extensions of these smeared matrix elements, the same exchange relation is their distributional support-separated boundary value.

6.5 Field Coordinates And Local Algebras

Definition 6.11 (Local polynomial field algebra on a common domain)**.** For a bounded open region $\mathcal{O}$, let

$$\mathcal{P}(\mathcal{O})$$

denote the polynomial $*$-algebra on $\mathcal{D}$ generated by finite sums and products of smeared fields $\widehat{\Phi}_A(f)$ with $\operatorname{supp} f \subset \mathcal{O}$, together with their adjoints when the adjoints preserve the chosen domain. This algebra records local unbounded field coordinates.

Isotony and graded locality for polynomial field algebras. If $\mathcal{O}_1 \subset \mathcal{O}_2$, then $\mathcal{P}(\mathcal{O}_1) \subset \mathcal{P}(\mathcal{O}_2)$. If $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated and the fields satisfy Definition 6.10, then homogeneous monomials $X \in \mathcal{P}(\mathcal{O}_1)$ and $Y \in \mathcal{P}(\mathcal{O}_2)$ satisfy

$$XY = (-1)^{|X||Y|}YX$$

on the common invariant domain, after expanding X and Y into ordered products of homogeneous smeared fields. The isotony statement follows directly from support inclusion: every test function supported in $\mathcal{O}_1$ is also supported in $\mathcal{O}_2$. For locality, every generating smeared field from $\mathcal{P}(\mathcal{O}_1)$ has spacelike separated support from every generating smeared field from $\mathcal{P}(\mathcal{O}_2)$. Microcausality therefore permits each generator in X to be moved past each generator in Y. Each exchange of homogeneous factors contributes the sign $(-1)^{|A||B|}$. Multiplying these signs over all crossings gives the total Koszul sign $(-1)^{|X||Y|}$, where $|X|$ and $|Y|$ are the sums of the parities of their constituent fields modulo 2.

The observable algebra $\mathcal{A}(\mathcal{O}) \subset \mathcal{B}(\mathcal{H})$ is the bounded local algebra used in the opening framework. The relation between $\mathcal{P}(\mathcal{O})$ and $\mathcal{A}(\mathcal{O})$ depends on the analytic framework. For free scalar fields, Weyl operators are bounded functions of smeared fields and generate a local algebra. In Wightman language one works directly with operator-valued distributions on a common domain. In algebraic language one may take the bounded local net as primary and use fields as coordinates, charged fields, or affiliated unbounded operators when available. The precise comparison is the Wightman-to-net datum of Definition 3.12, strengthened to a complete observable coordinatization by Definition 3.13 when the generated bounded coordinate net is identified with the represented observable net. Thus a statement about polynomial fields, a statement about bounded functional calculus, and a statement about the neutral observable net are separate pieces of structure unless a construction proves that they coincide.

The monograph will use whichever of these frameworks is required by the construction at hand, with the framework declared before theorem-level claims are made.

6.6 Wightman Functions

Definition 6.12 (Wightman distribution of a field multiplet)**.** Let $\widehat{\Phi}_{A_1}, \ldots, \widehat{\Phi}_{A_n}$ be fields whose products on the vacuum vector are defined on the common domain. The n-point Wightman distribution is the multilinear functional

$$W_{A_1 \cdots A_n}(f_1, \ldots, f_n) = \langle \Omega | \widehat{\Phi}_{A_1}(f_1) \cdots \widehat{\Phi}_{A_n}(f_n) | \Omega \rangle.$$

Point notation writes this distribution as

$$W_{A_1 \cdots A_n}(x_1, \ldots, x_n) = \langle \Omega | \widehat{\Phi}_{A_1}(x_1) \cdots \widehat{\Phi}_{A_n}(x_n) | \Omega \rangle.$$

Field axioms inherited by Wightman distributions. Assume the common-domain and continuity hypotheses of Remark 6.4. If the vacuum is Poincare invariant and the field multiplet is covariant, inserting $U(g)U(g)^{-1}$ between neighboring smeared factors and using vacuum invariance gives the covariance law displayed in the covariance paragraph above. If the field multiplet satisfies microcausality, applying the vanishing graded commutator to adjacent factors with spacelike separated supports gives the graded exchange relation displayed above. The continuity of the smeared matrix elements then extends these identities from tensor products of test functions to the corresponding Wightman distributions.

Poincare covariance of the fields gives covariance of the Wightman distributions. Microcausality gives graded exchange relations when adjacent insertions have spacelike separated supports. The spectrum condition will give the analytic and spectral properties used in the Källén–Lehmann representation.

6.7 Position In The Construction

The data introduced in this chapter are local field data: test functions, smeared operators, covariance, and microcausality. They prepare the next stage, where Lagrangian and path-integral methods are introduced first as constructions of Green functions. Spectral representation will then connect two-point functions to particle content before scattering theory is defined.

Chapter 7

Hamiltonian Evolution and Time-Sliced Path Integrals

Conventions in this chapter.

- **Signature.** real time; no spacetime metric unless a field-theory example is explicitly introduced.
- **Metric sign.** field-theory examples use $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ when a vacuum vector is present.
- **Generator convention.** time evolution is $\exp(-\mathrm{i}Ht)$, and spacetime translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$ when introduced.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

7.1 Classical Lagrangian and Hamiltonian Data

Definition 7.1 (Regular classical Lagrangian datum)**.** Let Q be a smooth d-dimensional configuration manifold. Local coordinates on Q are denoted by q^a, $a = 1, \ldots, d$. A tangent vector is written $(q, \dot{q}) \in TQ$, and a cotangent vector is written $(q, p) \in T^*Q$, with $p = p_a \, \mathrm{d}q^a$. A classical Lagrangian is a function

$$L : TQ \to \mathbb{R}.$$

For a path $q : [t_i, t_f] \to Q$, the action is

$$S[q] = \int_{t_i}^{t_f} L(q(t), \dot{q}(t)) \, \mathrm{d}t.$$

The variational principle with fixed endpoints gives the Euler–Lagrange equations

$$\frac{\mathrm{d}}{\mathrm{d}t} \frac{\partial L}{\partial \dot{q}^a} = \frac{\partial L}{\partial q^a}.$$

Thus a Lagrangian description uses the pair $(q, \dot{q})$ as local Cauchy data for the classical second-order equation.

Assume now that the fiber derivative of L,

$$(q, \dot{q}) \longmapsto \left(q, p_a = \frac{\partial L}{\partial \dot{q}^a} \right),$$

is invertible on the region under consideration. The Hamiltonian associated to this regular Lagrangian is the Legendre transform

$$H(q, p) = p_a \dot{q}^a - L(q, \dot{q}) \quad \text{with } \dot{q} = \dot{q}(q, p).$$

The canonical Poisson bracket on T^*Q is

$$\{f, g\}_{\mathrm{P}} = \frac{\partial f}{\partial q^a} \frac{\partial g}{\partial p_a} - \frac{\partial f}{\partial p_a} \frac{\partial g}{\partial q^a},$$

where repeated indices are summed. Hamiltonian time evolution is

$$\dot{f} = \{f, H\}_{\mathrm{P}},$$

and, in particular,

$$\dot{q}^a = \frac{\partial H}{\partial p_a}, \qquad \dot{p}_a = -\frac{\partial H}{\partial q^a}.$$

The Lagrangian and Hamiltonian descriptions are equivalent only after the regularity hypothesis above has been imposed; without it, constraints must be included as part of the classical data.

7.2 Canonical Quantum-Mechanical Data

Definition 7.2 (Schrodinger representation datum)**.** Let d be the number of degrees of freedom and let $\mathcal{Q} = \mathbb{R}^d$ be the configuration space. The Hilbert space is

$$\mathcal{H}_{\mathcal{Q}} = L^2(\mathcal{Q}, \mathrm{d}^d q).$$

The coordinate operators $\widehat{q}^a$, $a = 1, \ldots, d$, act by multiplication. The momentum operators are

$$\widehat{p}_a = -\mathrm{i}\hbar \frac{\partial}{\partial q^a}$$

first on the common invariant test domain $\mathcal{S}(\mathbb{R}^d) \subset \mathcal{H}_{\mathcal{Q}}$, and satisfy

$$[\widehat{q}^a, \widehat{p}_b] = \mathrm{i}\hbar\, \delta^a_b.$$

Closures or self-adjoint extensions are specified when a Hamiltonian is chosen. The Schwartz-domain convention is enough for the distributional kernel manipulations below; the operator limit is then stated at the Hilbert-space level.

Let $\widehat{H}$ be a self-adjoint Hamiltonian on $\mathcal{H}_{\mathcal{Q}}$. This is an analytic hypothesis on the chosen Hilbert-space realization of the formal classical Hamiltonian. By Stone's theorem, self-adjointness of $\widehat{H}$ is exactly the condition that the following formula defines a strongly continuous unitary one-parameter group with generator $-\mathrm{i}\widehat{H}/\hbar$. The time-evolution operator over time $T \in \mathbb{R}$ is

$$U(T) = \exp\left(-\frac{\mathrm{i}}{\hbar} T \widehat{H} \right).$$

In the Schrödinger picture, a vector evolves as

$$|\psi\rangle \longmapsto U(t)|\psi\rangle.$$

In the Heisenberg picture, an operator $\widehat{O}$ evolves as

$$\widehat{O}(t) = U(t)^{-1}\widehat{O}\,U(t), \qquad \frac{\mathrm{d}}{\mathrm{d}t}\widehat{O}(t) = \frac{\mathrm{i}}{\hbar}[\widehat{H}, \widehat{O}(t)]$$

on vectors for which the commutator expression is defined. The path integral constructed below gives a regulated representation of matrix elements of this Hamiltonian time evolution.

Definition 7.3 (Position-momentum rigging and kernel notation)**.** The position and momentum generalized eigenstates are denoted by $|q\rangle$ and $|p\rangle$. They are elements of $\mathcal{S}'(\mathbb{R}^d)$ in the rigged Hilbert space

$$\mathcal{S}(\mathbb{R}^d) \subset L^2(\mathbb{R}^d, \mathrm{d}^d q) \subset \mathcal{S}'(\mathbb{R}^d),$$

with the $\hbar$-dependent Fourier convention

$$\widetilde{\psi}(p) = \int_{\mathbb{R}^d} \mathrm{d}^d q\, \mathrm{e}^{-\frac{\mathrm{i}}{\hbar}p_a q^a}\psi(q).$$

They are normalized by

$$\langle q \mid p\rangle = \mathrm{e}^{\frac{\mathrm{i}}{\hbar}p_a q^a},$$

and used through the resolutions

$$\int_{\mathbb{R}^d} \mathrm{d}^d q\, |q\rangle\langle q| = 1, \qquad \int_{\mathbb{R}^d} \frac{\mathrm{d}^d p}{(2\pi\hbar)^d}\, |p\rangle\langle p| = 1.$$

These are weak identities: after inserting test vectors on the left and right they become the ordinary Fourier inversion formula. The transition amplitude is the distributional kernel

$$K(q_f, T; q_i, 0) = \langle q_f|U(T)|q_i\rangle.$$

The continuum Lagrangian path-integral notation for this same kernel is

$$\langle q_f|U(T)|q_i\rangle = \int_{q(0)=q_i}^{q(T)=q_f} [Dq]\, \exp\left(\frac{\mathrm{i}}{\hbar}S[q]\right).$$

This displayed equation is a compact name for the regulated construction below. The bracketed symbols $[Dq]$ and, in phase-space formulas, $[Dp]$ are determined by the regulator, limiting procedure, operator symbol, and boundary conditions; at fixed regulator the object is a finite-dimensional oscillatory integral. Unbracketed products such as $\mathrm{d}^d q_n$ and $\mathrm{d}^d p_n$ are reserved for the finite-dimensional measures that define the regulated expression.

7.3 Finite Time Slicing

Finite phase-space time-sliced construction. Fix the data of Definition 7.3 and an operator symbol $h(q,p)$ for $\widehat{H}$ in a specified ordering convention. The finite-N phase-space expression K_N is the regulated oscillatory integral obtained by inserting position and momentum resolutions in the product formula for $U(T)$. The theorem-level analytic input enters later, through the operator convergence theorem for the limiting procedure. We record the construction explicitly. Choose an integer $N \geq 1$, set $\epsilon = T/N$, and define

$$t_n = n\epsilon, \qquad n = 0, \ldots, N,$$

with $q_0 = q_i$ and $q_N = q_f$. Inserting $N-1$ position resolutions and

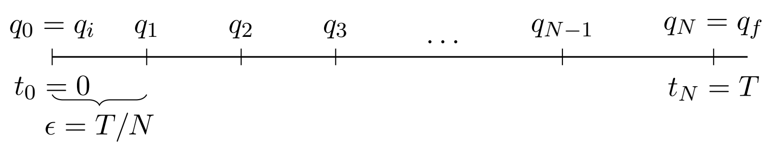
$$U(T) = \left[\exp\left(-\frac{\mathrm{i}}{\hbar}\epsilon\widehat{H}\right)\right]^N$$

gives first the position-space finite product

$$K(q_f, T; q_i, 0) = \int \prod_{n=1}^{N-1} \mathrm{d}^d q_n \prod_{n=0}^{N-1} \langle q_{n+1}| \exp\left(-\frac{\mathrm{i}}{\hbar}\epsilon\widehat{H}\right) |q_n\rangle.$$

Inserting N momentum resolutions gives

$$\begin{aligned} K(q_f, T; q_i, 0) = \int \prod_{n=1}^{N-1} \mathrm{d}^d q_n \prod_{n=0}^{N-1} \frac{\mathrm{d}^d p_n}{(2\pi\hbar)^d} \\ \times \prod_{n=0}^{N-1} \langle q_{n+1}|p_n\rangle\langle p_n| \exp\left(-\frac{\mathrm{i}}{\hbar}\epsilon\widehat{H}\right) |q_n\rangle. \end{aligned}$$



Suppose a symbol $h(q,p)$ for $\widehat{H}$ has been fixed by an operator ordering convention, for example by

$$\langle p|\widehat{H}|q\rangle = h(q,p)\langle p \mid q\rangle$$

on the chosen domain. Replacing each short-time matrix element by the first terms of its symbol expansion gives

$$\langle q_{n+1}|p_n\rangle\langle p_n|\mathrm{e}^{-\mathrm{i}\epsilon\widehat{H}/\hbar}|q_n\rangle = \exp\left[\frac{\mathrm{i}}{\hbar}\left(p_{n,a}(q^a_{n+1} - q^a_n) - \epsilon h(q_n, p_n) + O(\epsilon^2) + O(\hbar\epsilon)\right)\right]$$

for this convention, with the error understood in the regulated operator-symbol expansion rather than as a pointwise statement about an undefined continuum integral. The associated finite-N phase-space approximant is

$$K_N(q_f, T; q_i, 0) = \int \prod_{n=1}^{N-1} \mathrm{d}^d q_n \prod_{n=0}^{N-1} \frac{\mathrm{d}^d p_n}{(2\pi\hbar)^d} \exp\left(\frac{\mathrm{i}}{\hbar} S_N[p,q]\right),$$

where the discrete phase-space action is

$$S_N[p,q] = \sum_{n=0}^{N-1} \left[p_{n,a}(q^a_{n+1} - q^a_n) - \epsilon\, h(q_n, p_n)\right].$$

The continuum notation

$$\int [Dq]\,[Dp]\,\exp\left[\frac{\mathrm{i}}{\hbar}\int_0^T \big(p_a\dot q^a - h(q,p)\big)\mathrm{d}t\right]$$

denotes this regulated construction together with the specified limiting procedure. In the present chapter, the finite-N expression is the defined object.

7.4 Trotter Limits, Wiener Measure, and Kernel Convergence

Theorem 7.4 (Trotter product formula in the form used here)**.** *The passage from the finite product to a continuum path integral is a convergence statement about operators before it is a statement about kernels. Let $\widehat{A}$ and $\widehat{B}$ be self-adjoint operators on $\mathcal{H}_Q$. For the real-time statement, assume that* $\operatorname{Dom}\widehat{A}\cap\operatorname{Dom}\widehat{B}$ *is dense and that the algebraic sum*

$$\widehat{A}+\widehat{B}$$

on this domain is essentially self-adjoint, with self-adjoint closure $\widehat{H}$. Then

$$\exp\left(-\frac{\mathrm{i}T}{\hbar}\widehat{H}\right) = \operatorname*{s-lim}_{N\to\infty}\left[\exp\left(-\frac{\mathrm{i}\epsilon}{\hbar}\widehat{A}\right)\exp\left(-\frac{\mathrm{i}\epsilon}{\hbar}\widehat{B}\right)\right]^N, \qquad \epsilon=\frac{T}{N},$$

where the limit is in the strong operator topology on $\mathcal{H}_Q$. For the Euclidean statement, assume instead that $\widehat{A}$ and $\widehat{B}$ are lower-semibounded and that their closed quadratic forms $\mathfrak{a}$ and $\mathfrak{b}$ have dense common form domain

$$\mathcal{Q}_{\mathfrak{h}} = \operatorname{Dom}\mathfrak{a}\cap\operatorname{Dom}\mathfrak{b},$$

with $\mathfrak{h}=\mathfrak{a}+\mathfrak{b}$ closed and lower-semibounded on $\mathcal{Q}_{\mathfrak{h}}$. If $\widehat{H}=\widehat{A}\dotplus\widehat{B}$ is the self-adjoint form sum associated to $\mathfrak{h}$, then

$$\exp\left(-\frac{\tau}{\hbar}\widehat{H}\right) = \operatorname*{s-lim}_{N\to\infty}\left[\exp\left(-\frac{\delta}{\hbar}\widehat{A}\right)\exp\left(-\frac{\delta}{\hbar}\widehat{B}\right)\right]^N, \qquad \delta=\frac{\tau}{N},$$

again in the strong operator topology.

Proof. The product formula is a statement in $\mathcal{H}_Q$, not a pointwise identity between formal path-integral densities. In the bounded case the mechanism can be seen without domain issues. If A and B are bounded self-adjoint operators and t is fixed, Taylor expansion in operator norm gives, uniformly for $0\le\delta\le t$,

$$\mathrm{e}^{-\delta A}\mathrm{e}^{-\delta B} = 1-\delta(A+B)+O(\delta^2), \qquad \mathrm{e}^{-\delta(A+B)} = 1-\delta(A+B)+O(\delta^2).$$

Hence

$$\big\|\mathrm{e}^{-\delta A}\mathrm{e}^{-\delta B}-\mathrm{e}^{-\delta(A+B)}\big\| \le C_t\delta^2.$$

The telescoping identity

$$X^N - Y^N = \sum_{j=0}^{N-1} X^{N-1-j}(X-Y)Y^j$$

with $X = \mathrm{e}^{-tA/N}\mathrm{e}^{-tB/N}$ and $Y = \mathrm{e}^{-t(A+B)/N}$ then gives

$$\|X^N - Y^N\| \le N\,\|X - Y\| \max_{j,k\le N} \|X^j\|\,\|Y^k\| = O(N^{-1}).$$

Thus the noncommutativity of A and B first appears in terms of order δ^2, and the accumulated error over $N = t/\delta$ time slices vanishes.

For Schrödinger Hamiltonians $T + V$ the same calculation cannot be read as a proof, because T and V are unbounded and may not have a useful operator-domain intersection. The semibounded Euclidean statement is instead form-theoretic. After adding constants to make A and B nonnegative if necessary–which only multiplies the product formula by the corresponding scalar exponential factors–one starts from closed semibounded quadratic forms

$$\mathfrak{a}[\psi] = \langle A^{1/2}\psi, A^{1/2}\psi\rangle, \qquad \mathfrak{b}[\psi] = \langle B^{1/2}\psi, B^{1/2}\psi\rangle,$$

with common form domain $\operatorname{Dom}\mathfrak{a} \cap \operatorname{Dom}\mathfrak{b}$. If $\mathfrak{h} = \mathfrak{a} + \mathfrak{b}$ is closed and semibounded, the representation theorem for closed forms defines the self-adjoint form sum $H = A \dotplus B$ by

$$\mathfrak{h}(\varphi, \psi) = \langle \varphi, H\psi\rangle, \qquad \psi \in \operatorname{Dom} H, \quad \varphi \in \operatorname{Dom}\mathfrak{h}.$$

The Trotter–Kato form theorem proves that the alternating bounded contractions

$$\left(\mathrm{e}^{-tA/N}\mathrm{e}^{-tB/N}\right)^N$$

converge strongly to e^{-tH}. Its proof replaces the norm Taylor argument by resolvent and form convergence: the resolvent of H is characterized by the variational equation

$$\mathfrak{h}(\varphi, u) + \lambda\langle\varphi, u\rangle = \langle\varphi, f\rangle, \qquad \varphi \in \operatorname{Dom}\mathfrak{h},$$

and the product approximants have resolvents whose variational problems converge to this one on the common form domain. Strong resolvent convergence then gives strong semigroup convergence by the spectral theorem.

For the real-time statement, define

$$F(s) = \exp\left(-\frac{\mathrm{i}s}{\hbar}A\right)\exp\left(-\frac{\mathrm{i}s}{\hbar}B\right).$$

On the dense algebraic core $\operatorname{Dom} A \cap \operatorname{Dom} B$,

$$\lim_{s\to 0}\frac{F(s)\psi - \psi}{s} = -\frac{\mathrm{i}}{\hbar}(A + B)\psi.$$

The factors are unitary, hence $\|F(s)\| \le 1$. Chernoff's product theorem then identifies the strong limit of $F(T/N)^N$ with the unitary group whose generator is the closure of $-\mathrm{i}(A+B)/\hbar$, namely $\exp(-\mathrm{i}TH/\hbar)$. This real-time conclusion is therefore a theorem about self-adjoint generators; it should not be inferred by simply substituting $t \mapsto it$ into an uncontrolled kernel expression. $\square$

Definition 7.5 (Kato Schrodinger Euclidean datum)**.** For Schrödinger operators the words "suppose the hypotheses hold" can be replaced by concrete analytic criteria. Work on $L^2(\mathbb{R}^d, \mathrm{d}^d q)$, let

$$\widehat{p}_a = -\mathrm{i}\hbar\partial_a, \qquad T = \frac{1}{2m}\widehat{p}^2 = -\frac{\hbar^2}{2m}\Delta,$$

and let $V(\widehat{q})$ be multiplication by a real measurable function V. For a measurable function W, define the Kato class $\mathcal{K}_d$ by

$$\lim_{t\downarrow 0}\sup_{x\in\mathbb{R}^d}\int_0^t \big(\mathrm{e}^{s\Delta}|W|\big)(x)\,\mathrm{d}s = 0,$$

where $\mathrm{e}^{s\Delta}$ is the heat semigroup on $\mathbb{R}^d$. Define the local Kato class by requiring $\chi_K W \in \mathcal{K}_d$ for every compact $K \subset \mathbb{R}^d$. A standard sufficient Euclidean hypothesis is the Kato decomposition

$$V = V_+ - V_-, \qquad V_\pm \geq 0, \qquad V_+ \in \mathcal{K}_{d,\mathrm{loc}}, \qquad V_- \in \mathcal{K}_d,$$

together with a lower bound when the literal multiplication factors $\mathrm{e}^{-\delta V/\hbar}$ are used as bounded operators. Under these hypotheses the negative part is infinitesimally form-bounded relative to the free kinetic form: for every $a > 0$ there is $b_a < \infty$ such that

$$\int_{\mathbb{R}^d} V_-(q)|\psi(q)|^2\,\mathrm{d}^d q \leq a\int_{\mathbb{R}^d}|\nabla\psi|^2\,\mathrm{d}^d q + b_a\int_{\mathbb{R}^d}|\psi(q)|^2\,\mathrm{d}^d q.$$

Therefore the KLMN theorem applies. The quadratic form

$$Q[\psi] = \frac{\hbar^2}{2m}\int_{\mathbb{R}^d}|\nabla\psi|^2\,\mathrm{d}^d q + \int_{\mathbb{R}^d} V(q)|\psi(q)|^2\,\mathrm{d}^d q$$

on $H^1(\mathbb{R}^d)\cap L^2(V_+(q)\mathrm{d}^d q)$ is closed and semibounded, and it defines the Friedrichs Hamiltonian $H = T + V$. The Euclidean semigroup has the Trotter–Kato product formula, and its kernel is represented by the Feynman–Kac construction whenever the stated Kato hypotheses hold.

Theorem 7.6 (Wiener measure and the Feynman–Kac formula)**.** *Let $V : \mathbb{R}^d \to \mathbb{R}$ be real, locally Kato, and bounded from below. Let H be the Friedrichs Hamiltonian associated to*

$$Q[\psi] = \frac{\hbar^2}{2m}\int_{\mathbb{R}^d}|\nabla\psi|^2\,\mathrm{d}^d q + \int_{\mathbb{R}^d} V(q)|\psi(q)|^2\,\mathrm{d}^d q.$$

For each $x \in \mathbb{R}^d$ and $\tau > 0$, there is a countably additive probability measure $\mathbb{W}_x^\tau$ on

$$C([0,\tau],\mathbb{R}^d)$$

whose finite-dimensional distributions are

$$\begin{aligned}&\int F(\omega(t_1),\dots,\omega(t_n))\,\mathrm{d}\mathbb{W}_x^\tau(\omega)\\ &\quad= \int_{\mathbb{R}^{dn}} F(x_1,\dots,x_n)\prod_{j=1}^n k^0_{t_j - t_{j-1}}(x_{j-1},x_j)\,\mathrm{d}^d x_1\cdots\mathrm{d}^d x_n,\end{aligned}$$

for $0 < t_1 < \cdots < t_n \leq \tau$, with $t_0 = 0$, $x_0 = x$, and

$$k_s^0(x,y) = \Big(\frac{m}{2\pi\hbar s}\Big)^{d/2}\exp\left[-\frac{m|x-y|^2}{2\hbar s}\right].$$

This is Wiener measure with diffusion constant $\hbar/m$. For bounded Borel f, and then by extension for $f \in L^2(\mathbb{R}^d)$,

$$\big(\mathrm{e}^{-\tau H/\hbar}f\big)(x) = \int_{C([0,\tau],\mathbb{R}^d)}\exp\left[-\frac{1}{\hbar}\int_0^\tau V(\omega(s))\,\mathrm{d}s\right] f(\omega(\tau))\,\mathrm{d}\mathbb{W}_x^\tau(\omega)$$

for almost every x. Disintegrating $\mathbb{W}_x^\tau$ with respect to the endpoint $\omega(\tau) = y$ gives the Brownian-bridge probability measure $\mathbb{W}_{x,y}^\tau$, and the Euclidean transition kernel is

$$K_E(y, \tau; x, 0) = k_\tau^0(x, y) \int \exp\left[-\frac{1}{\hbar}\int_0^\tau V(\omega(s))\,\mathrm{d}s\right] \mathrm{d}\mathbb{W}_{x,y}^\tau(\omega).$$

Proof. The functions $k_s^0(x, y)$ are nonnegative, integrate to one in y, and satisfy the convolution identity

$$\int_{\mathbb{R}^d} k_s^0(x, z) k_t^0(z, y)\,\mathrm{d}^d z = k_{s+t}^0(x, y).$$

The displayed finite-dimensional distributions are therefore consistent. Kolmogorov extension gives a probability measure on paths with values in $(\mathbb{R}^d)^{[0,\tau]}$. The Gaussian increment moments obey

$$\mathbb{E}_{\mathbb{W}_x^\tau}|\omega(t) - \omega(s)|^{2r} = C_{d,r}\left(\frac{\hbar}{m}|t - s|\right)^r,$$

and Kolmogorov's continuity criterion gives a version supported on continuous paths. This proves the existence of the Wiener measure on $C([0, \tau], \mathbb{R}^d)$.

First assume that V is bounded and continuous. Let M_g denote multiplication by g, and let

$$L = \frac{\hbar}{2m}\Delta.$$

The heat semigroup e^{sL} has kernel k_s^0. Iterating the Markov property gives

$$\begin{aligned}&\left(\mathrm{e}^{\delta L} M_{\exp(-\delta V/\hbar)}\right)^N f(x)\\ &\quad = \mathbb{E}_x\left[\exp\left(-\frac{\delta}{\hbar}\sum_{j=1}^N V(B_{j\delta})\right) f(B_{N\delta})\right],\end{aligned}$$

where B is the coordinate process under $\mathbb{W}_x^\tau$ and $\delta = \tau/N$. Since Brownian paths are continuous and V is bounded continuous, the Riemann sums converge almost surely to $\int_0^\tau V(B_s)\,\mathrm{d}s$, and dominated convergence gives the Wiener expectation. The Trotter product formula identifies the same operator limit with $\mathrm{e}^{-\tau H/\hbar}$, because

$$-\frac{H}{\hbar} = L - \frac{1}{\hbar}V$$

as a form sum.

If V is continuous and bounded below, add a constant so that $V \geq 0$, prove the formula for $V_M = \min(V, M)$, and then let $M \to \infty$. The path weights decrease pointwise to the displayed weight, and the quadratic forms for $T + V_M$ increase to the quadratic form for $T + V$; monotone convergence of closed forms gives strong convergence of the semigroups. The locally Kato bounded-below case is obtained by approximating in the local Kato topology and using the Kato small-time estimate for the negative part. Finally, the bridge formula is the conditional-distribution form of the preceding identity with respect to the endpoint density $k_\tau^0(x, y)$. □

Thus in ordinary Euclidean quantum mechanics the continuum path integral is a genuine Wiener expectation on continuous paths, multiplied by the potential weight, under the hypotheses of Theorem 7.6. The time-sliced Lebesgue products are the approximating construction that converges to this measure-theoretic object. The Trotter product formula is still important, but its role is to identify the operator semigroup represented by the Wiener integral; it is weaker than, and should not be substituted for, the measure-level Feynman–Kac statement. This theorem governs bosonic Schrödinger quantum mechanics, and by extension supplies an important model for constructive scalar field theories when a positive Euclidean measure exists. The general path-integral framework is a typed assignment of mathematical objects by a regulator and limiting prescription. Fermionic fields use Berezin integration over Grassmann variables rather than countably additive Borel measures; gauge theories require quotient, gauge-fixing, BRST/BV, or lattice data in addition to any measure on fields; and topological terms such as a four-dimensional Yang–Mills θ-angle generally make the Euclidean weight complex. Every use of path-integral notation must therefore state the mathematical object being used: a measure, an oscillatory integral, a Berezin functional, a gauge-fixed/BV construction, a lattice regularization, a holonomy construction, or a formal perturbative expansion.

Theorem 7.7 (Faris–Lavine criterion)**.** *Essential self-adjointness on the algebraic core $C_c^\infty(\mathbb{R}^d)$ is a separate issue. One convenient sufficient theorem is the Faris–Lavine criterion, often cited as Reed–Simon Theorem X.41: if V is real, C^∞, and satisfies*

$$V(q) \geq -C(1+|q|^2)$$

for some $C < \infty$, then $-\Delta + V$ is essentially self-adjoint on $C_c^\infty(\mathbb{R}^d)$. Every smooth potential bounded below satisfies this growth-from-below hypothesis, and polynomial oscillator potentials with positive leading part do as well. These cases have a unique self-adjoint closure from the natural differential operator core, and the Trotter formula applies to that closure.

Proof. The criterion is a statement about the closure of a symmetric differential operator determined on the algebraic core $C_c^\infty(\mathbb{R}^d)$. Write $p_j = -\mathrm{i}\partial_j$, $p^2 = -\Delta$, and first reduce by rescaling and adding a constant to the model lower bound

$$V(x) \geq -|x|^2.$$

Let

$$A_0 = p^2 + V(x), \qquad N_0 = p^2 + V(x) + 2|x|^2$$

on $C_c^\infty(\mathbb{R}^d)$. Since $V+2|x|^2 \geq |x|^2 \geq 0$, the Kato theorem for nonnegative locally square-integrable potentials gives a positive self-adjoint closure N of N_0. The comparison with N is the point of the proof. On $C_c^\infty(\mathbb{R}^d)$,

$$N_0 - A_0 = 2|x|^2 \geq 0, \qquad N_0 + A_0 = 2p^2 + 2(V+|x|^2) \geq 0$$

as quadratic forms, hence

$$-N_0 \leq A_0 \leq N_0$$

in form order. The oscillator estimate, obtained by integration by parts from $p^2 + |x|^2$,

$$\||x|^2\psi\| \leq C\big(\|N_0\psi\| + \|\psi\|\big), \qquad \psi \in C_c^\infty(\mathbb{R}^d),$$

then implies that the N-graph norm controls A_0. Thus A_0 extends continuously from the N-graph domain, and one may apply Nelson's commutator theorem with comparison operator N.

It remains to check the commutator bound required by that theorem. The only noncommuting part is the added oscillator term:

$$\mathrm{i}[N_0, A_0] = \mathrm{i}[2|x|^2, p^2].$$

Using $[x_j, p_k] = \mathrm{i}\delta_{jk}$, one obtains, on the common algebraic core,

$$\mathrm{i}[N_0, A_0] = -4\sum_{j=1}^{d}(x_j p_j + p_j x_j).$$

The form bound follows from completing the square:

$$(p_j \pm x_j)^*(p_j \pm x_j) = p_j^2 + x_j^2 \pm (p_j x_j + x_j p_j) \geq 0,$$

and therefore

$$\pm\sum_{j=1}^{d}(x_j p_j + p_j x_j) \leq p^2 + |x|^2 \leq N_0$$

as quadratic forms. Hence

$$\big|\langle\psi, \mathrm{i}[N_0, A_0]\psi\rangle\big| \leq 4\,\langle\psi, N_0\psi\rangle.$$

Nelson's theorem says that a symmetric operator A_0 controlled in graph norm by a positive self-adjoint N, with the commutator bounded by $\langle\psi, N\psi\rangle$, is essentially self-adjoint on every N-core contained in its domain. Its proof uses the bounded regularized operators

$$A_\epsilon = (1 + \epsilon N)^{-1} A_0 (1 + \epsilon N)^{-1}$$

and the commutator inequality to obtain a uniform Gronwall bound on the $N^{1/2}$-energy of $\mathrm{e}^{\mathrm{i}tA_\epsilon}\psi$; after passing $\epsilon \downarrow 0$, the deficiency equations $(A_0^* \mp \mathrm{i})\eta = 0$ admit no nonzero L^2 solutions. This is the operator-theoretic reason that the quadratic lower bound prevents a boundary condition at infinity from being part of the Hamiltonian data. □

Example 7.8 (A limit-circle failure of formal Hamiltonian data)**.** The lower-growth hypothesis in the Faris–Lavine criterion is substantive. In one dimension, the symmetric differential operator

$$-\frac{\mathrm{d}^2}{\mathrm{d}q^2} + q^3$$

on $\mathcal{S}(\mathbb{R})$ is a concrete failure mode. At $q \to -\infty$, the deficiency equations

$$\left(-\frac{\mathrm{d}^2}{\mathrm{d}q^2} + q^3\right)\psi_\pm = \pm\mathrm{i}\,\psi_\pm$$

have two local solutions whose standard Liouville–Green asymptotics have leading behavior

$$\psi_\pm(q) \sim |q|^{-3/4}\exp\left(\pm\mathrm{i}\,\frac{2}{5}|q|^{5/2}\right).$$

Both branches are square-integrable at that end because the squared amplitude is asymptotic to $|q|^{-3/2}$ and $\int^\infty r^{-3/2}\mathrm{d}r < \infty$. By the Weyl limit-point/limit-circle classification theorem for one-dimensional Sturm–Liouville operators, this places the endpoint $q = -\infty$ in the limit-circle case. The symmetric operator is therefore not essentially self-adjoint on the Schwartz core: a self-adjoint Hamiltonian requires an additional boundary condition at this singular endpoint at infinity, and different self-adjoint extensions give different unitary groups. Thus the formal expression $\widehat{p}^2/2m + V(\widehat{q})$ does not by itself define the operator appearing in $\exp(-\mathrm{i}T\widehat{H}/\hbar)$.

For the standard Hamiltonian

$$\widehat{H} = \frac{1}{2m}\widehat{p}^2 + V(\widehat{q}),$$

the product formula says that the operator obtained by alternating free propagation and multiplication by the potential converges to the exact evolution operator. Inserting position resolutions between the factors gives a finite-dimensional integral at each N. Thus the time-sliced path integral is a representation of a product formula.

The distributional kernel

$$\langle q_f | \exp\left(-\frac{\mathrm{i}T}{\hbar}\widehat{H}\right) |q_i\rangle$$

requires an additional topology. The useful topologies include convergence after smearing q_i and q_f with test functions, convergence after analytic continuation to Euclidean time, and pointwise kernel convergence under stronger regularity assumptions on V. Therefore the continuum path-integral notation in this monograph always carries one of the following meanings: a finite regulator, a strong operator limit, a smeared distributional limit, a Euclidean measure or semigroup construction, or a perturbative asymptotic expansion.

7.5 Operator Ordering and Local Counterterms

Definition 7.9 (Regulated phase-space path-integral datum)**.** The function $h(q,p)$ depends on the ordering convention used to represent $\widehat{H}$. For example, using left endpoints q_n in the short-time matrix element and using right endpoints q_{n+1} define different symbols for the same operator. Their difference is of order $\hbar$ in the continuum action and appears as a local counterterm in the time-sliced description.

At fixed N, two representative choices are

$$\cdots\langle q_{n+1}|p_n\rangle\langle p_n|\mathrm{e}^{-\mathrm{i}\epsilon\widehat{H}/\hbar}|q_n\rangle\cdots, \qquad \langle p_n|\widehat{H}|q_n\rangle = h(q_n,p_n)\langle p_n \mid q_n\rangle,$$

and

$$\cdots\langle p_{n+1}|q_{n+1}\rangle\langle q_{n+1}|\mathrm{e}^{-\mathrm{i}\epsilon\widehat{H}/\hbar}|p_n\rangle\cdots, \qquad \langle q_n|\widehat{H}|p_n\rangle = h'(q_n,p_n)\langle q_n \mid p_n\rangle.$$

They discretize the kinetic term respectively as

$$\sum_{n=0}^{N-1} p_{n,a}(q^a_{n+1} - q^a_n), \qquad \sum_{n=0}^{N-1} p_{n+1,a}(q^a_{n+1} - q^a_n),$$

after relabelling endpoints where necessary. The two symbols h and h' represent the same operator only with their specified ordering conventions, and they can differ by terms of order $\hbar$. Such terms survive in the exponent as local regulator-dependent additions to the effective Lagrangian.

Thus the data of the regulated path integral are

$$(\text{partition},\ \text{measure},\ \text{operator symbol},\ \text{boundary conditions}).$$

A formula involving $[Dq]\,[Dp]$ is meaningful as notation for a regulated construction once these data have been declared.

7.6 Lagrangian Form for Quadratic Momentum Dependence

Gaussian elimination of quadratic momenta. Assume the Hamiltonian symbol has the form

$$h(q,p) = \frac{1}{2}\,G^{ab}(q)p_a p_b + V(q),$$

where $G^{ab}(q)$ is a positive-definite symmetric matrix and

$$G^{ab}(q)G_{bc}(q) = \delta^a_c.$$

At fixed time slice, the momentum integral is Gaussian:

$$\int \frac{\mathrm{d}^d p}{(2\pi\hbar)^d} \exp\left[\frac{\mathrm{i}}{\hbar}\left(p_a\Delta q^a - \frac{\epsilon}{2}G^{ab}(q)p_a p_b\right)\right] = \frac{\sqrt{\det G_{ab}(q)}}{(2\pi\mathrm{i}\hbar\epsilon)^{d/2}} \exp\left[\frac{\mathrm{i}\epsilon}{\hbar}\frac{1}{2}G_{ab}(q)v^a v^b\right],$$

where

$$\Delta q^a = q^a_{n+1} - q^a_n, \qquad v^a = \frac{\Delta q^a}{\epsilon}.$$

The Lagrangian function obtained by Legendre transform is

$$L(q,\dot{q}) = \frac{1}{2}G_{ab}(q)\dot{q}^a\dot{q}^b - V(q).$$

Conversely, if a classical Lagrangian in generalized coordinates has this metric form, as in the rigid-body configuration space example, then the corresponding quantum Hamiltonian symbol is

$$h(q,p) = \frac{1}{2}G^{ab}(q)p_a p_b + V(q) + O(\hbar)$$

until an ordering convention and measure convention have been fixed. The $O(\hbar)$ term records the same local regulator dependence described above. The finite-N configuration-space expression is therefore

$$\begin{aligned} K_N(q_f,T;q_i,0) = \int \prod_{n=1}^{N-1} \mathrm{d}^d q_n \prod_{n=0}^{N-1} \frac{\sqrt{\det G_{ab}(q_n)}}{(2\pi\mathrm{i}\hbar\epsilon)^{d/2}} \\ \times \exp\left[\frac{\mathrm{i}}{\hbar}\sum_{n=0}^{N-1} \epsilon\, L\left(q_n, \frac{q_{n+1}-q_n}{\epsilon}\right)\right]. \end{aligned}$$

For $G_{ab} = m\delta_{ab}$, the Lagrangian in this finite-dimensional time-sliced kernel is

$$L(q,\dot{q}) = \frac{m}{2}\delta_{ab}\dot{q}^a\dot{q}^b - V(q).$$

The calculation is the following finite-dimensional Gaussian completion. At fixed q_n, one rewrites the exponent as

$$p_a\Delta q^a - \frac{\epsilon}{2}G^{ab}p_a p_b = -\frac{\epsilon}{2}G^{ab}\left(p_a - \frac{1}{\epsilon}G_{ac}\Delta q^c\right)\left(p_b - \frac{1}{\epsilon}G_{bd}\Delta q^d\right) + \frac{1}{2\epsilon}G_{ab}\Delta q^a\Delta q^b.$$

The oscillatory Gaussian determinant gives $\sqrt{\det G_{ab}}(2\pi\mathrm{i}\hbar\epsilon)^{-d/2}$, and the remaining exponent is $\epsilon G_{ab}v^a v^b/2$. Multiplying over slices and including $-\epsilon V(q_n)$ gives the displayed configuration-space kernel.

7.7 Time-Ordered Insertions and Sources

Definition 7.10 (Finite-slice time-ordered insertions and source kernel)**.** Let $F(q(t_1), \ldots, q(t_r))$ be a product of coordinate insertions with

$$0 < t_1 < \cdots < t_r < T.$$

At finite N, choose the time slices nearest to the insertion times and insert the corresponding coordinate functions into the finite-dimensional integral. The resulting regulated expression represents

$$\langle q_f | T\{\widehat{q}^{a_1}(t_1) \cdots \widehat{q}^{a_r}(t_r)\} U(T) | q_i \rangle,$$

where

$$\widehat{q}^a(t) = U(t)^{-1} \widehat{q}^a U(t)$$

is the Heisenberg operator. The time ordering is inherited from the ordered product of short-time evolution operators.

For a smooth compactly supported source $J_a(t)$, define the finite-N source factor by

$$\exp\left[\frac{\mathrm{i}}{\hbar} \sum_{n=0}^{N-1} \epsilon\, J_a(t_n) q_n^a\right].$$

The source-dependent kernel $K_N[J]$ generates regulated time-ordered coordinate insertions by differentiation with respect to J. This is the finite-dimensional ancestor of QFT generating functionals for Green functions.

7.8 Euclidean Traces and Periodic Boundary Conditions

Trace and periodic Euclidean boundary conditions. Assume that $\widehat{H}$ is semibounded and that $\mathrm{e}^{-\beta_{\mathrm{T}} \widehat{H}/\hbar}$ is trace class for $\beta_{\mathrm{T}} > 0$. The Euclidean thermal trace is

$$Z(\beta_{\mathrm{T}}) = \mathrm{Tr}_{\mathcal{H}_Q}\, \mathrm{e}^{-\beta_{\mathrm{T}} \widehat{H}/\hbar}.$$

This trace-class hypothesis is a finite-volume or confining quantum-mechanical hypothesis. It is the correct assumption for a harmonic oscillator, for stable anharmonic oscillators with discrete spectrum growing fast enough, and for field theories after both an ultraviolet regulator and a finite spatial-volume regulator have been imposed. It is not the Hilbert-space structure of an infinite-volume translation-invariant QFT. In infinite spatial volume, translating a finite-energy local excitation through disjoint spatial regions produces the usual volume divergence; correspondingly $\mathrm{Tr}\, \mathrm{e}^{-\beta H}$ is infinite even when local thermal correlators exist.

Thermal QFT is therefore formulated by one of two equivalent local procedures. One may put the theory in a finite spatial box Λ, form

$$\rho_{\beta,\Lambda} = Z_{\beta,\Lambda}^{-1} \mathrm{e}^{-\beta H_\Lambda}, \qquad Z_{\beta,\Lambda} = \mathrm{Tr}_{\mathcal{H}_\Lambda}\, \mathrm{e}^{-\beta H_\Lambda},$$

and then take thermodynamic limits of local observables. Or one may define the infinite-volume thermal state directly as a KMS state on the quasilocal observable algebra, in the sense of Definition 4.5. Formal traces per unit volume, or traces with the translation volume divided out, compute densities rather than the literal trace over the full infinite-volume Hilbert space. For a trace-class quantum-mechanical Hamiltonian, the trace of the heat operator is obtained by integrating its diagonal position kernel:

$$Z(\beta_{\mathrm{T}}) = \int_{\mathbb{R}^d} \mathrm{d}^d q_0 \, \langle q_0 | \mathrm{e}^{-\beta_{\mathrm{T}} \widehat{H}/\hbar} | q_0 \rangle.$$

The same time-sliced construction as above, now with Euclidean time $\tau \in [0, \beta_{\mathrm{T}}]$, therefore has

$$q_N = q_0.$$

Thus the trace of a bosonic quantum-mechanical system is represented by the Euclidean path integral over periodic paths

$$q(\tau + \beta_{\mathrm{T}}) = q(\tau).$$

This conclusion is a statement about the boundary condition produced by the trace. When Theorem 7.6 applies, the corresponding continuum object is the Feynman–Kac weight integrated over Brownian loops, obtained by disintegrating Wiener measure with the endpoint constraint

$$q(\beta_{\mathrm{T}}) = q(0).$$

Outside such hypotheses, the trace path integral remains a regulated or formal expression whose convergence must be specified separately.

7.9 Vacuum Projection

Euclidean long-time projection to a gapped ground state. Assume $\widehat{H}$ has a normalized ground state $|0\rangle$, with energy E_0, and that a vector $|\psi\rangle \in \mathcal{H}_Q$ satisfies $\langle 0 \mid \psi \rangle \neq 0$. If the spectrum above E_0 is separated by a gap, then

$$\lim_{\tau \to \infty} \frac{\mathrm{e}^{-\tau(\widehat{H}-E_0)/\hbar} |\psi\rangle}{\left\| \mathrm{e}^{-\tau(\widehat{H}-E_0)/\hbar} |\psi\rangle \right\|} = |0\rangle$$

up to the phase of $\langle 0 \mid \psi \rangle$. Vacuum correlation functions can therefore be obtained from long Euclidean-time evolution:

$$\langle 0 | T\{\widehat{q}^{a_1}(t_1) \cdots \widehat{q}^{a_r}(t_r)\} | 0 \rangle$$

is the normalized long-time limit of the corresponding transition amplitude with insertions, after the Euclidean projection has been applied. This is the elementary spectral projection mechanism behind Euclidean vacuum boundary conditions. By the spectral theorem for $\widehat{H}$, write $|\psi\rangle = c_0|0\rangle + \eta$ with $c_0 = \langle 0 \mid \psi \rangle \neq 0$ and η orthogonal to the ground-state subspace. The gap assumption gives

$$\|\mathrm{e}^{-\tau(\widehat{H}-E_0)/\hbar} \eta\| \leq \mathrm{e}^{-\tau \Delta/\hbar} \|\eta\|$$

for some $\Delta > 0$. Therefore the normalized Euclidean evolution tends to $\mathrm{e}^{\mathrm{i} \arg c_0}|0\rangle$. Applying the same spectral projection to initial and final wave packets in a transition amplitude with time-ordered insertions selects the vacuum matrix element after the common exponential normalization is removed. The substantive hypotheses are the existence of the normalized ground state, the nonzero overlap of the boundary vector with it, and the gap. Without a gap the same formula can fail in norm, and one must specify the weaker spectral or distributional limit being used.

The next chapter will analyze the analytic continuation and Gaussian integrals that make this construction computationally useful. The present chapter has introduced the regulated path-integral data and its relation to Hamiltonian time evolution.

Chapter 8

Euclidean Correlation Functions and Gaussian Perturbation Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

8.1 Spectral Correlators and Euclidean Time

Let $\widehat{H}$ be a self-adjoint Hamiltonian on a Hilbert space $\mathcal{H}$. Assume in this section that $\widehat{H}$ has a normalized ground state $|0\rangle$ with energy E_0, and that the example under discussion admits a complete orthonormal basis $\{|n\rangle\}$ of energy eigenvectors,

$$\widehat{H}|n\rangle = E_n|n\rangle, \qquad E_n \geq E_0.$$

For a self-adjoint coordinate operator $\widehat{q}$, define the real-time Heisenberg operator

$$\widehat{q}(t) = \exp\left(\frac{\mathrm{i}}{\hbar}t\widehat{H}\right)\widehat{q}\exp\left(-\frac{\mathrm{i}}{\hbar}t\widehat{H}\right), \qquad t \in \mathbb{R}.$$

The ordered two-point function with the later insertion on the left is

$$W(t) = \langle 0|\widehat{q}(t)\widehat{q}(0)|0\rangle.$$

Inserting the energy basis gives

$$\begin{aligned} W(t) &= \sum_n \langle 0|\widehat{q}(0)|n\rangle\langle n|\widehat{q}(0)|0\rangle \, \exp\left[-\frac{\mathrm{i}}{\hbar}(E_n - E_0)t\right] \\ &= \sum_n |\langle n|\widehat{q}(0)|0\rangle|^2 \exp\left[-\frac{\mathrm{i}}{\hbar}(E_n - E_0)t\right]. \end{aligned}$$

Definition 8.1 (Spectral measure of a vacuum coordinate)**.** Let $P_{\widehat{H}}$ be the projection-valued spectral measure of $\widehat{H}$. For a vector

$$\eta_q := \widehat{q}|0\rangle,$$

assumed to lie in $\mathcal{H}$, define the positive finite Borel measure

$$\mu_q(B) = \langle \eta_q, P_{\widehat{H}}(B)\eta_q\rangle$$

for Borel sets $B \subset \mathbb{R}$. Its shifted version is the pushforward of μ_q under $E \mapsto E - E_0$. This is the one-dimensional prototype of the spectral measures that appear later in the Källén–Lehmann representation.

Lemma 8.2 (Lower-half-plane continuation from the spectral theorem)**.** *With the hypotheses above, the ordered two-point function admits the spectral representation*

$$W(t) = \int_{[E_0,\infty)} \exp\left[-\frac{\mathrm{i}}{\hbar}(E - E_0)t\right] \, \mathrm{d}\mu_q(E).$$

The same formula defines a holomorphic function for $\operatorname{Im} t < 0$*. For* $\tau > 0$*, its Euclidean boundary value at* $t = -\mathrm{i}\tau$ *is the Laplace transform*

$$G_E(\tau) = \int_{[E_0,\infty)} \exp\left[-\frac{1}{\hbar}(E - E_0)\tau\right] \, \mathrm{d}\mu_q(E).$$

If the spectral measure is pure point, the integral reduces to the displayed sum over energy eigenvectors.

Proof. The spectral theorem gives

$$\mathrm{e}^{-\frac{\mathrm{i}}{\hbar}t(\widehat{H}-E_0)} = \int_{[E_0,\infty)} \mathrm{e}^{-\frac{\mathrm{i}}{\hbar}t(E-E_0)} \, \mathrm{d}P_{\widehat{H}}(E)$$

in the functional calculus. Sandwiching this identity between $\eta_q = \widehat{q}|0\rangle$ and itself gives the stated formula for real t. The support is contained in $[E_0, \infty)$ because E_0 is the bottom of the spectrum, and the total mass is $\|\widehat{q}|0\rangle\|^2$.

If $t = x + \mathrm{i}y$ with $y < 0$, then

$$\left|\mathrm{e}^{-\frac{\mathrm{i}}{\hbar}t(E-E_0)}\right| = \mathrm{e}^{\frac{1}{\hbar}y(E-E_0)} \leq 1.$$

The finite measure μ_q therefore gives a locally dominated integral. The integrand is entire as a function of t, so differentiation under the integral is justified on compact subsets of the lower half-plane by the same estimate with one additional power of $E - E_0$ after inserting a compact vertical margin $y \leq -\epsilon < 0$. Hence the integral is holomorphic there. Setting $t = -\mathrm{i}\tau$ gives the Laplace transform. In the pure-point case $\mu_q = \sum_n |\langle n|\widehat{q}|0\rangle|^2 \delta_{E_n}$, so the integral is the sum already obtained by inserting the eigenbasis. □

For $\tau > 0$, define

$$G_E(\tau) = W(-\mathrm{i}\tau) = \int_{[E_0,\infty)} \exp\left[-\frac{1}{\hbar}(E - E_0)\tau\right] \mathrm{d}\mu_q(E),$$

which in the pure-point case is

$$G_E(\tau) = \sum_n |\langle n|\widehat{q}(0)|0\rangle|^2 \exp\left[-\frac{1}{\hbar}(E_n - E_0)\tau\right].$$

Thus Euclidean time converts the spectral decomposition into a sum of decaying exponentials. The decay rates are

$$\omega_n = \frac{E_n - E_0}{\hbar}.$$

For $\tau_1, \ldots, \tau_r \in \mathbb{R}$, let T_E denote Euclidean ordering: operators with larger τ are placed to the left. The Euclidean r-point function of a single coordinate operator is

$$G_E^{(r)}(\tau_1, \ldots, \tau_r) = \langle 0|T_E\{\widehat{q}_E(\tau_1) \cdots \widehat{q}_E(\tau_r)\}|0\rangle,$$

where

$$\widehat{q}_E(\tau) = \exp\left(\frac{1}{\hbar}\tau\widehat{H}\right)\widehat{q}\exp\left(-\frac{1}{\hbar}\tau\widehat{H}\right)$$

is the analytic continuation of $\widehat{q}(t)$ to $t = -\mathrm{i}\tau$.

Definition 8.3 (Euclidean ordered source functional in quantum mechanics)**.** For a smooth compactly supported function $J(\tau)$, define the Euclidean ordered source functional

$$Z_E[J] = \langle 0|T_E \exp\left[\frac{1}{\hbar}\int_{\mathbb{R}} J(\tau)\widehat{q}_E(\tau)\,\mathrm{d}\tau\right]|0\rangle.$$

The exponential is understood by its power series in the source, with Euclidean ordering applied term by term. Its functional derivatives recover the Euclidean ordered correlation functions:

$$G_E^{(r)}(\tau_1, \ldots, \tau_r) = \hbar^r \frac{\delta}{\delta J(\tau_1)} \cdots \frac{\delta}{\delta J(\tau_r)} Z_E[J]\bigg|_{J=0}.$$

8.2 Wick Rotation of the Path Integral

Consider a Lagrangian of the form

$$L(q, \dot{q}) = \frac{1}{2}G_{ab}(q)\dot{q}^a\dot{q}^b - V(q),$$

where $G_{ab}(q)$ is positive definite. Under the analytic continuation

$$t = -\mathrm{i}\tau, \qquad \dot{q}^a = \frac{\mathrm{d}q^a}{\mathrm{d}t} = \mathrm{i}\,\frac{\mathrm{d}q^a}{\mathrm{d}\tau},$$

Definition 8.4 (Euclidean Lagrangian associated with a mechanical action)**.** For a Lorentzian mechanical Lagrangian $L(q, \dot{q})$ whose expression is analytic in $\dot{q}$ near the real axis, the Euclidean Lagrangian in the coordinate chart q^a is

$$L_E(q, q') = -L(q, \mathrm{i}q'), \qquad q'^a = \frac{\mathrm{d}q^a}{\mathrm{d}\tau}.$$

For the displayed metric kinetic energy, this gives

$$L_E(q, q') = \frac{1}{2}G_{ab}(q)q'^a q'^b + V(q).$$

Sign of the Wick-rotated weight. Under $t = -\mathrm{i}\tau$, with the orientation of the integration contour rotated accordingly, the Lorentzian phase transforms formally as

$$\exp\left[\frac{\mathrm{i}}{\hbar}\int L(q,\dot q)\,\mathrm{d}t\right] \longmapsto \exp\left[-\frac{1}{\hbar}\int L_E(q,q')\,\mathrm{d}\tau\right].$$

Indeed, along the rotated contour $\mathrm{d}t = -\mathrm{i}\,\mathrm{d}\tau$ and $\dot q = \mathrm{d}q/\mathrm{d}t = \mathrm{i}\,\mathrm{d}q/\mathrm{d}\tau = \mathrm{i}q'$. Therefore

$$\frac{\mathrm{i}}{\hbar}L(q,\dot q)\,\mathrm{d}t = \frac{\mathrm{i}}{\hbar}L(q,\mathrm{i}q')(-\mathrm{i}\,\mathrm{d}\tau) = \frac{1}{\hbar}L(q,\mathrm{i}q')\,\mathrm{d}\tau = -\frac{1}{\hbar}L_E(q,q')\,\mathrm{d}\tau.$$

Exponentiating the integrated identity gives the stated weight. This is an identity of the formal action density after choosing the contour; analytic existence of the path-integral limit is a separate assertion supplied only in the regulated cases below.

Lemma 8.5 (Euclidean long-time projection onto the vacuum)**.** *Let $|\psi\rangle \in \mathcal{H}$ satisfy $\langle 0 \mid \psi\rangle \neq 0$, and assume that the ground state is separated from the rest of the spectrum by a gap. More precisely, suppose that the spectrum of $\widehat H - E_0$ on $\{|0\rangle\}^\perp$ lies in $[\Delta,\infty)$ with $\Delta > 0$. Then*

$$\frac{\exp[-T(\widehat H - E_0)/\hbar]|\psi\rangle}{\left\|\exp[-T(\widehat H - E_0)/\hbar]|\psi\rangle\right\|} \longrightarrow \frac{\langle 0 \mid \psi\rangle}{|\langle 0 \mid \psi\rangle|}|0\rangle$$

in Hilbert norm as $T \to \infty$. Consequently Euclidean matrix elements with endpoints $|\psi\rangle$ and fixed insertions separated from the endpoints converge to vacuum Euclidean ordered correlation functions, after division by the corresponding endpoint partition function.

Proof. Write

$$|\psi\rangle = c_0|0\rangle + |\psi_\perp\rangle, \qquad c_0 = \langle 0 \mid \psi\rangle, \qquad \langle 0 \mid \psi_\perp\rangle = 0,$$

and let the spectrum of $\widehat H - E_0$ on the closed subspace

$$\{|0\rangle\}^\perp = \{\eta \in \mathcal{H} : \langle 0 \mid \eta\rangle = 0\}$$

lie in $[\Delta,\infty)$ with $\Delta > 0$. Spectral calculus gives

$$\mathrm{e}^{-T(\widehat H - E_0)/\hbar}|\psi\rangle = c_0|0\rangle + O(\mathrm{e}^{-T\Delta/\hbar})$$

in Hilbert norm. Therefore

$$\frac{\exp[-T(\widehat H - E_0)/\hbar]|\psi\rangle}{\left\|\exp[-T(\widehat H - E_0)/\hbar]|\psi\rangle\right\|} \longrightarrow \frac{c_0}{|c_0|}|0\rangle$$

as $T \to \infty$. The same estimate applies independently to the bra endpoint. The phase $c_0/|c_0|$ cancels between bra and ket in normalized matrix elements. For $0 < \tau_1 < \cdots < \tau_r < T$, inserting the semigroup factors between consecutive operators writes the endpoint matrix element as a bounded product of fixed-time operators and exterior factors $\exp[-T(\widehat H - E_0)/\hbar]|\psi\rangle$ and its adjoint. The norm convergence of the exterior factors gives the vacuum Euclidean ordered correlator. If the inserted operators are unbounded, this last sentence is read on a common invariant domain or after smearing/truncating the insertions; the regulated path-integral constructions below implement precisely that domain control. □

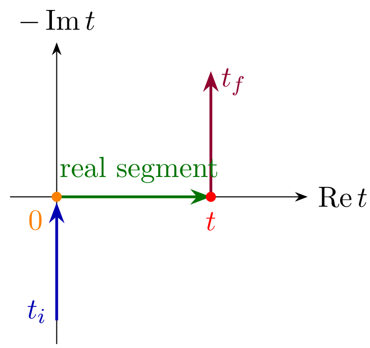
The same limit may be represented before Wick rotation by a regulated path integral on a complex-time contour. Let $\Gamma_{T,t}$ run from $t_i = \mathrm{i}T$ to 0, then along the real segment from 0 to t, and then to $t_f = t - \mathrm{i}T$, so that

$$\operatorname{Im} t_i \to +\infty, \qquad \operatorname{Im} t_f \to -\infty$$

as $T \to \infty$. If $[Dq]_{\Gamma,\psi}$ denotes the time-sliced measure on this contour with endpoint wavefunctions of a vector $|\psi\rangle$ included, then

$$\langle 0|\widehat{q}(t)\widehat{q}(0)|0\rangle = \lim_{T\to\infty} \frac{\int [Dq]_{\Gamma_{T,t},\psi} \exp\left[\frac{\mathrm{i}}{\hbar}\int_{\Gamma_{T,t}} L(q,\dot{q})\,\mathrm{d}t\right] q(t)q(0)}{\int [Dq]_{\Gamma_{T,t},\psi} \exp\left[\frac{\mathrm{i}}{\hbar}\int_{\Gamma_{T,t}} L(q,\dot{q})\,\mathrm{d}t\right]},$$

under the same ground-state overlap and gap hypotheses. This formula is a contour version of the operator projection above; the regulator and endpoint data are part of $[Dq]_{\Gamma,\psi}$.



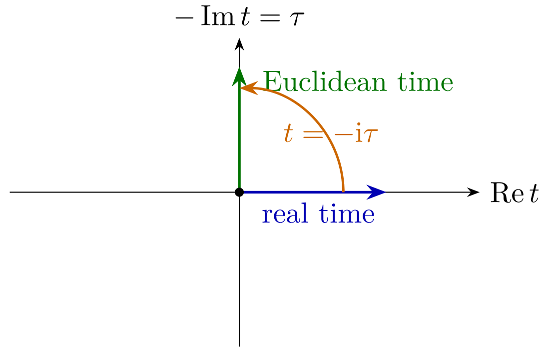
Convention 8.6 (Euclidean path-integral brackets in this chapter)**.** After the Wick rotation of the contour to Euclidean time, the Lagrangian path-integral notation

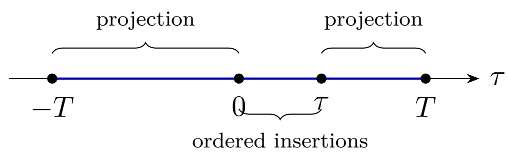
$$\langle 0|T_E\{\widehat{q}_E(\tau_1)\cdots\widehat{q}_E(\tau_r)\}|0\rangle = \lim_{T\to\infty} \frac{\int [Dq]\, \exp[-S_E[q]/\hbar]\, q(\tau_1)\cdots q(\tau_r)}{\int [Dq]\, \exp[-S_E[q]/\hbar]},$$

means the value produced by a specified regulator and limiting procedure, not an independently given translation-invariant measure on an infinite-dimensional space. The Euclidean action is

$$S_E[q] = \int_{-T}^{T} L_E(q,q')\,\mathrm{d}\tau.$$

For a bosonic Schrödinger operator satisfying the hypotheses of Theorem 7.6, this sentence can be read as a Wiener-measure statement: finite-interval transition amplitudes are Brownian bridge expectations with the potential weight, and vacuum correlators are obtained by the spectral projection limit described above. In the rest of this chapter the same bracket notation is also used for finite-dimensional Gaussian regulators and perturbative asymptotic expansions. These are different mathematical objects, and the text will specify which one is meant.





Definition 8.7 (Mode cutoff regulator)**.** A mode cutoff regulator consists of a finite set of functions $f_1, \ldots, f_{N_{\max}}$, a finite-dimensional coordinate map

$$q(\tau) = \sum_{n=1}^{N_{\max}} q_n f_n(\tau),$$

and a regulated measure defined by a finite product of Lebesgue measures in the coefficients q_n, together with the normalization and boundary conditions dictated by the chosen time-sliced construction. The limit $N_{\max} \to \infty$ is a further analytic operation and is not part of the symbol $[Dq]$ until its existence has been established for the observables under discussion.

The harmonic oscillator provides the basic Gaussian example.

Controlled Approximation 8.8 (Removing a mode cutoff)**.** In this chapter the phrase "remove the mode cutoff" has two distinct meanings. In the free Gaussian oscillator it denotes an actual limit of finite-dimensional Gaussian moments; the covariance kernels below converge after the finite mode projection is removed. In the interacting examples it denotes a coefficientwise operation on a perturbative expansion first defined at finite cutoff. No nonperturbative continuum measure, and no convergence of the formal power series in the coupling, is inferred from the notation.

8.3 The Harmonic Oscillator

Let

$$\widehat{H} = \frac{1}{2}(\widehat{p}^2 + \omega^2 \widehat{q}^2), \qquad L(q, \dot{q}) = \frac{1}{2}\dot{q}^2 - \frac{1}{2}\omega^2 q^2,$$

with $\omega > 0$. The Euclidean action on the interval $[-T, T]$ is

$$S_E[q] = \frac{1}{2} \int_{-T}^{T} \left[(q')^2 + \omega^2 q^2\right] \mathrm{d}\tau.$$

Impose Dirichlet boundary conditions $q(-T) = q(T) = 0$ and expand

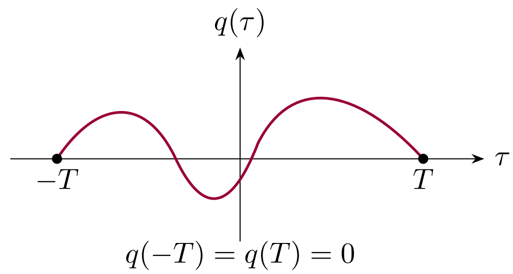
$$q(\tau) = \sum_{n=1}^{\infty} q_n f_n(\tau), \qquad f_n(\tau) = \frac{1}{\sqrt{T}} \sin \frac{n\pi(\tau + T)}{2T}.$$

The functions f_n obey

$$\int_{-T}^{T} f_n(\tau) f_m(\tau)\, \mathrm{d}\tau = \delta_{nm}, \qquad -\frac{\mathrm{d}^2}{\mathrm{d}\tau^2} f_n = \left(\frac{n\pi}{2T}\right)^2 f_n.$$

Consequently

$$S_E[q] = \frac{1}{2} \sum_{n=1}^{\infty} \left[\left(\frac{n\pi}{2T}\right)^2 + \omega^2 \right] q_n^2.$$



Definition 8.9 (Dirichlet harmonic-oscillator Gaussian cutoff)**.** For $N \in \mathbb{N}$, let

$$q^{(N)}(\tau) = \sum_{n=1}^{N} q_n f_n(\tau), \qquad S_{E,T,N}(q_1, \ldots, q_N) = \frac{1}{2} \sum_{n=1}^{N} \left[\left(\frac{n\pi}{2T}\right)^2 + \omega^2 \right] q_n^2.$$

The normalized finite-T, finite-mode expectation value is

$$\langle F \rangle_{T,N} = \frac{\int_{\mathbb{R}^N} \prod_{n=1}^{N} \mathrm{d}q_n \, \exp[-S_{E,T,N}/\hbar]\, F(q^{(N)})}{\int_{\mathbb{R}^N} \prod_{n=1}^{N} \mathrm{d}q_n \, \exp[-S_{E,T,N}/\hbar]}.$$

Proposition 8.10 (Harmonic-oscillator Euclidean covariance from the cutoff)**.** *For the cutoff of Definition 8.9, the finite-mode covariance converges at fixed T. For fixed insertion times τ_1, τ_2 and then $T \to \infty$, the limiting Euclidean two-point function on the line is*

$$\langle q(\tau_1) q(\tau_2) \rangle = \frac{\hbar}{2\omega} \mathrm{e}^{-\omega|\tau_1 - \tau_2|}.$$

Proof. This is an ordinary finite-dimensional Gaussian integral. In this free subsection, $\langle F \rangle_T$ denotes the limit $\lim_{N\to\infty} \langle F \rangle_{T,N}$ only for those observables for which that limit is being proved or has already been proved. The independent Gaussian integrals give, for $1 \le n, m \le N$,

$$\langle q_n q_m \rangle_{T,N} = \delta_{nm} \frac{\hbar}{\left(\frac{n\pi}{2T}\right)^2 + \omega^2}.$$

Therefore the finite-mode covariance kernel is

$$\langle q^{(N)}(\tau_1) q^{(N)}(\tau_2) \rangle_{T,N} = \sum_{n=1}^{N} \frac{\hbar\, f_n(\tau_1) f_n(\tau_2)}{\left(\frac{n\pi}{2T}\right)^2 + \omega^2}.$$

Since $\sum_{n\geq 1}((n\pi/2T)^2+\omega^2)^{-1}<\infty$, this sequence has a pointwise limit for every fixed $\tau_1,\tau_2\in[-T,T]$, and the finite-T Gaussian covariance is

$$\langle q(\tau_1)q(\tau_2)\rangle_T=\sum_{n=1}^{\infty}\frac{\hbar\, f_n(\tau_1)f_n(\tau_2)}{\left(\frac{n\pi}{2T}\right)^2+\omega^2}.$$

The passage to the infinite Euclidean line is not a formal replacement of a sum by an integral; it is a limit at fixed insertion points. Set

$$k_n=\frac{n\pi}{2T},\qquad \Delta k=\frac{\pi}{2T}.$$

Using the explicit sine basis,

$$\begin{aligned}\langle q(\tau_1)q(\tau_2)\rangle_T&=\sum_{n=1}^{\infty}\frac{\hbar}{T}\frac{\sin k_n(\tau_1+T)\sin k_n(\tau_2+T)}{k_n^2+\omega^2}\\&=\frac{2\hbar}{\pi}\sum_{n=1}^{\infty}\Delta k\,\frac{\sin k_n(\tau_1+T)\sin k_n(\tau_2+T)}{k_n^2+\omega^2}.\end{aligned}$$

To state the limit as an operation on the regulated path integral, insert temporarily an Abel factor $\mathrm{e}^{-\varepsilon k_n}$, $\varepsilon>0$, in the mode sum and the corresponding factor $\mathrm{e}^{-\varepsilon k}$ in the continuum integral. The Riemann limit is then taken at fixed ε, and the limit $\varepsilon\downarrow 0$ is taken after the Fourier integral has been evaluated. Suppressing this auxiliary factor from the notation, the continuum expression is

$$\frac{2\hbar}{\pi}\int_0^{\infty}\mathrm{d}k\,\frac{\sin k(\tau_1+T)\sin k(\tau_2+T)}{k^2+\omega^2}.$$

Writing $2\sin a\sin b=\cos(a-b)-\cos(a+b)$, equivalently

$$\begin{aligned}\langle q(\tau_1)q(\tau_2)\rangle_T=\frac{\hbar}{\pi}\int_{-\infty}^{\infty}\frac{\mathrm{d}k}{k^2+\omega^2}\Bigg[&\frac{1}{4}\mathrm{e}^{\mathrm{i}k(\tau_1-\tau_2)}+\frac{1}{4}\mathrm{e}^{-\mathrm{i}k(\tau_1-\tau_2)}\\&-\frac{1}{4}\mathrm{e}^{\mathrm{i}k(\tau_1+\tau_2+2T)}-\frac{1}{4}\mathrm{e}^{-\mathrm{i}k(\tau_1+\tau_2+2T)}\Bigg]+o(1),\end{aligned}$$

where $o(1)$ denotes the regulator error in the infinite-volume limit. Thus the finite interval produces, besides the translation-invariant term, an image term tied to the Dirichlet endpoints.

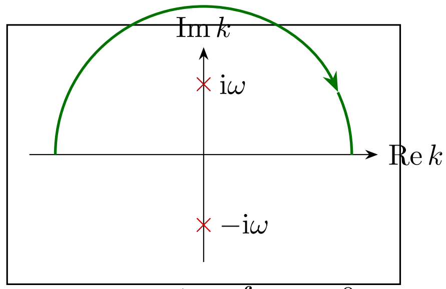
The elementary Fourier integral needed here is

$$I(\tau)=\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\mathrm{i}k\tau}}{k^2+\omega^2}\,\mathrm{d}k.$$

For $\tau>0$, $|\mathrm{e}^{\mathrm{i}k\tau}|=\mathrm{e}^{-(\operatorname{Im}k)\tau}$, so the large semicircle is suppressed in the upper half-plane and the pole enclosed is $k=\mathrm{i}\omega$. Therefore

$$I(\tau)=\frac{\pi}{\omega}\mathrm{e}^{-\omega\tau}.$$

For $\tau<0$, close the contour in the lower half-plane and obtain $\pi\omega^{-1}\mathrm{e}^{\omega\tau}$.



upper contour for $\tau > 0$

For fixed τ_1, τ_2, the quantity $\tau_1 + \tau_2 + 2T$ is positive for large T, and the preceding integral gives

$$\langle q(\tau_1)q(\tau_2)\rangle_T = \frac{\hbar}{2\omega}\mathrm{e}^{-\omega|\tau_1-\tau_2|} - \frac{\hbar}{2\omega}\mathrm{e}^{-\omega(\tau_1+\tau_2+2T)} + o(1).$$

The second term is the endpoint image contribution and vanishes as $T \to \infty$. Hence the Euclidean two-point function of the harmonic oscillator on the line is

$$\boxed{\langle q(\tau_1)q(\tau_2)\rangle = \frac{\hbar}{2\omega}\mathrm{e}^{-\omega|\tau_1-\tau_2|}}.$$

This agrees with the spectral expression, since the first operator $\widehat{q}$ connects the ground state of the harmonic oscillator to the first excited state. □

8.4 Gaussian Integrals and Wick Pairings

For the remainder of the chapter set $\hbar = 1$, unless $\hbar$ is displayed explicitly.

Definition 8.11 (Finite-dimensional real Gaussian datum)**.** Let A be a real symmetric positive-definite $N \times N$ matrix, let $J \in \mathbb{R}^N$, and write repeated finite indices as summed. Define

$$Z_A[J] = \int_{\mathbb{R}^N} \mathrm{d}^N q\ \exp\left(-\frac{1}{2}q_i A_{ij} q_j + J_i q_i\right),$$

and the normalized Gaussian expectation

$$\langle F(q)\rangle_A = \frac{1}{Z_A[0]}\int_{\mathbb{R}^N} \mathrm{d}^N q\ \exp\left(-\frac{1}{2}q_i A_{ij} q_j\right) F(q).$$

The covariance matrix is $C = A^{-1}$.

Proposition 8.12 (Gaussian generating functional and Wick theorem)**.** *For the datum of Definition 8.11,*

$$Z_A[J] = (2\pi)^{N/2}(\det A)^{-1/2}\exp\left(\frac{1}{2}J_i(A^{-1})_{ij}J_j\right).$$

Consequently all odd moments vanish, and

$$\langle q_{i_1}\cdots q_{i_{2r}}\rangle_A = \sum_{\textit{complete pairings } P}\ \prod_{(a,b)\in P}(A^{-1})_{i_a i_b}.$$

Proof. Completing the square gives the displayed formula for $Z_A[J]$. Indeed positive-definiteness of A permits the shift $q \mapsto q - A^{-1}J$, and the remaining Gaussian integral is $(2\pi)^{N/2}(\det A)^{-1/2}$. Differentiating with respect to J gives

$$\langle F(q)\rangle_A = F\left(\frac{\partial}{\partial J}\right) \frac{Z_A[J]}{Z_A[0]}\bigg|_{J=0}.$$

Let $C = A^{-1}$. Then

$$\langle q_i\rangle_A = \frac{\partial}{\partial J_i} \exp\left(\frac{1}{2} J_a C_{ab} J_b\right)\bigg|_{J=0} = 0$$

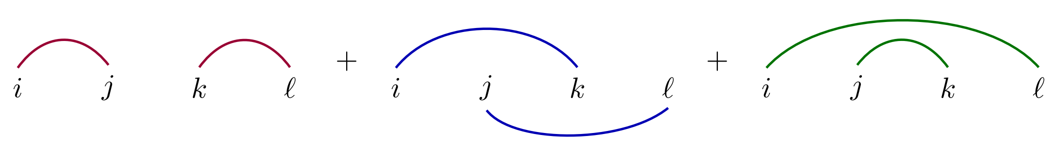
and

$$\langle q_i q_j\rangle_A = \frac{\partial}{\partial J_i}\frac{\partial}{\partial J_j} \exp\left(\frac{1}{2} J_a C_{ab} J_b\right)\bigg|_{J=0} = C_{ij}.$$

Write $\partial_i = \partial/\partial J_i$. For four variables,

$$\begin{aligned}
\langle q_i q_j q_k q_\ell\rangle_A &= \partial_i\partial_j\partial_k\partial_\ell \exp\left(\frac{1}{2} J_a C_{ab} J_b\right)\bigg|_{J=0} \\
&= \partial_i\partial_j\partial_k\partial_\ell \frac{1}{2}\left(\frac{1}{2} J_a C_{ab} J_b\right)^2\bigg|_{J=0} \\
&= C_{ij}C_{k\ell} + C_{ik}C_{j\ell} + C_{i\ell}C_{jk}.
\end{aligned}$$

Only the quadratic term squared in the exponential can survive after four source derivatives and then setting $J = 0$. The four derivatives can be assigned to the four source factors in $4!$ ways; these assignments group into the three displayed pairings, and the numerical factor $\frac{1}{2}(\frac{1}{2})^2 = \frac{1}{8}$ cancels the repeated orientations and the exchange of the two covariance factors inside each pairing.



A Wick contraction is an assigned pairing of two labels with value

$$(q_i q_j)_{\text{contr}} = C_{ij} = (A^{-1})_{ij}.$$

The same differentiation argument proves Wick's theorem for $2r$ variables: only the degree r term in $\exp(\frac{1}{2}J_a C_{ab} J_b)$ contributes after setting $J = 0$, and each surviving derivative assignment partitions the $2r$ labels into r unordered pairs. Thus the Gaussian expectation of $2r$ variables is the sum over all complete pairings, with one covariance factor for each pair:

$$\langle q_{i_1} \cdots q_{i_{2r}}\rangle_A = \sum_{\text{complete pairings } P} \prod_{(a,b)\in P} (A^{-1})_{i_a i_b}.$$

For an odd number of derivatives no monomial of odd total degree appears in the source exponential, so the moment vanishes. $\square$

8.5 Gaussian Functional Integrals

Definition 8.13 (Gaussian functional integral as a regulated limit)**.** Let A be the positive operator

$$A = -\frac{\mathrm{d}^2}{\mathrm{d}\tau^2} + \omega^2$$

on a function space with boundary conditions for which A is invertible. The Green function $G(\tau, \tau')$ is the integral kernel of A^{-1}:

$$(A^{-1}f)(\tau) = \int G(\tau, \tau') f(\tau') \, \mathrm{d}\tau',$$

and therefore satisfies

$$\left(-\frac{\mathrm{d}^2}{\mathrm{d}\tau^2} + \omega^2\right) G(\tau, \tau') = \delta(\tau - \tau').$$

With the inner product

$$(f, g) = \int f(\tau) g(\tau) \, \mathrm{d}\tau,$$

the Gaussian Euclidean action is

$$S_0[q] = \frac{1}{2}(q, Aq).$$

The source-dependent Gaussian functional integral is defined by a regulator, for instance a finite-mode cutoff, and has the finite-dimensional form in the cutoff variables. Its continuum notation is

$$Z_0[J] = \int [Dq] \, \exp\left[-\frac{1}{2}(q, Aq) + (J, q)\right].$$

This notation denotes the finite-dimensional Gaussian construction followed by a limit of covariance kernels in the specified topology; it does not assert the existence of a translation-invariant Lebesgue measure on the space of paths.

Gaussian functional source identity. For the regulated Gaussian construction of Definition 8.13, the normalization-independent source ratio is

$$\frac{Z_0[J]}{Z_0[0]} = \exp\left[\frac{1}{2} \int J(\tau) G(\tau, \tau') J(\tau') \, \mathrm{d}\tau \, \mathrm{d}\tau'\right],$$

and the two-point function is $G(\tau_1, \tau_2)$.

At finite cutoff this is exactly Proposition 8.12 with the matrix A_{ij} equal to the quadratic form of the cutoff action and with the source vector $J_i = (J, f_i)$. The inverse matrix has kernel equal to the cutoff Green function. Passing to the limit gives the displayed kernel identity whenever the cutoff Green functions converge against the chosen test sources.

The ratio independent of normalization is

$$\frac{Z_0[J]}{Z_0[0]} = \exp\left[\frac{1}{2} \int J(\tau) G(\tau, \tau') J(\tau') \, \mathrm{d}\tau \, \mathrm{d}\tau'\right].$$

Consequently

$$\langle q(\tau_1) q(\tau_2) \rangle_0 = G(\tau_1, \tau_2).$$

Gaussian integration by parts. In the same regulated Gaussian construction,

$$\langle q(\tau_1)q(\tau_2)\rangle_0 = G(\tau_1,\tau_2)$$

also follows from finite-dimensional integration by parts. Equivalently, the formal identity

$$q(\tau_1)\mathrm{e}^{-\frac{1}{2}(q,Aq)} = -\left(A^{-1}\frac{\delta}{\delta q}\right)(\tau_1)\mathrm{e}^{-\frac{1}{2}(q,Aq)}$$

is the continuum notation for that cutoff identity.

The same result can be obtained without tracking the normalization of the functional measure under discretization. At finite cutoff this is ordinary integration by parts in finitely many variables; the continuum notation is the limit of that identity. The functional derivative is normalized by

$$\frac{\delta q(\tau_2)}{\delta q(\tau')} = \delta(\tau'-\tau_2).$$

Since

$$\frac{\delta}{\delta q(\tau')}\exp\left[-\frac{1}{2}(q,Aq)\right] = -(Aq)(\tau')\exp\left[-\frac{1}{2}(q,Aq)\right],$$

one has

$$q(\tau_1)\exp\left[-\frac{1}{2}(q,Aq)\right] = -\left(A^{-1}\frac{\delta}{\delta q}\right)(\tau_1)\exp\left[-\frac{1}{2}(q,Aq)\right],$$

where

$$\left(A^{-1}\frac{\delta}{\delta q}\right)(\tau_1) = \int G(\tau_1,\tau')\frac{\delta}{\delta q(\tau')}\,\mathrm{d}\tau'.$$

The regulated Gaussian has no boundary term in this finite-dimensional integration by parts. Therefore

$$\begin{aligned}
&\int [Dq]\,\exp\left[-\frac{1}{2}(q,Aq)\right] q(\tau_1)q(\tau_2)\\
&= \int [Dq]\,\exp\left[-\frac{1}{2}(q,Aq)\right]\left(A^{-1}\frac{\delta}{\delta q}\right)(\tau_1)q(\tau_2)\\
&= \int [Dq]\,\exp\left[-\frac{1}{2}(q,Aq)\right]\int G(\tau_1,\tau')\delta(\tau'-\tau_2)\,\mathrm{d}\tau'.
\end{aligned}$$

After division by $Z_0[0]$, this gives again $\langle q(\tau_1)q(\tau_2)\rangle_0 = G(\tau_1,\tau_2)$.

On the infinite Euclidean line, write

$$q(\tau) = \int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\,\widetilde{q}(k)\mathrm{e}^{\mathrm{i}k\tau}, \qquad \widetilde{q}(k)^* = \widetilde{q}(-k).$$

Then

$$S_0[q] = \frac{1}{2}\int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\,\widetilde{q}(-k)(k^2+\omega^2)\widetilde{q}(k),$$

and

$$\langle\widetilde{q}(k_1)\widetilde{q}(k_2)\rangle_0 = \frac{2\pi\delta(k_1+k_2)}{k_1^2+\omega^2}.$$

Thus

$$G(\tau,\tau') = \int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\,\frac{\mathrm{e}^{\mathrm{i}k(\tau-\tau')}}{k^2+\omega^2} = \frac{1}{2\omega}\mathrm{e}^{-\omega|\tau-\tau'|}.$$

8.6 The Anharmonic Oscillator

Set $\omega = 1$ in this section. The anharmonic oscillator is defined by

$$\widehat{H} = \frac{1}{2}\widehat{p}^2 + \frac{1}{2}\widehat{q}^2 + \frac{g}{4!}\widehat{q}^4.$$

For real $g \geq 0$, this differential operator on $C_c^\infty(\mathbb{R})$ has a unique self-adjoint closure by the Faris–Lavine criterion stated in Chapter 7: the potential

$$V(q) = \frac{1}{2}q^2 + \frac{g}{4!}q^4$$

is smooth, bounded below, locally Kato, and has zero negative part. Hence the Euclidean semigroup and its time-sliced approximants are defined before the perturbative expansion in g is formed. The Euclidean Lagrangian is

$$L_E(q, q') = \frac{1}{2}(q')^2 + \frac{1}{2}q^2 + \frac{g}{4!}q^4.$$

Let

$$S_0[q] = \int \left[\frac{1}{2}(q')^2 + \frac{1}{2}q^2\right] \mathrm{d}\tau, \qquad S_{\mathrm{int}}[q] = \frac{g}{4!}\int q(\tau)^4 \,\mathrm{d}\tau.$$

Definition 8.14 (Cutoff perturbative expansion of the anharmonic oscillator)**.** At finite cutoff, perturbation theory is the coefficientwise expansion of $\exp[-S_{\mathrm{int}}]$ inside a finite-dimensional Gaussian integral:

$$\mathrm{e}^{-S_{\mathrm{int}}[q]} = \sum_{n=0}^{\infty} \frac{1}{n!}\left(-\frac{g}{4!}\int q(\tau)^4 \,\mathrm{d}\tau\right)^n.$$

No convergence of the infinite-dimensional integral or of the resulting power series in g is assumed at this point; the coefficients are first defined in the regulated Gaussian integral. Removing the mode cutoff in this interacting section means taking $N_{\max} \to \infty$, or equivalently $\Lambda \to \infty$, separately for each coefficient after its regulator dependence has been displayed. If the coefficient has a finite limit, that limit is part of the perturbative definition used here; if it does not, one must specify the local counterterm or subtraction coordinate before a finite coefficient is defined.

For the partition function,

$$Z_g = \int [Dq] \,\exp[-S_0[q] - S_{\mathrm{int}}[q]],$$

one obtains

$$\frac{Z_g}{Z_0} = \sum_{n=0}^{\infty} \frac{1}{n!}\left(-\frac{g}{4!}\right)^n \int \mathrm{d}\tau_1 \cdots \mathrm{d}\tau_n \,\left\langle q(\tau_1)^4 \cdots q(\tau_n)^4\right\rangle_0.$$

Here Z_0 is the Gaussian partition function and $\langle \cdots \rangle_0$ is evaluated with

$$G_0(\tau, \tau') = \frac{1}{2}\mathrm{e}^{-|\tau-\tau'|}.$$

At first order in g,

$$\begin{aligned}\left(\frac{Z_g}{Z_0} - 1\right)_{O(g)} &= -\frac{g}{4!}\int \mathrm{d}\tau \,\langle q(\tau)^4\rangle_0 \\ &= -\frac{g}{8}\int \mathrm{d}\tau \,G_0(\tau,\tau)^2.\end{aligned} \tag{8.1}$$

The factor 3 in $\langle q^4\rangle_0 = 3G_0(\tau,\tau)^2$ is the Wick count $(4-1)!! = 3$ for pairing four identical fields at the same Euclidean time among themselves. The 4! assignment count appears only when four labeled vertex half-edges are attached to four labeled insertions; that is a different combinatorial problem from the coincident self-contraction here. Since $G_0(\tau,\tau) = G_0(0)$ is independent of τ, this term is proportional to the Euclidean time interval. Its interpretation as a correction to the ground-state energy is derived below from the spectral decomposition of the Euclidean transition kernel.

At second order,

$$\frac{1}{2}\left(-\frac{g}{4!}\right)^2 \int \mathrm{d}\tau_1\, \mathrm{d}\tau_2\, \left\langle q(\tau_1)^4 q(\tau_2)^4\right\rangle_0$$

contains disconnected contractions and connected contractions. The connected sector already has distinct topologies: the two vertices may be joined by two propagators with one tadpole at each vertex, or they may be joined by four propagators. Figure 8.1 records this separation between disconnected vacuum products and the connected two-vertex topologies that enter the linked-cluster proof.

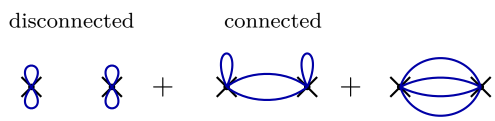


Figure 8.1: Second-order Wick topologies in the anharmonic oscillator expansion. The left pair is a product of disconnected one-vertex vacuum bubbles. The two right diagrams are connected two-vertex vacuum contractions: two inter-vertex lines with one tadpole at each vertex, and four inter-vertex lines.

Proposition 8.15 (Linked-cluster formula for the cutoff expansion)**.** *At every fixed cutoff and at the level of formal power series in g, $\log(Z_g/Z_0)$ is the sum of connected vacuum diagrams.*

Proof. Let $G^{(\ell)}$ be the sum of connected vacuum Wick contractions involving ℓ interaction vertices, including the coupling factors and integration over the ℓ vertex positions. If m_ℓ is the number of connected components of size ℓ, and if K is the total number of connected components, then

$$\sum_{\ell\geq 1} m_\ell = K, \qquad \sum_{\ell\geq 1} \ell\, m_\ell = n.$$

The number of ways to partition n labelled vertices into this pattern is

$$\frac{n!}{\prod_{\ell\geq 1}(\ell!)^{m_\ell} m_\ell!}.$$

For this fixed component pattern, the corresponding contribution to Z_g/Z_0 is therefore

$$\frac{1}{n!}\,\frac{n!}{\prod_{\ell\geq 1}(\ell!)^{m_\ell} m_\ell!}\prod_{\ell\geq 1}(G^{(\ell)})^{m_\ell} = \prod_{\ell\geq 1}\frac{1}{m_\ell!}\left(\frac{1}{\ell!}G^{(\ell)}\right)^{m_\ell}.$$

Summing over all nonnegative integers m_ℓ gives the linked-cluster formula

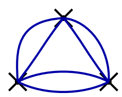
$$\frac{Z_g}{Z_0} = \sum_{\{m_\ell\}}\prod_{\ell\geq 1}\frac{1}{m_\ell!}\left(\frac{1}{\ell!}G^{(\ell)}\right)^{m_\ell} = \exp\left[\sum_{\ell\geq 1}\frac{1}{\ell!}G^{(\ell)}\right].$$

Equivalently, $\log Z_g$ is the sum of connected vacuum diagrams. The factor $1/\ell!$ is often absorbed into the symmetry factor assigned to the connected graph. □

For example, the connected three-vertex topology with two propagators on each edge has

$$N_{\triangle} = \binom{4}{2}^3 (2!)^3 = 1728$$

Wick-contraction assignments: at each vertex one chooses which two of the four half-edges go to one neighboring vertex, and along each of the three double edges one pairs the two half-edges. Its contribution to $\frac{1}{3!}G^{(3)}$ is therefore



$$\begin{aligned}\frac{1}{3!}\left(-\frac{g}{4!}\right)^3 N_{\triangle} \int \mathrm{d}\tau_1\,\mathrm{d}\tau_2\,\mathrm{d}\tau_3\, G_0(\tau_1,\tau_2)^2 G_0(\tau_2,\tau_3)^2 G_0(\tau_3,\tau_1)^2 \\ = -\frac{g^3}{48}\int \mathrm{d}\tau_1\,\mathrm{d}\tau_2\,\mathrm{d}\tau_3\, G_0(\tau_1,\tau_2)^2 G_0(\tau_2,\tau_3)^2 G_0(\tau_3,\tau_1)^2,\end{aligned}$$

where the last equality uses the normalization 4! in the interaction vertex. Translation invariance leaves one unrestricted center-of-time integral, so every connected vacuum graph is proportional to the total Euclidean time interval.

On a finite Euclidean interval of length T_{tot}, with endpoint values q_i and q_f, the path integral is the transition kernel

$$Z_g(T_{\mathrm{tot}}; q_f, q_i) = \langle q_f | \mathrm{e}^{-T_{\mathrm{tot}}\widehat{H}} | q_i \rangle.$$

Proposition 8.16 (Ground-state energy from the Euclidean kernel)**.** *Assume that the anharmonic oscillator Hamiltonian has discrete spectrum $E_0(g) < E_1(g) \le \cdots$, with nondegenerate ground state ψ_0. If the endpoint data used in the transition kernel have nonzero overlap with ψ_0, then*

$$E_0(g) = -\lim_{T_{\mathrm{tot}}\to\infty} \frac{1}{T_{\mathrm{tot}}} \log Z_g, \qquad E_0(g) - E_0(0) = -\lim_{T_{\mathrm{tot}}\to\infty} \frac{1}{T_{\mathrm{tot}}} \log \frac{Z_g}{Z_0}.$$

The first perturbative correction is

$$\Delta E_0 = \frac{g}{32} + O(g^2)$$

for $\omega = 1$.

Proof. For the anharmonic oscillator the spectrum is discrete and the ground state is nondegenerate. If the endpoint wavefunctions have nonzero overlap with the ground state, the spectral theorem gives

$$Z_g(T_{\mathrm{tot}}; q_f, q_i) = \psi_0(q_f)\overline{\psi_0(q_i)}\mathrm{e}^{-E_0(g)T_{\mathrm{tot}}} + O(\mathrm{e}^{-E_1(g)T_{\mathrm{tot}}}),$$

and hence

$$E_0(g) = -\lim_{T_{\mathrm{tot}}\to\infty} \frac{1}{T_{\mathrm{tot}}} \log Z_g.$$

The endpoint wavefunction factors contribute only $O(1)$ to $\log Z_g$, so they disappear after multiplication by T_{tot}^{-1}. Taking the difference between the interacting and free kernels gives

$$E_0(g) - E_0(0) = -\lim_{T_{\text{tot}}\to\infty} \frac{1}{T_{\text{tot}}} \log \frac{Z_g}{Z_0}.$$

The first-order term in (8.1) is connected, hence it is also the first-order term in $\log(Z_g/Z_0)$. On an interval of length T_{tot},

$$\frac{1}{T_{\text{tot}}} \log \frac{Z_g}{Z_0} = -\frac{g}{8} G_0(0)^2 + O(g^2).$$

The sign of the energy shift therefore comes from the minus sign in $E_0 = -T_{\text{tot}}^{-1} \log Z$ together with the per-vertex factor $-g/4!$ in (8.1). Thus

$$\Delta E_0 = \frac{g}{8} G_0(0)^2 + O(g^2) = \frac{g}{32} + O(g^2),$$

where the second equality uses $\omega = 1$; with general oscillator frequency the same term is $g(2\omega)^{-2}/8$. This agrees with first-order Hamiltonian perturbation theory:

$$\langle \psi_0 | \frac{g}{4!} \widehat{q}^4 | \psi_0 \rangle = \frac{g}{4!}\, 3 \left(\frac{1}{2}\right)^2 = \frac{g}{32}.$$

$\square$

8.7 Connected Two-Point Functions and Self-Energy

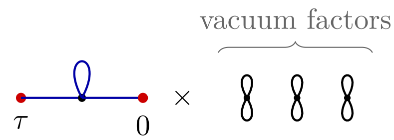
The normalized Euclidean two-point function is

$$G(\tau) = \langle q(\tau) q(0) \rangle_g = \frac{1}{Z_g} \int [Dq]\, \mathrm{e}^{-S_0[q] - S_{\text{int}}[q]}\, q(\tau) q(0).$$

Equivalently, at the regulated level,

$$G(\tau) = \frac{1}{Z_g} \left\langle q(\tau) q(0) \sum_{n=0}^{\infty} \frac{1}{n!} \left(-\frac{g}{4!} \int q(\tau')^4 \, \mathrm{d}\tau' \right)^n \right\rangle_0 .$$

Vacuum components in normalized two-point functions. At fixed cutoff and as a formal power series in g, the normalized two-point function is the sum of Wick diagrams whose connected component contains both external insertions. At fixed cutoff every coefficient of the formal series is a finite Gaussian moment, hence Wick's theorem expresses it as a finite sum over pairings. View a pairing as a graph whose vertices are the two external insertions and the interaction insertions, with an edge for each Wick contraction. Every such graph decomposes uniquely into connected components. The component containing the two external vertices carries all dependence on the external points; the remaining components contain interaction vertices only and are vacuum graphs. Conversely, a connected two-point graph together with an unordered finite collection of vacuum components determines a unique disconnected graph of the normalized numerator, with the exponential generating-function factors. Summing over all vacuum components therefore produces the same formal power series Z_g that appears in the denominator. Division by Z_g cancels this vacuum factor coefficientwise, leaving exactly the Wick graphs whose connected component contains both external insertions.



Consequently the normalized correlator is represented by connected diagrams with the two external insertions fixed at τ and 0. Figure 8.2 displays precisely the connected topologies that survive the division by $Z[0]$, so the vacuum factors drawn in the preceding bookkeeping figure are no longer present: The same path integral, with the same Euclidean ordering convention, computes

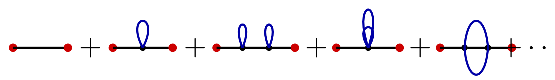


Figure 8.2: First connected topologies contributing to the normalized two-point function. Red endpoints mark the fixed insertions $q(\tau)$ and $q(0)$; black vertices are interaction insertions; blue arcs are contracted oscillator fields. Vacuum components are absent because they cancel against Z_g.

$\langle 0|\widehat{q}_E(0)\widehat{q}_E(\tau)|0\rangle$ when $\tau < 0$. Thus

$$G(\tau) = \begin{cases} \langle 0|\widehat{q}_E(\tau)\widehat{q}_E(0)|0\rangle, & \tau > 0, \\ \langle 0|\widehat{q}_E(0)\widehat{q}_E(\tau)|0\rangle, & \tau < 0. \end{cases}$$

At zeroth order,

$$G_0(\tau) = \frac{1}{2}\mathrm{e}^{-|\tau|} = \int_{-\infty}^{\infty} \frac{\mathrm{d}k}{2\pi}\,\frac{\mathrm{e}^{\mathrm{i}k\tau}}{k^2+1}.$$

At order g, the connected tadpole correction is

$$-\frac{g}{2}\int \mathrm{d}\tau'\, G_0(\tau-\tau')G_0(\tau')G_0(0).$$

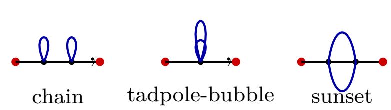
In momentum space this is

$$\begin{aligned} -\frac{g}{2}\int \mathrm{d}\tau' \int \frac{\mathrm{d}k}{2\pi}\frac{\mathrm{d}k'}{2\pi}\frac{\mathrm{d}k''}{2\pi}\,\widetilde{G}_0(k)\widetilde{G}_0(k')\widetilde{G}_0(k'')\,\mathrm{e}^{\mathrm{i}k(\tau-\tau')+\mathrm{i}k'\tau'} \\ = -\frac{g}{2}\left(\int \frac{\mathrm{d}k''}{2\pi}\,\widetilde{G}_0(k'')\right)\int \frac{\mathrm{d}k}{2\pi}\,\frac{\mathrm{e}^{\mathrm{i}k\tau}}{(k^2+1)^2}. \end{aligned}$$

Since $\int \mathrm{d}k''\,\widetilde{G}_0(k'')/(2\pi) = G_0(0) = 1/2$, this becomes

$$-\frac{g}{4}\int_{-\infty}^{\infty} \frac{\mathrm{d}k}{2\pi}\,\frac{\mathrm{e}^{\mathrm{i}k\tau}}{(k^2+1)^2}.$$

At second order the connected two-point graphs include



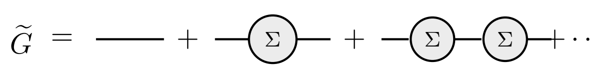
The first diagram is a chain of two one-loop insertions; the other two are the second-order amputated insertions that enter the self-energy below.

Definition 8.17 (Euclidean 1PI two-point insertion)**.** A connected two-point diagram is one-particle-irreducible, abbreviated 1PI, when it remains connected after cutting any one internal propagator. In this chapter the term is graph-theoretic and refers to Euclidean Green-function diagrams. Let $\Sigma(k)$ be the sum of amputated 1PI two-point insertions in momentum space, with the external free propagators removed.

With the sign convention of Definition 8.17, the full two-point function is the geometric series

$$\widetilde{G}(k) = \widetilde{G}_0(k)\sum_{r=0}^{\infty}\big(\widetilde{G}_0(k)\Sigma(k)\big)^r = \frac{1}{k^2+1-\Sigma(k)}, \qquad \widetilde{G}_0(k) = \frac{1}{k^2+1}.$$

Every connected two-point graph is obtained uniquely by arranging a finite chain of amputated 1PI two-point insertions along the external line and inserting one free propagator between consecutive amputated insertions. Cutting the propagators between adjacent insertions gives the unique chain decomposition; conversely gluing such a chain gives a connected two-point graph. Translation invariance diagonalizes the convolution in momentum space, so the chain with r insertions contributes $\widetilde{G}_0(k)(\widetilde{G}_0(k)\Sigma(k))^r$. Summing the formal geometric series gives the displayed denominator.



For the anharmonic oscillator, the two non-chain order-g^2 contributions are as follows. The perturbative coefficient before Wick contraction is $g^2/(2(4!)^2)$. For the tadpole-bubble topology, both external fields are contracted to one interaction vertex, two lines connect the two vertices, and the remaining two fields at the second vertex contract with each other. The number of such contractions is

$$2\cdot(4\cdot 3)\cdot\binom{4}{2}\,2! = 288,$$

so the net symmetry factor is $288/[2(4!)^2] = 1/4$. With

$$G_0(0) = \int_{-\infty}^{\infty}\frac{\mathrm{d}p}{2\pi}\,\widetilde{G}_0(p) = \frac{1}{2}, \qquad \int_{-\infty}^{\infty}\frac{\mathrm{d}p}{2\pi}\,\widetilde{G}_0(p)^2 = \frac{1}{4},$$

this topology contributes

$$\Sigma^{(2)}_{\mathrm{tb}}(k) = \frac{g^2}{4}\,G_0(0)\int_{-\infty}^{\infty}\frac{\mathrm{d}p}{2\pi}\,\widetilde{G}_0(p)^2 = \frac{g^2}{32} = \frac{g^2}{8}\,\frac{1}{4}.$$

For the sunset topology, the two external fields attach to different vertices and the remaining three legs at one vertex are paired with the remaining three legs at the other. The contraction count is

$$2\cdot 4\cdot 4\cdot 3! = 192,$$

so the symmetry factor is $192/[2(4!)^2] = 1/6$. Its momentum integral is the three-fold convolution

$$\begin{aligned}I_{\mathrm{sun}}(k) &= \int\frac{\mathrm{d}p}{2\pi}\frac{\mathrm{d}q}{2\pi}\,\widetilde{G}_0(p)\widetilde{G}_0(q)\widetilde{G}_0(k-p-q)\\ &= \int_{-\infty}^{\infty}\mathrm{d}\tau\,\mathrm{e}^{-\mathrm{i}k\tau}G_0(\tau)^3 = \frac{1}{8}\int_{-\infty}^{\infty}\mathrm{d}\tau\,\mathrm{e}^{-\mathrm{i}k\tau}\mathrm{e}^{-3|\tau|} = \frac{3}{4}\,\frac{1}{k^2+9}.\end{aligned}$$

Thus

$$\Sigma^{(2)}_{\text{sun}}(k)=\frac{g^2}{6}I_{\text{sun}}(k)=\frac{g^2}{8}\,\frac{1}{k^2+9}.$$

The momentum-independent term $\frac{g^2}{32}$ is the tadpole-bubble, equivalently the double-bubble insertion after external amputation. The term proportional to $(k^2+9)^{-1}$ is the sunset insertion. Its denominator is not an arbitrary algebraic remnant: the three-fold convolution is the Fourier transform of $\frac{1}{8}\mathrm{e}^{-3|\tau|}$, so its nearest singularities are $k=\pm 3\mathrm{i}$, or $k^2=-9=-(3\omega)^2$ with $\omega=1$. In the spectral language of this oscillator computation, this is the intermediate three-quantum energy carried by the sunset topology. Combining the one-loop term with these two order-g^2 contributions gives

$$\Sigma(k)=-\frac{g}{4}+\frac{g^2}{8}\left(\frac{1}{4}+\frac{1}{k^2+9}\right)+O(g^3).$$

The external free propagators are not part of Σ; in this convention the order-g term is the amputated tadpole, while the two displayed order-g^2 terms come from the two non-chain second-order topologies shown above after their external legs are amputated. The chain of two one-loop insertions is instead produced by the geometric series in $\widetilde{G}_0(k)\Sigma(k)$. Consequently

$$\widetilde{G}(k)=\frac{1}{k^2+1+\frac{g}{4}-\frac{g^2}{8}\left(\frac{1}{4}+\frac{1}{k^2+9}\right)+O(g^3)}.$$

Proposition 8.18 (Pole extraction of the first energy gap)**.** *For the anharmonic oscillator in the convention above, the pole of $\widetilde{G}(k)$ near $k=\mathrm{i}$ gives*

$$E_1-E_0=1+\frac{g}{8}-\frac{g^2}{32}+O(g^3).$$

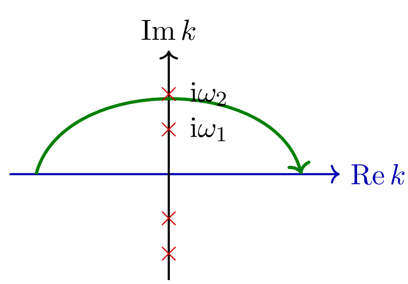
Proof. The spectral expansion says that for $\tau>0$,

$$G(\tau)=\sum_n |\langle n|\widehat{q}|0\rangle|^2\,\mathrm{e}^{-(E_n-E_0)\tau}.$$

The Fourier representation

$$G(\tau)=\int_{-\infty}^{\infty}\frac{\mathrm{d}k}{2\pi}\,\widetilde{G}(k)\mathrm{e}^{\mathrm{i}k\tau}$$

is evaluated for $\tau>0$ by closing the contour in the upper half-plane, where $\mathrm{e}^{\mathrm{i}k\tau}$ decays on the large semicircle.



If $\widetilde{G}(k)$ has simple poles at $k=\mathrm{i}\omega_n$, then

$$G(\tau)=\mathrm{i}\sum_n \operatorname*{Res}_{k=\mathrm{i}\omega_n}\widetilde{G}(k)\,\mathrm{e}^{-\omega_n\tau}.$$

Thus the pole positions encode the energy gaps $\omega_n = E_n - E_0$ in the $\hbar = 1$ convention.

It remains to solve the pole equation near $k = \mathrm{i}$. Write $\omega = 1 + ag + bg^2 + O(g^3)$ and set $k = \mathrm{i}\omega$. The denominator of $\widetilde{G}(k)$ is

$$-\omega^2 + 1 + \frac{g}{4} - \frac{g^2}{8}\left(\frac{1}{4} + \frac{1}{9 - \omega^2}\right) + O(g^3).$$

Since $9 - \omega^2 = 8 + O(g)$, the $O(g^2)$ part of the last factor is $\frac{1}{4} + \frac{1}{8} = \frac{3}{8}$. Also $\omega^2 = 1 + 2ag + (a^2 + 2b)g^2 + O(g^3)$. Vanishing of the denominator gives

$$-2a + \frac{1}{4} = 0, \qquad -(a^2 + 2b) - \frac{3}{64} = 0.$$

Thus $a = \frac{1}{8}$ and $b = -\frac{1}{32}$, proving the formula. □

8.8 Derivative Interactions, Regulators, and Counterterms

Consider the Lagrangian

$$L(q, \dot{q}) = \frac{1}{2}\dot{q}^2 - \frac{1}{2}q^2 - \frac{g}{8}q^2\dot{q}^2.$$

The canonical momentum is

$$p = \frac{\partial L}{\partial \dot{q}} = \dot{q}\left(1 - \frac{g}{4}q^2\right),$$

and the corresponding Hamiltonian function is

$$H(q, p) = \frac{1}{2}\left(1 - \frac{g}{4}q^2\right)^{-1} p^2 + \frac{1}{2}q^2.$$

Already at the classical level this Hamiltonian shows the point that will matter quantum mechanically: the product of the q-dependent coefficient and p^2 has no unique operator meaning until an ordering prescription, or equivalently a regulated path-integral prescription, has been specified.

Remark 8.19 (Classical field redefinition check). Define a new coordinate y, to first order in g, by

$$\frac{\mathrm{d}y}{\mathrm{d}q} = \left(1 - \frac{g}{4}q^2\right)^{1/2}, \qquad y = q - \frac{g}{24}q^3 + O(g^2).$$

Then $q = y + \frac{g}{24}y^3 + O(g^2)$, and the Lorentzian Lagrangian becomes

$$L = \frac{1}{2}\dot{y}^2 - \left(\frac{1}{2}y^2 + \frac{g}{24}y^4\right) + O(g^2).$$

Thus the derivative-coupled oscillator is classically equivalent, through order g, to an ordinary anharmonic oscillator. This is a classical coordinate calculation: The defining equation gives $\dot{y} = (1 - \frac{g}{4}q^2)^{1/2}\dot{q}$, hence

$$\frac{1}{2}\dot{q}^2 - \frac{g}{8}q^2\dot{q}^2 = \frac{1}{2}\left(1 - \frac{g}{4}q^2\right)\dot{q}^2 = \frac{1}{2}\dot{y}^2 + O(g^2).$$

Inverting $y = q - \frac{g}{24}q^3 + O(g^2)$ gives $q = y + \frac{g}{24}y^3 + O(g^2)$. Therefore

$$-\frac{1}{2}q^2 = -\frac{1}{2}y^2 - \frac{g}{24}y^4 + O(g^2),$$

which proves the displayed Lagrangian. The quantum computation below keeps the q-coordinate and shows where the ordering or path-integral prescription enters.

The Euclidean Lagrangian is

$$L_E(q,q') = \frac{1}{2}(q')^2 + \frac{1}{2}q^2 - \frac{g}{8}q^2(q')^2.$$

Using

$$q^2(q')^2 = \frac{1}{3}\frac{\mathrm{d}}{\mathrm{d}\tau}(q^3q') - \frac{1}{3}q^3q'',$$

the interaction may also be represented, up to endpoint terms, by

$$\frac{g}{24}q^3q''.$$

At first order in g, the two-point function contains contractions in which derivatives act on propagators at coincident points. A representative term is

$$\frac{g}{4}\int \mathrm{d}\tau'\, G_0(\tau-\tau')G_0(\tau')\ \left[-\partial_{\tau'}^2 G_0(\tau'-\tau'')\right]\big|_{\tau''=\tau'}.$$

The derivative is taken with respect to one endpoint of the propagator before the coincident-point limit $\tau'' \to \tau'$ is imposed. In momentum space this contains

$$\int \frac{\mathrm{d}k'}{2\pi}\frac{k'^2}{k'^2+1},$$

which depends on the high-frequency definition of the path integral. Other contractions in the same Wick expansion are finite or vanish by parity. For example, with $G_0(k) = 1/(k^2+1)$, one obtains terms of the form

$$\frac{g}{4}\int \frac{\mathrm{d}k}{2\pi}\frac{\mathrm{e}^{\mathrm{i}k\tau}k^2}{(k^2+1)^2}\int\frac{\mathrm{d}k'}{2\pi}\frac{1}{k'^2+1},$$

and

$$-\frac{g}{2}\int \frac{\mathrm{d}k}{2\pi}\frac{\mathrm{e}^{\mathrm{i}k\tau}\mathrm{i}k}{(k^2+1)^2}\int\frac{\mathrm{d}k'}{2\pi}\frac{\mathrm{i}k'}{k'^2+1} = 0.$$

The divergent term is local in the external momentum expansion; this is why a local counterterm can absorb it.

Figure 8.3 separates the derivative contractions according to their ultraviolet role: loop-derivative contractions produce the local divergent term, and the parity-odd loop contraction vanishes.

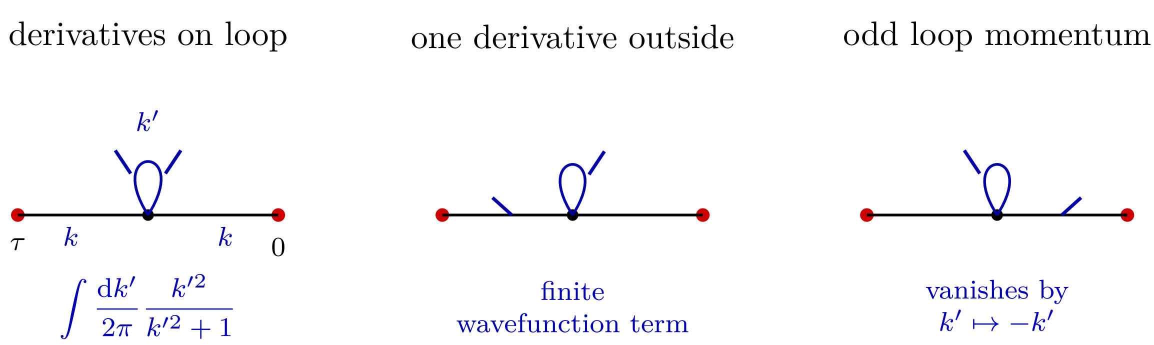


Figure 8.3: Derivative interactions produce derivatives acting on Wick contractions. When both derivatives act on the internal loop, the coincident-point contraction is sensitive to the high-frequency regulator. After cutoff regularization, the loop momentum k' in the first panel is restricted by $|k'| < \Lambda$. Other first-order contractions are finite or vanish by parity.

The divergent expression is therefore not a value assigned by an already defined continuum measure. It is a signal that the formal product $[Dq] = \prod_k \mathrm{d}\widetilde{q}(k)$ must first be replaced by a regulated finite-dimensional measure, and that the limiting prescription must be specified together with local counterterms.

Definition 8.20 (Frequency cutoff for the derivative interaction)**.** Define a frequency cutoff by

$$q(\tau) = \int_{|k|<\Lambda} \frac{\mathrm{d}k}{2\pi}\, \widetilde{q}(k) \mathrm{e}^{\mathrm{i}k\tau}, \qquad [Dq]_\Lambda = \prod_{|k|<\Lambda} \mathrm{d}\widetilde{q}(k),$$

with the real-field condition $\widetilde{q}(k)^* = \widetilde{q}(-k)$. After the finite-dimensional real slice has been chosen, $[Dq]_\Lambda$ denotes the corresponding finite product Lebesgue measure. The interaction is expanded before $\Lambda \to \infty$.

Local counterterm for the derivative interaction. After restoring $\hbar$, the first-order self-energy has the form

$$\Sigma_\Lambda(k) = \frac{\hbar g}{4}\left(\frac{\Lambda}{\pi} + \frac{k^2}{2} - \frac{1}{2} + O(\Lambda^{-1})\right) + O(\hbar^2 g^2).$$

A local Euclidean counterterm

$$\Delta L_E = C\, g\, \hbar\, \frac{q^2}{2}$$

adds $-Cg\hbar$ to $\Sigma_\Lambda(k)$, so that

$$\Sigma_\Lambda(k) = \hbar g\left(\frac{k^2}{8} + \frac{\Lambda}{4\pi} - \frac{1}{8} - C + O(\Lambda^{-1})\right) + O(g^2).$$

Choosing

$$C = \frac{\Lambda}{4\pi} + C_{\mathrm{fin}}$$

defines a finite limiting two-point function as $\Lambda \to \infty$. The finite constant C_{fin} is part of the quantum definition of the Hamiltonian represented by this regulated Lagrangian path integral. The contraction with two derivatives acting on the loop gives

$$\frac{g}{4}\int \frac{\mathrm{d}k}{2\pi}\frac{\mathrm{e}^{\mathrm{i}k\tau}}{(k^2+1)^2}\int_{|k'|<\Lambda}\frac{\mathrm{d}k'}{2\pi}\frac{k'^2}{k'^2+1}.$$

The cutoff integral is

$$\int_{-\Lambda}^{\Lambda}\frac{\mathrm{d}k'}{2\pi}\frac{k'^2}{k'^2+1} = \frac{1}{\pi}\int_0^\Lambda\left(1 - \frac{1}{k'^2+1}\right)\mathrm{d}k' = \frac{\Lambda - \arctan\Lambda}{\pi}.$$

The remaining first-order contractions are the finite even momentum term and the odd momentum term displayed above. Combining them and expanding $\arctan\Lambda = \pi/2 + O(\Lambda^{-1})$ gives the stated self-energy. The counterterm contributes a local two-point insertion $-Cg\hbar$ in the denominator convention used for Σ. Hence it shifts $\Sigma_\Lambda(k)$ by $-Cg\hbar$. Choosing $C = \Lambda/(4\pi) + C_{\mathrm{fin}}$ removes the linearly divergent local part. The remaining finite family is the one displayed above.

The pole of the regulated two-point function is read from the denominator of

$$\widetilde{G}_\Lambda(k) = \frac{\hbar}{k^2 + 1 - \Sigma_\Lambda(k)}.$$

Finite gap after choosing the finite local term. After the counterterm choice $C = \Lambda/(4\pi) + C_{\text{fin}}$, the first energy gap is

$$\omega_1 = 1 + \hbar g \left(\frac{C_{\text{fin}}}{2} + \frac{1}{8} \right) + O(g^2).$$

Setting $k = \mathrm{i}\omega_1$ in the denominator of $\widetilde{G}_\Lambda(k)$ and expanding to first order in g gives

$$\omega_1 = 1 + \hbar g \left(-\frac{\Lambda}{8\pi} + \frac{C}{2} + \frac{1}{8} \right) + O(g^2) = 1 + \hbar g \left(\frac{C_{\text{fin}}}{2} + \frac{1}{8} \right) + O(g^2).$$

Thus the finite part of the local counterterm is not a removable notation choice; it fixes which quantum Hamiltonian, within the ordering ambiguity of the derivative-coupled classical expression, the path integral represents. Once that quantum definition is fixed, the pole position is an ordinary observable.

Fixing C_{fin} requires physical input, for instance a renormalization condition on the energy gap or an independently specified operator ordering of the Hamiltonian. In a relativistic field theory the analogous finite local terms are constrained by Poincare covariance, locality/microcausality, internal symmetries, and the chosen normalization conditions on observables.

The structural statement carried forward to field theory is this: a path integral with interactions is a regulated construction of Green functions, and local counterterms are part of the data specifying the regulated construction and its limiting prescription. The next chapter replaces the single coordinate $q(\tau)$ by fields $\phi(x)$ and imposes relativistic covariance and locality on the resulting Green functions.

Chapter 9

Relativistic Scalar Fields and Canonical Quantization

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

9.1 Fields and Variational Equations

Definition 9.1 (Classical scalar Lagrangian field datum)**.** Let $\mathbb{M}^D$ be D-dimensional Minkowski spacetime with metric

$$\eta_{\mu\nu} = \mathrm{diag}(-1,+1,\dots,+1).$$

Write

$$x^\mu = (x^0, \vec{x}), \qquad x^0 = t, \qquad \vec{x} \in \mathbb{R}^{D-1}.$$

A real classical scalar field is a real-valued function

$$\phi : \mathbb{M}^D \to \mathbb{R}.$$

The field-theoretic analogue of finitely many coordinates $q^i(t)$ is the family of coordinates $\phi(t, \vec{x})$, labelled continuously by $\vec{x}$. A Lagrangian field theory is specified by an action functional

$$S[\phi] = \int_{\mathbb{M}^D} \mathrm{d}^D x\, \mathcal{L}\big(\phi(x), \partial_\mu \phi(x)\big),$$

where $\mathcal{L}$ is a Lorentz scalar Lagrangian density in the examples below.

For a compactly supported variation $\delta\phi$,

$$\begin{aligned}\delta S &= \int \mathrm{d}^D x \left[\frac{\partial \mathcal{L}}{\partial \phi}\,\delta\phi + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)}\,\partial_\mu \delta\phi\right] \\ &= \int \mathrm{d}^D x\,\delta\phi \left[\frac{\partial \mathcal{L}}{\partial \phi} - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)}\right].\end{aligned}$$

The Euler–Lagrange equation is therefore

$$\frac{\partial \mathcal{L}}{\partial \phi} - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)} = 0.$$

The first equality is the chain rule applied pointwise to $\mathcal{L}(\phi, \partial\phi)$. The second equality follows by integrating $\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi)}\partial_\mu \delta\phi$ by parts. Compact support of $\delta\phi$, or the boundary condition class chosen for the variational problem, removes the boundary term. Since $\delta\phi$ is otherwise arbitrary, the fundamental lemma of the calculus of variations gives the displayed Euler–Lagrange equation as a distributional identity.

9.2 The Free Massive Scalar

Definition 9.2 (Free real Klein–Gordon field)**.** The free massive real scalar field of mass $m \geq 0$ has Lagrangian density

$$\mathcal{L} = \frac{1}{2}(\partial_t \phi)^2 - \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i \phi)^2 - \frac{1}{2}m^2\phi^2.$$

Equivalently,

$$\mathcal{L} = -\frac{1}{2}\partial_\mu \phi\,\partial^\mu \phi - \frac{1}{2}m^2\phi^2, \qquad \partial^\mu = \eta^{\mu\nu}\partial_\nu.$$

The Euler–Lagrange equation is the Klein–Gordon equation

$$(\partial^\mu \partial_\mu - m^2)\phi = 0.$$

Use the Fourier convention

$$\phi(x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D}\,\widetilde{\phi}(k)\,\mathrm{e}^{\mathrm{i}k\cdot x}, \qquad k \cdot x = \eta_{\mu\nu}k^\mu x^\nu = -k^0 x^0 + \vec{k}\cdot\vec{x}.$$

The equation of motion implies

$$(k^2 + m^2)\widetilde{\phi}(k) = 0, \qquad k^2 = \eta_{\mu\nu}k^\mu k^\nu.$$

Thus $\widetilde{\phi}(k)$ is supported on the mass shell

$$k^2 + m^2 = 0, \qquad k^0 = \pm\omega_{\vec{k}}, \qquad \omega_{\vec{k}} = \sqrt{\vec{k}^{\,2} + m^2}.$$

With $k \cdot x = -k^0 x^0 + \vec{k}\cdot\vec{x}$, one has

$$\partial^\mu \partial_\mu \mathrm{e}^{\mathrm{i}k\cdot x} = -\big(k^2\big)\mathrm{e}^{\mathrm{i}k\cdot x}.$$

The Klein–Gordon equation therefore becomes $-(k^2+m^2)\widetilde{\phi}(k)=0$ in Fourier space. In distribution language this says that $\widetilde{\phi}$ is supported where $k^2+m^2=0$. Since $k^2=-(k^0)^2+\vec{k}^{\,2}$, this hypersurface is $(k^0)^2=\vec{k}^{\,2}+m^2$, hence the two branches $k^0=\pm\omega_{\vec{k}}$.

Figure 9.1 displays the two branches of this support condition and fixes the positive-frequency branch used in the canonical expansion below.

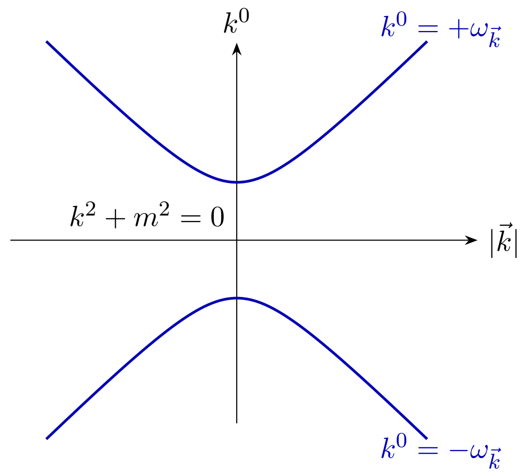

Figure 9.1: Mass shell for a real scalar solution. The Fourier transform $\widetilde{\phi}(k)$ is supported on the two branches $k^0=\pm\omega_{\vec{k}}$ of $k^2+m^2=0$.

Cauchy data and positive-frequency coefficients. A real solution can be written as

$$\phi(t,\vec{x})=\int\frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}}\left[A(\vec{k})\,\mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x}-\mathrm{i}\omega_{\vec{k}}t}+A(\vec{k})^*\,\mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{x}+\mathrm{i}\omega_{\vec{k}}t}\right],$$

with a complex coefficient function $A(\vec{k})$ subject to whatever regularity conditions are imposed on the classical solution. If $m=0$, the spatial zero mode $\vec{k}=0$ is an infrared mode and is treated separately by the chosen boundary condition, volume regulator, or test-function class; the displayed division by $\omega_{\vec{k}}$ applies on the modes with $\omega_{\vec{k}}>0$. The Cauchy data

$$\phi(0,\vec{x}),\qquad \partial_t\phi(0,\vec{x})$$

determine $A(\vec{k})$ and $A(\vec{k})^*$, hence determine the free solution for all t. Explicitly, write

$$\phi(0,\vec{x})=\int\frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}}\,\widetilde{\phi}_0(\vec{k})\mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x}},\qquad \partial_t\phi(0,\vec{x})=\int\frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}}\,\widetilde{\pi}_0(\vec{k})\mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x}}.$$

Then

$$\widetilde{\phi}_0(\vec{k})=A(\vec{k})+A(-\vec{k})^*,\qquad \widetilde{\pi}_0(\vec{k})=-\mathrm{i}\omega_{\vec{k}}\big(A(\vec{k})-A(-\vec{k})^*\big),$$

so that

$$A(\vec{k})=\frac{1}{2}\left(\widetilde{\phi}_0(\vec{k})+\frac{\mathrm{i}}{\omega_{\vec{k}}}\widetilde{\pi}_0(\vec{k})\right).$$

Evaluate the positive- and negative-frequency expansion at $t=0$ and also differentiate it once in time before setting $t=0$. Reality of ϕ identifies the coefficient of $\mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{x}}$ with the complex conjugate coefficient at momentum $\vec{k}$, equivalently $A(-\vec{k})^*$ in the $e^{i\vec{k}\cdot\vec{x}}$ coefficient. This gives the two displayed linear equations for $A(\vec{k})$ and $A(-\vec{k})^*$. Adding $\widetilde{\phi}_0(\vec{k})$ to $i\widetilde{\pi}_0(\vec{k})/\omega_{\vec{k}}$ solves the system and gives the stated formula. The Klein–Gordon equation is second order in time, so these two Cauchy data determine the solution on every time slice.

The displayed coefficient formula is a Fourier-coordinate expression for the free Cauchy problem. Questions about interacting fields and the domain of the quantum Hamiltonian belong to later constructions.

There are two constructions to keep distinct. Canonical quantization starts from the equal-time phase space (ϕ, Π) and a Hamiltonian. The Lagrangian path-integral construction is defined by first choosing a regulator that replaces the field by finitely many coordinates or modes:

$$\int_{\mathcal{C}_R} d\mu_R(\phi_R)\, \exp\left(\frac{i}{\hbar} S_R[\phi_R]\right).$$

Here R labels the chosen cutoff, $\mathcal{C}_R$ is the regulated configuration space, $d\mu_R$ is the corresponding finite-dimensional or lattice measure, and S_R is the regulated action. With the Lorentzian phase $\exp(iS_R/\hbar)$, this regulated object is an oscillatory integral or oscillatory distribution. For quadratic actions it is a Fresnel integral with a determinant magnitude and a phase fixed by the signature of the quadratic form; for general actions, stationary phase and distributional regularization are part of the definition. The continuum symbol $\int [D\phi] \exp(iS[\phi]/\hbar)$ denotes a specified limit or asymptotic expansion of these regulated oscillatory objects. This chapter develops the canonical construction; the scalar field path integral is introduced later.

9.3 Canonical Hamiltonian Formalism

Construction 9.3 (Canonical phase-space variables and Hamiltonian density)**.** Let

$$L(t) = \int d^{D-1}\vec{x}\, \mathcal{L}.$$

The canonical momentum density conjugate to $\phi(t, \vec{x})$ is

$$\Pi(t, \vec{x}) = \frac{\partial \mathcal{L}}{\partial(\partial_t \phi(t, \vec{x}))}.$$

For the free scalar,

$$\Pi(t, \vec{x}) = \partial_t \phi(t, \vec{x}).$$

This agrees with the covariant form of the Lagrangian. Treating the components $\partial_\mu \phi$ as independent variables in $-\frac{1}{2}\eta^{\alpha\beta}\partial_\alpha \phi\, \partial_\beta \phi$, one finds

$$\frac{\partial \mathcal{L}}{\partial(\partial_0 \phi)} = -\eta^{0\nu}\partial_\nu \phi = -\partial^0 \phi = \partial_0 \phi = \partial_t \phi,$$

because the mostly-plus metric gives $\partial^0 = \eta^{00}\partial_0 = -\partial_0$. The two minus signs, one from the covariant kinetic term and one from raising the time index, therefore cancel. The Hamiltonian density is

$$\mathcal{H} = \Pi\, \partial_t \phi - \mathcal{L},$$

and therefore

$$\mathcal{H} = \frac{1}{2}\Pi^2 + \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i\phi)^2 + \frac{1}{2}m^2\phi^2$$

for the free scalar field. The Hamiltonian is

$$H = \int \mathrm{d}^{D-1}\vec{x}\,\mathcal{H}.$$

This is a classical Hamiltonian density. After quantization $\widehat{\phi}(t,\vec{x})$ and $\widehat{\Pi}(t,\vec{x})$ are operator-valued distributions, so the pointwise products in $\frac{1}{2}(\widehat{\Pi}^2+(\nabla\widehat{\phi})^2+m^2\widehat{\phi}^2)$ are first understood with a spatial regulator or after smearing. The free Hamiltonian used below is the regulator limit of the normal-ordered quadratic Hamiltonian, equivalently the operator obtained by subtracting the vacuum scalar term from the regulated quadratic expression. We write this operator as $\widehat{H}_0^{\mathrm{ren}} =: \widehat{H}_0 :$ in the flat-space free theory.

Definition 9.4 (Equal-time scalar Poisson bracket)**.** For functionals $F[\phi,\Pi]$ and $G[\phi,\Pi]$, use the equal-time Poisson bracket

$$\{F,G\} = \int \mathrm{d}^{D-1}\vec{x}\left[\frac{\delta F}{\delta\phi(\vec{x})}\frac{\delta G}{\delta\Pi(\vec{x})} - \frac{\delta F}{\delta\Pi(\vec{x})}\frac{\delta G}{\delta\phi(\vec{x})}\right].$$

Then

$$\{\phi(\vec{x}),\Pi(\vec{y})\} = \delta^{(D-1)}(\vec{x}-\vec{y}),$$

with the ϕ-ϕ and Π-Π brackets equal to zero. Hamilton's equation is

$$\partial_t F = \{F,H\}.$$

Hamilton equations for the scalar field. Using the functional derivatives of H,

$$\frac{\delta H}{\delta\Pi(\vec{x})} = \Pi(\vec{x}), \qquad \frac{\delta H}{\delta\phi(\vec{x})} = -\sum_i \partial_i^2\phi(\vec{x}) + m^2\phi(\vec{x}),$$

where the spatial derivative term has been integrated by parts. Hence

$$\partial_t\phi = \{\phi,H\} = \Pi, \qquad \partial_t\Pi = \{\Pi,H\} = \sum_i \partial_i^2\phi - m^2\phi.$$

Eliminating Π gives $\partial_t^2\phi - \nabla^2\phi + m^2\phi = 0$, equivalently $(\partial^\mu\partial_\mu - m^2)\phi = 0$ with the mostly-plus convention.

9.4 Equal-Time Quantization

Definition 9.5 (Equal-time canonical commutation relations)**.** Canonical quantization promotes the classical fields to operator-valued distributions

$$\widehat{\phi}(t,\vec{x}), \qquad \widehat{\Pi}(t,\vec{x})$$

on a common dense domain. Their equal-time commutation relations are

$$[\widehat{\phi}(t,\vec{x}),\widehat{\Pi}(t,\vec{y})] = \mathrm{i}\hbar\,\delta^{(D-1)}(\vec{x}-\vec{y}),$$

and

$$[\widehat{\phi}(t,\vec{x}),\widehat{\phi}(t,\vec{y})] = 0 = [\widehat{\Pi}(t,\vec{x}),\widehat{\Pi}(t,\vec{y})].$$

All pointwise products are distributional notation. Smeared fields, for test functions $f, g \in C_c^\infty(\mathbb{R}^{D-1})$, are

$$\widehat{\phi}_t(f) = \int \mathrm{d}^{D-1}\vec{x}\, f(\vec{x})\widehat{\phi}(t,\vec{x}), \qquad \widehat{\Pi}_t(g) = \int \mathrm{d}^{D-1}\vec{x}\, g(\vec{x})\widehat{\Pi}(t,\vec{x}).$$

The smeared commutator is

$$[\widehat{\phi}_t(f),\widehat{\Pi}_t(g)] = \mathrm{i}\hbar \int \mathrm{d}^{D-1}\vec{x}\, f(\vec{x})g(\vec{x}).$$

For the rest of this chapter set $\hbar = 1$. With $\hbar$ retained, the oscillator algebra below reads

$$[b_{\vec{k}}, b^\dagger_{\vec{q}}] = \hbar(2\pi)^{D-1}\delta^{(D-1)}(\vec{k}-\vec{q}).$$

Equivalently, the $\hbar = 1$ variables are obtained from the $\hbar$-full variables by $b^{(\hbar=1)}_{\vec{k}} = \hbar^{-1/2} b^{(\hbar)}_{\vec{k}}$.

9.5 Oscillator Variables and the Hamiltonian

Equal-time oscillator variables and the CCR. Let $\nu_{\vec{k}} > 0$ be a positive even function of $\vec{k}$. Define operator-valued distributions $b_{\vec{k}}$ and $b^\dagger_{\vec{k}}$ by the equal-time expansion

$$\widehat{\phi}(0,\vec{x}) = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}} \frac{1}{\sqrt{2\nu_{\vec{k}}}} \left(b_{\vec{k}} \mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x}} + b^\dagger_{\vec{k}} \mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{x}} \right),$$

$$\widehat{\Pi}(0,\vec{x}) = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}} (-\mathrm{i}) \sqrt{\frac{\nu_{\vec{k}}}{2}} \left(b_{\vec{k}} \mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x}} - b^\dagger_{\vec{k}} \mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{x}} \right).$$

The equal-time commutation relations are equivalent to

$$[b_{\vec{k}}, b_{\vec{q}}] = 0 = [b^\dagger_{\vec{k}}, b^\dagger_{\vec{q}}], \qquad [b_{\vec{k}}, b^\dagger_{\vec{q}}] = (2\pi)^{D-1}\delta^{(D-1)}(\vec{k}-\vec{q}).$$

Substitute the mode expansions into the smeared equal-time commutator and use

$$\int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}} \mathrm{e}^{\mathrm{i}\vec{k}\cdot(\vec{x}-\vec{y})} = \delta^{(D-1)}(\vec{x}-\vec{y}).$$

The coefficient $(2\nu_{\vec{k}})^{-1/2}(-\mathrm{i})(\nu_{\vec{k}}/2)^{1/2}$, together with the term obtained by commuting $b^\dagger$ past b, gives exactly $\mathrm{i}\delta^{(D-1)}(\vec{x}-\vec{y})$ when the oscillator commutator has the displayed normalization. Conversely, Fourier transforming the canonical commutator against plane waves recovers the oscillator commutator. The ϕ-ϕ and Π-Π commutators vanish because the b-b and $b^\dagger$-$b^\dagger$ commutators vanish and the remaining terms cancel by $\vec{k} \mapsto -\vec{k}$.

Bogoliubov reparametrizations of oscillator variables. This algebra holds for every positive choice of $\nu_{\vec k}$. The notation $b_{\vec k}$, $b^\dagger_{\vec k}$ should therefore not yet be read as a particle interpretation. If $\lambda_{\vec k} > 0$ is another even function, define $c_{\vec k}$, $c^\dagger_{\vec k}$ by

$$c_{\vec k} + c^\dagger_{-\vec k} = \lambda_{\vec k}\big(b_{\vec k} + b^\dagger_{-\vec k}\big), \qquad c_{\vec k} - c^\dagger_{-\vec k} = \lambda^{-1}_{\vec k}\big(b_{\vec k} - b^\dagger_{-\vec k}\big).$$

Equivalently,

$$c_{\vec k} = \frac{\lambda_{\vec k} + \lambda^{-1}_{\vec k}}{2}\, b_{\vec k} + \frac{\lambda_{\vec k} - \lambda^{-1}_{\vec k}}{2}\, b^\dagger_{-\vec k}.$$

The c's obey the same canonical oscillator algebra. If a vector is annihilated by every $b_{\vec k}$, it is not annihilated by every $c_{\vec k}$ unless $\lambda_{\vec k} = 1$. The Hamiltonian is the datum that selects the oscillator normalization. Write $u_{\vec k} = (\lambda_{\vec k} + \lambda^{-1}_{\vec k})/2$ and $v_{\vec k} = (\lambda_{\vec k} - \lambda^{-1}_{\vec k})/2$. Evenness of λ gives $u_{-\vec k} = u_{\vec k}$ and $v_{-\vec k} = v_{\vec k}$. The only nonzero commutators in $[c_{\vec k}, c^\dagger_{\vec q}]$ are

$$u_{\vec k} u_{\vec q} [b_{\vec k}, b^\dagger_{\vec q}] - v_{\vec k} v_{\vec q} [b_{-\vec q}, b^\dagger_{-\vec k}],$$

and the delta functions set $\vec k = \vec q$. Since $u^2_{\vec k} - v^2_{\vec k} = 1$, the original oscillator normalization is preserved. The c-c and $c^\dagger$-$c^\dagger$ commutators vanish by the same cancellation. Finally, if $b_{\vec k}\Omega_b = 0$, then

$$c_{\vec k}\Omega_b = v_{\vec k} b^\dagger_{-\vec k}\Omega_b,$$

which vanishes for all $\vec k$ only when $v_{\vec k} = 0$, equivalently $\lambda_{\vec k} = 1$.

Free Hamiltonian diagonalization. Let

$$\omega_{\vec k} = \sqrt{\vec k^{\,2} + m^2}.$$

Substituting the mode expansion into the free Hamiltonian gives

$$\widehat H_0 = \int \frac{\mathrm{d}^{D-1}\vec k}{(2\pi)^{D-1}} \left[\frac{\nu^2_{\vec k} + \omega^2_{\vec k}}{2\nu_{\vec k}} \left(b^\dagger_{\vec k} b_{\vec k} + \frac{1}{2}(2\pi)^{D-1}\delta^{(D-1)}(0) \right) \right.$$
$$\left. + \frac{\omega^2_{\vec k} - \nu^2_{\vec k}}{4\nu_{\vec k}} \left(b_{\vec k} b_{-\vec k} + b^\dagger_{\vec k} b^\dagger_{-\vec k} \right) \right].$$

The off-diagonal terms vanish precisely for

$$\nu_{\vec k} = \omega_{\vec k}.$$

Insert the equal-time oscillator expansion into

$$H_0 = \frac{1}{2}\int \mathrm{d}^{D-1}\vec x\, \big(\Pi^2 + (\nabla\phi)^2 + m^2\phi^2\big).$$

The spatial integral pairs momenta $\vec k$ and $-\vec k$. The Π^2 term contributes $\nu_{\vec k}/2$ to $b^\dagger_{\vec k} b_{\vec k}$ and $-\nu_{\vec k}/4$ to the $b_{\vec k} b_{-\vec k} + b^\dagger_{\vec k} b^\dagger_{-\vec k}$ coefficient, while the gradient and mass terms together contribute $\omega^2_{\vec k}/(2\nu_{\vec k})$ to $b^\dagger_{\vec k} b_{\vec k}$ and $\omega^2_{\vec k}/(4\nu_{\vec k})$ to the off-diagonal coefficient. Adding the terms gives the displayed Hamiltonian. Since $\nu_{\vec k} > 0$, the off-diagonal coefficient vanishes if and only if $\nu^2_{\vec k} = \omega^2_{\vec k}$, hence $\nu_{\vec k} = \omega_{\vec k}$.

Definition 9.6 (Free scalar Fock representation)**.** With this choice,

$$\widehat{H}_0 = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}}\, \omega_{\vec{k}} \left(b^\dagger_{\vec{k}} b_{\vec{k}} + \frac{1}{2}(2\pi)^{D-1}\delta^{(D-1)}(0) \right).$$

At finite spatial volume and finite momentum cutoff, the second term is a finite scalar multiple of the identity. A constant multiple of the identity does not change Heisenberg evolution, but the quantum Hamiltonian must be a well-defined self-adjoint operator after the regulator is removed. We therefore choose the additive energy normalization so that the invariant vacuum has zero energy. This is a convention of the flat-spacetime framework with gravity decoupled. If the metric is dynamical, the vacuum expectation of the stress tensor contributes to the cosmological constant, and its finite renormalized value is additional physical data rather than a consequence of normal ordering. With this normalization the free Hamiltonian is

$$\widehat{H}_0^{\mathrm{ren}} = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}}\, \omega_{\vec{k}} b^\dagger_{\vec{k}} b_{\vec{k}}.$$

The free vacuum Ω is defined by

$$b_{\vec{k}}\Omega = 0 \qquad \text{for all } \vec{k},$$

and satisfies $\widehat{H}_0^{\mathrm{ren}}\Omega = 0$.

Heisenberg field and invariant mass-shell normalization. Time evolution generated by $\widehat{H}_0^{\mathrm{ren}}$ gives

$$\widehat{\phi}(x) = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}} \frac{1}{\sqrt{2\omega_{\vec{k}}}} \left(b_{\vec{k}} \mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x} - \mathrm{i}\omega_{\vec{k}} t} + b^\dagger_{\vec{k}} \mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{x} + \mathrm{i}\omega_{\vec{k}} t} \right).$$

The invariant mass-shell normalization used earlier is obtained by defining

$$a(\vec{k}) = \sqrt{2\omega_{\vec{k}}}\, b_{\vec{k}}, \qquad a^\dagger(\vec{k}) = \sqrt{2\omega_{\vec{k}}}\, b^\dagger_{\vec{k}}.$$

Then

$$[a(\vec{k}), a^\dagger(\vec{q})] = (2\pi)^{D-1} 2\omega_{\vec{k}}\, \delta^{(D-1)}(\vec{k} - \vec{q}),$$

and

$$\widehat{\phi}(x) = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1} 2\omega_{\vec{k}}} \left(a(\vec{k}) \mathrm{e}^{\mathrm{i}k\cdot x} + a^\dagger(\vec{k}) \mathrm{e}^{-\mathrm{i}k\cdot x} \right), \qquad k^0 = \omega_{\vec{k}}.$$

This is the convention used for the free scalar field in the earlier Fock-space construction.

The commutator with the normal-ordered Hamiltonian gives

$$[\widehat{H}_0^{\mathrm{ren}}, b_{\vec{k}}] = -\omega_{\vec{k}} b_{\vec{k}}, \qquad [\widehat{H}_0^{\mathrm{ren}}, b^\dagger_{\vec{k}}] = \omega_{\vec{k}} b^\dagger_{\vec{k}},$$

so Heisenberg evolution multiplies $b_{\vec{k}}$ by $\mathrm{e}^{-\mathrm{i}\omega_{\vec{k}} t}$ and $b^\dagger_{\vec{k}}$ by $\mathrm{e}^{+\mathrm{i}\omega_{\vec{k}} t}$. This gives the displayed field. The rescaling $a(\vec{k}) = \sqrt{2\omega_{\vec{k}}}\, b_{\vec{k}}$ transforms the Lebesgue momentum measure into the invariant one-particle mass-shell measure $\mathrm{d}^{D-1}\vec{k}/((2\pi)^{D-1} 2\omega_{\vec{k}})$ and gives the stated commutator for $a, a^\dagger$.

9.6 Covariance and Microcausality

Definition 9.7 (Free scalar field on the finite-particle domain)**.** Let $\mathcal{D}_0$ be the finite-particle domain generated by applying finitely many smeared creation operators to Ω. On $\mathcal{D}_0$, $\widehat{\phi}(x)$ is an operator-valued distribution. For $f \in C_c^\infty(\mathbb{M}^D)$,

$$\widehat{\phi}(f) = \int \mathrm{d}^D x\, f(x)\widehat{\phi}(x)$$

is the corresponding smeared operator on $\mathcal{D}_0$.

Proposition 9.8 (Covariance and microcausality of the free scalar field)**.** *The free Fock representation carries the unitary Poincare representation induced from the one-particle mass shell. With the above normalization, the field transforms as a scalar:*

$$U(a,\Lambda)^{-1}\widehat{\phi}(x)U(a,\Lambda) = \widehat{\phi}(\Lambda x + a).$$

The commutator is

$$[\widehat{\phi}(x), \widehat{\phi}(y)] = \mathrm{i}\,\Delta(x-y),$$

where the Pauli–Jordan distribution is

$$\Delta(x) = \frac{1}{\mathrm{i}}\int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}2\omega_{\vec{k}}}\left(\mathrm{e}^{\mathrm{i}k\cdot x} - \mathrm{e}^{-\mathrm{i}k\cdot x}\right), \qquad k^0 = \omega_{\vec{k}}.$$

This distribution is Lorentz invariant. If x is spacelike, a Lorentz transformation sends it to $(0,\vec{r})$. At equal time,

$$\Delta(0,\vec{r}) = \frac{1}{\mathrm{i}}\int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}2\omega_{\vec{k}}}\left(\mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{r}} - \mathrm{e}^{-\mathrm{i}\vec{k}\cdot\vec{r}}\right) = 0,$$

because the two terms are exchanged by $\vec{k} \mapsto -\vec{k}$. Therefore

$$[\widehat{\phi}(x), \widehat{\phi}(y)] = 0 \qquad \text{when } (x-y)^2 > 0.$$

Equivalently,

$$[\widehat{\phi}(f), \widehat{\phi}(g)] = 0$$

when $\operatorname{supp} f$ *and* $\operatorname{supp} g$ *are spacelike separated. This verifies microcausality for the canonically quantized free scalar field.*

Proof. The one-particle Hilbert space is

$$L^2\left(\{k^2 + m^2 = 0,\ k^0 > 0\}, \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1}2\omega_{\vec{k}}}\right),$$

and the positive-energy mass-shell measure is Lorentz invariant. The induced unitary representation acts by translating phases and by pulling back the mass-shell momentum under Lorentz transformations; second quantization gives the Fock-space representation. Substituting this action into the mass-shell expansion of $\widehat{\phi}(x)$ gives the displayed scalar covariance law.

The commutator computation uses only $[a(\vec{k}), a^\dagger(\vec{q})] = (2\pi)^{D-1}2\omega_{\vec{k}}\delta^{(D-1)}(\vec{k}-\vec{q})$, and yields $[\widehat{\phi}(x), \widehat{\phi}(y)] = \mathrm{i}\Delta(x-y)$. The distribution Δ is Lorentz invariant because the mass-shell measure and the condition $k^0 > 0$ are invariant under proper orthochronous Lorentz transformations, and the difference between the two exponentials gives the antisymmetric solution of the Klein–Gordon equation. If $x - y$ is spacelike, a Lorentz transformation sends it to an equal-time vector $(0, \vec{r})$. The equal-time integral vanishes by the change of variables $\vec{k} \mapsto -\vec{k}$. Thus $\Delta(x - y) = 0$ for spacelike separation. After smearing, the commutator is the pairing of $\Delta(x - y)$ with $f(x)g(y)$, so it vanishes whenever the two supports are spacelike separated. $\square$

Remark 9.9. For the scalar field, locality is carried by the commutator. The Pauli–Jordan distribution is the difference of the positive-frequency two-point distribution and its reversed argument, and this difference is supported on the causal cone. The anticommutator has the symmetric vacuum distribution

$$\Delta_+(x - y) + \Delta_+(y - x),$$

whose equal-time spacelike kernel is proportional to

$$\int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1} 2\omega_{\vec{k}}} \cos(\vec{k} \cdot \vec{r}).$$

This distribution is not supported in the causal cone and generally has nonzero spacelike matrix elements. The graded sign in the locality bracket is therefore part of the structure fixed by spin and positivity, rather than an optional convention. The corresponding spin-statistics theorem-level hypotheses are stated in Chapter 40.

The next step in the construction is to identify the local currents and charges attached to spacetime symmetries. That is the role of Noether's theorem in the following chapter.

Chapter 10

Symmetries, Noether Currents, and Stress Tensors

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

10.1 Variational Framework

Definition 10.1 (First-derivative classical field datum)**.** Work on D-dimensional Minkowski spacetime $\mathbb{M}^D$, with mostly-plus metric $\eta_{\mu\nu}$. Let A range over a finite set of bosonic field components. A classical field configuration is a smooth map

$$\phi : M \longrightarrow \mathbb{R}^N, \qquad x \longmapsto \{\phi^A(x)\},$$

on a spacetime region $M \subset \mathbb{M}^D$. In this chapter a Lagrangian density means a first-derivative local expression

$$\mathcal{L} = \mathcal{L}(\phi^A, \partial_\mu \phi^A)$$

with no dependence on derivatives of order two or higher. The corresponding action over M is

$$S_M[\phi] = \int_M \mathrm{d}^D x\, \mathcal{L}(\phi, \partial\phi).$$

A variation is a smooth one-parameter family ϕ_s with $\phi_0 = \phi$; its tangent is

$$\delta\phi^A = \frac{\mathrm{d}}{\mathrm{d}s}\phi^A_s\bigg|_{s=0}.$$

When the boundary term is not part of the question, $\delta\phi^A$ is assumed to have compact support in M°, the interior of M.

First variational identity. For the datum of Definition 10.1, define the Euler–Lagrange expression

$$E_A(\mathcal{L}) = \frac{\partial \mathcal{L}}{\partial \phi^A} - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}.$$

Then every smooth variation satisfies

$$\delta\mathcal{L} = E_A(\mathcal{L})\,\delta\phi^A + \partial_\mu \theta^\mu(\delta\phi), \qquad \theta^\mu(\delta\phi) = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}\delta\phi^A,$$

where repeated component and spacetime indices are summed. Consequently

$$\delta S_M = \int_M \mathrm{d}^D x\, E_A(\mathcal{L})\,\delta\phi^A + \int_{\partial M} \mathrm{d}\Sigma_\mu\, \theta^\mu(\delta\phi),$$

where $\mathrm{d}\Sigma_\mu$ is the oriented hypersurface measure on ∂M.

The chain rule gives

$$\delta\mathcal{L} = \frac{\partial \mathcal{L}}{\partial \phi^A}\delta\phi^A + \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}\partial_\mu \delta\phi^A.$$

Apply the product rule to the second term:

$$\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}\partial_\mu \delta\phi^A = \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}\delta\phi^A \right) - \partial_\mu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)}\delta\phi^A.$$

Combining the two non-divergence terms gives $E_A(\mathcal{L})\delta\phi^A$. Integrating the pointwise identity over M and applying Stokes' theorem gives the displayed formula for δS_M.

Definition 10.2 (Classical solution)**.** A classical solution of the first-derivative Lagrangian problem is a field configuration obeying

$$E_A(\mathcal{L}) = 0$$

for every component A, together with the boundary or asymptotic conditions specified by the variational problem. The Euler–Lagrange equation alone is not a complete boundary-value or Cauchy problem; the boundary data are part of the definition of the classical problem being solved.

10.2 Infinitesimal Symmetries

Definition 10.3 (Infinitesimal variational symmetry)**.** An infinitesimal field-space transformation is a rule

$$\delta_R \phi^A = R^A[\phi],$$

where $R^A[\phi]$ is a local expression in x, the fields, and finitely many derivatives of the fields. The transformation is a variational symmetry of the action if there exists a local vector K_R^μ such that

$$\delta_R \mathcal{L} = \partial_\mu K_R^\mu.$$

This equation is the definition of the symmetry in the present classical Lagrangian framework. It is an off-shell identity of local functions of the fields; no Euler–Lagrange equation has yet been imposed.

Noether identity for a variational symmetry. Let R be a variational symmetry in the sense of Definition 10.3. The local current

$$j^\mu_R = \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} R^A - K^\mu_R$$

obeys the off-shell identity

$$E_A(\mathcal{L})R^A + \partial_\mu j^\mu_R = 0. \tag{10.1}$$

This identity is an equality in the algebra of local functions on the finite jet bundle used by the Lagrangian; it is not an equality only after integrating over spacetime. The current is defined modulo an identically conserved improvement $\partial_\nu B^{[\nu\mu]}$, and the identity is unchanged by such a replacement. In particular, on every classical solution,

$$\partial_\mu j^\mu_R = 0.$$

The first variational identity from the preceding section is the load-bearing input. It separates the variation of the Lagrangian density into the Euler–Lagrange part and a total derivative before imposing any equation of motion. For the variation $\delta_R \phi^A = R^A$, it gives the pointwise jet identity

$$\delta_R \mathcal{L} = E_A(\mathcal{L})R^A + \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} R^A \right).$$

The variational-symmetry condition is the second independent input: there exists a local K^μ_R such that $\delta_R \mathcal{L} = \partial_\mu K^\mu_R$ as an off-shell local identity. Subtracting this total derivative from the preceding display gives

$$0 = E_A(\mathcal{L})R^A + \partial_\mu \left(\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} R^A - K^\mu_R \right),$$

which is the stated Noether identity. On a classical solution the Euler–Lagrange term vanishes componentwise, and the current is conserved. The improvement statement follows because $\partial_\mu \partial_\nu B^{[\nu\mu]} = 0$ by antisymmetry and commutativity of ordinary partial derivatives.

Localized-parameter form of Noether's theorem. Let $\epsilon \in C^\infty_c(M)$, and localize the transformation by

$$\delta_{\epsilon R} \phi^A = \epsilon R^A.$$

For a first-derivative Lagrangian,

$$\delta_{\epsilon R} \mathcal{L} = \partial_\mu(\epsilon K^\mu_R) + (\partial_\mu \epsilon) j^\mu_R.$$

Thus, for compactly supported ϵ,

$$\delta_{\epsilon R} S_M = \int_M \mathrm{d}^D x \, (\partial_\mu \epsilon) \, j^\mu_R.$$

If the field is a classical solution, this identity is equivalent, as a distributional statement, to $\partial_\mu j^\mu_R = 0$. The verification is the local variation formula with the parameter left unintegrated. Using the chain rule,

$$\delta_{\epsilon R} \mathcal{L} = \epsilon \, \delta_R \mathcal{L} + (\partial_\mu \epsilon) \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} R^A.$$

Since $\delta_R\mathcal{L} = \partial_\mu K_R^\mu$,

$$\epsilon\,\partial_\mu K_R^\mu = \partial_\mu(\epsilon K_R^\mu) - (\partial_\mu\epsilon)K_R^\mu.$$

Combining the two $\partial_\mu\epsilon$ terms gives $(\partial_\mu\epsilon)j_R^\mu$. The integral of $\partial_\mu(\epsilon K_R^\mu)$ vanishes because ϵ has compact support in M. On a solution the first variation of the action by a compactly supported variation vanishes, hence

$$0 = \int_M \mathrm{d}^D x\,(\partial_\mu\epsilon)j_R^\mu = -\int_M \mathrm{d}^D x\,\epsilon\,\partial_\mu j_R^\mu.$$

The fundamental lemma of distributions then gives $\partial_\mu j_R^\mu = 0$. The converse follows by integrating by parts.

Definition 10.4 (Current improvement)**.** The Noether current is a representative of a local equivalence class. If

$$B_R^{\nu\mu} = -B_R^{\mu\nu},$$

then

$$j_R^\mu \longmapsto j_R^\mu + \partial_\nu B_R^{\nu\mu}$$

is called a current improvement. It has the same local divergence because $\partial_\mu\partial_\nu B_R^{\nu\mu} = 0$. The corresponding integrated charge is unchanged when the surface integral of B_R at spatial boundary vanishes in the stated boundary condition or asymptotic domain.

10.3 Charges and Generators

Definition 10.5 (Classical charge of a conserved current)**.** Let $\Sigma_t = \{x^0 = t\}$ be a constant-time slice. If j_R^μ is conserved and the spatial integral exists, the charge on Σ_t is

$$Q_R(t) = \int_{\Sigma_t} \mathrm{d}^{D-1}\vec{x}\,j_R^0(t,\vec{x}).$$

For a spatial region $V \subset \mathbb{R}^{D-1}$, the finite-region charge is

$$Q_R^V(t) = \int_V \mathrm{d}^{D-1}\vec{x}\,j_R^0(t,\vec{x}).$$

The existence of $Q_R(t)$ is an analytic condition on the solution and on the asymptotic domain; it is not implied by the local equation $\partial_\mu j_R^\mu = 0$ alone.

Remark 10.6 (Charge balance in a spacetime slab). Let $V \subset \mathbb{R}^{D-1}$ be a spatial region with piecewise smooth boundary, and assume j_R^μ is smooth on $[t_1, t_2] \times V$ with $\partial_\mu j_R^\mu = 0$. Then

$$Q_R^V(t_2) - Q_R^V(t_1) = -\int_{t_1}^{t_2} \mathrm{d}x^0 \int_{\partial V} \mathrm{d}S_i\,j_R^i(x^0,\vec{x}),$$

where $\mathrm{d}S_i = n_i\,\mathrm{d}S$, n_i is the outward unit normal to ∂V, and $\mathrm{d}S$ is the Euclidean surface measure on ∂V. Hence $Q_R(t)$ is time independent whenever the boundary flux tends to zero in the limit $V \nearrow \mathbb{R}^{D-1}$. It follows by integrating $\partial_0 j_R^0 + \partial_i j_R^i = 0$ over the slab and applying the ordinary divergence theorem. The sign follows from using the outward spatial normal: positive outward flux reduces the charge remaining inside V. For an exhaustion $V_R \nearrow \mathbb{R}^{D-1}$, the infinite-volume charge is conserved provided $Q_R^{V_R}(t)$ has a limit and the corresponding boundary-flux integral tends to zero.

Figure 10.1 records the slab geometry behind the charge-conservation identity: time-slice charges differ exactly by flux through the spatial boundary.

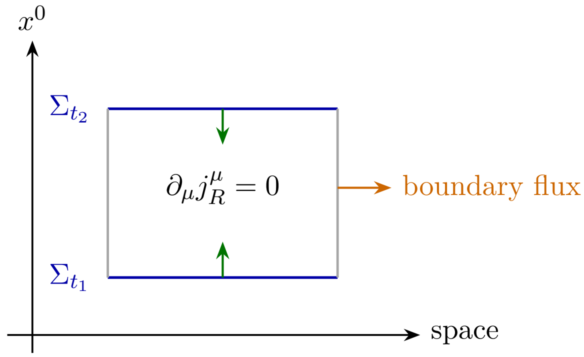

Figure 10.1: Current conservation in a spacetime slab. The difference between charges on Σ_{t_1} and Σ_{t_2} is the flux through the spatial boundary.

Definition 10.7 (Equal-time Poisson bracket and Hamiltonian generator)**.** Let Π_A denote the canonical momentum conjugate to ϕ^A. On the phase-space functionals whose variational derivatives and boundary terms are defined, the equal-time Poisson bracket is

$$\{F, G\} = \int \mathrm{d}^{D-1}\vec{x} \left[\frac{\delta F}{\delta \phi^A(\vec{x})} \frac{\delta G}{\delta \Pi_A(\vec{x})} - \frac{\delta F}{\delta \Pi_A(\vec{x})} \frac{\delta G}{\delta \phi^A(\vec{x})} \right].$$

In particular,

$$\{\phi^A(\vec{x}), \Pi_B(\vec{y})\} = \delta^A{}_B \, \delta^{(D-1)}(\vec{x} - \vec{y}).$$

A charge Q_R generates the infinitesimal transformation R on canonical observables if

$$\delta_R F = \{F, Q_R\}$$

for every functional F in the stated domain. Applied to the coordinate field this condition reads

$$R^A(t, \vec{x}) = \{\phi^A(t, \vec{x}), Q_R\}.$$

First-order Noether charges as phase-space generators. Assume $K^0_R = 0$, and assume R^A depends on the canonical coordinates and their spatial derivatives but not on the velocities or momenta. If the Noether charge is represented on phase space by

$$Q_R = \int_{\Sigma_t} \mathrm{d}^{D-1}\vec{x} \, \Pi_A R^A$$

up to spatial-divergence improvements whose boundary integrals vanish, then

$$\{\phi^A(t, \vec{x}), Q_R\} = R^A(t, \vec{x}).$$

More generally, if R^A or K^0_R contains velocities, the current obtained from the Lagrangian calculation must first be expressed as a functional on phase space before the generator statement is tested.

Under the stated hypotheses the functional derivative of Q_R with respect to $\Pi_A(\vec{x})$ is $R^A(\vec{x})$. The equal-time bracket in Definition 10.7 therefore gives

$$\{\phi^A(\vec{x}), Q_R\} = \frac{\delta Q_R}{\delta \Pi_A(\vec{x})} = R^A(\vec{x}).$$

Spatial-divergence improvements do not change the result under the assumed boundary condition. If velocities occur, the expression $\int j_R^0$ is not yet a function on canonical phase space; the Legendre map must be used first, and the displayed derivative calculation is then performed on the resulting phase-space functional.

Example 10.8 (Time translation)**.** For a time translation by τ,

$$R^A = -\tau\dot{\phi}^A, \qquad Q_R = -\tau H.$$

Hamilton's equation yields

$$\{\phi^A, -\tau H\} = -\tau\dot{\phi}^A.$$

Thus the generator statement is a phase-space statement with the Noether charge expressed in canonical variables.

10.4 Poincare Transformations of Scalar Fields

Definition 10.9 (Scalar representation of the Poincare group)**.** For a scalar field, a finite proper orthochronous Poincare transformation is described by

$$x'^\mu = \Lambda^\mu{}_\nu x^\nu + a^\mu, \qquad \phi'(x') = \phi(x),$$

where $\Lambda^T\eta\Lambda = \eta$. Equivalently,

$$\phi'(x) = \phi\big(\Lambda^{-1}(x-a)\big).$$

Write $\Lambda^\mu{}_\nu = \delta^\mu{}_\nu + \omega^\mu{}_\nu + O(\omega^2)$, with $\omega_{\mu\nu} = -\omega_{\nu\mu}$. The fixed-coordinate infinitesimal variation is

$$\delta\phi(x) = -\left(a^\mu + \omega^\mu{}_\nu x^\nu\right)\partial_\mu\phi(x).$$

The translation and Lorentz currents below are the Noether currents for the two independent parameters a^μ and $\omega_{\mu\nu}$.

10.5 Translation Symmetry and the Stress Tensor

Canonical stress tensor from translations. Assume that $\mathcal{L}$ has no explicit dependence on x. For a constant vector ξ^ν, use the fixed-coordinate field variation

$$\delta_\xi\phi^A(x) = -\xi^\nu\partial_\nu\phi^A(x).$$

Then the translation Noether current can be written

$$j_\xi^\mu = \xi^\nu T^\mu{}_\nu,$$

where

$$T^{\mu}{}_{\nu} = -\frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} \partial_\nu \phi^A + \delta^{\mu}{}_{\nu}\, \mathcal{L}.$$

On solutions,

$$\partial_\mu T^{\mu}{}_{\nu} = 0.$$

Equivalently, for compactly supported $\xi^\nu(x)$,

$$\delta_\xi S_M = \int_M \mathrm{d}^D x\, (\partial_\mu \xi^\nu)\, T^{\mu}{}_{\nu},$$

after the compactly supported total derivative has been separated. Thus $T^{\mu}{}_{\nu}$ is the response coefficient for a localized translation.

For constant ξ^ν, the density has no explicit coordinate dependence. Translation invariance of the scalar local density gives

$$\delta_\xi \mathcal{L} = -\xi^\nu \partial_\nu \mathcal{L} = \partial_\mu K^\mu_\xi, \qquad K^\mu_\xi = -\xi^\mu \mathcal{L}.$$

Substituting $R^A = -\xi^\nu \partial_\nu \phi^A$ and this K^μ_ξ into the identity (10.1) gives

$$j^\mu_\xi = -\xi^\nu \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} \partial_\nu \phi^A + \xi^\mu \mathcal{L} = \xi^\nu T^{\mu}{}_{\nu}.$$

Since ξ^ν is arbitrary, conservation of j^μ_ξ for every constant ξ^ν is equivalent to $\partial_\mu T^{\mu}{}_{\nu} = 0$.

For local $\xi^\nu(x)$, compute directly:

$$\delta_\xi \mathcal{L} = -\xi^\nu \partial_\nu \mathcal{L} - (\partial_\mu \xi^\nu) \frac{\partial \mathcal{L}}{\partial(\partial_\mu \phi^A)} \partial_\nu \phi^A.$$

The first term is $-\partial_\mu(\xi^\mu \mathcal{L}) + (\partial_\mu \xi^\mu)\mathcal{L}$. The coefficient of $\partial_\mu \xi^\nu$ is therefore precisely $T^{\mu}{}_{\nu}$. Integration over M gives the localized-translation formula because the total derivative has compact support.

Definition 10.10 (Translation charges)**.** When the spatial integrals exist, the momentum covector and vector are

$$P_\nu = \int \mathrm{d}^{D-1}\vec{x}\, T^{0}{}_{\nu}, \qquad P^\nu = \eta^{\nu\rho} P_\rho = \int \mathrm{d}^{D-1}\vec{x}\, T^{0\nu}.$$

With the mostly-plus metric, P^0 is the energy. Equivalently, $P_0 = -P^0$.

Stress tensor of a real scalar field. For

$$\mathcal{L} = -\frac{1}{2} \partial_\rho \phi\, \partial^\rho \phi - V(\phi),$$

the canonical stress tensor is

$$T^{\mu}{}_{\nu} = \partial^\mu \phi\, \partial_\nu \phi - \delta^{\mu}{}_{\nu} \left(\frac{1}{2} \partial_\rho \phi\, \partial^\rho \phi + V(\phi) \right).$$

Raising the second index,

$$T^{\mu\nu} = \eta^{\nu\rho} T^{\mu}{}_{\rho},$$

gives a symmetric tensor in this example. Its energy density is

$$T^{00} = \frac{1}{2}(\partial_0\phi)^2 + \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i\phi)^2 + V(\phi).$$

For the free scalar field, $V(\phi) = \frac{1}{2}m^2\phi^2$, this is the Hamiltonian density obtained by canonical quantization.

The derivative of the Lagrangian with respect to $\partial_\mu\phi$ is

$$\frac{\partial\mathcal{L}}{\partial(\partial_\mu\phi)} = -\partial^\mu\phi.$$

Substitution into the translation-current formula above gives the displayed $T^{\mu}{}_{\nu}$. Since

$$T^{\mu\nu} = \partial^\mu\phi\,\partial^\nu\phi - \eta^{\mu\nu}\left(\frac{1}{2}\partial_\rho\phi\,\partial^\rho\phi + V(\phi)\right),$$

the tensor is symmetric. Finally, with $\eta_{00} = -1$,

$$\partial_\rho\phi\,\partial^\rho\phi = -(\partial_0\phi)^2 + \sum_{i=1}^{D-1}(\partial_i\phi)^2,$$

and the displayed expression for T^{00} follows.

10.6 Metric Variation and Improvement

Definition 10.11 (Lorentzian Hilbert stress tensor)**.** Suppose the flat-space action is obtained by restricting a generally covariant background-metric action $S_g[\phi]$ to $g_{\mu\nu} = \eta_{\mu\nu}$. With the Lorentzian mostly-plus action convention used in this volume, the Hilbert stress tensor is defined by

$$T_{\mathrm{H}}^{\mu\nu}(x) = \frac{2}{\sqrt{|g|}}\frac{\delta S_g}{\delta g_{\mu\nu}(x)}\bigg|_{g=\eta}.$$

Equivalently,

$$\delta_g S_g = \frac{1}{2}\int \mathrm{d}^D x\,\sqrt{|g|}\,T_{\mathrm{H}}^{\mu\nu}\,\delta g_{\mu\nu}.$$

Using $\delta g^{\mu\nu} = -g^{\mu\rho}g^{\nu\sigma}\delta g_{\rho\sigma}$, this is the same as

$$T_{\mathrm{H}}^{\mu\nu}(x) = -\frac{2}{\sqrt{|g|}}g^{\mu\rho}g^{\nu\sigma}\frac{\delta S_g}{\delta g^{\rho\sigma}(x)}\bigg|_{g=\eta}.$$

The Euclidean source-functional chapters state their Euclidean sign convention separately. The chain-rule conversion between covariant and contravariant metric variations is the same; the sign attached to the stress tensor depends on whether one is varying the Lorentzian action or the Euclidean $\exp(-S_E)$ source functional.

Minimal scalar Hilbert tensor. For the minimally coupled scalar action

$$S_g[\phi] = \int \mathrm{d}^D x \, \sqrt{|g|} \left(-\frac{1}{2} g^{\rho\sigma} \partial_\rho \phi \, \partial_\sigma \phi - V(\phi) \right),$$

Definition 10.11 gives

$$T_{\mathrm{H}}^{\mu\nu} = \partial^\mu \phi \, \partial^\nu \phi - g^{\mu\nu} \left(\frac{1}{2} \partial_\rho \phi \, \partial^\rho \phi + V(\phi) \right),$$

which agrees in flat space with the canonical tensor computed above.

Vary with respect to the contravariant metric. The determinant identity is

$$\delta \sqrt{|g|} = -\frac{1}{2} \sqrt{|g|} \, g_{\mu\nu} \delta g^{\mu\nu}.$$

Therefore

$$\delta_g S_g = -\frac{1}{2} \int \mathrm{d}^D x \, \sqrt{|g|} \left[\partial_\mu \phi \, \partial_\nu \phi + g_{\mu\nu} \left(-\frac{1}{2} g^{\rho\sigma} \partial_\rho \phi \, \partial_\sigma \phi - V \right) \right] \delta g^{\mu\nu}.$$

Comparing with the contravariant form of Definition 10.11 gives

$$T_{\mathrm{H}\,\mu\nu} = \partial_\mu \phi \, \partial_\nu \phi + g_{\mu\nu} \left(-\frac{1}{2} \partial_\rho \phi \, \partial^\rho \phi - V \right).$$

Raising both indices gives the displayed expression.

Definition 10.12 (Stress-tensor improvement)**.** Stress tensors that differ by

$$T^{\mu\nu} \longmapsto T^{\mu\nu} + \partial_\rho B^{\rho\mu\nu}, \qquad B^{\rho\mu\nu} = -B^{\mu\rho\nu},$$

have the same local conservation law. They define the same translation charges when the resulting surface integrals vanish. The choice of representative matters for local operator identities and for couplings to background geometry, so the representative is part of the framework.

10.7 Lorentz Currents

Lorentz current from a symmetric stress tensor. For a scalar field, an infinitesimal Lorentz transformation is specified by $\omega_{\mu\nu} = -\omega_{\nu\mu}$ and

$$\delta_\omega \phi(x) = -\omega^\mu{}_\nu x^\nu \partial_\mu \phi(x).$$

If $T^{\mu\nu} = T^{\nu\mu}$ and $\partial_\mu T^{\mu\nu} = 0$, then

$$M^{\mu,\rho\sigma} = x^\rho T^{\mu\sigma} - x^\sigma T^{\mu\rho}$$

is conserved:

$$\partial_\mu M^{\mu,\rho\sigma} = 0.$$

The Lorentz current for parameter $\omega_{\rho\sigma}$ is

$$j^\mu_\omega = \frac{1}{2} \omega_{\rho\sigma} M^{\mu,\rho\sigma},$$

and the corresponding charges, when the spatial integrals exist, are

$$J^{\rho\sigma} = \int \mathrm{d}^{D-1}\vec{x}\, \left(x^\rho T^{0\sigma} - x^\sigma T^{0\rho}\right).$$

The current is obtained by contracting the antisymmetric Lorentz parameter with the antisymmetric tensor $M^{\mu,\rho\sigma}$. The factor 1/2 compensates for the double counting of the ordered pairs (ρ, σ) and (σ, ρ). To verify conservation, differentiate $M^{\mu,\rho\sigma}$ as an ordinary distribution:

$$\partial_\mu M^{\mu,\rho\sigma} = T^{\rho\sigma} + x^\rho \partial_\mu T^{\mu\sigma} - T^{\sigma\rho} - x^\sigma \partial_\mu T^{\mu\rho}.$$

Stress-tensor conservation removes the terms proportional to x, and symmetry of $T^{\mu\nu}$ removes the remaining difference. Therefore $\partial_\mu M^{\mu,\rho\sigma} = 0$, and contraction with the constant $\omega_{\rho\sigma}$ gives $\partial_\mu j^\mu_\omega = 0$. If the spatial integral of $M^{0,\rho\sigma}$ exists after the boundary conditions or smearing prescription have been specified, this conserved current defines the charge $J^{\rho\sigma}$.

Remark 10.13 (Spin terms and Belinfante improvement). For fields carrying Lorentz or spinor indices, the Lorentz current includes an additional spin current. In such cases one either keeps the canonical spin current explicitly or passes to a Belinfante-improved symmetric stress tensor, provided the improvement is defined and the boundary conditions make the charges equivalent. The spinor chapter fixes the corresponding representation matrices before using these currents.

10.8 Quantum Currents and Charges

Definition 10.14 (Quantum current)**.** In a quantum field theory, a current is a vector of operator-valued distributions j^μ_R on a common dense domain $\mathcal{D} \subset \mathcal{H}$. For $f \in C_c^\infty(\mathbb{M}^D)$, the smeared current is denoted

$$j^\mu_R(f) = \int \mathrm{d}^D x\, f(x) j^\mu_R(x).$$

Current conservation is a distributional statement:

$$\partial_\mu j^\mu_R = 0.$$

Equivalently, for all $\psi, \chi \in \mathcal{D}$ and all $f \in C_c^\infty(\mathbb{M}^D)$,

$$\sum_{\mu=0}^{D-1} \langle \psi, j^\mu_R(\partial_\mu f)\chi \rangle = 0,$$

with the derivative acting on the test function. This is the operator-valued distributional version of integration by parts.

Definition 10.15 (Regulated Ward identity and contact terms)**.** In correlation functions with local insertions, the quantum statement is a Ward identity of distributions and includes contact terms on collision diagonals. Its precise form is part of the chosen quantum construction. In a regulated source-functional presentation, let

$$X = \prod_{i=1}^{n} \mathcal{O}_i(x_i)$$

be a product of renormalized local insertions and let the local symmetry parameter be $\epsilon(x)$. The finite-regulator change of variables gives

$$\int \mathrm{d}^D x\,(\partial_\mu\epsilon)(x)\,\left\langle j^\mu_R(x)X\right\rangle_{\mathrm{reg}} = \langle\delta_{\epsilon R}X\rangle_{\mathrm{reg}} + \langle\mathcal{A}_{\epsilon,R}X\rangle_{\mathrm{reg}}\,. \tag{10.2}$$

Here $\mathcal{A}_{\epsilon,R}$ is the local term produced by the variation of the regulated integration density and by the local counterterms in the source-coordinate system; in a fermionic path integral this density is the finite Berezinian density described in Chapter 40. If the symmetry is implemented without anomaly in the chosen regularization and source-coordinate system, $\mathcal{A}_{\epsilon,R}=0$. The first term on the right of (10.2) gives contact distributions supported at $x=x_i$:

$$\delta_{\epsilon R}X = \sum_i \epsilon(x_i)\,\mathcal{O}_1(x_1)\cdots(\delta_R\mathcal{O}_i)(x_i)\cdots\mathcal{O}_n(x_n),$$

with the corresponding spin or derivative-of-delta terms when the inserted operators carry spacetime indices or derivatives. After the regulator is removed, (10.2) becomes an identity in the renormalized source-functional contact-term chart. The fixed-point version used later is formulated in Section 56.6, with the status of the source brackets specified in Definition 56.5.

Definition 10.16 (Quantum charge as a smeared limit)**.** A quantum charge is defined as a limit of smeared local charges when that limit exists. Choose a compactly supported time smearing $f_t(x^0)$ concentrated near t, normalized by $\int \mathrm{d}x^0\, f_t(x^0)=1$, and spatial cutoff functions $\chi_R(\vec{x})$ with $\chi_R\to 1$ as $R\to\infty$. The regulated charge is

$$Q_R[f_t,\chi_R] = \int \mathrm{d}^D x\, f_t(x^0)\chi_R(\vec{x})j^0_R(x).$$

If these operators converge on a specified domain, the limit is the charge operator Q_R. If Q_R is essentially self-adjoint or has a chosen self-adjoint extension, it exponentiates to a one-parameter unitary group by Stone's theorem.

Definition 10.17 (Quantum generator convention)**.** With the fixed-coordinate Noether convention, the infinitesimal quantum action on an operator $\widehat{\mathcal{O}}$ is

$$\delta_R\widehat{\mathcal{O}} = \frac{\mathrm{i}}{\hbar}[Q_R,\widehat{\mathcal{O}}]$$

on the common domain where the commutator is defined. For spacetime translations the covariance convention of the earlier chapters is

$$U(a)^{-1}\widehat{\Phi}_A(x)U(a) = \widehat{\Phi}_A(x+a), \qquad U(a) = \exp\left(\frac{\mathrm{i}}{\hbar}a^\nu P_\nu\right).$$

Translation commutator convention. The convention in Definition 10.17 is equivalent to

$$[P_\nu,\widehat{\Phi}_A(x)] = \mathrm{i}\hbar\,\partial_\nu\widehat{\Phi}_A(x)$$

in distributional notation. Differentiate

$$U(a)^{-1}\widehat{\Phi}_A(x)U(a) = \widehat{\Phi}_A(x+a)$$

with respect to a^ν at $a=0$, using $U(a)=\exp(\mathrm{i}a^\rho P_\rho/\hbar)$. The derivative of the left hand side is

$$-\frac{\mathrm{i}}{\hbar}P_\nu\widehat{\Phi}_A(x) + \frac{\mathrm{i}}{\hbar}\widehat{\Phi}_A(x)P_\nu = -\frac{\mathrm{i}}{\hbar}[P_\nu,\widehat{\Phi}_A(x)].$$

The derivative of the right hand side is $\partial_\nu\widehat{\Phi}_A(x)$. Multiplying by $\mathrm{i}\hbar$ gives the claimed commutator.

Definition 10.18 (Stress-tensor charges in the quantum theory)**.** When a renormalized stress tensor exists as a local operator-valued distribution, the Poincare generators are represented by

$$P^\nu = \int \mathrm{d}^{D-1}\vec{x}\, T^{0\nu}(x),$$

and, for a symmetric stress tensor in the scalar case,

$$J^{\rho\sigma} = \int \mathrm{d}^{D-1}\vec{x}\, \left(x^\rho T^{0\sigma}(x) - x^\sigma T^{0\rho}(x)\right),$$

with the same regulator-and-limit interpretation as for general charges. The quantum theory must specify the operator domains, renormalization prescription, conservation law, and boundary behavior under which the classical Noether densities define these charges.

Once those data are fixed, the stress tensor is the local bridge between spacetime symmetry and the generators that act on states and fields.

Chapter 11

Scalar Path Integrals and Green Functions

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

11.1 Field-Configuration Kernels

Convention 11.1 (Units)**.** Set $\hbar = 1$ throughout this chapter.

Definition 11.2 (Regulated equal-time configuration representation)**.** Let $\widehat{\phi}(t, \vec{x})$ be the canonical real scalar field at time $t = x^0$. The notation involving a spatial field configuration is defined through finite regulators. Let Λ be a spatial regulator and let E_Λ be the resulting finite-dimensional real vector space of spatial field variables. Its elements are denoted by φ_Λ, and a linear functional $\ell \in E_\Lambda^\vee$ evaluates the regulated field by $\ell(\varphi_\Lambda)$. The regulated configuration Hilbert space is

$$\mathcal{H}_\Lambda = L^2(E_\Lambda, \mathrm{d}_\Lambda\varphi),$$

where $\mathrm{d}_\Lambda\varphi$ is the Lebesgue measure determined by the chosen coordinates, lattice cell factors, or Fourier-mode normalization. The regulated equal-time field operator associated with ℓ acts by multiplication:

$$(\widehat{\phi}_\Lambda(\ell)\Psi)(\varphi_\Lambda) = \ell(\varphi_\Lambda)\Psi(\varphi_\Lambda).$$

A field-configuration generalized vector at time t and regulator Λ is the distributional vector

$|\varphi_\Lambda; t\rangle_\Lambda$ defined by evaluation:

$$_\Lambda\langle\varphi_\Lambda; t|\Psi\rangle = \Psi_t(\varphi_\Lambda), \qquad \Psi \in \mathcal{S}(E_\Lambda) \subset \mathcal{H}_\Lambda.$$

Here $\mathcal{S}(E_\Lambda)$ is the Schwartz test space after choosing a linear coordinate system on E_Λ. The resolution of identity is the weak identity

$$\int_{E_\Lambda} \mathrm{d}_\Lambda\varphi \, |\varphi; t\rangle_{\Lambda\Lambda}\langle\varphi; t| = 1$$

on $\mathcal{S}(E_\Lambda)$. Accordingly,

$$_\Lambda\langle\varphi; t_i|\varphi_i; t_i\rangle_\Lambda = \delta_\Lambda(\varphi - \varphi_i),$$

where δ_Λ is the Dirac delta distribution relative to $\mathrm{d}_\Lambda\varphi$. The continuum symbols $|\varphi; t\rangle$, $\Psi_t[\varphi]$, and $\delta[\varphi - \varphi_i]$ mean a compatible family of these regulated objects together with a stated limiting topology.

Definition 11.3 (Regulated scalar integration conventions)**.** For a finite-dimensional bosonic scalar regulator, the canonical reference density is the coordinate density

$$D_\Lambda^{\mathrm{ref}}\phi = \mathrm{d}_\Lambda\phi,$$

including the lattice cell factors or Fourier-mode normalization chosen with the regulator. If the Euclidean quadratic part is

$$S_{\mathrm{kin},\Lambda}[\phi] = \frac{1}{2}\langle\phi, C_\Lambda^{-1}\phi\rangle_\Lambda$$

with positive covariance C_Λ, the normalized Gaussian reference measure is

$$\mathrm{d}\mu_{C_\Lambda}(\phi) = Z_{0,\Lambda}^{-1} \exp\{-S_{\mathrm{kin},\Lambda}[\phi]\} \, D_\Lambda^{\mathrm{ref}}\phi. \tag{11.1}$$

If $L_\Lambda[\phi]$ denotes the remaining interaction, the unnormalized full Euclidean density is

$$\mathrm{d}\rho_{\Lambda,S}(\phi) = \exp\{-L_\Lambda[\phi]\} \, \mathrm{d}\mu_{C_\Lambda}(\phi) = Z_{0,\Lambda}^{-1} \exp\{-S_{\mathrm{kin},\Lambda}[\phi] - L_\Lambda[\phi]\} \, D_\Lambda^{\mathrm{ref}}\phi. \tag{11.2}$$

Thus $D_\Lambda^{\mathrm{ref}}\phi$, $\mathrm{d}\mu_{C_\Lambda}$, and $\mathrm{d}\rho_{\Lambda,S}$ are distinct named objects related by explicit Radon–Nikodym factors. In formulas where the older compact notation $[D\phi]_\Lambda$ appears, it denotes the reference density $D_\Lambda^{\mathrm{ref}}\phi$ in the finite-dimensional bosonic scalar setting. Gaussian-measure formulas must use $\mathrm{d}\mu_{C_\Lambda}$, and full source-functional formulas must display the action weight or the density $\mathrm{d}\rho_{\Lambda,S}$.

For fermionic, gauge, BV, Lorentzian oscillatory, dimensional regularization, and other schemes beyond finite Lebesgue densities, a chapter must specify the corresponding regulated integration object and its algebraic or analytic status separately.

Finite lattice or finite spin system. The object is a finite product of site variables, link variables, or spins. The measure is an ordinary finite product measure, counting measure, compact Haar measure, or finite-dimensional density. Thermodynamic and continuum limits are separate questions.

Finite Fourier-mode cutoff. At finite volume and finite mode number, this is a finite-dimensional field space with a reference density and, after the quadratic part is chosen, a Gaussian measure. Sharp momentum cutoffs are useful perturbatively but need not preserve locality or reflection positivity.

Smooth covariance or Wilsonian cutoff. A profile such as $C_\Lambda(k) = \chi(k^2/\Lambda^2)/(k^2 + m^2)$ defines a regulated covariance. With a genuine finite regulator it gives a Gaussian measure or density; in continuum perturbation theory it is a covariance assignment for graphs and Wilsonian pushforwards.

Heat-kernel, spectral, or point-splitting cutoff. These are smoothing kernels, finite-rank projectors, or separated insertion prescriptions. They regulate kernels, traces, determinants, or composite operators; they are not automatically measures on field configurations.

Pauli–Villars auxiliary-field or determinant regulator. This is a massive auxiliary-field or determinant-ratio prescription with specified statistics, coefficients, masses, and symmetry action. It is not a measure on the original field space. If written as a path integral, the enlarged field space, its density or integration cycle, and the sign or indefinite-metric structure of the auxiliary sector must be part of the definition. The monograph does not use Pauli–Villars as a default path-integral construction.

Dimensional regularization. This is a meromorphic assignment to perturbative graph distributions, with specified tensor, spinor, polarization, and external-state algebra in $D = d - \varepsilon$. It is not a Borel measure, not a Berezin measure, and not a measure on a noninteger-dimensional field-configuration space.

BPHZ, momentum subtraction, MS. These are subtraction and coordinate schemes imposed on already specified amplitudes or graph distributions. They are not by themselves regulators of a field measure.

Table 11.1: Regulator and subtraction classes used in the monograph. The catalog names the object that exists before a limit is taken or before a formal expansion is interpreted, and separates cutoff measures from regulated covariances, operator-insertion regulators, Pauli–Villars auxiliary determinants, dimensional regularization, and subtraction prescriptions.

Table 11.1 controls the shorthand used later. A formula written with a lattice spacing, a Fourier cutoff, or a smooth covariance cutoff may denote an actual finite-regulator integral only after the finite field space and density have been specified. A formula written in dimensional regularization denotes a perturbative meromorphic graph assignment; it is not an integral over a noninteger-dimensional space of fields. A formula described as Pauli–Villars regulated must display the auxiliary field or determinant data; without that data it is only the name of a possible subtraction mechanism, not a path-integral measure. A subtraction prescription is a further coordinate choice on regulated or meromorphic data, not a replacement for stating what was regulated.

Definition 11.4 (Finite-regulator time-sliced scalar kernel)**.** At fixed finite-dimensional Λ, the field theory is represented by a quantum-mechanical system with finitely many coordinates. Choose a time partition

$$t_i = t_0 < t_1 < \cdots < t_N = t_f.$$

With boundary fields $\varphi_0 = \varphi_i$ and $\varphi_N = \varphi_f$, the finite time-sliced kernel has the form

$$K_{\Lambda,N}(\varphi_f, t_f; \varphi_i, t_i) = \int_{E_\Lambda^{N-1}} \prod_{n=1}^{N-1} \mathrm{d}_\Lambda\varphi_n \, \mathcal{N}_{\Lambda,N} \, \exp\bigl[\mathrm{i}S_{\Lambda,N}(\varphi_0, \ldots, \varphi_N)\bigr].$$

The normalization factor $\mathcal{N}_{\Lambda,N}$, the discrete action $S_{\Lambda,N}$, and possible local measure factors are part of the chosen operator-symbol and time-slicing convention, exactly as in the finite-dimensional construction of Chapter 7.

Finite-dimensional Schrödinger regulators and Trotter–Kato. The finite-dimensional Trotter–Kato and Feynman–Kac theorems recalled in Chapter 7 apply to a spatial regulator only after the regulator has actually reduced the theory to a finite-dimensional Schrödinger problem. The regulator must have the following properties. The configuration space is a finite-dimensional real vector space $E_\Lambda \simeq \mathbb{R}^{M_\Lambda}$, the kinetic energy is a positive constant-coefficient quadratic form in the conjugate momenta, and the Hamiltonian on $L^2(E_\Lambda, \mathrm{d}_\Lambda\varphi)$ is the Friedrichs Hamiltonian associated to

$$Q_\Lambda[\Psi] = \frac{1}{2}\int_{E_\Lambda} G_\Lambda^{AB}\partial_A\overline{\Psi}\,\partial_B\Psi\,\mathrm{d}_\Lambda\varphi + \int_{E_\Lambda} U_\Lambda(\varphi)|\Psi(\varphi)|^2\,\mathrm{d}_\Lambda\varphi,$$

where G_Λ^{AB} is positive definite and $U_\Lambda : E_\Lambda \to \mathbb{R}$ is locally Kato and bounded from below. Under these hypotheses the fixed-Λ transition kernels are exactly the objects governed by the finite-dimensional theorem: the Euclidean transition kernel is a Wiener or Brownian-bridge expectation on $C([0,\tau], E_\Lambda)$ with potential weight $\exp[-\int_0^\tau U_\Lambda(\Phi(s))\mathrm{d}s]$, after the linear change of variables that puts G_Λ^{AB} in Euclidean form.

This hypothesis is satisfied, for example, by a finite spatial lattice in a finite box with stable real polynomial potential energy, and by a genuine finite-mode truncation with a stable real polynomial potential. It is not satisfied by a continuum smooth cutoff that leaves infinitely many spatial degrees of freedom, nor by a formal rule that only modifies the propagator in a functional integral. In those cases the phrase "the Trotter limit for H_Λ" has no content until the Hilbert space, domain, closed quadratic form, and limiting topology have been specified.

Under the finite-dimensional Schrödinger-regulator hypotheses just stated, the Lorentzian time-sliced kernels of Definition 11.4 have the corresponding strong operator or distributional limits after smearing boundary configurations. In that case

$$\lim_{N\to\infty} K_{\Lambda,N}(\varphi_f, t_f; \varphi_i, t_i) = {}_\Lambda\langle\varphi_f; t_i|\exp[-\mathrm{i}H_\Lambda(t_f - t_i)]|\varphi_i; t_i\rangle_\Lambda$$

as a distributional kernel after smearing the boundary configurations. The continuum expression

$$\langle\varphi_f; t_f|\varphi_i; t_i\rangle = \int_{\phi(t_i)=\varphi_i}^{\phi(t_f)=\varphi_f} [D\phi]\,\exp\left(\mathrm{i}S[\phi]\right)$$

is a compact notation for this two-stage construction: first a finite regulator and time slicing, then a stated continuum or perturbative limiting procedure. If the regulator is instead a Euclidean covariance cutoff, a Euclidean spacetime lattice action introduced directly, or a purely perturbative cutoff, the construction requires its own definition: a Gaussian measure with an interaction, a finite lattice integral, a transfer-matrix or Hamiltonian construction, a constructive limit, or a formal asymptotic expansion. At fixed finite-dimensional Λ, the same hypotheses identify the time-sliced kernels with the Trotter products for the self-adjoint Hamiltonian H_Λ. The strong operator convergence acts on square-integrable wavefunctions. Pairing the resulting operator kernel with Schwartz test functions in the boundary variables gives the distributional kernel displayed above. Passing from the regulated family to a continuum symbol is therefore notation for the specified continuum or perturbative limiting prescription.

Definition 11.5 (Compact scalar path-integral notation)**.** The compact path-integral notation

$$Z = \int [D\phi]\,\mathrm{e}^{\mathrm{i}S[\phi]}$$

is used only as an abbreviation for such regulated limits or for asymptotic expansions derived from them. Its meaning is part of the chosen regularization and limiting prescription. A positive Borel measure is one possible mathematical object for some bosonic Euclidean scalar theories; it is not the definition of a general QFT path integral and is not implied by the symbol $[D\phi]$.

Definition 11.6 (Lorentzian oscillatory path-integral notation)**.** Fix a finite spatial regulator Λ, a finite time partition, and coordinates $u = (u^1, \ldots, u^M)$ on all intermediate field variables. With an insertion F, the regulated Lorentzian expression has the form

$$I_{\Lambda,N}(F) = \int_{\mathbb{R}^M} \exp(\mathrm{i}S_{\Lambda,N}(u))\, a_{\Lambda,N}(u; F)\, \mathrm{d}^M u.$$

This formula is classified as an oscillatory integral or oscillatory distribution. One concrete definition is the Abel boundary value

$$I_{\Lambda,N}(F) = \lim_{\epsilon \downarrow 0} \int_{\mathbb{R}^M} \exp(\mathrm{i}S_{\Lambda,N}(u) - \epsilon Q(u))\, a_{\Lambda,N}(u; F)\, \mathrm{d}^M u,$$

whenever the limit exists in the stated distribution topology; here Q is a positive definite quadratic form used only to approach the boundary value. Equivalent finite-dimensional formulations use the Fourier-transform definition of oscillatory integrals with amplitudes in a specified symbol class.

For a nondegenerate quadratic phase

$$S(u) = \frac{1}{2} u^T A u + J^T u, \qquad A = A^T, \quad \det A \neq 0,$$

the normalized Fresnel value is

$$\lim_{\epsilon \downarrow 0} \int_{\mathbb{R}^M} \exp\left(\frac{\mathrm{i}}{2} u^T A u + \mathrm{i} J^T u - \frac{\epsilon}{2} u^T u\right) \mathrm{d}^M u = (2\pi)^{M/2} \mathrm{e}^{\mathrm{i}\pi \,\mathrm{sgn}(A)/4} |\det A|^{-1/2} \exp\left(-\frac{\mathrm{i}}{2} J^T A^{-1} J\right),$$

where $\mathrm{sgn}(A) = n_+(A) - n_-(A)$ is the signature. The phase $\mathrm{e}^{\mathrm{i}\pi\,\mathrm{sgn}(A)/4}$ is part of the finite-regulator definition; in families of quadratic phases its changes are recorded by the Maslov index. For a nonlinear phase, perturbation theory is the stationary phase expansion of the finite-regulator oscillatory distribution around the chosen critical configurations, with Hessian signatures and contour or boundary-value data included in the definition.

The continuum Lorentzian symbol

$$\int [D\phi]\, \mathrm{e}^{\mathrm{i}S[\phi]}$$

is therefore an oscillatory pseudo-integral: a shorthand for compatible finite-regulator oscillatory distributions, their Abel or Fourier boundary values, or their stationary-phase asymptotic expansions. This classification is separate from the Euclidean positive-measure construction used in constructive scalar examples, from Berezin integration for fermionic variables, and from gauge-fixed, BRST/BV, lattice, or holonomy constructions for gauge theories. The relevant analytic frameworks are finite-dimensional oscillatory-integral theory and stationary phase in the sense of Hörmander, the Maslov-index refinement of the Fresnel phase, and the Albeverio–Høegh-Krohn theory of infinite-dimensional Fresnel integrals when such infinite-dimensional oscillatory objects are constructed directly.

Regime	Rigorous status	Scope of the statement
$P(\phi)_2$, including ϕ_2^4	Constructed non-Gaussian Euclidean and Wightman models for bounded-below polynomial interactions after Wick ordering and the required local renormalizations.	This is the basic scalar positive-measure constructive class in two spacetime dimensions. Reflection positivity, locality, and the Wightman/OS structures can be verified in the constructed models.
ϕ_3^4	Constructed non-Gaussian massive scalar models with stable quartic interaction after mass, coupling, and vacuum-energy counterterms.	The construction is substantially harder than $P(\phi)_2$ and is tied to superrenormalizability in three spacetime dimensions.
Selected low-dimensional superrenormalizable scalar–fermion models	Constructive results exist for specific Yukawa-type and related models after the ultraviolet cutoff, Wick ordering, fermion determinant/Pfaffian conventions, and local renormalizations are fixed.	Each theorem is model-specific. The label of a Lagrangian family does not define a uniform constructive theorem; the required hypotheses must be cited when such a model is used.
Two-dimensional Yang–Mills	Constructed continuum gauge theory for compact gauge group through heat-kernel/holonomy measures on generalized connections or lattice projective limits.	This is a gauge-theory construction, not a scalar Borel measure on ordinary fields. The theory has no local propagating gluon degrees of freedom, and its status should not be extrapolated to $D = 4$.
ϕ_D^4, $D \geq 5$	For the standard reflection-positive lattice/Ising/$\lambda\phi^4$ critical scaling problem with positive quartic coupling, the scaling limits covered by the triviality theorems are Gaussian.	The theorem concerns that constructive scaling-limit family. It is a nonperturbative obstruction to the standard scalar route to an interacting continuum limit above four dimensions.
ϕ_4^4	For the standard reflection-positive lattice/Ising/$\lambda\phi^4$ critical scaling problem, marginal triviality theorems show Gaussian scaling limits.	This is sharper than the perturbative Landau-pole argument. It still leaves open the logically different question whether another UV-complete four-dimensional QFT could agree with formal ϕ_4^4 perturbation theory to all orders while differing nonperturbatively.
Four-dimensional pure Yang–Mills	Finite Wilson lattices are rigorous compact-group integrals, and asymptotic freedom gives the perturbative ultraviolet mechanism. Continuum existence with mass gap remains a separate constructive problem.	The finite-regulator theory is not the desired continuum QFT. A continuum limit must produce gauge-invariant Schwinger functions satisfying positivity, locality, covariance, and the spectral requirements used for reconstruction.
Four-dimensional interacting local QFT of scalar/gauge type	Open constructive problem once one asks for non-Gaussian local fields or gauge-invariant observables with Wightman/OS positivity, covariance, locality, and the spectral properties used later in the monograph.	Perturbative formal power series, finite regulators, and generalized-free fields do not supply this construction. The status of each four-dimensional model must be stated separately: free, perturbative, finite-regulator, conditional continuum limit, trivial scaling limit, or open problem.

Table 11.2: Selected rigorous existence and triviality regimes relevant to the symbol $[D\phi]$ and to continuum-limit claims. The table records theorem classes and open construction problems; it is not a general definition of path integrals.

References for Table 11.2. Standard entry points are E. Nelson's construction of the two-dimensional quartic interaction, B. Simon's *The $P(\phi)_2$ Euclidean (Quantum) Field Theory*, and J. Glimm and A. Jaffe, *Quantum Physics: A Functional Integral Point of View*, for $P(\phi)_2$ and ϕ_3^4 constructive scalar models; B. Driver, A. Sengupta, and T. Lévy for rigorous two-dimensional Yang–Mills constructions; M. Aizenman and J. Fröhlich for scalar triviality above four dimensions; and M. Aizenman and H. Duminil-Copin, "Marginal triviality of the scaling limits of critical 4D Ising and ϕ_4^4 models," *Ann. of Math.* **194** (2021) 163–235, for the four-dimensional marginal triviality theorem. The Glimm–Jaffe functional-integral construction is used here as a reference for the positive-measure scalar sector. The organizing framework of this monograph is broader: a path integral is specified by the mathematical object assigned by the chosen regulator and limiting prescription, which may be a Borel measure, an oscillatory distribution, a Berezin functional, a gauge-fixed or BV integral, a lattice or holonomy construction, or a formal asymptotic expansion. A broader catalog of constructive routes and theorem status appears in Table 136.1 of the constructive volume; the present table records only the examples needed for the first path-integral distinctions.

Vacuum correlation functions avoid direct use of field-configuration eigenvectors. For points $x_a = (x_a^0, \vec{x}_a)$, the basic Lorentzian operator distributions are

$$\langle\Omega|\widehat{\phi}(x_1)\cdots\widehat{\phi}(x_n)|\Omega\rangle.$$

These are distributions in the spacetime variables, and their analytic continuations require spectral and growth assumptions.

11.2 Complex Time Contours

Definition 11.7 (Complex-time contour with ordered insertions)**.** Let z^0 be a complex time coordinate. If a contour C in the z^0-plane is used for the time variable, the corresponding action is

$$S_C[\phi] = \int_C \mathrm{d}z^0 \int \mathrm{d}^{D-1}\vec{x}\,\mathcal{L}(\phi, \partial_\mu\phi).$$

Insertions are ordered along the contour. For vacuum correlation functions the useful contour has insertion times whose imaginary parts are ordered:

$$\operatorname{Im} z_1^0 < \operatorname{Im} z_2^0 < \cdots < \operatorname{Im} z_n^0.$$

The real parts are free variables. The ordering in imaginary time provides the analytic separation that will become time ordering after a uniform rotation to real time.

Figure 11.1 records the contour-ordering convention: the contour carries the action, and the imaginary parts of insertion times impose the analytic ordering used for later time ordering.

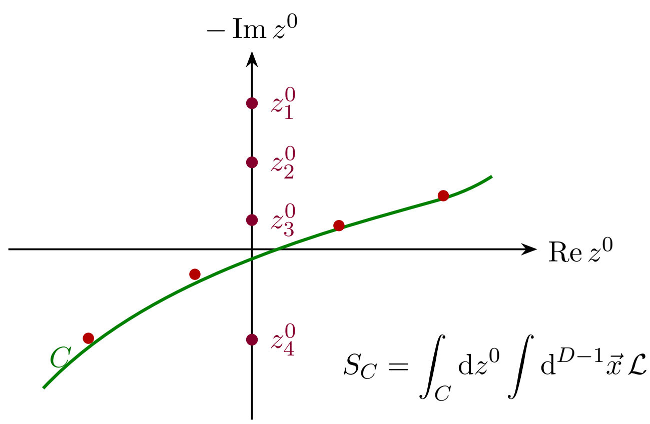

Figure 11.1: Complex-time contour data for ordered vacuum insertions. The ordering of imaginary parts determines the analytic domain that rotates to Lorentzian time ordering.

The figure records only the ordering data. The analytic statement is the existence of a holomorphic continuation of the relevant correlation function in the domain where the imaginary parts are ordered.

Hypothesis 11.8 (Ordered tube analyticity for scalar vacuum correlators)**.** For the scalar vacuum n-point distribution under consideration, assume there exists a holomorphic function

$$\mathcal{W}_n(z_1, \ldots, z_n), \qquad z_a = (z_a^0, \vec{x}_a),$$

on the ordered domain

$$\operatorname{Im} z_1^0 < \operatorname{Im} z_2^0 < \cdots < \operatorname{Im} z_n^0$$

for fixed real spatial points, with distributional boundary value equal to the Lorentzian Wightman distribution in the corresponding operator order. The hypothesis includes the growth condition needed for the boundary value to exist as a tempered or otherwise specified distribution. In a Wightman theory this is a consequence of the spectral condition and locality in the usual tube-domain construction; in a path-integral construction it is an assumption or theorem of the chosen reconstruction framework.

11.3 Euclidean Functional Expression

Definition 11.9 (Euclidean continuation of a scalar Lagrangian)**.** Put the complex time on the Euclidean axis by writing

$$z^0 = -\mathrm{i}\tau, \qquad x_E = (\tau, \vec{x}) \in \mathbb{R}^D.$$

When the analytic continuation of vacuum correlators exists, Euclidean field-insertion notation is defined inside ordered correlation functions by

$$\widehat{\phi}(z^0, \vec{x})\big|_{z^0=-\mathrm{i}\tau}.$$

This is a shorthand for the analytic continuation of Lorentzian Hilbert-space matrix elements; the Euclidean functional variable in $S_E[\phi]$ remains the unhatted field ϕ. For Euclidean times ordered as

$$\tau_{i_1} > \tau_{i_2} > \cdots > \tau_{i_n},$$

this notation records the same analytic boundary value that rotates to the Lorentzian time-ordered product with $x_{i_1}^0 > x_{i_2}^0 > \cdots > x_{i_n}^0$. For a Lorentzian Lagrangian density

$$\mathcal{L}(\phi, \partial_0\phi, \partial_i\phi),$$

define the Euclidean Lagrangian density by

$$\mathcal{L}_E(\phi, \partial_\tau\phi, \partial_i\phi) = -\mathcal{L}(\phi, \mathrm{i}\partial_\tau\phi, \partial_i\phi),$$

when this analytic substitution is meaningful for the regulated theory. The Euclidean action is

$$S_E[\phi] = \int \mathrm{d}^D x_E\, \mathcal{L}_E(\phi, \partial_E\phi).$$

Euclidean scalar action. For the real scalar field with

$$\mathcal{L} = -\frac{1}{2}\eta^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi - V(\phi),$$

this gives

$$\mathcal{L}_E = \frac{1}{2}(\partial_\tau\phi)^2 + \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i\phi)^2 + V(\phi).$$

With mostly-plus Lorentzian metric,

$$-\frac{1}{2}\eta^{\mu\nu}\partial_\mu\phi\,\partial_\nu\phi = \frac{1}{2}(\partial_0\phi)^2 - \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i\phi)^2.$$

Substitution of $\partial_0 = \mathrm{i}\partial_\tau$ gives

$$\mathcal{L}(\phi, \mathrm{i}\partial_\tau\phi, \partial_i\phi) = -\frac{1}{2}(\partial_\tau\phi)^2 - \frac{1}{2}\sum_{i=1}^{D-1}(\partial_i\phi)^2 - V(\phi).$$

The definition $\mathcal{L}_E = -\mathcal{L}|_{\partial_0=\mathrm{i}\partial_\tau}$ then gives the displayed positive kinetic terms.

Definition 11.10 (Regulated Euclidean scalar Green function)**.** With a regulator in place, the normalized Euclidean n-point function is

$$\langle\phi(x_{E,1})\cdots\phi(x_{E,n})\rangle_{E,\Lambda} = \frac{1}{Z_{E,\Lambda}}\int D_\Lambda^{\mathrm{ref}}\phi\,\mathrm{e}^{-S_{E,\Lambda}[\phi]}\,\phi(x_{E,1})\cdots\phi(x_{E,n}),$$

where

$$Z_{E,\Lambda} = \int D_\Lambda^{\mathrm{ref}}\phi\,\mathrm{e}^{-S_{E,\Lambda}[\phi]}.$$

Here the Euclidean action $S_{E,\Lambda}$ includes its quadratic part and $D_\Lambda^{\mathrm{ref}}\phi$ is the reference density of Definition 11.3. If

$$S_{E,\Lambda} = S_{\mathrm{kin},\Lambda} + L_\Lambda,$$

the same normalized correlation function may equivalently be written with the Gaussian measure $\mathrm{d}\mu_{C_\Lambda}$ and interaction weight $\mathrm{e}^{-L_\Lambda[\phi]}$. The choice of notation therefore records which factor carries the quadratic kinetic form. The continuum Euclidean Green function is the limit of these distributions when the limit exists in the chosen topology and with the chosen renormalization conditions.

11.4 Uniform Wick Rotation

Definition 11.11 (Uniform Wick-rotation path for ordered times)**.** Fix real numbers

$$t_1 > t_2 > \cdots > t_n.$$

For $0 < \alpha \leq \pi/2$, set

$$z_a^0(\alpha) = \mathrm{e}^{-\mathrm{i}\alpha}t_a.$$

At $\alpha = \pi/2$, the insertion lies on the Euclidean axis:

$$z_a^0 = -\mathrm{i}t_a.$$

As $\alpha \to 0^+$, the insertion approaches the Lorentzian time t_a. Since

$$\operatorname{Im} z_a^0(\alpha) = -t_a \sin\alpha,$$

the ordering

$$\operatorname{Im} z_1^0(\alpha) < \cdots < \operatorname{Im} z_n^0(\alpha)$$

is maintained throughout the rotation.

Figure 11.2 displays the uniform rotation of all insertion times and the preserved imaginary-time ordering along the rotation path.

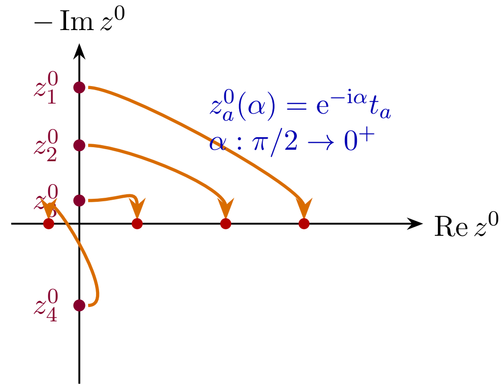

Figure 11.2: Uniform Wick rotation of ordered insertion times. The deformation $z_a^0(\alpha) = \mathrm{e}^{-\mathrm{i}\alpha} t_a$ preserves the imaginary-time ordering until the Lorentzian boundary is reached.

Euclidean boundary value and the time-ordered function. Under Hypothesis 11.8, the Euclidean correlation function continued along this common rotation becomes the Lorentzian time-ordered correlator with $t_1 > \cdots > t_n$:

$$\langle \phi(x_{E,1}) \cdots \phi(x_{E,n}) \rangle_E \longrightarrow \langle \Omega | \, \mathrm{T}\{\widehat{\phi}(x_1) \cdots \widehat{\phi}(x_n)\} | \Omega \rangle.$$

Here T denotes time ordering of the operator-valued distributions.

By Definition 11.11, the points $z_a^0(\alpha) = \mathrm{e}^{-\mathrm{i}\alpha} t_a$ stay inside the ordered domain of Hypothesis 11.8 for every $0 < \alpha \leq \pi/2$. At $\alpha = \pi/2$, the points lie on the Euclidean axis and give the Euclidean boundary value. As $\alpha \to 0^+$, the ordered tube boundary value is the Lorentzian Wightman distribution in the operator order $1, \ldots, n$. Since the real times already obey $t_1 > \cdots > t_n$, that Wightman order is exactly the time-ordered product.

11.5 The Free Euclidean Gaussian Measure

Definition 11.12 (Finite-regulator Euclidean Gaussian datum)**.** At finite Euclidean regulator, the free scalar path integral is an ordinary Gaussian integral. Let F_Λ be the finite-dimensional real vector space of regulated Euclidean fields, let $\mathrm{d}_\Lambda\phi$ be the regulator Lebesgue measure, and let

$$A_\Lambda : F_\Lambda \longrightarrow F_\Lambda^\vee$$

be a symmetric positive-definite operator. The pairing between $F_\Lambda^\vee$ and F_Λ is denoted by $\langle J, \phi\rangle_\Lambda$. The regulated free action is

$$S_{E,0,\Lambda}[\phi] = \frac{1}{2}\langle A_\Lambda\phi, \phi\rangle_\Lambda.$$

The corresponding normalized Gaussian expectation is

$$\langle F(\phi)\rangle_{0,\Lambda} = \frac{1}{Z_{0,\Lambda}}\int_{F_\Lambda} \mathrm{d}_\Lambda\phi\, \mathrm{e}^{-\frac{1}{2}\langle A_\Lambda\phi,\phi\rangle_\Lambda} F(\phi),$$

with

$$Z_{0,\Lambda} = \int_{F_\Lambda} \mathrm{d}_\Lambda\phi\, \mathrm{e}^{-\frac{1}{2}\langle A_\Lambda\phi,\phi\rangle_\Lambda}.$$

The covariance is the inverse map

$$C_\Lambda = A_\Lambda^{-1} : F_\Lambda^\vee \to F_\Lambda.$$

Finite-dimensional Gaussian source functional. For sources $J \in F_\Lambda^\vee$, completing the square gives

$$-\frac{1}{2}\langle A_\Lambda\phi, \phi\rangle_\Lambda + \langle J, \phi\rangle_\Lambda = -\frac{1}{2}\langle A_\Lambda(\phi - C_\Lambda J), \phi - C_\Lambda J\rangle_\Lambda + \frac{1}{2}\langle J, C_\Lambda J\rangle_\Lambda.$$

Therefore

$$\frac{Z_{0,\Lambda}[J]}{Z_{0,\Lambda}[0]} = \exp\left(\frac{1}{2}\langle J, C_\Lambda J\rangle_\Lambda\right), \qquad Z_{0,\Lambda}[J] = \int_{F_\Lambda} \mathrm{d}_\Lambda\phi\, \mathrm{e}^{-S_{E,0,\Lambda}[\phi]+\langle J,\phi\rangle_\Lambda}.$$

Differentiating at $J = 0$ gives, for $f, g \in F_\Lambda^\vee$,

$$\big\langle \langle f, \phi\rangle_\Lambda \langle g, \phi\rangle_\Lambda \big\rangle_{0,\Lambda} = \langle f, C_\Lambda g\rangle_\Lambda,$$

and all higher moments are sums over pairings with this covariance. This is Wick's theorem as a finite-dimensional Gaussian identity.

The completion-of-the-square identity follows from $A_\Lambda C_\Lambda = \mathrm{id}_{F_\Lambda^\vee}$. Translation invariance of the Lebesgue density gives

$$\int_{F_\Lambda} \mathrm{d}_\Lambda\phi\, \mathrm{e}^{-\frac{1}{2}\langle A_\Lambda\phi,\phi\rangle_\Lambda + \langle J,\phi\rangle_\Lambda} = \mathrm{e}^{\frac{1}{2}\langle J, C_\Lambda J\rangle_\Lambda} \int_{F_\Lambda} \mathrm{d}_\Lambda\phi\, \mathrm{e}^{-\frac{1}{2}\langle A_\Lambda\phi,\phi\rangle_\Lambda},$$

after the shift $\phi \mapsto \phi + C_\Lambda J$. Dividing by $Z_{0,\Lambda}[0]$ gives the source functional. Applying $\partial_s\partial_t$ to the identity with $J = sf + tg$ and setting $s = t = 0$ gives the two-point formula. Repeated differentiation gives the sum over pairings because the exponent is quadratic in J; odd derivatives vanish at $J = 0$, and even derivatives contract derivatives in pairs. This finite-dimensional calculation is the regulator-level meaning of the free Euclidean Gaussian path integral. The nontrivial continuum questions are the choice of regulator, the topology in which C_Λ converges, and the existence of limiting distributions after the test functions have been fixed.

Definition 11.13 (Continuum free scalar Euclidean covariance)**.** For the continuum free scalar field of mass $m \geq 0$,

$$V(\phi) = \frac{1}{2}m^2\phi^2,$$

and the Euclidean action is

$$S_{E,0}[\phi] = \frac{1}{2}\int \mathrm{d}^D x_E\, \phi(x_E)(-\partial_E^2 + m^2)\phi(x_E),$$

after integration by parts with the chosen boundary conditions. The operator

$$A_E = -\partial_E^2 + m^2$$

is the continuum counterpart of A_Λ. If $m > 0$, or if boundary conditions or an infrared regulator remove the constant zero mode when $m = 0$, the inverse covariance is represented by the Green function Δ_E defined by

$$A_E \Delta_E(x_E - y_E) = \delta^{(D)}(x_E - y_E).$$

For test functions f, g, the continuum covariance is the distributional limit

$$\lim_\Lambda \langle f_\Lambda, C_\Lambda g_\Lambda\rangle_\Lambda = \int \mathrm{d}^D x_E\, \mathrm{d}^D y_E\, f(x_E)\Delta_E(x_E - y_E)g(y_E),$$

where f_Λ, g_Λ are the regulated images of f, g. On $\mathbb{R}^D$, translation invariance gives the momentum-space kernel

$$\Delta_E(x_E - y_E) = \int \frac{\mathrm{d}^D k_E}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k_E\cdot(x_E - y_E)}}{k_E^2 + m^2},$$

where

$$k_E^2 = (k_\tau)^2 + \vec{k}^2, \qquad k_E \cdot x_E = k_\tau \tau + \vec{k}\cdot\vec{x}.$$

In point notation, after the distribution has been paired with test functions, the free two-point function is written

$$\langle \phi(x_E)\phi(y_E)\rangle_E = \Delta_E(x_E - y_E)$$

for the free theory. This equation is precisely the continuum form of the finite-dimensional covariance identity above.

11.6 Spectral Zeta Determinants

The finite-dimensional Gaussian normalization contains the determinant of the quadratic operator:

$$\int_{\mathbb{R}^N} \mathrm{d}^N\phi\, \exp\left[-\frac{1}{2}\phi^i A_{ij}\phi^j\right] = (2\pi)^{N/2}(\det A)^{-1/2}$$

for a positive-definite symmetric matrix A. In field theory the analogous quantity is a determinant of a differential operator and requires its own regularized definition. A spectral zeta determinant is one such definition for operators with discrete positive spectrum. It regulates the determinant; it does not by itself choose the continuum theory or the subtraction coordinates of an interacting path integral.

Definition 11.14 (Spectral zeta determinant)**.** Let A be a positive self-adjoint elliptic operator of order $r > 0$ on a compact d-dimensional Euclidean manifold, with boundary condition chosen so that A has compact resolvent. Let

$$0 < \lambda_1 \leq \lambda_2 \leq \cdots$$

be the positive eigenvalues of A, repeated with multiplicity. Zero modes, if present, are omitted from this list and must be integrated or treated as collective coordinates separately. For $\operatorname{Re} s > d/r$, set

$$\zeta_A(s) = \sum_j \lambda_j^{-s}. \tag{11.3}$$

Equivalently, in the same half-plane,

$$\zeta_A(s) = \frac{1}{\Gamma(s)} \int_0^\infty \mathrm{d}t\, t^{s-1} \operatorname{Tr} \mathrm{e}^{-tA}. \tag{11.4}$$

Assume that the heat trace has the usual small-t asymptotic expansion and that the meromorphic continuation of $\zeta_A(s)$ is regular at $s = 0$. For a reference scale μ of mass dimension 1, define

$$\log \det_\zeta \left(\frac{A}{\mu^r} \right) = - \left. \frac{\mathrm{d}}{\mathrm{d}s} \right|_{s=0} \sum_j \left(\frac{\lambda_j}{\mu^r} \right)^{-s} = -\zeta_A'(0) - \zeta_A(0) \log \mu^r. \tag{11.5}$$

Scale dependence of a zeta determinant. In the setting of Definition 11.14, suppose

$$\operatorname{Tr} \mathrm{e}^{-tA} \sim \sum_{j \geq 0} a_j(A)\, t^{(j-d)/r} \qquad (t \downarrow 0)$$

with no logarithmic term at order t^0, and suppose zero modes have been removed. Then

$$\zeta_A(0) = a_d(A).$$

Consequently a change $\mu \mapsto \mathrm{e}^\sigma \mu$ changes the determinant by

$$\log \det_\zeta \left(\frac{A}{(\mathrm{e}^\sigma \mu)^r} \right) - \log \det_\zeta \left(\frac{A}{\mu^r} \right) = -r\sigma\, a_d(A).$$

Thus the μ-dependence of the one-loop determinant is controlled by the local heat-kernel coefficient $a_d(A)$. The Mellin representation

$$\zeta_A(s) = \frac{1}{\Gamma(s)} \int_0^\infty \mathrm{d}t\, t^{s-1} \operatorname{Tr} \mathrm{e}^{-tA}$$

continues meromorphically by subtracting the small-t heat-kernel asymptotic series. The coefficient $a_d(A)$ multiplies t^0, hence contributes $a_d(A)/(s\Gamma(s))$ to $\zeta_A(s)$ near $s = 0$. Since $\Gamma(s)^{-1} = s + O(s^2)$, this contribution has value $a_d(A)$ at $s = 0$. The remaining subtracted terms are either regular and vanish at $s = 0$ after multiplication by $\Gamma(s)^{-1}$, or have poles away from $s = 0$ under the stated no-log hypothesis. This gives $\zeta_A(0) = a_d(A)$. Substituting $(\mathrm{e}^\sigma \mu)^r = \mathrm{e}^{r\sigma} \mu^r$ into the defining formula gives

$$\log \det_\zeta \left(\frac{A}{(\mathrm{e}^\sigma \mu)^r} \right) = -\zeta_A'(0) - \zeta_A(0)(\log \mu^r + r\sigma),$$

and subtracting

$$\log \det_\zeta \left(\frac{A}{\mu^r}\right) = -\zeta_A'(0) - \zeta_A(0)\log \mu^r$$

leaves $-r\sigma\zeta_A(0) = -r\sigma a_d(A)$.

This is the determinant counterpart of the regulator/subtraction distinction recorded in Table 11.1: changing the determinant scale changes a one-loop effective action by a local heat-kernel coefficient, not by a new nonlocal observable.

One-loop determinant from a quadratic fluctuation. Let $\phi = \phi_{\mathrm{cl}} + \eta$ be a background split for a bosonic Euclidean path integral, and suppose that the quadratic fluctuation operator

$$A_{\phi_{\mathrm{cl}}} = S_E''[\phi_{\mathrm{cl}}]$$

is positive and satisfies the hypotheses of Definition 11.14. With the Gaussian normalization chosen by spectral zeta regularization, the one-loop contribution of the nonzero modes to the effective action is

$$\Gamma_1[\phi_{\mathrm{cl}}] = \frac{1}{2}\log \det_\zeta \left(\frac{A_{\phi_{\mathrm{cl}}}}{\mu^r}\right). \tag{11.6}$$

For fermionic Gaussian variables the corresponding Pfaffian or determinant appears with the opposite statistics sign and with the spinor and reality structure stated as part of the regulator. At finite regulator,

$$S_E[\phi_{\mathrm{cl}} + \eta] = S_E[\phi_{\mathrm{cl}}] + \frac{1}{2}\langle \eta, A_{\phi_{\mathrm{cl}},\Lambda}\eta\rangle_\Lambda + O(\eta^3)$$

when ϕ_{cl} obeys the regulated equation of motion. The Gaussian integral over the nonzero fluctuation modes gives

$$Z_\Lambda^{1-\mathrm{loop}}[\phi_{\mathrm{cl}}] = \exp[-S_E[\phi_{\mathrm{cl}}]](2\pi)^{N_\Lambda/2}\big(\det A_{\phi_{\mathrm{cl}},\Lambda}\big)^{-1/2}$$

up to the finite-dimensional zero-mode and collective-coordinate factors that were excluded. The factor $(2\pi)^{N_\Lambda/2}$ is independent of the background in a fixed bosonic coordinate density and is part of the vacuum normalization. Replacing the divergent determinant by $\det_\zeta(A_{\phi_{\mathrm{cl}}}/\mu^r)$ gives the logarithm (11.6). The argument uses only the quadratic Gaussian identity; interactions beyond quadratic order are additional vertices in perturbation theory.

Example 11.15 (Thermal harmonic oscillator determinant)**.** Let $S^1_\beta = \mathbb{R}/\beta\mathbb{Z}$ and

$$A_\omega = -\frac{\mathrm{d}^2}{\mathrm{d}\tau^2} + \omega^2, \qquad \omega > 0,$$

acting on periodic functions. The eigenvalues are

$$\lambda_n = \left(\frac{2\pi n}{\beta}\right)^2 + \omega^2, \qquad n \in \mathbb{Z}.$$

For this one-dimensional second-order operator $\zeta_{A_\omega}(0) = 0$, so the determinant is independent of μ. Differentiate the logarithm before integrating it:

$$\frac{\mathrm{d}}{\mathrm{d}\omega}\log \det_\zeta A_\omega = 2\omega \sum_{n\in\mathbb{Z}} \frac{1}{(2\pi n/\beta)^2 + \omega^2}.$$

The partial-fraction identity

$$\sum_{n\in\mathbb{Z}} \frac{1}{n^2+a^2} = \frac{\pi}{a}\coth(\pi a), \qquad a>0,$$

with $a=\beta\omega/(2\pi)$ gives

$$\frac{\mathrm{d}}{\mathrm{d}\omega}\log\det\nolimits_\zeta A_\omega = \beta\coth\frac{\beta\omega}{2}.$$

Therefore

$$\log\det\nolimits_\zeta A_\omega = 2\log\left(2\sinh\frac{\beta\omega}{2}\right)+C.$$

The constant is fixed by the small-ω behavior: $\det_\zeta A_\omega \sim \omega^2 \det'_\zeta(-\mathrm{d}^2/\mathrm{d}\tau^2)$ and $\det'_\zeta(-\mathrm{d}^2/\mathrm{d}\tau^2) = \beta^2$. Hence

$$\det\nolimits_\zeta A_\omega = 4\sinh^2\frac{\beta\omega}{2}, \qquad Z_{\mathrm{osc}}(\beta,\omega) = (\det\nolimits_\zeta A_\omega)^{-1/2} = \frac{1}{2\sinh(\beta\omega/2)}. \tag{11.7}$$

The last expression is the canonical thermal partition function of the oscillator,

$$\operatorname{Tr}\mathrm{e}^{-\beta\omega(a^\dagger a+1/2)} = \frac{\mathrm{e}^{-\beta\omega/2}}{1-\mathrm{e}^{-\beta\omega}}.$$

Example 11.16 (Circle Casimir finite part)**.** For a massless real scalar on a spatial circle of circumference L, remove the constant zero mode and write the oscillator frequencies as

$$\omega_n = \frac{2\pi|n|}{L}, \qquad n\in\mathbb{Z}\setminus\{0\}.$$

The zeta-regularized finite part of the vacuum energy is

$$E_0^\zeta(L) = \frac{1}{2}\sum_{n\neq 0}\omega_n = \frac{2\pi}{L}\zeta_{\mathrm{R}}(-1) = -\frac{\pi}{6L}, \tag{11.8}$$

where $\zeta_{\mathrm{R}}(-1)=-1/12$ is the analytic continuation of the Riemann zeta function. The zero mode and any additive local vacuum-energy normalization are separate data. In two-dimensional CFT language the result is the $c=1$ case of $E_0=-\pi c/(6L)$ on the cylinder.

11.7 The Feynman Prescription

Definition 11.17 (Wick-rotated free propagator poles)**.** Let

$$\omega_{\vec{k}} = \sqrt{\vec{k}^2+m^2}.$$

For a Euclidean separation $(\tau,\vec{r})$, with $\tau>0$, the free propagator is

$$\Delta_E(\tau,\vec{r}) = \int \frac{\mathrm{d}k_\tau\,\mathrm{d}^{D-1}\vec{k}}{(2\pi)^D}\frac{\mathrm{e}^{\mathrm{i}k_\tau\tau+\mathrm{i}\vec{k}\cdot\vec{r}}}{k_\tau^2+\omega_{\vec{k}}^2}.$$

Continue to complex time by setting $z^0 = \mathrm{e}^{-\mathrm{i}\alpha} t$, with $0 < \alpha \le \pi/2$, and rotate the momentum variable by

$$k_\tau = \mathrm{i}\mathrm{e}^{\mathrm{i}\alpha} k^0.$$

Then

$$\Delta_E = -\mathrm{i}\mathrm{e}^{\mathrm{i}\alpha} \int \frac{\mathrm{d}k^0\, \mathrm{d}^{D-1}\vec{k}}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{r} - \mathrm{i}k^0 t}}{-\mathrm{e}^{2\mathrm{i}\alpha}(k^0)^2 + \vec{k}^2 + m^2},$$

with the contour orientation chosen to match the original Euclidean k_τ-contour. The denominator vanishes at

$$k^0 = \pm \mathrm{e}^{-\mathrm{i}\alpha} \omega_{\vec{k}}.$$

As $\alpha \to 0^+$, these poles approach the real axis as

$$-\omega_{\vec{k}} + \mathrm{i}0, \qquad +\omega_{\vec{k}} - \mathrm{i}0.$$

Figure 11.3 shows how the Euclidean poles rotate toward the Lorentzian contour and become the Feynman $\mathrm{i}\epsilon$ placement.

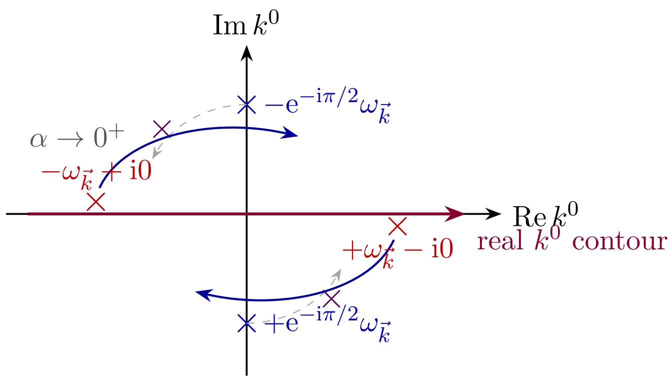

Figure 11.3: Pole motion under Wick rotation. The Euclidean poles rotate to the Lorentzian Feynman positions $-\omega_{\vec{k}} + \mathrm{i}0$ and $+\omega_{\vec{k}} - \mathrm{i}0$.

Feynman boundary value from pole rotation. The limiting Lorentzian distribution is therefore

$$\Delta_F(x; m^2) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k\cdot x}}{k^2 + m^2 - \mathrm{i}\epsilon}, \qquad \epsilon > 0,$$

where

$$k \cdot x = -k^0 x^0 + \vec{k}\cdot\vec{x}, \qquad k^2 = -(k^0)^2 + \vec{k}^2.$$

The limit $\epsilon \to 0^+$ is taken after the distribution has been paired with test functions or after the contour integral has been evaluated. Definition 11.17 shows that the positive-frequency pole approaches the real k^0-axis from below and the negative-frequency pole approaches it from above. The denominator $k^2 + m^2 - \mathrm{i}\epsilon$, with $k^2 = -(k^0)^2 + \vec{k}^2$, has precisely these pole placements:

$$k^2 + m^2 - \mathrm{i}\epsilon = -(k^0)^2 + \omega_{\vec{k}}^2 - \mathrm{i}\epsilon.$$

Solving to first order in ϵ gives

$$k^0 = +\omega_{\vec{k}} - \mathrm{i}0, \qquad k^0 = -\omega_{\vec{k}} + \mathrm{i}0.$$

The prefactor $-\mathrm{i}$ is the Jacobian and orientation factor obtained from the rotation $k_\tau = \mathrm{i}e^{\mathrm{i}\alpha}k^0$. The limit is a boundary value of meromorphic functions in k^0, hence is interpreted only after pairing with test functions or after an equivalent contour evaluation.

11.8 Three Green Functions

Definition 11.18 (Wightman, time-ordered, and Euclidean Green functions)**.** Let $\widehat{\phi}$ be a scalar operator-valued distribution with vacuum Ω. The Wightman n-point distribution is

$$W_n(x_1, \ldots, x_n) = \langle \Omega | \widehat{\phi}(x_1) \cdots \widehat{\phi}(x_n) | \Omega \rangle.$$

The order displayed in the formula is part of the definition.

For distinct time coordinates, the time-ordered Green function is

$$G_{T,n}(x_1, \ldots, x_n) = \langle \Omega | \, \mathrm{T}\{\widehat{\phi}(x_1) \cdots \widehat{\phi}(x_n)\} | \Omega \rangle.$$

If

$$x^0_{i_1} > x^0_{i_2} > \cdots > x^0_{i_n},$$

then

$$G_{T,n}(x_1, \ldots, x_n) = W_n(x_{i_1}, \ldots, x_{i_n}).$$

Coincident-time prescriptions are contact-term data and must be fixed in the chosen operator or path-integral framework.

The Euclidean Green function is a distribution in Euclidean points $x_{E,a} = (\tau_a, \vec{x}_a)$. It is denoted $G_{E,n}$ in this path-integral construction. When the same distributions are used as OS reconstruction data, they are denoted S_n and called Schwinger functions. When the analytic continuation from Wightman functions exists and

$$\tau_{i_1} > \tau_{i_2} > \cdots > \tau_{i_n},$$

it is given by

$$G_{E,n}(x_{E,1}, \ldots, x_{E,n}) = W_n(x_{i_1}, \ldots, x_{i_n})\big|_{x^0_a = -\mathrm{i}\tau_a}.$$

These three distributions encode different boundary values of the same analytic structure when the required analyticity and spectral assumptions are available. The next chapter uses this structure in the two-point function to derive the Källén–Lehmann spectral representation.

Chapter 12

Osterwalder–Schrader Reconstruction

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

12.1 Euclidean Correlation Data

Let $E = \mathbb{R}^D$ be Euclidean space with coordinates

$$x = (\tau, \mathbf{x}), \qquad \mathbf{x} \in \mathbb{R}^{D-1}.$$

Let V be the complex vector space of field labels. For scalar fields $V = \mathbb{C}$. For tensor, spinor, or internal multiplets, V carries the corresponding Euclidean rotation and internal representations. An n-point Euclidean test insertion is an element of

$$\mathcal{S}(E^n; V^{\otimes n}),$$

or of $C_c^\infty(E^n; V^{\otimes n})$ if compactly supported test functions are the chosen test class. The test class is part of the data because it determines the topology in which the Schwinger functions are distributions. Let

$$\Delta_n = \bigcup_{1 \le i < j \le n} \{(x_1, \ldots, x_n) \in E^n \mid x_i = x_j\}$$

be the union of partial diagonals. The corrected OS reconstruction theorem is most honestly stated on the zero-diagonal Schwartz space

$$\mathcal{S}_\circ(E^n; V^{\otimes n}) = \{f \in \mathcal{S}(E^n; V^{\otimes n}) \mid \partial^\alpha f|_{\Delta_n} = 0 \text{ for every multi-index } \alpha\}.$$

Pairing with $\mathcal{S}_\circ$ treats the Schwinger functions as distributions away from coincident points. A choice of contact-term extension to the full Schwartz space is extra structure and is not part of the OS reconstruction input used here.

Definition 12.1 (Schwinger hierarchy)**.** A Schwinger hierarchy with field-label space V is a family

$$S_n \in \mathcal{S}'_\circ(E^n; (V^*)^{\otimes n}), \qquad n \geq 0,$$

with $S_0 = 1$. The value $S_n(f_n)$ denotes the distributional pairing of S_n with the $V^{\otimes n}$-valued test function f_n. In component notation this is written as

$$S_{\alpha_1 \cdots \alpha_n}(x_1, \ldots, x_n), \qquad \alpha_j \in I,$$

where I is a basis of labels for V. The component notation is a kernel notation for the distributional pairing; the pairing with test functions is the primary object.

In a construction by a Euclidean measure, these distributions are moments of random distributions. In an axiomatic Euclidean formulation, the hierarchy $\{S_n\}_{n\geq 0}$ is primary data.

Let θ be time reflection:

$$\theta(\tau, \mathbf{x}) = (-\tau, \mathbf{x}).$$

The Euclidean group is

$$\mathrm{Euc}(D) = \mathbb{R}^D \rtimes O(D).$$

It acts on test insertions by pullback on E^n and by the declared label representation on V. The reflection also acts on labels. We denote by $J : V \to V$ the antilinear label map induced by field adjunction and by the Euclidean reflection of tensor or spinor indices. For a scalar Hermitian field, J is ordinary complex conjugation. For a test function f_n supported in the ordered positive-time region

$$E^n_> = \{(x_1, \ldots, x_n) : 0 < \tau_1 < \cdots < \tau_n\},$$

define the reflected adjoint test function Θf_n by reversing the order, reflecting all arguments, and applying J to the labels. For a scalar test function this reads

$$(\Theta f_n)(x_1, \ldots, x_n) = \overline{f_n(\theta x_n, \ldots, \theta x_1)}.$$

With labels, the same formula is composed with $J^{\otimes n}$. Let Θ denote the same antilinear operation on arbitrary n-point test functions; positive-time support is needed only when we form the OS pre-Hilbert space below. Let $\mathcal{E}_+$ be the vector space of finite sequences

$$F = (f_0, f_1, f_2, \ldots),$$

where only finitely many f_n are nonzero and every f_n is a labelled zero-diagonal test function supported in positive Euclidean time with a chosen ordering of its time variables. Reflection positivity is the requirement that the sesquilinear form

$$\langle F, G \rangle_{\mathrm{OS}} = \sum_{m,n} S_{m+n}(\Theta f_m, g_n) \tag{12.1}$$

satisfy

$$\langle F,F\rangle_{\mathrm{OS}}\geq 0 \tag{12.2}$$

for every $F\in\mathcal{E}_+$.

The notation $S_{m+n}(\Theta f_m,g_n)$ means that the reflected m negative-time insertions are followed by the n positive-time insertions in the argument of the distribution. Thus the object required to be positive is the reflected positive-time sesquilinear form on $\mathcal{E}_+$.

Definition 12.2 (OS-admissible Euclidean data)**.** An OS-admissible Euclidean field presentation is a Schwinger hierarchy $\{S_n\}_{n\geq 0}$, together with the label reflection J, satisfying:

(i) normalization: $S_0=1$;

(ii) Euclidean covariance: $S_n(gf_n)=S_n(f_n)$ for $g\in\mathrm{Euc}(D)$;

(iii) permutation symmetry: S_n is invariant under simultaneous permutation of arguments and labels;

(iv) Hermiticity: for every $n\geq 0$ and every labelled n-point test function f_n,

$$S_n(\Theta f_n)=\overline{S_n(f_n)}. \tag{12.3}$$

(v) reflection positivity: $\langle F,F\rangle_{\mathrm{OS}}\geq 0$ for all $F\in\mathcal{E}_+$;

(vi) positive-time semigroup regularity: the positive-time translation operators defined on the OS quotient form a strongly continuous symmetric contraction semigroup, as stated in (12.5)–(12.8);

(vii) corrected OS-II analytic regularity: the difference-variable hierarchy satisfies a many-variable continuation and growth theorem strong enough to give the Lorentzian boundary-value package of Definition 12.8. A standard sufficient hypothesis is the OS-II linear-growth condition (12.4), together with the OS-II several-complex-variable construction described below.

For fermionic or graded fields, the permutation line is replaced by graded permutation symmetry with the Koszul sign determined by the declared parity of each label. Clustering is added when the target Lorentzian theory is required to have a unique vacuum vector.

The last line is a load-bearing analytic hypothesis, not a cosmetic regularity clause. Let S_n^{red} denote the translation-reduced Schwinger distribution in $n-1$ difference variables, acting on the corresponding zero-diagonal difference-test space. With a fixed family of Schwartz seminorms

$$q_{n,N}(F)=\sum_{|\alpha|,|\beta|\leq N}\sup_{\Xi\in E^{n-1}}\left|\Xi^\beta\partial^\alpha F(\Xi)\right|,\qquad F\in\mathcal{S}_\circ(E^{n-1};V^{\otimes n}),$$

one convenient OS-II linear-growth condition is the existence of constants

$$C_{\mathrm{OS}},N_0\in\mathbb{N},\qquad A,B,\gamma>0,$$

independent of n, such that

$$|S_n^{\mathrm{red}}(F)|\leq A\,B^n\,(n!)^\gamma\,q_{n,N_0+C_{\mathrm{OS}}n}(F) \tag{12.4}$$

for all F in that test space. Equivalent OS-II formulations package the same content by using a fixed seminorm family $|\cdot|_{s,n}$ whose definition already contains the n-dependence, together with constants $\sigma_n \leq AB^n(n!)^\gamma$. The word "linear" refers to the allowed growth of the distributional seminorm order with the number of insertions. It is not a statement that a fixed n-point function grows linearly in spacetime.

Together with the positive-time semigroup hypotheses (12.5)–(12.8), this condition has a specific OS-II role. The positive-time Hilbert space and the one-variable semigroup continuation are constructed before the linear-growth estimate is used. The linear-growth estimate controls the many-variable analytic continuation and the polynomial boundary estimates needed to obtain tempered Lorentzian Wightman distributions. The correction from the first Osterwalder–Schrader reconstruction paper to the second is precisely that reflection positivity, Euclidean covariance, symmetry, clustering, and ordinary temperedness do not by themselves prove that the separately obtained one-variable Laplace continuations assemble into a joint many-variable Fourier–Laplace transform with tempered boundary values. Thus an application of OS reconstruction must either prove an OS-II growth condition such as (12.4), or replace it by a different theorem that supplies the same Lorentzian boundary-value estimates. [1]

Remark 12.3 (CFT reconstruction is a different route). For a Euclidean CFT, one should not silently replace the OS-II growth package by conformal terminology. Conformal kinematics gives additional structure: radial ordering, the inversion pairing, positivity of the state-operator inner product, and conformal covariance of operator insertions. In that setting a Lorentzian theory can be reconstructed by proving the convergence and distributional boundary-value properties of conformal correlation functions directly from the conformal Hilbert-space and OPE data. This is a different theorem from OS reconstruction. Kravchuk, Qiao, and Rychkov prove the relevant Lorentzian distribution and OPE-convergence estimates for CFT correlators using conformal kinematics and radial variables;[2] the CFT volume uses that route only after the state-operator Hilbert space and conformal representation theory have been stated as hypotheses.

Figure 12.1 fixes the geometry used in the OS reflection form. In this Euclidean reconstruction figure the reflection time τ is drawn horizontally, so that the fixed plane $\tau = 0$ is the vertical dashed line.

[1]See K. Osterwalder and R. Schrader, "Axioms for Euclidean Green's Functions," Commun. Math. Phys. **31** (1973) 83–112, and "Axioms for Euclidean Green's Functions II," Commun. Math. Phys. **42** (1975) 281–305. The second paper states the corrected reconstruction theorem with the linear-growth input. Modern checks of this analytic input are model dependent. For example, Gubinelli and Hofmanová, "A PDE Construction of the Euclidean Φ^4_3 Quantum Field Theory," Commun. Math. Phys. **384** (2021) 1–75, construct limit measures with reflection positivity, translation invariance, non-Gaussianity, and stretched exponential integrability estimates strong enough for the OS distributional regularity axiom in their formulation; rotation invariance and clustering remain separate inputs in that construction [7, 8, 9].

[2]See P. Kravchuk, J. Qiao, and S. Rychkov, "Distributions in CFT II. Minkowski Space," JHEP **08** (2021) 094, arXiv:2104.02090 [13].

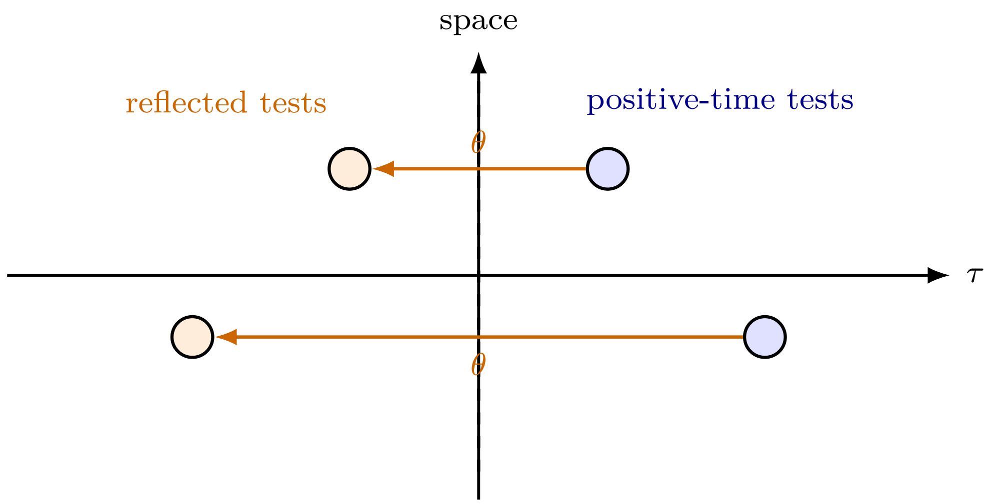

Figure 12.1: Reflection positivity turns Euclidean reflection through $\tau = 0$ into Hilbert-space positivity after reconstruction. The positive quadratic form $\sum S(\Theta f, f) \geq 0$ descends, after quotient by null vectors, to the reconstructed Lorentzian inner product.

12.2 Hilbert Space From Positive Time

Use the positive-time vector space $\mathcal{E}_+$ and the form (12.1). Reflection positivity says that this form is nonnegative. Let

$$\mathcal{N} = \{F \in \mathcal{E}_+ \mid \langle F, F\rangle_{\mathrm{OS}} = 0\}.$$

The reconstructed Hilbert space is

$$\mathcal{H}_{\mathrm{OS}} = \overline{\mathcal{E}_+/\mathcal{N}}.$$

The vector represented by $F = (1, 0, 0, \dots)$ is the vacuum. The quotient is taken before completion. Since (12.1) is positive semidefinite, the Cauchy–Schwarz inequality holds on $\mathcal{E}_+$, and $\mathcal{N}$ is exactly the subspace of zero-norm vectors. Therefore $\mathcal{E}_+/\mathcal{N}$ is a pre-Hilbert space with inner product induced by $\langle \cdot, \cdot\rangle_{\mathrm{OS}}$.

Euclidean time translations by $s \geq 0$ preserve positive-time support and therefore act on $\mathcal{E}_+$. Write $a_s(\tau, \mathbf{x}) = (\tau + s, \mathbf{x})$, and let R_s be the induced action on test sequences, so that each component is translated by a_s. The OS regularity hypotheses needed at this point are the following seminorm statements on $\mathcal{E}_+$:

$$R_0 = \mathbf{1}, \qquad R_{s+t} = R_s R_t, \tag{12.5}$$

$$\|R_s F\|_{\mathrm{OS}} \leq \|F\|_{\mathrm{OS}}, \tag{12.6}$$

$$\langle R_s F, G\rangle_{\mathrm{OS}} = \langle F, R_s G\rangle_{\mathrm{OS}}, \tag{12.7}$$

$$\lim_{s\downarrow 0} \|R_s F - F\|_{\mathrm{OS}} = 0, \tag{12.8}$$

for all $F, G \in \mathcal{E}_+$, where $\|F\|^2_{\mathrm{OS}} = \langle F, F\rangle_{\mathrm{OS}}$. The inequality (12.6) is the contraction statement needed to obtain a nonnegative Hamiltonian. In the classical scalar OS proof it is derived from reflection positivity, Euclidean covariance, the semigroup law, and a polynomial bound on translated matrix elements by the iterative Cauchy–Schwarz argument written below. In the abstract formulation of OS-admissible data we record the contraction and strong continuity explicitly, so that every later use of the Hamiltonian has a named hypothesis.

Remark 12.4 (Failure mode of the first OS reconstruction theorem). The famous error in the first Osterwalder–Schrader reconstruction paper is not the positive-time Hilbert-space quotient and not the one-variable semigroup continuation. Those parts are the reliable core of the construction. The faulty step was the passage from separately controlled one-variable Laplace continuations to a joint many-variable Fourier–Laplace transform. A function on $(0,\infty)^2$ may be a Laplace transform of a tempered distribution in each variable separately without being a joint Laplace transform; the model obstruction is $F(x,y) = \exp(-xy)$. The corrected OS-II proof replaces that step by a several-complex-variable continuation ladder and then uses a linear-growth estimate to prove the polynomial bounds that make the boundary values tempered distributions.[3]

Proposition 12.5 (Contraction from the OS semigroup estimate)**.** *Let $R_t : \mathcal{E}_+ \to \mathcal{E}_+$, $t \geq 0$, satisfy the semigroup law $R_{t+s} = R_t R_s$, the OS symmetry relation*

$$\langle R_t F, G\rangle_{\mathrm{OS}} = \langle F, R_t G\rangle_{\mathrm{OS}}, \qquad F, G \in \mathcal{E}_+,$$

and, for each $F \in \mathcal{E}_+$, a polynomial growth bound

$$|\langle F, R_u F\rangle_{\mathrm{OS}}| \leq C_F (1+u)^{N_F}, \qquad u \geq 0.$$

Then

$$\|R_t F\|_{\mathrm{OS}} \leq \|F\|_{\mathrm{OS}}, \qquad t \geq 0.$$

In particular $R_t \mathcal{N} \subset \mathcal{N}$, so R_t descends to a contraction on the OS quotient.

Proof. Assume first that $\|F\|_{\mathrm{OS}} > 0$. Put

$$a_j = \langle F, R_{2^j t} F\rangle_{\mathrm{OS}}, \qquad j = 0, 1, 2, \ldots.$$

For $j \geq 1$, the semigroup law and OS symmetry give

$$a_j = \langle R_{2^{j-1}t} F, R_{2^{j-1}t} F\rangle_{\mathrm{OS}} \geq 0.$$

The Cauchy–Schwarz inequality in the positive semidefinite OS form gives, for $j \geq 1$,

$$a_j^2 = |\langle F, R_{2^j t} F\rangle_{\mathrm{OS}}|^2 \leq \|F\|_{\mathrm{OS}}^2 \|R_{2^j t} F\|_{\mathrm{OS}}^2 = a_0\, a_{j+1}.$$

Induction therefore yields

$$a_1 \leq a_0^{1-2^{-N}} a_N^{2^{-N}}, \qquad N \geq 1.$$

The polynomial bound gives

$$a_N^{2^{-N}} \leq C_F^{2^{-N}} (1 + 2^N t)^{N_F 2^{-N}} \longrightarrow 1.$$

Letting $N \to \infty$ gives $a_1 \leq a_0$. Since

$$a_1 = \langle F, R_{2t} F\rangle_{\mathrm{OS}} = \langle R_t F, R_t F\rangle_{\mathrm{OS}} = \|R_t F\|_{\mathrm{OS}}^2,$$

the contraction estimate follows. If $\|F\|_{\mathrm{OS}} = 0$, Cauchy–Schwarz already gives $\langle F, R_u F\rangle_{\mathrm{OS}} = 0$ for all $u \geq 0$, and the same identity gives $\|R_t F\|_{\mathrm{OS}} = 0$. Thus null vectors are preserved, and the quotient operator is a contraction. □

[3]OS II states explicitly that Lemma 8.8 of OS I is wrong and gives the $F(x,y) = \exp(-xy)$ obstruction. See K. Osterwalder and R. Schrader, "Axioms for Euclidean Green's Functions II," Commun. Math. Phys. **42** (1975) 281–305, Introduction and Chapters IV–VI [8].

Contractivity implies $R_s\mathcal{N} \subset \mathcal{N}$, so R_s descends to a bounded operator $T_E(s)$ on the quotient and then to $\mathcal{H}_{\mathrm{OS}}$. Equations (12.5)–(12.8) say precisely that $\{T_E(s)\}_{s\geq 0}$ is a strongly continuous semigroup of self-adjoint contractions. Indeed, (12.7) gives, on the dense quotient,

$$\langle [F], T_E(s)[G]\rangle_{\mathrm{OS}} = \langle [F], [R_sG]\rangle_{\mathrm{OS}} = \langle [R_sF], [G]\rangle_{\mathrm{OS}} = \langle T_E(s)[F], [G]\rangle_{\mathrm{OS}}.$$

The equality descends to the quotient because $R_s\mathcal{N} \subset \mathcal{N}$, and it extends to $\mathcal{H}_{\mathrm{OS}}$ because $T_E(s)$ is bounded by (12.6). Thus the self-adjointness of the Euclidean time semigroup is not inferred from a formal reflection manipulation outside positive time; it is precisely the OS-II symmetry condition on the reflection-positive quotient.

Let A be its infinitesimal generator,

$$A\psi = \lim_{s\downarrow 0} \frac{T_E(s)\psi - \psi}{s},$$

on the vectors for which the limit exists in $\mathcal{H}_{\mathrm{OS}}$. The self-adjoint contraction-semigroup theorem gives $A = A^*$ and $\sigma(A) \subset (-\infty, 0]$. Setting $H = -A$, the spectral theorem gives

$$T_E(s) = \mathrm{e}^{-sH}, \qquad H = H^*, \qquad H \geq 0.$$

Stone's theorem then applies to the strongly continuous unitary group $U_{\mathrm{time}}(t) = \mathrm{e}^{-\mathrm{i}tH}$: its named hypotheses are the unitary group law, strong continuity in t, and self-adjointness of the generator. This H is the Lorentzian Hamiltonian in the reconstructed vacuum sector.

Proposition 12.6 (One-gap continuation from the OS semigroup)**.** *Let $F, G \in \mathcal{E}_+$ be two positive-time test sequences whose supports are arranged so that, for $s > 0$, R_sG remains later than the insertions in F. Let*

$$\psi_F = [F], \qquad \psi_G = [G] \in \mathcal{H}_{\mathrm{OS}}.$$

Then the Euclidean matrix element with distinguished time gap s is

$$\langle \psi_F, T_E(s)\psi_G\rangle_{\mathrm{OS}} = \langle \psi_F, \mathrm{e}^{-sH}\psi_G\rangle_{\mathcal{H}_{\mathrm{OS}}}.$$

For $z \in \mathbb{C}$ with $\Re z > 0$, define

$$M_{F,G}(z) = \langle \psi_F, \mathrm{e}^{-zH}\psi_G\rangle_{\mathcal{H}_{\mathrm{OS}}}.$$

Then $M_{F,G}$ is holomorphic on the right half-plane and satisfies

$$|M_{F,G}(z)| \leq \|\psi_F\|\,\|\psi_G\|, \qquad \Re z > 0.$$

Moreover, for every $t \in \mathbb{R}$,

$$\lim_{\epsilon\downarrow 0} M_{F,G}(\epsilon + \mathrm{i}t) = \langle \psi_F, \mathrm{e}^{-\mathrm{i}tH}\psi_G\rangle_{\mathcal{H}_{\mathrm{OS}}}.$$

Proof. The first identity is the definition of the descended positive-time translation semigroup:

$$T_E(s)[G] = [R_sG], \qquad T_E(s) = \mathrm{e}^{-sH}.$$

For the holomorphic extension, let E_H be the spectral resolution of the nonnegative self-adjoint operator H, and let

$$\mu_{F,G}(\Delta) = \langle \psi_F, E_H(\Delta)\psi_G\rangle$$

be the finite complex spectral measure associated to ψ_F, ψ_G. Its total variation is bounded by $|\mu_{F,G}|([0,\infty)) \le \|\psi_F\| \, \|\psi_G\|$. The spectral theorem gives

$$M_{F,G}(z) = \int_{[0,\infty)} \mathrm{e}^{-z\lambda} \, \mathrm{d}\mu_{F,G}(\lambda), \qquad \Re z > 0.$$

On compact subsets of the right half-plane, derivatives with respect to z are obtained by differentiating under the integral:

$$\partial_z^k M_{F,G}(z) = \int_{[0,\infty)} (-\lambda)^k \mathrm{e}^{-z\lambda} \, \mathrm{d}\mu_{F,G}(\lambda),$$

because $\lambda^k \mathrm{e}^{-(\Re z)\lambda}$ is bounded on $[0,\infty)$ uniformly for $\Re z$ bounded below by a positive constant. This proves holomorphy. The norm bound follows from $|\mathrm{e}^{-z\lambda}| \le 1$. Finally, $\mathrm{e}^{-(\epsilon+\mathrm{i}t)\lambda} \to \mathrm{e}^{-\mathrm{i}t\lambda}$ pointwise and is bounded by 1; dominated convergence for the finite measure $|\mu_{F,G}|$ gives the stated boundary value. $\square$

This proposition is the sound one-variable part of the OS construction. It does not by itself produce an n-variable Wightman distribution. The next QFT-specific task is to show that all one-gap continuations coming from different cuts of the same Schwinger function assemble into a joint many-variable analytic function with the spectral support and boundary-value estimates required below. That assembly is the content of the corrected OS-II analytic theorem.

Spatial translations and rotations act unitarily on the quotient. Together with the analytic continuation of Euclidean rotations, the full OS theorem gives a strongly continuous unitary representation of the connected Poincare group with joint translation spectrum contained in the closed forward cone.

The passage from Euclidean covariance to Lorentzian covariance occurs here. Reflection positivity constructs the positive-time quotient and Euclidean time semigroup. The corrected OS-II analytic theorem, with its growth hypothesis, then supplies the joint Lorentzian boundary values and the Poincare representation. These are distinct steps: the one-variable semigroup argument above is necessary, but the many-variable analytic continuation is the additional QFT-specific content.

12.3 Fields on the Reconstructed Domain

Let $\mathcal{D}_{\mathrm{OS}} \subset \mathcal{H}_{\mathrm{OS}}$ be the image of $\mathcal{E}_+$ in the quotient. This dense subspace is the natural common domain for the reconstructed fields before closure. If h is a Euclidean test function valued in V, with support at positive time and ordered before the supports appearing in $F \in \mathcal{E}_+$, define

$$\Phi_E(h)[F] = [h \otimes F],$$

where $h \otimes F$ denotes the sequence obtained by inserting one additional Euclidean field smeared with h. This formula is only meaningful after one checks that it descends through the null quotient. The check is a reflection-positive adjointness argument, not a formal manipulation with point fields.

Proposition 12.7 (Well-definedness and closability of ordered insertions)**.** *Assume the operator-domain part of the OS data supplies the following adjoint-insertion identity. For every ordered* *positive-time test insertion h there is an ordered test insertion $h^\sharp$, with adjoint label and with supports arranged by a common positive time translation, such that for all $F, G \in \mathcal{E}_+$*

$$\langle [G], [h \otimes F] \rangle_{\mathrm{OS}} = \langle [h^\sharp \otimes G], [F] \rangle_{\mathrm{OS}}. \tag{12.9}$$

Then $F \in \mathcal{N}_{\mathrm{OS}}$ implies $h \otimes F \in \mathcal{N}_{\mathrm{OS}}$. Hence $\Phi_E(h)[F] = [h \otimes F]$ is a well-defined operator on the quotient domain $\mathcal{D}_{\mathrm{OS}}$. This operator is closable.

Proof. Let $F \in \mathcal{N}_{\mathrm{OS}}$. In a positive semidefinite Hermitian form, Cauchy–Schwarz gives, for every $K \in \mathcal{E}_+$,

$$\langle K, F \rangle_{\mathrm{OS}} = 0.$$

Therefore, for every $G \in \mathcal{E}_+$,

$$\langle [G], [h \otimes F] \rangle_{\mathrm{OS}} = \langle [h^\sharp \otimes G], [F] \rangle_{\mathrm{OS}} = 0.$$

Taking $G = h \otimes F$, with the common positive time translation already included in the ordered-support hypothesis, gives $\|h \otimes F\|_{\mathrm{OS}}^2 = 0$. Thus $h \otimes F \in \mathcal{N}_{\mathrm{OS}}$, and the quotient operator is well defined.

Let $\psi_k \in \mathcal{D}_{\mathrm{OS}}$ satisfy $\psi_k \to 0$ and $\Phi_E(h)\psi_k \to \eta$ in $\mathcal{H}_{\mathrm{OS}}$. To prove closability it suffices to show $\eta = 0$. For a dense test vector $[G] \in \mathcal{D}_{\mathrm{OS}}$, the adjoint-insertion identity gives

$$\langle [G], \eta \rangle_{\mathrm{OS}} = \lim_k \langle [G], \Phi_E(h)\psi_k \rangle_{\mathrm{OS}} = \lim_k \langle [h^\sharp \otimes G], \psi_k \rangle_{\mathrm{OS}} = 0,$$

because $[h^\sharp \otimes G]$ is a fixed vector in $\mathcal{D}_{\mathrm{OS}}$ and $\psi_k \to 0$. Since $\mathcal{D}_{\mathrm{OS}}$ is dense, η is orthogonal to all of $\mathcal{H}_{\mathrm{OS}}$, hence $\eta = 0$. This is the standard closability criterion, with the QFT-specific content isolated in the matrix-element identity (12.9). □

Lorentzian fields are obtained by continuing these matrix elements on the reconstructed Hilbert space. For ordered imaginary parts

$$\epsilon_1 > \epsilon_2 > \cdots > \epsilon_n > 0,$$

the Wightman distributions are boundary values of the Schwinger functions continued to

$$\tau_j = \epsilon_j + \mathrm{i}t_j, \qquad j = 1, \ldots, n. \tag{12.10}$$

Equivalently, the complex Lorentzian time coordinate is

$$z_j^0 = -\mathrm{i}\tau_j = t_j - \mathrm{i}\epsilon_j.$$

Thus for an ordered adjacent difference,

$$z_j - z_{j+1} = (x_j - x_{j+1}) - \mathrm{i}(\epsilon_j - \epsilon_{j+1})e_0, \qquad e_0 = (1, \mathbf{0}).$$

The tube depth is the future vector $(\epsilon_j - \epsilon_{j+1})e_0 \in V_+^\circ$, while the literal imaginary part of $z_j - z_{j+1}$ is its negative. Throughout this chapter the "forward tube" in mostly-plus signature means

$$z = \xi - \mathrm{i}\eta, \qquad \eta \in V_+^\circ,$$

matching the Wightman convention of Proposition 2.5. This sign is not notation: for $p, \eta \in \overline{V}_+$, the mostly-plus pairing obeys $p \cdot \eta \leq 0$, so the factor $\exp(\mathrm{i}p \cdot (\xi - \mathrm{i}\eta)) = \exp(\mathrm{i}p \cdot \xi + p \cdot \eta)$ is damped. The reconstructed operator $\widehat{\Phi}_\alpha(t, \mathbf{f})$ is the operator-valued distribution whose vacuum matrix elements are these boundary values and whose time dependence is implemented by the unitary group

$$\mathrm{e}^{-\mathrm{i}tH}.$$

Thus the OS construction produces the vacuum vector, the Hilbert space, the positive Hamiltonian, and the field domains from the same Euclidean correlation hierarchy.

As in the Wightman presentation, these reconstructed fields are generally unbounded distributional coordinates. A represented local observable algebra $\mathcal{R}(\mathcal{O})$ is obtained by specifying a closure, affiliation, or bounded functional-calculus construction, or by building a local net directly and proving that the reconstructed fields are affiliated with it. The OS theorem reconstructs a Lorentzian Wightman field presentation; comparison with AQFT local observable content is a further construction with its own hypotheses.

12.4 Analytic Continuation Input

The OS-II regularity assumptions are used through the following boundary-value package. It is stated separately because this is the part of the reconstruction theorem where the first OS paper needed correction.

Definition 12.8 (OS Lorentzian boundary-value package)**.** For each n, the Schwinger distribution S_n is said to satisfy the OS Lorentzian boundary-value package if the following data and estimates are available.

(i) For every Euclidean time ordering there is a holomorphic function

$$\mathcal{W}_n(z_1, \ldots, z_n)$$

on the corresponding mostly-plus forward tube in the difference variables

$$z_j - z_{j+1} = \xi_j - \mathrm{i}\eta_j, \qquad \eta_j \in V_+^\circ,$$

equivalently $-\operatorname{Im}(z_j - z_{j+1}) \in V_+^\circ$. Here V_+° is the open Lorentzian forward cone. The restriction of $\mathcal{W}_n$ to ordered imaginary times agrees with S_n away from coincident points.

(ii) The holomorphic functions obey tempered tube bounds: for every compact subcone $K \subset (V_+^\circ)^{n-1}$ and every positive lower bound on the distance of the tube-depth variables η_j from the boundary of the cone, the boundary pairings with Schwartz tests are bounded by finitely many Schwartz seminorms with polynomial dependence on the reciprocal distance to the cone boundary.

(iii) The permuted Euclidean orderings give holomorphic functions on the corresponding permuted tubes that agree on their common Euclidean real submanifolds. For spacelike separated adjacent insertions, the two permuted tubes have a connected continuation through the corresponding Jost domain by the distributional edge-of-the-wedge theorem 16.6, with the Koszul sign included for graded fields.

Theorem 12.9 (Tempered boundary values from polynomial tube bounds). *Let $C \subset \mathbb{R}^d$ be an open convex cone and let*

$$T_C = \mathbb{R}^d + \mathrm{i}C$$

be the corresponding tube. Let F be holomorphic on T_C. Suppose that for every closed subcone $K \Subset C$ there are integers M, N and a constant A_K such that

$$|\langle F(\cdot + \mathrm{i}y), f\rangle| \leq A_K \ \mathrm{dist}(y, \partial C)^{-M} \sum_{|\alpha|,|\beta| \leq N} \sup_{x \in \mathbb{R}^d} |x^\beta \partial^\alpha f(x)| \tag{12.11}$$

for all $y \in K$ and all $f \in \mathcal{S}(\mathbb{R}^d)$, whenever the left hand side is defined by integration over x. Then F has a unique tempered boundary value

$$\mathrm{bv}\, F \in \mathcal{S}'(\mathbb{R}^d)$$

in the sense that $F(\cdot + \mathrm{i}y) \to \mathrm{bv}\, F$ in $\mathcal{S}'(\mathbb{R}^d)$ as $y \to 0$ inside any proper subcone of C. If, in addition, F is the Fourier–Laplace transform of a distribution carried by the dual closed cone

$$C^* = \{p \in \mathbb{R}^d \mid p \cdot y \geq 0 \textit{ for all } y \in C\},$$

then the Fourier transform of $\mathrm{bv}\, F$ *is carried by C^*.*

The cone-support statement used for the spectral condition has a direct Fourier–Laplace proof, recorded first because it is the part of the theorem that enters the QFT interpretation most explicitly.

Lemma 12.10 (Fourier–Laplace boundary and cone support). *Let $C \subset \mathbb{R}^d$ be an open convex cone whose dual closed cone C^* has the following proper-separation property: for every $K \Subset C$ there is $c_K > 0$ such that*

$$p \cdot y \geq c_K |p|\,|y|, \qquad p \in C^*, \ y \in K. \tag{12.12}$$

Let $u \in \mathcal{S}'(\mathbb{R}^d)$ have support contained in C^*. For $y \in C$, put

$$u_y = \mathrm{e}^{-p \cdot y} u$$

as a product of a distribution with a smooth multiplier, defined in a conic neighborhood of $\operatorname{supp} u$, *and let*

$$F(\cdot + \mathrm{i}y) = \mathcal{F}^{-1} u_y.$$

Then F is holomorphic in the tube $T_C = \mathbb{R}^d + \mathrm{i}C$, and

$$F(\cdot + \mathrm{i}y) \longrightarrow \mathcal{F}^{-1} u \quad \textit{in } \mathcal{S}'(\mathbb{R}^d)$$

as $y \to 0$ inside every proper subcone of C. Consequently the Fourier transform of the boundary value is u, hence is carried by C^*.

Proof. The only point needing care is the multiplication by $\mathrm{e}^{-p \cdot y}$, because this function may grow outside the dual cone. Fix $K \Subset C$. Choose a closed conic neighborhood U of $C^* \setminus \{0\}$ so small that

$$p \cdot y \geq \frac{c_K}{2} |p|\,|y|, \qquad p \in U, \ y \in K, \tag{12.13}$$

and choose a smooth conic cutoff χ which is equal to 1 on a neighborhood of $C^* \setminus \{0\}$ and whose support is contained in U outside a compact ball. Near the origin modify χ smoothly so that it is identically 1 on a neighborhood of $\operatorname{supp} u \cap B_R$ for a fixed large R. Since distributions are tested only in a neighborhood of their support, the product $\mathrm{e}^{-p\cdot y}u$ is the same as $(\chi(p)\mathrm{e}^{-p\cdot y})u$; a different cutoff with the same property gives the same distribution because the two multipliers agree near $\operatorname{supp} u$.

For $y \in K$, (12.13) implies that every derivative of $\chi(p)\mathrm{e}^{-p\cdot y}$ is bounded by a polynomial in $|y|$ times an exponentially decaying factor on the support of χ, apart from a compact set. Hence multiplication by $\chi\mathrm{e}^{-p\cdot y}$ is a continuous operation on $\mathcal{S}'(\mathbb{R}^d)$, uniformly for y in compact subsets of K. If $f \in \mathcal{S}(\mathbb{R}^d)$, then

$$\langle u_y, \widehat{f}\rangle = \langle u, \chi(p)\mathrm{e}^{-p\cdot y}\widehat{f}(p)\rangle.$$

As $y \to 0$ in K, the Schwartz functions

$$\chi(p)\big(\mathrm{e}^{-p\cdot y} - 1\big)\widehat{f}(p)$$

converge to zero in $\mathcal{S}(\mathbb{R}^d)$. Indeed, after applying any derivative, each term contains either a factor tending uniformly to zero on compact sets or a positive power of y; on the conic part the rapid decay of $\widehat{f}$ and (12.13) dominate all polynomial weights. Therefore $u_y \to u$ in $\mathcal{S}'(\mathbb{R}^d)$, and continuity of the inverse Fourier transform on tempered distributions gives

$$\mathcal{F}^{-1}u_y \to \mathcal{F}^{-1}u.$$

Holomorphy follows from the same estimates. Differentiating the pairing $\langle u, \chi\mathrm{e}^{-p\cdot y}\mathrm{e}^{-\mathrm{i}p\cdot x}\rangle$ with respect to the complex variable $z = x + \mathrm{i}y$ brings down polynomial factors in p, which preserve the preceding tempered estimates. The Cauchy–Riemann relations hold at the level of pairings with Schwartz tests, hence F is a holomorphic $\mathcal{S}'$-valued function on the tube. The boundary value has Fourier transform u by construction, so its Fourier support is contained in C^*. □

Proof of Theorem 12.9. The theorem is an analytic statement about holomorphic functions with values in a finite-order dual of the Schwartz space. We spell out the mechanism because OS reconstruction uses exactly the distinction between polynomial tube growth and spectral cone support.

Let

$$p_N(f) = \sum_{|\alpha|,|\beta|\le N} \sup_{x\in\mathbb{R}^d} |x^\beta \partial^\alpha f(x)|$$

be a Schwartz seminorm. The hypothesis says that, for y in every proper subcone $K \Subset C$, the distribution

$$F_y : f \longmapsto \langle F(\cdot + \mathrm{i}y), f\rangle$$

belongs to the Banach dual of the completion of $\mathcal{S}(\mathbb{R}^d)$ in the norm p_N, with norm bounded by a fixed power of $\operatorname{dist}(y, \partial C)^{-1}$. Cauchy's integral formula in small polydiscs contained in the tube gives the same type of bound for all complex derivatives of F, with the exponent increased by the derivative order. Thus $y \mapsto F_y$ is a weakly holomorphic, locally bounded finite-order distribution-valued function on every proper subtube.

Fix a vector $\eta \in C$ and choose $K \Subset C$ containing the ray $\mathbb{R}_{>0}\eta$ near the origin. For $0 < s < t$ and $f \in \mathcal{S}(\mathbb{R}^d)$, apply Cauchy's formula to the scalar holomorphic function obtained by translating the test function:

$$z \longmapsto \big\langle F(\cdot + \mathrm{i}z\eta), f(\cdot - a)\big\rangle, \qquad a \in \mathbb{R}^d.$$

After integrating the resulting identity against a compactly supported approximate identity in a, and then moving derivatives from the Cauchy kernel onto the test function, one obtains an estimate of the form

$$|\langle F_{t\eta} - F_{s\eta}, f\rangle| \le C_{K,m}\, \omega_{f,m}(s,t), \tag{12.14}$$

where m is chosen larger than the polynomial-growth exponent and $\omega_{f,m}(s,t) \to 0$ as $s,t \downarrow 0$. The point of choosing m larger than the growth order is that the normal antiderivative supplied by the Cauchy kernel is locally integrable at the edge; all singular powers are absorbed by finitely many derivatives of the test function. Hence $\{F_{t\eta}\}_{t>0}$ is Cauchy in $\mathcal{S}'(\mathbb{R}^d)$ and defines a tempered distribution b_η.

The limit is independent of the proper approach cone. If $\eta_0, \eta_1 \in C$, the convexity of C puts the segment $(1-r)\eta_0 + r\eta_1$ in a proper subcone after shrinking to small t. Applying the preceding Cauchy estimate in the two real variables (t,r) to the holomorphic function in the corresponding two-dimensional complex slice shows that

$$\lim_{t\downarrow 0} F_{t\eta_0} = \lim_{t\downarrow 0} F_{t\eta_1}$$

in $\mathcal{S}'(\mathbb{R}^d)$. We denote the common limit by $\operatorname{bv} F$. The same argument with $y \to 0$ inside an arbitrary proper subcone, using a polygonal chain of rays inside that subcone, gives the full boundary-value convergence stated in the theorem. Uniqueness is immediate: a tempered distribution is determined by its pairings with Schwartz tests, and any two candidate limits agree with the radial limit just constructed.

If F is given as a Fourier–Laplace transform of a distribution carried by C^*, Lemma 12.10 identifies the boundary value with the inverse Fourier transform of that distribution. Therefore the Fourier transform of the boundary value is carried by C^*. □

Thus the QFT-specific work in OS reconstruction is not the analytic boundary-value theorem or the Fourier–Laplace cone-support argument above, but the proof that the holomorphic functions constructed from the Schwinger hierarchy obey the polynomial tube estimates to which the boundary-value theorem applies.

Proposition 12.11 (OS-II analytic route to the boundary-value package)**.** *Fix $k = n-1$ and write the ordered difference variables as*

$$\xi_j = x_{j+1} - x_j, \qquad j = 1, \dots, k.$$

Assume the following OS-II analytic data have been constructed from the Schwinger hierarchy.

(i) There are scalar analyticity domains $C_k^{(N)}$ in the complexified time-difference variables and mixed Hilbert-vector domains $D_m^{(N)}$ for the OS vectors Ψ_m, with

$$\bigcup_{N\ge 0} C_k^{(N)} = \{(\zeta_1, \dots, \zeta_k) : \Re\zeta_j > 0 \text{ for all } j\}.$$

(ii) On each $C_k^{(N)}$ there is a holomorphic representative $S_k^{(N)}$ of the difference-variable Schwinger function, and the representatives agree on overlaps.

(iii) The Hilbert-vector fields $\Psi_m(x,\zeta)$ are holomorphic on $D_m^{(N)}$ and satisfy the OS scalar-product formula

$$\langle \Psi_r(x,\zeta), \Psi_s(y,\eta)\rangle_{\mathcal{H}_{\mathrm{OS}}} = S^{(N)}_{r+s-1}\big(-\overline{\zeta},\ x+y,\ \eta\big) \tag{12.15}$$

whenever both sides are defined. The block $-\overline{\zeta}$ is the reflected left block, $x+y$ is the real bridge time, and η is the right block.

(iv) The local step $A_N \Rightarrow P_N$ is obtained by Hilbert-space Taylor reconstruction: the squared norm of the vector Taylor remainder is the scalar Taylor remainder of the function on the right hand side of (12.15). The step $P_N \Rightarrow A_{N+1}$ is obtained from the scalar products of these vector fields and extension to the envelope of holomorphy defining $C_k^{(N+1)}$.

(v) The continued scalar functions obey a uniform polynomial tube estimate: for every closed subcone $K \Subset (V_+^\circ)^k$ and every $\delta > 0$, if the Lorentzian difference variables are written as $\xi_j - \mathrm{i}\eta_j$ with tube-depth variables $\eta = (\eta_1, \ldots, \eta_k)$ lying in K at distance at least δ from its boundary, then

$$|\langle S_k(\cdot - \mathrm{i}\eta), f\rangle| \le C_{k,K}\, \delta^{-N_k} \sum_{|\alpha|,|\beta|\le N_k} \sup_\xi |\xi^\beta \partial^\alpha f(\xi)| \tag{12.16}$$

for all Schwartz tests f in the reduced difference variables.

(vi) Euclidean covariance identifies the product right-half-plane continuation with the standard forward-tube continuation in Lorentzian difference variables, and the corresponding statements hold for every permutation of the field insertions, with the Koszul sign for graded labels.

Then the Schwinger hierarchy satisfies the OS Lorentzian boundary-value package of Definition 12.8.

Proof. Items (i)–(iii) provide a single holomorphic function in the ordered difference variables: the functions $S_k^{(N)}$ agree on overlaps, and the union of their domains is the full product right half-plane in the ordered time gaps. Item (vi) transports this function by Euclidean covariance to the mostly-plus forward tube $z = \xi - \mathrm{i}\eta$, $\eta \in V_+^\circ$, in Lorentzian difference variables. This gives part (i) of Definition 12.8.

The estimate (12.16) is exactly the tempered tube-bound input in part (ii) of the boundary-value package. The right hand side is a finite Schwartz seminorm, and the dependence on the distance to the cone boundary is polynomial. Therefore the family of functionals $f \mapsto \langle S_k(\cdot - \mathrm{i}\eta), f\rangle$ is bounded in a fixed finite-order tempered-distribution topology on each closed subtube. Theorem 12.9 then gives tempered boundary values as $\eta \to 0$ inside the cone, after the sign conversion $y = -\eta$ explained below.

For a permutation of insertions, item (vi) gives the corresponding permuted tube. Euclidean permutation symmetry says that the permuted holomorphic functions have the same values on their common Euclidean ordered real submanifolds, after inserting the Koszul sign for odd labels. The identity theorem and the distributional edge-of-the-wedge theorem 16.6 applied at Jost configurations therefore give the connected continuation through the common real edge. This is part (iii) of Definition 12.8. □

Theorem 12.12 (Corrected OS-II analytic theorem)**.** *Let the Schwinger hierarchy satisfy normalization, Euclidean covariance, graded permutation symmetry, Hermiticity, reflection positivity, the positive-time semigroup regularity stated above, and the linear-growth condition (12.4). Work* *componentwise in a fixed finite field-label basis; graded signs enter only when two labelled insertions are permuted. Then the OS-II analytic data listed in Proposition 12.11 are obtained from the Schwinger hierarchy. Hence the hierarchy satisfies the OS Lorentzian boundary-value package.*

Proof. We write the proof for scalar components. Since V is finite dimensional in the present field presentation, labelled components are handled by the same argument applied to matrix-valued distributions; the label reflection J and the Koszul signs only change the component bookkeeping.

Let $k = n - 1$. Translation invariance lets us write the ordered Euclidean n-point function in reduced variables

$$\xi = (\xi_1, \ldots, \xi_k), \qquad \xi_j = x_{j+1} - x_j \in E.$$

On a fixed ordered component of the complement of the partial diagonals, write

$$\xi_j = (t_j, \mathbf{x}_j), \qquad t_j > 0,$$

after a Euclidean transformation if necessary. The complex variables used below are the time gaps

$$\zeta = (\zeta_1, \ldots, \zeta_k), \qquad C_+^k = \{\zeta \in \mathbb{C}^k : \Re\zeta_j > 0\}.$$

Spatial difference variables are kept as real parameters until the final Euclidean covariance step; this is only a notational separation, not a restriction on covariance.

Step 1: local one-direction continuation. Choose a split of the insertions into a reflected left block and a positive right block, and separate the two blocks by one positive Euclidean time gap $s > 0$. Reflection positivity gives OS vectors ψ_F, ψ_G and Proposition 12.6 gives

$$s \longmapsto S_{r+s-1}(-\xi_L, s, \xi_R) = \langle \psi_F, \mathrm{e}^{-sH}\psi_G\rangle_{\mathcal{H}_{\mathrm{OS}}}$$

as the boundary value on $s > 0$ of a function holomorphic for $\Re z > 0$. Euclidean covariance lets us rotate the distinguished positive direction. Thus every noncoincident real configuration has finitely many one-complex-variable continuations in directions spanning the complexified difference-variable space.

The passage from these one-variable continuations to a local many-variable continuation is an application of the Malgrange–Zerner extension theorem for compatible holomorphic continuations from flat wedges. Explicitly, choose D real directions e_μ which form a Euclidean basis and a radius $\rho(\xi) > 0$ small enough that every displacement

$$\xi_j + \sum_{\mu=1}^{D} z_{j\mu} e_\mu, \qquad |z_{j\mu}| < \rho(\xi),$$

stays in the same noncoincident ordered component after the relevant rotations. The one-variable continuations agree on their common real slices because they all restrict to the same Schwinger distribution. The Malgrange–Zerner theorem therefore gives a holomorphic function in the polydisc $|z_{j\mu}| < c\rho(\xi)$, whose real restriction is the original Schwinger function. This proves real analyticity away from the partial diagonals and gives the initial assertion A_0.

Step 2: the A_N/P_N induction. We now define the induction precisely. $A_N(k)$ means that the reduced k-gap Schwinger function has a holomorphic representative

$$S_k^{(N)}(\zeta \mid \mathbf{x})$$

for $\zeta \in C_k^{(N)}$, continuous in the real spatial differences $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_k)$, and agreeing with the previous representatives on overlaps. The initial domain $C_k^{(0)}$ is the union of the local polydiscs supplied by Step 1 around positive real time gaps.

Given $C_\ell^{(N)}$, define the vector domain $D_m^{(N)}$ as the set of pairs (x, ζ), with $x > 0$ a real bridge time and $\zeta = (\zeta_1, \dots, \zeta_{m-1})$, for which the reflected norm argument

$$(-\overline{\zeta}_{m-1}, \dots, -\overline{\zeta}_1,\ 2x,\ \zeta_1, \dots, \zeta_{m-1})$$

lies in $C_{2m-1}^{(N)}$. $P_N(m)$ means that there is a holomorphic $\mathcal{H}_{\mathrm{OS}}$-valued function $\Psi_m(x, \zeta)$ on this domain such that, whenever the displayed scalar argument lies in $C_{r+s-1}^{(N)}$,

$$\big\langle \Psi_r(x, \zeta), \Psi_s(y, \eta) \big\rangle_{\mathcal{H}_{\mathrm{OS}}} = S_{r+s-1}^{(N)}(-\overline{\zeta},\ x + y,\ \eta). \tag{12.17}$$

This is the scalar-product formula (12.15).

The implication $A_N \Rightarrow P_N$ is the Hilbert Taylor argument. Fix a real point $(x, \xi) \in D_m^{(N)}$ and a polydisc $P \Subset D_m^{(N)}$. At the real point the vector $\Psi_m(x, \xi)$ is the OS class of the ordered test insertion. Its strong derivatives are defined by differentiating the test insertion before passing to the OS quotient. For $\zeta \in P$ set the L-th vector Taylor remainder

$$R_L(\zeta) = \Psi_m(x, \zeta) - \sum_{|\alpha| \le L} \frac{(\zeta - \xi)^\alpha}{\alpha!}\, \partial_\xi^\alpha \Psi_m(x, \xi).$$

Using (12.17) for real ξ and then $A_N(2m-1)$, the squared norm of this remainder is the scalar Taylor remainder of the holomorphic function

$$S_{2m-1}^{(N)}(-\overline{\zeta}, 2x, \zeta)$$

about $(-\xi, 2x, \xi)$. The scalar Taylor remainder tends to zero uniformly on smaller polydiscs. Hence $R_L(\zeta) \to 0$ in $\mathcal{H}_{\mathrm{OS}}$, and the Taylor series defines a holomorphic vector $\Psi_m(x, \zeta)$. Polarizing the norm identity gives (12.17), so P_N follows.

Conversely, assume $P_N(r)$ and $P_N(s)$ for all lower vector lengths. For $k = r + s - 1$ the scalar product

$$(x, \zeta; y, \eta) \longmapsto \langle \Psi_r(x, \zeta), \Psi_s(y, \eta) \rangle_{\mathcal{H}_{\mathrm{OS}}}$$

is holomorphic on the mixed vector domain and agrees with S_k on the real ordered slice. Let $C_k^{(N+1)}$ be the envelope of holomorphy of the union of all scalar domains generated in this way, together with $C_k^{(N)}$. The identity theorem gives a single extension $S_k^{(N+1)}$. Thus $P_N \Rightarrow A_{N+1}$. Starting from A_0, induction gives

$$A_0 \Rightarrow P_0 \Rightarrow A_1 \Rightarrow P_1 \Rightarrow \cdots .$$

Step 3: exhaustion of the product half-plane. The induction just defined enlarges only the time-gap domains. To see that it reaches all of C_+^k, use logarithmic coordinates

$$\zeta_j = \mathrm{e}^{u_j + \mathrm{i} v_j}, \qquad -\frac{\pi}{2} < v_j < \frac{\pi}{2}.$$

Let $c_k^{(N)}$ be the closed set of allowed argument vectors $(v_1, \dots, v_k)$ for $C_k^{(N)}$, and let $d_m^{(N)}$ be the corresponding set for $D_m^{(N)}$. The envelope-of-holomorphy theorem for tubes says that the passage to $C_k^{(N+1)}$ replaces the union of the argument bases by its convex hull. In these variables the recurrence is

$$c_k^{(N+1)} = \operatorname{conv}\{(-v, \vartheta, w) : (0, v) \in d_r^{(N)},\ (0, w) \in d_s^{(N)},\ r + s - 1 = k,\ |\vartheta| \le \frac{\pi}{2}\}, \tag{12.18}$$

with the evident deletion of empty blocks. The vector domains satisfy the same recurrence with one distinguished real bridge argument fixed to 0.

The exhaustion needed here follows from an explicit insertion induction, not from a qualitative appeal to convexity. For $0 < a < \pi/2$ put

$$B_k(a) = [-a, a]^k.$$

We claim that for every k there is an integer $N_k(a)$ such that

$$B_k(a) \subset c_k^{(N_k(a))}.$$

For $k = 1$, $c_1^{(1)}$ contains the whole interval $[-\pi/2, \pi/2]$, because the single time gap may be chosen as the bridge variable in the one-gap OS semigroup continuation; hence $N_1(a) = 1$. Now assume $B_{k-1}(a) \subset c_{k-1}^{(N)}$. In the recurrence (12.18), choose the split with empty left block and a right block carrying the remaining $k - 1$ gap arguments. In the notation of the recurrence this is the term obtained after deleting the empty v-block:

$$(\vartheta, w), \qquad |\vartheta| \le \frac{\pi}{2}, \qquad w \in B_{k-1}(a).$$

The vector-domain recurrence with the distinguished real bridge argument fixed to 0 identifies this right block with an element of the corresponding d-domain. Therefore every point of $B_k(a) = [-a, a] \times B_{k-1}(a)$ lies in the generating set whose convex hull is $c_k^{(N+1)}$. Thus

$$B_k(a) \subset c_k^{(N+1)}.$$

Induction gives $N_k(a) \le k$. Since every point of C_+^k has arguments strictly between $-\pi/2$ and $\pi/2$, choose $a < \pi/2$ larger than the maximum absolute argument of the point. This proves

$$[-\frac{\pi}{2} + \epsilon, \frac{\pi}{2} - \epsilon]^k \subset c_k^{(k)} \tag{12.19}$$

for every $\epsilon > 0$, and hence

$$\bigcup_{N \ge 0} C_k^{(N)} = C_+^k.$$

Step 4: real-domain polynomial bounds from linear growth. The preceding steps prove holomorphic continuation but not tempered boundary values. The linear-growth condition enters here. Fix a real noncoincident configuration ξ and let $\rho(\xi)$ be the local analyticity radius from Step 1, chosen so that

$$\rho(\xi) \ge c_k (1 + \|\xi\|)^{-a_k} \operatorname{dist}(\xi, \Delta)^{b_k} \tag{12.20}$$

on each ordered component; the exponents depend only on k and the dimension. Choose a nonnegative C^∞ radial kernel g_ρ on $\mathbb{C}^D$ with support in $|z| < \rho/8$, total integral 1, and derivative bounds

$$\|\partial^\alpha g_\rho\|_\infty \le C_\alpha \rho^{-2D-|\alpha|}.$$

Let $k_\rho = g_\rho * g_\rho$, so k_ρ is supported in $|z| < \rho/4$ and has total integral 1. Applying the mean-value theorem for holomorphic functions blockwise and inserting k_ρ, one obtains a regularized function $T_{k,\rho}$ such that for $|\eta_j| < \rho/2$

$$S_k(\xi+\eta) = \int T_{k,\rho}(\xi+\eta+\mathrm{i}y)\,\mathrm{d}\nu_\rho(y), \tag{12.21}$$

where ν_ρ is a positive probability measure supported in $|y_j| < \rho/4$. Consequently

$$|S_k(\xi+\eta)| \le \sup_{|y_j|<\rho/4} |T_{k,\rho}(\xi+\eta+\mathrm{i}y)|. \tag{12.22}$$

The regularized function is designed so that OS positivity still applies. For each split $k = r+s-1$ and each of the finitely many Euclidean basis directions, the value of $T_{k,\rho}$ after a real displacement in that direction can be written as

$$T_{k,\rho}(\xi+ue_\mu) = \langle \Phi_{L,\rho}(\xi,u), \Phi_{R,\rho}(\xi,u)\rangle_{\mathcal{H}_{\mathrm{OS}}}, \tag{12.23}$$

where the two OS vectors are obtained by smearing the left and right ordered blocks with the kernels g_ρ and k_ρ. This is an identity of test functions before quotienting: the reflected left test and the right test have exactly the convolution kernel appearing in $T_{k,\rho}$. The semigroup continuation in the distinguished direction gives

$$|T_{k,\rho}(\xi+we_\mu)| \le \|\Phi_{L,\rho}(\xi,u)\|_{\mathcal{H}_{\mathrm{OS}}}\,\|\Phi_{R,\rho}(\xi,u)\|_{\mathcal{H}_{\mathrm{OS}}}, \qquad \Re w > 0. \tag{12.24}$$

The norm of, say, $\Phi_{L,\rho}$ is an OS quadratic form $S(\Theta F, F)$ with an explicitly known test function F. If the left vector has r ordered insertions, this quadratic form is a $(2r-1)$-point reduced Schwinger distribution, in the notation of (12.17). The linear-growth hypothesis gives a seminorm of order

$$N_{\mathrm{OS}}(2r-1) = N_0 + C_{\mathrm{OS}}(2r-1). \tag{12.25}$$

Each derivative landing on a smearing kernel g_ρ or k_ρ costs a power of ρ^{-1}; each polynomial weight in the seminorm is evaluated on a point whose coordinates are bounded by a constant times $1+\|\xi\|+\|u\|+\rho$. Since $\rho \le 1$ after shrinking the local polydisc, (12.4) gives

$$\|\Phi_{L,\rho}(\xi,u)\|^2_{\mathcal{H}_{\mathrm{OS}}} \le A_r\,B_r\,\rho^{-M_r}(1+\|\xi\|+\|u\|)^{M_r}, \qquad M_r = M_0 + M_1\,N_{\mathrm{OS}}(2r-1), \tag{12.26}$$

with constants depending on the fixed kernel family, the dimension, and the field labels in the finite component under consideration. The right vector obeys the same estimate with r replaced by s. Because the scalar block has $k = r+s-1$ gaps, both $2r-1$ and $2s-1$ are bounded by $2k+1$. Thus the product of the square-root estimates is controlled by a single exponent affine in the number of gaps. In particular there are constants A_k, B_k, M_k, with at most the factorial growth inherited from (12.4), such that

$$\|\Phi_{L,\rho}(\xi,u)\|_{\mathcal{H}_{\mathrm{OS}}}\,\|\Phi_{R,\rho}(\xi,u)\|_{\mathcal{H}_{\mathrm{OS}}} \le A_kB_k\,\rho^{-M_k}(1+\|\xi\|+\|u\|)^{M_k}. \tag{12.27}$$

Combining (12.24) and (12.27) gives polynomial bounds in each direction. Passing to logarithmic variables turns the directional wedge domains into flat tubes. The Malgrange–Zerner theorem glues the directional continuations, and the maximum principle on the envelope of holomorphy propagates the same bound to the whole local polydisc. Returning through (12.22) gives a real-domain estimate of the form

$$|S_k(\xi)| \le A'_k\, \rho(\xi)^{-M'_k}(1+\|\xi\|)^{M'_k}. \tag{12.28}$$

Together with (12.20), this is a polynomial growth estimate on every ordered real component, with finite distributional order controlled linearly in k by (12.4).

Step 5: continuation of the estimates to C_+^k. It remains to carry the real-domain estimate through the A_N/P_N ladder. Let $\mathcal{B}_{k,t}$ be the Banach space of continuous functions of the k spatial difference variables with norm

$$\|f\|_{k,t} = \sup_{\mathbf{x}}(1+\max_j |\mathbf{x}_j|)^{-t}|f(\mathbf{x})|.$$

For t larger than the exponent in (12.28), the functions $\zeta \mapsto S_k^{(N)}(\zeta \mid \cdot)$ are $\mathcal{B}_{k,t}$-valued holomorphic functions on $C_k^{(N)}$. Introduce a regulator $\epsilon > 0$ and divide by a positive scalar majorant $Q_{k,\epsilon}(\zeta)$ whose logarithm is convex in the variables $\Re\zeta_j$:

$$S_{k,\epsilon}^{(N)}(\zeta) = Q_{k,\epsilon}(\zeta)^{-1} S_k^{(N)}(\zeta + \epsilon\mathbf{1} \mid \cdot).$$

The majorant is chosen so that the real-domain estimate gives

$$\|S_{k,\epsilon}^{(0)}(\zeta)\|_{k,t} \le A_k \qquad (\zeta \in C_k^{(0)}), \tag{12.29}$$

uniformly in ϵ.

Assume the bound is known on $C_\ell^{(N)}$ for all relevant lower scalar lengths. On a mixed domain generated by P_N, the scalar-product formula and Cauchy–Schwarz give

$$\|S_{r+s-1}^{(N)}(-\overline{\zeta}, x+y, \eta)\|_{r+s-1,t} \le \|S_{2r-1}^{(N)}(-\overline{\zeta}, 2x, \zeta)\|_{2r-1,t}^{1/2} \|S_{2s-1}^{(N)}(-\overline{\eta}, 2y, \eta)\|_{2s-1,t}^{1/2}. \tag{12.30}$$

The convexity of $\log Q_{k,\epsilon}$ is precisely the algebraic statement that the denominator for the left side is dominated by the product of the two denominators on the right. Therefore

$$\|S_{k,\epsilon}^{(N)}\|_{k,t} \le A_k$$

on the generating mixed region. Since $C_k^{(N+1)}$ is the envelope of holomorphy of that region and the functions take values in the Banach space $\mathcal{B}_{k,t}$, the Banach-valued maximum principle extends the same bound to all of $C_k^{(N+1)}$. Induction gives the estimate on every $C_k^{(N)}$.

Finally choose $N = N(\zeta)$ using the exhaustion (12.19); the required N is bounded by a constant times a logarithm of the inverse angular distance of ζ to ∂C_+^k. Undoing the harmless regulator ϵ and the majorant $Q_{k,\epsilon}$ yields the tube estimate

$$|\langle S_k(\cdot - \mathrm{i}\eta), f\rangle| \le C_{k,K}\, \delta^{-N_k} \sum_{|\alpha|,|\beta| \le N_k} \sup_\xi |\xi^\beta \partial^\alpha f(\xi)|$$

for η in any closed subcone $K \Subset (V_+^\circ)^k$ at distance δ from the cone boundary. This is (12.16). Euclidean covariance transports the product right-half-plane continuation to the mostly-plus Lorentzian forward tubes, and permutation symmetry supplies the permuted tubes with the graded signs. Thus all hypotheses of Proposition 12.11 have been constructed from the stated Euclidean data and the linear-growth condition. $\square$

Proposition 12.13 (Fourier–Laplace boundary values from spectral support)**.** *Let $d = D(n-1)$, let $\Gamma \subset \mathbb{R}^d$ be a closed convex cone, and let $\Gamma^{\circledast}$ be its open dual cone:*

$$\Gamma^{\circledast} = \{y \in \mathbb{R}^d \mid p \cdot y > 0 \textit{ for every } 0 \neq p \in \Gamma\}.$$

Let $W \in \mathcal{S}'(\mathbb{R}^d)$ have Fourier transform $\widehat{W}$ supported in Γ. For $y \in \Gamma^{\circledast}$ define, by using any smooth cutoff equal to 1 on a conic neighbourhood of Γ on which $p \cdot y$ is nonnegative,

$$\mathcal{W}(x + \mathrm{i}y) = (2\pi)^{-d} \big\langle \widehat{W}(p), \exp(-\mathrm{i}p \cdot x) \exp(-p \cdot y) \big\rangle. \tag{12.31}$$

Then $\mathcal{W}$ is holomorphic on the tube $\mathbb{R}^d + \mathrm{i}\Gamma^{\circledast}$. If $K \Subset \Gamma^{\circledast}$ is a closed subcone and $\operatorname{dist}(y, \partial\Gamma^{\circledast}) \geq \delta > 0$*, then for every Schwartz test function f*

$$\left| \int_{\mathbb{R}^d} \mathcal{W}(x + \mathrm{i}y) f(x) \, \mathrm{d}^d x \right| \leq C_{K,N} \, \delta^{-N} \sum_{|\alpha|, |\beta| \leq N} \sup_p |p^\beta \partial_p^\alpha \widehat{f}(p)|$$

for some N determined by the distributional order of $\widehat{W}$. Moreover,

$$\mathcal{W}(\cdot + \mathrm{i}y) \longrightarrow W \qquad \textit{in } \mathcal{S}'(\mathbb{R}^d)$$

as $y \to 0$ inside K.

Proof. Because $\widehat{W}$ is a tempered distribution, there are C, N such that

$$|\langle \widehat{W}, \psi \rangle| \leq C \sum_{|\alpha|, |\beta| \leq N} \sup_p |p^\beta \partial_p^\alpha \psi(p)| \qquad \psi \in \mathcal{S}(\mathbb{R}^d).$$

For $y \in \Gamma^{\circledast}$, the multiplier $\exp(-p \cdot y)$ is exponentially decreasing on the support cone Γ. To make the pairing literally a Schwartz pairing, choose a smooth conic cutoff χ_y equal to 1 near Γ and supported where $p \cdot y \geq c_y |p| - C_y$; then $\chi_y \exp(-p \cdot y) \exp(-\mathrm{i}p \cdot x)$ is a Schwartz multiplier after testing in x. Different choices of χ_y give the same value, because their difference vanishes in a neighbourhood of $\operatorname{supp} \widehat{W}$. Derivatives in $x + \mathrm{i}y$ only multiply the cutoff multiplier by polynomials in p, so the same estimate proves holomorphy by differentiation under the distributional pairing.

If y stays in a closed subcone at distance δ from the boundary, one cutoff may be chosen uniformly on that subcone, and cone duality gives

$$p \cdot y \geq c_K \delta |p| \qquad (p \in \Gamma)$$

with $c_K > 0$. Hence every derivative of $\exp(-p \cdot y) \widehat{f}(p)$ is bounded by a finite linear combination of Schwartz seminorms of $\widehat{f}$ times a power of δ^{-1}. This gives the displayed tube bound.

For the boundary value, test against f. The pairing equals

$$(2\pi)^{-d} \langle \widehat{W}(p), \mathrm{e}^{-p \cdot y} \widehat{f}(p) \rangle.$$

More explicitly, the left side is computed with the same cutoff convention, and this convention is invisible to $\widehat{W}$. The cutoff functions $\chi \, \mathrm{e}^{-p \cdot y} \widehat{f}(p)$ converge to $\chi \, \widehat{f}(p)$ in the Schwartz topology on every conic neighbourhood of Γ on which $\chi = 1$ near Γ: the exponential is bounded by 1 on Γ, the derivative terms are controlled by the rapid decrease of $\widehat{f}$, and the factors $\mathrm{e}^{-p \cdot y} - 1$ converge uniformly on compact p-sets while the tails are uniformly small. Continuity of $\widehat{W}$ gives convergence to $(2\pi)^{-d} \langle \widehat{W}, \widehat{f} \rangle = W(f)$. ☐

The linear-growth estimate (12.4) is one standard route to this package in the OS-II theorem: the controlled growth of distributional seminorm order is what keeps the Fourier–Laplace continuation inside the tempered distribution class as the tube-depth variables approach the Lorentzian boundary. In a concrete constructive model, this route is a separate analytic estimate to be proved, not a formal consequence of reflection positivity alone.

Applied to reconstruction, Proposition 12.13 is used with $d = D(n-1)$, spectral cone $\Gamma = (\overline{V}_+)^{n-1}$, literal imaginary variable $y \in (-V_+)^{n-1}$, and tube depth $\eta = -y \in (V_+)^{n-1}$. The proposition is written for an abstract tube $x + \mathrm{i}y$ with $p \cdot y > 0$ on the spectral cone. In the mostly-plus Wightman convention the same point is written as $\xi - \mathrm{i}\eta$, and the damping factor is $\exp(p \cdot \eta)$ because $p \cdot \eta \leq 0$. The distribution W is the translation-reduced Wightman distribution. The OS-II linear-growth condition is the Euclidean-side estimate that makes the reconstructed matrix elements have the required finite distributional order uniformly in the number of insertions. The spectral support itself comes from the nonnegative Hamiltonian, spatial translation covariance, and the OS-continued Lorentz transformations. Thus the corrected OS theorem has two distinct analytic duties: it must construct the positive-energy translation representation, and it must prove the polynomial tube bounds needed for the boundary-value theorem above.

Warning 12.14 (Tube-sign conversion). The abstract Fourier–Laplace theorem above uses the variable $x + \mathrm{i}y$ with $p \cdot y > 0$ on the spectral cone. The physical Wightman tube in the mostly-plus convention is instead written $\xi - \mathrm{i}\eta$, with $\eta \in V_+$ and $p \cdot \eta \leq 0$ for $p \in \overline{V}_+$. Therefore the substitution in OS reconstruction is $y = -\eta$. Replacing y by η flips the damping factor and would reverse the spectral-support statement. This is a convention-sensitive point of the corrected OS-II boundary-value construction, not a typographical preference.

Proposition 12.15 (Consequences of the OS boundary-value package)**.** *Assume Definition 12.8. Then:*

(a) The limits of $\mathcal{W}_n(\xi - \mathrm{i}\eta)$ as $\eta \to 0$ within the ordered tube exist in $\mathcal{S}'((\mathbb{M}^D)^n)$ and define tempered Wightman distributions.

(b) Permutation symmetry of the Schwinger hierarchy gives graded commutativity of the boundary-value fields at spacelike separation.

(c) Continuing the Wightman distributions back to ordered imaginary time recovers the original S_n away from the partial diagonals.

Proof. For (a), fix one ordering and write the reduced difference variables as $\xi = (\xi_1, \ldots, \xi_{n-1})$. The tube bound in Definition 12.8 says that, for each smaller cone of tube depths, the function $\xi \mapsto \mathcal{W}_n(\xi - \mathrm{i}\eta)$ defines a continuous functional on $\mathcal{S}(\mathbb{R}^{D(n-1)})$ with seminorm constants polynomial in the distance of η to the cone boundary. Proposition 12.13 displays the model estimate after the sign conversion $y = -\eta$: after Fourier transformation, the tube depth inserts exponential damping against a distribution whose spectral support lies in the forward cone. Hence, for every Schwartz test f, the pairings $\langle \mathcal{W}_n(\cdot - \mathrm{i}\eta), f \rangle$ have a limit as $\eta \to 0$ within the ordered cone. The limiting functional is continuous in the same finite collection of Schwartz seminorms and is therefore a tempered distribution. This distribution is the ordered Wightman distribution.

For (b), first treat unsmeared configurations away from diagonals. In reduced variables, a real point ξ is a Jost point if every nonzero positive linear combination of the successive differences $\xi_j = x_j - x_{j+1}$ is spacelike. Such points are precisely the real edges at which the forward tube for one ordering and the forward tube for a permuted ordering meet after complex Lorentz transformations. Euclidean permutation symmetry gives equality, with the Koszul sign, of the two holomorphic functions on the Euclidean real slice where both orderings are defined. By the identity theorem this equality holds in the common analytic continuation region. The edge-of-the-wedge theorem applies because the two tempered boundary values have a common real edge at the Jost set and agree there as distributions. Therefore their analytic continuations coincide in the envelope of holomorphy of the union of the two tubes.

Now smear the adjacent fields with Lorentzian test functions whose supports are spacelike separated. A partition of unity reduces the support of the smearing to coordinate neighbourhoods whose relative configurations lie in Jost neighbourhoods. The boundary-value equality obtained above can then be paired with these test functions. The result is

$$\langle \Omega, \cdots \widehat{\Phi}_\alpha(f)\widehat{\Phi}_\beta(g) \cdots \Omega\rangle = (-1)^{|\alpha||\beta|}\langle \Omega, \cdots \widehat{\Phi}_\beta(g)\widehat{\Phi}_\alpha(f) \cdots \Omega\rangle$$

for every surrounding finite string of test insertions. Since the finite-insertion vectors are dense in $\mathcal{D}_{\mathrm{OS}}$, this is exactly local graded commutativity on the reconstructed common domain.

For (c), let $0 < \tau_1 < \cdots < \tau_n$ be an ordered Euclidean configuration away from Δ_n. The original Schwinger function and the function obtained by first taking the Lorentzian boundary value and then substituting $z_j^0 = -\mathrm{i}\tau_j$ are restrictions of the same holomorphic function $\mathcal{W}_n$ on the connected ordered tube. If two such holomorphic functions had the same Lorentzian boundary value but differed in the ordered Euclidean interior, their difference would have zero distributional boundary value on a nonempty real edge and hence, by the same edge-of-the-wedge uniqueness theorem, would vanish in the connected tube. Thus the continuation back to ordered imaginary time recovers the original S_n away from the partial diagonals. Contact-term extensions on the diagonals are additional Euclidean data and are not recovered from off-diagonal analytic continuation alone. □

12.5 Reconstruction Theorem

The source trace for the corrected reconstruction theorem is the Osterwalder–Schrader pair of papers, with the linear-growth correction in the second paper [7, 8].

Theorem 12.16 (Osterwalder–Schrader reconstruction)**.** *Let $\{S_n\}_{n\geq 0}$ be Euclidean distributions satisfying Euclidean covariance, permutation symmetry, reflection positivity, Hermiticity, normalization, the OS-II positive-time semigroup conditions* (12.5)–(12.8)*, and the linear-growth condition* (12.4)*. Assume also the ordered-insertion adjoint identity* (12.9) *for the field labels to be reconstructed. By the corrected OS-II analytic theorem, Theorem 12.12, these hypotheses supply the analytic route of Proposition 12.11. Then there exists Wightman field data*

$$(\mathcal{H}_{\mathrm{OS}}, \Omega_{\mathrm{OS}}, U, \mathcal{D}_{\mathrm{OS}}, \{\widehat{\Phi}_\alpha\}_{\alpha\in I})$$

whose Schwinger functions are $\{S_n\}$ at noncoincident Euclidean points. The reconstructed Wightman functions are obtained as boundary values of analytic continuations of the S_n. The symbol Ω_{OS} denotes the vacuum vector produced by this reconstruction; it is a subscripted instance of the global vacuum notation Ω.

Proof. Step 1 constructs the Hilbert space. Let $\mathcal{E}_+$ be the vector space of finite labelled Euclidean insertions whose time coordinates are strictly positive. Reflection positivity makes

$$\langle F, G\rangle_{\mathrm{OS}} := S_{m+n}(\Theta F, G)$$

a positive semidefinite Hermitian form on $\mathcal{E}_+$. Its null space is

$$\mathcal{N}_{\mathrm{OS}} = \{F \in \mathcal{E}_+ : \langle F, F\rangle_{\mathrm{OS}} = 0\}.$$

The Cauchy–Schwarz inequality for positive semidefinite forms implies that $\langle F, G\rangle_{\mathrm{OS}} = 0$ whenever $F \in \mathcal{N}_{\mathrm{OS}}$; therefore the form descends to $\mathcal{E}_+/\mathcal{N}_{\mathrm{OS}}$. Completing gives $\mathcal{H}_{\mathrm{OS}} = \overline{\mathcal{E}_+/\mathcal{N}_{\mathrm{OS}}}$. The class of the empty insertion is Ω_{OS}, and finite positive-time insertions are dense by construction.

Step 2 constructs the positive-energy time evolution. For $s \geq 0$, Euclidean time translation by s maps $\mathcal{E}_+$ to itself. The semigroup law, OS symmetry, and polynomial matrix-element growth imply contractivity by Proposition 12.5; strong continuity is the hypothesis (12.8). Hence the descended operators $T_E(s)$ form a strongly continuous semigroup of self-adjoint contractions on $\mathcal{H}_{\mathrm{OS}}$. The self-adjoint contraction-semigroup theorem gives a nonnegative self-adjoint generator

$$H, \qquad T_E(s) = e^{-sH}, \qquad \sigma(H) \subset [0, \infty).$$

Stone's theorem gives Lorentzian time translations

$$U_{\mathrm{time}}(t) = \mathrm{e}^{-\mathrm{i}tH}.$$

This is the part of the reconstruction theorem that uses reflection positivity directly; it does not use the flawed separate-Laplace step of the first OS paper.

Step 3 constructs the spacetime symmetry representation. Spatial translations and rotations preserve the positive-time half-space after a common positive time shift. Euclidean covariance and the same null-space argument used in Step 1 therefore give unitary operators on $\mathcal{H}_{\mathrm{OS}}$. Proposition 12.11 and Theorem 12.12 supply the missing many-variable analytic continuation: Euclidean rotations mixing time and space continue to real Lorentzian boosts, and the continued matrix elements obey the polynomial tube estimates required for tempered boundary values. The resulting unitary representation U of the connected Poincare group has joint translation spectrum in the closed forward light cone. The forward spectral support follows from $H \geq 0$, spatial covariance, and the Lorentzian boost covariance just obtained.

Step 4 constructs the field-valued distributions on the common dense domain. For a labelled test function f supported at positive Euclidean time, define, before taking Lorentzian boundary values,

$$\Phi_E(\alpha, f)[F] = [(\alpha, f) \otimes F],$$

after translating all supports by a common positive Euclidean time if necessary so that the concatenated configuration is strictly ordered. Proposition 12.7 proves that this operation descends through the OS null quotient and gives closable operators on the dense domain $\mathcal{D}_{\mathrm{OS}}$. The continuity estimates in the OS data make all vacuum and finite-domain matrix elements distributions in the test function. Their Lorentzian boundary values define the Wightman distributions and the corresponding operator-valued distributions $\widehat{\Phi}_\alpha$ on $\mathcal{D}_{\mathrm{OS}}$.

Step 5 verifies the Wightman properties. Hermiticity of the Schwinger hierarchy gives the adjoint relation on $\mathcal{D}_{\mathrm{OS}}$, and Euclidean covariance gives the Poincare covariance of the reconstructed fields. Proposition 12.15 gives temperedness, the edge-of-the-wedge/Jost-domain proof of local graded commutativity at spacelike separation, and the reverse continuation back to the original ordered Euclidean Schwinger functions away from the partial diagonals. The restriction to noncoincident Euclidean points is essential: contact extensions on the diagonals are part of the declared Schwinger hierarchy and are not recovered from off-diagonal analytic continuation alone. □

Output ledger for AQFT use. Theorem 12.16 is the Euclidean-to-Wightman bridge used later in the local-net chapters. Its output has a precise boundary. It constructs

$$\mathcal{H}_{\mathrm{OS}}, \qquad \Omega_{\mathrm{OS}}, \qquad U, \qquad \mathcal{D}_{\mathrm{OS}}, \qquad \widehat{\Phi}_\alpha(f),$$

with positive-energy Poincare covariance, tempered Wightman distributions, domain-level adjoints, and graded locality on the common finite-insertion domain. If a cluster condition is added, it also identifies the vacuum sector as in Corollary 12.19. These are field-presentation outputs, not yet a Haag–Kastler net in the sense of Definition 3.1.

To use an OS-constructed model as an AQFT model one must supply the bounded local-algebra layer separately. A typical route is the comparison structure of Definition 3.12: prove self-adjoint closures for the relevant Hermitian smeared fields, prove strong commutation of their spectral measures for spacelike separated supports, form the represented von Neumann algebras generated by the spectral projections, and prove isotony, covariance, additivity, and time-slice or causal propagation properties for those bounded algebras. If the OS fields are charged, gauge-fixed, or otherwise larger than the observable content, one must then pass to the observable subnet by fixed points, BRST/BV physical cohomology, Gauss-law constraints, or another declared operation and verify that operation preserves the local-net properties. Equality with a proposed observable net is the completeness condition of Definition 3.13, not a formal consequence of equality of Schwinger functions.

The same boundary applies to stronger structural properties. OS reconstruction by itself does not prove Reeh–Schlieder for the bounded net, Haag duality, nuclearity, split inclusions, type-III local factor classification, DHR transportability, Doplicher–Roberts reconstruction, or Bisognano–Wichmann modular covariance. Some of these properties can be proved later from the Wightman spectral condition plus weak additivity, as in the Reeh–Schlieder theorem of Chapter 3; others require model-specific phase-space estimates, duality arguments, sector constructions, or wedge-domain theorems. Thus the correct dependency chain is

$$\begin{aligned} \text{OS Schwinger data} &\Longrightarrow \text{Wightman field presentation} \\ &\Longrightarrow \text{bounded local-net comparison} \\ &\Longrightarrow \text{additional AQFT structure.} \end{aligned}$$

Skipping the middle two arrows is precisely the hidden proof debt that the AQFT chapters keep separate.

Proposition 12.17 (Uniqueness of OS reconstruction)**.** *Two OS reconstructions from the same Schwinger hierarchy are unitarily equivalent on the reconstructed Wightman field presentation.*

Proof. Let

$$(\mathcal{H}_1, \Omega_1, U_1, \mathcal{D}_1, \widehat{\Phi}^{(1)}_\alpha), \qquad (\mathcal{H}_2, \Omega_2, U_2, \mathcal{D}_2, \widehat{\Phi}^{(2)}_\alpha)$$

be two reconstructions from the same hierarchy. Both start from the same positive-time vector space $\mathcal{E}_+$ and the same OS sesquilinear form, hence from the same null space $\mathcal{N}$. On the dense quotient define

$$V_0[F]_1 = [F]_2.$$

This is well defined because $[F]_1 = 0$ iff $\langle F, F\rangle_{\mathrm{OS}} = 0$ iff $[F]_2 = 0$. It is isometric because both inner products are the same OS form:

$$\langle V_0[F]_1, V_0[G]_1\rangle_{\mathcal{H}_2} = \langle F, G\rangle_{\mathrm{OS}} = \langle [F]_1, [G]_1\rangle_{\mathcal{H}_1}.$$

Since the quotient is dense in both completions, V_0 extends uniquely to a unitary $V : \mathcal{H}_1 \to \mathcal{H}_2$. The empty insertion is mapped to the empty insertion, so $V\Omega_1 = \Omega_2$. Euclidean translations, rotations, and the continued Poincare transformations are all defined on the dense quotient by the same operations on test sequences, hence

$$VU_1(g) = U_2(g)V$$

on a dense domain and therefore on the Hilbert spaces. Field insertions are also defined by the same operation on the common quotient:

$$V\widehat{\Phi}^{(1)}_\alpha(f)[F]_1 = V[(\alpha, f), F]_1 = [(\alpha, f), F]_2 = \widehat{\Phi}^{(2)}_\alpha(f)V[F]_1,$$

with equality on the common invariant domain. Thus the two reconstructions are unitarily equivalent as Wightman field presentations. □

Path-integral Schwinger limits as Wightman data. Let $\{\mathcal{E}_\Lambda, \langle\cdot\rangle_\Lambda\}$ be a regulated Euclidean path-integral presentation, where Λ denotes the regulator and $\langle\cdot\rangle_\Lambda$ is the regulated expectation functional on a declared algebra of Euclidean field insertions. Assume that for every n and every labelled test insertion f_n in the chosen test class the regulated moments

$$S_{n,\Lambda}(f_n) := \langle f_n(\Phi_E, \ldots, \Phi_E)\rangle_\Lambda$$

converge to a distributional limit $S_n(f_n)$, and that the limiting hierarchy $\{S_n\}_{n\geq 0}$ satisfies the OS-admissibility hypotheses of Definition 12.2. Then the continuum path-integral presentation determines a Wightman field presentation by applying Theorem 12.16 to the limiting Schwinger hierarchy. If the limiting hierarchy also satisfies the Euclidean cluster condition in Corollary 12.19, the reconstructed zero-momentum subspace is $\mathbb{C}\Omega_{\mathrm{OS}}$.

The convergence assumption defines a family $\{S_n\}_{n\geq 0}$ of continuous linear functionals on the declared test-function spaces; $S_0 = 1$ is the normalization of the regulated expectation functional after taking the limit. The OS-admissibility assumption supplies Euclidean covariance, permutation symmetry, Hermiticity, reflection positivity, and the OS-II semigroup and linear-growth estimates used in Theorem 12.16. Applying that theorem constructs

$$(\mathcal{H}_{\mathrm{OS}}, \Omega_{\mathrm{OS}}, U, \mathcal{D}_{\mathrm{OS}}, \{\widehat{\Phi}_\alpha\})$$

whose Wightman boundary values have the limiting Schwinger hierarchy as their Euclidean continuation at noncoincident points. The last sentence is exactly Corollary 12.19.

Remark 12.18 (Constructive status of OS inputs). OS reconstruction is a bridge theorem. It turns a Schwinger hierarchy with reflection positivity, Euclidean covariance, permutation symmetry, Hermiticity, clustering when desired, and the OS-II analytic bounds into a Lorentzian Wightman presentation. It does not by itself construct the Schwinger hierarchy. Completed constructions verifying such inputs are model-dependent and concentrated in low-dimensional regimes, including $P(\phi)_2$, massive ϕ^4_3, selected two-dimensional scalar–fermion models, and two-dimensional Yang–Mills in holonomy or heat-kernel formulations. Standard reflection-positive Ising/$\lambda\phi^4$ routes in $D \geq 4$ are constrained by triviality theorems, while four-dimensional Yang–Mills, QCD-like theories, and the full Standard Model remain open as complete constructive continuum theorems. Chapter 136 gives the status table and route-by-route discussion.

Corollary 12.19 (OS reconstruction with and without clustering)**.** *Let P_0^{OS} be the joint spectral projection of the reconstructed Lorentzian translation representation onto zero momentum. The reconstruction theorem by itself produces an invariant cyclic vector Ω_{OS} and a positive-energy representation, but it leaves the dimension of $P_0^{\mathrm{OS}}\mathcal{H}_{\mathrm{OS}}$ to the Schwinger hierarchy. Thus, in the absence of a cluster condition, the reconstructed representation may contain several translation-invariant vacuum vectors.*

If the Euclidean hierarchy clusters, then for finite polynomial Euclidean field insertions A_E and B_E separated by a large spatial Euclidean translation,

$$\lim_{\lambda\to+\infty} \langle A_E\, B_E(\lambda a)\rangle_E = \langle A_E\rangle_E\, \langle B_E\rangle_E, \qquad a \in \mathbb{R}^{D-1},\ a \neq 0,$$

then its Lorentzian reconstruction satisfies the Wightman weak cluster property. Consequently

$$P_0^{\mathrm{OS}}\mathcal{H}_{\mathrm{OS}} = \mathbb{C}\Omega_{\mathrm{OS}}$$

by Theorem 2.3. Conversely, a one-dimensional reconstructed zero-momentum subspace gives Wightman clustering, and its restriction back to noncoincident Euclidean points gives the corresponding Euclidean cluster property.

When $P_0^{\mathrm{OS}}\mathcal{H}_{\mathrm{OS}}$ has dimension larger than one, the Schwinger functional is a translation-invariant state that is not extremal. Its central decomposition is a direct integral, or in finite mixtures a convex sum, of pure vacuum sectors. OS positivity and covariance still reconstruct a valid Wightman presentation, while clustering is the additional condition that selects a single pure infinite-volume phase.

The theorem has three distinct pieces. First, reflection positivity constructs the Hilbert space, vacuum vector, and positive Hamiltonian by the positive-time quotient. Second, Euclidean covariance and the OS regularity assumptions construct the Lorentzian Poincare representation and its spectrum condition. Third, growth and analyticity assumptions control the distributional boundary values and produce Wightman functions in the intended test-function class. In the tempered case, this target class is $\mathcal{S}'(M^n)$. In larger analytic frameworks, such as hyperfunction versions of reconstruction, the target distribution class is correspondingly larger and the growth hypotheses are changed.

The uniqueness statement is internal to the specified Euclidean hierarchy, label space, reflection map, and test-function class. Two reconstructions of the same OS-admissible data are related by a unitary equivalence preserving the vacuum, the reconstructed Poincare representation, and the smeared fields. Equivalence of two different Euclidean presentations, or of the local nets generated after taking closures and affiliations, is an additional comparison problem.

12.6 Two-Point Spectral Positivity

For a scalar field, OS positivity gives a direct Euclidean form of spectral positivity. Let $f(\mathbf{x})$ be a spatial test function and let $\Phi_E(\tau, f)$ denote the reconstructed Euclidean field smeared at positive time τ. The notation $\Phi_E(0, f)$ below denotes the boundary value from positive Euclidean time when this domain limit exists. For $\tau > 0$, time translation in the reconstructed Hilbert space gives

$$\langle \Omega_{\mathrm{OS}}, \Phi_E(\tau, f)\Phi_E(0, g)\Omega_{\mathrm{OS}}\rangle_{\mathrm{OS}} = \langle \Phi_E(0, f)^\dagger \Omega_{\mathrm{OS}}, \mathrm{e}^{-\tau H}\Phi_E(0, g)\Omega_{\mathrm{OS}}\rangle_{\mathrm{OS}}.$$

Applying the spectral theorem to the nonnegative operator H, this is

$$\int_{[0,\infty)} \mathrm{e}^{-\tau E}\, \mathrm{d}\nu_{f,g}(E),$$

where

$$\nu_{f,g}(\Delta) = \langle \Phi_E(0, f)^\dagger \Omega_{\mathrm{OS}}, E_H(\Delta)\Phi_E(0, g)\Omega_{\mathrm{OS}}\rangle_{\mathrm{OS}}$$

and E_H is the spectral measure of H. For $f = g$, the measure is positive. Including spatial translations refines this to the joint spectral measure of $(H, \mathbf{P})$. Lorentz covariance and the spectrum condition then repackage the scalar two-point measure by invariant mass, giving the Källén–Lehmann representation used in Chapter 14.

This calculation identifies the precise bridge: reflection positivity builds the Hilbert-space inner product, the Euclidean time semigroup gives the nonnegative Hamiltonian, and the spectral theorem supplies the positive energy-momentum measure.

12.7 Euclidean Measures and Generating Functionals

Suppose a Euclidean theory is given by a probability measure μ on a specified measurable space of scalar distributions φ, with generating functional

$$Z_E[J] = \int \exp\left(\int_E J(x)\varphi(x)\,\mathrm{d}^D x\right) \mathrm{d}\mu(\varphi)$$

for real test functions J in a neighborhood of the origin. The Schwinger functions are moments:

$$S_n(x_1, \ldots, x_n) = \int \varphi(x_1)\cdots\varphi(x_n)\,\mathrm{d}\mu(\varphi).$$

Reflection positivity is then a property of the measure together with the chosen time reflection. It is stable under lattice approximations only when the regulator action, observable insertions, and continuum limit preserve the positive-time quadratic form.

Remark 12.20. Ordinary positivity of the probability measure μ means $\int |F(\varphi)|^2\,\mathrm{d}\mu(\varphi) \geq 0$ for measurable functions F. OS positivity is the reflected statement $\int \overline{F(\theta\varphi)}F(\varphi)\,\mathrm{d}\mu(\varphi) \geq 0$ for positive-time cylinder functions F, with the label adjunction included. It is this reflected positivity that becomes the Lorentzian Hilbert-space inner product.

12.8 Reflection Positivity for Generating Functionals

When the Euclidean moments are encoded by $Z_E[J]$, reflection positivity has an equivalent source form. Let J_r be finitely many sources supported in positive Euclidean time and let $c_r \in \mathbb{C}$. Define the reflected source by

$$(\Theta J_r)(x) = \overline{J_r(\theta x)}$$

with the field adjunction included when the source carries labels. The generating functional is reflection positive when

$$\sum_{r,s} \bar{c}_r c_s \, Z_E[\Theta J_r + J_s] \geq 0. \tag{12.32}$$

Expanding Z_E in powers of the sources recovers (12.2) for all Schwinger functions. Conversely, if the moment expansion is valid in a neighborhood of the origin, the Schwinger-function inequalities imply (12.32).

For a Gaussian scalar measure with covariance $C(x-y)$, the criterion reduces to positivity of the kernel reflected across $\tau = 0$:

$$\int_{\tau_x>0} \mathrm{d}^D x \int_{\tau_y>0} \mathrm{d}^D y \, \overline{f(x)} \, C(\theta x - y) \, f(y) \geq 0$$

for all positive-time test functions f. The free massive covariance

$$C(x-y) = \int \frac{\mathrm{d}^D k_E}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k_E\cdot(x-y)}}{k_E^2 + m^2}$$

satisfies this condition because its Fourier representation in spatial momentum is

$$C(\tau, \mathbf{x}) = \int \frac{\mathrm{d}^{D-1}\mathbf{p}}{(2\pi)^{D-1}} \frac{\mathrm{e}^{\mathrm{i}\mathbf{p}\cdot\mathbf{x}} \mathrm{e}^{-\omega_{\mathbf{p}}|\tau|}}{2\omega_{\mathbf{p}}}, \qquad \omega_{\mathbf{p}} = \sqrt{\mathbf{p}^2 + m^2},$$

so the reflected quadratic form is an integral of absolute squares with positive weight. This computation is the Euclidean shadow of the positive one-particle Hilbert space of the free scalar field.

In this free example, covariance gives the Schwinger functions, reflection positivity gives the inner product, and the positive-frequency kernel gives the one-particle space. For an interacting Euclidean measure the same sentences become obligations: one must verify the full OS positivity, covariance, regularity, and growth requirements before invoking reconstruction.

12.9 Relation To Wick Rotation

For time-ordered Green functions in perturbation theory, Wick rotation was used earlier as a contour and boundary-value operation. OS reconstruction is the nonperturbative counterpart at the level of complete Euclidean correlation data. It supplies the Hilbert space, Hamiltonian, vacuum, and Lorentzian Wightman functions from Euclidean data satisfying precise positivity and growth conditions.

The framework identifies the Euclidean information that reconstructs a Lorentzian theory: a full compatible hierarchy of Schwinger distributions together with covariance, reflection positivity, growth, regularity, and normalization conditions.

Chapter 13

Kontsevich–Segal Functorial Quantum Field Theory

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

13.1 Functorial Data and the Path-Integral Problem

The Wightman, Osterwalder–Schrader, and Haag–Kastler frameworks encode different shadows of locality. Wightman fields encode distributional Lorentzian local operators on a Hilbert space; OS data encode Euclidean reflection-positive correlation distributions; Haag–Kastler nets encode bounded observable algebras localized in spacetime regions. The Kontsevich–Segal viewpoint begins from the geometric operation that a path integral is expected to satisfy before any choice of coordinates on fields is made: cut a background along hypersurfaces, assign state spaces to the cuts, and recover the amplitude of the glued background by composing the amplitudes of the pieces. The source trace for this chapter's functorial and allowability language is Segal's conformal-field-theory sewing framework and the Kontsevich–Segal Wick-rotation criterion [35, 36].

Let D be the spacetime dimension. The intended datum is a symmetric monoidal assignment

$$Z : \mathrm{Bord}_D^{\mathrm{adm}} \longrightarrow \mathrm{TVect}_{\mathbb{C}},$$

where $\mathrm{Bord}_D^{\mathrm{adm}}$ is a category of $(D-1)$-manifolds and D-dimensional bordisms with admissible complex metrics and auxiliary background fields, and $\mathrm{TVect}_{\mathbb{C}}$ is a category of complex topological vector spaces and continuous linear maps. The target cannot be restricted in advance to Hilbert spaces. Hilbert spaces arise from a reflection-positive pairing on suitable real slices; before that pairing is imposed and completed, the natural state spaces are locally convex spaces or distribution spaces.

The word "admissible" carries the physical content of positive energy. The complex metric is allowed to move inside a domain containing Riemannian metrics and having Lorentzian metrics on its boundary. Analytic dependence inside this domain replaces the upper-half-plane analyticity of $\exp(\mathrm{i}tH)$ in quantum mechanics. The objective is therefore sharper than a generic functorial field theory: the functor must be holomorphic in admissible complex metrics, compatible with sewing, and equipped with a reflection structure whose Lorentzian boundary values produce unitary evolution and microcausal fields when the required analytic hypotheses hold.

13.2 The One-Dimensional Semigroup Model

The smallest model of the Kontsevich–Segal idea is ordinary positive-energy quantum mechanics written without choosing a preferred real time coordinate. Let $\mathcal{H}$ be a Hilbert space and let H be a self-adjoint operator bounded below. After subtracting the infimum of the spectrum, assume $H \geq 0$. The Euclidean time evolution is

$$T(\tau) = \exp(-\tau H), \qquad \tau > 0.$$

It is a strongly continuous semigroup of self-adjoint contractions. The Lorentzian evolution is the boundary value

$$U(t) = \lim_{\epsilon \downarrow 0} T(\epsilon + \mathrm{i}t) = \exp(-\mathrm{i}tH), \qquad t \in \mathbb{R},$$

in the strong operator topology. Thus positive energy is equivalently the existence of a bounded holomorphic semigroup

$$z \longmapsto T(z) = \exp(-zH), \qquad \operatorname{Re} z > 0,$$

whose boundary values on the imaginary axis are unitary.

Proposition 13.1 (Holomorphic semigroup and positive generator)**.** *Let $T(z)$, $\operatorname{Re} z > 0$, be a holomorphic family of bounded operators on a Hilbert space $\mathcal{H}$. Assume:*

1. *$T(z + w) = T(z)T(w)$ for $\operatorname{Re} z, \operatorname{Re} w > 0$;*
2. *$T(\tau)$ is self-adjoint and positive for every real $\tau > 0$;*
3. *$T(\tau)$ is strongly continuous in τ and $\|T(\tau)\| \leq 1$;*
4. *$T(\tau) \to \mathbf{1}$ strongly as $\tau \downarrow 0$.*

Then there is a unique self-adjoint operator $H \geq 0$ such that

$$T(\tau) = \exp(-\tau H), \qquad \tau > 0.$$

If the non-tangential strong boundary values $\lim_{\epsilon \downarrow 0} T(\epsilon + \mathrm{i}t)$ exist for all t, they are the unitary group $\exp(-\mathrm{i}tH)$.

Proof. The real-time family $\tau \mapsto T(\tau)$ is a strongly continuous contraction semigroup, so the Hille–Yosida theorem gives a closed densely defined generator $-H$ with $T(\tau) = \exp(-\tau H)$. Because each $T(\tau)$ is self-adjoint, the generator is self-adjoint. Positivity of $T(\tau)$ and the spectral mapping theorem give $\operatorname{spec}(T(\tau)) \subset [0,1]$, hence $\operatorname{spec}(H) \subset [0,\infty)$. Equivalently, the spectral calculus gives $T(\tau) = \int e^{-\tau\lambda}\, dE_H(\lambda)$ with $\lambda \geq 0$. The holomorphic semigroup is then uniquely determined by this spectral formula:

$$T(z) = \int e^{-z\lambda}\, dE_H(\lambda), \qquad \operatorname{Re} z > 0.$$

Letting $z = \epsilon + \mathrm{i}t$ and using dominated convergence in the spectral integral gives the strong boundary value

$$\lim_{\epsilon \downarrow 0} T(\epsilon + \mathrm{i}t) = \int e^{-\mathrm{i}t\lambda}\, dE_H(\lambda) = e^{-\mathrm{i}tH},$$

which is unitary by the spectral theorem. □

In the functorial language, an interval of complex length z with $\operatorname{Re} z > 0$ is a one-dimensional admissible bordism. Sewing intervals gives the semigroup law. Reflection positivity gives positivity of the real-length operators. The Lorentzian line is not an interior part of the domain; it is a boundary where the holomorphic contraction semigroup has unitary boundary values. The higher-dimensional Kontsevich–Segal condition is designed so that every time-thickness and every local quadratic field mode has this same analytic structure.

13.3 Segal Sewing in Two-Dimensional CFT

The two-dimensional conformal case is the prototype. Let $\mathrm{Bord}_2^{\mathrm{conf}}$ denote the category whose objects are finite disjoint unions of analytically parametrized oriented circles and whose morphisms are compact Riemann surfaces with incoming and outgoing parametrized boundary components. Composition is sewing along boundary circles with inverse parametrizations. A Segal CFT assigns a topological vector space $\mathcal{H}_S$ to each object S and a continuous linear map

$$Z(\Sigma) : \mathcal{H}_{S_{\mathrm{in}}} \longrightarrow \mathcal{H}_{S_{\mathrm{out}}}$$

to a Riemann surface $\Sigma : S_{\mathrm{in}} \to S_{\mathrm{out}}$, with

$$Z(\Sigma_2 \circ \Sigma_1) = Z(\Sigma_2) Z(\Sigma_1), \qquad Z(\Sigma \sqcup \Sigma') = Z(\Sigma) \otimes Z(\Sigma').$$

The sewing map is required to be continuous or holomorphic with respect to the relevant moduli of surfaces and boundary parametrizations. Reflection of a Riemann surface across a parametrized boundary circle gives an antilinear involution on the state space, and reflection positivity requires the doubled surface to define a positive semidefinite pairing.

The operator product in a Segal CFT is a sewing statement. A pair of punctures contained in a disk determines a state on the boundary circle of that disk. Expanding this state in the spectral decomposition of the annulus semigroup gives the local fields that may replace the pair of insertions when the disk is sewn into a larger surface. Thus convergence of the OPE is not an extra mnemonic; it is the convergence of a state-vector expansion in the boundary state space chosen by the sewing theory.

13.4 Allowable Complex Metrics

Let V be a real vector space of dimension D. A complex metric on V is a nondegenerate complex-valued symmetric bilinear form

$$g \in \mathrm{Sym}^2(V^*) \otimes_{\mathbb{R}} \mathbb{C}.$$

Let $|\wedge^D V^*|$ be the real density line. A choice of square root of $\det g$ defines a complex density

$$\mathrm{vol}_g = (\det g)^{1/2} |dy^1 \cdots dy^D| \in |\wedge^D V^*| \otimes_{\mathbb{R}} \mathbb{C}$$

in a basis $y^1, \ldots, y^D$. The sign of the square root is fixed by requiring the 0-form positivity condition below.

Definition 13.2 (Kontsevich–Segal allowability)**.** A complex metric g on V is allowable when, for every $q = 0, \ldots, D$, the quadratic map

$$Q_{q,g} : \wedge^q V^* \longrightarrow |\wedge^D V^*| \otimes_{\mathbb{R}} \mathbb{C}, \qquad \alpha \longmapsto \alpha \wedge *_g \alpha$$

has positive real part on every nonzero real q-form α. For $q = 0$, this says that $\mathrm{Re}\,\mathrm{vol}_g$ is a positive real density.

For a q-form gauge field strength F, the Euclidean quadratic action is

$$I_q(F; g) = \frac{1}{2q!} \int_M \sqrt{\det g}\, g^{i_1 j_1} \cdots g^{i_q j_q} F_{i_1 \cdots i_q} F_{j_1 \cdots j_q}\, \mathrm{d}^D x.$$

Definition 13.2 is precisely the pointwise condition that the real part of this quadratic form be positive for every real q-form field strength, simultaneously for all q. Imposing all degrees is essential because a field theory may contain scalars, gauge fields, higher-form fields, dual fields, and quantized flux sectors whose integration cycles cannot all be repaired by a degree-dependent phase rotation.

Theorem 13.3 (Argument criterion for allowability)**.** *Let g be a complex metric on V. It is allowable if and only if there is a real basis in which*

$$g = \sum_{a=1}^{D} \lambda_a (dy^a)^2, \qquad \lambda_a \in \mathbb{C} \setminus (-\infty, 0],$$

and, with the principal argument $\theta_a = \mathrm{Arg}\,\lambda_a \in (-\pi, \pi)$,

$$\sum_{a=1}^{D} |\theta_a| < \pi. \tag{13.1}$$

Proof. Assume first that g is allowable. The $q = 0$ condition chooses the branch of $(\det g)^{1/2}$ with positive real part. The $q = 1$ condition states that the complex symmetric matrix

$$W^{ij} = (\det g)^{1/2} g^{ij}$$

has positive-definite real part. Write $W = A + \mathrm{i}B$ with A, B real symmetric and $A > 0$. A real change of basis puts A in the identity form. A further orthogonal change of basis diagonalizes B.

Hence W is diagonal in a real basis, so W^{-1} and then g are diagonal in the same basis. Write the diagonal entries as λ_a.

For a subset $S \subset \{1, \dots, D\}$, the real basis q-form $\mathrm{d}y^S = \wedge_{a\in S}\mathrm{d}y^a$ has

$$\mathrm{d}y^S \wedge *_g \mathrm{d}y^S = A_S\, |dy^1 \cdots dy^D|, \qquad A_S = (\det g)^{1/2} \prod_{a\in S} \lambda_a^{-1}. \tag{13.2}$$

The q-form positivity conditions are therefore equivalent to $\operatorname{Re} A_S > 0$ for all subsets S. If $\theta_a = \operatorname{Arg}\lambda_a$, then

$$\operatorname{Arg} A_S = \frac{1}{2}\sum_{a=1}^{D}\theta_a - \sum_{a\in S}\theta_a = \frac{1}{2}\left(\sum_{a\notin S}\theta_a - \sum_{a\in S}\theta_a\right).$$

Let $P = \{a : \theta_a \geq 0\}$. Positivity for $S = P$ gives

$$-\frac{\pi}{2} < -\frac{1}{2}\sum_{a=1}^{D}|\theta_a| < \frac{\pi}{2},$$

and hence (13.1). Conversely, if (13.1) holds, then for every subset S,

$$|\operatorname{Arg} A_S| \leq \frac{1}{2}\sum_{a=1}^{D}|\theta_a| < \frac{\pi}{2}.$$

Thus every A_S has positive real part. Since the form coefficients are diagonal in the real basis, every nonzero real q-form has $\operatorname{Re} Q_{q,g} > 0$. This is Definition 13.2. □

Example 13.4 (Euclidean, Lorentzian, and multi-time signatures)**.** A positive Riemannian metric has all $\theta_a = 0$, hence is allowable. A Lorentzian metric with diagonal entries $(-1, 1, \dots, 1)$ has one argument equal to π, so it lies on the boundary of the allowable domain. The regularized metrics

$$-(1 - \mathrm{i}\epsilon)(dy^1)^2 + \sum_{a=2}^{D}(dy^a)^2, \qquad -(1 + \mathrm{i}\epsilon)(dy^1)^2 + \sum_{a=2}^{D}(dy^a)^2, \qquad \epsilon > 0,$$

lie in the two adjacent allowable components approaching that Lorentzian boundary point. A real metric with two negative directions has two arguments equal to π and does not lie on this boundary. The criterion therefore distinguishes Lorentzian signature from signatures with more than one time direction.

13.5 The Admissible Bordism Category

Definition 13.5 (Admissible complex-metric bordism)**.** An admissible D-bordism is a smooth compact D-manifold M with boundary decomposed into incoming and outgoing collars, together with:

$$g \in \Gamma(\mathrm{Sym}^2\, T^*M \otimes \mathbb{C}), \qquad \text{background bundles and sources,}$$

where g_x is allowable for every $x \in M$. Boundary collars are part of the datum so that gluing is defined by identifying collars with matching induced complex metrics and background fields. The category is symmetric monoidal under disjoint union.

The collar is not decorative. Without a collar, equality of boundary metrics does not determine a smooth glued metric; with a collar, composition is ordinary gluing of germs. A morphism is therefore an equivalence class of collared backgrounds, where two representatives are identified only when there is a collar-preserving diffeomorphism respecting the complex metric and all background fields. This convention keeps sewing as an exact categorical composition, not as a limiting operation.

The target category must remember topology. A useful minimal target is the symmetric monoidal category of complete locally convex complex vector spaces with continuous linear maps and completed projective tensor product $\widehat{\otimes}_\pi$. In examples with trace or nuclear sewing estimates, one may restrict to nuclear spaces; in Hilbert-space boundary sectors one passes only after reflection positivity and null-state quotient. Thus the symbols $E(Y_1)\widehat{\otimes}_\pi E(Y_2)$ and $E(Y_1 \sqcup Y_2)$ are identified as part of the monoidal datum, not by an algebraic tensor product completion chosen after the fact.

The state space assigned to a boundary germ Y will be denoted

$$E(Y).$$

The notation emphasizes that Y is a germ of a hypersurface together with its collar metric and background fields, rather than only the underlying $(D-1)$-manifold. For a bordism $M : Y_0 \to Y_1$, the amplitude is a continuous linear map

$$Z(M) : E(Y_0) \longrightarrow E(Y_1).$$

For a closed M, $Z(M) \in \mathbb{C}$ is the partition function. For marked points or extended insertions, $E(Y)$ is replaced by a multilinear observable bundle over the configuration space of insertions.

Definition 13.6 (K-S functorial QFT datum)**.** A Kontsevich–Segal functorial QFT on a specified class of backgrounds consists of:

1. a symmetric monoidal functor Z from admissible complex bordism categories to complex topological vector spaces;
2. holomorphic dependence of $Z(M, g)$ on the admissible complex metric and on complexified sources in local coordinate charts on the space of background data;
3. collar locality: if $M = M_2 \circ_Y M_1$, then
$$Z(M) = Z(M_2)Z(M_1)$$
as a continuous map after the matching state-space identifications along Y;
4. a reflection operation $Y \mapsto \bar{Y}$ and $M \mapsto \bar{M}$ compatible with complex conjugation of metric and sources;
5. reflection positivity on real Riemannian reflection doubles, as stated below.

13.6 Reflection Positivity and Hilbert Spaces

Let Y be a real Riemannian boundary germ fixed by an orientation-reversing reflection ρ. Suppose M_+ is a bordism from the empty object to Y, and let $\bar{M}_+$ be its reflected conjugate from Y to the empty object. The double

$$\bar{M}_+ \circ_Y M_+$$

is a closed Riemannian background. If $u, v \in E(Y)$ arise from states created by such half-bordisms with insertions, define

$$\langle u, v\rangle_Y = Z(\bar{M}_u \circ_Y M_v).$$

Reflection positivity requires this sesquilinear form to be positive semidefinite on the subspace generated by positive-side states. The physical Hilbert space associated to Y is then

$$\mathcal{H}_Y = \overline{E_+(Y)/\{u : \langle u, u\rangle_Y = 0\}}, \tag{13.3}$$

where the bar denotes Hilbert completion.

Theorem 13.7 (Positive-energy cylinder from K-S reflection positivity)**.** *Let Y be a real Riemannian boundary germ for which the reflection-positive construction above gives a Hilbert space $\mathcal{H}_Y$. Suppose the K-S functor assigns to each real positive cylinder*

$$C_\tau = [0, \tau] \times Y, \qquad \tau > 0,$$

a continuous operator $T_Y(\tau)$ on the positive-side state space and that:

1. *sewing gives $T_Y(\tau + \sigma) = T_Y(\tau)T_Y(\sigma)$;*
2. *reflection of the cylinder gives $\langle u, T_Y(\tau)v\rangle_Y = \langle T_Y(\tau)u, v\rangle_Y$;*
3. *the doubled cylinder form gives $\langle u, T_Y(\tau)u\rangle_Y \geq 0$;*
4. *$T_Y(\tau)$ descends to a strongly continuous contraction semigroup on $\mathcal{H}_Y$, after the vacuum-energy normalization of the cylinder.*

Then there is a unique self-adjoint $H_Y \geq 0$ on $\mathcal{H}_Y$ such that

$$T_Y(\tau) = e^{-\tau H_Y}.$$

If the functor is holomorphic for the corresponding admissible complex cylinders and has strong boundary values at imaginary cylinder length, those boundary values are the unitary Lorentzian propagators

$$U_Y(t) = e^{-\mathrm{i}tH_Y}.$$

Proof. Let $N_Y = \{u : \langle u, u\rangle_Y = 0\}$. Since the doubled form is positive semidefinite, Cauchy–Schwarz gives $u \in N_Y$ precisely when $\langle u, w\rangle_Y = 0$ for every positive-side state w. We first check that the cylinder operator is compatible with quotienting by this null space. If $u \in N_Y$, then reflection and sewing give

$$\|T_Y(\tau)u\|_Y^2 = \langle T_Y(\tau)u, T_Y(\tau)u\rangle_Y = \langle u, T_Y(2\tau)u\rangle_Y = 0.$$

Thus $T_Y(\tau)N_Y \subset N_Y$, and $T_Y(\tau)$ descends to $E_+(Y)/N_Y$. The contraction hypothesis is part of the analytic input: after the vacuum-energy normalization,

$$\|T_Y(\tau)[u]\|_{\mathcal{H}_Y} \leq \|[u]\|_{\mathcal{H}_Y},$$

so the descended operator extends uniquely to a bounded contraction on the Hilbert completion. Sewing descends to the semigroup law $T_Y(\tau + \sigma) = T_Y(\tau)T_Y(\sigma)$. Reflection gives symmetry on the dense quotient:

$$\langle [u], T_Y(\tau)[v]\rangle_Y = \langle T_Y(\tau)[u], [v]\rangle_Y.$$

Boundedness then extends this symmetry to all of $\mathcal{H}_Y$, so $T_Y(\tau)$ is self-adjoint. Doubled-cylinder positivity gives $\langle\psi, T_Y(\tau)\psi\rangle \geq 0$ first on the dense quotient and then by continuity on the Hilbert space.

We now apply the Hilbert-space semigroup statement isolated in Proposition 13.1. A strongly continuous self-adjoint contraction semigroup with positive operators has a unique self-adjoint generator H_Y satisfying

$$T_Y(\tau) = e^{-\tau H_Y}.$$

The spectrum of H_Y lies in $[0, \infty)$, because otherwise $\|e^{-\tau H_Y}\| \leq 1$ would fail for $\tau > 0$. If the K-S functor is holomorphic on the corresponding complex cylinder semigroup, spectral calculus gives the strong boundary values

$$\lim_{\epsilon \downarrow 0} e^{-(\epsilon+\mathrm{i}t)H_Y} = e^{-\mathrm{i}tH_Y}.$$

These boundary values are unitary since $|e^{-\mathrm{i}t\lambda}| = 1$ for $\lambda \in \mathrm{spec}(H_Y)$. □

This theorem is the precise point at which functorial gluing becomes positive energy. It also explains why reflection positivity alone is insufficient: one still needs domain control for the quotient, strong continuity of the cylinder semigroup, and the boundedness or vacuum-energy normalization needed to apply the semigroup theorem. These analytic requirements are part of the K-S construction problem in every infinite-dimensional QFT example.

In a real-analytic globally hyperbolic Lorentzian spacetime, a Lorentzian time-slab appears as a boundary limit of admissible complex slabs. Under the holomorphic and boundedness hypotheses needed to take this limit, the K-S construction gives unitary propagation between the Hilbert spaces of time-symmetric hypersurfaces. Local field operators on a time slice are obtained as limits of insertion bordisms pinched to the slice; operators at spacelike separated points commute because both insertions can be represented on one common slice and the Euclidean sewing map is symmetric under exchanging their order.

13.7 Comparison with OS, Wightman, and Local Nets

Flat-space comparison with OS Schwinger functions. Assume a K-S functorial QFT is defined on Euclidean $\mathbb{R}^D$ with translation-invariant vacuum state, local observable bundles $\mathcal{O}_x$, and tempered boundary values for point insertions. For local observables $A_1, \ldots, A_n$, define

$$S_n(A_1, x_1; \ldots; A_n, x_n) = Z(\mathbb{R}^D; A_1(x_1), \ldots, A_n(x_n))$$

for distinct Euclidean points, extended as a distribution by the assumed tempered boundary value. Then Euclidean covariance, symmetry at separated points, reflection positivity, and clustering of the Schwinger functions follow from the functorial axioms plus the corresponding covariance and vacuum uniqueness assumptions on Z.

Euclidean covariance is functoriality under background isomorphisms. Symmetry follows by moving separated point insertions inside a Riemannian background without crossing. The configuration space with diagonals removed records the possible permutation monodromy; ordinary bosonic local observables have trivial monodromy. Reflection positivity is the positivity of the doubled half-space bordism. Clustering is not a pure sewing identity: it is the assertion that the translation semigroup on a long cylinder has a unique zero-energy vector and that the remaining spectrum is separated or decays in the topology used for the state spaces. Under that spectral hypothesis, inserting a long cylinder between two groups of observables projects to the vacuum state, giving the OS cluster property.

Construction 13.8 (K-S Lorentzian boundary problem)**.** Let $M_L : \Sigma_0 \to \Sigma_1$ be a real-analytic globally hyperbolic Lorentzian bordism with real-analytic Cauchy collars. A K-S Lorentzian boundary construction for M_L consists of the following data and estimates.

(i) An admissible family of complex metrics g_ϵ, $\epsilon > 0$, on the same collared bordism, with g_ϵ in the K-S allowable domain pointwise and $g_\epsilon \to g_L$ as a boundary value of complex metrics on compact subsets of the collars and interior.

(ii) Hilbert spaces $\mathcal{H}_{\Sigma_i}$ obtained from the reflection positive pairing on the time-symmetric boundary germs Σ_i, including the null-space quotient and completion.

(iii) Continuous amplitude maps
$$Z(M, g_\epsilon) : \mathcal{H}^{\mathrm{core}}_{\Sigma_0} \longrightarrow \mathcal{H}_{\Sigma_1}$$
on a dense reflection-positive core, together with a topology in which the limit
$$U(M_L) = \lim_{\epsilon \downarrow 0} Z(M, g_\epsilon)$$
exists on that core and extends to a bounded operator $\mathcal{H}_{\Sigma_0} \to \mathcal{H}_{\Sigma_1}$.

(iv) Independence of $U(M_L)$ from the admissible approach g_ϵ to g_L, within a specified approach class.

(v) Compatibility with sewing: if $M_L = M_{2,L} \circ_\Sigma M_{1,L}$, then the boundary limits obey
$$U(M_L) = U(M_{2,L})U(M_{1,L})$$
on the common dense domain and hence on Hilbert completions.

(vi) Reflection compatibility:
$$U(\bar{M}_L) = U(M_L)^*.$$
For a slab whose reflected reverse is the inverse Lorentzian evolution, this identity and sewing imply that $U(M_L)$ is unitary.

(vii) Local insertion limits. If two insertion germs have spacelike separated Lorentzian supports and can be represented on a common admissible complex slice without crossing singular diagonals, then the two boundary operators commute, with the Koszul sign for graded fields.

Construction 13.8 is deliberately not stated as a theorem about all K-S functors. The finite-dimensional metric allowability criterion is Theorem 13.3; the product-cylinder positive-energy statement is Theorem 13.7. The passage from an arbitrary admissible complex slab to a Lorentzian globally hyperbolic slab requires additional analysis: uniform bounds for the amplitudes, existence and approach-independence of boundary values, stability of the null-space quotient under the limiting maps, and sewing estimates strong enough to pass through Hilbert completion.

The mechanism is nevertheless precise. Reflection positivity supplies the Hilbert spaces on time-symmetric cuts. Holomorphic dependence on admissible complex metrics gives a candidate family $Z(M, g_\epsilon)$. If the limit exists and is independent of the approach, reflection gives
$$U(M_L)^* = U(\bar{M}_L).$$

When $\bar{M}_L \circ M_L$ and $M_L \circ \bar{M}_L$ are the identity cylinders after Lorentzian boundary limiting, sewing gives

$$U(M_L)^* U(M_L) = \mathbf{1}_{\mathcal{H}_{\Sigma_0}}, \qquad U(M_L) U(M_L)^* = \mathbf{1}_{\mathcal{H}_{\Sigma_1}},$$

so the boundary evolution is unitary. For insertions, spacelike commutativity is the same sewing statement applied to two punctures: if the punctures can be exchanged inside the admissible complex configuration space without crossing the diagonal, functoriality identifies the two sewn amplitudes. Thus the open analytic work is not the algebraic conclusion once the limits exist; it is proving the boundary limits and their stability for a given infinite-dimensional QFT.

Combining this flat-space compatibility statement with OS reconstruction gives the route

$$\text{K-S functorial data} \longrightarrow \text{OS Schwinger functions} \longrightarrow \text{Wightman fields.}$$

After Wightman fields have been reconstructed, local nets are obtained by taking von Neumann algebras generated by bounded functions of smeared fields, provided the self-adjointness and strong-locality hypotheses needed for those bounded functions are verified. Thus the arrow from K-S to Haag–Kastler is a composite arrow with analytic and operator-domain assumptions at each stage.

The reverse direction requires additional structure. OS Schwinger functions on flat space do not by themselves assign state spaces to arbitrary hypersurface germs, nor do they define amplitudes for all admissible complex bordisms. A reconstruction of a K-S functor from OS data therefore requires sewing estimates, collar factorization, and control of metric dependence. Those hypotheses are available in selected two-dimensional constructions and topological theories; they are open in physically central higher-dimensional interacting theories.

13.8 OPE from Sewing

Let $B_r(x) \subset M$ be a small ball whose boundary sphere is $S_r(x)$. A collection of local insertions inside $B_r(x)$ defines, by the K-S amplitude of the punctured ball, a vector

$$\Psi_{A_1,\ldots,A_k}(r; \xi_1, \ldots, \xi_k) \in E(S_r(x)),$$

where ξ_i are coordinates of the insertion points relative to x. Suppose the annular evolution identifying $E(S_r(x))$ with $E(S_1(x))$ has a discrete generalized eigenspace decomposition

$$E(S_1(x)) = \widehat{\bigoplus_{\Delta,s}} E_{\Delta,s}$$

with nuclear convergence for the expansion of punctured-ball states. Choose a basis of local operators $\mathcal{O}_{\Delta,s,a}$ corresponding to the dual basis of these eigenspaces. Then sewing the punctured ball into the complement $M \setminus B_r(x)$ gives

$$A_1(x+\xi_1) \cdots A_k(x+\xi_k) \sim \sum_{\Delta,s,a} C^{\Delta,s,a}_{A_1 \ldots A_k}(\xi_1, \ldots, \xi_k)\, \mathcal{O}_{\Delta,s,a}(x), \tag{13.4}$$

with convergence in the topology in which the boundary-state expansion converges. In a CFT, annular evolution is generated by dilations, so the coefficients have homogeneous leading behavior determined by scaling dimensions and spin. In a massive theory the same construction gives a local short-distance expansion when the small-ball state admits the corresponding asymptotic spectral expansion.

This derivation identifies the analytic hypotheses behind OPE convergence: state spaces on spheres, trace or nuclear bounds for annuli, spectral control of the annular semigroup, and continuity of sewing. Without these hypotheses, (13.4) is a formal expansion rather than a theorem.

13.9 Stoyanovsky-Style Wick Rotation

Stoyanovsky's axiomatic Wick-rotation program may be viewed as a hypersurface-evolution formulation of the same problem. The basic object is a bundle of state spaces over a space of embedded hypersurfaces in a complexified spacetime, equipped with flat evolution maps for deformations of the hypersurface. Local fields act by insertion when the hypersurface passes the insertion point. Flatness expresses independence of the chosen interpolating family of hypersurfaces; positivity and boundary-value conditions select the Lorentzian real slice.

The K-S metric formulation supplies a concrete admissible domain for those hypersurface deformations. Rather than complexifying the time coordinate alone, it complexifies the metric and imposes (13.1) pointwise. This gives a finite-dimensional linear-algebra condition at each tangent space and a gluing category of admissible metric bordisms. The two viewpoints should agree when both are defined: hypersurface evolution is the local expression of the functor on thin bordisms.

13.10 Examples and Construction Status

Topological theories are the cleanest functorial examples. If Z is independent of the metric and satisfies Atiyah–Segal sewing, then it is a K-S-type theory restricted to the topological subcategory: the admissible metric dependence is constant. Finite gauge theory, Dijkgraaf–Witten theory, and Reshetikhin–Turaev theories provide theorem-level examples in this topological sector, with their anomaly and extended-boundary data recorded in Volume VIII.

Two-dimensional CFT supplies the deepest non-topological testing ground. Segal's sewing axioms have been verified in important representation-theoretic and probabilistic settings, including free-fermionic and loop-group examples in the operator-algebraic literature and Liouville-theory sewing results in the probabilistic conformal-bootstrap program. Each such result is a two-dimensional Segal-CFT theorem with its own topology on state spaces and moduli dependence. Passing from these theorems to a general-dimensional K-S construction is a separate problem.

Two-dimensional Yang–Mills has exact heat-kernel formulas on surfaces and a rigorous measure-theoretic construction in several formulations. These formulas obey cutting identities at the level of class functions and holonomy kernels. A full continuum Segal functor with all state spaces, collar topologies, and boundary field insertions specified is a further structure that must be supplied before calling it a completed K-S example.

Free Gaussian theory illustrates both what is clear and what remains unfinished. Let A be a positive self-adjoint operator on a Hilbert space of spatial modes, and first replace it by a finite-dimensional positive matrix. The Euclidean cylinder kernel is the harmonic-oscillator Mehler kernel

$$K_\tau(\varphi_0,\varphi_1) = \det\left(\frac{A^{1/2}}{2\pi\sinh(\tau A^{1/2})}\right)^{1/2} \exp\left[-\frac{1}{2}\begin{pmatrix}\varphi_0\\ \varphi_1\end{pmatrix}^T B_\tau \begin{pmatrix}\varphi_0\\ \varphi_1\end{pmatrix}\right],$$

where

$$B_\tau = \begin{pmatrix} A^{1/2}\coth(\tau A^{1/2}) & -A^{1/2}\operatorname{csch}(\tau A^{1/2}) \\ -A^{1/2}\operatorname{csch}(\tau A^{1/2}) & A^{1/2}\coth(\tau A^{1/2}) \end{pmatrix}.$$

For $\operatorname{Re}\tau > 0$ this kernel is holomorphic and composes by Gaussian integration. Reflection positivity follows because the same kernel is the integral kernel of $e^{-\tau H_A}$ for a positive harmonic-oscillator Hamiltonian H_A. Thus every finite collection of modes is a genuine one-dimensional K-S semigroup.

The continuum free scalar in $D \geq 3$ is obtained formally by replacing the finite determinant and finite Gaussian integral by zeta, heat-kernel, or Fock-space constructions. A complete K-S construction still has to specify state spaces for arbitrary hypersurface germs, prove trace or nuclear sewing for admissible collars, control point-field insertions as distributions or hyperfunctions, prove reflection positivity for the chosen completions, and show holomorphic dependence on the admissible metric. The monograph therefore treats the free scalar in $D \geq 3$ as a principal construction problem rather than as an already completed K-S theorem.

13.11 Open Problems and Construction Targets

Open Problem 13.9 (Free fields as K-S functors). Construct the full K-S functor for the free massive scalar field in $D \geq 3$. The construction must specify hypersurface state spaces, Gaussian amplitudes for admissible collars, holomorphic metric dependence, reflection positivity, distributional field insertions, and sewing estimates.

Open Problem 13.10 ($P(\phi)_2$ and constructive scalar models). Starting from constructive OS data for $P(\phi)_2$, build state spaces on curves, prove collar factorization, and extend the Schwinger functions to a Segal/K-S functor on the relevant admissible two-dimensional bordism category.

Open Problem 13.11 (Liouville and nonrational CFT). Determine the exact relation between probabilistic Liouville correlators, the DOZZ/bootstrap construction, Segal sewing, and a complete functorial state-space assignment. The required output is a functor with specified boundary state spaces and sewing maps, not only closed-surface correlators.

Open Problem 13.12 (Two-dimensional Yang–Mills). Upgrade the heat-kernel and holonomy-cutting formulas of two-dimensional Yang–Mills to a continuum Segal functor with boundary Hilbert spaces, defect insertions, and compatibility with the admissible complex metric domain.

Open Problem 13.13 (Three-dimensional constructive models). For ϕ^4_3, Gross–Neveu type models, and related constructive theories, identify the additional estimates needed to pass from OS correlators to state spaces on arbitrary surfaces and to admissible complex-metric sewing.

Open Problem 13.14 (Four-dimensional gauge theory). Construct four-dimensional Yang–Mills with mass gap as a K-S functor. This is at least as hard as the corresponding OS, Wightman, and Haag–Kastler existence problems and additionally requires functorial gluing and holomorphic admissible-metric dependence.

Open Problem 13.15 (Fermions and gauge fields in K-S form). Develop K-S functorial constructions for fermionic and gauge theories in a regularization that preserves the relevant reflection positivity, anomaly bookkeeping, and sewing identities. For gauge theory the BV formulation of regularized path integrals and the lattice formulation are the currently available frameworks with a precise gauge-consistency condition.

Open Problem 13.16 (Extended K-S structures). Formulate and construct extended K-S theories assigning data to corners and higher-codimension strata, analogous to extended TQFT but with non-topological metric dependence and analytic sewing. The target should record defects, boundary conditions, and local operator categories.

Chapter 14

Källén–Lehmann Spectral Representation

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

14.1 Spectral Data of a Scalar Field

Definition 14.1 (Centered scalar two-point spectral datum)**.** Let $\mathcal{H}$ carry a strongly continuous unitary representation of spacetime translations with commuting self-adjoint generators P^μ. Let

$$E(\Delta)$$

be the joint projection-valued spectral measure of P^μ, where $\Delta \subset \mathbb{R}^D$ is Borel. Assume the spectrum condition

$$\mathrm{Spec}(P) \subset \overline{V}_+ = \{p \in \mathbb{R}^D : p^0 \geq 0,\ p^2 \leq 0\},$$

with $p^2 = \eta_{\mu\nu} p^\mu p^\nu$. Let Ω be a translation-invariant vacuum vector in the pure vacuum sector,

$$E(\{0\})\mathcal{H} = \mathbb{C}\Omega.$$

Let $\widehat{\phi}$ be a scalar operator-valued distribution. If

$$\langle \Omega | \widehat{\phi}(x) | \Omega \rangle$$

is nonzero, replace $\widehat{\phi}$ by $\widehat{\phi} - \langle\Omega|\widehat{\phi}|\Omega\rangle$. This removes the vacuum atom from the two-point function and keeps the connected spectral data: because the zero-momentum spectral projection is $|\Omega\rangle\langle\Omega|$, there is no remaining translation-invariant component after this subtraction. Point-field notation below is distributional notation; after smearing, the matrix elements are ordinary Hilbert-space pairings.

Proposition 14.2 (Two-point spectral measure of a scalar field)**.** *In the datum of Definition 14.1, the centered two-point distribution determines a unique positive tempered Borel measure ν_ϕ on $\mathbb{R}^D$ by*

$$W_2(f) = \int_{\mathbb{R}^D} \widetilde{f}(-p)\,\mathrm{d}\nu_\phi(p), \qquad f \in \mathcal{S}(\mathbb{M}^D), \tag{14.1}$$

where

$$\widetilde{f}(p) = \int \mathrm{d}^D x\, f(x)\mathrm{e}^{-\mathrm{i}p\cdot x}.$$

Equivalently, for smeared fields,

$$\langle\widehat{\phi}(f)\Omega, \widehat{\phi}(g)\Omega\rangle = \int_{\mathbb{R}^D} \overline{\widetilde{f}(p)}\,\widetilde{g}(p)\,\mathrm{d}\nu_\phi(p), \qquad f, g \in \mathcal{S}(\mathbb{M}^D). \tag{14.2}$$

The measure is supported in $\overline{V}_+$. If $\widehat{\phi}$ is Lorentz scalar and the vacuum is Lorentz invariant, ν_ϕ is invariant under $SO^+(1, D-1)$. In formal point-field notation one writes

$$\nu_\phi(\Delta) = \langle\Omega|\widehat{\phi}(0)E(\Delta)\widehat{\phi}(0)|\Omega\rangle,$$

but this line is shorthand for the smeared characterization above, not a literal assertion that $\widehat{\phi}(0)\Omega$ is a Hilbert-space vector. The Wightman two-point distribution is the Fourier–Stieltjes transform

$$W_2(x-y) = \int_{\overline{V}_+} \mathrm{e}^{\mathrm{i}p\cdot(x-y)}\,\mathrm{d}\nu_\phi(p).$$

Proof. The centered Wightman distribution

$$W_2(x-y) = \langle\Omega|\widehat{\phi}(x)\widehat{\phi}(y)|\Omega\rangle$$

is a tempered distribution of positive type. Indeed, for every $f \in \mathcal{S}(\mathbb{M}^D)$,

$$\int \mathrm{d}^D x\,\mathrm{d}^D y\,\overline{f(x)}\,f(y)\,W_2(x-y) = \|\widehat{\phi}(f)\Omega\|^2 \geq 0.$$

The Bochner–Schwartz theorem for positive-type tempered distributions therefore gives a unique positive tempered Borel measure ν_ϕ whose Fourier–Stieltjes transform is W_2, namely (14.1). Positivity is thus a Hilbert-space positivity statement before it is a statement about a measure.

The support is fixed by the spectrum condition. In the present translation convention,

$$U(a)^{-1}\widehat{\phi}(0)U(a) = \widehat{\phi}(a), \qquad U(a) = \mathrm{e}^{\mathrm{i}a^\mu P_\mu},$$

so $W_2(x)$ has spectral Fourier transform supported in $\mathrm{Spec}(P)$. Since $E(\mathbb{R}^D \setminus \overline{V}_+) = 0$, this support lies in $\overline{V}_+$. Equivalently, after smearing, the spectral theorem gives the same measure by the identity (14.2); the unsmeared expression $\langle\Omega|\widehat{\phi}(0)E(\Delta)\widehat{\phi}(0)|\Omega\rangle$ is the customary notation for the corresponding spectral-measure matrix element.

Finally suppose the field is a scalar and the vacuum is Lorentz invariant. Then $W_2(\Lambda x) = W_2(x)$ for every $\Lambda \in SO^+(1, D-1)$. Applying this equality to test functions and using uniqueness in the Bochner–Schwartz representation gives $\nu_\phi(\Lambda\Delta) = \nu_\phi(\Delta)$ for every Borel set Δ. $\square$

Equivalently, if one writes the same statement in generalized energy-momentum eigenvector notation, with

$$P^\mu|\alpha\rangle = p_\alpha^\mu|\alpha\rangle,$$

then

$$W_2(x-y) = \int \mathrm{d}\alpha\, \mathrm{e}^{\mathrm{i}p_\alpha\cdot(x-y)} \left|\langle\alpha|\widehat{\phi}(0)|\Omega\rangle\right|^2.$$

This formula is only notation for the spectral measure above; the measure $d\nu_\phi$ is the invariant object.

14.2 Invariant-Mass Decomposition

For a scalar field and invariant vacuum, ν_ϕ is invariant under the proper orthochronous Lorentz group. The Lorentz-invariant parameter on the forward cone is the invariant mass squared

$$\mu^2 = -p^2 \geq 0.$$

Let

$$\pi : \overline{V}_+ \to [0,\infty), \qquad \pi(p) = -p^2,$$

which is a Borel map between standard Borel spaces. The spectral density measure below is a quotient measure for the Lorentz orbits of this map, not the literal pushforward $\pi_*\nu_\phi$: a single massive shell has infinite Lorentz-invariant volume, so the raw pushforward would assign infinite mass to an isolated one-particle shell. The normalization of the invariant measure on each shell must be fixed first.

Proposition 14.3 (Invariant mass-shell disintegration)**.** *Let ν be a positive locally finite Borel measure on $\overline{V}_+$ that is invariant under $SO^+(1,D-1)$. Assume that ν has no atom at $p=0$. Then there is a positive Borel measure ρ on $[0,\infty)$ such that for every $F \in C_c(\overline{V}_+)$,*

$$\int_{\overline{V}_+} F(p)\,\mathrm{d}\nu(p) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2) \int \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\,\theta(p^0)\delta(p^2+\mu^2)F(p).$$

The measure ρ is the spectral density measure after the normalization of the invariant measure on each shell has been fixed.

Proof. Let

$$G = SO^+(1,D-1), \qquad X = \overline{V}_+ \setminus \{0\}.$$

The excluded point has zero ν-measure by hypothesis, so it may be removed throughout the proof. The space X is locally compact, second countable, σ-compact, and standard Borel. The group G is a locally compact second countable Lie group, and its action on X is continuous.

We first verify the regular-orbit hypotheses in the Mackey–Effros decomposition theorem. The G-orbits in X are

$$\Sigma_s^+ = \{p \in \overline{V}_+ : -p^2 = s\}, \qquad s > 0,$$

together with the punctured future light cone

$$\Sigma_0^{+\times} = \{p \in \overline{V}_+ : p^2 = 0,\ p \neq 0\}.$$

For $s > 0$, a representative is $k_s = (\sqrt{s}, 0, \ldots, 0)$, and the stabilizer is the compact group $SO(D-1)$. For the null orbit, a representative is $\ell = (1, 1, 0, \ldots, 0)$, and the stabilizer is the Euclidean group

$$ISO(D-2) = \mathbb{R}^{D-2} \rtimes SO(D-2)$$

embedded as the usual massless little group. These stabilizers are closed subgroups of G, and the orbit maps identify the orbits with the homogeneous spaces

$$\Sigma_s^+ \simeq G/SO(D-1), \qquad \Sigma_0^{+\times} \simeq G/ISO(D-2).$$

The orbit space is the standard Borel space $[0, \infty)$, with orbit map $\pi(p) = -p^2$, after the origin has been removed from the fiber over 0. A Borel cross-section is

$$c(0) = \ell, \qquad c(s) = k_s \quad (s > 0).$$

Thus the action is smooth in Mackey's sense: the orbit equivalence relation is regularly embedded, the quotient is standard Borel, and a Borel section exists. Since G, $SO(D-1)$, and $ISO(D-2)$ are unimodular, each homogeneous orbit carries a nonzero G-invariant Radon measure, unique up to a positive scalar. The Mackey–Effros disintegration theorem for smooth Borel actions of locally compact second countable groups therefore applies to the σ-finite invariant Radon measure $\nu|_X$.

Consequently there are conditional invariant Radon measures ν_s, supported on the orbit $\pi^{-1}(s) \cap X$, and a positive Borel measure λ on $[0, \infty)$ such that

$$\int F(p)\, \mathrm{d}\nu(p) = \int_{[0,\infty)} \left(\int_{\pi^{-1}(s)} F(p)\, \mathrm{d}\nu_s(p) \right) \mathrm{d}\lambda(s)$$

for all $F \in C_c(X)$. This λ is an orbit-space measure; it is determined by the chosen normalization of conditional orbit measures. A single massive orbit has infinite invariant volume, so this normalization is part of the data entering the quotient measure.

It remains to identify the orbit measures and fix their normalization. For $s > 0$, the standard invariant measure on the positive mass shell is

$$\mathrm{d}\sigma_s(p) = \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\, \theta(p^0) \delta(p^2 + s).$$

Indeed, the distribution $\theta(p^0)\delta(p^2 + s)\mathrm{d}^D p$ is Lorentz invariant, and in coordinates $p = (\omega_{\vec{p}}, \vec{p})$, $\omega_{\vec{p}} = (\vec{p}^2 + s)^{1/2}$, it is

$$\mathrm{d}\sigma_s(p) = \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2\omega_{\vec{p}}}.$$

For $s = 0$ the same formula gives the invariant measure on the punctured future light cone,

$$\mathrm{d}\sigma_0(p) = \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2|\vec{p}|}, \qquad \vec{p} \neq 0,$$

which is locally finite on X. The origin would give a separate orbit and a possible atom; it was removed by hypothesis.

The uniqueness of invariant Radon measure on each homogeneous orbit gives

$$\nu_s = c(s)\sigma_s$$

for λ-almost every s, with $c(s) \geq 0$. The family $s \mapsto \sigma_s$ is measurable: for $F \in C_c(X)$,

$$s \longmapsto \int_{\pi^{-1}(s)} F(p)\, \mathrm{d}\sigma_s(p)$$

is Borel, and it is continuous on $(0, \infty)$ by the displayed $\vec{p}$-coordinate formula and dominated convergence on compact supports; the $s = 0$ value is the corresponding null-shell limit whenever the support stays away from the origin. The measurable scalar $c(s)$ is then fixed λ-almost everywhere by testing ν_s against any countable measure-determining family of compactly supported continuous functions on X. Absorbing $c(s)$ into $\mathrm{d}\lambda(s)$ defines the positive Borel measure $\mathrm{d}\rho(s) := c(s)\mathrm{d}\lambda(s)$. Substituting $\nu_s = c(s)\sigma_s$ gives the stated formula for every $F \in C_c(X)$, and hence for every $F \in C_c(\overline{V}_+)$ because the removed origin has zero ν-measure. □

Definition 14.4 (Källén–Lehmann spectral measure)**.** Applying Proposition 14.3 to ν_ϕ, with the vacuum atom removed as above, gives

$$\mathrm{d}\nu_\phi(p) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2)\, \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\, \theta(p^0)\delta(p^2 + \mu^2).$$

Here $d\rho$ is a positive Borel measure on $[0, \infty)$. When it is absolutely continuous one writes $\mathrm{d}\rho(\mu^2) = \rho(\mu^2)\mathrm{d}\mu^2$; when it has atoms, the atomic weights are part of the same measure. In the special case in which $d\nu_\phi$ has a density with respect to $\mathrm{d}^D p$, scalar covariance and the spectrum condition say equivalently that the density is of the form

$$\frac{\theta(p^0)}{(2\pi)^{D-1}}\rho(-p^2),$$

with support on $-p^2 \geq 0$. The measure notation is retained because the one-particle contribution is an atom, not an ordinary function.

Definition 14.5 (Positive-frequency massive scalar distribution)**.** Define the positive-frequency scalar two-point function of mass μ by

$$\Delta_+(x; \mu^2) = \int \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\, \theta(p^0)\delta(p^2 + \mu^2)\, \mathrm{e}^{\mathrm{i}p\cdot x}.$$

Equivalently,

$$\Delta_+(x; \mu^2) = \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}}\, \frac{\mathrm{e}^{\mathrm{i}\vec{p}\cdot\vec{x} - \mathrm{i}\sqrt{\vec{p}^2+\mu^2}\, x^0}}{2\sqrt{\vec{p}^2 + \mu^2}}.$$

Proposition 14.6 (Källén–Lehmann representation for W_2)**.** *The Wightman two-point function is then*

$$W_2(x) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2)\, \Delta_+(x; \mu^2).$$

This is the Källén–Lehmann representation for the Wightman two-point function.

Proof. Let $f \in \mathcal{S}(\mathbb{M}^D)$. The spectral Fourier representation of Proposition 14.2 gives

$$W_2(f) = \int_{\overline{V}_+} \mathrm{d}\nu(p)\, \widetilde{f}(-p),$$

with ν the positive translation-spectral measure carried by the vacuum two-point vector. By Definition 14.4, ν disintegrates over the invariant mass coordinate $s = -p^2 \geq 0$ as

$$\mathrm{d}\nu(p) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2)\, \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\, \theta(p^0)\delta(p^2 + \mu^2).$$

Pairing with $\widetilde{f}(-p)$ is legitimate because f is Schwartz and the spectral measure is tempered by the Wightman distribution hypothesis. The positive measure permits Tonelli for nonnegative test majorants, and the Schwartz decay supplies the finite signed/complex integrals by decomposing $\widetilde{f}$ into real and imaginary parts. Hence

$$W_2(f) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2) \int \frac{\mathrm{d}^D p}{(2\pi)^{D-1}}\, \theta(p^0)\delta(p^2 + \mu^2)\, \widetilde{f}(-p).$$

The inner integral is precisely the distributional pairing $\Delta_+(\,\cdot\,; \mu^2)(f)$ in Definition 14.5. Therefore the displayed formula holds as an identity on every Schwartz test function, hence as an identity of tempered distributions. □

Spacelike symmetry of the scalar two-point function. For each μ^2, the distribution $\Delta_+(x; \mu^2)$ is even at spacelike separation:

$$\Delta_+(x; \mu^2) = \Delta_+(-x; \mu^2), \qquad x^2 > 0,$$

and hence $W_2(x) = W_2(-x)$ for spacelike x. No such equality follows from the spectral representation for timelike x. For $x^2 > 0$, choose a proper orthochronous Lorentz transformation carrying x to $(0, \vec{r})$. The mass-shell measure in Definition 14.5 is Lorentz invariant, so $\Delta_+(x; \mu^2) = \Delta_+(0, \vec{r}; \mu^2)$. In that frame the integral is

$$\int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}} \frac{\mathrm{e}^{\mathrm{i}\vec{p}\cdot\vec{r}}}{2\sqrt{\vec{p}^2 + \mu^2}},$$

which has an even denominator. Changing variables $\vec{p} \mapsto -\vec{p}$ gives $\Delta_+(0, \vec{r}; \mu^2) = \Delta_+(0, -\vec{r}; \mu^2)$, which is $\Delta_+(-x; \mu^2)$. Integrating this equality against the positive measure $d\rho(\mu^2)$ gives the statement for W_2.

14.3 Time-Ordered and Euclidean Forms

Definition 14.7 (Time-ordered scalar two-point distribution)**.** The time-ordered two-point function is

$$G_T(x) = \langle \Omega |\, \mathrm{T}\{\widehat{\phi}(x)\widehat{\phi}(0)\} | \Omega \rangle.$$

Using the definition of time ordering,

$$G_T(x) = \theta(x^0) W_2(x) + \theta(-x^0) W_2(-x).$$

Definition 14.8 (Massive Feynman two-point kernel)**.** For $\mu^2 \geq 0$, define

$$\Delta_F(x; \mu^2) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k\cdot x}}{k^2 + \mu^2 - \mathrm{i}\epsilon}.$$

Proposition 14.9 (Time-ordered Källén–Lehmann representation)**.** *The time-ordered two-point function satisfies*

$$G_T(x) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2)\, \Delta_F(x;\mu^2)$$

as a distribution. Equivalently,

$$\Delta_F(x;\mu^2) = \theta(x^0)\Delta_+(x;\mu^2) + \theta(-x^0)\Delta_+(-x;\mu^2).$$

Proof. The first equality follows from Definition 14.7, Proposition 14.6, and the second displayed identity for Δ_F. It remains to prove that the iϵ kernel in Definition 14.8 has this time-ordered boundary value.

Set

$$\omega_{\vec{k},\mu} = \sqrt{\vec{k}^{\,2} + \mu^2}.$$

Since $k^2 + \mu^2 = -(k^0)^2 + \omega^2_{\vec{k},\mu}$, the k^0-integral in Δ_F is

$$I(x^0,\vec{k};\mu^2) = \int_{-\infty}^{\infty} \frac{\mathrm{d}k^0}{2\pi\mathrm{i}} \frac{\mathrm{e}^{-\mathrm{i}k^0x^0}}{-(k^0)^2 + \omega^2_{\vec{k},\mu} - \mathrm{i}\epsilon}.$$

The two poles are displaced to

$$k^0 = +\omega_{\vec{k},\mu} - \mathrm{i}0, \qquad k^0 = -\omega_{\vec{k},\mu} + \mathrm{i}0.$$

For $x^0 > 0$, the exponential damps in the lower half-plane and the closed contour has clockwise orientation. For $x^0 < 0$, the exponential damps in the upper half-plane. The residue theorem gives

$$I(x^0,\vec{k};\mu^2) = \theta(x^0)\frac{\mathrm{e}^{-\mathrm{i}\omega_{\vec{k},\mu}x^0}}{2\omega_{\vec{k},\mu}} + \theta(-x^0)\frac{\mathrm{e}^{+\mathrm{i}\omega_{\vec{k},\mu}x^0}}{2\omega_{\vec{k},\mu}}.$$

After the remaining spatial Fourier transform this is exactly

$$\Delta_F(x;\mu^2) = \theta(x^0)\Delta_+(x;\mu^2) + \theta(-x^0)\Delta_+(-x;\mu^2).$$

□

Figure 14.1 displays the two contour closures used in the residue calculation, with the pole placement matching the time-ordering terms in Δ_F.

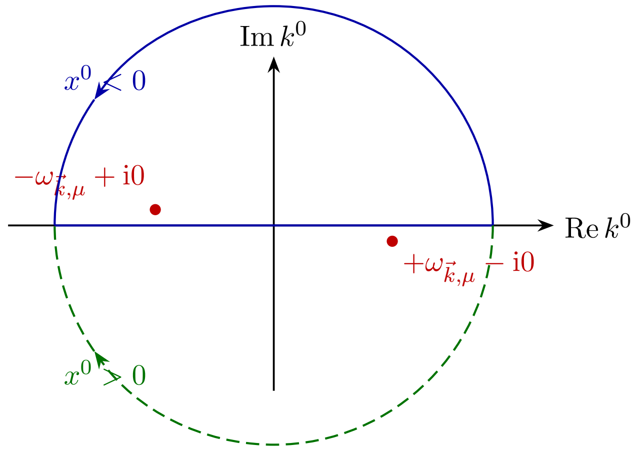

Figure 14.1: Contour closures for the Feynman two-point kernel. Closing below ($x^0 > 0$) is drawn dashed, while closing above ($x^0 < 0$) is drawn solid. Together the residues produce the time-ordered combination of positive-frequency two-point functions.

Equivalently,

$$G_T(x) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \mathrm{e}^{\mathrm{i}k\cdot x} \int_{[0,\infty)} \frac{\mathrm{d}\rho(\mu^2)}{k^2 + \mu^2 - \mathrm{i}\epsilon}.$$

Proposition 14.10 (Euclidean Källén–Lehmann representation)**.** *Let G_E be the Euclidean two-point distribution obtained from the ordered Wightman boundary values by $x^0 = -\mathrm{i}\tau_x$, $y^0 = -\mathrm{i}\tau_y$. Then*

$$G_E(x_E) = \int_{[0,\infty)} \mathrm{d}\rho(\mu^2) \, \Delta_E(x_E; \mu^2),$$

where

$$\Delta_E(x_E; \mu^2) = \int \frac{\mathrm{d}^D k_E}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k_E\cdot x_E}}{k_E^2 + \mu^2}. \tag{14.3}$$

Thus the same positive measure $d\rho$ controls the Wightman, time-ordered, and Euclidean scalar two-point functions.

Proof. The Euclidean function is obtained by analytic continuation of the Wightman functions in the time variable. For

$$z = x - y, \qquad z^0 \in \mathbb{C}, \qquad \mathrm{Im}\, z^0 < 0,$$

the factor $\exp(-\mathrm{i}p^0 z^0)$ is damped by the spectrum condition $p^0 \geq 0$, so $W_2(z)$ is analytic in this tube after smearing in the spatial variables. Set $x^0 = -\mathrm{i}\tau_x$, $y^0 = -\mathrm{i}\tau_y$. If $\tau_x > \tau_y$, then $z^0 = -\mathrm{i}(\tau_x - \tau_y)$ lies in the lower half plane and the Euclidean two-point function is the continuation of $W_2(x-y)$. If $\tau_x < \tau_y$, the time-ordered function instead continues $W_2(y-x)$. This gives a single symmetric Euclidean distribution. For each fixed μ^2, the same continuation of $\Delta_+(x;\mu^2)$ gives the free Euclidean kernel (14.3); this is the one-particle Wick rotation already derived in Chapter 11. Substituting the spectral integral of Proposition 14.6 and testing against compactly supported Euclidean test functions permits the continuation under the positive spectral integral. The result is the displayed formula for G_E. The three Green functions are therefore different boundary values or analytic continuations of the same positive spectral data. $\square$

14.4 Stieltjes Positivity of the Euclidean Propagator

Definition 14.11 (Stieltjes datum of a scalar Euclidean two-point function)**.** The Euclidean momentum-space two-point function contains the same information in a form that is often the most robust for constructive and lattice arguments. In this section z denotes the complex continuation of the Euclidean invariant Q^2. On the physical Euclidean axis set

$$Q^2 = k_E^2 \geq 0.$$

If the spectral measure obeys the Stieltjes integrability condition

$$\int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{1+s} < \infty, \tag{14.4}$$

then, after Fourier transform,

$$\widetilde{G}_E(Q^2) = \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{Q^2+s}. \tag{14.5}$$

Equation (14.4) is automatic if $\rho([0,\infty)) < \infty$, as in the canonically normalized elementary scalar case discussed below. It is not automatic for arbitrary local composite operators; for them the two-point function may require subtractions, and polynomial ambiguities in Q^2 are precisely the momentum-space form of contact terms at coincident Euclidean points.

Proposition 14.12 (Stieltjes positivity and spectral recovery)**.** *Under the integrability condition* (14.4)*, the function*

$$F(z) = \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{z+s}$$

is holomorphic on $\mathbb{C} \setminus (-\infty, 0]$, restricts to $\widetilde{G}_E(Q^2)$ on $Q^2 > 0$, obeys

$$(-1)^r \frac{\mathrm{d}^r}{\mathrm{d}(Q^2)^r} \widetilde{G}_E(Q^2) \geq 0, \qquad Q^2 > 0, \quad r = 0, 1, 2, \ldots,$$

and recovers the absolutely continuous spectral density by the discontinuity formula

$$\rho_{\mathrm{ac}}(s) = -\frac{1}{2\pi\mathrm{i}} \operatorname{Disc}_{z=-s} \widetilde{G}_E(z).$$

Atoms of $d\rho$ are simple poles on the cut with positive residues.

Proof. Under (14.4), $\widetilde{G}_E$ is a Stieltjes transform of a positive measure. More precisely,

$$F(z) = \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{z+s}$$

converges absolutely and uniformly on compact subsets of $\mathbb{C} \setminus (-\infty, 0]$: for every compact $K \subset \mathbb{C} \setminus (-\infty, 0]$ there is $c_K > 0$ such that $|z + s| \geq c_K(1 + s)$ for $z \in K$ and $s \geq 0$. Dominated convergence then permits differentiation under the integral sign, so F is holomorphic on this cut plane and its restriction to $z = Q^2 > 0$ is the Euclidean function in (14.5). The endpoint $z = 0$ is part of the cut if the spectrum has support arbitrarily near $s = 0$; no continuation through that endpoint is being assumed. If the spectral support begins at a positive mass gap $s = m_0^2 > 0$, the cut instead begins at $z = -m_0^2$, and the function is analytic in a neighborhood of $z = 0$. Consequently, for every $Q^2 > 0$,

$$(-1)^r \frac{\mathrm{d}^r}{\mathrm{d}(Q^2)^r} \widetilde{G}_E(Q^2) = r! \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{(Q^2+s)^{r+1}} \geq 0, \qquad r = 0, 1, 2, \ldots.$$

These inequalities are not perturbative statements. They are Hilbert-space positivity written in Euclidean momentum variables.

The measure can be recovered from the discontinuity across the negative real z-axis. The continuation is performed by treating z as a complex variable on the cut plane and approaching the point $z = -s$ from the two sides of the cut. If the absolutely continuous part has density $\rho_{\mathrm{ac}}(s)$, then

$$\rho_{\mathrm{ac}}(s) = -\frac{1}{2\pi \mathrm{i}} \operatorname{Disc}_{z=-s} \widetilde{G}_E(z), \qquad s > 0,$$

with atoms appearing as simple poles at $z = -s_0$ of positive residue. This is the Euclidean form of the statement that stable particles are isolated positive atoms of the spectral measure and multiparticle states are continuous spectral support. □

Proposition 14.13 (Subtracted Stieltjes form and contact terms)**.** *If the spectral measure has tempered growth in the sense that there is $N \geq 0$ with*

$$\int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{(1+s)^{N+1}} < \infty,$$

then the $(N+1)$-st derivative of the nonlocal Euclidean momentum-space two-point function is the convergent Stieltjes transform

$$F^{(N+1)}(z) = (-1)^{N+1}(N+1)! \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{(z+s)^{N+2}}.$$

Integrating back determines F only up to a polynomial of degree N, which is the momentum-space ambiguity of contact terms at coincident points. Under inverse Fourier transform this polynomial is precisely a finite linear combination of derivatives of the delta distribution supported at the coincident diagonal.

Proof. For a more singular local field, the spectral measure may have only tempered growth, by which we mean here that there is an integer $N \geq 0$ such that

$$\int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{(1+s)^{N+1}} < \infty.$$

The unsubtracted Stieltjes integral need not define an ordinary function. The nonlocal part of the Euclidean momentum-space distribution is nevertheless characterized by its $(N+1)$-st derivative,

$$F^{(N+1)}(z) = (-1)^{N+1}(N+1)! \int_{[0,\infty)} \frac{\mathrm{d}\rho(s)}{(z+s)^{N+2}}.$$

The right-hand side is holomorphic on the same cut plane. If F_1 and F_2 are two distributional momentum-space representatives with this same $(N+1)$-st derivative, their difference $P = F_1 - F_2$ satisfies $\partial_z^{N+1} P = 0$ on the cut plane. On every simply connected subdomain this implies that

P is a polynomial of degree at most N; the polynomial pieces agree on overlaps, so the same polynomial ambiguity is global. In momentum space a polynomial in p_E^2 and, in the nonscalar case, polynomial tensor structures, Fourier-transform to finite linear combinations of derivatives of $\delta(x)$. These are exactly coincident-point contact terms. They have no discontinuity across the cut, and therefore do not change the spectral measure away from coincident-point ambiguities. $\square$

14.5 Canonical Normalization and Spectral Weight

Definition 14.14 (Canonical equal-time normalization of a scalar field)**.** The measure $d\rho$ depends on the normalization of the local field. A canonical equal-time normalization consists of a regularity datum on the operator-valued distribution together with a smeared commutator identity. Let $d = D - 1$. Assume there is a dense common invariant domain $\mathcal{D} \subset \mathcal{H}$, with $\Omega \in \mathcal{D}$, such that for every $f \in \mathcal{S}(\mathbb{R}^d)$ the smeared equal-time fields

$$\widehat{\phi}_t(f) = \int \mathrm{d}^d\vec{x}\, f(\vec{x})\widehat{\phi}(t,\vec{x}), \qquad \widehat{\pi}_t(f) = \int \mathrm{d}^d\vec{x}\, f(\vec{x})\widehat{\pi}(t,\vec{x})$$

preserve $\mathcal{D}$, and

$$\frac{\mathrm{d}}{\mathrm{d}t}\widehat{\phi}_t(f)\psi = \widehat{\pi}_t(f)\psi, \qquad \psi \in \mathcal{D},$$

where the derivative is taken in the Hilbert norm. This is C^1 distributional time-regularity of $\widehat{\phi}$. The canonical normalization is the domain identity

$$[\widehat{\phi}_t(f), \widehat{\pi}_t(g)]\psi = \mathrm{i}\int_{\mathbb{R}^d} f(\vec{x})g(\vec{x})\,\mathrm{d}^d\vec{x}\,\psi, \qquad f, g \in \mathcal{S}(\mathbb{R}^d), \quad \psi \in \mathcal{D}.$$

The formal notation

$$[\widehat{\phi}(t,\vec{x}), \partial_t\widehat{\phi}(t,\vec{y})] = \mathrm{i}\,\delta^{(d)}(\vec{x}-\vec{y})\mathbf{1}$$

means precisely this smeared statement with $\widehat{\pi}_t = \partial_t\widehat{\phi}_t$ as an operator-valued distribution. An interacting local field used as an interpolating operator need not satisfy this canonical identity. If an analogous equal-time commutator exists with a central normalization $C_\phi \geq 0$,

$$[\widehat{\phi}_t(f), \widehat{\pi}_t(g)]\psi = \mathrm{i}C_\phi \int_{\mathbb{R}^d} f(\vec{x})g(\vec{x})\,\mathrm{d}^d\vec{x}\,\psi,$$

then the same argument below gives $\int \mathrm{d}\rho = C_\phi$. If no such equal-time normalization is part of the field data, the Källén–Lehmann representation by itself gives positivity and support, but not a total-weight sum rule.

Proposition 14.15 (Canonical spectral-weight sum rule)**.** *Assume the canonical equal-time normalization of Definition 14.14, and assume that the spectral truncations converge after applying $\partial_t|_{t=0}$ in $\mathcal{S}'(\mathbb{R}^{D-1})$. Then*

$$\int_{[0,\infty)} \mathrm{d}\rho(s) = 1.$$

If the equal-time commutator has central normalization C_ϕ, then

$$\int_{[0,\infty)} \mathrm{d}\rho(s) = C_\phi.$$

Proof. The commutator two-point distribution is

$$C(x) := \langle\Omega|[\widehat{\phi}(x), \widehat{\phi}(0)]|\Omega\rangle = \int_{[0,\infty)} \mathrm{d}\rho(s)\,\big(\Delta_+(x;s) - \Delta_+(-x;s)\big).$$

The sign of the equal-time derivative is fixed by commutator antisymmetry. The canonical identity gives, in smeared form, $[\widehat{\phi}_0(\vec{r}), \widehat{\pi}_0(\vec{0})] = \mathrm{i}\delta^{(d)}(\vec{r})\mathbf{1}$. Since the derivative $\partial_t C(t,\vec{r})|_{t=0}$ differentiates the first field in $[\widehat{\phi}(t,\vec{r}), \widehat{\phi}(0,\vec{0})]$, it produces

$$[\widehat{\pi}_0(\vec{r}), \widehat{\phi}_0(\vec{0})] = -[\widehat{\phi}_0(\vec{0}), \widehat{\pi}_0(\vec{r})] = -\mathrm{i}\delta^{(d)}(\vec{r})\mathbf{1},$$

where the last equality uses the symmetry of the spatial delta distribution. The C^1 hypothesis gives the equal-time derivative as a spatial tempered distribution:

$$\partial_t C(t,\vec{r})|_{t=0} = \langle\Omega|[\widehat{\pi}_0(\vec{r}), \widehat{\phi}_0(\vec{0})]|\Omega\rangle = -\mathrm{i}\,\delta^{(d)}(\vec{r}). \tag{14.6}$$

It remains to justify the spectral calculation of the same derivative. Let ρ_R be the restriction of ρ to $[0,R]$, and let

$$C_R(t,\vec{r}) = \int_{[0,R]} \mathrm{d}\rho(s)\,\big(\Delta_+(t,\vec{r};s) - \Delta_+(-t,-\vec{r};s)\big).$$

The measure ρ_R is finite by local finiteness. For a spatial test function $h \in \mathcal{S}(\mathbb{R}^d)$, set

$$F_s(t;h) = \int_{\mathbb{R}^d} \mathrm{d}^d\vec{r}\, h(\vec{r})\big(\Delta_+(t,\vec{r};s) - \Delta_+(-t,-\vec{r};s)\big).$$

Writing $\omega_{\vec{p},s} = \sqrt{\vec{p}^2 + s}$, the spatial Fourier representation gives

$$\frac{\mathrm{d}}{\mathrm{d}t}F_s(t;h) = -\frac{\mathrm{i}}{2}\int \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d}\left(\widetilde{h}(\vec{p})\mathrm{e}^{-\mathrm{i}\omega_{\vec{p},s}t} + \widetilde{h}(-\vec{p})\mathrm{e}^{+\mathrm{i}\omega_{\vec{p},s}t}\right),$$

where

$$\widetilde{h}(\vec{p}) = \int_{\mathbb{R}^d} \mathrm{d}^d\vec{r}\, h(\vec{r})\mathrm{e}^{\mathrm{i}\vec{p}\cdot\vec{r}}.$$

The bound

$$\left|\frac{\mathrm{d}}{\mathrm{d}t}F_s(t;h)\right| \le \int \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d}\,|\widetilde{h}(\vec{p})|$$

is uniform in $s \ge 0$ and t. Hence, for every finite R, dominated convergence permits the derivative to pass through the s-integral. At $t = 0$,

$$\left.\frac{\mathrm{d}}{\mathrm{d}t}F_s(t;h)\right|_{t=0} = -\mathrm{i}h(\vec{0}).$$

Therefore

$$\langle\, \partial_t C_R(t,\cdot)|_{t=0}\,, h\rangle = -\mathrm{i}\,\rho([0,R])\,h(\vec{0}).$$

The final limiting step is part of the equal-time regularity assumption: the spectral truncations C_R converge to C after applying the operation $\partial_t|_{t=0}$ in $\mathcal{S}'(\mathbb{R}^d)$. Comparing with (14.6) gives

$$\rho([0,R]) \longrightarrow 1 \qquad (R \to \infty),$$

and monotone convergence yields the canonical sum rule

$$\int_{[0,\infty)} \mathrm{d}\rho(s) = 1. \tag{14.7}$$

It fixes the chosen field normalization; changing the field normalization rescales the spectral measure. If the equal-time commutator has central normalization C_ϕ, the right hand side of (14.6) is multiplied by C_ϕ, and the same comparison gives $\int_{[0,\infty)} \mathrm{d}\rho(s) = C_\phi$. □

One-particle residue bound for a canonically normalized field. If a canonically normalized scalar field has a one-particle atomic contribution $Z\,\delta_{m^2}(\mathrm{d}s)$, then

$$0 \le Z \le 1.$$

More generally, if the equal-time commutator has central normalization C_ϕ, then $0 \le Z \le C_\phi$. Without such a finite equal-time normalization, the atom weight Z is positive for the chosen field but has no universal upper bound.

If the same canonically normalized field has a one-particle atomic contribution $Z\,\delta_{m^2}(\mathrm{d}s)$, where δ_{m^2} is the unit point measure at $s = m^2$, positivity of $d\rho$ and (14.7) imply

$$0 \le Z \le 1.$$

The remainder $1 - Z$ is the total spectral weight carried by all continuum states and by any other atoms in this normalization. For a noncanonical interpolating field, a composite operator, or a renormalized field in a different convention, the same Källén–Lehmann representation holds, but (14.7) is replaced, when an equal-time commutator normalization exists, by

$$\int_{[0,\infty)} \mathrm{d}\rho(s) = C_\phi.$$

Then positivity gives $0 \le Z \le C_\phi$. Without such a finite normalization, the coefficient Z is still a positive spectral weight of the chosen interpolating field, but it has no universal upper bound; rescaling the field rescales Z. The canonical free field used later in LSZ is the asymptotic field on the one-particle Fock space, normalized separately from the interpolating local field whose correlators contain the pole.

Remark 14.16 (Support hypothesis for a single massive scalar channel). The lower endpoint 0 in the Källén–Lehmann integral is conventional: it is the possible lower endpoint of invariant mass squared under the spectrum condition, not a claim that the chosen field has spectral weight at zero. In the special situation used by the elementary scalar LSZ discussion, assume:

(i) the theory has no massless particle seen by $\widehat{\phi}$, so $d\rho_\phi(\{0\}) = 0$;

(ii) the field has nonzero overlap with a stable scalar one-particle mass $m > 0$, giving the atom $Z_\phi \delta_{m^2}(\mathrm{d}s)$;

(iii) there are no lighter massive particles or bound-state atoms in this channel; and

(iv) the non-one-particle part created by $\widehat{\phi}$ begins with states containing at least two particles of mass m.

Then the non-vacuum spectral measure has the support decomposition

$$\operatorname{supp} d\rho_\phi \subset \{m^2\} \cup [4m^2, \infty), \qquad \mathrm{d}\rho_\phi(s) = Z_\phi \delta_{m^2}(\mathrm{d}s) + \mathrm{d}\rho_{\phi,\mathrm{c}}(s),$$

with $\operatorname{supp} d\rho_{\phi,\mathrm{c}} \subset [4m^2, \infty)$. This gap between the atom and the rest of the support is the spectral input used later by Haag–Ruelle and LSZ. If massless particles, infraparticle thresholds, or additional bound-state atoms are present, the displayed support decomposition must be replaced by the corresponding spectral statement.

Remark 14.17 (Existence of an isolated mass shell is a spectral statement). The Källén–Lehmann representation does not imply the existence of a one-particle state. For a fixed scalar local field $\widehat{\phi}$, a term

$$\mathrm{d}\rho_\phi(s) = Z_\phi \, \delta_{m^2}(\mathrm{d}s) + \mathrm{d}\rho_{\phi,\mathrm{c}}(s), \qquad Z_\phi > 0,$$

is exactly the statement that $\widehat{\phi}\Omega$ has nonzero spectral projection onto the positive mass shell of invariant mass m. A positive measure whose support begins at m^2 but has no atom at m^2 gives a threshold, not a normalizable Wigner one-particle vector created by that field.

The field-independent Hilbert-space assertion needed by Haag–Ruelle theory is stronger and has two parts. With E the joint spectral measure of P^μ and

$$\Sigma_m^+ = \{p : p^0 > 0,\ p^2 = -m^2\},$$

one must have

$$E(\Sigma_m^+)\mathcal{H} \neq \{0\}, \qquad \operatorname{Spec}(P) \cap N = \Sigma_m^+$$

for some open neighborhood N of Σ_m^+. The first condition says that the one-particle subspace is nonzero; the second says that the shell is isolated from the rest of the energy-momentum spectrum. If the first condition fails, the notation $E(\Sigma_m^+)\mathcal{H}$ denotes the zero subspace and the corresponding scattering construction is vacuous. If the second condition fails, the sharp Wigner particle hypothesis required by ordinary Haag–Ruelle estimates is absent even when spectral weight accumulates at the same invariant mass.

An atom may be invisible to a particular interpolating field if that field has zero matrix element to the corresponding superselection sector or internal channel. Conversely, absence of an atom in every physical local interpolating field is evidence for absence of that stable particle sector, but the invariant statement is the vanishing of the spectral projection on the physical Hilbert space. The nonzero isolated-shell property is a theorem in free massive fields and in those constructive massive models for which the Wightman theory, the mass gap, and a separated one-particle spectral component have actually been proved. Formal perturbation theory alone supplies candidate pole data rather than this Hilbert-space spectral theorem.

14.6 Scalar One-Particle States and Normalization

Definition 14.18 (Scalar massive one-particle normalization datum)**.** Assume now that the Hilbert space contains an isolated positive-mass one-particle subspace with mass $m > 0$. In this section "scalar particle" means that the corresponding massive Wigner representation has trivial little-group representation and no internal degeneracy. This is a property of the one-particle representation; it is not the same statement as saying that a particular local field is a Lorentz scalar.

Let

$$k_R^\mu = (m, \vec{0}), \qquad k^\mu = (\omega_{\vec{k}}, \vec{k}), \qquad \omega_{\vec{k}} = \sqrt{\vec{k}^{\,2} + m^2}.$$

Choose, for every $\vec{k}$, a standard boost $L(\vec{k}) \in SO^+(1, D-1)$ such that

$$L(\vec{k})k_R = k.$$

With generalized momentum eigenvectors normalized by

$${}_\delta\langle \vec{k}\,' | \vec{k}\rangle_\delta = \delta^{(D-1)}(\vec{k}\,' - \vec{k}),$$

write

$$|\vec{k}\rangle_\delta = N(\vec{k})\, U(L(\vec{k}))|\vec{0}\rangle_\delta, \qquad N(\vec{0}) = 1.$$

Figure 14.2 fixes the geometric meaning of the chosen standard boost $L(\vec{k})$: it carries the rest momentum k_R to the point k on the positive mass shell.

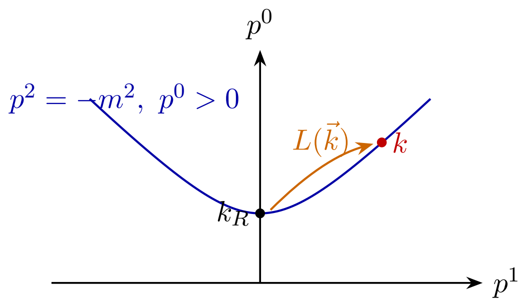

Figure 14.2: Standard boost from the rest momentum to a point on the positive mass shell. The choice of $L(\vec{k})$ fixes the Wigner-rotation convention used for one-particle states.

Lemma 14.19 (Delta-normalized and invariant scalar momentum states)**.** *For the scalar massive one-particle representation,*

$$N(\vec{k}) = \sqrt{\frac{m}{\omega_{\vec{k}}}},$$

up to a phase convention. The invariantly normalized states

$$|\vec{k}\rangle_{\text{inv}} = \sqrt{(2\pi)^{D-1} 2\omega_{\vec{k}}}\, |\vec{k}\rangle_\delta$$

obey

$${}_{\text{inv}}\langle \vec{k}\,' | \vec{k}\rangle_{\text{inv}} = (2\pi)^{D-1} 2\omega_{\vec{k}}\, \delta^{(D-1)}(\vec{k}\,' - \vec{k}), \qquad U(\Lambda)|\vec{k}\rangle_{\text{inv}} = |\Lambda\vec{k}\rangle_{\text{inv}}.$$

Proof. For a Lorentz transformation Λ, define the Wigner rotation

$$W(\Lambda, k) = L(\Lambda k)^{-1} \Lambda L(k).$$

It fixes k_R, hence lies in the little group $SO(D-1)$. For the scalar one-particle representation, $U(W(\Lambda, k))$ acts trivially on the rest state. Therefore

$$U(\Lambda)|\vec{k}\rangle_\delta = \frac{N(\vec{k})}{N(\Lambda\vec{k})} |\Lambda\vec{k}\rangle_\delta,$$

where $\Lambda\vec{k}$ denotes the spatial part of Λk. Unitarity fixes N. Since the on-shell measure

$$\frac{\mathrm{d}^{D-1}\vec{k}}{2\omega_{\vec{k}}}$$

is Lorentz invariant,

$$\delta^{(D-1)}(\Lambda\vec{k}\,' - \Lambda\vec{k}) = \frac{k^0}{(\Lambda k)^0}\delta^{(D-1)}(\vec{k}\,' - \vec{k}).$$

Comparing

$${}_\delta\langle\vec{k}\,'|\vec{k}\rangle_\delta = {}_\delta\langle\vec{k}\,'|U(\Lambda)^\dagger U(\Lambda)|\vec{k}\rangle_\delta$$

gives

$$|N(\Lambda\vec{k})|^2 = |N(\vec{k})|^2\,\frac{k^0}{(\Lambda k)^0}.$$

Taking $k = k_R$ and $\Lambda = L(\vec{k})$, together with $N(\vec{0}) = 1$, yields

$$N(\vec{k}) = \sqrt{\frac{m}{\omega_{\vec{k}}}},$$

after fixing the harmless phase convention.

It is often better to use invariantly normalized states

$$|\vec{k}\rangle_{\mathrm{inv}} = \sqrt{(2\pi)^{D-1}2\omega_{\vec{k}}}\,|\vec{k}\rangle_\delta,$$

for which

$${}_{\mathrm{inv}}\langle\vec{k}\,'|\vec{k}\rangle_{\mathrm{inv}} = (2\pi)^{D-1}2\omega_{\vec{k}}\,\delta^{(D-1)}(\vec{k}\,' - \vec{k}), \qquad U(\Lambda)|\vec{k}\rangle_{\mathrm{inv}} = |\Lambda\vec{k}\rangle_{\mathrm{inv}}.$$

□

Proposition 14.20 (Scalar field matrix element on an isolated scalar shell)**.** *Work in a selected spin-zero isolated one-particle channel with the delta-normalized and invariantly normalized states of Lemma 14.19. If $\widehat{\phi}$ is a scalar local field and the vacuum is invariant, then the matrix element*

$$A(\vec{k}) = {}_\delta\langle\vec{k}|\widehat{\phi}(0)|\Omega\rangle$$

has the same $\vec{k}$-dependence as $N(\vec{k})$. Equivalently, there is a nonnegative number Z, depending on the chosen field, such that

$${}_\delta\langle\vec{k}|\widehat{\phi}(0)|\Omega\rangle = \left[\frac{Z}{(2\pi)^{D-1}2\omega_{\vec{k}}}\right]^{1/2},$$

or equivalently

$${}_{\mathrm{inv}}\langle\vec{k}|\widehat{\phi}(0)|\Omega\rangle = Z^{1/2}.$$

Proof. The point notation is distributional: equivalently one may smear $\widehat{\phi}$ in a small neighborhood of the origin and then read the coefficient of the isolated shell. The isolated-shell projection removes continuum contributions, and the assumption of a selected spin-zero channel means that the little group acts trivially on the rest vector up to the phase already fixed in Lemma 14.19.

The scalar covariance equation $U(\Lambda)\widehat{\phi}(0)U(\Lambda)^{-1} = \widehat{\phi}(0)$, vacuum invariance, and Lemma 14.19 imply the transformation law

$$A(\vec{k}) = \frac{N(\vec{k})}{N(\Lambda\vec{k})} A(\Lambda\vec{k}).$$

Taking $\Lambda = L(\vec{k})^{-1}$ reduces the matrix element to its rest-frame value and gives $A(\vec{k}) = N(\vec{k})A(\vec{0})$. If $A(\vec{0}) = 0$, then the field has zero overlap with this channel and $Z = 0$. Otherwise the remaining phase freedom of the one-particle states fixes $A(\vec{0}) \geq 0$. Writing $Z = (2\pi)^{D-1}2m\,|A(\vec{0})|^2$ gives the delta-normalized formula, and the invariant normalization removes the kinematic factor. If several spin-zero channels of the same mass are present, the same argument applies to the vector of rest-frame overlaps in the finite or direct-integral multiplicity space; choosing a normalized component gives the scalar formula above, while Z for the full field is the squared norm of that overlap vector. □

14.7 One-Particle Atoms

Proposition 14.21 (One-particle atom in the scalar spectral measure)**.** *Assume the spectrum contains an isolated scalar one-particle mass $m > 0$, and assume the local field $\widehat{\phi}$ has nonzero projection onto that one-particle subspace. With the invariant normalization from Lemma 14.19, define $Z \geq 0$ by*

$${}_{\text{inv}}\langle\vec{p}|\widehat{\phi}(0)|\Omega\rangle = Z^{1/2}.$$

Then the one-particle contribution to the spectral measure is

$$\mathrm{d}\rho_1(\mu^2) = Z\,\delta_{m^2}(\mathrm{d}\mu^2),$$

so

$$\mathrm{d}\rho(\mu^2) = Z\,\delta_{m^2}(\mathrm{d}\mu^2) + \mathrm{d}\rho_{\mathrm{c}}(\mu^2)$$

with $\mathrm{d}\rho_{\mathrm{c}}$ positive.

Proof. With the invariant normalization from the one-particle construction,

$$\langle\vec{p}\,'|\vec{p}\rangle = (2\pi)^{D-1}2\omega_{\vec{p}}\,\delta^{(D-1)}(\vec{p}\,' - \vec{p}), \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^{\,2} + m^2},$$

define $Z \geq 0$ by

$${}_{\text{inv}}\langle\vec{p}|\widehat{\phi}(0)|\Omega\rangle = Z^{1/2}$$

for scalar one-particle states. Lorentz covariance makes the right-hand side independent of $\vec{p}$ in this normalization. Let δ_{m^2} denote the unit point measure at $\mu^2 = m^2$. The one-particle contribution to the spectral measure is

$$\mathrm{d}\rho_1(\mu^2) = Z\,\delta_{m^2}(\mathrm{d}\mu^2).$$

Thus

$$\mathrm{d}\rho(\mu^2) = Z\,\delta_{m^2}(\mathrm{d}\mu^2) + \mathrm{d}\rho_{\mathrm{c}}(\mu^2),$$

where $d\rho_{\mathrm{c}}$ is the remaining positive measure. At the level of the momentum-space measure, using the delta-normalized states in the previous section, the same statement is the calculation

$$\begin{aligned}\mathrm{d}\nu_{\phi,1}(p) &= \int \mathrm{d}^{D-1}\vec{k}\, \left|{}_{\delta}\langle \vec{k}|\widehat{\phi}(0)|\Omega\rangle\right|^2 \delta^{(D)}(p-k)\,\mathrm{d}^D p \\ &= \int \mathrm{d}^{D-1}\vec{k}\, \frac{Z}{(2\pi)^{D-1}2\omega_{\vec{k}}}\,\delta^{(D)}(p-k)\,\mathrm{d}^D p = \frac{Z\,\mathrm{d}^D p}{(2\pi)^{D-1}}\,\theta(p^0)\delta(p^2+m^2).\end{aligned}$$

Comparison with the invariant-mass decomposition then gives $\mathrm{d}\rho_1(\mu^2) = Z\,\delta_{m^2}(\mathrm{d}\mu^2)$. □

The spectral decomposition of $\widehat{\phi}(f)\Omega$ used in the preceding measure calculation is the orthogonal sum of the vacuum atom $E(\{0\})\widehat{\phi}(f)\Omega$, the isolated one-particle atom $E(\mu^2 = m^2)\widehat{\phi}(f)\Omega$, and the continuum projection $E_{\mathrm{c}}\widehat{\phi}(f)\Omega$. After subtracting the vacuum expectation value of $\widehat{\phi}$, the vacuum projection is absent. The one-particle atom remains precisely when the field has nonzero overlap with the isolated mass shell.

Under the same assumptions,

$$G_T(x) = Z\,\Delta_F(x;m^2) + \int_{[0,\infty)} \mathrm{d}\rho_{\mathrm{c}}(\mu^2)\,\Delta_F(x;\mu^2).$$

If the theory has a single stable particle of mass m, no lighter particles, and the continuum part is generated by states containing at least two such particles, then

$$\operatorname{supp} d\rho_{\mathrm{c}} \subset [4m^2,\infty).$$

When $d\rho_{\mathrm{c}}$ has a density $\sigma(\mu^2)$ in that region,

$$G_T(x) = Z\,\Delta_F(x;m^2) + \int_{4m^2}^{\infty} \mathrm{d}\mu^2\,\sigma(\mu^2)\Delta_F(x;\mu^2).$$

Figure 14.3 displays this threshold structure in the spectral measure: the isolated atom at m^2 and the continuum support beginning at $4m^2$ under the stated assumption.

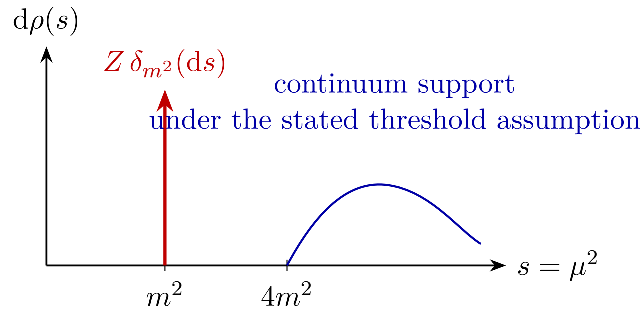

Figure 14.3: One-particle pole and continuum part of the Källén–Lehmann measure. Under the stated threshold assumption the atom at m^2 is separated from continuum support beginning at $4m^2$.

The number Z is attached to the chosen local field. Rescaling the field rescales Z. Once the field normalization is fixed, Z is a definite matrix element and the one-particle pole residue of its two-point function. It is therefore not an unphysical datum in the following precise sense: it is not invariant under changing the operator whose two-point function is being studied, but for a fixed operator it is an unambiguous spectral weight.

14.8 Role in the Construction

The Källén–Lehmann representation is nonperturbative. It states that Hilbert-space positivity and the spectrum condition force the scalar two-point function to be a positive superposition of free massive two-point functions. Isolated atoms of the measure identify stable one-particle mass shells seen by the local field. Continuous spectral support records the remaining invariant-mass spectrum.

The local field $\widehat{\phi}$ in this chapter is an interpolating local field. Its time-ordered two-point function contains the full spectral measure

$$G_T^{\phi}(x) = Z\,\Delta_F(x; m^2) + \int_{[0,\infty)} \mathrm{d}\rho_{\mathrm{c}}(s)\,\Delta_F(x; s)$$

whenever an isolated one-particle atom of mass m is present. The asymptotic scalar field associated with that atom is a different object: it is the canonical free scalar field on the asymptotic Fock space generated by the one-particle Hilbert space $\mathcal{H}_1$, and its two-point function is

$$G_T^{\mathrm{as}}(x) = \Delta_F(x; m^2)$$

with unit one-particle residue and no continuum part. The relation between the two fields is the one-particle projection and normalization

$$P_1\widehat{\phi}(f)\Omega = Z^{1/2}\psi_f,$$

where, in the Fourier convention

$$f_-(p) = \int \mathrm{d}^D x\, f(x)\mathrm{e}^{\mathrm{i}p\cdot x},$$

$$\psi_f = \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, f_-(p)|p\rangle \in \mathcal{H}_1.$$

Haag–Ruelle constructs the asymptotic Fock space from such vectors, and LSZ extracts the corresponding pole coefficient from correlation functions of the interpolating local field.

Remark 14.22 (Infraparticle spectrum in charged QED). The word "atom" here means a literal point mass in the positive spectral measure, for example $Z\,\delta_{m^2}(\mathrm{d}s)$ with $Z > 0$. This is exactly the input needed later by Haag–Ruelle theory and by LSZ pole-coefficient extraction. The charged sector of QED with a massless photon realizes a different spectral structure. It contains the charged threshold together with states differing by photons of arbitrarily small energy; the energy-momentum spectral support therefore accumulates at the threshold instead of leaving an open neighborhood containing only Σ_m^+. Equivalently, the charged particle is an infraparticle: threshold spectral support replaces the simple one-particle pole, and the charged sector has no normalizable one-particle Wigner subspace obtained from $P_1 = E(\Sigma_m^+)$.

Gauge-fixed perturbative notation must be interpreted through this physical spectral statement. A gauge-dependent electron propagator is not, by itself, the positive Källén–Lehmann measure of a compactly localized physical observable in the Hilbert space. Physical charged asymptotic data require either inclusive probabilities or dressed charged states. The later infrared chapters develop the corresponding Bloch–Nordsieck cancellation and Faddeev–Kulish-type dressing constructions in Chapter 42 and Chapter 44.

Remark 14.23 (Confinement and physical spectral atoms). In a confining nonabelian gauge theory the positive Hilbert-space spectral measure is attached to fields or observables that act on the physical Hilbert space. Gauge-invariant color-singlet interpolating fields have Källén–Lehmann measures supported on hadronic states; when such a measure has an isolated atom, the atom corresponds to a stable hadron or glueball seen by that interpolating field. Gauge-dependent quark and gluon fields are not local physical observables with positive spectral measures on the physical Hilbert space, and confinement excludes isolated quark or gluon mass-shell atoms from the physical asymptotic spectrum. Consequently the Haag–Ruelle and LSZ constructions later in this volume apply in a confining theory only to stable color-singlet particles, after the corresponding physical interpolating operators and isolated hadronic atoms have been identified.

The next step in the construction is the perturbative computation of Green functions. The construction of scattering states and the S-matrix comes later, after the spectral one-particle data have been separated from the local two-point functions.

Chapter 15

Perturbative Green Functions and Feynman Graphs

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

15.1 Regulated Euclidean Scalar Theory

Definition 15.1 (Regulated Euclidean ϕ^4 datum)**.** Let $D \geq 1$. In this chapter $x \in \mathbb{R}^D$ denotes a Euclidean spacetime point and $k \in \mathbb{R}^D$ denotes the corresponding Euclidean momentum. The field variable is a real scalar function ϕ. For the perturbative Euclidean construction in this chapter, henceforth assume $m > 0$; this is a stricter infrared convention than the nonnegative invariant mass parameter allowed in the spectral discussion. The Lorentzian model whose Green functions are studied perturbatively has classical density, in the mostly-plus convention,

$$\mathcal{L} = -\frac{1}{2}\partial_\mu\phi\,\partial^\mu\phi - \frac{1}{2}m^2\phi^2 - \frac{g}{4!}\phi^4.$$

The perturbative construction in this chapter is made first for Euclidean Green functions. Its Euclidean density is

$$\mathcal{L}_E = \frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m^2\phi^2 + \frac{g}{4!}\phi^4,$$

so that the interaction part of the Euclidean action is

$$S_{\mathrm{int},E}[\phi] = \frac{g}{4!}\int \mathrm{d}^D x\,\phi(x)^4,$$

where $g \in \mathbb{R}$ is the quartic coupling. This expression is a regulated interaction coordinate. With the finite-dimensional cutoff introduced below, $\phi_\Lambda(x)^4$ is an ordinary function on the regulated configuration space and the integral is a well-defined polynomial. The continuum symbol $\phi(x)^4$ is not, by itself, a defined local operator: products of continuum fields at coincident points require a renormalization prescription. In this chapter the symbol denotes the regulated monomial together with the counterterm and renormalization conditions used to define Green functions order by order. Renormalized composite insertions, obtained by coupling local sources and differentiating with respect to renormalized source coordinates, are constructed later in Chapter 34.

The free covariance is the Euclidean propagator

$$\Delta_E(x-y;m^2) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k\cdot(x-y)}}{k^2+m^2},$$

with $m > 0$.

The status of the regulator-removal problem depends sharply on D. For $D = 2$ and $D = 3$, the renormalized ϕ^4 models have constructive non-Gaussian continuum realizations: in $D = 2$ this belongs to the $P(\phi)_2$ construction, and in $D = 3$ the ϕ^4_3 construction is obtained after the required local counterterms. For the standard reflection-positive lattice $\lambda\phi^4$ model with $\lambda \geq 0$ in $D = 4$, the continuum scaling limits selected by the usual critical or near-critical tuning are Gaussian. This is the four-dimensional marginal triviality theorem completed by the Aizenman–Duminil-Copin analysis, together with the earlier triviality results of Aizenman and Fröhlich. The theorem is a statement about that constructive scaling-limit problem. The broader question whether some ultraviolet-complete QFT can have a small-coupling expansion agreeing with formal ϕ^4_4 perturbation theory to all orders is a separate nonperturbative existence problem. Thus the four-dimensional perturbative expansion below should be read as a finite-cutoff and renormalized asymptotic expansion, and as a valid effective-field-theory expansion below a cutoff, unless an additional nonperturbative ultraviolet construction is supplied.

The corresponding constructive question for pure Yang–Mills theory in $D = 4$ has a different status. The Clay Millennium problem called "Yang–Mills existence and mass gap" asks, for every compact simple gauge group G, for a continuum quantum Yang–Mills theory on $\mathbb{R}^4$ whose gauge-invariant Schwinger functions satisfy the structural requirements needed for Euclidean reconstruction and whose reconstructed physical Hamiltonian has a unique vacuum at energy 0 and spectrum contained in $\{0\} \cup [\Delta, \infty)$ for some $\Delta > 0$. Perturbative asymptotic freedom, lattice regularizations, strong-coupling expansions in finite cutoff systems, and numerical evidence all belong to the surrounding mathematical and physical picture; the continuum existence theorem together with the positive physical mass gap is the open problem. This is logically distinct from the ϕ^4_4 triviality statement above: the latter is a proved obstruction for the standard reflection-positive scalar scaling-limit family, while the former is an open constructive existence and spectral problem for a gauge theory.

The functional notation is used with a regulator. One concrete choice is a finite Euclidean box with periodic boundary conditions and only finitely many Fourier modes retained. Equivalently, in infinite-volume notation, choose a smooth cutoff function $\chi_\Lambda(k)$ which is 1 for $|k| \ll \Lambda$ and rapidly decays for $|k| \gg \Lambda$, and replace the free covariance by

$$C_\Lambda(x-y) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\chi_\Lambda(k)\,\mathrm{e}^{\mathrm{i}k\cdot(x-y)}}{k^2+m^2}.$$

At finite regulator the Gaussian expectation $\langle\cdots\rangle_{0,\Lambda}$ is an ordinary finite-dimensional Gaussian expectation, or the limit of such expectations. Formulas written without Λ are coefficientwise perturbative formulas or shorthand for regulator-dependent formulas before the limit is studied.

Remark 15.2 (Constructive status of the scalar example). The constructive comments above are not used as hidden axioms in the perturbative derivations below. They delimit the status of the continuum limit: every formula in this chapter is first an identity at finite regulator or a coefficient of a regulated formal power series; the additional question of removing Λ is a separate renormalization or constructive existence problem.

Definition 15.3 (Finite Fourier cutoff Gaussian scalar datum)**.** With a sharp Fourier cutoff this finite-dimensional statement is represented by

$$\int [\mathrm{d}\phi]_\Lambda \quad \rightsquigarrow \quad \int \prod_{|k|\le\Lambda} \mathrm{d}\widetilde{\phi}(k), \qquad \widetilde{\phi}(-k) = \overline{\widetilde{\phi}(k)}$$

after choosing independent real coordinates for one representative of each pair $k, -k$ and fixing the resulting finite-dimensional Gaussian normalization. More explicitly, put the theory first on a Euclidean torus of side L, let $\mathcal{K}_{\Lambda,L}$ be a finite symmetric set of allowed momenta, and set

$$E_{\Lambda,L} = \left\{\widetilde{\phi} : \mathcal{K}_{\Lambda,L} \to \mathbb{C} : \widetilde{\phi}(-k) = \overline{\widetilde{\phi}(k)}\right\}.$$

After choosing real coordinates on $E_{\Lambda,L}$, the free expectation is the centered Gaussian probability measure with covariance

$$\langle\widetilde{\phi}(k)\widetilde{\phi}(k')\rangle_{0,\Lambda,L} = L^D \,\frac{\delta_{k+k',0}}{k^2+m^2}.$$

Equivalently, for a real source J whose Fourier transform is supported in $\mathcal{K}_{\Lambda,L}$,

$$Z_{0,\Lambda,L}[J] = \exp\left[\frac{1}{2}\int_{T_L^D} \mathrm{d}^D x\, \mathrm{d}^D y\, J(x) C_{\Lambda,L}(x-y) J(y)\right].$$

The infinite-volume smooth-cutoff formulas in this chapter are shorthand for the corresponding limit or for the directly regulated covariance C_Λ. The symbol $[\mathrm{d}\phi]$ is not used here as an unregulated Lebesgue measure on an infinite-dimensional vector space.

Definition 15.4 (Normalized regulated Euclidean Green functions)**.** The normalized Euclidean n-point function is

$$G_{E,n,\Lambda,L}(x_1,\ldots,x_n) = \frac{\langle\phi(x_1)\cdots\phi(x_n)\exp[-S_{\mathrm{int},E}[\phi]]\rangle_{0,\Lambda,L}}{\langle\exp[-S_{\mathrm{int},E}[\phi]]\rangle_{0,\Lambda,L}}.$$

In infinite-volume shorthand the subscript L is suppressed. It is a distribution in the insertion points after the regulator is removed, when that limit exists or has been renormalized. Perturbation theory is the coefficientwise expansion of this expression in powers of the coupling g, with the regulator kept fixed before renormalized limits are considered.

Coefficientwise perturbation at fixed regulator. At any finite regulator for which $S_{\mathrm{int},E}$ is a polynomial on a finite-dimensional Gaussian space, the coefficient of g^V in $G_{E,n,\Lambda}$ is obtained by expanding numerator and denominator in powers of $S_{\mathrm{int},E}$, taking ordinary Gaussian moments, and then dividing the resulting formal power series by the denominator series. This is finite-dimensional formal power-series algebra. At finite regulator the Gaussian expectation is an ordinary normalized finite-dimensional integral with positive covariance. The exponential $\exp[-S_{\mathrm{int},E}]$ is treated either as an honest integrable function for values of g where the integral converges, or as the formal series

$$\sum_{V\geq 0}\frac{(-1)^V}{V!}S_{\mathrm{int},E}[\phi]^V.$$

Since $S_{\mathrm{int},E}$ is polynomial, each coefficient is a finite sum of Gaussian moments. The denominator has constant term 1, so it has a unique inverse as a formal power series in g. Multiplication by that inverse gives the displayed normalized Green function coefficient by coefficient. This algebraic step uses only finite-dimensional Gaussian moments and the formal inverse of a series with constant term 1; regulator removal and renormalization enter later.

15.2 Wick Expansion and Connected Functions

Wick graph expansion and connected cumulants. For the centered Gaussian expectation,

$$\langle\phi(x_1)\cdots\phi(x_{2r})\rangle_{0,\Lambda}=\sum_{\text{pairings }P}\prod_{\{a,b\}\in P}C_\Lambda(x_a-x_b),$$

and odd moments vanish. Expanding the interaction gives

$$\begin{aligned}&\langle\phi(x_1)\cdots\phi(x_n)\exp[-S_{\mathrm{int},E}[\phi]]\rangle_{0,\Lambda}\\&=\sum_{V=0}^{\infty}\frac{(-g)^V}{V!(4!)^V}\int\prod_{a=1}^{V}\mathrm{d}^Dz_a\,\langle\phi(x_1)\cdots\phi(x_n)\prod_{a=1}^{V}\phi(z_a)^4\rangle_{0,\Lambda}.\end{aligned}$$

Each Gaussian moment on the right is a sum over pairings. A pairing is drawn as an edge; an integration point z_a is drawn as a four-valent vertex; an insertion x_i is an external labelled endpoint. This is the origin of the Feynman graphs in this chapter.

The denominator in $G_{E,n,\Lambda}$ cancels components that have no external endpoint. Therefore a normalized n-point function is a sum over graphs whose every connected component contains at least one external label. The connected n-point function is the part in which all external labels belong to one connected component. The first displayed formula is Wick's theorem for the finite-dimensional Gaussian vector obtained by evaluating the regulated field at the indicated test functions or points. Substituting the fixed-regulator formal exponential expansion expresses each coefficient as a finite sum over pairings of the $n+4V$ field factors. Every pair in a Wick pairing supplies one covariance C_Λ; grouping the paired half-edges incident to the same interaction point gives precisely the graph description.

The cancellation of vacuum components is the exponential formula for labelled structures applied to Wick pairings. Equivalently, write every pairing graph as the disjoint union of connected components. Components with no external label are generated by the same series that appears in $Z_\Lambda[0]$, so division by $Z_\Lambda[0]$ removes them. The connected part is then selected by requiring that the external labels lie in one component.

Figure 15.1 records this component selection: vacuum components cancel against $Z_\Lambda[0]$, and surviving components contain external insertions.

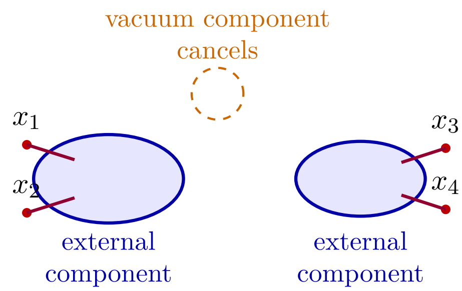

Figure 15.1: Component selection in normalized Euclidean correlators. Vacuum components cancel against the denominator, while every surviving component contains at least one external insertion.

Introduce a source J and define

$$Z_\Lambda[J] = \langle \exp\left[-S_{\mathrm{int},E}[\phi] + \int \mathrm{d}^D x\, J(x)\phi(x)\right]\rangle_{0,\Lambda}.$$

The connected generating functional is

$$W_\Lambda[J] = \log Z_\Lambda[J].$$

For $n \geq 1$,

$$G^{\mathrm{conn}}_{E,n,\Lambda}(x_1, \ldots, x_n) = \left.\frac{\delta^n W_\Lambda[J]}{\delta J(x_1)\cdots\delta J(x_n)}\right|_{J=0}.$$

This identity is the cumulant identity for the regulated probability measure. At finite regulator $Z_\Lambda[J]$ is the moment generating functional of a finite-dimensional random vector after adjoining the polynomial weight $\exp[-S_{\mathrm{int},E}]$. The logarithm of a moment generating function is the cumulant generating function. Differentiating $W_\Lambda[J]$ at $J = 0$ therefore gives the joint cumulant of the n inserted fields. The moment-cumulant relation is equivalent to the connected-component expansion of the preceding proposition, so the functional derivatives of W_Λ are exactly the connected regulated Green functions.

15.3 Momentum-Space Graph Weights

Definition 15.5 (Euclidean graph weight)**.** In translation-invariant infinite-volume notation, write

$$G^{\mathrm{conn}}_{E,n}(x_1, \ldots, x_n) = \int \prod_{i=1}^{n} \frac{\mathrm{d}^D k_i}{(2\pi)^D}\, \mathrm{e}^{\mathrm{i}\sum_i k_i\cdot x_i}\, \widetilde{G}^{\mathrm{conn}}_{E,n}(k_1, \ldots, k_n).$$

A connected graph Γ with labelled external legs contributes a distribution of the form

$$\mathcal{A}_E(\Gamma; k_1, \ldots, k_n) = (2\pi)^D \delta^{(D)}\left(\sum_{i=1}^{n} k_i\right) I_E(\Gamma; k_1, \ldots, k_n).$$

The reduced integrand I_E is computed as follows. Assign momentum to every edge, impose momentum conservation at every vertex, integrate over one independent momentum for each loop, and multiply by

$$\frac{(-g)^{V(\Gamma)}}{|\operatorname{Aut}\Gamma|}\prod_{e\in E(\Gamma)}\frac{1}{p_e^2+m^2}.$$

Here $V(\Gamma)$ is the number of quartic vertices, $E(\Gamma)$ is the set of internal and external propagator edges, p_e is the momentum carried by edge e, and $\operatorname{Aut}\Gamma$ is the group of graph automorphisms preserving all external labels. This convention includes the factor 1/4! in the action and the Wick-contraction multiplicities in the single symmetry factor.

For a connected graph with $I(\Gamma)$ internal edges and $V(\Gamma)$ vertices, the number of independent loop momenta is

$$L(\Gamma) = I(\Gamma) - V(\Gamma) + 1.$$

This is the first Betti number of the graph. Momentum conservation at all vertices gives $V(\Gamma)$ linear constraints, but the sum of those constraints is the external momentum-conservation delta function already displayed, so only $V(\Gamma) - 1$ vertex constraints eliminate independent internal edge momenta.

Figure 15.2 fixes the two momentum-space rules used below: the regulated scalar propagator on each edge and the quartic vertex with momentum conservation.

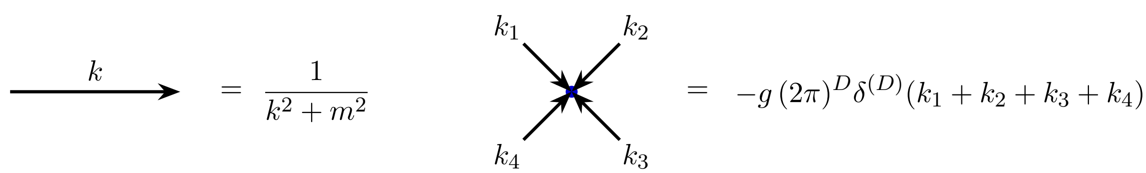

Figure 15.2: Momentum-space Feynman rules for Euclidean ϕ^4 theory with labelled external legs. The propagator is $(k^2+m^2)^{-1}$, and the quartic vertex includes momentum conservation.

The displayed vertex rule is the labelled-leg rule. If instead one expands directly from the action, each vertex gives $-g/4!$ and the 4! is recovered by counting Wick contractions.

15.4 Symmetry Factors from Wick Pairings

Automorphism denominator from Wick pairings. The coefficient $|\operatorname{Aut}\Gamma|^{-1}$ in the graph rule is the residual count left by the regulated Wick expansion. Consider a connected graph Γ with V quartic vertices and labelled external endpoints. Let $\operatorname{Aut}\Gamma$ denote the automorphism group preserving the external labels and the incidence relation between vertices and half-edges. The V-th term of the interaction expansion carries the prefactor

$$\frac{(-g)^V}{V!(4!)^V}.$$

If the abstract graph Γ is fixed, the number of choices of ordered interaction vertices, ordered half-edges at each vertex, and Wick pairings which realize this same labelled graph is

$$\frac{V!(4!)^V}{|\operatorname{Aut}\Gamma|}.$$

Multiplying the two factors gives precisely

$$\frac{(-g)^V}{|\operatorname{Aut}\Gamma|}.$$

Thus the graph automorphism factor is the quotient between the arbitrary labellings introduced by the expansion and the relabellings leaving the graph unchanged.

Start with the V-th term of the regulated expansion, where the integration variables $z_1, \ldots, z_V$ are ordered and the four field factors at each vertex are ordered by their position in $\phi(z_a)^4$. These choices give $V!(4!)^V$ auxiliary labels for the same abstract incidence graph. The Wick pairing then identifies half-edges in pairs to form internal edges or connects half-edges to the fixed external labels. For a fixed labelled external graph Γ, the group $\operatorname{Aut}\Gamma$ is exactly the stabilizer of this labelling data: it consists of the vertex and half-edge relabellings that leave the incidence relations and all external labels unchanged. By the orbit-stabilizer identity, the number of labelled Wick contractions giving the same abstract Γ is $V!(4!)^V/|\operatorname{Aut}\Gamma|$. Multiplying by the expansion prefactor gives $(-g)^V/|\operatorname{Aut}\Gamma|$.

For example, the order-g tadpole correction to the two-point function has one quartic vertex. The two external labels are fixed, while the two remaining half-edges form the loop and may be interchanged. Hence $|\operatorname{Aut}\Gamma| = 2$, and the coefficient is $-g/2$. In the unlabelled-vertex convention this same count is

$$\left(-\frac{g}{4!}\right)\left(4 \cdot 3 \cdot \frac{2!}{2}\right) = -\frac{g}{2}.$$

Here the 4 chooses the vertex half-edge contracted with the first external endpoint, and the 3 chooses the half-edge contracted with the second external endpoint. The remaining two half-edges form the loop. If they are temporarily ordered this gives a factor 2!, and the quotient by 2 identifies the interchange of the two ends of the same loop, leaving one loop pairing.

For the two-vertex sunset insertion in the two-point function, the expansion prefactor and the Wick-pairing count give

$$\frac{1}{2!}\left(-\frac{g}{4!}\right)^2 \left(2 \cdot 4^2 \cdot 3!\right) = 4 \cdot 4! \left(-\frac{g}{4!}\right)^2 = \frac{g^2}{6}.$$

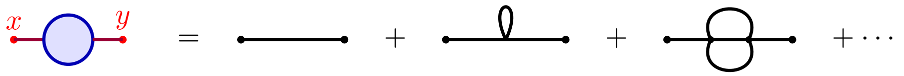
The first factor 2 assigns the two external endpoints to the two interaction vertices, each 4 chooses the external half-edge at one vertex, and 3! pairs the remaining half-edges between the vertices. The single quartic contribution to the connected four-point function with four labelled external insertions has trivial automorphism group, and its coefficient is $-g$. Vacuum components have already been removed by normalization; the logarithm of the generating functional then selects the component in which all external labels are connected.

15.5 Two-Point Function and Self-Energy

The connected Euclidean two-point function has Fourier transform

$$G_E(x, y) = \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, \mathrm{e}^{\mathrm{i}k\cdot(x-y)}\, \widetilde{G}_E(k).$$

Its perturbative expansion begins as



Definition 15.6 (Two-point one-particle irreducibility)**.** A connected two-point graph is one-particle reducible if it contains an internal edge whose removal disconnects the two external endpoints. It is one-particle irreducible, abbreviated 1PI, if no such edge exists. The amputated reduced value of a 1PI two-point graph is obtained by omitting the two external propagator factors attached to the external endpoints while keeping the loop integrals, vertex factors, and graph automorphism factor.

This is a statement about connected Green-function graphs. Its role here is only to organize the two-point function. The systematic functional definition of the one-particle-irreducible effective action is developed later in Chapter 30.

Definition 15.7 (Euclidean self-energy)**.** Define the Euclidean self-energy $\Sigma_E(k)$ by the Dyson form

$$\widetilde{G}_E(k) = \frac{1}{k^2 + m^2 - \Sigma_E(k)}. \tag{15.1}$$

Equivalently,

$$\widetilde{G}_E = G_{0,E} + G_{0,E}\Sigma_E G_{0,E} + G_{0,E}\Sigma_E G_{0,E}\Sigma_E G_{0,E} + \cdots , \qquad G_{0,E}(k) = \frac{1}{k^2 + m^2}.$$

With this sign convention Σ_E is the sum of amputated connected one-particle-irreducible two-point insertions.

Proposition 15.8 (Dyson decomposition of the connected two-point function)**.** *As a formal power series at fixed regulator, every connected two-point graph decomposes uniquely into a chain of* 1PI *two-point blocks joined by free propagator edges. If* $\Sigma_E(k)$ *denotes the sum of amputated* 1PI *two-point insertions with the sign convention of Definition 15.7, then*

$$\widetilde{G}_E(k) = G_{0,E}(k) + G_{0,E}(k)\Sigma_E(k)G_{0,E}(k) + G_{0,E}(k)\Sigma_E(k)G_{0,E}(k)\Sigma_E(k)G_{0,E}(k) + \cdots .$$

Equivalently,

$$\widetilde{G}_E(k) = \frac{1}{G_{0,E}(k)^{-1} - \Sigma_E(k)} = \frac{1}{k^2 + m^2 - \Sigma_E(k)}.$$

Proof. Work at finite regulator and at a fixed order in g, so only finitely many Wick graphs occur. In a connected two-point graph, call an internal edge a separating edge if deleting it disconnects the two external endpoints. The set of separating edges on any path from one external endpoint to the other is linearly ordered by separation: an edge e_1 precedes e_2 if the component containing the left external endpoint after deleting e_1 is contained in the corresponding component after deleting e_2. Cutting all separating edges decomposes the graph into maximal subgraphs with two distinguished attachment half-edges and no further separating internal edge between them. These maximal subgraphs are exactly the 1PI two-point blocks; the cut separating edges are free propagator factors.

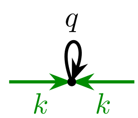
The decomposition is unique because the separating edges are intrinsic to the incidence graph. Conversely, any ordered chain of 1PI two-point blocks joined by free propagators gives a connected two-point graph, and the automorphism factors multiply correctly once the two attachment half-edges of each block are distinguished by their position in the chain. Summing over chains therefore gives the displayed geometric series. Since $G_{0,E}(k) = (k^2 + m^2)^{-1}$, the formal geometric series is

$$G_{0,E}(k) \sum_{r \geq 0} \big(\Sigma_E(k) G_{0,E}(k)\big)^r = \frac{1}{G_{0,E}(k)^{-1} - \Sigma_E(k)},$$

as an identity of formal power series. □

$\Sigma_E(k) =$  $+$  $+$  $+ \cdots .$

One-loop tadpole self-energy and cutoff growth. The order-g tadpole is



$$= \quad -\frac{g}{2} \int \frac{\mathrm{d}^D q}{(2\pi)^D} \frac{1}{q^2 + m^2}.$$

The factor $1/2$ is the symmetry factor of the tadpole graph. This insertion is independent of the external momentum k, because no external momentum flows through the closed loop. In the continuum notation the loop integral is ultraviolet divergent for $D \geq 2$. With a sharp momentum cutoff used only to display the degree of divergence,

$$C_1(\Lambda, m) = \frac{1}{2} \int_{|q| \leq \Lambda} \frac{\mathrm{d}^D q}{(2\pi)^D} \frac{1}{q^2 + m^2}$$

equals

$$\frac{1}{2} \frac{\mathrm{vol}(S^{D-1})}{(2\pi)^D} \int_0^\Lambda \mathrm{d}r \, \frac{r^{D-1}}{r^2 + m^2}, \qquad \mathrm{vol}(S^{D-1}) = \frac{2\pi^{D/2}}{\Gamma(D/2)}.$$

Thus

$$C_1(\Lambda, m) \sim \begin{cases} \dfrac{1}{4\pi} \log \dfrac{\Lambda}{m}, & D = 2, \\ \dfrac{1}{2} \dfrac{\mathrm{vol}(S^{D-1})}{(2\pi)^D} \dfrac{\Lambda^{D-2}}{D-2}, & D \geq 3, \end{cases}$$

up to finite terms and convention-dependent cutoff terms. The first line uses

$$\int_0^\Lambda \frac{r \, \mathrm{d}r}{r^2 + m^2} = \frac{1}{2} \log \frac{\Lambda^2 + m^2}{m^2} = \log \frac{\Lambda}{m} + O(\Lambda^{-2})$$

inside the radial expression. The second line uses $r^{D-1}(r^2 + m^2)^{-1} = r^{D-3} + O(r^{D-5})$ at large r. Hence

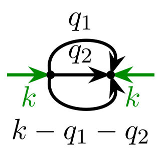
$$\Sigma_E^{(1)}(k) = -g \, C_1(\Lambda, m).$$

The coefficient $-g/2$ is the symmetry factor from the Wick-pairing automorphism count above: the two unattached half-edges at the quartic vertex form one loop and may be interchanged. No external momentum enters the loop propagator, so the amputated insertion is momentum independent and equals the displayed regulated integral. In spherical coordinates the cutoff integral is

$$\frac{1}{2}\frac{\mathrm{vol}(S^{D-1})}{(2\pi)^D}\int_0^{\Lambda}\frac{r^{D-1}\,\mathrm{d}r}{r^2+m^2}.$$

For $D=2$ the integral is $\frac{1}{2}\log((\Lambda^2+m^2)/m^2)=\log(\Lambda/m)+O(\Lambda^{-2})$. For $D\geq 3$, subtract the leading asymptotic term r^{D-3}; the remainder is lower degree at infinity, so the leading growth is $\Lambda^{D-2}/(D-2)$ with the displayed prefactor. The Dyson sign convention of Definition 15.7 then gives $\Sigma_E^{(1)}=-gC_1$.

Two-loop sunset insertion. The order-g^2 sunset insertion is



$$= \frac{g^2}{6}\int\frac{\mathrm{d}^Dq_1\,\mathrm{d}^Dq_2}{(2\pi)^{2D}}$$

$$\times\,\frac{1}{(q_1^2+m^2)(q_2^2+m^2)\big((k-q_1-q_2)^2+m^2\big)}.$$

This formula is a Euclidean integral. Its Lorentzian boundary values are obtained by analytic continuation with contour-deformation control; for timelike external momentum the three-particle Landau threshold of this graph prevents a naive independent Wick rotation of the loop energies.

The graph has two quartic vertices and three internal lines joining them. After the two external half-edges are fixed, the remaining three internal edges may be permuted, giving the automorphism factor 3!. Thus the coefficient is $g^2/6$, in agreement with the Wick-pairing count in the preceding section. Momentum conservation at the two vertices leaves two independent loop momenta, chosen as q_1, q_2; the third internal momentum is then $k-q_1-q_2$. Multiplication of the three Euclidean propagators gives the displayed integral. The final statement follows because the Euclidean integral is defined on real D-momenta, while Lorentzian boundary values are obtained by continuing external energy and deforming loop-energy contours without crossing singularities. At the three-particle threshold the Landau equations allow simultaneous on-shell internal lines, so this deformation cannot be represented as an independent rotation of each loop energy.

15.6 Pole Mass and Counterterm Bookkeeping

Definition 15.9 (Pole mass of an interpolating scalar field)**.** As derived in Chapter 14, the spectral representation of the Euclidean two-point function has the form

$$\widetilde{G}_E(k)=\frac{Z}{k^2+m_*^2}+\int_{[0,\infty)}\frac{\mathrm{d}\rho_{\mathrm{c}}(s)}{k^2+s},$$

with an isolated atom at $s=m_*^2$ when the chosen field has nonzero overlap with a stable one-particle state. The parameter m_* is the pole mass read from the two-point function. Equivalently, singularities of the Euclidean function in the complex k^2-plane lie at $k^2=-s$, and an isolated one-particle state gives the nearest such pole when no lighter state couples to the field. At fixed spatial momentum, the same pole appears in the complex Euclidean energy plane at

$$k_D=\pm\mathrm{i}\sqrt{\vec{k}^{\,2}+m_*^2}.$$

The field variable ϕ appearing in the regulated Lagrangian and in the source J is the perturbative representative of an interpolating local field. Its renormalized two-point function is the full function $\widetilde{G}_E(k)$, with pole residue Z and continuum spectral contributions. The asymptotic scalar field used in scattering theory is the free field on the isolated one-particle asymptotic Fock space with pole mass m_* and unit residue. Perturbation theory in this chapter locates the pole and residue of the interpolating-field Green function; the LSZ theorem later uses those data to project external legs onto the asymptotic one-particle states.

One-loop pole shift and mass-coordinate prescription. Using

$$\widetilde{G}_E(k) = \frac{1}{k^2 + m^2 - \Sigma_E(k)}$$

and the tadpole value above, the pole position satisfies, to first order,

$$m_*^2 = m^2 + gC_1(\Lambda, m) + O(g^2)$$

in this cutoff scheme. The parameter m is therefore a parameter of the regulated quadratic action. Its relation to the spectral pole mass depends on the regulator and on the prescription used to define the finite theory. At fixed regulator, g is a bookkeeping parameter for the coefficientwise expansion. The coefficient $C_1(\Lambda, m)$ grows with the cutoff in $D \geq 2$, so the product $gC_1(\Lambda, m)$ is not uniformly small as $\Lambda \to \infty$. Thus the distinction between a cutoff-dependent quadratic action coordinate and a mass defined by spectral data is operational in the cutoff-dependent calculation.

A perturbative mass prescription introduces a renormalized parameter m_R and a counterterm δm^2:

$$m^2 = m_R^2 + \delta m^2, \qquad \delta m^2 = \sum_{r \geq 1} g^r (\delta m^2)^{(r)}.$$

The Euclidean Lagrangian density is written as

$$\mathcal{L}_E = \frac{1}{2}(\partial\phi)^2 + \frac{1}{2}m_R^2\phi^2 + \frac{g}{4!}\phi^4 + \frac{1}{2}\delta m^2\phi^2.$$

The counterterm coefficient is part of this same regulated Lagrangian, written in the renormalized coordinate m_R. In perturbative bookkeeping it is treated as part of the interaction. At order g, the two-valent counterterm vertex contributes

 $\qquad\longleftrightarrow\qquad -(\delta m^2)^{(1)} g.$

The condition $m_* = m_R + O(g^2)$, written at the level of squared masses, requires

$$(\delta m^2)^{(1)} = -C_1(\Lambda, m_R) + \text{finite prescription term}.$$

Different finite terms correspond to different renormalization prescriptions. The split into m_R^2 and δm^2 is a prescription-dependent reorganization of the regulated perturbative calculation. Its role is to make the cancellation of cutoff-dependent local terms occur coefficient by coefficient in the expansion in g. The physical statement is made after Green functions are expressed in terms of the chosen finite parameters, such as the pole mass m_*. In the on-shell mass prescription the finite terms are chosen so that $m_R = m_*$ order by order.

To first order, insert $\Sigma_E^{(1)}(k) = -gC_1(\Lambda, m)$ from the tadpole calculation above into the Dyson denominator:

$$k^2 + m^2 - \Sigma_E(k) = k^2 + m^2 + gC_1(\Lambda, m) + O(g^2).$$

The pole in the variable k^2 is therefore at $k^2 = -m^2 - gC_1(\Lambda, m) + O(g^2)$, equivalently $m_*^2 = m^2 + gC_1(\Lambda, m) + O(g^2)$. If the quadratic coordinate of the regulated action is rewritten as $m_R^2 + \delta m^2$, the counterterm is a two-valent interaction vertex with the sign displayed above. Requiring the pole to sit at m_R^2 through order g forces the order-g part of δm^2 to cancel $C_1(\Lambda, m_R)$, up to the chosen finite renormalization convention.

15.7 Connected Four-Point Function

Remark 15.10 (Four-point moment-cumulant decomposition). For four insertions, the normalized Green function decomposes into pairwise products of two-point functions and a connected part:

$$\begin{aligned} &G_{E,4}(x_1, x_2, x_3, x_4) \\ &\quad = G_E(x_1, x_2)G_E(x_3, x_4) + G_E(x_1, x_3)G_E(x_2, x_4) + G_E(x_1, x_4)G_E(x_2, x_3) \\ &\qquad + G_{E,4}^{\text{conn}}(x_1, x_2, x_3, x_4). \end{aligned}$$

The identity is not a separate theorem: applying the moment-cumulant identity to four fields gives it directly. If the theory is $\mathbb{Z}_2$-invariant, as the regulated ϕ^4 theory is, all odd cumulants vanish. The partitions of four labels therefore contribute either one four-label cumulant or one of the three partitions into two pairs. The pair cumulants are the full two-point functions G_E, and the four-label cumulant is, by definition, $G_{E,4}^{\text{conn}}$.

Figure 15.3 displays the three pair partitions and the connected four-point cumulant that appear in the moment-cumulant identity.

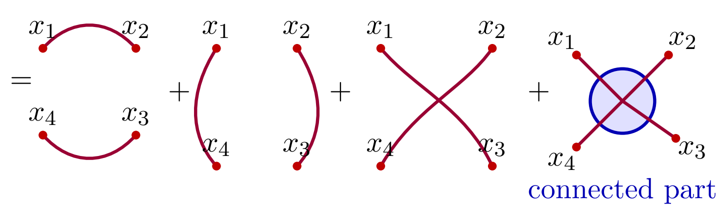


Figure 15.3: Disconnected and connected parts of the Euclidean four-point function. The three Wick pairings are separated from $G_{E,4}^{\text{conn}}$.

The Fourier transform of the connected part is defined by

$$G_{E,4}^{\text{conn}}(x_1, \ldots, x_4) = \int \prod_{i=1}^{4} \frac{\mathrm{d}^D k_i}{(2\pi)^D} \, \mathrm{e}^{\mathrm{i} \sum_i k_i \cdot x_i} \, \widetilde{G}_{E,4}^{\text{conn}}(k_1, \ldots, k_4).$$

To leading order,

$$\begin{aligned} \widetilde{G}_{E,4}^{\text{conn}}(k_1, \ldots, k_4) &= (2\pi)^D \delta^{(D)}(k_1 + k_2 + k_3 + k_4) \\ &\qquad \times \left[-g \prod_{i=1}^{4} \frac{1}{k_i^2 + m^2} + O(g^2) \right]. \end{aligned}$$

This is a connected Green function with external propagators included. Later, after scattering states and LSZ have been constructed, the operation of removing the external propagators will acquire its scattering interpretation. The order-g connected four-point graph has one quartic vertex and four labelled external endpoints. The $1/4!$ in the interaction is cancelled by the $4!$ assignments of the four labelled external fields to the four half-edges of the vertex, so the vertex coefficient is $-g$. Translation invariance supplies the momentum-conserving delta function. Each external field remains connected to the vertex by a Euclidean free propagator, giving $\prod_i(k_i^2 + m^2)^{-1}$. Since this is a Green function rather than an amputated scattering amplitude, those external propagators are part of the coefficient.

Definition 15.11 (Euclidean amputation of connected four-point Green functions)**.** Away from the free Euclidean pole hypersurfaces $k_i^2 + m^2 = 0$, define the amputated connected Euclidean four-point kernel by the algebraic operation

$$\widetilde{\Gamma}_{E,4}(k_1, k_2, k_3, k_4) := \left(\prod_{i=1}^{4}(k_i^2 + m^2)\right) \widetilde{G}^{\text{conn}}_{E,4}(k_1, k_2, k_3, k_4).$$

This definition removes the external free propagator factors from the connected Green function. It is not a definition of a scattering amplitude: scattering requires the nonperturbative one-particle subspace, asymptotic states, and the LSZ limiting operation developed later.

Tree-level four-point kernel. With the convention of Definition 15.11, the leading amputated connected four-point kernel is

$$\widetilde{\Gamma}_{E,4}(k_1, k_2, k_3, k_4) = -(2\pi)^D g\, \delta^{(D)}(k_1 + k_2 + k_3 + k_4) + O(g^2).$$

This is obtained by multiplying the leading connected Green function in the formula above by $\prod_i(k_i^2 + m^2)$. The four free external propagators cancel coefficientwise, leaving the momentum-conserving delta distribution and the quartic vertex coefficient $-g$.

Chapter 16

Lorentzian Green Functions and Analytic Continuation

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

16.1 Time-Ordered Boundary Values

Definition 16.1 (Lorentzian scalar vacuum-sector datum)**.** Let $x^\mu = (x^0, \vec{x}) \in \mathbb{R}^{1,D-1}$ and use the mostly-plus metric

$$\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+), \qquad k^2 = \eta_{\mu\nu}k^\mu k^\nu.$$

Write $M = \mathbb{R}^{1,D-1}$. The framework in this chapter is a scalar Wightman field presentation in a vacuum sector: a Hilbert space $\mathcal{H}$, a vacuum vector Ω, a strongly continuous unitary representation of translations with self-adjoint generators P^μ whose joint spectrum lies in the closed forward cone

$$\overline{V}_+ = \{p \in M : p^0 \geq 0,\ p^2 \leq 0\},$$

and a scalar operator-valued distribution $\widehat{\phi}$ defined on a common invariant dense domain. Point-field notation denotes the kernel notation for smeared operator-valued distributions.

For $r \geq 1$, $\mathcal{S}(M^r)$ denotes the Schwartz space on M^r, and $\mathcal{S}'(M^r)$ its continuous dual. This chapter works in the tempered distribution category:

$$W_r,\ G_r \in \mathcal{S}'(M^r).$$

Every compactly supported smearing used to define a local field matrix element is also a Schwartz test function, so this convention is compatible with the local operator-valued-distribution notation. After translation invariance is used, analytic boundary values are paired with test functions in the relative variables. Thus a holomorphic function F on a tube over M^{r-1} has boundary value $T \in \mathcal{S}'(M^{r-1})$ when, for every $f \in \mathcal{S}(M^{r-1})$,

$$\lim_{y \to 0} \int_{M^{r-1}} \mathrm{d}^{D(r-1)}\xi \, F(\xi - \mathrm{i}y) f(\xi) = \langle T, f \rangle,$$

with y approaching the real edge inside the specified tube cone.

Definition 16.2 (Wightman and time-ordered distributions)**.** The Wightman n-point distribution is

$$W_n(x_1, \ldots, x_n) = \langle \Omega | \widehat{\phi}(x_1) \cdots \widehat{\phi}(x_n) | \Omega \rangle \in \mathcal{S}'(M^n).$$

For a permutation $\pi \in S_n$, set

$$M^n_\pi = \{(x_1, \ldots, x_n) : x^0_{\pi(1)} > \cdots > x^0_{\pi(n)}\}.$$

A vacuum time-ordered Green function for this field is a distribution

$$G_n \in \mathcal{S}'(M^n)$$

whose restriction to M^n_π is

$$G_n(x_1, \ldots, x_n)\big|_{M^n_\pi} = \langle \Omega | \widehat{\phi}(x_{\pi(1)}) \cdots \widehat{\phi}(x_{\pi(n)}) | \Omega \rangle.$$

Equivalently, on M^n_π away from coincident insertion points,

$$G_n(x_1, \ldots, x_n) = \langle \Omega | \widehat{\phi}(x_{\pi(1)}) \cdots \widehat{\phi}(x_{\pi(n)}) | \Omega \rangle.$$

Local commutativity makes the restrictions compatible across spacelike equal-time boundaries. A choice of G_n is therefore an extension across partial diagonals $x_{a_1} = \cdots = x_{a_r}$. The possible differences between two such extensions are local distributions supported on these diagonals. In perturbation theory this extension datum is fixed together with the renormalization prescription for local products. The compact operator notation

$$G_n(x_1, \ldots, x_n) = \langle \Omega | \, \mathrm{T}\{\widehat{\phi}(x_1) \cdots \widehat{\phi}(x_n)\} | \Omega \rangle$$

refers to this specified distribution.

Proposition 16.3 (Compatibility of time-ordered Wightman pieces)**.** *Let G°_n denote the piecewise distribution on the complement of the partial diagonals $x_a = x_b$, obtained by assigning the Wightman ordering corresponding to each strict time-ordering chamber M^n_π. If $\widehat{\phi}$ obeys scalar microcausality,*

$$[\widehat{\phi}(f), \widehat{\phi}(g)] = 0$$

whenever $\operatorname{supp} f$ *and* $\operatorname{supp} g$ *are spacelike separated, then the definitions on adjacent chambers agree across a common spacelike boundary. Thus G°_n is a well-defined distribution on*

$$M^n \setminus \bigcup_{a<b} \{x_a = x_b\}.$$

Proof. Let $U \subset M^n \setminus \bigcup_{a<b}\{x_a = x_b\}$ be a sufficiently small product coordinate neighborhood. The equal-time hyperplanes cut U into finitely many strict time-ordering chambers. If two such chambers share a codimension-one wall in U, then only two labels, say a, b, have been exchanged; on the wall $x_a^0 = x_b^0$, while $x_a \neq x_b$ because partial diagonals have been removed. After shrinking U, the projections of U to the two M-factors keep the supports of the corresponding localized test functions spacelike separated. For such test functions, microcausality gives

$$\widehat{\phi}(f_a)\widehat{\phi}(f_b) = \widehat{\phi}(f_b)\widehat{\phi}(f_a)$$

on the common invariant domain of local-field products. All remaining field operators in the smeared product are unchanged, so inserting this equality at the adjacent positions in the Wightman matrix element shows that the two chamber formulae have the same restriction to U.

Higher-codimension walls, where several time coordinates coincide but no two points coincide in spacetime, are handled by the same local argument. The permutations labeling the chambers meeting such a wall form a parabolic subgroup of the symmetric group, generated by adjacent transpositions of labels whose equal-time points remain spacelike separated in U. Since each generator leaves the smeared vacuum matrix element unchanged, any two chamber prescriptions meeting U agree on their common restriction. Thus the Wightman pieces form a compatible family on the chamber cover of the off-diagonal open set. Distributions form a sheaf: a compatible family of local distributions has a unique glued distribution. The glued object is the claimed G_n°. □

Proposition 16.4 (Contact-term freedom of the time-ordered extension)**.** *Let G_n and G_n' be two tempered extensions of the same off-diagonal time-ordered distribution G_n° to M^n. Then*

$$G_n - G_n'$$

is supported on the union of partial diagonals

$$\bigcup_{\mathcal{P}} \{x_a = x_b \text{ whenever } a, b \text{ lie in the same block of } \mathcal{P}\},$$

where $\mathcal{P}$ ranges over partitions of $\{1, \dots, n\}$ with at least one block of size ≥ 2. Locally near a fixed diagonal, this difference is a finite sum of derivatives of delta distributions in the normal coordinates, with distributional coefficients along the diagonal. In a translation-invariant local renormalization prescription these coefficients are local polynomials in derivatives acting on delta functions, with finite coefficients fixed by the chosen extension convention.

Proof. The two extensions agree by hypothesis on the open set

$$M^n \setminus \bigcup_{a<b}\{x_a = x_b\}.$$

Let $T = G_n - G_n'$. If a test function is supported in this open set, both extensions evaluate it by G_n°, hence T vanishes on such test functions. Therefore

$$\operatorname{supp} T \subset \bigcup_{a<b}\{x_a = x_b\}.$$

Refining this closed cover by the coincidence pattern of the labels gives the displayed union over partitions $\mathcal{P}$: the block structure records exactly which variables are forced to coincide.

For the local normal form, fix one such stratum and choose coordinates (u, v), where u are coordinates along the diagonal and v are normal relative coordinates. A distribution supported on $v = 0$ has finite transverse order on every compact coordinate chart. Equivalently, there are an integer N and distributions T_α along the diagonal such that locally

$$\sum_{|\alpha|\leq N} T_\alpha(u)\, \partial_v^\alpha \delta(v).$$

The finite order follows from the seminorm estimate defining continuity of a distribution on compactly supported tests; Taylor expansion in the normal variables reduces the action of T to finitely many normal derivatives at $v = 0$. Translation invariance removes dependence on the common center-of-mass coordinate in flat space. Locality of the renormalization prescription further restricts the coefficient distributions to derivatives of delta functions in relative diagonal variables, with numerical coupling-dependent coefficients. These supported delta-derivative contributions are precisely the contact terms. □

Free scalar Feynman boundary value. For the free scalar field of mass $m > 0$, the two-point time-ordered Green function has Fourier representation

$$\Delta_F(x; m^2) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k\cdot x}}{k^2 + m^2 - \mathrm{i}\epsilon}, \qquad \epsilon > 0.$$

At fixed $\vec{k}$, with

$$\omega_{\vec{k}} = \sqrt{\vec{k}^{\,2} + m^2},$$

the poles in the complex k^0-plane are

$$k^0 = -\omega_{\vec{k}} + \mathrm{i}0, \qquad k^0 = +\omega_{\vec{k}} - \mathrm{i}0.$$

This is the Feynman boundary value of the meromorphic function of k^0. The positive-frequency Wightman two-point function is

$$\Delta_+(x; m^2) = \int \frac{\mathrm{d}^{D-1}\vec{k}}{(2\pi)^{D-1} 2\omega_{\vec{k}}}\, \mathrm{e}^{-\mathrm{i}\omega_{\vec{k}} x^0 + \mathrm{i}\vec{k}\cdot\vec{x}}.$$

The time-ordered distribution is $\theta(x^0)\Delta_+(x) + \theta(-x^0)\Delta_+(-x)$, with the value on $x^0 = 0$ fixed as a distributional extension. For $x^0 > 0$, close the k^0-contour of

$$-\mathrm{i} \int \frac{\mathrm{d}k^0}{2\pi} \frac{\mathrm{e}^{-\mathrm{i}k^0 x^0}}{-(k^0)^2 + \omega_{\vec{k}}^2 - \mathrm{i}0}$$

in the lower half-plane; the pole at $+\omega_{\vec{k}} - \mathrm{i}0$ gives $\mathrm{e}^{-\mathrm{i}\omega_{\vec{k}} x^0}/(2\omega_{\vec{k}})$. For $x^0 < 0$, close the contour in the upper half-plane; the pole at $-\omega_{\vec{k}} + \mathrm{i}0$ gives $\mathrm{e}^{+\mathrm{i}\omega_{\vec{k}} x^0}/(2\omega_{\vec{k}})$. Combining the two time regions yields the displayed Fourier representation. The pole placement is therefore not an independent rule: it is the boundary-value encoding of time ordering and positive energy.

16.2 Tube Analyticity From the Spectrum Condition

Proposition 16.5 (Forward-tube analyticity from the spectrum condition)**.** *The* $i\epsilon$ *prescription is the two-point perturbative expression of a more general analytic fact. Let*

$$W_n(x_1,\ldots,x_n) = \langle\Omega|\widehat{\phi}(x_1)\cdots\widehat{\phi}(x_n)|\Omega\rangle$$

be a Wightman distribution. By translation invariance write it in the relative variables

$$\xi_j = x_j - x_{j+1}, \qquad j = 1,\ldots,n-1.$$

Let

$$w_n(\xi_1,\ldots,\xi_{n-1}) \in \mathcal{S}'(M^{n-1})$$

be the corresponding relative-coordinate distribution. Its Fourier transform $\widetilde{w}_n$ *is defined with the convention*

$$w_n(\xi) = \int \frac{\mathrm{d}^{D(n-1)}p}{(2\pi)^{D(n-1)}}\,\mathrm{e}^{\mathrm{i}\sum_j p_j\cdot\xi_j}\,\widetilde{w}_n(p)$$

in distribution notation. Equivalently, for $f \in \mathcal{S}(M^{n-1})$*,*

$$\langle w_n, f\rangle = \left\langle \widetilde{w}_n, \check{f}\right\rangle, \qquad \check{f}(p) = \int \frac{\mathrm{d}^{D(n-1)}\xi}{(2\pi)^{D(n-1)}}\,\mathrm{e}^{\mathrm{i}\sum_j p_j\cdot\xi_j}\,f(\xi).$$

The spectrum condition gives the support inclusion

$$\operatorname{supp}\widetilde{w}_n \subset \overline{V}_+^{\,n-1}.$$

For $\eta = (\eta_1,\ldots,\eta_{n-1}) \in V_+^{n-1}$*, the function* $\exp(\sum_j p_j\cdot\eta_j)$ *decreases exponentially on every closed subcone of* $\overline{V}_+^{\,n-1}$ *which contains the support of* $\widetilde{w}_n$*. Multiplication of* $\widetilde{w}_n$ *by this function is therefore a well-defined tempered distribution after inserting any smooth cutoff equal to one on a conic neighborhood of the support; the result is independent of the cutoff. The inverse Fourier transform is a holomorphic function of*

$$z_j = \xi_j - \mathrm{i}\eta_j, \qquad \eta_j \in V_+, \qquad j = 1,\ldots,n-1, \tag{16.1}$$

where V_+ *is the open future light cone. In distribution notation this Fourier-Laplace transform is written as*

$$\mathcal{W}_n(z) = \frac{1}{(2\pi)^{D(n-1)}}\left\langle \widetilde{w}_n(p), \exp\left\{\mathrm{i}\sum_{j=1}^{n-1} p_j\cdot z_j\right\}\right\rangle.$$

Indeed, for $p \in \overline{V}_+$ *and* $\eta \in V_+$*, the mostly-plus inner product satisfies*

$$p\cdot\eta \le 0,$$

so the factor

$$\exp\{\mathrm{i}p\cdot(\xi - \mathrm{i}\eta)\} = \exp\{\mathrm{i}p\cdot\xi + p\cdot\eta\}$$

is damped rather than enlarged. The boundary value is w_n *in* $\mathcal{S}'(M^{n-1})$*:*

$$\lim_{\eta\to 0,\ \eta_j\in V_+} \int_{M^{n-1}} \mathrm{d}^{D(n-1)}\xi\,\mathcal{W}_n(\xi - \mathrm{i}\eta)f(\xi) = \langle w_n, f\rangle, \qquad f \in \mathcal{S}(M^{n-1}).$$

Proof. Insert a complete spectral resolution of the translation generators between successive fields. In relative coordinates the Fourier variables are the successive momentum transfers carried by these intermediate states. The joint spectral condition therefore implies $\operatorname{supp}\widetilde{w}_n \subset \overline{V}_+^{n-1}$. If $\eta_j \in V_+$ and $p_j \in \overline{V}_+$, the mostly-plus metric gives $p_j \cdot \eta_j \le 0$, with strict negativity away from the boundary unless one vector is null and parallel to the other. Hence the factor $\exp(\sum_j p_j \cdot \eta_j)$ supplies exponential damping on every closed subcone inside the tube direction.

For fixed $\eta \in V_+^{n-1}$, multiplication of the tempered distribution $\widetilde{w}_n$ by the smooth function $\exp(\sum_j p_j \cdot \eta_j)$ is defined by first inserting a conic cutoff equal to one near the support; two such cutoffs differ away from the support and therefore give the same product. Differentiation with respect to z_j brings down polynomial factors in p_j, which remain valid multipliers of tempered distributions after the same exponential damping. Thus the Fourier-Laplace transform is holomorphic in the forward tube. Letting $\eta \downarrow 0$ inside the tube removes the damping multiplier and recovers the original Fourier transform in the topology of tempered distributions, which is exactly the stated boundary value. $\square$

Different operator orderings give holomorphic functions in corresponding permuted tubes. Local commutativity identifies their boundary values on real regions where the exchanged neighboring points are spacelike separated.

Theorem 16.6 (Distributional edge-of-the-wedge statement used here)**.** *Let $U \subset \mathbb{R}^N$ be open, and let C_+ and C_- be open convex cones in $\mathbb{R}^N$ whose convex hull is all of $\mathbb{R}^N$. Suppose $F_\pm$ are holomorphic on the tubes $U + \mathrm{i}C_\pm$. Assume the following polynomial boundary growth: for every compact $K \subset U$ and every closed cone $C'_\pm$ whose nonzero vectors lie in $C_\pm$, there are constants $A, N < \infty$ such that*

$$|F_\pm(x + \mathrm{i}y)| \le A(1 + |x|)^N |y|^{-N}, \qquad x \in K, \quad y \in C'_\pm, \quad 0 < |y| < 1.$$

These estimates define distributional boundary values

$$b_\pm \in \mathcal{D}'(U).$$

If $b_+ = b_-$ on a nonempty open real subset $O \subset U$, then there is a connected complex neighborhood $\mathcal{N}$ of O and a holomorphic function F on $\mathcal{N}$ whose restrictions agree with F_+ and F_- wherever the original tubes meet $\mathcal{N}$.

Proof. This is analytic infrastructure from several complex variables and distribution theory; the proof is included here to make clear exactly which part is analytic and which part is supplied by Wightman locality. The convex-hull hypothesis is part of the full-neighborhood form of the theorem. In the more general wedge theorem the continuation lies in the wedge with imaginary cone $\operatorname{conv}(C_+ \cup C_-)$; a genuine complex neighborhood of the real edge is obtained when this cone contains all imaginary directions. The permuted Wightman tubes used at a Jost configuration supply precisely this two-sided normal data after restricting to the relevant spacelike edge.

First, the polynomial tube bounds put each normal translate

$$F_{\pm,\epsilon v} : x \longmapsto F_\pm(x + \mathrm{i}\epsilon v), \qquad v \in C_\pm,$$

in a fixed finite-order distribution class on every $K \Subset U$. The point is not the pointwise bound itself, which may diverge as $\epsilon \downarrow 0$, but the combination of that bound with Cauchy's formula.

If m is larger than the normal growth order, Cauchy's integral formula in a polydisc of radius comparable to ϵ expresses $F_{\pm,\epsilon v}$ paired with $\varphi \in C_c^\infty(K)$ as a finite sum of pairings of $F_\pm(\cdot + \mathrm{i}\epsilon' v')$ with derivatives of φ, where ϵ' remains comparable to ϵ and v' remains in a proper subcone. Integrating by parts transfers the singular normal powers to finitely many derivatives of φ. Thus, for some integer M_K,

$$\left|\langle F_{\pm,\epsilon v}, \varphi\rangle\right| \le C_{K,v} \sum_{|\alpha|\le M_K} \sup_{x\in K} |\partial^\alpha \varphi(x)| \qquad (0 < \epsilon < \epsilon_0).$$

Weak compactness in this finite-order dual gives distributional accumulation points. Holomorphy makes the accumulation point unique: if $v_0, v_1 \in C_\pm$, integrate $\bar\partial F_\pm = 0$ over the truncated two-real-dimensional surface $\{x + \mathrm{i}\epsilon((1-r)v_0 + rv_1) : 0 < \epsilon < \epsilon_0,\ 0 < r < 1\}$, paired with a test density in x. The side contributions vanish as the truncation shrinks, and the two normal boundary terms are the two candidate limits. Hence the limit is independent of the approach direction and defines the boundary distribution $b_\pm \in \mathcal{D}'(U)$.

The gluing step is local. Choose a ball $B \Subset O$. In one complex variable, take a test $(1,1)$-form supported in a small disc crossing the real edge and define a distribution by using F_+ in the upper wedge and F_- in the lower wedge. Pairing its $\bar\partial$ with the test form is the limit of the contour integral over a rectangle whose horizontal sides lie at heights $\pm\epsilon$. The holomorphic interiors contribute zero. The two horizontal boundary terms converge to $\langle b_+, \varphi\rangle - \langle b_-, \varphi\rangle$, with the orientation of the lower side supplying the minus sign. Since $b_+ = b_-$ on B, the glued distribution has $\bar\partial = 0$. The Weyl lemma for the $\bar\partial$-operator, equivalently Morera's theorem in distribution form, therefore represents it by a holomorphic function across the edge.

For $N > 1$, apply this one-variable argument to complex lines whose real directions are tangent to B and whose imaginary directions lie in $\mathrm{conv}(C_+ \cup C_-)$. The same boundary-jump cancellation gives holomorphic continuation on each line. Separate holomorphy on the resulting family of line slices and Hartogs' theorem give joint holomorphy on the local wedge generated by the convex hull. Bochner's tube theorem then identifies the envelope of holomorphy of this local tube with the tube over that convex hull. Under the hypothesis $\mathrm{conv}(C_+ \cup C_-) = \mathbb{R}^N$, the envelope contains a complex neighborhood of B. Gluing the local holomorphic extensions over overlapping balls in O gives the connected neighborhood $\mathcal{N}$.

The pure analytic inputs in this last paragraph are Hartogs' theorem, the $\bar\partial$ Weyl lemma, and Bochner's tube theorem. The QFT-specific burden in this chapter is the verification of the hypotheses that enter the analytic theorem: tube growth from the spectrum condition and equality of boundary distributions from local commutativity. □

Verification of the real-edge equality in the Wightman case. Fix two adjacent field labels a, b and let $O_{ab} \subset M^n$ be an open real set on which $x_a - x_b$ is spacelike and no partial diagonal $x_i = x_j$ is met. Let $W_{\dots ab \dots}$ and $W_{\dots ba \dots}$ denote the two Wightman distributions that differ only by interchanging the adjacent fields $\widehat{\phi}(x_a)$ and $\widehat{\phi}(x_b)$. If $f \in C_c^\infty(O_{ab})$, a partition of unity subordinate to sufficiently small product neighborhoods writes the smeared matrix element as a finite sum in which the a- and b-smearings have spacelike separated supports. Scalar microcausality gives

$$\widehat{\phi}(f_a)\widehat{\phi}(f_b) = \widehat{\phi}(f_b)\widehat{\phi}(f_a)$$

on the common invariant domain of the field products appearing in the vacuum matrix element. All other smeared fields are unchanged, hence

$$\langle W_{\cdots ab\cdots} - W_{\cdots ba\cdots}, f\rangle = 0, \qquad f \in C_c^\infty(O_{ab}).$$

The boundary values of the two corresponding tube functions therefore agree as distributions on O_{ab}. For fields with a $\mathbb{Z}_2$-grading, the same argument gives the Koszul sign determined by moving the two homogeneous fields past one another. This is the real-edge input used by the distributional edge-of-the-wedge theorem at Jost configurations.

The theorem therefore supplies the common holomorphic continuation of the permuted tube functions across those spacelike real regions. Time-ordered Green functions are boundary values obtained by approaching real Lorentzian points from imaginary time orderings compatible with the chosen operator order. For two points, this general construction is exactly the pole displacement

$$\frac{1}{k^2 + m^2 - \mathrm{i}\epsilon}$$

appearing in the Feynman propagator.

16.3 Boundary-Value Dictionary

Definition 16.7 (Ordered Lorentzian and Euclidean boundary values)**.** The preceding tube statement gives a precise dictionary among Wightman, time-ordered, and Euclidean functions. Fix an ordering π and real Lorentzian points with

$$x^0_{\pi(1)} > x^0_{\pi(2)} > \cdots > x^0_{\pi(n)}.$$

Choose positive numbers

$$\epsilon_1 > \epsilon_2 > \cdots > \epsilon_n > 0$$

and set

$$z_{\pi(j)} = x_{\pi(j)} - \mathrm{i}\epsilon_j e_0, \qquad e_0 = (1, \vec{0}).$$

Then

$$z_{\pi(j)} - z_{\pi(j+1)} = x_{\pi(j)} - x_{\pi(j+1)} - \mathrm{i}(\epsilon_j - \epsilon_{j+1})e_0$$

lies in the forward tube for the j-th relative variable. The time-ordered boundary value on the region M^n_π is

$$G_n(x_1, \ldots, x_n)\big|_{M^n_\pi} = \lim_{\epsilon_1 > \cdots > \epsilon_n \downarrow 0} \mathcal{W}_{n,\pi}(z_{\pi(1)}, \ldots, z_{\pi(n)}),$$

where $\mathcal{W}_{n,\pi}$ denotes the holomorphic continuation of the Wightman ordering displayed by π. The limit is a distributional boundary value: it is taken after pairing with a Schwartz test function in the relative variables.

Euclidean Schwinger functions arise from the same holomorphic functions by restriction to imaginary time. For Euclidean points

$$x_{E,a} = (\tau_a, \vec{x}_a),$$

with

$$\tau_{\pi(1)} > \tau_{\pi(2)} > \cdots > \tau_{\pi(n)},$$

define

$$z^0_{\pi(j)} = -\mathrm{i}\tau_{\pi(j)}, \qquad \vec{z}_{\pi(j)} = \vec{x}_{\pi(j)}.$$

Then

$$\begin{aligned} &S_n(x_{E,1}, \ldots, x_{E,n})\big|_{\tau_{\pi(1)} > \cdots > \tau_{\pi(n)}} \\ &\quad = \mathcal{W}_{n,\pi}(z_{\pi(1)}, \ldots, z_{\pi(n)}). \end{aligned}$$

Source sign under Wick rotation. The same dictionary fixes the sign in source functionals. Let

$$Z_L^{(+)}[J] = \langle\Omega|\, \mathrm{T}\exp\left(\mathrm{i}\int_{\mathbb{R}^{1,D-1}} J(x)\widehat{\phi}(x)\,\mathrm{d}^D x\right)|\Omega\rangle$$

denote the Lorentzian source convention in which functional derivatives produce factors of i. Its opposite-source convention is

$$Z_L^{(-)}[J] = Z_L^{(+)}[-J].$$

To compare with a Euclidean source one must specify the contour, because a real Euclidean test function and a real Lorentzian test function live on different real slices. Let C_- be the imaginary-time contour

$$z^0 = -\mathrm{i}\tau, \qquad \mathrm{d}z^0 = -\mathrm{i}\,\mathrm{d}\tau,$$

with the orientation inherited from increasing τ, and let J_C be a source density defined on this contour. Term by term in the source expansion, or in a regulated theory where the contour-ordered source exponential is an operator-valued analytic function of the source, the source part of the exponent is

$$\mathrm{i}\int_{C_-} \mathrm{d}z^0\,\mathrm{d}^d\vec{x}\,J_C(z^0,\vec{x})\widehat{\phi}(z^0,\vec{x}) = \int_{\mathbb{R}} \mathrm{d}\tau\,\mathrm{d}^d\vec{x}\,J_C(-\mathrm{i}\tau,\vec{x})\widehat{\phi}_E(\tau,\vec{x}).$$

Thus the Euclidean convention

$$Z_E[J_E] = \langle\Omega|T_E\exp\left(\int J_E(\tau,\vec{x})\widehat{\phi}_E(\tau,\vec{x})\,\mathrm{d}\tau\,\mathrm{d}^d\vec{x}\right)|\Omega\rangle$$

is the C_- boundary value of $Z_L^{(+)}$ with

$$J_E(\tau,\vec{x}) = J_C(-\mathrm{i}\tau,\vec{x}).$$

No additional minus sign is produced in this convention; the factor i in the Lorentzian source and the Jacobian $-\mathrm{i}$ of the lower-half-plane Wick contour multiply to $+1$. If one instead rotates through the opposite contour C_+, $z^0 = +\mathrm{i}\tau$, then $\mathrm{d}z^0 = \mathrm{i}\,\mathrm{d}\tau$ and the same Lorentzian convention gives

$$\mathrm{i}\int_{C_+} \mathrm{d}z^0\,J_C\widehat{\phi} = -\int \mathrm{d}\tau\,J_C(\mathrm{i}\tau)\widehat{\phi}_E.$$

In that contour convention the Euclidean functional with $+\int J_E\phi_E$ is represented by $Z_L^{(+)}[-J_C]$, equivalently by $Z_L^{(-)}[J_C]$, after setting $J_E(\tau,\vec{x}) = -J_C(\mathrm{i}\tau,\vec{x})$. The two formulas describe different contour/source-sign conventions, not two different Green functions. Expand the contour-ordered exponential in powers of the source. Each Lorentzian source insertion carries the factor $\mathrm{i}\,\mathrm{d}z^0$. On the lower imaginary-time contour $z^0 = -\mathrm{i}\tau$, the one-dimensional volume form is $\mathrm{d}z^0 = -\mathrm{i}\,\mathrm{d}\tau$, and therefore $\mathrm{i}\,\mathrm{d}z^0 = +\mathrm{d}\tau$. The source term becomes $+\int J_E\phi_E$ after the identification

$J_E(\tau, \vec{x}) = J_C(-\mathrm{i}\tau, \vec{x})$. On the upper contour $z^0 = +\mathrm{i}\tau$, one instead has $\mathrm{i}\,\mathrm{d}z^0 = -\mathrm{d}\tau$, so the same Lorentzian source convention produces the opposite Euclidean sign unless the source is replaced by its negative. The calculation is termwise in the regulated source expansion, hence fixes all Euclidean n-point signs.

Conversely, an OS-admissible Schwinger hierarchy reconstructs Wightman boundary values by the positive-time quotient and analytic-continuation theorem of Chapter 12. Thus the boundary-value dictionary has two controlled entrances: spectral Wightman data with tube analyticity, and Euclidean data satisfying the OS positivity, covariance, regularity, and growth hypotheses.

Two-point Feynman prescription from ordered tubes. For $n = 2$, the dictionary gives the Feynman prescription. If $x^0 > 0$, the ordered boundary value is obtained with the positive-energy pole below the real k^0-axis and the negative-energy pole above it:

$$k^0 = +\omega_{\vec{k}} - \mathrm{i}0, \qquad k^0 = -\omega_{\vec{k}} + \mathrm{i}0.$$

If $x^0 < 0$, the contour closure selects the opposite residue in the same single distribution Δ_F. This two-point pole rule is the momentum space encoding of the ordered tube boundary value above. The ordered tube prescription for $x^0 > 0$ approaches the first field from a larger negative imaginary time than the second. In Fourier variables this is the same damping choice as in the free two-point boundary-value calculation above, so the positive-energy pole is passed below the real axis. If $x^0 < 0$, the operator order is reversed and the contour closure selects the negative-energy pole above the axis. The two cases are precisely the two boundary values of the single meromorphic denominator $k^2 + m^2$, hence the denominator is $k^2 + m^2 - \mathrm{i}0$.

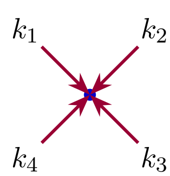
16.4 Lorentzian Feynman Rules for Green Functions

Definition 16.8 (Lorentzian labelled graph rules for Green functions)**.** Consider the same scalar ϕ^4 interaction as in the Euclidean chapter, with Lorentzian interaction density

$$\mathcal{L}_{\text{int}} = -\frac{g}{4!}\phi^4.$$

The perturbative rules below compute time-ordered Green functions. They use Lorentzian momenta on every line.

$$= \frac{-\mathrm{i}}{k^2 + m^2 - \mathrm{i}\epsilon}$$



$$= \quad -\mathrm{i}g\,(2\pi)^D \delta^{(D)}(k_1 + k_2 + k_3 + k_4)$$

This is the labelled-leg convention matching the Euclidean convention of the previous chapter. Direct expansion of the interaction density instead assigns

$$-\frac{\mathrm{i}g}{4!}\,(2\pi)^D \delta^{(D)}(k_1 + k_2 + k_3 + k_4)$$

to an unlabelled four-field insertion and recovers the labelled rule by counting contractions. In the labelled-leg convention used below, the factor 4! associated with assigning the four incident half-edges to a quartic vertex has already been absorbed into the vertex rule $-\mathrm{i}g$. Therefore a connected graph Γ with labelled external legs carries only the residual factor

$$\frac{1}{|\operatorname{Aut}_{\mathrm{ext}}\Gamma|},$$

where $\operatorname{Aut}_{\mathrm{ext}}\Gamma$ is the automorphism group of the graph that fixes every external label and preserves the incidence relations. For the tadpole graph below this residual group has order 2, coming from the interchange of the two internal half-edges forming the loop; this is why the tadpole coefficient is $-\mathrm{i}g/2$, not $-\mathrm{i}g$.

Lorentzian–Euclidean graph factor under simultaneous rotation. Consider a connected ϕ^4 graph contributing to a time-ordered n-point Green function with external propagators included. Suppose the external momenta lie in the first-sheet Euclidean domain and the internal loop energy contours can be simultaneously deformed to imaginary axes without crossing or pinching singularities. Let I be the number of internal propagators, V the number of quartic vertices, and

$$L = I - V + 1$$

the number of loop momenta. With the labelled conventions of this chapter and Chapter 15, the Lorentzian graph boundary value at $k_a^0 = \mathrm{i}k_{E,a}^D$ is

$$(-1)^n \mathrm{i}^{\,n+1}$$

times the corresponding Euclidean connected Green-function graph. In particular, a connected two-point graph gives the factor $-\mathrm{i}$, while a connected four-point graph gives the factor $+\mathrm{i}$. The Lorentzian labelled graph contains one factor $-\mathrm{i}g$ for each quartic vertex, one factor

$$\frac{-\mathrm{i}}{p_e^2 + m^2 - \mathrm{i}0}$$

for each propagator edge, and one real loop measure for each independent loop momentum. In a connected n-point Green function with external propagators included, the total number of propagator edges is $I + n$, because each external insertion is attached to the interaction graph by one external propagator. Rotating each independent loop energy by $\ell^0 = \mathrm{i}\ell_E^D$ gives one Jacobian factor i for each loop. The denominator of every propagator becomes the corresponding Euclidean denominator by the assumed contour deformation.

Thus the total phase multiplying the Euclidean denominators and the factor g^V is

$$(-\mathrm{i})^V (-\mathrm{i})^{I+n} \mathrm{i}^L.$$

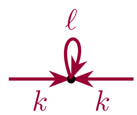
The Euclidean graph with the same labelled convention has vertex factor $(-g)^V$, the same symmetry factor, and no propagator numerator phase. Dividing by the Euclidean vertex phase gives the ratio

$$\frac{(-\mathrm{i})^{V+I+n}\mathrm{i}^{I-V+1}}{(-1)^V} = (-1)^n \mathrm{i}^{\,n+1},$$

where $L = I - V + 1$ has been used. The result is independent of the number of vertices and internal lines. The assumption on contour deformation is what excludes threshold pinches; without it the graph is defined by boundary value on the cut rather than by this direct simultaneous rotation.

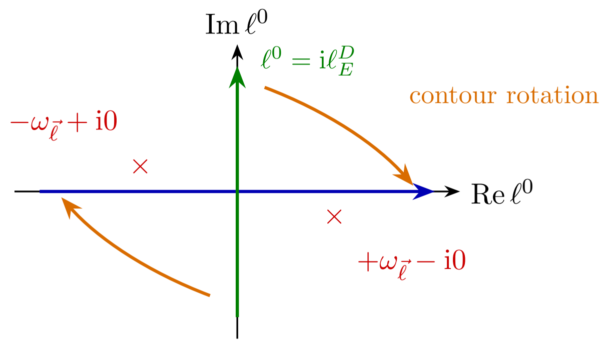
16.5 Loop Rotation and the Tadpole

Tadpole contour rotation and self-energy matching. The one-loop tadpole contribution to the Lorentzian two-point self-energy insertion is



$$= \quad -\frac{\mathrm{i}g}{2}\int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\,\frac{-\mathrm{i}}{\ell^2+m^2-\mathrm{i}\epsilon}.$$

The factor $1/2$ is the same tadpole symmetry factor as in Euclidean signature. This is a combinatorial statement: the Wick contraction count depends only on the polynomial ϕ^4 and on the residual graph automorphism, while the signature-dependent factors enter separately through the labelled Lorentzian vertex $-\mathrm{i}g$ and propagator numerator $-\mathrm{i}$. The loop energy ℓ^0 is integrated along the real axis with the Feynman pole displacement. The Euclidean integral is obtained by rotating the contour to $\ell^0 = \mathrm{i}\ell_E^D$, with the contour passing between the two displaced poles.



With this orientation,

$$\ell^0 = \mathrm{i}\ell_E^D, \qquad \mathrm{d}\ell^0 = \mathrm{i}\,\mathrm{d}\ell_E^D, \qquad \mathrm{d}^D\ell = \mathrm{i}\,\mathrm{d}^D\ell_E,$$
$$\ell^2+m^2-\mathrm{i}\epsilon = -(\ell^0)^2+\vec{\ell}^{\,2}+m^2-\mathrm{i}\epsilon \longrightarrow \ell_E^2+m^2.$$

Therefore the measure and propagator numerator together give

$$\mathrm{d}^D\ell\,\frac{-\mathrm{i}}{\ell^2+m^2-\mathrm{i}\epsilon} \longrightarrow \mathrm{i}\,\mathrm{d}^D\ell_E\,\frac{-\mathrm{i}}{\ell_E^2+m^2} = \mathrm{d}^D\ell_E\,\frac{1}{\ell_E^2+m^2}.$$

Including the vertex factor, this gives

$$-\frac{\mathrm{i}g}{2}\int\frac{\mathrm{d}^D\ell}{(2\pi)^D}\frac{-\mathrm{i}}{\ell^2+m^2-\mathrm{i}\epsilon} = \mathrm{i}\left[-\frac{g}{2}\int\frac{\mathrm{d}^D\ell_E}{(2\pi)^D}\frac{1}{\ell_E^2+m^2}\right].$$

Thus the Lorentzian two-point insertion is $\mathrm{i}\Sigma(k)$, where $\Sigma(k)$ is the first-sheet analytic continuation of the Euclidean self-energy $\Sigma_E(k_E)$ with the sign convention of Chapter 15. More explicitly, in the same regulator and the same local two-point subtraction convention, the denominator self-energy obeys

$$\Sigma\big(k^0 = \mathrm{i}k_E^D, \vec{k} = \vec{k}_E\big) = \Sigma_E(k_E), \tag{16.2}$$

where Σ_E is defined by Eq. (15.1). The factor i displayed above belongs to the Lorentzian two-point insertion in the Dyson series; it is not an extra sign in the scalar function Σ appearing in the denominator of $\widetilde{G}(k)$. The coefficient $-\mathrm{i}g/2$ follows from Definition 16.8: the labelled quartic vertex supplies $-\mathrm{i}g$, and the loop made from the two remaining half-edges has residual automorphism group of order 2. The Feynman pole displacement places the positive-energy pole below and the negative-energy pole above the real loop-energy axis. Rotating the real ℓ^0-cycle to $\ell^0 = \mathrm{i}\ell_E^D$ crosses no pole in this tadpole because no external energy flows through the loop. The Jacobian gives $\mathrm{d}^D\ell = \mathrm{i}\mathrm{d}^D\ell_E$, while the propagator numerator gives $-\mathrm{i}$; their product is $+1$. The remaining vertex factor is exactly i times the Euclidean tadpole insertion. Since the Lorentzian two-point Green function is written with a global propagator numerator $-\mathrm{i}$, this extra i belongs to the insertion in the Dyson series and not to the denominator self-energy scalar itself. This gives (16.2).

Proposition 16.9 (Loop rotation and pinch obstruction)**.** *The contour rotation just used is a special case with no external energy flowing through the loop. The same direct rotation is also legitimate for loop integrals with Euclidean external momenta, where the external energies lie on the imaginary axis and the Feynman poles can be separated continuously from the rotating contours. For general Lorentzian timelike external momenta, one must instead analyze the full contour deformation in the complex loop energy variables. The obstruction is a pinch singularity: poles from different propagators can trap the integration cycle so that it cannot be deformed to the Euclidean cycle without crossing singularities.*

For example, the Lorentzian continuation of the order-g^2 sunset self-energy contains the denominator product

$$\frac{1}{(q_1^2 + m^2 - \mathrm{i}0)(q_2^2 + m^2 - \mathrm{i}0)\big((k - q_1 - q_2)^2 + m^2 - \mathrm{i}0\big)}.$$

At $\vec{k} = 0$, the Landau equations have a solution with all three internal lines on shell and carrying positive energy when

$$(k^0)^2 \geq (3m)^2.$$

At and above this three-particle threshold the q_1^0, q_2^0 contours are pinched. Thus the Euclidean sunset integral defines a first-sheet analytic function away from its Landau singularities, and the physical Lorentzian value above threshold is the specified boundary value on the cut, not the result of a naive independent rotation of each loop energy. The discontinuity across such cuts is computed by the Cutkosky rules, which are the perturbative expression of the same spectral and unitarity structure developed in Chapter 28.

Proof. For Euclidean external energies, every external energy entering a propagator has imaginary value. For fixed spatial loop momenta, the pole locations in each loop-energy variable remain a positive distance away from the rotating contour on compact subsets of the Euclidean external domain. The Feynman $i0$ prescription places the positive- and negative-energy poles on opposite sides of the original real contour, and the imaginary external energies prevent a pole from crossing the homotopy from the real contour to the imaginary contour. Cauchy's theorem for the regularized meromorphic integrand identifies the Lorentzian integral with the Euclidean integral on this first-sheet domain. Equivalently, insert a rapidly decreasing regulator, perform the contour deformation with vanishing large arcs, and remove the regulator inside the common analytic domain.

For real timelike k, the sunset denominators admit the simultaneous on-shell solution

$$q_1^2 = q_2^2 = (k - q_1 - q_2)^2 = -m^2, \qquad q_1^0, q_2^0, k^0 - q_1^0 - q_2^0 > 0$$

when $k^0 \geq 3m$ in the rest frame. At threshold the three internal spatial momenta may be zero; above threshold they may share the total energy k^0. The Landau stationarity condition says that the gradients of the three on-shell denominators are linearly dependent with nonnegative coefficients, so the singular hypersurfaces meet the integration cycle in a trapping configuration. In the q_1^0, q_2^0 variables, poles approach from opposite sides as the external energy is continued to the physical value. No deformation to the imaginary cycle exists without crossing a pole. The Lorentzian value above threshold is therefore a specified boundary value on the cut of the first-sheet analytic function, not the result of an independent Euclidean rotation of each loop energy. □

16.6 Full Two-Point Function and First Sheet

Definition 16.10 (First-sheet two-point continuation)**.** The perturbative time-ordered two-point function is written as

$$G(x,y) = \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, \mathrm{e}^{\mathrm{i}k\cdot(x-y)} \widetilde{G}(k),$$

where

$$\widetilde{G}(k) = \frac{-\mathrm{i}}{k^2 + m^2 - \mathrm{i}\epsilon - \Sigma(k)}.$$

The function $\Sigma(k)$ is initially computed for Euclidean external momenta, where loop integrals have Euclidean denominators. Using

$$k^0 = \mathrm{i}k_E^D,$$

the Euclidean external energy lies on the imaginary k^0-axis. The matching identity (16.2) gives

$$\widetilde{G}(\mathrm{i}k_E^D, \vec{k}_E) = -\mathrm{i}\, \widetilde{G}_E(k_E),$$

because $k^2 = k_E^2$ at $k^0 = \mathrm{i}k_E^D$ with the mostly-plus convention. The Lorentzian value is the boundary value obtained by analytic continuation of k^0 from this axis to the prescribed side of the real axis without crossing the first-sheet cuts.

Spectral thresholds and first-sheet cuts. The spectral representation fixes the location of the first singular thresholds. Suppose the continuum part $d\rho_{\mathrm{c}}$ in the two-point spectral measure has lowest invariant mass M, meaning

$$M^2 = \inf \operatorname{supp} d\rho_{\mathrm{c}}$$

in the Källén–Lehmann variable $s = \mu^2$. Under the two-particle threshold assumption stated in Chapter 14, namely $\operatorname{supp} d\rho_{\mathrm{c}} \subset [4m^2, \infty)$ with the $\phi\phi$ continuum saturating the lower endpoint, this notation gives

$$M^2 = 4m^2, \qquad M = 2m.$$

If the first continuum channel has a different threshold, M denotes that actual square-root threshold. At fixed spatial momentum $\vec{k}$, define

$$E_M(\vec{k}) = \sqrt{\vec{k}^{\,2} + M^2}.$$

The continuum denominators have singular support when

$$(k^0)^2 = \vec{k}^{\,2} + s, \qquad s \geq M^2.$$

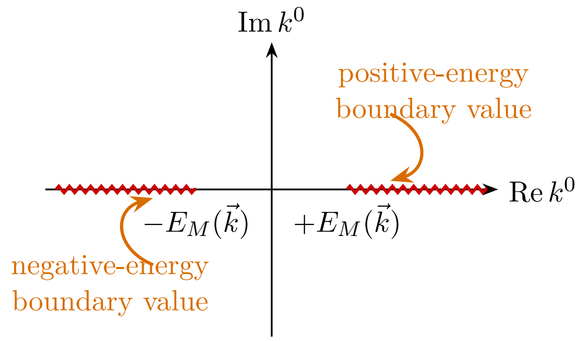
Consequently the first sheet has branch cuts beginning at

$$k^0 = +E_M(\vec{k}), \qquad k^0 = -E_M(\vec{k}).$$

The Feynman boundary value on the positive-energy cut is reached from the upper half-plane. Thus the value of $\Sigma(k)$ at real positive k^0 is the boundary value approached from $\operatorname{Im} k^0 > 0$ on the first sheet. The negative-energy cut is reached with the conjugate placement. The reason is direct but important. The Källén–Lehmann representation writes the connected two-point function as an integral of free denominators over the positive spectral measure:

$$\int_{[M^2,\infty)} \frac{\mathrm{d}\rho_{\mathrm{c}}(s)}{k^2 + s - \mathrm{i}0}.$$

At fixed $\vec{k}$, each value of s has branch points or poles at $k^0 = \pm\sqrt{\vec{k}^{\,2} + s}$. The union of these singular loci over $s \geq M^2$ is exactly the pair of cuts beginning at $\pm E_M(\vec{k})$. The Feynman prescription puts the positive-energy denominator below the real axis, so the physical positive-energy boundary value is obtained by approaching the cut from $\operatorname{Im} k^0 > 0$. The negative-energy side is the conjugate boundary value imposed by the same real spectral measure.



The output of the continuation is a family of Lorentzian time-ordered Green functions with specified singularity prescriptions. The spectral poles and cuts identify one-particle and continuum invariant masses seen by the field. The next construction concerns asymptotic states: it asks for Hilbert-space limits in which separated wave packets behave as freely propagating stable particles in the far past or far future. That construction is logically additional to the analytic continuation of Green functions.

Part II

Particles, Scattering, and Analyticity

Chapter 17

Haag–Ruelle Scattering Theory

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

17.1 Scattering States as Hilbert-Space Limits

The previous chapters constructed local fields, their spectral content, and Lorentzian time-ordered Green functions. We now add a new kind of object: asymptotic particle states. These are vectors in the physical Hilbert space obtained as large-time limits of localized wave packets. Once these limits are constructed, the scattering operator is a comparison between two Hilbert-space identifications: one made in the far past and one made in the far future.

The construction in this chapter is for a massive stable bosonic particle. It uses a Hilbert space $\mathcal{H}$, a vacuum vector Ω, local operators, the Poincare representation, the spectrum condition, and an isolated one-particle mass shell. These hypotheses are stated explicitly because the large-time limit is a theorem under hypotheses, not an algebraic manipulation of Green functions.

This chapter is the introductory construction layer. It works with scalar local fields and displays the velocity-support geometry, spectral filtering, and Cook estimates that make the large-time limits plausible and usable in physics applications. The theorem-level algebraic statement, formulated for vacuum local nets and almost-local operators, is Theorem 22.1 in Chapter 22. The present chapter should therefore be read as the point-field model and estimate layer feeding the later theorem, not as a second independent foundation of scattering theory.

Let spacetime have dimension D, and write $d = D - 1$. The mostly-plus metric is

$$\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +), \qquad p^2 = \eta_{\mu\nu} p^\mu p^\nu.$$

Let $U(a, \Lambda)$ be a strongly continuous unitary representation of the proper orthochronous Poincare group on $\mathcal{H}$. Its translation subgroup is written

$$U(a, \mathbf{1}) = \mathrm{e}^{\mathrm{i} a_\mu P^\mu},$$

where the commuting self-adjoint generators P^μ are the energy-momentum operators. The spectrum condition is

$$\mathrm{Spec}(P) \subset \overline{V}_+ = \{p \in \mathbb{R}^D : p^0 \geq 0,\ p^2 \leq 0\}.$$

The invariant mass operator is

$$M^2 = -P_\mu P^\mu.$$

Definition 17.1 (Massive one-particle sector)**.** Fix $m > 0$. A massive one-particle sector of mass m is a closed subspace $\mathcal{H}_1 \subset \mathcal{H}$ such that:

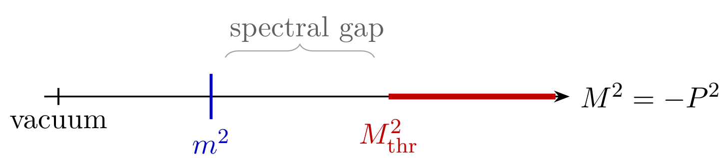
1. $\mathcal{H}_1$ reduces the Poincare representation;
2. $M^2 = m^2$ on $\mathcal{H}_1$;
3. the spectrum of P^μ on $\mathcal{H}_1$ lies on

$$\Sigma_m^+ = \{(\omega_{\vec{p}}, \vec{p}) : \vec{p} \in \mathbb{R}^d\}, \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^{\,2} + m^2};$$

4. there is an open interval around m^2 in the spectrum of M^2 whose only spectral point is m^2.

Let P_1 denote the orthogonal projection from $\mathcal{H}$ onto $\mathcal{H}_1$.

The last condition is the mass-gap form of stability used in this chapter. It says that the one-particle shell is separated from the continuum. In a scalar theory with a lightest stable particle, the picture is:



Here M_{thr} is the lowest invariant mass in the continuum channel under discussion.

For the scalar multiplicity-one sector used below, the abstract Hilbert space $\mathcal{H}_1$ is represented concretely as wave functions on the positive mass shell. Let

$$\mathrm{d}\mu_m(p) = \frac{\mathrm{d}^d \vec{p}}{(2\pi)^d 2\omega_{\vec{p}}}, \qquad p = (\omega_{\vec{p}}, \vec{p}).$$

After fixing the relativistic normalization of one-particle states, choose a unitary map

$$W_1 : L^2(\Sigma_m^+, \mathrm{d}\mu_m) \longrightarrow \mathcal{H}_1$$

which intertwines translations by

$$U(a, \mathbf{1}) W_1 f = W_1\big(p \mapsto \mathrm{e}^{\mathrm{i} a_\mu p^\mu} f(p)\big).$$

In generalized momentum notation this is

$$W_1 f = \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, f(p)|p\rangle, \qquad \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, |p\rangle\langle p| = \mathbf{1}_{\mathcal{H}_1}.$$

The kets in this display are distributional symbols for the spectral representation; Hilbert vectors are obtained after L^2-smearing. With an internal multiplicity space or nontrivial spin, the scalar model is replaced by

$$\mathcal{H}_1 \simeq L^2(\Sigma_m^+, \mathrm{d}\mu_m; \mathfrak{k}),$$

where $\mathfrak{k}$ carries the little-group/internal representation and the Poincare action contains the corresponding Wigner rotations. The present chapter takes $\mathfrak{k} = \mathbb{C}$.

Remark 17.2 (When the isolated shell is a theorem). The definition above is an assumption on the Hilbert-space spectrum. It is automatic for a free massive scalar field, and it is a proved property in constructive massive scalar models only when the construction supplies both the Wightman theory and the relevant mass-gap/one-particle spectral theorem. In particular, low-dimensional $P(\phi)_2$ and massive $\lambda\phi_3^4$ models provide the standard constructive setting for such statements in stable massive sectors. By contrast, a four-dimensional perturbative $\lambda\phi^4$ calculation by itself does not prove the existence of a UV-complete Hilbert-space theory with an isolated mass shell. In QED, long-range soft photons destroy the sharp charged-particle mass hyperboloid expected by this definition; in QCD, colored quark and gluon shells are absent from the gauge-invariant observable spectrum. Stable hadrons, if isolated below decay thresholds, may satisfy the hypothesis, while resonances and unstable particles do not.

17.2 Local Operators and One-Particle Wave Packets

To state the large-time construction without domain distractions, use bounded local operators. A bounded operator A is localized in a bounded spacetime region O when it belongs to the local algebra $\mathcal{A}(O)$. Locality means that if O_1 and O_2 are spacelike separated, then

$$[A_1, A_2] = 0, \qquad A_i \in \mathcal{A}(O_i).$$

For unbounded point fields, this is the corresponding statement after smearing and restricting to the common invariant domain on which the products are defined.

Definition 17.3 (Almost-local bounded operator)**.** Let $\mathcal{O}_R$ be a cofinal family of double cones whose radii tend to infinity; for example, one may take

$$\mathcal{O}_R = \{(x^0, \vec{x}) : |x^0| + |\vec{x}| < R\}, \qquad R \geq 1.$$

A bounded operator $B \in \mathcal{B}(\mathcal{H})$ is *almost local* if there are bounded operators $B_R \in \mathcal{A}(\mathcal{O}_R)$ such that, for every integer $N \geq 1$, there is a constant $C_N < \infty$ with

$$\|B - B_R\| \leq C_N R^{-N} \qquad (R \geq 1).$$

The particle must be creatable from the vacuum by local operations. In the present scalar setting this means that there is a local operator A such that

$$P_1 A\Omega \neq 0.$$

Definition 17.4 (Spectrally filtered interpolating creator)**.** Choose a Schwartz test function $\chi \in \mathcal{S}(\mathbb{R}^D)$ whose Fourier transform is supported in a small neighborhood of the positive mass shell Σ_m^+ and avoids the rest of the energy-momentum spectrum. Define

$$B = A(\chi) = \int_{\mathbb{R}^D} \mathrm{d}^D x\, \chi(x)\, A(x), \qquad A(x) = U(x)AU(x)^{-1}.$$

Proposition 17.5 (Filtered local creators are almost local)**.** *If $A \in \mathcal{A}(O)$ is bounded and $\chi \in \mathcal{S}(\mathbb{R}^D)$, then the filtered operator $B = A(\chi)$ of Definition 17.4 is almost local. If the support of $\widehat{\chi}$ meets the joint spectrum of P^μ only on the isolated one-particle shell in Definition 17.1, then $B\Omega$ has no spectral component outside $\mathcal{H}_1$ in that support window.*

Proof. Let O be contained in a double cone of radius R_0. Choose smooth cutoff functions θ_R on spacetime, equal to 1 on $\{x : |x^0| + |\vec{x}| \le R\}$, supported in $\{x : |x^0| + |\vec{x}| \le 2R\}$, and with derivatives bounded uniformly after rescaling. Define

$$B_R = \int \mathrm{d}^D x\, \theta_R(x)\chi(x)A(x).$$

The integral is a norm-convergent Bochner integral because $\chi \in \mathcal{S}(\mathbb{R}^D)$ and $\|A(x)\| = \|A\|$. Since $\operatorname{supp}\theta_R$ is bounded and $A(x)$ is localized in $O + x$, the operator B_R belongs to the local algebra of a double cone whose radius is $2R + R_0$. Reindexing the cofinal family of double cones is irrelevant in the definition of almost locality.

The tail is bounded in operator norm by

$$\|B - B_R\| \le \|A\| \int_{|x^0|+|\vec{x}|\ge R} \mathrm{d}^D x\, |\chi(x)|.$$

For every N, the Schwartz seminorm $\sup_x (1+|x^0|+|\vec{x}|)^{N+D+1}|\chi(x)|$ is finite, and the last integral is bounded by $C_N R^{-N}$. Hence B is almost local.

For the spectral statement, write the joint spectral measure of P^μ as $E(\cdot)$ and use the Fourier convention

$$\widehat{\chi}(p) = \int \mathrm{d}^D x\, \chi(x)\mathrm{e}^{\mathrm{i}x_\mu p^\mu}.$$

Because $U(x)\Omega = \Omega$,

$$B\Omega = \int \mathrm{d}^D x\, \chi(x)U(x)A\Omega = \int_{\mathrm{Spec}(P)} \widehat{\chi}(p)\, \mathrm{d}E(p)A\Omega,$$

where the last equality is the joint spectral theorem applied to the vector $A\Omega$. Thus $B\Omega$ has spectral support contained in $\operatorname{supp}\widehat{\chi} \cap \mathrm{Spec}(P)$. If this set is contained in the isolated mass shell Σ_m^+, the corresponding vector lies in $E(\Sigma_m^+)\mathcal{H} = \mathcal{H}_1$, and all components outside $\mathcal{H}_1$ in the chosen support window vanish. $\square$

Let $h \in C_c^\infty(\mathbb{R}^d)$ be a smooth compactly supported momentum wave packet. Define the positive-energy Klein–Gordon solution

$$h_t(\vec{x}) = \int \frac{\mathrm{d}^d \vec{p}}{(2\pi)^d}\, h(\vec{p})\, \mathrm{e}^{\mathrm{i}\omega_{\vec{p}}t - \mathrm{i}\vec{p}\cdot\vec{x}}.$$

The associated Haag–Ruelle operator is

$$B_t(h) = \int_{\mathbb{R}^d} \mathrm{d}^d\vec{x}\, h_t(\vec{x})\, B(t,\vec{x}), \qquad B(t,\vec{x}) = U(t,\vec{x}) B U(t,\vec{x})^{-1}.$$

The one-particle vector created by this family is

$$\psi_h := P_1 B_t(h)\Omega.$$

It is independent of t. The role of the phase in h_t is precisely to cancel the free time evolution on the mass shell.

Spectral filter and one-particle time independence. Let B be an almost-local operator whose energy-momentum transfer is contained in a neighborhood of Σ_m^+ disjoint from the rest of $\mathrm{Spec}(P)$. Write the one-particle spectral wavefunction of $B\Omega$ as

$$P_1 B\Omega = W_1 b, \qquad b \in L^2(\Sigma_m^+, \mathrm{d}\mu_m).$$

For $h \in C_c^\infty(\mathbb{R}^d)$, the Haag–Ruelle approximant satisfies

$$P_1 B_t(h)\Omega = W_1(bh), \qquad P_1 \frac{\mathrm{d}}{\mathrm{d}t} B_t(h)\Omega = 0.$$

In particular, the one-particle vector represented by $B_t(h)\Omega$ is independent of t. The verification is the mass-shell phase cancellation: because $U(t,\vec{x})\Omega = \Omega$ and P_1 commutes with translations, the mass-shell component of $B(t,\vec{x})\Omega$ is

$$P_1 B(t,\vec{x})\Omega = W_1\left(p \mapsto \mathrm{e}^{-\mathrm{i}\omega_{\vec{p}} t + \mathrm{i}\vec{p}\cdot\vec{x}} b(p)\right),$$

using $a_\mu p^\mu = -t\omega_{\vec{p}} + \vec{x}\cdot\vec{p}$. Substitution in the definition of $B_t(h)$ gives

$$\begin{aligned}
P_1 B_t(h)\Omega &= W_1\left(p \mapsto b(p) \int_{\mathbb{R}^d} \mathrm{d}^d\vec{x}\, h_t(\vec{x}) \mathrm{e}^{-\mathrm{i}\omega_{\vec{p}} t + \mathrm{i}\vec{p}\cdot\vec{x}}\right) \\
&= W_1\left(p \mapsto b(p) \int \frac{\mathrm{d}^d\vec{q}}{(2\pi)^d}\, h(\vec{q}) \mathrm{e}^{\mathrm{i}(\omega_{\vec{q}} - \omega_{\vec{p}})t} \int_{\mathbb{R}^d} \mathrm{d}^d\vec{x}\, \mathrm{e}^{\mathrm{i}(\vec{p}-\vec{q})\cdot\vec{x}}\right) \\
&= W_1(bh).
\end{aligned}$$

The last expression is independent of t. Differentiating the first line under the smooth compactly supported momentum integral gives $P_1 \frac{\mathrm{d}}{\mathrm{d}t} B_t(h)\Omega = 0$.

17.3 Point-Field Smearing and Propagation

The bounded-operator formulation is the cleanest theorem statement. In applications one often starts from a scalar Wightman field $\hat{\phi}(x)$. The same construction is then expressed by smearing $\hat{\phi}$ against spacetime test functions and by choosing the Fourier support so that only the isolated one-particle shell is selected.

Proposition 17.6 (Point-field projection to the isolated shell). *Assume that $\hat{\phi}$ is a scalar local field whose matrix element between the vacuum and the one-particle sector is nonzero. The kets below are generalized vectors in the rigged-Hilbert-space sense of Section 5.2. With relativistically normalized generalized one-particle kets,*

$$\langle q|p\rangle = (2\pi)^d 2\omega_{\vec{p}}\,\delta^{(d)}(\vec{q}-\vec{p}), \qquad \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\,|p\rangle\langle p| = \mathbf{1}_{\mathcal{H}_1},$$

where

$$\mathrm{d}\mu_m(p) = \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d 2\omega_{\vec{p}}}, \qquad p = (\omega_{\vec{p}}, \vec{p}),$$

the one-particle part of $\hat{\phi}(x)\Omega$ has the form

$$P_1\hat{\phi}(x)\Omega = Z_\phi^{1/2}\int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\,\mathrm{e}^{-\mathrm{i}p\cdot x}|p\rangle.$$

Here $Z_\phi > 0$ is the residue of the two-point function at this particular field's one-particle pole. All remaining spectral components of $\hat{\phi}(x)\Omega$ have invariant mass separated from m by the assumed gap.

Let

$$f(x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D}\,\tilde{f}(k)\,\mathrm{e}^{\mathrm{i}k\cdot x}, \qquad \hat{\phi}_f = \int \mathrm{d}^D x\, f(x)\hat{\phi}(x).$$

If $\tilde{f}$ is supported in a small neighborhood of Σ_m^+ and away from the rest of the energy-momentum spectrum, then

$$\hat{\phi}_f\Omega = Z_\phi^{1/2}\int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\,\tilde{f}(p)|p\rangle,$$

with no continuum contribution.

Proof. The point-field expression is a distributional statement. The actual Hilbert vectors are obtained after smearing in x. In the scalar multiplicity-one sector, define the one-particle form-factor distribution by

$$F_x(p) = \langle p|\hat{\phi}(x)\Omega\rangle.$$

Translation covariance and $U(x)\Omega = \Omega$ give

$$F_x(p) = \langle p|U(x)\hat{\phi}(0)\Omega\rangle = \mathrm{e}^{-\mathrm{i}p\cdot x}F_0(p),$$

because $U(x)|p\rangle = \mathrm{e}^{\mathrm{i}p\cdot x}|p\rangle$. Scalar Lorentz covariance gives $F_0(\Lambda p) = F_0(p)$ on the positive mass shell. Since Σ_m^+ is a single $SO^+(1,d)$-orbit and the multiplicity space is $\mathbb{C}$, F_0 is a constant distribution on the shell. After fixing the phase of the interpolating field, write this constant as $Z_\phi^{1/2} > 0$; equivalently $Z_\phi = |F_0|^2$ is the coefficient of the one-particle delta mass in the Källén–Lehmann measure of this field.

Therefore, in the rigged-Hilbert notation,

$$P_1\hat{\phi}(x)\Omega = Z_\phi^{1/2}\int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\,\mathrm{e}^{-\mathrm{i}p\cdot x}|p\rangle.$$

For a Schwartz smearing function with

$$f(x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \tilde{f}(k) \mathrm{e}^{\mathrm{i}k\cdot x},$$

pairing this distribution with f gives

$$P_1 \hat{\phi}_f \Omega = Z_\phi^{1/2} \int_{\Sigma_m^+} \mathrm{d}\mu_m(p) \left(\int \mathrm{d}^D x\, f(x) \mathrm{e}^{-\mathrm{i}p\cdot x} \right) |p\rangle = Z_\phi^{1/2} \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, \tilde{f}(p) |p\rangle.$$

The remaining spectral part of the smeared vector $\hat{\phi}_f \Omega$ is obtained by applying the joint spectral measure of P^μ to the part of the field-created distribution supported away from the isolated shell. If $\operatorname{supp} \tilde{f}$ is contained in the chosen isolated-shell neighborhood and avoids the rest of the spectrum, that spectral projection is zero. The displayed mass-shell integral is then the full vector $\hat{\phi}_f \Omega$. □

A Gaussian packet centered near a spacetime point $(t_*, \vec{x}_*)$ and a momentum $(E_*, \vec{P}_*)$ may be used as an approximation,

$$f(x) = \exp\left[-\frac{(x^0 - t_*)^2 + |\vec{x} - \vec{x}_*|^2}{L^2} + \mathrm{i}\vec{P}_* \cdot (\vec{x} - \vec{x}_*) - \mathrm{i}E_*(x^0 - t_*) \right], \qquad E_*^2 = \vec{P}_*^{\,2} + m^2.$$

For exact spectral separation it is better to choose $\tilde{f}$ smooth and compactly supported in momentum space; the spacetime function is then rapidly decreasing rather than compactly supported. This is the analytic setting used by Haag–Ruelle theory.

Define the translated family $f^{(T)}$ by

$$\tilde{f}^{(T)}(k) = \mathrm{e}^{\mathrm{i}(k^0 - \omega_{\vec{k}})T} \tilde{f}(k), \qquad \omega_{\vec{k}} = \sqrt{\vec{k}^{\,2} + m^2}.$$

On the positive mass shell the extra phase is equal to 1. Consequently

$$P_1 \hat{\phi}_{f^{(T)}} \Omega = P_1 \hat{\phi}_f \Omega$$

for all T, while the spacetime profile of the smearing function moves. In position space,

$$\begin{aligned} f^{(T)}(x^0, \vec{x}) &= \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, \mathrm{e}^{\mathrm{i}k\cdot x + \mathrm{i}(k^0 - \omega_{\vec{k}})T} \tilde{f}(k) \\ &= \int \mathrm{d}^d \vec{y}\, K(\vec{x} - \vec{y}; T)\, f(x^0 - T, \vec{y}), \end{aligned}$$

where

$$K(\vec{x}; T) = \int \frac{\mathrm{d}^d \vec{k}}{(2\pi)^d}\, \mathrm{e}^{\mathrm{i}\vec{k}\cdot\vec{x} - \mathrm{i}\omega_{\vec{k}} T}.$$

The kernel satisfies the Klein–Gordon equation in the variables $(T, \vec{x})$,

$$\left(\partial_T^2 - \Delta_{\vec{x}} + m^2 \right) K(\vec{x}; T) = 0, \qquad K(\vec{x}; 0) = \delta^{(d)}(\vec{x})$$

in the distributional sense. If $\tilde{f}$ is concentrated near $\vec{P}_*$, stationary phase shows that the packet center moves as

$$(t_*, \vec{x}_*) \longmapsto (t_* + T, \vec{x}_* + \vec{v}_* T), \qquad \vec{v}_* = \nabla_{\vec{p}} \omega_{\vec{p}} \big|_{\vec{p} = \vec{P}_*} = \frac{\vec{P}_*}{E_*}.$$

Thus the same one-particle vector may be represented by smearing a local field over different large spacetime regions. The equality is only after projection to $\mathcal{H}_1$; the parts outside the isolated shell are removed by the spectral support condition.

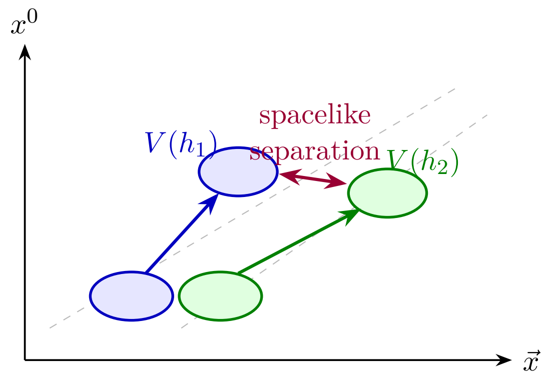
The velocity support of h is

$$V(h) = \left\{ \frac{\vec{p}}{\omega_{\vec{p}}} : \vec{p} \in \operatorname{supp} h \right\} \subset \mathbb{R}^d.$$

Stationary phase gives the spacetime localization of h_t: for large $|t|$, the wave packet is concentrated near rays

$$\vec{x} = t\, \frac{\vec{p}}{\omega_{\vec{p}}}, \qquad \vec{p} \in \operatorname{supp} h.$$

Thus two wave packets with disjoint velocity supports become spacelike separated as $|t| \to \infty$.



17.4 Velocity Support Separation

The phrase "disjoint velocity supports" has a precise geometric content. Let $K_i = \operatorname{supp} h_i$ and set

$$V_i = \left\{ \vec{p}/\omega_{\vec{p}} : \vec{p} \in K_i \right\}.$$

If $V_i \cap V_j = \varnothing$, compactness gives a number

$$\delta_{ij} := \operatorname{dist}(V_i, V_j) > 0.$$

Choose $0 < \epsilon < \delta_{ij}/4$ and define the equal-time tubes

$$\Gamma_i(t, \epsilon) = \{\vec{x} \in \mathbb{R}^d : \operatorname{dist}(\vec{x}/t, V_i) < \epsilon\} \qquad (t \neq 0).$$

For $\vec{x} \in \Gamma_i(t, \epsilon)$ and $\vec{y} \in \Gamma_j(t, \epsilon)$,

$$|\vec{x} - \vec{y}| \geq |t|(\delta_{ij} - 2\epsilon) \geq \frac{1}{2}|t|\delta_{ij}.$$

The spacetime points $(t, \vec{x})$ and $(t, \vec{y})$ are therefore spacelike separated with a separation growing linearly in $|t|$.

The part of $h_{i,t}$ outside $\Gamma_i(t,\epsilon)$ is rapidly decreasing. Indeed, away from the stationary set $\vec{x}/t = \vec{p}/\omega_{\vec{p}}$, the phase

$$\omega_{\vec{p}}t - \vec{p}\cdot\vec{x}$$

has no stationary point on K_i, and repeated integration by parts in $\vec{p}$ gives a bound $O(|t|^{-N})$ for every N. Thus the Haag–Ruelle operators can be replaced, up to rapidly decreasing errors, by almost-local operators supported in mutually spacelike tubes. Locality then turns geometric separation into the commutator estimate used in the existence proof.

Proposition 17.7 (Velocity-tube separation and off-tube decay)**.** *Let $h \in C_c^\infty(\mathbb{R}^d)$, and let*

$$V(h) = \{\nabla_{\vec{p}}\omega_{\vec{p}} : \vec{p} \in \operatorname{supp} h\}.$$

For every $\epsilon > 0$ and every $N \geq 1$, there is $C_{N,\epsilon}$ such that

$$\sup_{\operatorname{dist}(\vec{x}/t, V(h)) \geq \epsilon} |h_t(\vec{x})| \leq C_{N,\epsilon}(1+|t|)^{-N}, \qquad |t| \geq 1.$$

If h_i, h_j have compact velocity supports with $\delta_{ij} = \operatorname{dist}(V(h_i), V(h_j)) > 0$, then for $0 < \epsilon < \delta_{ij}/4$ and $\vec{x} \in \Gamma_i(t,\epsilon)$, $\vec{y} \in \Gamma_j(t,\epsilon)$,

$$|\vec{x} - \vec{y}| \geq \frac{1}{2}\delta_{ij}|t|.$$

Thus the equal-time spacetime points $(t,\vec{x})$ and $(t,\vec{y})$ are spacelike separated by a distance growing linearly in $|t|$.

Proof. Write

$$h_t(\vec{x}) = \int \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d} h(\vec{p})\, \mathrm{e}^{\mathrm{i}t\Phi_{\vec{x}/t}(\vec{p})}, \qquad \Phi_{\vec{u}}(\vec{p}) = \omega_{\vec{p}} - \vec{p}\cdot\vec{u}.$$

On the compact set $\operatorname{supp} h$, the gradient is

$$\nabla_{\vec{p}}\Phi_{\vec{u}}(\vec{p}) = \frac{\vec{p}}{\omega_{\vec{p}}} - \vec{u}.$$

If $\operatorname{dist}(\vec{u}, V(h)) \geq \epsilon$, then $|\nabla_{\vec{p}}\Phi_{\vec{u}}| \geq \epsilon$ on $\operatorname{supp} h$. Apply repeatedly the adjoint of

$$L_{\vec{u}} = \frac{1}{\mathrm{i}t}\frac{\nabla_{\vec{p}}\Phi_{\vec{u}}\cdot\nabla_{\vec{p}}}{|\nabla_{\vec{p}}\Phi_{\vec{u}}|^2}, \qquad L_{\vec{u}}\mathrm{e}^{\mathrm{i}t\Phi_{\vec{u}}} = \mathrm{e}^{\mathrm{i}t\Phi_{\vec{u}}}.$$

Derivatives of $\Phi_{\vec{u}}$ are uniformly bounded for $\vec{p}$ in the fixed compact support and for the relevant $\vec{u}$. Each integration by parts gives a factor $|t|^{-1}$, proving the displayed off-tube estimate.

For the geometric separation, choose $\vec{v}_i \in V(h_i)$ and $\vec{v}_j \in V(h_j)$ with

$$|\vec{x}/t - \vec{v}_i| < \epsilon, \qquad |\vec{y}/t - \vec{v}_j| < \epsilon.$$

Then

$$|\vec{x} - \vec{y}| = |t|\,|\vec{x}/t - \vec{y}/t| \geq |t|(\delta_{ij} - 2\epsilon) \geq \frac{1}{2}\delta_{ij}|t|.$$

Equal-time separation is spacelike when $\vec{x} \neq \vec{y}$, since the Minkowski squared separation is $|\vec{x} - \vec{y}|^2$. ∎

17.5 Multi-Particle Limits

Let $B_1, \dots, B_n$ be almost-local operators obtained as above, and let $h_1, \dots, h_n \in C_c^\infty(\mathbb{R}^d)$ have pairwise disjoint velocity supports. Define the time-dependent vector

$$\Psi_t(h_1, \dots, h_n) = B_{1,t}(h_1) \cdots B_{n,t}(h_n)\Omega.$$

Proposition 17.8 (Cook estimate form of the Haag–Ruelle limits)**.** *Assume the locality, spectrum, isolated-shell, and regularity hypotheses stated above. Suppose, in addition, that the Haag–Ruelle product $\Psi_t(h_1, \dots, h_n)$ is strongly differentiable on the large-time tails and that there are integrable functions $R_\pm$ such that*

$$\left\| \frac{\mathrm{d}}{\mathrm{d}t} \Psi_t(h_1, \dots, h_n) \right\| \le R_+(t) \quad (t \ge T_0), \qquad \left\| \frac{\mathrm{d}}{\mathrm{d}t} \Psi_t(h_1, \dots, h_n) \right\| \le R_-(t) \quad (t \le -T_0).$$

Suppose also that the recursive scalar-product contraction estimates hold: large-time scalar products of velocity-separated products are obtained by pairing one-particle vectors, up to errors that vanish on the large-time tails. Finally, suppose the same Cook and contraction estimates hold after replacing one creator by the difference of two creators with the same one-particle vector. Then the limits

$$\Psi^{\mathrm{out}}(h_1, \dots, h_n) = \lim_{t \to +\infty} \Psi_t(h_1, \dots, h_n),$$

$$\Psi^{\mathrm{in}}(h_1, \dots, h_n) = \lim_{t \to -\infty} \Psi_t(h_1, \dots, h_n)$$

exist in the norm topology of $\mathcal{H}$. The limits depend only on the one-particle vectors

$$\psi_j = P_1 B_{j,t}(h_j)\Omega \in \mathcal{H}_1, \qquad j = 1, \dots, n,$$

and not on the auxiliary operators B_j used to interpolate them.

Proof. For $t' > t \ge T_0$,

$$\|\Psi_{t'} - \Psi_t\| \le \int_t^{t'} \left\| \frac{\mathrm{d}}{\mathrm{d}s} \Psi_s \right\| \mathrm{d}s \le \int_t^{t'} R_+(s)\, \mathrm{d}s.$$

Since $R_+ \in L^1([T_0, \infty))$, the right side tends to zero when $t, t' \to +\infty$. Hence Ψ_t is Cauchy in the Hilbert norm and has an outgoing limit. The incoming proof is identical with R_- on the negative tail.

If B_j and B_j' have the same one-particle vector, multilinearity writes the difference of the two n-particle approximants as a finite sum in which one factor is $D_j = B_j - B_j'$. For that factor

$$P_1 D_{j,t}(h_j)\Omega = 0.$$

The assumed Cook estimate for such zero-one-particle replacements implies that each difference term has a norm limit. Its limiting Fock inner product with all velocity-separated Haag–Ruelle vectors is zero, because the recursive contraction of asymptotic scalar products contains no one-particle contraction for the D_j entry. Density of the velocity-separated algebraic Fock domain then gives that this limit vector is zero. Thus the large-time vector depends only on $\psi_j = P_1 B_{j,t}(h_j)\Omega$. □

The proposition has two analytic inputs. First, disjoint velocity supports imply that the effective localization regions of $B_{j,t}(h_j)$ separate spacelike at large $|t|$. Locality then gives rapid decay of commutators

$$[B_{i,t}(h_i), B_{j,t}(h_j)]$$

for $i \neq j$. Second, spectral isolation of the mass shell controls the part of $B_{j,t}(h_j)\Omega$ orthogonal to $\mathcal{H}_1$. In Cook's method one estimates $\frac{\mathrm{d}}{\mathrm{d}t}\Psi_t$; the commutator terms and the orthogonal spectral-error terms are integrable in t, hence Ψ_t is a Cauchy family at $+\infty$ and at $-\infty$.

For $n = 2$, the essential estimate is visible from the norm difference

$$\|\Psi_{t'} - \Psi_t\|^2 = \langle \Psi_{t'} - \Psi_t, \Psi_{t'} - \Psi_t \rangle.$$

The scalar products entering this expression are vacuum correlation functions of four almost-local operators. At large positive or negative times, the two velocity clusters are separated by spacelike distances growing linearly in $|t|$. The cluster property and locality reduce the large-time scalar product to the product of the corresponding one-particle scalar products.

In the point-field notation above, for two packets with disjoint velocity supports one may write

$$\Psi_T = \hat{\phi}_{f_1^{(T)}} \hat{\phi}_{f_2^{(T)}} \Omega.$$

For fixed ΔT,

$$\langle \Psi_T, \Psi_{T+\Delta T} \rangle = \langle \Omega | \hat{\phi}^*_{f_2^{(T)}} \hat{\phi}^*_{f_1^{(T)}} \hat{\phi}_{f_1^{(T+\Delta T)}} \hat{\phi}_{f_2^{(T+\Delta T)}} | \Omega \rangle.$$

As $T \to +\infty$ or $T \to -\infty$, the two spacetime clusters separate spacelike. The vacuum cluster property gives

$$\langle \Psi_T, \Psi_{T+\Delta T} \rangle - \langle \hat{\phi}_{f_1}\Omega, \hat{\phi}_{f_1}\Omega \rangle \langle \hat{\phi}_{f_2}\Omega, \hat{\phi}_{f_2}\Omega \rangle \longrightarrow 0,$$

and the same limit is obtained for $\Delta T = 0$. Therefore

$$\|\Psi_{T+\Delta T} - \Psi_T\| \longrightarrow 0.$$

Under the smooth spectral separation hypotheses of Haag–Ruelle theory, the error decreases faster than any inverse power of $|T|$. This explicit two-packet calculation is the concrete model for the general Cook estimate.

17.6 The Estimate Behind the Limit

The preceding proposition is a norm-convergence statement. Its proof is governed by an estimate of the following form. Let $B_{i,t}(h_i)$ and $B_{j,t}(h_j)$ be Haag–Ruelle operators with disjoint velocity supports. For every $N \geq 1$, almost locality and stationary phase give constants C_N such that

$$\|[B_{i,t}(h_i), B_{j,t}(h_j)]\| \leq C_N (1 + |t|)^{-N} \tag{17.1}$$

for sufficiently large $|t|$. The estimate says more than that the operators eventually commute: it gives an integrable error.

The time derivative of a single approximant has no one-particle component:

$$P_1 \frac{\mathrm{d}}{\mathrm{d}t} B_{j,t}(h_j)\Omega = 0.$$

The remaining spectral support lies away from the isolated mass shell. By choosing the energy-momentum support of the smearing function χ inside the mass-gap neighborhood, that remainder is controlled by integration by parts in the energy variable. In the multi-particle product, $\frac{\mathrm{d}}{\mathrm{d}t}\Psi_t$ is a sum of terms in which either a one-particle remainder appears or two factors must be commuted past each other. The one-particle remainders are integrable by the spectral gap, and the commutator terms are integrable by (17.1). Therefore

$$\int_T^\infty \left\| \frac{\mathrm{d}}{\mathrm{d}t}\Psi_t \right\| \mathrm{d}t \longrightarrow 0 \qquad (T \to \infty),$$

which is Cook's Cauchy criterion for the outgoing limit. The incoming limit is the same argument with $t \to -\infty$.

This estimate is the point at which locality, spectrum, and particle stability meet. Without locality the commutator decay is unavailable; without the spectral gap the one-particle remainder need not be integrable; without positive energy the large-time stationary-phase localization has no stable direction of propagation.

17.7 Fock Structure and Wave Operators

Definition 17.9 (Scalar asymptotic Fock space)**.** Let

$$\mathcal{F}_s(\mathcal{H}_1) = \bigoplus_{n=0}^{\infty} \mathcal{H}_1^{\odot n}$$

be the bosonic Fock space over $\mathcal{H}_1$, where $\mathcal{H}_1^{\odot n}$ denotes the symmetric n-fold tensor product and $\mathcal{H}_1^{\odot 0} = \mathbb{C}\Omega_F$. The vector Ω_F is the Fock vacuum.

The construction is intrinsic: it is the Hilbert completion of the algebraic finite symmetric tensor algebra over $\mathcal{H}_1$. The mass-shell model above turns this intrinsic object into the familiar wave-function representation

$$\mathcal{F}_s(\mathcal{H}_1) \simeq \mathbb{C}\Omega_F \oplus \bigoplus_{n\geq 1} L^2_{\mathrm{sym}}\big((\Sigma_m^+)^n, \mathrm{d}\mu_m(p_1)\cdots \mathrm{d}\mu_m(p_n)\big).$$

Under this identification a decomposable n-particle vector is represented by

$$(f_1 \odot \cdots \odot f_n)(p_1, \dots, p_n) = \frac{1}{\sqrt{n!}} \sum_{\sigma\in S_n} \prod_{j=1}^{n} f_j(p_{\sigma(j)}),$$

which gives

$$\langle f_1 \odot \cdots \odot f_n, g_1 \odot \cdots \odot g_n\rangle = \sum_{\sigma\in S_n} \prod_{j=1}^{n} \langle f_j, g_{\sigma(j)}\rangle_{L^2(\Sigma_m^+, \mathrm{d}\mu_m)}.$$

This is the Fock-space inner product that the Haag–Ruelle limits reproduce inside the physical Hilbert space.

Remark 17.10 (Statistics of the asymptotic Fock space). The notation $\mathcal{F}_s(\mathcal{H}_1)$ is appropriate here because the one-particle sector under discussion is the scalar bosonic sector constructed earlier. For several stable species the asymptotic Fock space is the graded tensor product determined by their statistics: integer-spin bosonic species contribute symmetric factors, while half-integer-spin fermionic species contribute antisymmetric factors. The spin-statistics theorem gives this assignment under the Wightman hypotheses stated in Chapter 40; the present Haag–Ruelle construction uses the scalar instance.

Definition 17.11 (Haag–Ruelle wave operators on the separated algebraic domain)**.** The asymptotic identifications from the free Fock space $\mathcal{F}_s(\mathcal{H}_1)$ to the physical Hilbert space are called the incoming and outgoing Haag–Ruelle wave operators. On the dense algebraic domain generated by velocity-separated decomposable vectors, each wave operator assigns to an abstract collection of asymptotic one-particle wave packets the physical Hilbert-space vector obtained as a large-time Haag–Ruelle limit.

The topology in this statement is pointwise Hilbert-norm convergence on the asymptotic Fock domain. Choose, for a dense algebraic subspace $\mathcal{F}^{\mathrm{alg}}_{s,\mathrm{sep}}(\mathcal{H}_1) \subset \mathcal{F}_s(\mathcal{H}_1)$, Haag–Ruelle creators and velocity-separated wave packets representing each decomposable vector F. The time-dependent identification map $\Omega^{\mathrm{HR}}_{\mathrm{out},t}$ is defined on that vector by the corresponding product of Haag–Ruelle operators applied to the vacuum. The Cook-limit statement says

$$\lim_{t\to+\infty} \left\|\Omega^{\mathrm{HR}}_{\mathrm{out},t}F - \Omega_{\mathrm{out}}F\right\|_{\mathcal{H}} = 0, \qquad F \in \mathcal{F}^{\mathrm{alg}}_{s,\mathrm{sep}}(\mathcal{H}_1), \tag{17.2}$$

and analogously for $t \to -\infty$ and Ω_{in}. Packaged as maps from the asymptotic Fock domain to $\mathcal{H}$, this is strong operator convergence on that domain: convergence holds after applying the approximating map to each fixed vector F. The weak convergence of all matrix elements $\langle \eta, \Omega^{\mathrm{HR}}_{\mathrm{out},t}F\rangle$ follows immediately from (17.2), while the converse weak statement does not by itself give the isometric wave operator. Operator-norm convergence,

$$\sup_{\|F\|_{\mathcal{F}_s}=1} \left\|\Omega^{\mathrm{HR}}_{\mathrm{out},t}F - \Omega_{\mathrm{out}}F\right\|_{\mathcal{H}} \longrightarrow 0,$$

is not asserted in Haag–Ruelle theory. The isometric extension of $\Omega_{\mathrm{out/in}}$ to all of $\mathcal{F}_s(\mathcal{H}_1)$ is obtained after the Fock inner product has been reproduced on the dense algebraic domain.

Proposition 17.12 (Definition and isometry of the scalar Haag–Ruelle maps)**.** *Under the Cook and scalar-product contraction hypotheses of Proposition 17.8, the following assignments on velocity-separated decomposable vectors are well-defined:*

$$\Omega_{\mathrm{out}}(\psi_1 \odot \cdots \odot \psi_n) = \Psi^{\mathrm{out}}(h_1, \dots, h_n),$$
$$\Omega_{\mathrm{in}}(\psi_1 \odot \cdots \odot \psi_n) = \Psi^{\mathrm{in}}(h_1, \dots, h_n),$$

where $\psi_j = P_1 B_{j,t}(h_j)\Omega$. The Cook-limit statement above makes these definitions independent of the choice of interpolating operators. By linearity and continuity they extend from such vectors to all of $\mathcal{F}_s(\mathcal{H}_1)$.

The Fock inner product is reproduced by the Hilbert-space inner product of asymptotic states:

$$\begin{aligned}&\left\langle \Psi^{\mathrm{out}}(\psi_1, \dots, \psi_n), \Psi^{\mathrm{out}}(\varphi_1, \dots, \varphi_m)\right\rangle_{\mathcal{H}} \\ &= \delta_{nm} \sum_{\sigma\in S_n} \prod_{j=1}^{n} \langle \psi_j, \varphi_{\sigma(j)}\rangle_{\mathcal{H}_1},\end{aligned}$$

and the same formula holds for incoming states. Therefore

$$\Omega_{\rm out}, \Omega_{\rm in} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{H}$$

are isometric wave operators. Their ranges are the outgoing and incoming scattering subspaces,

$$\mathcal{H}_{\rm out} = \operatorname{Ran}\Omega_{\rm out}, \qquad \mathcal{H}_{\rm in} = \operatorname{Ran}\Omega_{\rm in}.$$

Proof. Suppose two choices of almost-local creators and wave packets give the same one-particle vector ψ_j. The Cook-limit hypothesis gives large-time limits for both choices, and the independence part of Proposition 17.8 says that the difference of the two limiting vectors has Hilbert norm zero. Hence the assignment depends only on $\psi_1, \ldots, \psi_n$, not on the interpolating coordinates used to produce them.

On the velocity-separated algebraic domain, the scalar-product contraction estimate of Proposition 17.8 gives the permanent formula displayed above. That formula is precisely the inner product of the symmetric Fock tensor $\psi_1 \odot \cdots \odot \psi_n$ with $\varphi_1 \odot \cdots \odot \varphi_m$. Thus the map preserves inner products on a dense subspace of $\mathcal{F}_s(\mathcal{H}_1)$. A norm-preserving linear map on a dense subspace extends uniquely to an isometry on the Hilbert completion, and the range of an isometry is closed because a Cauchy sequence of image vectors has a Cauchy preimage sequence. $\square$

The Poincare group acts on $\mathcal{F}_s(\mathcal{H}_1)$ by the free Fock representation U_F induced from its action on $\mathcal{H}_1$. The Haag–Ruelle wave operators intertwine the physical and free actions:

$$U(a,\Lambda)\Omega_{\rm out/in} = \Omega_{\rm out/in} U_F(a,\Lambda).$$

This equation states that an asymptotic n-particle state transforms as the corresponding symmetrized tensor product of one-particle Wigner states.

Equivalently, the wave operators may be described by generalized momentum kernels. For bosons,

$$\begin{aligned} &{}^{\rm out/in}\langle q_1, \ldots, q_m | p_1, \ldots, p_n \rangle^{\rm out/in} \\ &\qquad = \delta_{mn} \sum_{\sigma \in S_n} \prod_{j=1}^{n} (2\pi)^d 2\omega_{\vec{p}_j}\, \delta^{(d)}(\vec{q}_j - \vec{p}_{\sigma(j)}). \end{aligned}$$

For smooth wave packets,

$$\Psi^{\rm out/in}(f_1, \ldots, f_n) = Z_\phi^{n/2} \int \prod_{j=1}^{n} \mathrm{d}\mu_m(p_j) \prod_{j=1}^{n} \tilde{f}_j(p_j)\, |p_1, \ldots, p_n\rangle^{\rm out/in},$$

whenever the f_j are chosen with separated velocity supports. This is the precise form of the statement that either the incoming or the outgoing asymptotic basis labels states by free particle momenta, while the comparison between the two bases is the scattering matrix.

$$\begin{tikzcd} \mathcal{F}_s(\mathcal{H}_1) \arrow[r, "\Omega_{\rm in}"] \arrow[d, "S"'] & \mathcal{H}_{\rm in} \subset \mathcal{H} \arrow[d, dashed, leftrightarrow] \\ \mathcal{F}_s(\mathcal{H}_1) \arrow[r, "\Omega_{\rm out}"'] & \mathcal{H}_{\rm out} \subset \mathcal{H} \end{tikzcd}$$

17.8 The Scattering Operator

Definition 17.13 (Scattering operator in a massive Haag–Ruelle sector)**.** If

$$\mathcal{H}_{\mathrm{in}} = \mathcal{H}_{\mathrm{out}},$$

then incoming scattering states evolve into outgoing scattering states in the sector under consideration. The scattering operator on the asymptotic Fock space is

$$S = \Omega_{\mathrm{out}}^* \Omega_{\mathrm{in}} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{F}_s(\mathcal{H}_1).$$

Unitarity and matrix elements of S. When the incoming and outgoing ranges coincide, the operator

$$S = \Omega_{\mathrm{out}}^* \Omega_{\mathrm{in}}$$

is unitary. The matrix element between an incoming n-particle wave packet $\psi_1 \odot \cdots \odot \psi_n$ and an outgoing m-particle wave packet $\varphi_1 \odot \cdots \odot \varphi_m$ is

$$\begin{aligned}
&\langle \varphi_1 \odot \cdots \odot \varphi_m,\, S(\psi_1 \odot \cdots \odot \psi_n)\rangle_{\mathcal{F}_s(\mathcal{H}_1)} \\
&\qquad = \langle \Omega_{\mathrm{out}}(\varphi_1 \odot \cdots \odot \varphi_m),\, \Omega_{\mathrm{in}}(\psi_1 \odot \cdots \odot \psi_n)\rangle_{\mathcal{H}}\,.
\end{aligned}$$

This equation is the nonperturbative definition of the scattering matrix elements in the massive sector. The right hand side is an inner product in the physical Hilbert space; the left hand side records the same number in the free asymptotic particle basis. Let $\mathcal{R} = \operatorname{Ran}\Omega_{\mathrm{in}} = \operatorname{Ran}\Omega_{\mathrm{out}}$. Because the wave operators are isometries from $\mathcal{F}_s(\mathcal{H}_1)$ onto $\mathcal{R}$,

$$\Omega_{\mathrm{in}}^*\Omega_{\mathrm{in}} = \Omega_{\mathrm{out}}^*\Omega_{\mathrm{out}} = I_{\mathcal{F}_s(\mathcal{H}_1)}, \qquad \Omega_{\mathrm{in}}\Omega_{\mathrm{in}}^* = \Omega_{\mathrm{out}}\Omega_{\mathrm{out}}^* = P_{\mathcal{R}}.$$

Consequently

$$S^*S = \Omega_{\mathrm{in}}^*\Omega_{\mathrm{out}}\Omega_{\mathrm{out}}^*\Omega_{\mathrm{in}} = \Omega_{\mathrm{in}}^* P_{\mathcal{R}} \Omega_{\mathrm{in}} = I_{\mathcal{F}_s(\mathcal{H}_1)}$$

using $S^* = \Omega_{\mathrm{in}}^*\Omega_{\mathrm{out}}$, and

$$SS^* = \Omega_{\mathrm{out}}^*\Omega_{\mathrm{in}}\Omega_{\mathrm{in}}^*\Omega_{\mathrm{out}} = \Omega_{\mathrm{out}}^* P_{\mathcal{R}} \Omega_{\mathrm{out}} = I_{\mathcal{F}_s(\mathcal{H}_1)}.$$

Thus S is unitary. For asymptotic vectors $\Phi, \Psi \in \mathcal{F}_s(\mathcal{H}_1)$, the defining property of the Hilbert adjoint gives

$$\langle \Phi, S\Psi\rangle = \langle \Phi, \Omega_{\mathrm{out}}^*\Omega_{\mathrm{in}}\Psi\rangle = \langle \Omega_{\mathrm{out}}\Phi, \Omega_{\mathrm{in}}\Psi\rangle_{\mathcal{H}},$$

which is the displayed matrix-element formula after substituting the symmetrized tensor wave packets.

Definition 17.14 (Range and completeness statements)**.** There are three logically distinct range statements.

(a) *Range coincidence for the chosen asymptotic species.* The equality

$$\mathcal{H}_{\mathrm{in}} = \mathcal{H}_{\mathrm{out}} =: \mathcal{H}_{\mathrm{sc}}$$

says that the incoming and outgoing Haag–Ruelle constructions based on the selected isolated one-particle subspace have the same physical range. This is exactly the hypothesis needed for S above to be a unitary operator on the corresponding asymptotic Fock space.

(b) *Completeness in a specified massive scattering sector.* Let $\mathcal{H}_{\text{sec}} \subset \mathcal{H}$ be a closed reducing subspace selected by superselection charge, mass gap, and a finite list of stable isolated particle species. Replacing $\mathcal{F}_s(\mathcal{H}_1)$ by the appropriate graded Fock space over the direct sum of those one-particle spaces, sector completeness is the statement

$$\mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}} = \mathcal{H}_{\text{sec}}.$$

This is the level used by later cluster and partial-wave arguments for a closed massive sector: all states in that sector are accounted for by the listed asymptotic particles, while other superselection sectors or other parts of the full theory may remain outside the discussion.

(c) *Full asymptotic completeness.* After including every stable particle species and superselection sector in the physical theory, full asymptotic completeness is the statement

$$\mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}} = \mathcal{H}$$

on the relevant finite-energy physical Hilbert space.

Thus ordinary asymptotic completeness is the last statement: it includes the range coincidence in (a) and asserts that the resulting scattering sector is all of $\mathcal{H}$. The definition of S on a chosen scattering sector requires (a). The later closed-channel unitarity formulae require the sector statement (b) for the sector under analysis. Full asymptotic completeness asserts

$$\mathcal{H} = \mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}}$$

for the whole chosen physical Hilbert space. This is an additional dynamical theorem or hypothesis. For nontrivial interacting massive local Wightman theories in four spacetime dimensions, full asymptotic completeness is presently an open problem rather than a known consequence of the axioms. Proofs exist only in restricted model classes, notably constructive or integrable models in lower spacetime dimensions and related weakened-locality settings.

17.9 Relation to Local Correlation Functions

The construction above produces the S-operator from Hilbert-space limits. It also identifies what a later reduction formula must compute. If $\psi_j = P_1 B_{j,t}(h_j)\Omega$ and $\varphi_i = P_1 C_{i,t}(g_i)\Omega$, then an m-out, n-in matrix element is

$$\begin{aligned}
&\langle \Omega_{\text{out}}(\varphi_1 \odot \cdots \odot \varphi_m),\, \Omega_{\text{in}}(\psi_1 \odot \cdots \odot \psi_n)\rangle_{\mathcal{H}} \\
&\quad = \lim_{T\to+\infty} \langle \Omega | C_{m,T}(g_m)^* \cdots C_{1,T}(g_1)^* B_{1,-T}(h_1) \cdots B_{n,-T}(h_n) | \Omega \rangle.
\end{aligned}$$

For large T, the outgoing packets are localized near future timelike directions and the incoming packets near past timelike directions. Locality permits these vacuum matrix elements to be reorganized into time-ordered correlation functions up to terms that vanish in the scattering limit. The next chapter turns this statement into LSZ reduction: one extracts the above matrix elements from the one-particle poles of time-ordered Green functions.

17.10 Scope of the Massive Construction

The massive Haag–Ruelle construction gives a precise scattering theory for stable particles whose one-particle mass shell is isolated and whose sector is generated by the local creators used in the theorem. Gauge theories require an additional localization check. A local gauge-invariant observable cannot change an unscreened Gauss-law surface charge, so charged particles require charged field algebras or noncompact gauge-invariant dressings rather than ordinary bounded-region observable creators; the algebraic formulation is developed in Chapter 22. Massless particles, long-range gauge forces, infraparticle sectors, and confinement then add further asymptotic questions with their own hypotheses and limiting procedures.

The logical output of this chapter is therefore fixed. A scattering operator has been defined before any LSZ formula and before any perturbative interpretation of Feynman graphs as scattering amplitudes. Perturbative scattering calculations, when available, compute matrix elements of this operator after the reduction theorem has connected the Hilbert-space limits to Green functions.

Chapter 18

LSZ Reduction

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

18.1 The Reduction Problem

Haag–Ruelle theory defines incoming and outgoing scattering states by large-time Hilbert-space limits. LSZ reduction is the theorem that computes matrix elements of that already-defined scattering operator from the singular part of time-ordered Green functions at the one-particle mass shell.

Definition 18.1 (Massive scalar LSZ datum)**.** This chapter keeps the same massive scalar particle as in the Haag–Ruelle chapter. The assumptions are:

1. the particle has mass $m > 0$ and an isolated one-particle subspace $\mathcal{H}_1$;
2. the Haag–Ruelle construction gives isometric wave operators

   $$\Omega_{\mathrm{in}}, \Omega_{\mathrm{out}} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{H}$$

   from the bosonic asymptotic Fock space over $\mathcal{H}_1$;
3. the incoming and outgoing scattering subspaces for this particle coincide, so the scattering operator

   $$S = \Omega_{\mathrm{out}}^* \Omega_{\mathrm{in}}$$

   is unitary on $\mathcal{F}_s(\mathcal{H}_1)$;

4. the scalar local field $\widehat{\phi}$ has nonzero one-particle matrix element;
5. the time-ordered products used below have been defined as distributions.

Definition 18.2 (Relativistic external-state normalization)**.** Let generalized one-particle momentum states, understood as distributional vectors as in Section 5.2, be normalized by

$$\langle \vec{q}|\vec{p}\rangle = (2\pi)^d \, 2\omega_{\vec{p}} \, \delta^{(d)}(\vec{q}-\vec{p}), \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^2+m^2},$$

where $d = D-1$. The Lorentz-invariant mass-shell measure is

$$\mathrm{d}\mu_m(\vec{p}) = \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d \, 2\omega_{\vec{p}}}.$$

The corresponding positive-energy mass shell is

$$\Sigma_m^+ = \{p = (\omega_{\vec{p}}, \vec{p}) : \vec{p} \in \mathbb{R}^d\}.$$

The field normalization on this shell is recorded by the positive number Z_ϕ defined by

$$\langle \Omega|\widehat{\phi}(0)|\vec{p}\rangle = Z_\phi^{1/2}.$$

Kernel notation such as

$${}_{\mathrm{out}}\langle \vec{q}_1, \ldots, \vec{q}_m|\vec{p}_1, \ldots, \vec{p}_n\rangle_{\mathrm{in}}$$

means the distributional kernel obtained after smearing all momenta with smooth compactly supported wave packets.

Definition 18.3 (Wave-packet scattering matrix element)**.** For wave packets $f_i, g_j \in C_c^\infty(\mathbb{R}^d)$, set

$$F_{\mathrm{out}} = f_1 \odot \cdots \odot f_m, \qquad F_{\mathrm{in}} = g_1 \odot \cdots \odot g_n$$

as vectors in $\mathcal{F}_s(\mathcal{H}_1)$, where a momentum-space packet f denotes the one-particle vector

$$\psi_f = \int \mathrm{d}\mu_m(\vec{p}) \, f(\vec{p})|\vec{p}\rangle.$$

The scattering matrix element is the Hilbert-space number

$$\langle F_{\mathrm{out}}, SF_{\mathrm{in}}\rangle_{\mathcal{F}_s(\mathcal{H}_1)} = \langle \Omega_{\mathrm{out}}F_{\mathrm{out}}, \Omega_{\mathrm{in}}F_{\mathrm{in}}\rangle_{\mathcal{H}}.$$

Its connected component is obtained by subtracting the contributions assigned to proper partitions of the incoming and outgoing labels. The partition formula is stated in Section 18.10; the theorem below identifies each connected component with an external one-particle residue of a time-ordered Green function.

18.2 The LSZ Theorem as a Wave-Packet Statement

Let

$$q_i = (q_i^0, \vec{q}_i), \qquad p_j = (p_j^0, \vec{p}_j)$$

be external momentum variables. Their physical boundary values lie on Σ_m^+:

$$q_i^0 = \omega_{\vec{q}_i}, \qquad p_j^0 = \omega_{\vec{p}_j}.$$

Introduce all-incoming Green-function momenta

$$k_i = q_i \quad (1 \le i \le m), \qquad k_{m+j} = -p_j \quad (1 \le j \le n).$$

Let G^{conn}_{m+n} be the connected time-ordered distribution and let $\widetilde{G}^{\mathrm{conn}}_{m+n}$ denote its Fourier transform in the convention of Section 18.8.

For off-shell external variables in a neighborhood of the physical mass shells, define the amputated external-residue distribution

$$\begin{aligned} &\mathcal{L}_{m,n}(q_1, \dots, q_m | p_1, \dots, p_n) \\ &\quad = \left[\prod_{a=1}^{m+n} Z_\phi^{-1/2}\, \mathrm{i}(k_a^2 + m^2) \right] \widetilde{G}^{\mathrm{conn}}_{m+n}(k_1, \dots, k_{m+n}). \end{aligned} \tag{18.1}$$

The notation $\mathcal{L}^{\mathrm{on}}_{m,n}$ denotes the distributional boundary value of (18.1) obtained after smearing the spatial momenta with wave packets, taking the simultaneous external one-particle residues, and then setting $q_i^0 = \omega_{\vec{q}_i}$, $p_j^0 = \omega_{\vec{p}_j}$. Here "residue" means the coefficient of the isolated Feynman denominator in each external variable after the boundary value has been taken. It is not a complex residue in a one-dimensional variable k_a^2; for fixed spatial momentum the meromorphic variable is k_a^0.

Definition 18.4 (LSZ external boundary-value extraction)**.** Let $H(k)$ be a distribution of one external momentum variable, with all other variables already smeared, and suppose that in a neighborhood of the positive or negative mass shell selected by the external wave packet it has the decomposition

$$H(k) = \frac{-\mathrm{i} Z_\phi\, H_{\mathrm{red}}(k)}{k^2 + m^2 - \mathrm{i}0} + H_{\mathrm{less}}(k),$$

where H_{red} has a boundary value on that shell and $(k^2 + m^2) H_{\mathrm{less}}(k)$ has zero boundary value there. The LSZ extraction of that external leg is

$$\mathrm{LSZ}_{\phi,k}\, H := \operatorname*{bv}_{\Sigma_m} \left[Z_\phi^{-1/2}\, \mathrm{i}(k^2 + m^2) H(k) \right].$$

Under the displayed decomposition,

$$\mathrm{LSZ}_{\phi,k}\, H = Z_\phi^{1/2} \operatorname*{bv}_{\Sigma_m} H_{\mathrm{red}}.$$

For several external legs the operation is the iterated distributional boundary value after all spatial momenta have been paired with wave packets.

Theorem 18.5 (LSZ reduction for a massive scalar)**.** *Under the assumptions above,*

$$\begin{aligned} &\big(\langle F_{\mathrm{out}}, S F_{\mathrm{in}} \rangle_{\mathcal{F}_s(\mathcal{H}_1)} \big)_{\mathrm{conn}} \\ &\quad = \int \prod_{i=1}^{m} \mathrm{d}\mu_m(\vec{q}_i)\, f_i(\vec{q}_i)^* \prod_{j=1}^{n} \mathrm{d}\mu_m(\vec{p}_j)\, g_j(\vec{p}_j) \\ &\qquad\quad \times \mathcal{L}^{\mathrm{on}}_{m,n}(q_1, \dots, q_m | p_1, \dots, p_n). \end{aligned} \tag{18.2}$$

The left side is the connected component in the partition expansion of the scattering kernel. The right side is the simultaneous external one-particle residue of the connected time-ordered distribution, paired with the same incoming and outgoing wave packets.

Proof. The theorem compares two already constructed objects. The left side is the Haag–Ruelle scattering matrix element. The right side is obtained from time-ordered boundary-value distributions by connected truncation and external pole extraction. The residue factor $Z_\phi^{-1/2}$ is attached to the chosen interpolating field $\widehat{\phi}$; the resulting scattering matrix element is a Hilbert-space matrix element of S on the asymptotic Fock space.

We give the proof at the level at which the theorem is stated: all external variables are paired with compactly supported wave packets in the isolated mass-shell neighborhood, and the time-ordered products are assumed to be defined distributions with the stated one-particle pole.

First replace the incoming and outgoing Fock wave packets by the Haag–Ruelle approximants from Chapter 17. For large $T > 0$, the connected part of

$$\langle\Omega|\hat{\phi}^*_{f_m^{(T)}}\cdots\hat{\phi}^*_{f_1^{(T)}}\hat{\phi}_{g_1^{(-T)}}\cdots\hat{\phi}_{g_n^{(-T)}}|\Omega\rangle$$

has the same limit as the connected scattering matrix element on the left of (18.2). This is the definition of the Haag–Ruelle in/out vectors together with the connected partition subtraction described in Section 18.10.

Second use locality and the velocity separation of the Haag–Ruelle packets. The outgoing packets lie in future velocity tubes and the incoming packets lie in past velocity tubes. Reordering the corresponding fields into the time-ordered product changes the large-T expression by a term whose norm goes to zero by the same commutator estimates used in the Haag–Ruelle construction. Thus the connected scattering matrix element is the large-time limit of the connected time-ordered distribution smeared with the translated external packets.

Third take the Fourier transform in the external variables. Each outgoing external packet contributes an oscillatory factor selecting the positive-energy pole $k^0 = \omega_{\vec{k}} - \mathrm{i}0$, and each incoming packet, written with all Green-function momenta incoming, contributes the oscillatory factor selecting the negative-energy pole $k^0 = -\omega_{\vec{k}} + \mathrm{i}0$. The Riemann–Lebesgue estimate, equivalently repeated integration by parts away from the selected pole, kills the part regular at the selected shell. The only surviving contribution is the coefficient of

$$\frac{-\mathrm{i}Z_\phi}{k^2 + m^2 - \mathrm{i}0}$$

in every external variable. Definition 18.4 is exactly this coefficient extraction, with one factor $Z_\phi^{-1/2}$ for each external interpolating field.

Finally, after all external residues are extracted, the remaining variables are the physical on-shell momenta $q_i \in \Sigma_m^+$ and $p_j \in \Sigma_m^+$, with all-incoming Green-function momenta $k_i = q_i$ and $k_{m+j} = -p_j$. Pairing this on-shell distribution with the same wave packets gives the right side of (18.2). The disconnected two-point pole factors have been removed by connected truncation on both sides; the full kernel is recovered from connected kernels by the partition formula in Section 18.10. □

18.3 The One-Particle Pole

Definition 18.6 (Interpolating-field pole datum)**.** The matrix element defining Z_ϕ says that $\widehat{\phi}$ is an interpolating scalar field for the particle species under consideration. With the normalization above, the Källén–Lehmann measure of $\widehat{\phi}$ contains the atom

$$\mathrm{d}\rho(s) = Z_\phi \, \delta(s - m^2) \, \mathrm{d}s + \mathrm{d}\rho_{\mathrm{cont}}(s).$$

Consequently the Fourier transform of the time-ordered two-point function has the pole

$$\widetilde{G}_2(k) = \frac{-\mathrm{i}Z_\phi}{k^2 + m^2 - \mathrm{i}0} + \widetilde{G}_{2,\mathrm{less}}(k),$$

where $\widetilde{G}_{2,\mathrm{less}}$ has no pole at the isolated one-particle mass shell. The number Z_ϕ depends on the chosen local field. The particle state and the S-operator are invariant data; changing the interpolating field changes the residue factor appearing in the reduction formula.

The preceding display identifies the coefficient of the invariant Feynman denominator. For fixed $\vec{k}$, the actual meromorphic variable is k^0, and

$$k^2 + m^2 - \mathrm{i}0 = -\big(k^0 - \omega_{\vec{k}} + \mathrm{i}0\big)\big(k^0 + \omega_{\vec{k}} - \mathrm{i}0\big).$$

Consequently

$$\frac{-\mathrm{i}Z_\phi}{k^2 + m^2 - \mathrm{i}0} = \frac{\mathrm{i}Z_\phi}{2\omega_{\vec{k}}} \left[\frac{1}{k^0 - \omega_{\vec{k}} + \mathrm{i}0} - \frac{1}{k^0 + \omega_{\vec{k}} - \mathrm{i}0} \right].$$

Thus the complex residues at the two linear k^0-poles are $\mathrm{i}Z_\phi/(2\omega_{\vec{k}})$ and $-\mathrm{i}Z_\phi/(2\omega_{\vec{k}})$, whereas $-\mathrm{i}Z_\phi$ is the coefficient of the invariant denominator $k^2 + m^2 - \mathrm{i}0$. LSZ uses the latter coefficient, together with the mass-shell measure, to match the Haag–Ruelle one-particle normalization.

The operation

$$Z_\phi^{-1/2} \, \mathrm{i}(k^2 + m^2)$$

removes an external one-particle propagator with the conventions of the Lorentzian Green-function chapter:

$$Z_\phi^{-1/2} \, \mathrm{i}(k^2 + m^2) \, \frac{-\mathrm{i}Z_\phi}{k^2 + m^2 - \mathrm{i}0} \longrightarrow Z_\phi^{1/2}$$

as a mass-shell boundary-value coefficient. Applying one such operation to every external field is the analytic core of LSZ reduction.

Invariant denominator coefficient and linear pole residues. With the mostly-plus convention $k^2 = -(k^0)^2 + \vec{k}^{\,2}$ and $\omega_{\vec{k}} = (\vec{k}^{\,2} + m^2)^{1/2}$,

$$k^2 + m^2 - \mathrm{i}0 = -\big(k^0 - \omega_{\vec{k}} + \mathrm{i}0\big)\big(k^0 + \omega_{\vec{k}} - \mathrm{i}0\big).$$

Consequently the one-particle part of the Feynman two-point function obeys

$$\frac{-\mathrm{i}Z_\phi}{k^2 + m^2 - \mathrm{i}0} = \frac{\mathrm{i}Z_\phi}{2\omega_{\vec{k}}} \left[\frac{1}{k^0 - \omega_{\vec{k}} + \mathrm{i}0} - \frac{1}{k^0 + \omega_{\vec{k}} - \mathrm{i}0} \right],$$

so the coefficient extracted by invariant-denominator LSZ is $-\mathrm{i}Z_\phi$, while the linear k^0-residues are $\mathrm{i}Z_\phi/(2\omega_{\vec{k}})$ and $-\mathrm{i}Z_\phi/(2\omega_{\vec{k}})$. Since

$$k^2 + m^2 = -(k^0)^2 + \omega_{\vec{k}}^2 = -(k^0 - \omega_{\vec{k}})(k^0 + \omega_{\vec{k}}),$$

the displayed Feynman prescription assigns the positive-energy pole below the real k^0-axis and the negative-energy pole above it. The partial-fraction identity

$$\frac{1}{(k^0-\omega_{\vec{k}}+\mathrm{i}0)(k^0+\omega_{\vec{k}}-\mathrm{i}0)}=\frac{1}{2\omega_{\vec{k}}}\left[\frac{1}{k^0-\omega_{\vec{k}}+\mathrm{i}0}-\frac{1}{k^0+\omega_{\vec{k}}-\mathrm{i}0}\right]$$

then gives the second display after multiplying by the overall minus sign in the invariant denominator and by $-\mathrm{i}Z_\phi$. The listed residues are the coefficients of the two linear factors.

18.4 The Pole as a Spectral Projection

The preceding discussion can be stated without treating the pole as a formal singularity. Let P_1 denote the spectral projection of the translation representation onto the isolated positive-energy mass shell

$$\Sigma_m^+=\{p\in\mathbb{R}^{1,d}:p^0>0,\ p^2=-m^2\}.$$

For a test function $f\in C_c^\infty(\mathbb{R}^{1,d})$, define its two mass-shell restrictions by

$$f_+(\vec{p})=\int \mathrm{d}^D x\, f(x)e^{-ip\cdot x},\qquad f_-(\vec{p})=\int \mathrm{d}^D x\, f(x)e^{ip\cdot x},\qquad p^0=\omega_{\vec{p}}.$$

With the translation convention $U(a)=\exp(\mathrm{i}a_\mu P^\mu)$, the matrix element above gives

$$P_1\widehat{\phi}(f)\Omega=Z_\phi^{1/2}\int \mathrm{d}\mu_m(\vec{p})\, f_-(\vec{p})|\vec{p}\rangle.$$

Equivalently, for another test function g,

$$\langle\Omega|\widehat{\phi}(f)P_1\widehat{\phi}(g)|\Omega\rangle=Z_\phi\int \mathrm{d}\mu_m(\vec{p})\, f_+(\vec{p})g_-(\vec{p}).$$

This identity is the Hilbert-space origin of the pole in the two-point function. The remaining spectral projection $1-P_1$ has spectral support away from Σ_m^+ in a neighborhood of the isolated shell, so its Fourier transform has no one-particle pole there. Thus the residue of the two-point function is the mass-shell kernel induced by P_1 and by the chosen field-state matrix element.

Lemma 18.7 (External pole as one-particle spectral projection)**.** *Let $f,g\in C_c^\infty(\mathbb{R}^{1,d})$, and let*

$$f_\pm(\vec{p})=\int \mathrm{d}^D x\, f(x)\mathrm{e}^{\mp\mathrm{i}p\cdot x},\qquad g_\pm(\vec{p})=\int \mathrm{d}^D x\, g(x)\mathrm{e}^{\mp\mathrm{i}p\cdot x},\qquad p^0=\omega_{\vec{p}}.$$

Then the isolated one-particle projection of the smeared field is

$$P_1\widehat{\phi}(f)\Omega=Z_\phi^{1/2}\int \mathrm{d}\mu_m(\vec{p})\, f_-(\vec{p})|\vec{p}\rangle,$$

and

$$\langle\Omega|\widehat{\phi}(f)P_1\widehat{\phi}(g)|\Omega\rangle=Z_\phi\int \mathrm{d}\mu_m(\vec{p})\, f_+(\vec{p})g_-(\vec{p}).$$

The coefficient of the external LSZ pole is therefore exactly the kernel of the projection P_1, multiplied by the field-state matrix-element factors.

Proof. Translation covariance gives

$$\widehat{\phi}(x) = U(x)\widehat{\phi}(0)U(x)^{-1}, \qquad U(x)\Omega = \Omega.$$

On the one-particle subspace, the generalized momentum ket satisfies

$$U(x)|\vec{p}\rangle = \mathrm{e}^{\mathrm{i}x_\mu p^\mu}|\vec{p}\rangle.$$

The normalization $\langle\Omega|\widehat{\phi}(0)|\vec{p}\rangle = Z_\phi^{1/2}$ and hermiticity of the scalar interpolating field give the one-particle component of $\widehat{\phi}(x)\Omega$ as

$$P_1\widehat{\phi}(x)\Omega = Z_\phi^{1/2}\int \mathrm{d}\mu_m(\vec{p})\,\mathrm{e}^{\mathrm{i}x_\mu p^\mu}|\vec{p}\rangle.$$

Smearing with $f(x)$ gives the first displayed identity, because the definition of f_- uses $\mathrm{e}^{+\mathrm{i}p\cdot x}$. Taking the inner product of the corresponding f- and g-smeared vectors, and using the relativistic delta-function normalization of $|\vec{p}\rangle$, gives the second display. Since the complement $1 - P_1$ has spectral support separated from the isolated shell in the chosen neighborhood, it contributes no one-particle pole there. □

For an N-point time-ordered function, LSZ extraction applies this one-particle projection in each external variable. After the external projections have been taken, connected truncation removes vacuum-disconnected factors, and the result is compared with the Haag–Ruelle wave operators. This is the precise sense in which the reduction formula converts time-ordered correlation functions into scattering matrix elements.

18.5 Connected Truncation and External Amputation

Definition 18.8 (Connected Lorentzian source convention)**.** The pole extracted by LSZ is an external one-particle pole. It is useful to separate this operation from two other operations that are often compressed in notation. First, the connected time-ordered functions are obtained from the generating functional by taking cumulants. If

$$Z[J] = \langle\Omega|\,\mathrm{T}\exp\left(\mathrm{i}\int J(x)\widehat{\phi}(x)\,\mathrm{d}^Dx\right)|\Omega\rangle,$$

then

$$G_N^{\mathrm{conn}}(x_1,\ldots,x_N) = \mathrm{i}^{-N}\frac{\delta^N \log Z[J]}{\delta J(x_1)\cdots\delta J(x_N)}\bigg|_{J=0}. \tag{18.3}$$

With the sign convention for J inherited from the exponential above, this is the cumulant part of the time-ordered distribution: it contains precisely the vacuum-connected components. External one-particle propagators remain until the residue operation is applied. The prefactor is part of the source convention. If instead one defines

$$Z_-[J] = \langle\Omega|\,\mathrm{T}\exp\left(-\mathrm{i}\int J(x)\widehat{\phi}(x)\,\mathrm{d}^Dx\right)|\Omega\rangle,$$

then the same connected distribution is recovered by

$$G_N^{\mathrm{conn}}(x_1,\ldots,x_N) = (-\mathrm{i})^{-N}\frac{\delta^N \log Z_-[J]}{\delta J(x_1)\cdots\delta J(x_N)}\bigg|_{J=0} = \mathrm{i}^N\frac{\delta^N \log Z_-[J]}{\delta J(x_1)\cdots\delta J(x_N)}\bigg|_{J=0}.$$

Thus the Jacobian between source derivatives and time-ordered fields changes with the sign chosen in the source coupling; the Green function itself does not.

The Euclidean source convention is compatible with this normalization. Let

$$Z_E[J_E] = \langle\Omega|T_E \exp\left(\int J_E(\tau,\vec{x})\widehat{\phi}_E(\tau,\vec{x})\,\mathrm{d}\tau\,\mathrm{d}^d\vec{x}\right)|\Omega\rangle$$

denote the corresponding Euclidean ordered source functional. Along the imaginary-time contour used in Chapter 16,

$$x^0 = -\mathrm{i}\tau, \qquad \mathrm{d}x^0 = -\mathrm{i}\,\mathrm{d}\tau,$$

the Lorentzian source term transforms as

$$\mathrm{i}\int \mathrm{d}x^0\,\mathrm{d}^d\vec{x}\,J_L(x^0,\vec{x})\widehat{\phi}(x^0,\vec{x}) \longmapsto \int \mathrm{d}\tau\,\mathrm{d}^d\vec{x}\,J_L(-\mathrm{i}\tau,\vec{x})\widehat{\phi}_E(\tau,\vec{x}).$$

Thus $Z_E[J_E]$ is the imaginary-time restriction of $Z[J_L]$ with $J_E(\tau,\vec{x}) = J_L(-\mathrm{i}\tau,\vec{x})$, in the convention where the Euclidean exponential contains $+\int J_E\phi_E$. Before this contour rotation is made, differentiating the Lorentzian exponential N times with respect to the real-time source produces a factor i^N; the prefactor i^{-N} in Eq. (18.3) is exactly the compensation that leaves the connected time-ordered distribution rather than the source-normalized derivative.

Definition 18.9 (LSZ external amputation map)**.** Second, amputation in LSZ is extraction of the coefficient of the isolated external denominator, not a residue in the complex variable k^2. More precisely,

$$\operatorname*{bv}_{\Sigma_m}\left[(k^2+m^2)\widetilde{G}_2(k)\right] = -\mathrm{i}Z_\phi.$$

The symbol bv_{Σ_m} denotes the Feynman mass-shell boundary value: one first regards the two-point function, for fixed $\vec{k}$, as a boundary value of a meromorphic function of k^0, then multiplies by the invariant denominator and restricts to the appropriate positive- or negative-energy shell selected by the external wave packet. Multiplication by $Z_\phi^{-1/2}\mathrm{i}(k^2+m^2)$ is meaningful after smearing in a neighborhood of the mass shell and taking the boundary value. It removes only the external pole associated with the chosen stable particle. Internal propagators, threshold singularities, bound-state poles in other channels, and contact terms remain part of the amputated connected kernel.

Thus the reduction map has three logically distinct inputs:

$$\text{time-ordered distributions} \longrightarrow \text{connected distributions}$$
$$\longrightarrow \text{external one-particle residues} \longrightarrow \text{scattering matrix elements.}$$

The Haag–Ruelle construction supplies the last target independently of perturbation theory; the Green functions supply a way to compute its matrix elements when the one-particle pole hypotheses hold.

18.6 Contact Terms and Interpolating Fields

The LSZ operation depends only on the simultaneous external one-particle pole. This fact gives two useful stability properties.

First, different definitions of time-ordered products may differ by contact terms supported on partial diagonals, for example on $x_i = x_j$. In momentum space such terms are polynomial, or more generally local, in the momenta associated with the coincident insertions. They have no one-particle pole in each external variable. After multiplication by

$$\prod_a (k_a^2 + m^2)$$

and taking the on-shell boundary value with separated wave packets, these local terms do not contribute to the connected scattering kernel. They still matter for Ward identities, composite operators, and renormalized local products; they are local insertions rather than external one-particle residues.

Second, the local field used in the reduction is an interpolating field. Let $\widehat{\phi}'$ be another scalar local field with

$$\langle \Omega | \widehat{\phi}'(0) | \vec{p} \rangle = a\, Z_\phi^{1/2}, \qquad a \neq 0,$$

on the same isolated one-particle subspace. Its two-point function has one-particle residue $Z_{\phi'} = |a|^2 Z_\phi$. The LSZ factors $Z_{\phi'}^{-1/2}$ remove the changed residue, and the resulting S-matrix element is the same. Terms in $\widehat{\phi}'$ whose vacuum-to-one-particle matrix elements vanish, such as equation-of-motion terms of the form $(\Box - m^2)\widehat{\chi}$ in these sign conventions, do not create the external particle pole and therefore drop out of the reduction formula. The scattering operator belongs to the asymptotic Hilbert space; the interpolating local fields are coordinates used to access its matrix elements.

External-pole stability. Let $C(k_1, \ldots, k_N)$ be a distribution that is polynomial in one external momentum k_a in a neighborhood of the isolated mass shell, after all other variables have been smeared. Then

$$\operatorname*{bv}_{\Sigma_m} \left[(k_a^2 + m^2) C(k_1, \ldots, k_N) \right] = 0.$$

Consequently local contact terms in time-ordered products do not contribute to the simultaneous LSZ external residue. If another interpolating field $\widehat{\phi}'$ has

$$\langle \Omega | \widehat{\phi}'(0) | \vec{p} \rangle = a\, \langle \Omega | \widehat{\phi}(0) | \vec{p} \rangle, \qquad a \neq 0,$$

then its pole residue is $Z_{\phi'} = |a|^2 Z_\phi$, and the LSZ-normalized scattering matrix element is unchanged after the corresponding external field-coordinate factors are included.

The first assertion follows directly from the definition of the boundary-value coefficient. A polynomial in k_a has no factor $(k_a^2 + m^2 - \mathrm{i}0)^{-1}$. Multiplication by $k_a^2 + m^2$ gives a distribution whose restriction to $k_a^2 = -m^2$ is zero in the external coefficient sense used by Definition 18.4. Such terms can affect local Ward identities or composite-operator contact relations, but they are not external one-particle poles.

For the field-coordinate statement, the two-point one-particle term for $\widehat{\phi}'$ is multiplied by $a^* a$, hence

$$Z_{\phi'} = |a|^2 Z_\phi.$$

An N-leg Green function with external fields ϕ'_a has its simultaneous one-particle pole coefficient multiplied by the product of the corresponding one-particle overlap factors. The LSZ normalization contributes the inverse square roots of the same positive residues. These factors cancel in the pairing with normalized Haag–Ruelle one-particle wave packets, leaving the same Hilbert-space matrix element of S. If a component of $\widehat{\phi}'$ has zero vacuum-to-one-particle matrix element, then Lemma 18.7 gives zero projection to $\mathcal{H}_1$, so that component contributes no external LSZ pole.

18.7 Large-Time Oscillations and External Residues

The wave-packet statement above can be made more explicit. Let $\hat{\phi}_{f_i^{(T)}}$ create the outgoing packets at large positive time and $\hat{\phi}_{g_j^{(-T)}}$ create the incoming packets at large negative time, as in the Haag–Ruelle construction. The scattering matrix element is obtained from

$$\lim_{T\to+\infty}\langle\Omega|\hat{\phi}^*_{f_m^{(T)}}\cdots\hat{\phi}^*_{f_1^{(T)}}\hat{\phi}_{g_1^{(-T)}}\cdots\hat{\phi}_{g_n^{(-T)}}|\Omega\rangle.$$

For large T, locality permits this expression to be written as the corresponding time-ordered vacuum distribution, up to errors that vanish in the Haag–Ruelle limit. After Fourier transform each outgoing external variable carries an oscillatory phase of the form

$$\mathrm{e}^{-\mathrm{i}(k^0-\omega_{\vec{k}})T},$$

and each incoming external variable carries a phase of the form

$$\mathrm{e}^{\mathrm{i}(-k^0-\omega_{\vec{k}})(-T)}=\mathrm{e}^{\mathrm{i}(k^0+\omega_{\vec{k}})T},$$

where the Green-function momentum k is taken as entering the time-ordered correlator. If the Fourier-transformed Green function is regular at $k^0=\omega_{\vec{k}}$ or $k^0=-\omega_{\vec{k}}$, the large-T integral vanishes by repeated integration by parts. A nonzero limit is produced by the one-particle pole.

The following contour integral displays the residue. With the denominator convention used in the Lorentzian Green functions,

$$\begin{aligned}\lim_{T\to+\infty}&\int\frac{\mathrm{d}^Dk}{(2\pi)^D}\,\frac{\widetilde{g}(-k)\,\mathrm{e}^{\mathrm{i}(k^0+\omega_{\vec{k}})T}}{k^2+m^2-\mathrm{i}0}\\&=\int\frac{\mathrm{d}^d\vec{k}}{(2\pi)^d}\,\widetilde{g}(\omega_{\vec{k}},-\vec{k})\,\frac{\mathrm{i}}{2\omega_{\vec{k}}}.\end{aligned}$$

The pole enclosed by the large-time prescription is

$$k^0=-\omega_{\vec{k}}+\mathrm{i}0.$$

For an outgoing external variable the conjugate calculation selects

$$k^0=\omega_{\vec{k}}-\mathrm{i}0.$$

Large-time pole selector. Let $a\in\mathcal{S}(\mathbb{R}^{1,d})$. With the Feynman prescription above,

$$\begin{aligned}\lim_{T\to+\infty}&\int\frac{\mathrm{d}^Dk}{(2\pi)^D}\,\frac{a(k)\,\mathrm{e}^{\mathrm{i}(k^0+\omega_{\vec{k}})T}}{k^2+m^2-\mathrm{i}0}\\&=\int\frac{\mathrm{d}^d\vec{k}}{(2\pi)^d}\,a(-\omega_{\vec{k}},\vec{k})\,\frac{\mathrm{i}}{2\omega_{\vec{k}}},\end{aligned}$$

provided the spatial support is kept in the isolated mass-shell neighborhood. The conjugate large-time factor selects the positive-energy pole with the opposite boundary prescription. For fixed $\vec{k}$, factor the denominator as in the linear-residue calculation above. The phase $\mathrm{e}^{\mathrm{i}(k^0+\omega_{\vec{k}})T}$ has a nonzero large-T limit only against the singular distribution at

$$k^0 = -\omega_{\vec{k}} + \mathrm{i}0.$$

Equivalently, close the k^0-contour in the upper half-plane for $T > 0$. The enclosed pole is the negative-energy Feynman pole, and the residue of

$$\frac{1}{k^2 + m^2 - \mathrm{i}0}$$

there is $\mathrm{i}/(2\omega_{\vec{k}})$ with the Fourier normalization used in the display. The part of $a(k)$ multiplied by a function regular at the selected shell gives zero by repeated integration by parts in k^0. The positive-energy statement is the complex-conjugate contour calculation.

If the full Feynman two-point singularity $-\mathrm{i}Z_\phi/(k^2+m^2-\mathrm{i}0)$ is used instead of the denominator in the displayed integral, the extra factor $-\mathrm{i}Z_\phi$ combines with the residue above to give the mass-shell measure and the external factor $Z_\phi^{1/2}$. The LSZ operator $Z_\phi^{-1/2}\mathrm{i}(k^2+m^2)$ is the distributional way of extracting this same residue from every external leg at once.

This also explains the identity term in the S-matrix. A disconnected two-point factor

$$(2\pi)^D \delta^{(D)}(k+k') \, \frac{-\mathrm{i}Z_\phi}{k^2+m^2-\mathrm{i}0}$$

has a simultaneous one-particle pole and gives, after the same limiting procedure,

$$Z_\phi \int \mathrm{d}\mu_m(\vec{p}) \, f(\vec{p})^* g(\vec{p}),$$

which is the one-particle inner product created by the chosen field. In a multi-particle matrix element these two-point factors reproduce the free permutation terms; the remaining part is the connected scattering kernel.

18.8 Momentum-Space Kernel

The time-ordered N-point function is

$$G_N(x_1,\ldots,x_N) = \langle\Omega|\,\mathrm{T}\{\widehat{\phi}(x_1)\cdots\widehat{\phi}(x_N)\}|\Omega\rangle.$$

Its Fourier transform is defined by

$$G_N(x_1,\ldots,x_N) = \int \prod_{a=1}^{N} \frac{\mathrm{d}^D k_a}{(2\pi)^D} \, \mathrm{e}^{\mathrm{i}\sum_a k_a\cdot x_a} \, \widetilde{G}_N(k_1,\ldots,k_N).$$

Translation invariance gives

$$\widetilde{G}_N(k_1,\ldots,k_N) = (2\pi)^D \delta^{(D)}(k_1+\cdots+k_N) \, \widetilde{\mathcal{G}}_N(k_1,\ldots,k_{N-1}),$$

where $\widetilde{\mathcal{G}}_N$ denotes the reduced distribution after removing the overall momentum-conservation delta function.

For m outgoing and n incoming scalar particles, set

$$k_i = q_i \quad (1 \le i \le m), \qquad k_{m+j} = -p_j \quad (1 \le j \le n).$$

The word scalar fixes the statistics used in this section: the external asymptotic particles lie in the symmetric Fock space constructed in Chapter 17. For fermionic external particles the same Hilbert-space and distributional logic is applied in the graded asymptotic Fock space, and permutations carry the Koszul signs fixed by the spin-statistics theorem; the free spinor verification and the theorem-level hypotheses are recorded in Chapter 40. The wave-packet theorem is abbreviated by the distributional kernel notation

$$\begin{aligned}
&{}_{\mathrm{out}}\langle \vec{q}_1, \dots, \vec{q}_m | \vec{p}_1, \dots, \vec{p}_n \rangle_{\mathrm{in,conn}} \\
&\quad = \mathcal{L}^{\mathrm{on}}_{m,n}(q_1, \dots, q_m | p_1, \dots, p_n).
\end{aligned}$$

This equality is not a pointwise evaluation of generalized momentum states. It means that both sides give the same result after smearing with test wave packets and taking the external boundary value specified in Theorem 18.5.

Disconnected terms are treated by the same rule, but one-particle two-point factors reproduce the identity contribution to the scattering operator. For two identical scalar particles,

$$\begin{aligned}
&{}_{\mathrm{out}}\langle \vec{q}_1, \vec{q}_2 | \vec{p}_1, \vec{p}_2 \rangle_{\mathrm{in}} \\
&\quad = (2\pi)^d 2\omega_{\vec{p}_1} \delta^{(d)}(\vec{q}_1 - \vec{p}_1)\, (2\pi)^d 2\omega_{\vec{p}_2} \delta^{(d)}(\vec{q}_2 - \vec{p}_2) \\
&\qquad + (2\pi)^d 2\omega_{\vec{p}_1} \delta^{(d)}(\vec{q}_2 - \vec{p}_1)\, (2\pi)^d 2\omega_{\vec{p}_2} \delta^{(d)}(\vec{q}_1 - \vec{p}_2) \\
&\qquad + {}_{\mathrm{out}}\langle \vec{q}_1, \vec{q}_2 | \vec{p}_1, \vec{p}_2 \rangle_{\mathrm{in,conn}}.
\end{aligned}$$

Remark 18.10 (Identity kernel and statistics). The plus sign between the two delta-function products is the identity kernel on the two-particle symmetric tensor product. For two identical fermions the corresponding identity kernel has the antisymmetric sign. Thus the permutation sums in LSZ are part of the asymptotic Fock-space structure, not an additional convention imposed after the reduction formula.

18.9 Invariant Amplitudes

Definition 18.11 (Invariant scalar amplitude convention)**.** The connected kernel contains the overall conservation law

$$q_1 + \cdots + q_m = p_1 + \cdots + p_n.$$

It is conventional to define the invariant amplitude $\mathcal{M}$ by

$$\begin{aligned}
&{}_{\mathrm{out}}\langle \vec{q}_1, \dots, \vec{q}_m | \vec{p}_1, \dots, \vec{p}_n \rangle_{\mathrm{in,conn}} \\
&\quad = \mathrm{i}(2\pi)^D \delta^{(D)}(q_1 + \cdots + q_m - p_1 - \cdots - p_n)\, \mathcal{M}(q_1, \dots, q_m | p_1, \dots, p_n).
\end{aligned}$$

With this convention the operator identity $S = \mathbf{1} + \mathrm{i}T$ gives

$${}_{\mathrm{out}}\langle q | T | p \rangle = (2\pi)^D \delta^{(D)}(P_{\mathrm{out}} - P_{\mathrm{in}})\, \mathcal{M}(q|p).$$

Here $P_{\text{out}} = \sum_i q_i$ and $P_{\text{in}} = \sum_j p_j$.

This convention uses relativistically normalized external momentum states. If one instead uses δ-normalized states

$${}_\delta\langle \vec{q} | \vec{p} \rangle_\delta = \delta^{(d)}(\vec{q} - \vec{p}),$$

related to the relativistic states by

$$|\vec{p}\rangle = \left[(2\pi)^d 2\omega_{\vec{p}}\right]^{1/2} |\vec{p}\rangle_\delta,$$

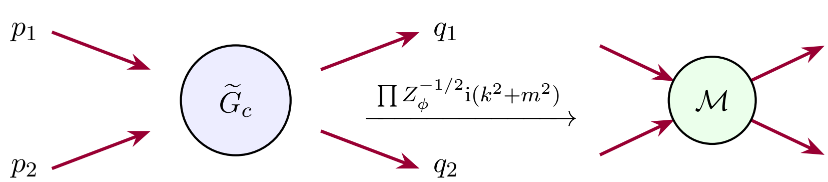
then the connected kernel is often written

$${}_{\delta,\text{out}}\langle q|p\rangle_{\delta,\text{in,conn}} = \mathrm{i}(2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) M_\delta(q|p),$$

where

$$M_\delta(q|p) = \left[\prod_{i=1}^{m} \left((2\pi)^d 2\omega_{\vec{q}_i}\right)^{-1/2} \prod_{j=1}^{n} \left((2\pi)^d 2\omega_{\vec{p}_j}\right)^{-1/2}\right] \mathcal{M}(q|p).$$

The invariant object is $\mathcal{M}$; M_δ carries the normalization factors attached to a nonrelativistic delta-function basis.



The diagram displays the operation. The left object is the connected time-ordered Green function with its external one-particle poles. The right object is the on-shell invariant amplitude obtained after the pole residues have been extracted.

18.10 Cluster Decomposition of the Scattering Kernel

Partition formula for connected scattering kernels. Let $S(\beta|\alpha)$ denote the distributional kernel of the scattering operator on the Haag–Ruelle asymptotic Fock space, where α is the ordered list of incoming external labels and β is the ordered list of outgoing external labels. Connected scattering kernels S^{conn} are defined by the following moment–cumulant relation:

$$S(\beta|\alpha) = \sum_{\mathcal{P}} \prod_{I \in \mathcal{P}} S^{\text{conn}}(\beta_I|\alpha_I).$$

Here $\mathcal{P}$ runs over simultaneous partitions

$$\alpha = \bigsqcup_{I \in \mathcal{P}} \alpha_I, \qquad \beta = \bigsqcup_{I \in \mathcal{P}} \beta_I,$$

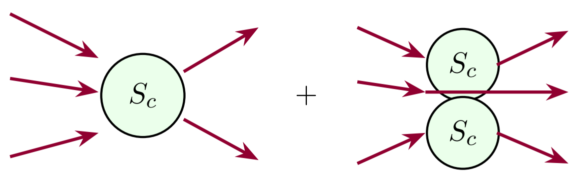
and the singleton identity kernels of the identity operator in $S = \mathbf{1} +$ interaction are included as allowed one-particle blocks. Equivalently, S^{conn} is obtained from S by Möbius inversion on this finite partition lattice. With this definition, Haag–Ruelle cluster decomposition says that S^{conn}

is the part of the distribution that cannot be written as a product of scattering kernels for mutually separated spacetime clusters. The statement is not perturbative: perturbation theory later represents the connected kernels by connected Feynman graphs, but the connected/disconnected separation is already defined on the asymptotic Hilbert space.

The scattering kernel is a distributional matrix coefficient of S on the asymptotic Fock space. For each finite set of external labels the set of simultaneous partitions is finite, so the displayed relation can be solved recursively for $S^{\rm conn}$, beginning with the one-block partition. Explicitly,

$$S^{\rm conn}(\beta|\alpha) = S(\beta|\alpha) - \sum_{\mathcal{P}\neq\{\text{all}\}} \prod_{I\in\mathcal{P}} S^{\rm conn}(\beta_I|\alpha_I),$$

which is the Möbius inversion formula written in recursive form. The identity operator contributes the one-particle pass-through kernel $(2\pi)^d 2\omega_{\vec{p}}\delta^{(d)}(\vec{q}-\vec{p})$ in the corresponding singleton block; if one instead works with $T = S - \mathbf{1}$, these identity blocks are removed before taking connected interaction kernels. Finally, the Haag–Ruelle cluster property states that translating one group of wave-packet creation operators far from another makes the Hilbert-space matrix coefficient factor into the product of the corresponding cluster matrix coefficients. The recursive inversion is precisely the subtraction of all such factorized contributions, hence it isolates the non-factorizing connected kernel.



18.11 Perturbative Evaluation After Reduction

Tree-level ϕ^4 amplitude after LSZ. Perturbation theory supplies an expansion of the time-ordered Green function. LSZ then turns that expansion into an expansion of matrix elements of the scattering operator. This is the point where Feynman graphs acquire their scattering-amplitude interpretation.

For the scalar interaction

$$\mathcal{L}_{\rm int} = -\frac{g}{4!}\phi^4,$$

the leading connected four-point Green function is

$$\begin{aligned}&\widetilde{G}_4^{\rm conn}(q_1,q_2,-p_1,-p_2)\\ &\quad = (2\pi)^D\delta^{(D)}(q_1+q_2-p_1-p_2)(-\mathrm{i}g)\prod_{a=1}^{4}\frac{-\mathrm{i}}{k_a^2+m^2-\mathrm{i}0} + O(g^2),\end{aligned}$$

with

$$k_1 = q_1,\quad k_2 = q_2,\quad k_3 = -p_1,\quad k_4 = -p_2,\qquad Z_\phi = 1 + O(g^2).$$

The four numerator factors in the external propagators are

$$\prod_{a=1}^{4}(-\mathrm{i}) = (-\mathrm{i})^4 = 1.$$

Equivalently, applying the four LSZ multipliers gives, for each external leg,

$$\mathrm{i}(k_a^2 + m^2)\,\frac{-\mathrm{i}}{k_a^2 + m^2 - \mathrm{i}0} \longrightarrow 1,$$

after the mass-shell boundary value. Thus the external-leg factors contribute

$$\prod_{a=1}^{4}\left[\mathrm{i}(k_a^2 + m^2)\frac{-\mathrm{i}}{k_a^2 + m^2 - \mathrm{i}0}\right] \longrightarrow \big(\mathrm{i}(-\mathrm{i})\big)^4 = 1.$$

For an N-point connected Green function with N external scalar propagators the same bookkeeping is $\mathrm{i}^N(-\mathrm{i})^N = 1$; the remaining nontrivial factor is the connected amputated kernel. Applying LSZ gives

$${}_{\mathrm{out}}\langle \vec{q}_1, \vec{q}_2 | \vec{p}_1, \vec{p}_2 \rangle_{\mathrm{in,conn}} = (2\pi)^D \delta^{(D)}(q_1 + q_2 - p_1 - p_2)\left[-\mathrm{i}g + O(g^2)\right].$$

Therefore

$$\mathcal{M}(q_1, q_2 | p_1, p_2) = -g + O(g^2)$$

with the amplitude convention above. Higher orders are obtained from the same Green-function expansion together with the external residue factors $Z_\phi^{-1/2}$.

The leading connected four-point Green function has one local quartic vertex and four external scalar Feynman denominators. The LSZ theorem has already identified the physical scattering matrix element with the simultaneous external pole coefficient of this connected Green function. Applying $\mathrm{i}(k_a^2 + m^2)$ to each external scalar denominator gives one for each external leg in the displayed convention, and $Z_\phi = 1 + O(g^2)$ at this order. After the four external poles are removed, the remaining connected kernel is the vertex factor $-\mathrm{i}g$ times the momentum-conservation delta function. Comparing with Definition 18.11, where the connected kernel equals $\mathrm{i}(2\pi)^D\delta^{(D)}(\sum q - \sum p)\mathcal{M}$, gives $\mathcal{M} = -g + O(g^2)$.

18.12 Scope of the Formula

Remark 18.12 (Scope of scalar LSZ reduction). The LSZ theorem in this chapter applies to stable massive particles represented by isolated one-particle poles in local-field Green functions. It is a statement about boundary values of distributions after wave-packet smearing. Its hypotheses include the existence of the asymptotic states constructed in Haag–Ruelle theory and the existence of the relevant time-ordered products.

Massless gauge theories, infraparticle sectors, confined degrees of freedom, unstable resonances, and conformal theories require different asymptotic objects or different observables. In particular, an unstable resonance is not an external LSZ particle: it is represented by pole data of analytically continued amplitudes between stable asymptotic states, as discussed in Chapter 26. The common principle remains the same: first construct the asymptotic Hilbert-space or detector data, then relate that data to correlation functions in the regime where a reduction theorem is available.

There is a separate gauge-theoretic localization issue before the infrared question is reached. In a theory with an unscreened Gauss-law charge, a bounded gauge-invariant observable cannot create a charged vector from the vacuum. A charged LSZ formula must therefore be formulated, when it exists, for charged field-algebra operators or for gauge-invariant noncompact dressed operators such as Wilson-line or Coulomb dressings. The external factor is then the residue or threshold coefficient of the dressed correlator, including the renormalization of the dressing itself. The scalar local-field formula above contains none of this dressing data.

In a confining gauge theory such as QCD, this means that LSZ is applied, when its hypotheses hold, to gauge-invariant color-singlet interpolating operators whose Källén–Lehmann measures contain isolated hadronic atoms. There are no physical quark or gluon one-particle atoms for Haag–Ruelle to generate and for LSZ to amputate; gauge-fixed quark and gluon propagators therefore cannot be read as physical scattering amplitudes by the scalar-particle formula above. High-energy QCD observables involving jets are therefore not colored-particle S-matrix elements; they are color-singlet, detector-defined observables, such as inclusive hadronic tensors and energy-flow correlators, whose nonperturbative definitions are given in terms of physical states and the stress tensor.

Cross Sections, Phase Space, and Unitarity

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

19.1 Transition Probabilities

Definition 19.1 (Transition probability for an outgoing event class)**.** Let $\mathcal{H}_{\mathrm{as}}$ be the asymptotic Hilbert space in a sector where the incoming and outgoing Haag–Ruelle ranges coincide. The scattering operator

$$S : \mathcal{H}_{\mathrm{as}} \to \mathcal{H}_{\mathrm{as}}$$

is then unitary. Write

$$S = \mathbf{1} + \mathrm{i}T.$$

For a normalized incoming vector $\Psi_{\mathrm{in}} \in \mathcal{H}_{\mathrm{as}}$ and an outgoing class of states $\mathcal{D}$, let $\Pi^{\mathrm{out}}_{\mathcal{D}}$ be the orthogonal projection onto the closed subspace spanned by $\mathcal{D}$. The transition probability into $\mathcal{D}$ is

$$P_{\Psi\to\mathcal{D}} = \left\| \Pi^{\mathrm{out}}_{\mathcal{D}} S \Psi_{\mathrm{in}} \right\|^2 .$$

This is the primary definition. Sharp-momentum formulas are distributional kernels obtained from this expression after smearing with wave packets and then taking a narrow-packet limit.

Definition 19.2 (Invariant amplitude convention)**.** For positive-energy momenta in the mostly-plus metric,

$$p_i = (E_i, \vec{p}_i), \qquad q_a = (E_a, \vec{q}_a),$$

with

$$p_i^2 = -m_i^2, \qquad q_a^2 = -M_a^2,$$

set

$$P_{\text{in}} = \sum_i p_i, \qquad P_{\text{out}} = \sum_a q_a.$$

The invariant amplitude convention inherited from LSZ is

$$\langle q_1, \ldots, q_m | T | p_1, \ldots, p_n \rangle = (2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) \mathcal{M}(q_1, \ldots, q_m | p_1, \ldots, p_n).$$

The bra and ket are generalized basis vectors in $\mathcal{H}_{\text{as}}$. They are elements of the appropriate dual test-vector space, as in Section 5.2. Equivalently, the same distribution is obtained from the connected part of the Haag–Ruelle kernel

$$_{\text{out}}\langle q_1, \ldots, q_m | p_1, \ldots, p_n \rangle_{\text{in}}$$

after subtracting the identity contribution. The connected contribution to S is therefore

$$\mathrm{i}(2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) \mathcal{M}.$$

Throughout this chapter, $\mathcal{M}(f|i)$ means the T-matrix element with ket label i and bra label f, namely the transition $i \to f$. The notation is ordered; $\mathcal{M}(f|i)$ and $\mathcal{M}(i|f)$ are different matrix elements unless an additional reciprocity symmetry is assumed.

19.2 Sharp-Momentum Limit and Delta-Squares

Example 19.3 (Sharp-momentum density limit)**.** The wave-packet definition is primary, but the conventional plane-wave formula is useful as a check on all factors. Temporarily use δ-normalized one-particle states in $d = D - 1$ spatial dimensions,

$$_\delta\langle \vec{q} | \vec{p} \rangle_\delta = \delta^{(d)}(\vec{q} - \vec{p}),$$

and write the connected kernel as

$$S^{\text{conn}}_{\beta\alpha} = \mathrm{i}(2\pi)^D \delta^{(D)}(P_\beta - P_\alpha) M_\delta(\beta|\alpha).$$

The subscript in M_δ is part of the notation: it records the $\delta^{(d)}$-normalized sharp-momentum basis used in this temporary calculation. It is neither the invariant amplitude $\mathcal{M}$ nor a partial-wave coefficient. Later in this chapter the invariant amplitude is expanded in partial waves with coefficients $a_\ell(s)$, while $S_\ell(s)$ denotes an eigenvalue of the scattering operator on a partial-wave channel:

$M_\delta(\beta\|\alpha)$	$\delta^{(d)}$-normalized connected sharp-momentum kernel,
$\mathcal{M}(f\|i)$	invariant amplitude after external normalization factors,
$a_\ell(s)$	coefficient in the ordered 16π partial-wave expansion,
$S_\ell(s)$	elastic partial-wave S-matrix eigenvalue.

Let $\mathcal{D}$ be a final region that does not contain the identity no-scattering contribution. Squaring the distributional kernel gives

$$P_{\alpha\to\mathcal{D}} = (2\pi)^D\delta^{(D)}(0)\int_{\mathcal{D}} \mathrm{d}\beta_\delta\,(2\pi)^D\delta^{(D)}(P_\beta - P_\alpha)|M_\delta(\beta|\alpha)|^2,$$

where $\mathrm{d}\beta_\delta$ is the product of the final $\mathrm{d}^d\vec{q}$ measures, with the resolution-of-identity factors appropriate to the outgoing Fock sector. A finite box regularization of spatial volume V and observation time $\mathcal{T}$ gives

$$(2\pi)^D\delta^{(D)}(0) = V\mathcal{T}, \qquad \delta^{(d)}(0) = \frac{V}{(2\pi)^d}.$$

For two sharp incoming particles, the normalized box state carries the factor $\delta^{(d)}(0)^{-2}$. Hence

$$P_{\alpha\to\mathcal{D}} = \frac{(2\pi)^{2d}\mathcal{T}}{V}\int_{\mathcal{D}} \mathrm{d}\beta_\delta\,(2\pi)^D\delta^{(D)}(P_\beta - P_\alpha)|M_\delta(\beta|\alpha)|^2.$$

If the two beams have relative speed $v_{\mathrm{rel}} = |\vec{v}_1 - \vec{v}_2|$ in the frame used for the box, the geometric probability to scatter into $\mathcal{D}$ during time $\mathcal{T}$ is

$$P_{\alpha\to\mathcal{D}} = \frac{\sigma_{\mathcal{D}} v_{\mathrm{rel}}\mathcal{T}}{V}.$$

Therefore

$$\sigma_{\mathcal{D}} = \frac{(2\pi)^{2D-2}}{v_{\mathrm{rel}}}\int_{\mathcal{D}} \mathrm{d}\beta_\delta\,(2\pi)^D\delta^{(D)}(P_\beta - P_\alpha)|M_\delta(\beta|\alpha)|^2.$$

Converting M_δ to the invariant amplitude $\mathcal{M}$ by the external normalization factors stated in the LSZ chapter gives the covariant phase-space formula below.

The connected sharp kernel contains a single total momentum-conservation distribution. In the probability, the square of this distribution is defined by putting the theory in a spatial box of volume V and evolving for an observation time $\mathcal{T}$. In that regulator,

$$\left[(2\pi)^D\delta^{(D)}(P_\beta - P_\alpha)\right]^2 = (2\pi)^D\delta^{(D)}(0)\,(2\pi)^D\delta^{(D)}(P_\beta - P_\alpha)$$

with $(2\pi)^D\delta^{(D)}(0) = V\mathcal{T}$. A two-particle incoming δ-normalized box state contributes $\delta^{(d)}(0)^{-2} = [(2\pi)^d/V]^2$. Multiplying these factors gives the displayed probability density $(2\pi)^{2d}\mathcal{T}/V$ times the final-state phase-space integral. Dividing by the geometric probability $v_{\mathrm{rel}}\mathcal{T}/V$ for a unit transverse area gives the sharp cross-section density. The last conversion is exactly the external normalization conversion between M_δ and $\mathcal{M}$ fixed in Definition 19.2.

19.3 Wave-Packet Origin of Cross Sections

Cross sections are transition probabilities per incoming transverse flux. Let $\psi_1, \psi_2 \in \mathcal{H}_1$ be normalized incoming one-particle packets with narrow momentum supports and distinct group velocities. In the center-of-mass frame let $\vec{p}_*$ be the central momentum of the first packet, and let

$$\mathbb{R}^{D-2}_\perp = \{b \in \mathbb{R}^{D-1} : b\cdot\vec{p}_* = 0\}$$

be the transverse impact-parameter plane. If τ_b denotes the spatial translation acting on the one-particle Hilbert space, define

$$\Psi_b = \psi_1 \odot \tau_b\psi_2.$$

Here $\odot$ denotes the two-particle product in the asymptotic Fock space, with the species labels and Bose or Fermi statistics appropriate to the sector under consideration. For an outgoing channel $\mathcal{D}$ whose projection removes the identity no-scattering component, the wave-packet cross section is

$$\sigma_{\psi_1,\psi_2}(\mathcal{D}) = \int_{\mathbb{R}_\perp^{D-2}} \mathrm{d}^{D-2}b \, \left\| \Pi_{\mathcal{D}}^{\mathrm{out}} S\Psi_b \right\|^2 .$$

The dimension is length to the power $D-2$, the dimension of transverse area in D spacetime dimensions.

The plane-wave formula is the narrow-packet density of this Hilbert-space quantity. The Fourier transform in b enforces transverse momentum conservation. The long-time Haag–Ruelle localization enforces energy and longitudinal momentum conservation in the scattering limit. Together these produce the single overall distribution

$$(2\pi)^D \delta^{(D)}(P_{\mathrm{out}} - P_{\mathrm{in}})$$

appearing in the invariant amplitude convention. The incoming current through the transverse impact-parameter plane is the invariant relative speed multiplied by the one-particle normalizations. Thus the denominator in the sharp-momentum two-particle formula is the invariant flux

$$\mathcal{F}(p_1, p_2) = 4E_1 E_2 v_{\mathrm{rel}}.$$

The next section expresses the same factor in covariant form.

19.4 Invariant Phase Space and Flux

Definition 19.4 (Invariant phase space)**.** For one on-shell final particle of mass M, the Lorentz-invariant positive-energy measure is

$$\mathrm{d}\mu_M(q) = \frac{\mathrm{d}^D q}{(2\pi)^{D-1}} \, \theta(q^0)\delta(q^2 + M^2) = \frac{\mathrm{d}^{D-1}\vec{q}}{(2\pi)^{D-1} 2E_{\vec{q}}},$$

where

$$E_{\vec{q}} = \sqrt{\vec{q}^{\,2} + M^2}.$$

For m final particles with total incoming momentum P, define the m-body phase-space measure

$$\mathrm{d}\Phi_m(P; q_1, \ldots, q_m) = (2\pi)^D \delta^{(D)}\left(P - \sum_{a=1}^m q_a \right) \prod_{a=1}^m \mathrm{d}\mu_{M_a}(q_a).$$

This formula is written first for labeled outgoing particles. The identical particle factors come from the resolution of the identity on the asymptotic Fock space. For one bosonic species, the r-particle space is $\mathcal{H}_1^{\odot r}$. If

$$|\vec{q}_1, \ldots, \vec{q}_r\rangle_{\mathrm{sym}} = a^\dagger(\vec{q}_1) \cdots a^\dagger(\vec{q}_r)\Omega_F,$$

with the relativistic one-particle normalization used above, then the identity on this symmetric sector is

$$\mathbf{1}_{\mathcal{H}_1^{\odot r}} = \frac{1}{r!} \int \prod_{j=1}^r \mathrm{d}\mu_m(q_j) \, |\vec{q}_1, \ldots, \vec{q}_r\rangle_{\mathrm{sym}\,\mathrm{sym}}\langle \vec{q}_1, \ldots, \vec{q}_r|.$$

The factor $1/r!$ compensates for the $r!$ labeled tuples that represent the same unordered Bose state. For several species, the physical phase-space measure carries the product

$$\prod_{\lambda} \frac{1}{n_\lambda!},$$

where n_λ is the number of identical outgoing particles of species λ. Fermionic sectors have the corresponding antisymmetric identity resolution; the same factorial appears, with signs carried by the antisymmetric external wavefunctions and matrix elements.

Invariant two-particle flux. For a two-particle initial state, the invariant flux factor used in the cross-section normalization is

$$\mathcal{F}(p_1, p_2) = 4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}.$$

Equivalently,

$$\mathcal{F} = 4E_1 E_2 v_{\text{rel}}, \qquad v_{\text{rel}} = \frac{\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}}{E_1 E_2}.$$

In the center-of-mass frame,

$$p_1 = (E_1, \vec{p}_*), \qquad p_2 = (E_2, -\vec{p}_*),$$

so

$$\mathcal{F} = 4(E_1 + E_2)|\vec{p}_*|.$$

The verification is the center-of-mass evaluation of the invariant. The quantity $(p_1 \cdot p_2)^2 - m_1^2 m_2^2$ is Lorentz invariant, so it suffices to evaluate it in the center-of-mass frame. With mostly-plus metric,

$$p_1 \cdot p_2 = -E_1 E_2 - \vec{p}_*^{\,2}.$$

Using $E_i^2 = \vec{p}_*^{\,2} + m_i^2$,

$$\begin{aligned} (p_1 \cdot p_2)^2 - m_1^2 m_2^2 &= (E_1 E_2 + \vec{p}_*^{\,2})^2 - (E_1^2 - \vec{p}_*^{\,2})(E_2^2 - \vec{p}_*^{\,2}) \\ &= \vec{p}_*^{\,2}(E_1 + E_2)^2. \end{aligned}$$

Thus $\mathcal{F} = 4(E_1 + E_2)|\vec{p}_*|$. Since $\vec{v}_1 = \vec{p}_*/E_1$ and $\vec{v}_2 = -\vec{p}_*/E_2$, the relative speed is

$$v_{\text{rel}} = |\vec{v}_1 - \vec{v}_2| = \frac{(E_1 + E_2)|\vec{p}_*|}{E_1 E_2},$$

which proves the equivalent form $\mathcal{F} = 4E_1 E_2 v_{\text{rel}}$.

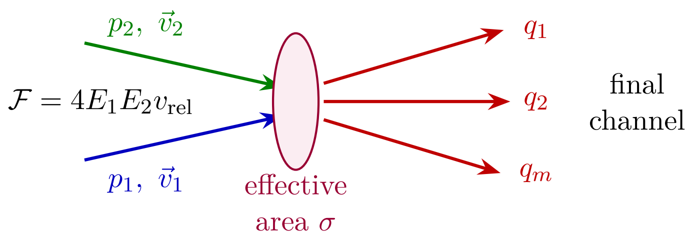
Definition 19.5 (Differential cross section from invariant data)**.** The differential cross section for

$$p_1 + p_2 \longrightarrow q_1 + \cdots + q_m$$

is

$$\mathrm{d}\sigma = \frac{1}{\mathcal{F}(p_1, p_2)} \left|\mathcal{M}(q_1, \ldots, q_m | p_1, p_2)\right|^2 \mathrm{d}\Phi_m(P_{\text{in}}; q_1, \ldots, q_m).$$

All factors in this expression have now been fixed: the asymptotic state normalization, the amplitude convention, the final-state measure, and the incoming flux.



19.5 Two-Body Final States in Four Dimensions

Set $D = 4$. For a two-body final state, define

$$s = -(p_1 + p_2)^2 = P_{\text{in}}^{0\,2} - \vec{P}_{\text{in}}^{\,2}.$$

In the center-of-mass frame,

$$P_{\text{in}} = (\sqrt{s}, \vec{0}).$$

The Källén polynomial is

$$\lambda_K(s, a, b) = s^2 + a^2 + b^2 - 2sa - 2sb - 2ab.$$

For incoming masses m_1, m_2 and final masses M_1, M_2,

$$|\vec{p}_*| = \frac{\sqrt{\lambda_K(s, m_1^2, m_2^2)}}{2\sqrt{s}}, \qquad |\vec{q}_*| = \frac{\sqrt{\lambda_K(s, M_1^2, M_2^2)}}{2\sqrt{s}}.$$

The next calculation performs the two-body phase-space integral over the energy-conserving delta function. Here $\mathrm{d}\Omega$ is the solid-angle measure of one final momentum in the center-of-mass frame.

Two-body phase-space reduction in four dimensions. With the normalization of Definition 19.4, the two-body final-state measure in the center-of-mass frame is

$$\mathrm{d}\Phi_2 = \frac{1}{16\pi^2} \frac{|\vec{q}_*|}{\sqrt{s}} \, \mathrm{d}\Omega.$$

Consequently

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{64\pi^2 s} \frac{|\vec{q}_*|}{|\vec{p}_*|} |\mathcal{M}(s, \Omega)|^2.$$

In the center-of-mass frame the spatial delta function in $\mathrm{d}\Phi_2$ sets $\vec{q}_2 = -\vec{q}_1$. Writing $q = |\vec{q}_1|$, the remaining radial integral contains

$$\delta(\omega_1(q) + \omega_2(q) - \sqrt{s}), \qquad \omega_a(q) = \sqrt{q^2 + M_a^2}.$$

At the root $q = |\vec{q}_*|$,

$$\frac{\mathrm{d}}{\mathrm{d}q}(\omega_1 + \omega_2) = q \left(\frac{1}{\omega_1} + \frac{1}{\omega_2} \right) = \frac{q\sqrt{s}}{\omega_1 \omega_2}.$$

Therefore

$$\int \frac{q^2 \mathrm{d}q \, \mathrm{d}\Omega}{(2\pi)^2 \, 4\omega_1\omega_2} \, \delta(\omega_1 + \omega_2 - \sqrt{s}) = \frac{|\vec{q}_*|}{16\pi^2 \sqrt{s}} \, \mathrm{d}\Omega.$$

Dividing by the center-of-mass flux $\mathcal{F} = 4\sqrt{s}\,|\vec{p}_*|$ gives the displayed differential cross-section formula.

For two identical final particles, the symmetric two-particle identity resolution supplies the factor 1/2 when the integral is written over the full labeled solid angle.

For elastic scattering of identical scalar particles the preceding formula already gives the total cross section. Since $|\vec{q}_*| = |\vec{p}_*|$ and $s = E_{\rm cm}^2$,

$$\sigma^{\rm id}_{2\to2} = \frac{1}{2}\int \mathrm{d}\Omega\,\frac{|\mathcal{M}(E_{\rm cm},\Omega)|^2}{64\pi^2 s} = \frac{1}{2^7\pi^2 E_{\rm cm}^2}\int \mathrm{d}\Omega\,|\mathcal{M}(E_{\rm cm},\Omega)|^2.$$

The direct delta-function integration gives the same expression and is a useful normalization check. In the center-of-mass frame the spatial delta function sets $\vec{q}_2 = -\vec{q}_1$. Writing $q = |\vec{q}_1|$, the radial energy-conservation integral is

$$\int q^2 \mathrm{d}q\,\delta(\omega_1(q)+\omega_2(q)-E_{\rm cm}) = \frac{q\,\omega_1\omega_2}{E_{\rm cm}}.$$

Together with $E_1E_2v_{\rm rel} = |\vec{p}_*|E_{\rm cm}$, this reduces the labeled two-body phase-space integral to the same result above, with the factor 1/2 supplied by the symmetric two-particle resolution of the identity.

For the tree-level ϕ^4 example with a single scalar mass m, the elastic kinematics obey

$$|\vec{q}_*| = |\vec{p}_*|, \qquad \sqrt{s} = E_{\rm cm}.$$

If the tree-level ϕ^4 invariant amplitude is

$$\mathcal{M} = -g + O(g^2),$$

then

$$\sigma_{2\to2} = \frac{g^2}{32\pi s} + O(g^3)$$

for identical final particles.

19.6 Unitarity and the Optical Theorem

Theorem 19.6 (Sharp-kernel unitarity and the optical theorem)**.** *Let $S = \mathbf{1} + \mathrm{i}T$ be unitary on the asymptotic Hilbert space. With the amplitude convention of Definition 19.2, the connected sharp kernels obey*

$$-\mathrm{i}\,[\mathcal{M}(f|i) - \mathcal{M}(i|f)^*] = \sum_X \int \mathrm{d}\Phi_X\,\mathcal{M}(X|f)^*\mathcal{M}(X|i),$$

where X runs over a complete orthogonal resolution of outgoing asymptotic channels, including the corresponding phase-space measures and identical-particle symmetry factors. In the forward case $f = i$,

$$2\ \mathrm{Im}\,\mathcal{M}(i|i) = \sum_X \int \mathrm{d}\Phi_X\,|\mathcal{M}(X|i)|^2.$$

For two incoming particles,

$$\sigma_{\rm tot} = \frac{2\ \mathrm{Im}\,\mathcal{M}(i|i)}{\mathcal{F}(p_1,p_2)}.$$

Proof. The operator identity

$$S^\dagger S = \mathbf{1}, \qquad S = \mathbf{1} + \mathrm{i}T,$$

is equivalent to

$$-\mathrm{i}(T - T^\dagger) = T^\dagger T.$$

Let i and f denote incoming and outgoing asymptotic momentum labels, including all discrete quantum numbers. Insert a complete set of outgoing asymptotic states between $T^\dagger$ and T. Removing the common overall momentum-conservation delta function gives the first displayed sharp-kernel identity. The conjugated factor on the right is fixed by Hilbert-space adjunction:

$$\langle f|T^\dagger|X\rangle = \langle X|T|f\rangle^*.$$

Thus it is $\mathcal{M}(X|f)^*$, not in general $\mathcal{M}(f|X)^*$. Replacing one by the other would require an additional reciprocity statement, for example from a time-reversal or detailed-balance symmetry after its antiunitary phases have been fixed.

Setting $f = i$ gives the optical theorem. No time-reversal invariance is used in this forward specialization: $\langle i|T^\dagger|X\rangle = \langle X|T|i\rangle^*$ by the definition of the adjoint, so each term is the norm square of the outgoing transition amplitude from the fixed incoming state. Dividing the complete transition probability per unit time by the incoming flux gives the total cross section. The amplitude on the left is the forward amplitude: the outgoing labels are the same as the incoming labels. □

Remark 19.7 (Complete sums and detector resolution)*.* The symbol X in the optical theorem denotes a complete orthogonal resolution of the outgoing scattering Hilbert space in the ideal theory under discussion. A detector with finite resolution is represented more accurately by a positive outgoing effect $E_{\mathcal{C}}$, $0 \le E_{\mathcal{C}} \le \mathbf{1}$, associated with an observed event class $\mathcal{C}$. The corresponding measured transition probability is

$$\langle i|T^\dagger E_{\mathcal{C}} T|i\rangle,$$

or, in sharp-kernel notation, the same phase-space sum as above with the weights and integration region specified by $E_{\mathcal{C}}$. The forward imaginary part $2\,\mathrm{Im}\,\mathcal{M}(i|i)$ corresponds to the special choice $E_{\mathcal{C}} = \mathbf{1}$, namely the complete inclusive sum over all exact outgoing states of the theory. Angular cuts, energy cuts, jet definitions, and unresolved soft radiation define different effects $E_{\mathcal{C}}$ and hence different cross sections.

In a theory with massless long-range fields the complete sharp fixed-particle-number terms are infrared-regulator dependent. The operational quantity is obtained by first keeping an infrared regulator, summing over the states that the detector cannot distinguish, and only then removing the regulator. Chapter 44 carries this out for charged QED, where real unresolved photons and virtual soft photons combine into a finite resolution-inclusive probability.

19.7 Partial-Wave States in Four Dimensions

Partial waves are most transparently defined as generalized eigenstates of the free two-particle asymptotic representation. In the center-of-mass frame use the δ-normalized two-particle basis and write, for scalar particles,

$$_\delta\langle \vec{k}_1, \vec{k}_2|E, \vec{P} = \vec{0}, \ell, m\rangle = \delta^{(3)}(\vec{k}_1 + \vec{k}_2)\,\delta(\omega_1 + \omega_2 - E)\,\mathcal{N}(E) Y_{\ell m}(\widehat{k}_1).$$

The angular momentum labels satisfy

$$J^2 = \ell(\ell+1), \qquad J_3 = m.$$

For identical spinless bosons, only even ℓ occurs. The normalization is chosen so that

$$\langle E', \vec{P}', \ell', m' | E, \vec{P}, \ell, m\rangle = \delta(E'-E)\delta^{(3)}(\vec{P}'-\vec{P})\delta_{\ell'\ell}\delta_{m'm}.$$

Using

$$\int k^2 \mathrm{d}k\, \delta(\omega_1(k)+\omega_2(k)-E) = \frac{k\,\omega_1\omega_2}{E},$$

and using the 1/2 in the symmetric two-particle resolution of the identity, one finds

$$\mathcal{N}(E) = \left(\frac{2E}{k\,\omega_1\omega_2}\right)^{1/2} \qquad \text{for identical scalar bosons.}$$

For distinguishable particles the same formula lacks the factor of 2 under the square root.

Rotational invariance in the center-of-mass frame makes the elastic partial waves diagonal:

$$S(E', \vec{P}', \ell', m' | E, \vec{P}, \ell, m) = \delta(E'-E)\delta^{(3)}(\vec{P}'-\vec{P})\delta_{\ell'\ell}\delta_{m'm}\, S_\ell(E)$$

in an elastic single-channel region. If inelastic channels are present, this equation describes the elastic matrix element of a larger unitary matrix, so

$$|S_\ell(E)| \le 1,$$

with equality in a purely elastic partial wave.

In the same δ-normalized convention, the connected elastic sharp-momentum kernel is obtained by inserting the resolution of the identity in partial waves. For identical scalar bosons in the center-of-mass frame,

$$\mathrm{i}(2\pi)^4 M_\delta(\widehat{q}|\widehat{p}) = \frac{\mathcal{N}(E)^2}{4\pi} \sum_{\substack{\ell=0\\ \ell\ \text{even}}}^{\infty} (2\ell+1)P_\ell(\widehat{q}\cdot\widehat{p})\big(S_\ell(E)-1\big).$$

This formula is the direct bridge between the partial-wave diagonalization of the S-operator and the sharp-momentum amplitude. Multiplying by the external normalization factors converts M_δ into the invariant amplitude $\mathcal{M}$ used in the cross-section formula.

19.8 Partial-Wave Amplitudes in Four Dimensions

For scalar $2 \to 2$ scattering in the center-of-mass frame, rotational invariance makes the amplitude a function of s and

$$x = \cos\theta = \widehat{p}_* \cdot \widehat{q}_*.$$

For distinguishable particles, or for an ordered pair of external labels, use the partial-wave expansion

$$\mathcal{M}(s,x) = 16\pi \sum_{\ell=0}^{\infty} (2\ell+1) a_\ell(s) P_\ell(x),$$

where P_ℓ is the Legendre polynomial. The inverse formula is

$$a_\ell(s) = \frac{1}{32\pi}\int_{-1}^{1} \mathrm{d}x\, P_\ell(x)\mathcal{M}(s,x).$$

This section fixes the ordered 16π normalization. For an unordered identical-boson channel the physical amplitude is the Bose symmetrization of the ordered amplitude; the corresponding even-ℓ 32π convention is displayed below. For equal incoming masses in the elastic region, define

$$\beta(s) = \frac{2|\vec{p}_*|}{\sqrt{s}}.$$

This $\beta(s)$ is a scalar two-body kinematic factor. The letter ρ is reserved in this monograph for spectral measures and their densities, such as the Källén–Lehmann measure $d\rho$. The partial-wave S-matrix eigenvalue is

$$S_\ell(s) = 1 + 2\mathrm{i}\beta(s)a_\ell(s).$$

Elastic unitarity is

$$|S_\ell(s)| = 1.$$

Equivalently, there is a real phase shift $\delta_\ell(s)$ such that

$$S_\ell(s) = \mathrm{e}^{2\mathrm{i}\delta_\ell(s)}$$

and

$$a_\ell(s) = \frac{\mathrm{e}^{2\mathrm{i}\delta_\ell(s)} - 1}{2\mathrm{i}\beta(s)} = \frac{\mathrm{e}^{\mathrm{i}\delta_\ell(s)}\sin\delta_\ell(s)}{\beta(s)}.$$

The same condition can be written

$$\operatorname{Im} a_\ell(s) = \beta(s)|a_\ell(s)|^2.$$

With inelastic channels open,

$$|S_\ell(s)| \le 1,$$

with equality precisely in a purely elastic partial wave.

For distinguishable scalar particles, the elastic total cross section is

$$\sigma_{\mathrm{el}} = \frac{\pi}{|\vec{p}_*|^2}\sum_{\ell=0}^{\infty}(2\ell+1)|S_\ell(s)-1|^2 = \frac{4\pi}{|\vec{p}_*|^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\delta_\ell(s).$$

For identical scalar bosons, the physical two-particle amplitude on unordered states is Bose symmetric. With the convention

$$\mathcal{M}_{\mathrm{id}}(s,x) = 32\pi \sum_{\substack{\ell=0\\ \ell\ \mathrm{even}}}^{\infty} (2\ell+1)a_\ell(s)P_\ell(x),$$

and the full-solid-angle final-state factor $1/2$, the elastic cross section is

$$\sigma_{\mathrm{el}}^{\mathrm{id}} = \frac{2\pi}{|\vec{p}_*|^2} \sum_{\substack{\ell=0\\ \ell\ \mathrm{even}}}^{\infty} (2\ell+1)|S_\ell(s)-1|^2.$$

This is the convention used later for identical-particle high-energy bounds.

19.9 Partial-Wave Unitarity Geometry

Partial-wave unitarity circle. Define

$$b_\ell(s) = \beta(s)a_\ell(s), \qquad S_\ell(s) = 1 + 2\mathrm{i}b_\ell(s).$$

In an elastic partial wave, $|S_\ell| = 1$. Writing

$$b_\ell = x_\ell + \mathrm{i}y_\ell,$$

this condition becomes

$$x_\ell^2 + \left(y_\ell - \frac{1}{2}\right)^2 = \frac{1}{4}.$$

Thus the elastic amplitude lies on the circle of radius $1/2$ centered at $\mathrm{i}/2$ in the complex b_ℓ-plane. Equivalently,

$$y_\ell = |b_\ell|^2.$$

The phase-shift form

$$b_\ell = \mathrm{e}^{\mathrm{i}\delta_\ell} \sin \delta_\ell$$

parametrizes this circle.

When inelastic channels are open, the elastic partial wave is a matrix element of a unitary matrix on a larger channel space. It is convenient to write

$$S_\ell = \eta_\ell \mathrm{e}^{2\mathrm{i}\delta_\ell}, \qquad 0 \le \eta_\ell \le 1.$$

Then $b_\ell = (S_\ell - 1)/(2\mathrm{i})$ lies inside the same circle:

$$x_\ell^2 + \left(y_\ell - \frac{1}{2}\right)^2 \le \frac{1}{4}, \qquad y_\ell \ge |b_\ell|^2.$$

The difference

$$y_\ell - |b_\ell|^2 = \frac{1 - \eta_\ell^2}{4}$$

is the contribution of inelastic final states in that angular-momentum channel. This is the partial-wave form of the optical theorem.

Substitute $S_\ell = 1 + 2\mathrm{i}b_\ell$ with $b_\ell = x_\ell + \mathrm{i}y_\ell$. Then

$$S_\ell = (1 - 2y_\ell) + 2\mathrm{i}x_\ell.$$

The elastic condition $|S_\ell| = 1$ is therefore

$$(1 - 2y_\ell)^2 + 4x_\ell^2 = 1,$$

which is equivalent to the displayed circle equation and to $y_\ell = |b_\ell|^2$. If $S_\ell = \eta_\ell \mathrm{e}^{2\mathrm{i}\delta_\ell}$ with $0 \le \eta_\ell \le 1$, the same substitution gives

$$|1 + 2\mathrm{i}b_\ell|^2 = \eta_\ell^2.$$

Rearranging yields

$$y_\ell - |b_\ell|^2 = \frac{1 - \eta_\ell^2}{4} \ge 0,$$

and the inequality form of the unitarity disk follows. The right side is the deficit $1 - \eta_\ell^2$ in the norm of the elastic component, expressed in the $b_\ell = (S_\ell - 1)/(2\mathrm{i})$ normalization. This is the partial-wave optical theorem.

19.10 Thresholds, Poles, and Resonances

The same variables organize the analytic structure of scattering. A threshold is the value of s at which a new on-shell intermediate channel becomes kinematically available. Across such a threshold, unitarity gives the discontinuity of amplitudes in terms of phase-space integrals over lower amplitudes.

A stable bound state in a two-particle channel appears as a pole of the partial-wave amplitude on the physical, or first, sheet below threshold. A resonance is represented by a pole reached after analytic continuation through a unitarity cut to an adjacent sheet. The sheet terminology and the distinction between a physical real region and the physical analytic sheet are fixed in Section 28.1; the organizing data are already present here: the S-operator, phase space, unitarity, and partial waves.

Chapter 20

Massive Particles and Spin

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

20.1 Massive One-Particle Representations

Definition 20.1 (Massive one-particle spin datum)**.** Work in $D = 4$. A massive one-particle datum consists of a Hilbert space $\mathcal{H}_1$ carrying an irreducible positive-energy unitary representation of the Poincare group whose translation generators P^μ have joint spectrum supported on a single positive-energy mass shell of mass $m > 0$. Equivalently, it is the massive row of Table 5.1. The mass shell is

$$\Sigma_m^+ = \{p = (p^0, \vec{p}) : p^0 = \omega_{\vec{p}},\ p^2 = -m^2\}, \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^2 + m^2}.$$

Generalized momentum states, understood as distributional vectors in the rigged-Hilbert-space sense of Section 5.2, are normalized by

$$\langle \vec{q}, \tau | \vec{p}, \sigma \rangle = (2\pi)^3\, 2\omega_{\vec{p}}\, \delta^{(3)}(\vec{q} - \vec{p})\, \delta_{\tau\sigma}.$$

The labels σ, τ span a finite-dimensional internal vector space which is fixed by Lorentz symmetry.

Remark 20.2 (Spacelike Wigner orbits). The full representation theory of the Poincare group also contains spacelike orbits $p^2 = \mu^2 > 0$, sometimes called tachyonic orbits. They are absent from this chapter and the following massless chapter because the spectrum condition assumed in Chapter 5 requires $\mathrm{Spec}(P) \subset \overline{V}_+$, while a spacelike orbit lies outside the closed forward lightcone.

Definition 20.3 (Standard rest momentum and normalization frames)**.** Choose the reference momentum

$$p_R = (m, \vec{0}).$$

For every $p \in \Sigma_m^+$, choose a standard Lorentz transformation

$$L(p) \in SO^+(1,3), \qquad L(p)p_R = p, \qquad L(p_R) = 1.$$

It is sometimes useful to compare this covariant normalization with the delta-function normalization

$${}_\delta\langle \vec{q}, \tau | \vec{p}, \sigma \rangle_\delta = \delta^{(3)}(\vec{q} - \vec{p})\delta_{\tau\sigma}.$$

In that convention one may define

$$|\vec{p}, \sigma\rangle_\delta = N(\vec{p})\, U(L(p))|\vec{0}, \sigma\rangle_\delta, \qquad N(\vec{p}) = \left(\frac{m}{\omega_{\vec{p}}}\right)^{1/2}.$$

The factor $N(\vec{p})$ is the Jacobian needed to keep the measure $d^3\vec{p}$ compatible with Lorentz transformations in a delta-normalized basis. The covariantly normalized states used below absorb this factor into the invariant mass-shell measure.

Definition 20.4 (Massive Wigner rotation)**.** The stabilizer of p_R in $SO^+(1,3)$ is the rotation group $SO(3)$. Whenever a Wigner rotation is inserted into a spin representation below, it is understood through its lift to the universal cover of $SO(3)$; the reason for this lift is explained in Section 20.2. The same letter denotes the projected Lorentz transformation when it acts on four-vectors.

For a Lorentz transformation Λ, define the Wigner rotation

$$W(\Lambda, p) = L(\Lambda p)^{-1}\Lambda L(p).$$

It obeys

$$W(\Lambda, p)p_R = p_R,$$

and is therefore an element of the massive little group. If the particle has spin j, with

$$j = 0, \frac{1}{2}, 1, \frac{3}{2}, \dots,$$

let $D^{(j)}$ be the corresponding irreducible unitary representation of $SU(2)$ on a vector space V_j of dimension $2j+1$. For a four-vector r, write $\mathrm{sp}(r)$ for its spatial part, so

$$p = (\omega_{\vec{p}}, \vec{p}), \qquad \mathrm{sp}(p) = \vec{p}.$$

Massive Wigner transformation law. The covariantly normalized one-particle states transform as

$$U(\Lambda)|\vec{p}, \sigma\rangle = \sum_{\tau=-j}^{j} D^{(j)}_{\tau\sigma}(W(\Lambda, p))\,|\,\mathrm{sp}(\Lambda p), \tau\rangle,$$

where $\sigma, \tau = -j, -j+1, \dots, j$. The covariant normalization above absorbs the Jacobian of the mass-shell measure, so no additional $\sqrt{(\Lambda p)^0/p^0}$ factor appears. In the delta-normalized convention the same computation gives

$$U(\Lambda)|\vec{p}, \sigma\rangle_\delta = \left(\frac{(\Lambda p)^0}{p^0}\right)^{1/2} \sum_{\tau=-j}^{j} D^{(j)}_{\tau\sigma}(W(\Lambda, p))\,|\,\mathrm{sp}(\Lambda p), \tau\rangle_\delta.$$

This is the same representation written in a basis adapted to $d^3\vec{p}$ rather than to $d^3\vec{p}/(2p^0)$. Keeping both formulas visible prevents the normalization factor from being mistaken for a property of spin. By definition $L(p)p_R = p$ and $L(\Lambda p)p_R = \Lambda p$. Therefore

$$W(\Lambda, p)p_R = L(\Lambda p)^{-1}\Lambda L(p)p_R = p_R,$$

so $W(\Lambda, p)$ belongs to the little group of the rest momentum. The restriction of the Poincare representation to the little group at p_R is an irreducible $SU(2)$ representation $D^{(j)}$. Acting first by $L(p)$, then by Λ, and finally comparing with the chosen standard transformation $L(\Lambda p)$ gives exactly the displayed spin matrix $D^{(j)}(W(\Lambda, p))$.

The absence or presence of the square-root factor is a statement about the basis measure. The invariant mass-shell measure satisfies

$$\frac{d^3\vec{p}}{2p^0} = \frac{d^3\,\mathrm{sp}(\Lambda p)}{2(\Lambda p)^0}.$$

Equivalently,

$$d^3\,\mathrm{sp}(\Lambda p) = \frac{(\Lambda p)^0}{p^0}\,d^3\vec{p}.$$

Thus the covariantly normalized basis, whose resolution of the identity uses $d^3\vec{p}/(2p^0)$, transforms without a scalar Jacobian. A basis normalized against $d^3\vec{p}$ must instead carry the unitary half-density factor $((\Lambda p)^0/p^0)^{1/2}$. This proves both formulas.

20.2 Projective Rotations and the Covering Group

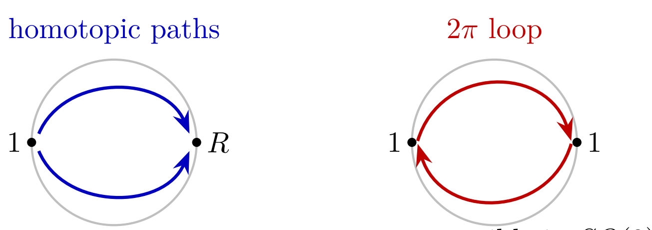
The appearance of $SU(2)$ rather than only $SO(3)$ is forced by the quantum implementation of rotations. A physical pure state is a ray, so the operator associated with a rotation $R \in SO(3)$ is defined on Hilbert space only up to a phase if no continuity convention has been chosen. Thus a projective representation may obey

$$U(R_2)U(R_1) = \mathrm{e}^{\mathrm{i}\alpha(R_2,R_1)}U(R_2R_1)$$

for a real phase function α. The phase ambiguity is removed by lifting rotations to paths. If $\gamma : [0, 1] \to SO(3)$ is a continuous path with $\gamma(0) = 1$ and $\gamma(1) = R$, continuity of the infinitesimal generators determines an operator U_γ starting from $U_{\gamma(0)} = 1$. If γ and γ' are homotopic with endpoints fixed, then

$$U_\gamma = U_{\gamma'}.$$

Consequently the correct group acting linearly is the universal cover of $SO(3)$, whose points are endpoint-fixed homotopy classes of such paths.



not contractible in $SO(3)$
but its square is

Massive spin labels from the covering group. The universal cover of the massive rotation little group is

$$\widetilde{SO(3)} \simeq SU(2).$$

Its finite-dimensional irreducible unitary representations are indexed by

$$j = 0, \frac{1}{2}, 1, \frac{3}{2}, \ldots,$$

with representation space V_j of dimension $2j+1$. The nontrivial central element of $SU(2)$, namely the lift of a 2π rotation, acts by

$$D^{(j)}(-1) = (-1)^{2j}\mathbf{1}_{V_j}.$$

The lift of a 4π rotation is the identity. Hence an irreducible massive one-particle representation carries exactly one such spin label j. The group $SO(3)$ is $\mathbb{RP}^3$. Its fundamental group is therefore

$$\pi_1(SO(3)) \simeq \mathbb{Z}_2.$$

The nontrivial class is represented by a 2π rotation loop, while the double loop representing a 4π rotation is contractible. The simply connected compact Lie group with Lie algebra $\mathfrak{so}(3)$ is $SU(2)$, and the covering map $SU(2) \to SO(3)$ has kernel $\{\pm 1\}$. The highest-weight classification of irreducible unitary $SU(2)$ representations gives one representation $D^{(j)}$ for each nonnegative half-integer j, of dimension $2j+1$. In the spin-j representation the central element -1 is the exponential of a 2π rotation and acts by $(-1)^{2j}$. Irreducibility of the one-particle Poincare representation means that its little-group representation is one irreducible summand, not a direct sum. With column vectors the matrices obey $D(W_2W_1) = D(W_2)D(W_1)$; row-index conventions on bras or matrix elements transpose this order and do not alter the representation.

20.3 Spin Frames on the Mass Shell

Definition 20.5 (Massive spin frame)**.** The choice of standard transformations $L(p)$ is a choice of spin frame over the mass shell. To make this statement precise, let

$$d\mu_m(p) = \frac{d^3p}{(2\pi)^3\, 2\omega_{\vec{p}}}$$

be the invariant measure on Σ_m^+. After choosing $L(p)$, the one-particle Hilbert space is represented as

$$\mathcal{H}_1 \simeq L^2(\Sigma_m^+, d\mu_m; V_j).$$

The generalized basis associated to this frame is the distributional map

$$F_L(p) : V_j \longrightarrow \mathcal{H}_1, \qquad F_L(p)e_\sigma = |\vec{p}, \sigma\rangle,$$

where $\{e_\sigma\}_{\sigma=-j}^{j}$ is an orthonormal basis of V_j.

Lemma 20.6 (Wigner cocycle and spin-frame change)**.** *The Lorentz action is*

$$U(\Lambda)F_L(p) = F_L(\Lambda p)D^{(j)}(W(\Lambda, p)).$$

This formula is a representation of the Lorentz group because the Wigner rotation obeys the cocycle identity

$$W(\Lambda_2\Lambda_1, p) = W(\Lambda_2, \Lambda_1 p)W(\Lambda_1, p).$$

If $Q : \Sigma_m^+ \to SU(2)$ *is a smooth little-group-valued function, then*

$$L'(p) = L(p)Q(p)$$

is another choice of standard transformations. The corresponding Wigner rotation is

$$W'(\Lambda, p) = Q(\Lambda p)^{-1}W(\Lambda, p)Q(p).$$

The associated generalized basis is

$$F_{L'}(p) = F_L(p)D^{(j)}(Q(p)).$$

Thus a wavefunction written as a column $\psi_L(p) \in V_j$ *in the L frame is written in the* L' *frame as*

$$\psi_{L'}(p) = D^{(j)}(Q(p))^{-1}\psi_L(p).$$

The inner product

$$\langle \psi, \chi \rangle = \int_{\Sigma_m^+} d\mu_m(p)\, \psi_L(p)^\dagger \chi_L(p)$$

is independent of the spin frame because $D^{(j)}(Q(p))$ *is unitary. In this language, a scattering amplitude with external massive spin states is a multilinear pairing of spin-frame components and dual spin-frame components whose value is invariant under the simultaneous transformations above.*

Proof. The action formula is the massive Wigner transformation law above written as a map $V_j \to \mathcal{H}_1$. The cocycle identity follows from a direct factorization:

$$\begin{aligned}
W(\Lambda_2\Lambda_1, p) &= L(\Lambda_2\Lambda_1 p)^{-1}\Lambda_2\Lambda_1 L(p) \\
&= L(\Lambda_2\Lambda_1 p)^{-1}\Lambda_2 L(\Lambda_1 p)\, L(\Lambda_1 p)^{-1}\Lambda_1 L(p) \\
&= W(\Lambda_2, \Lambda_1 p)W(\Lambda_1, p).
\end{aligned}$$

If $L'(p) = L(p)Q(p)$, then

$$\begin{aligned}
W'(\Lambda, p) &= L'(\Lambda p)^{-1}\Lambda L'(p) \\
&= Q(\Lambda p)^{-1}L(\Lambda p)^{-1}\Lambda L(p)Q(p) \\
&= Q(\Lambda p)^{-1}W(\Lambda, p)Q(p).
\end{aligned}$$

The basis relation

$$F_{L'}(p) = F_L(p)D^{(j)}(Q(p))$$

therefore forces the component relation $\psi_{L'}(p) = D^{(j)}(Q(p))^{-1}\psi_L(p)$. Since $D^{(j)}$ is unitary,

$$\psi_{L'}(p)^\dagger \chi_{L'}(p) = \psi_L(p)^\dagger \chi_L(p)$$

pointwise on the mass shell, and the displayed inner product is spin-frame independent. Dual spin-frame components transform by the inverse dual matrices, so any contracted scattering amplitude is independent of the choice of $L(p)$. □

20.4 Covariant Fields as Intertwiners

Proposition 20.7 (Vacuum-to-particle intertwiners)**.** *Let $\widehat{\Phi}_A(x)$ be a local field whose index A transforms in a finite-dimensional representation R of the double cover* $\mathrm{Spin}^+(1,3) \simeq SL(2,\mathbb{C})$*:*

$$U(\Lambda)\widehat{\Phi}_A(x)U(\Lambda)^{-1} = R_A{}^B(\Lambda)\widehat{\Phi}_B(\Lambda x).$$

The vacuum-to-particle matrix element is

$$\langle\Omega|\widehat{\Phi}_A(0)|\vec{p},\sigma\rangle = u_A{}^\sigma(p).$$

Translation covariance gives the spacetime dependence

$$\langle\Omega|\widehat{\Phi}_A(x)|\vec{p},\sigma\rangle = \mathrm{e}^{\mathrm{i}p\cdot x}u_A{}^\sigma(p).$$

Lorentz covariance and the Wigner transformation law imply

$$\sum_{\tau=-j}^{j} u_A{}^\tau(\Lambda p)D^{(j)}_{\tau\sigma}(W(\Lambda,p)) = R_A{}^B(\Lambda^{-1})u_B{}^\sigma(p).$$

This is the equivariance condition that connects the covariant field index A to the spin-frame index σ.

At the reference momentum p_R, the matrix

$$u_A{}^\sigma(p_R) : V_j \longrightarrow R|_{SU(2)}$$

is an intertwiner of $SU(2)$ representations:

$$R(W)_A{}^B u_B{}^\sigma(p_R) = \sum_{\tau=-j}^{j} u_A{}^\tau(p_R)D^{(j)}_{\tau\sigma}(W), \qquad W \in SU(2).$$

Thus a covariant field can have nonzero overlap with a spin-j particle exactly through the spin-j part contained in the restriction of R to the massive little group. The boosted wavefunctions are

$$u_A{}^\sigma(p) = R_A{}^B(L(p)^{-1})\, u_B{}^\sigma(p_R),$$

with the convention for $L(p)$ fixed above. Different choices of standard boost are spin-frame changes of the type described in the previous section, and the field intertwiners are used with the corresponding transformed spin-frame components.

Proof. Translation covariance gives

$$\widehat{\Phi}_A(x) = \mathrm{e}^{-\mathrm{i}P\cdot x}\widehat{\Phi}_A(0)\mathrm{e}^{\mathrm{i}P\cdot x}$$

in the convention used throughout this volume. Since $P^\mu|\vec{p},\sigma\rangle = p^\mu|\vec{p},\sigma\rangle$ and $\langle\Omega|P^\mu = 0$, the spacetime dependence is $\mathrm{e}^{\mathrm{i}p\cdot x}u_A{}^\sigma(p)$.

For Lorentz covariance, compute the same matrix element in two ways. The Wigner transformation law gives

$$\langle\Omega|\widehat{\Phi}_A(0)U(\Lambda)|\vec{p},\sigma\rangle = \sum_{\tau=-j}^{j} u_A{}^\tau(\Lambda p)D^{(j)}_{\tau\sigma}(W(\Lambda,p)).$$

Vacuum invariance and field covariance give

$$\begin{aligned}\langle\Omega|\widehat{\Phi}_A(0)U(\Lambda)|\vec{p},\sigma\rangle &= \langle\Omega|U(\Lambda)U(\Lambda)^{-1}\widehat{\Phi}_A(0)U(\Lambda)|\vec{p},\sigma\rangle\\ &= R_A{}^B(\Lambda^{-1})u_B{}^\sigma(p).\end{aligned}$$

Equating these expressions proves the equivariance condition. If $\Lambda = W$ fixes p_R, and the standard section has $L(p_R) = 1$, the equivariance equation becomes precisely the displayed $SU(2)$-intertwiner condition at the rest momentum. Conversely, a rest intertwiner satisfying this condition determines the boosted functions by

$$u_A{}^\sigma(p) = R_A{}^B(L(p)^{-1})u_B{}^\sigma(p_R),$$

and substituting the cocycle identity of Lemma 20.6 verifies the equivariance equation for arbitrary Λ. The possible nonzero intertwiners are therefore exactly the copies of V_j appearing in the restriction of R to the massive little group. □

20.5 Spin One Half

For spin $j = \frac{1}{2}$, the smallest Lorentz-covariant field space is a Dirac spinor. Let the gamma matrices obey

$$\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}, \qquad \eta = \mathrm{diag}(-,+,+,+).$$

The global spinor and gamma-matrix conventions are collected in Section 40.16; the present section uses the same symbols and fixes the particle-intertwiner normalizations. One concrete realization, useful for checking signs, is

$$\gamma^0 = -\mathrm{i}\begin{pmatrix}0 & I_2\\ I_2 & 0\end{pmatrix}, \qquad \gamma^i = -\mathrm{i}\begin{pmatrix}0 & \sigma_i\\ -\sigma_i & 0\end{pmatrix}, \qquad i = 1,2,3,$$

where

$$\sigma_1 = \begin{pmatrix}0 & 1\\ 1 & 0\end{pmatrix}, \quad \sigma_2 = \begin{pmatrix}0 & -\mathrm{i}\\ \mathrm{i} & 0\end{pmatrix}, \quad \sigma_3 = \begin{pmatrix}1 & 0\\ 0 & -1\end{pmatrix}.$$

The following formulas are basis-independent statements about the Clifford module. Define

$$S^{\mu\nu} = -\frac{\mathrm{i}}{4}[\gamma^\mu, \gamma^\nu], \qquad R(\Lambda) = \exp\left(-\frac{\mathrm{i}}{2}\omega_{\mu\nu}S^{\mu\nu}\right)$$

for

$$\Lambda = \exp(\omega), \qquad \omega_{\mu\nu} = -\omega_{\nu\mu}.$$

The generators satisfy

$$[S^{\mu\nu}, \gamma^\rho] = -\mathrm{i}\gamma^\mu\eta^{\nu\rho} + \mathrm{i}\gamma^\nu\eta^{\mu\rho},$$

and therefore

$$R(\Lambda)\gamma^\mu R(\Lambda)^{-1} = \Lambda^\mu{}_\nu\gamma^\nu.$$

On the rest subspace, a spatial rotation by angle θ about the 3-axis acts in the spin-$\frac{1}{2}$ representation as

$$D(R_{12}(\theta)) = \exp\left(-\frac{\mathrm{i}\theta}{2}\sigma_3\right) = \begin{pmatrix}\mathrm{e}^{-\mathrm{i}\theta/2} & 0\\ 0 & \mathrm{e}^{\mathrm{i}\theta/2}\end{pmatrix}.$$

Thus a 2π rotation acts by -1 on a spinor, while a 4π rotation acts by $+1$. This is the infinitesimal form of the covering-group discussion above.

Proposition 20.8 (Massive Dirac eigenspaces, projectors, and spin sums). *Write*

$$\not p = p_\mu \gamma^\mu.$$

For $p_R = (m, \vec{0})$,

$$\not p_R = -m\gamma^0, \qquad \not p_R^2 = -m^2.$$

Choose two rest spinors u_R^σ *and two rest spinors* v_R^σ, $\sigma = 1, 2$, *by*

$$\not p_R u_R^\sigma = \mathrm{i}m\, u_R^\sigma, \qquad \not p_R v_R^\sigma = -\mathrm{i}m\, v_R^\sigma.$$

Their boosts are

$$u^\sigma(p) = R(L(p)^{-1})u_R^\sigma, \qquad v^\sigma(p) = R(L(p)^{-1})v_R^\sigma.$$

Using covariance of γ^μ, *these spinors obey*

$$(\not p - \mathrm{i}m)u^\sigma(p) = 0, \qquad (\not p + \mathrm{i}m)v^\sigma(p) = 0.$$

These are the momentum-space Dirac equations associated with the two eigenspaces of $\not p$ *on the mass shell.*

Let

$$\beta = \mathrm{i}\gamma^0, \qquad \bar{u} = u^\dagger\beta, \qquad \bar{v} = v^\dagger\beta.$$

The hermiticity identities in the above signature are

$$(\gamma^0)^\dagger = -\gamma^0, \qquad (\gamma^i)^\dagger = \gamma^i, \qquad R(\Lambda)^\dagger = \beta R(\Lambda^{-1})\beta.$$

They imply that the β*-pairing is Lorentz invariant:*

$$(R(\Lambda)s)^\dagger\beta R(\Lambda)t = s^\dagger\beta t.$$

The projectors onto the two eigenspaces of $\not p$ *are*

$$\Pi_+(p) = \frac{m - \mathrm{i}\not p}{2m}, \qquad \Pi_-(p) = \frac{m + \mathrm{i}\not p}{2m}.$$

For the delta-normalized one-particle states it is useful to include the same Jacobian factor as in the state normalization and define

$$\mathcal{U}^\sigma(p) = \left(\frac{m}{p^0}\right)^{1/2} R(L(p)^{-1})\mathcal{U}_R^\sigma, \qquad \mathcal{V}^\sigma(p) = \left(\frac{m}{p^0}\right)^{1/2} R(L(p)^{-1})\mathcal{V}_R^\sigma.$$

Choose rest spinors so that

$$\mathcal{U}_R^{\sigma\dagger}\beta\mathcal{U}_R^\tau = \delta^{\sigma\tau}, \qquad \mathcal{V}_R^{\sigma\dagger}\beta\mathcal{V}_R^\tau = -\delta^{\sigma\tau}, \qquad \mathcal{U}_R^{\sigma\dagger}\beta\mathcal{V}_R^\tau = 0.$$

Then

$$\mathcal{U}^\sigma(p)^\dagger\beta\mathcal{U}^\tau(p) = \frac{m}{p^0}\delta^{\sigma\tau}, \qquad \mathcal{V}^\sigma(p)^\dagger\beta\mathcal{V}^\tau(p) = -\frac{m}{p^0}\delta^{\sigma\tau}.$$

The corresponding spin sums, with ordinary matrix multiplication in spinor indices, are

$$\sum_{\sigma=1}^{2}\mathcal{U}^\sigma(p)\mathcal{U}^\sigma(p)^\dagger = \frac{m - \mathrm{i}\not p}{2p^0}\,\beta, \qquad \sum_{\sigma=1}^{2}\mathcal{V}^\sigma(p)\mathcal{V}^\sigma(p)^\dagger = \frac{-m - \mathrm{i}\not p}{2p^0}\,\beta.$$

Equivalently,

$$\sum_{\sigma=1}^{2}\mathcal{U}^\sigma(p)\overline{\mathcal{U}}^\sigma(p)=\frac{m-\mathrm{i}\not{p}}{2p^0},\qquad \sum_{\sigma=1}^{2}\mathcal{V}^\sigma(p)\overline{\mathcal{V}}^\sigma(p)=-\frac{m+\mathrm{i}\not{p}}{2p^0}.$$

The minus sign in the second identity is fixed by the sign of the β-norm on the negative Dirac eigenspace; the particle Hilbert-space inner product remains positive.

Proof. The Clifford relation gives

$$\not{p}^2=p_\mu p_\nu\gamma^\mu\gamma^\nu=p^2\mathbf{1}=-m^2\mathbf{1}$$

on the mass shell, because the antisymmetric commutator part drops out after contraction with $p_\mu p_\nu$. Hence the minimal polynomial of $\not{p}$ divides λ^2+m^2, and the two spectral projectors are

$$\Pi_+(p)=\frac{m-\mathrm{i}\not{p}}{2m},\qquad \Pi_-(p)=\frac{m+\mathrm{i}\not{p}}{2m}.$$

They satisfy $\Pi_\pm^2=\Pi_\pm$, $\Pi_+\Pi_-=0$, and $\Pi_++\Pi_-=1$. The defining equations for u_R^σ and v_R^σ say that they span the $\Pi_+(p_R)$ and $\Pi_-(p_R)$ eigenspaces.

The covariance identity

$$R(\Lambda)\gamma^\mu R(\Lambda)^{-1}=\Lambda^\mu{}_\nu\gamma^\nu$$

implies

$$\not{p}\,R(L(p)^{-1})=R(L(p)^{-1})\not{p}_R,$$

with $p=L(p)p_R$. Applying this identity to u_R^σ and v_R^σ proves the two momentum-space Dirac equations.

The relation

$$R(\Lambda)^\dagger=\beta R(\Lambda^{-1})\beta$$

is equivalent to $R(\Lambda)^\dagger\beta R(\Lambda)=\beta$, so the β-pairing is Lorentz invariant. Multiplication by $(m/p^0)^{1/2}$ in the delta-normalized spinors therefore changes the rest norms only by the factor m/p^0, giving the displayed β-inner-products.

It remains to identify the matrix-valued completeness relations. At fixed p, the vectors $\mathcal{U}^\sigma(p)$ form a β-orthogonal basis of the positive eigenspace, while $\mathcal{V}^\sigma(p)$ form a β-orthogonal basis of the negative eigenspace with negative β-norm. Hence

$$\sum_{\sigma=1}^{2}\mathcal{U}^\sigma(p)\overline{\mathcal{U}}^\sigma(p)=\frac{m}{p^0}\Pi_+(p),\qquad \sum_{\sigma=1}^{2}\mathcal{V}^\sigma(p)\overline{\mathcal{V}}^\sigma(p)=-\frac{m}{p^0}\Pi_-(p).$$

Substituting the projectors gives the two spin sums with bars. Since $\beta^2=1$, the identities without bars follow by multiplying on the right by β. This proves all displayed projector and spin-sum formulas. $\square$

For the explicit gamma matrices displayed above, an adapted rest basis is

$$\mathcal{U}_R^1=\frac{1}{\sqrt{2}}\begin{pmatrix}1\\0\\1\\0\end{pmatrix},\qquad \mathcal{U}_R^2=\frac{1}{\sqrt{2}}\begin{pmatrix}0\\1\\0\\1\end{pmatrix},$$

$$\mathcal{V}_R^1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ 0 \\ -1 \\ 0 \end{pmatrix}, \qquad \mathcal{V}_R^2 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ 1 \\ 0 \\ -1 \end{pmatrix}.$$

If

$$\gamma_5 = -\mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3 = \begin{pmatrix} I_2 & 0 \\ 0 & -I_2 \end{pmatrix},$$

then

$$\mathcal{V}_R^\sigma = \gamma_5 \mathcal{U}_R^\sigma.$$

These projector identities are the algebraic source of the external spinor factors in spinorial LSZ reduction.

20.6 Particle Spin and Field Indices

The spin j labels an irreducible unitary representation of the massive little group on the one-particle Hilbert space. A field index A labels a finite-dimensional Lorentz representation used by a local operator. The two are related by the intertwiner

$$u_A{}^\sigma(p) = \langle \Omega | \widehat{\Phi}_A(0) | \vec{p}, \sigma \rangle.$$

This distinction is part of the basic architecture of relativistic quantum theory. The same spin-j particle may be created by different local operators, and a single covariant field representation may contain several little-group spins when restricted to $SU(2)$. LSZ for spinning particles uses the pole of the relevant two-point function together with the intertwiner $u_A{}^\sigma(p)$ to convert field indices into external particle spin labels.

The next chapter constructs spinor field operators and their functional integral calculus. The representation-theoretic data established here will then become the spinor completeness relations, propagator numerators, and external-line factors used in perturbative calculations.

Massless Particles, Helicity, and Gauge Redundancy

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

21.1 The Massless Orbit

Work in $D = 4$ with mostly-plus metric

$$\eta_{\mu\nu} = \mathrm{diag}(-, +, +, +).$$

The positive-energy massless orbit is

$$\Sigma_0^+ = \{k = (k^0, \vec{k}) : k^2 = 0,\ k^0 = |\vec{k}|,\ k^0 > 0\}.$$

Together with the massive positive-energy shells of Chapter 20, this is one of the orbit types compatible with the spectrum condition; the complete four-dimensional orbit classification is summarized in Table 5.1. Spacelike Wigner orbits $k^2 > 0$ are excluded by $\mathrm{Spec}(P) \subset \overline{V}_+$, as stated there. Choose a reference momentum

$$q = (\kappa, 0, 0, \kappa), \qquad \kappa > 0.$$

For each $k \in \Sigma_0^+$, choose a standard Lorentz transformation

$$L(k) \in SO^+(1, 3), \qquad L(k)q = k.$$

As in the massive case, Hilbert-space formulas use the universal cover of $SO^+(1,3)$ when spinorial phases are involved, while the same symbols denote the projected Lorentz transformations acting on four-vectors. The little group of q is

$$G_q = \{W \in SO^+(1,3) : Wq = q\}.$$

Definition 21.1 (Massless one-particle orbit and standard section)**.** The positive-energy massless orbit is the homogeneous space $\Sigma_0^+ \simeq SO^+(1,3)/G_q$, where G_q is the stabilizer of $q = (\kappa, 0, 0, \kappa)$. A standard section is a choice of Lorentz transformation $L(k)$ for each $k \in \Sigma_0^+$ such that $L(k)q = k$. It is not canonical: replacing $L(k)$ by $L(k)Q(k)$, with $Q(k) \in G_q$, changes the one-particle helicity frame.

The non-uniqueness of $L(k)$ is the origin of helicity-frame phases and of the representative freedom of vector polarizations. It is the choice of local trivialization of a line bundle over the null orbit.

For vector indices, write a Lorentz transformation as

$$\Lambda = \exp\left(\frac{\mathrm{i}}{2}\omega_{\mu\nu}M^{\mu\nu}\right), \qquad \omega_{\mu\nu} = -\omega_{\nu\mu},$$

where

$$(M^{\mu\nu})^{\rho}{}_{\sigma} = -\mathrm{i}\,(\eta^{\mu\rho}\delta^{\nu}_{\sigma} - \eta^{\nu\rho}\delta^{\mu}_{\sigma})\,.$$

Then, for infinitesimal ω,

$$\Lambda^{\mu}{}_{\nu} = \delta^{\mu}{}_{\nu} + \omega^{\mu}{}_{\nu},$$

and

$$[M^{\mu\nu}, M^{\rho\sigma}] = -\mathrm{i}\,(\eta^{\nu\rho}M^{\mu\sigma} - \eta^{\mu\rho}M^{\nu\sigma} - (\rho \leftrightarrow \sigma))\,.$$

Let $J_{\mu\nu}$ denote the corresponding Hilbert-space generators on the one-particle representation:

$$U(\Lambda) = \exp\left(\frac{\mathrm{i}}{2}\omega_{\mu\nu}J^{\mu\nu}\right), \qquad [J^{\mu\nu}, J^{\rho\sigma}] = -\mathrm{i}\,(\eta^{\nu\rho}J^{\mu\sigma} - \eta^{\mu\rho}J^{\nu\sigma} - (\rho \leftrightarrow \sigma))\,.$$

The three Hilbert-space generators

$$J_3 = J_{12}, \qquad N_1 = J_{01} + J_{31}, \qquad N_2 = J_{02} + J_{32}$$

generate G_q. Their commutators are

$$[N_1, N_2] = 0, \qquad [J_3, N_1] = \mathrm{i}N_2, \qquad [J_3, N_2] = -\mathrm{i}N_1.$$

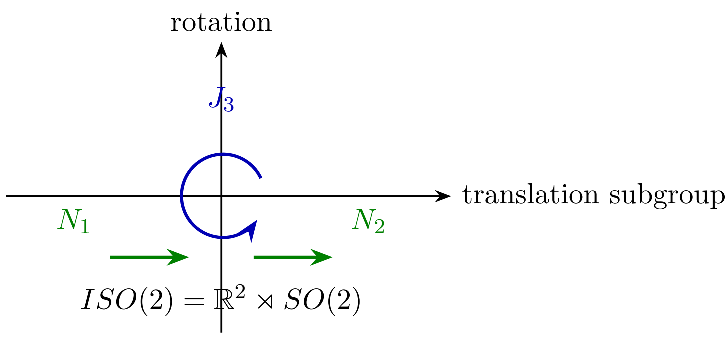
Little algebra of a future null momentum. The infinitesimal stabilizer of $q = (\kappa, 0, 0, \kappa)$ is generated by $J_3 = J_{12}$, $N_1 = J_{01} + J_{31}$, and $N_2 = J_{02} + J_{32}$, and these generators obey

$$[N_1, N_2] = 0, \qquad [J_3, N_1] = \mathrm{i}N_2, \qquad [J_3, N_2] = -\mathrm{i}N_1.$$

Hence the connected little group is the double cover of $\mathbb{R}^2 \rtimes SO(2)$. In the four-vector representation the matrices M_{12}, $M_{01} + M_{31}$, and $M_{02} + M_{32}$ annihilate q. Conversely, if an infinitesimal Lorentz transformation $\omega^{\mu}{}_{\nu}$ stabilizes q, then $\omega q = 0$. With $q^0 = q^3 = \kappa$, this condition and the η-antisymmetry of ω leave precisely one rotation parameter in the $1,2$-plane and two null-translation parameters, represented by the three generators displayed above.

The commutators follow by substituting these linear combinations into the Lorentz algebra. The translation commutator cancels between the $(01,02)$ and $(31,32)$ contributions, while J_{12} rotates the pair $(J_{01}+J_{31}, J_{02}+J_{32})$ as a two-vector. This is the Lie algebra of the Euclidean group of the transverse plane.

This is the Lie algebra of the Euclidean group $ISO(2)$: J_3 generates rotations in a two-dimensional transverse plane, while N_1, N_2 generate commuting translations in that plane. The double cover is used on Hilbert space.



21.2 Little-Group Matrices

The matrix representatives make the $ISO(2)$ structure explicit. The rotation around the x^3-axis is generated by

$$(M_{12})^{\mu}{}_{\nu} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & -\mathrm{i} & 0 \\ 0 & \mathrm{i} & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

so

$$R_3(\theta) = \mathrm{e}^{\mathrm{i}\theta M_{12}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta & \sin\theta & 0 \\ 0 & -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The two null-translation generators are

$$A = M_{01} + M_{31} = -\mathrm{i}\begin{pmatrix} 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & -1 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix},$$

and

$$B = M_{02} + M_{32} = -\mathrm{i}\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{pmatrix}.$$

Since $A^3 = B^3 = A^2B = AB^2 = 0$ in this representation and $[A, B] = 0$, their exponential is the finite polynomial

$$T(\alpha, \beta) = \mathrm{e}^{\mathrm{i}\alpha A + \mathrm{i}\beta B} = \begin{pmatrix} 1+\zeta & \alpha & \beta & -\zeta \\ \alpha & 1 & 0 & -\alpha \\ \beta & 0 & 1 & -\beta \\ \zeta & \alpha & \beta & 1-\zeta \end{pmatrix}, \qquad \zeta = \frac{\alpha^2 + \beta^2}{2}.$$

Every displayed matrix fixes q, and the little-group element with parameters (α, β, θ) is

$$W(\alpha, \beta, \theta) = T(\alpha, \beta)R_3(\theta).$$

The matrix $T(\alpha, \beta)$ satisfies

$$T(\alpha, \beta)^T \eta\, T(\alpha, \beta) = \eta, \qquad T(\alpha, \beta)q = q,$$

and the product law

$$T(\alpha, \beta)T(\alpha', \beta') = T(\alpha + \alpha', \beta + \beta').$$

The rotation $R_3(\theta)$ acts on the pair (α, β) by the ordinary rotation of the transverse plane. The displayed $T(\alpha, \beta)$ is the exponential of $\mathrm{i}\alpha A + \mathrm{i}\beta B$. Since A and B are Lorentz Lie-algebra matrices, the exponential preserves η. Multiplication of the displayed matrix by $(\kappa, 0, 0, \kappa)^T$ gives $(\kappa, 0, 0, \kappa)^T$, so $T(\alpha, \beta)$ fixes q. Because A and B commute, their exponentials multiply by adding parameters. The commutators $[M_{12}, A] = \mathrm{i}B$ and $[M_{12}, B] = -\mathrm{i}A$ give the stated rotational action on the null-translation parameters.

The vector-space commutators

$$[M_{12}, A] = \mathrm{i}B, \qquad [M_{12}, B] = -\mathrm{i}A$$

are the matrix form of the semidirect product $\mathbb{R}^2 \rtimes SO(2)$.

21.3 Helicity Representations

The Hilbert-space counterparts of A and B are N_1 and N_2. Since $[N_1, N_2] = 0$, a fixed-q generalized basis, in the sense of Section 5.2, may be chosen so that

$$N_1|q, a, b; \lambda\rangle = a|q, a, b; \lambda\rangle, \qquad N_2|q, a, b; \lambda\rangle = b|q, a, b; \lambda\rangle.$$

Here λ denotes any remaining degeneracy label. The commutators with J_3 imply that, on these labels,

$$J_3 = \mathrm{i}b\frac{\partial}{\partial a} - \mathrm{i}a\frac{\partial}{\partial b} + J_3^{(0)},$$

where $J_3^{(0)}$ acts on the degeneracy space at fixed (a, b). Consequently

$$\mathrm{e}^{\mathrm{i}\theta J_3}|q, a, b; \lambda\rangle = |q, a\cos\theta - b\sin\theta, a\sin\theta + b\cos\theta; \lambda_\theta\rangle$$

up to the action of $J_3^{(0)}$. If $a^2 + b^2 > 0$, the one-particle labels at fixed momentum include the full $SO(2)$-orbit of (a, b). Those irreducible representations are continuous-spin representations. The helicity sectors are the massless one-particle irreducible representations for which

$$N_1|q, h\rangle = 0, \qquad N_2|q, h\rangle = 0.$$

The remaining little-group generator acts by

$$J_3|q,h\rangle = h|q,h\rangle.$$

Equivalently, for

$$W(\alpha,\beta,\theta) = \exp(\mathrm{i}\alpha N_1 + \mathrm{i}\beta N_2)\exp(\mathrm{i}\theta J_3),$$

the state transforms as

$$U(W(\alpha,\beta,\theta))|q,h\rangle = \mathrm{e}^{\mathrm{i}h\theta}|q,h\rangle.$$

The double-cover rotation condition gives

$$h \in \frac{1}{2}\mathbb{Z}.$$

Definition 21.2 (Massless helicity representation)**.** A massless one-particle helicity representation is the induced positive-energy Poincare representation built from the little-group character

$$\chi_h(W(\alpha,\beta,\theta)) = \mathrm{e}^{\mathrm{i}h\theta}, \qquad h \in \frac{1}{2}\mathbb{Z},$$

in which the translation subgroup $\mathbb{R}^2 \subset ISO(2)$ acts trivially. Equivalently, at the reference momentum q, $N_1 = N_2 = 0$ and J_3 acts by the scalar h.

Continuous-spin alternative. The commuting self-adjoint generators N_1, N_2 have a joint spectral measure. The little-algebra commutators above imply

$$\mathrm{e}^{\mathrm{i}\theta J_3}(N_1,N_2)\mathrm{e}^{-\mathrm{i}\theta J_3} = (N_1\cos\theta - N_2\sin\theta,\ N_1\sin\theta + N_2\cos\theta).$$

Consequently the support of the joint spectral measure is invariant under rotations of the (a,b)-plane. If it contains a point with $a^2+b^2=\rho^2>0$, the little-group orbit contains the full circle

$$(a,b) \mapsto (a\cos\theta - b\sin\theta,\ a\sin\theta + b\cos\theta).$$

On this circle the rotation generator acts by the regular $SO(2)$ action, or by its double-cover lift, and the angular Fourier modes form an integer-spaced infinite tower. This is the representation-theoretic continuous-spin alternative. Finite-helicity representations are the $\rho = 0$ case in which the translation subgroup acts trivially and only the character of the rotation subgroup remains.

Remark 21.3 (Continuous-spin sectors)*.* The alternative $a^2 + b^2 = \rho^2 > 0$ gives the massless continuous-spin, or infinite-spin, Wigner representations. They are legitimate irreducible positive-energy representations of the Poincare group, so the restriction to $\rho = 0$ is an additional physical and structural choice. At fixed momentum the little-group orbit is a circle, and the Fourier modes on that circle form an infinite tower of helicity labels mixed by boosts. A gas of such particles therefore has infinitely many internal polarizations at each momentum; ordinary finite-helicity thermodynamic counting is lost unless further structure controls the occupation of those modes.

There is also a sharper locality obstruction. Under the usual assumptions of positive energy, covariance, local commutativity, and pointlike covariant local fields, the zero-mass infinite-spin representations cannot be interpolated by a local field with a nonzero vacuum-to-one-particle matrix element. Equivalently, their natural localization in algebraic constructions is spacelike-cone or string localization rather than point localization in bounded regions. Such sectors are therefore possible representation-theoretic options, but they do not enter the point-local or gauge-redundant helicity field constructions used for photons, gravitons, and the gauge theories developed in this volume.

There are two useful normalization conventions. The covariant convention used below is

$$\langle k', h' | k, h \rangle = (2\pi)^3 \, 2k^0 \, \delta^{(3)}(\vec{k}' - \vec{k}) \delta_{h'h}.$$

In the delta-normalized convention

$$_\delta\langle \vec{k}', h' | \vec{k}, h \rangle_\delta = \delta^{(3)}(\vec{k}' - \vec{k}) \delta_{h'h},$$

the corresponding state is

$$|\vec{k}, h\rangle_\delta = \sqrt{\frac{q^0}{k^0}} \, U(L(k)) |\vec{q}, h\rangle_\delta.$$

The factor is fixed by the Lorentz transformation of the three-dimensional delta function on the mass shell. It gives

$$U(\Lambda)|\vec{k}, h\rangle_\delta = \sqrt{\frac{(\Lambda k)^0}{k^0}} \, e^{ih\theta(\Lambda,k)} |\overrightarrow{\Lambda k}, h\rangle_\delta.$$

For general $k \in \Sigma_0^+$, define generalized one-particle states by

$$|k, h\rangle = U(L(k))|q, h\rangle,$$

with the covariant normalization displayed above. For a Lorentz transformation Λ, the Wigner little-group element is

$$W(\Lambda, k) = L(\Lambda k)^{-1} \Lambda L(k),$$

and the helicity state transforms by

$$U(\Lambda)|k, h\rangle = e^{ih\theta(\Lambda,k)} |\Lambda k, h\rangle,$$

where $\theta(\Lambda, k)$ is the $SO(2)$ rotation angle of $W(\Lambda, k)$ in the helicity representation. Different choices of $L(k)$ change the phase convention for $|k, h\rangle$ but leave invariant matrix elements unchanged.

21.4 Helicity Frames

For a fixed helicity h, let $V_h \simeq \mathbb{C}$ be the one-dimensional little-group representation with character

$$\chi_h(W(\alpha, \beta, \theta)) = e^{ih\theta}.$$

The translation parameters α, β do not appear in χ_h because this is the helicity sector. With

$$d\mu_0(k) = \frac{d^3k}{(2\pi)^3 \, 2|\vec{k}|},$$

the one-particle Hilbert space of a single helicity is represented, after choosing $L(k)$, as

$$\mathcal{H}_{1,h} \simeq L^2(\Sigma_0^+, d\mu_0; V_h).$$

The distributional frame $F_L(k) : V_h \to \mathcal{H}_{1,h}$ satisfies

$$U(\Lambda) F_L(k) = F_L(\Lambda k) \chi_h(W(\Lambda, k)).$$

The little-group element again obeys

$$W(\Lambda_2 \Lambda_1, k) = W(\Lambda_2, \Lambda_1 k) W(\Lambda_1, k),$$

so the helicity phase is a one-dimensional cocycle.

Wigner cocycle and helicity-frame change. For a standard section $L(k)$, the little-group element $W(\Lambda, k) = L(\Lambda k)^{-1}\Lambda L(k)$ obeys

$$W(\Lambda_2\Lambda_1, k) = W(\Lambda_2, \Lambda_1 k)W(\Lambda_1, k).$$

If $L'(k) = L(k)Q(k)$, then

$$W'(\Lambda, k) = Q(\Lambda k)^{-1}W(\Lambda, k)Q(k),$$

and the corresponding helicity-frame wavefunctions obey

$$\psi_{L'}(k) = \chi_h(Q(k))^{-1}\psi_L(k).$$

The cocycle identity is the associative identity

$$L(\Lambda_2\Lambda_1 k)^{-1}\Lambda_2\Lambda_1 L(k) = \big(L(\Lambda_2\Lambda_1 k)^{-1}\Lambda_2 L(\Lambda_1 k)\big)\big(L(\Lambda_1 k)^{-1}\Lambda_1 L(k)\big).$$

For $L'(k) = L(k)Q(k)$, substitution gives

$$L'(\Lambda k)^{-1}\Lambda L'(k) = Q(\Lambda k)^{-1}L(\Lambda k)^{-1}\Lambda L(k)Q(k),$$

which is the displayed conjugation law. The distributional frame changes by right action of the one-dimensional representation,

$$F_{L'}(k) = F_L(k)\chi_h(Q(k)).$$

Since a vector is written as

$$\int_{\Sigma_0^+} F_L(k)\psi_L(k)\, d\mu_0(k),$$

invariance of this vector under the frame change forces the inverse character on the wavefunction component.

21.5 Photon Intertwiners and Vector Representatives

Consider helicity $h = \pm 1$. A vector polarization representative at the reference momentum is

$$\epsilon^+_\mu(q) = \frac{1}{\sqrt{2}}(0, 1, -\mathrm{i}, 0), \qquad \epsilon^-_\mu(q) = \frac{1}{\sqrt{2}}(0, 1, \mathrm{i}, 0).$$

It obeys

$$q^\mu\epsilon^\pm_\mu(q) = 0, \qquad \epsilon^\pm_\mu(q)\epsilon^{\pm *\,\mu}(q) = 1, \qquad \epsilon^\pm_\mu(q)\epsilon^{\mp *\,\mu}(q) = 0.$$

The rotation generated by J_3 gives

$$W(0, 0, \theta)^\nu{}_\mu\epsilon^\pm_\nu(q) = \mathrm{e}^{\pm\mathrm{i}\theta}\epsilon^\pm_\mu(q),$$

which is the vector-representative phase entering the covariance equation; the one-particle state contributes the inverse little-group phase. The sign in this equation follows from the lower-index action. With the rotation matrix displayed above, restricted to the transverse $1, 2$ components,

$$\begin{aligned} R_3(\theta)^\nu{}_\mu\epsilon^+_\nu(q) &= \frac{1}{\sqrt{2}}\big(0, \cos\theta + \mathrm{i}\sin\theta,\, \sin\theta - \mathrm{i}\cos\theta, 0\big) \\ &= \mathrm{e}^{\mathrm{i}\theta}\epsilon^+_\mu(q), \end{aligned}$$

and the complex conjugate vector $\epsilon^-_\mu(q)$ gives the phase $\mathrm{e}^{-\mathrm{i}\theta}$.

Let $\widehat{\Phi}_\mu$ be a covariant vector local field, in a positive-metric physical Hilbert space, with a nonzero one-photon matrix element. In the delta-normalized convention write

$$_\delta\langle \vec{k}, h|\widehat{\Phi}_\mu(0)|\Omega\rangle = C_h u^h_\mu(\vec{k}).$$

If

$$U(\Lambda)\widehat{\Phi}_\mu(x)U(\Lambda)^{-1} = \Lambda^\nu{}_\mu\,\widehat{\Phi}_\nu(\Lambda x),$$

then the transformation law of the delta-normalized states gives

$$u^h_\mu(\vec{k}) = \sqrt{\frac{(\Lambda k)^0}{k^0}}\,\mathrm{e}^{-\mathrm{i}h\theta(\Lambda,k)}\Lambda^\nu{}_\mu u^h_\nu(\Lambda\vec{k}).$$

At $k = q$ and $\Lambda = W(\alpha, \beta, \theta)$, this specializes to

$$u^h_\mu(\vec{q}) = \mathrm{e}^{-\mathrm{i}h\theta}W^\nu{}_\mu u^h_\nu(\vec{q}).$$

The $SO(2)$ part of this equation fixes the transverse representatives above. The null-translation part acts by a shift along q_μ. For

$$W(\alpha,\beta,0) = \begin{pmatrix} 1+\zeta & \alpha & \beta & -\zeta \\ \alpha & 1 & 0 & -\alpha \\ \beta & 0 & 1 & -\beta \\ \zeta & \alpha & \beta & 1-\zeta \end{pmatrix}, \qquad \zeta = \frac{\alpha^2+\beta^2}{2},$$

one finds

$$W(\alpha,\beta,0)^\nu{}_\mu\epsilon^\pm_\nu(q) = \frac{1}{\sqrt{2}}\begin{pmatrix} \alpha \mp \mathrm{i}\beta \\ 1 \\ \mp\mathrm{i} \\ -\alpha \pm \mathrm{i}\beta \end{pmatrix} = \epsilon^\pm_\mu(q) - \frac{\alpha\mp\mathrm{i}\beta}{\sqrt{2}\,\kappa}\,q_\mu,$$

where $q_\mu = (-\kappa, 0, 0, \kappa)$. Hence the vector representative is defined modulo the null direction:

$$\epsilon^\pm_\mu(k) \sim \epsilon^\pm_\mu(k) + c\,k_\mu.$$

For helicity $h = \pm1$, the null-translation subgroup of the massless little group acts on the covariant vector representative by the displayed q_μ-shift, and therefore the vector representative of a helicity-one state is naturally an equivalence class modulo k_μ-shifts. Multiplying $T(\alpha, \beta)$ by $\epsilon^\pm_\nu(q)$ gives the four-component column displayed above. Since $q_\mu = (-\kappa, 0, 0, \kappa)$, the difference between that column and $\epsilon^\pm_\mu(q)$ is $-(\alpha\mp\mathrm{i}\beta)q_\mu/(\sqrt{2}\,\kappa)$. For a general null momentum $k = L(k)q$, applying $L(k)$ transports the same statement to a shift proportional to k_μ.

For general k, choose

$$\epsilon^\pm_\mu(k) = L(k)_\mu{}^\nu\epsilon^\pm_\nu(q).$$

If $L'(k) = L(k)Q(k)$ and $Q(k) = W(\alpha(k), \beta(k), \theta(k))$, then

$$\epsilon^{\pm\prime}_\mu(k) = \mathrm{e}^{\pm\mathrm{i}\theta(k)}\epsilon^\pm_\mu(k) + c_\pm(k)k_\mu.$$

The phase is the vector-representative helicity phase, and the term proportional to k_μ is the representative change generated by the null-translation part of the little group.

21.6 Field Strength Matrix Elements

A vector potential A_μ is a representative variable whose polarization matrix element uses $\epsilon^h_\mu(k)$. Its representative freedom is

$$A_\mu(x) \sim A_\mu(x) + \partial_\mu \xi(x),$$

where ξ is a scalar gauge parameter. The gauge-invariant local tensor constructed from A_μ is

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

For a one-photon state of helicity $h = \pm 1$, the field-strength matrix element has the form

$$\langle k, h|\, \widehat{F}_{\mu\nu}(x)\, |\Omega\rangle = C_h \mathrm{e}^{-\mathrm{i}k\cdot x} \left(-\mathrm{i}k_\mu \epsilon^{h*}_\nu(k) + \mathrm{i}k_\nu \epsilon^{h*}_\mu(k) \right),$$

where C_h is a normalization constant fixed by the field normalization. The shift

$$\epsilon^h_\mu(k) \mapsto \epsilon^h_\mu(k) + c\, k_\mu$$

leaves this expression unchanged because

$$k_\mu k_\nu - k_\nu k_\mu = 0.$$

Thus the antisymmetric field strength is well-defined on the quotient of vector representatives by the null direction. Equivalently, the linear map

$$\epsilon_\mu \longmapsto k_\mu \epsilon_\nu - k_\nu \epsilon_\mu$$

has the null line $\mathbb{C}k_\mu$ in its kernel and therefore descends to the quotient polarization line used for helicity-one states. The x-dependence and the normalization C_h are unaffected because the representative change acts only on $\epsilon^h_\mu(k)$. The local photon observable at this stage is therefore the field strength, while the potential is a representative used to write local equations, actions, and perturbative Green functions.

Remark 21.4. This statement is made in the physical positive-metric Hilbert space and its local observable algebra. Gauge-fixed quantization later introduces A_μ on an enlarged space with constraints, ghosts, or BRST cohomology. In that formulation the vector potential is a calculational representative, and $F_{\mu\nu}$ descends to the physical local algebra.

Remark 21.5 (Two external photons). For an amplitude with an incoming photon of momentum k and an outgoing photon of momentum k', write the reduced tensor before choosing polarization representatives as $\mathcal{M}^{\mu\nu}$. Descent to the two helicity lines requires two Ward identities,

$$k_\mu \mathcal{M}^{\mu\nu} = 0, \qquad k'_\nu \mathcal{M}^{\mu\nu} = 0.$$

In tree-level spinor Compton scattering these identities are obtained by summing the two electron-exchange diagrams. Let

$$N(q) = -\mathrm{i}\; \not{q} + m, \qquad D(q) = q^2 + m^2 - \mathrm{i}0,$$

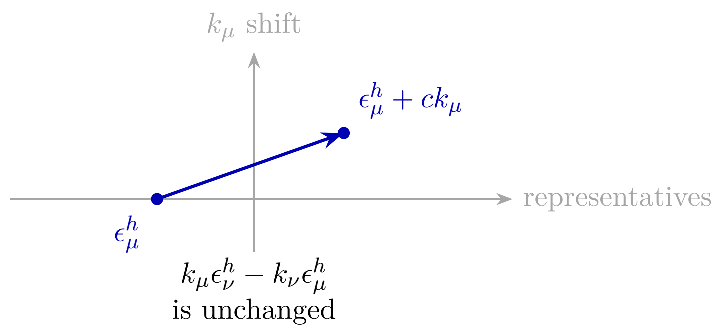
with $/q = \gamma^\rho q_\rho$, and impose the external on-shell Dirac equations. Replacing the incoming polarization by k_μ gives, up to the common charge and normalization factor, the two terms

$$\bar{u}(p') \;\not{\epsilon}'^*(k')\, \frac{N(p+k)\; \not{k}}{D(p+k)}\, u(p) = -\mathrm{i}\, \bar{u}(p') \;\not{\epsilon}'^*(k') u(p),$$

and

$$\bar{u}(p')\ \not{k}\,\frac{N(p-k')}{D(p-k')}\ \not{\epsilon}'^{*}(k')\,u(p) = +\mathrm{i}\,\bar{u}(p')\ \not{\epsilon}'^{*}(k')u(p).$$

The contact terms produced by the Ward contraction of the s- and u-channel diagrams therefore cancel. Replacing the outgoing polarization by k'_ν gives the same cancellation with k and k' interchanged.



21.7 Polarization Sums

For calculations with external helicity states it is useful to choose representatives by imposing an auxiliary linear condition. Let n^μ be a fixed vector satisfying

$$n \cdot k \neq 0.$$

Choose $\epsilon^h_\mu(k;n)$ so that

$$k^\mu\epsilon^h_\mu(k;n) = 0, \qquad n^\mu\epsilon^h_\mu(k;n) = 0, \qquad \epsilon^h(k;n)\cdot\epsilon^{h'*}(k;n) = \delta_{hh'}.$$

The sum over the two physical helicities is

$$\Pi_{\mu\nu}(k;n) = \sum_{h=\pm1}\epsilon^h_\mu(k;n)\epsilon^{h*}_\nu(k;n),$$

with

$$\Pi_{\mu\nu}(k;n) = \eta_{\mu\nu} - \frac{k_\mu n_\nu + n_\mu k_\nu}{k\cdot n} + \frac{n^2 k_\mu k_\nu}{(k\cdot n)^2}.$$

It satisfies

$$k^\mu\Pi_{\mu\nu}(k;n) = 0, \qquad n^\mu\Pi_{\mu\nu}(k;n) = 0.$$

Changing n changes the representative polarization vectors by terms proportional to k_μ. Therefore, if a quantity $M^\mu(k)$ obeys

$$k_\mu M^\mu(k) = 0,$$

then

$$M^\mu(k)\Pi_{\mu\nu}(k;n)M^{\nu*}(k)$$

is independent of the representative choice. This is the form in which polarization sums will enter gauge-invariant scattering calculations.

Let $k^2 = 0$ and $n \cdot k \neq 0$. The tensor

$$\Pi_{\mu\nu}(k;n) = \eta_{\mu\nu} - \frac{k_\mu n_\nu + n_\mu k_\nu}{k \cdot n} + \frac{n^2 k_\mu k_\nu}{(k \cdot n)^2}$$

annihilates k^μ and n^μ. If $M^\mu k_\mu = 0$, then the contraction $M^\mu \Pi_{\mu\nu}(k;n) M^{\nu *}$ is unchanged under a change of polarization representatives by k_μ-shifts. Contracting with k^μ gives

$$k_\nu - \frac{k^2 n_\nu + (k \cdot n) k_\nu}{k \cdot n} + \frac{n^2 k^2 k_\nu}{(k \cdot n)^2} = 0,$$

using $k^2 = 0$. Contracting with n^μ gives

$$n_\nu - \frac{(n \cdot k) n_\nu + n^2 k_\nu}{k \cdot n} + \frac{n^2 (n \cdot k) k_\nu}{(k \cdot n)^2} = 0.$$

If the representative basis is changed, the projector changes only by terms with at least one factor k_μ or k_ν. Such terms vanish in $M^\mu \Pi_{\mu\nu} M^{\nu *}$ when $M^\mu k_\mu = 0$.

21.8 Four-Dimensional Spinor-Helicity Variables

The preceding sections described helicity as a line bundle over the massless orbit. In four dimensions this bundle has a concrete spinorial trivialization. The statements in this and the next two sections concern tree-level perturbative massless amplitudes after the scattering operator and LSZ extraction have already been defined; they are not a definition of the S-operator.

For a real four-vector p^μ, define the Hermitian 2×2 matrix

$$p_{a\dot{a}} = p^0 \delta_{a\dot{a}} + p^i (\sigma_i)_{a\dot{a}}, \qquad a, \dot{a} = 1, 2. \tag{21.1}$$

With the mostly-plus metric used in this monograph,

$$\det(p_{a\dot{a}}) = (p^0)^2 - \vec{p}^{\,2} = -p^2.$$

Thus a complexified null momentum is equivalently a rank-one matrix, and may be written

$$p_{a\dot{a}} = \lambda_a \widetilde{\lambda}_{\dot{a}}. \tag{21.2}$$

For a real future-directed null momentum one may choose $\widetilde{\lambda}_{\dot{a}} = \overline{\lambda_a}$, up to a phase. In analytic amplitude formulae λ and $\widetilde{\lambda}$ are treated as independent complex spinors; the real physical region is a boundary value. The factorization (21.2) is unchanged by the little-group scaling

$$\lambda_a \longmapsto t\, \lambda_a, \qquad \widetilde{\lambda}_{\dot{a}} \longmapsto t^{-1} \widetilde{\lambda}_{\dot{a}}, \qquad t \in \mathbb{C}^\times. \tag{21.3}$$

This is the complexified version of the helicity-frame freedom.

Definition 21.6 (Spinor-helicity frame)**.** A spinor-helicity frame for a complex null momentum p is a factorization $p_{a\dot{a}} = \lambda_a \widetilde{\lambda}_{\dot{a}}$, with the equivalence relation

$$(\lambda, \widetilde{\lambda}) \sim (t\lambda, t^{-1}\widetilde{\lambda}), \qquad t \in \mathbb{C}^\times.$$

A helicity-h amplitude component is a section of the corresponding helicity line and therefore has weight t^{-2h} under this scaling.

Spinor contractions are

$$\langle ij\rangle = \epsilon^{ab}\lambda_{i,a}\lambda_{j,b}, \qquad [ij] = \epsilon^{\dot a\dot b}\widetilde{\lambda}_{i,\dot a}\widetilde{\lambda}_{j,\dot b}, \tag{21.4}$$

with the same $\epsilon^{12} = 1$ convention as Section 40.16. They are antisymmetric: $\langle ij\rangle = -\langle ji\rangle$ and $[ij] = -[ji]$. A direct determinant calculation gives the mostly-plus invariant

$$\langle ij\rangle[ji] = 2p_i \cdot p_j. \tag{21.5}$$

For a sum $P^\mu = \sum_{r\in I} p_r^\mu$, use the abbreviation

$$\langle i|P|j] := \lambda_i^a P_{a\dot a}\widetilde{\lambda}_j^{\dot a}.$$

Momentum conservation for an all-outgoing amplitude is

$$\sum_{i=1}^{n} \lambda_{i,a}\widetilde{\lambda}_{i,\dot a} = 0. \tag{21.6}$$

An n-point helicity amplitude with external helicities h_i is a section of the tensor product of the helicity lines. In a spinor-helicity frame this means

$$A_n(\ldots, t_i\lambda_i, t_i^{-1}\widetilde{\lambda}_i, \ldots) = t_i^{-2h_i} A_n(\ldots, \lambda_i, \widetilde{\lambda}_i, \ldots). \tag{21.7}$$

This equation is not a mnemonic: it is the helicity character χ_h of the little group, written in the coordinates (21.2).

Null factorization and mostly-plus spinor invariant. The matrix $p_{a\dot a}$ has determinant $-p^2$. Hence $p^2 = 0$ is equivalent, over the complex numbers, to the existence of a rank-one factorization $p_{a\dot a} = \lambda_a\widetilde{\lambda}_{\dot a}$. For two null momenta $p_i = \lambda_i\widetilde{\lambda}_i$ and $p_j = \lambda_j\widetilde{\lambda}_j$,

$$\langle ij\rangle[ji] = 2p_i \cdot p_j$$

in the mostly-plus convention of this monograph.

The determinant of $p^0\mathbf{1} + p^i\sigma_i$ is $(p^0)^2 - \vec{p}^{\,2} = -p^2$. A 2×2 complex matrix has determinant zero iff it has rank at most one; the zero matrix corresponds to $p = 0$, and a nonzero rank-one matrix factors as a column spinor times a row spinor. For two rank-one matrices, the antisymmetric contraction identity for 2×2 matrices gives

$$\det(p_i + p_j) = \epsilon^{ab}\lambda_{i,a}\lambda_{j,b}\,\epsilon^{\dot a\dot b}\widetilde{\lambda}_{j,\dot a}\widetilde{\lambda}_{i,\dot b} = -\langle ij\rangle[ji].$$

Since $p_i^2 = p_j^2 = 0$, the determinant side is $-(p_i + p_j)^2 = -2p_i \cdot p_j$, yielding $\langle ij\rangle[ji] = 2p_i \cdot p_j$.

The vector polarization representatives can also be written spinorially. Let $r_a, \widetilde{r}_{\dot a}$ be reference spinors with $\langle r\,\lambda\rangle \neq 0$ and $[\widetilde{\lambda}\,\widetilde{r}] \neq 0$. Define

$$\varepsilon^+_{a\dot a}(k; r) = \sqrt{2}\,\frac{r_a\widetilde{\lambda}_{\dot a}}{\langle r\,\lambda\rangle}, \qquad \varepsilon^-_{a\dot a}(k; r) = \sqrt{2}\,\frac{\lambda_a\widetilde{r}_{\dot a}}{[\widetilde{\lambda}\,\widetilde{r}]}. \tag{21.8}$$

They obey $k^{a\dot a}\varepsilon^{\pm}_{a\dot a} = 0$. Changing the reference spinors changes $\varepsilon^{\pm}$ by a term proportional to $k_{a\dot a} = \lambda_a\widetilde{\lambda}_{\dot a}$, hence by exactly the representative shift discussed above. Gauge-invariant amplitudes are independent of this reference choice.

21.9 Color-Ordered Yang–Mills Tree Amplitudes

Now specialize to the perturbative tree amplitudes of four-dimensional Yang–Mills theory, with all external momenta outgoing and the overall momentum-conservation delta function removed. The complete color-dressed amplitude is a sum over trace structures and permutations. The partial amplitude

$$A_n(1^{h_1}, 2^{h_2}, \dots, n^{h_n})$$

denotes the coefficient of a fixed cyclic ordering after stripping the common coupling and color factor. The cyclic ordering is part of the datum; poles of A_n occur only in sums of adjacent momenta in that cyclic order.

At three points, real massless momenta with momentum conservation are collinear, but complexified on-shell kinematics has two branches. On the holomorphic branch all square brackets vanish and angle brackets need not; on the antiholomorphic branch all angle brackets vanish and square brackets need not. Locality, mass dimension, and the little-group weights (21.7) fix the nonzero color-ordered three-gluon amplitudes, in the normalization used here, to be

$$A_3(1^-, 2^-, 3^+) = \frac{\langle 12\rangle^3}{\langle 23\rangle\langle 31\rangle}, \qquad A_3(1^+, 2^+, 3^-) = \frac{[12]^3}{[23][31]}. \tag{21.9}$$

For example, the first formula transforms as

$$A_3(1^-, 2^-, 3^+) \longmapsto t_1^2 t_2^2 t_3^{-2}\, A_3(1^-, 2^-, 3^+),$$

which is exactly the helicity weight for $(-1, -1, +1)$. Its mass dimension is that of a tree-level three-gluon partial amplitude after the coupling has been stripped.

The maximally helicity-violating, or MHV, tree amplitudes are the amplitudes with exactly two negative-helicity gluons. With negative-helicity labels r and s, the Parke–Taylor formula is

$$A_n(1^+, \dots, r^-, \dots, s^-, \dots, n^+) = \frac{\langle rs\rangle^4}{\langle 12\rangle\langle 23\rangle \cdots \langle n1\rangle}. \tag{21.10}$$

The expression is cyclic, has the correct little-group weight on every leg, and has only adjacent collinear and multi-particle singularities. The recursion theorem below turns these consistency checks into a construction from factorization and the three-point amplitudes.

Theorem 21.7 (Adjacent-negative Parke–Taylor tree amplitude)**.** *In color-ordered tree-level Yang–Mills theory, assuming the three-point amplitudes* (21.9)*, tree factorization with the all-outgoing internal-line convention displayed below, and a BCFW shift for which the boundary term at infinity vanishes, the n-gluon amplitude with negative-helicity gluons at adjacent labels* 1 *and* 2 *is*

$$A_n(1^-, 2^-, 3^+, \dots, n^+) = \frac{\langle 12\rangle^4}{\langle 12\rangle\langle 23\rangle \cdots \langle n1\rangle}.$$

Proof. The formula has the correct helicity weight because legs 1 and 2 receive t_1^2 and t_2^2, while every positive-helicity leg receives t_i^{-2}, exactly as required by (21.7). The base case is the three-point amplitude displayed in (21.9), interpreted on the holomorphic complex branch.

For the induction step use the $(-, +)$ BCFW shift involving one negative-helicity leg and one positive-helicity leg:

$$\widehat{\widetilde{\lambda}}_1 = \widetilde{\lambda}_1 + z\widetilde{\lambda}_n, \qquad \widehat{\lambda}_n = \lambda_n - z\lambda_1.$$

The boundary term in the BCFW residue formula below vanishes by hypothesis. The helicity selection rules of the three-point amplitudes imply that all recursive channels vanish except the channel

$$A_{n-1}(\widehat{1}^-, 2^-, 3^+, \dots, (n-2)^+, -\widehat{P}^+)\frac{1}{P^2_{1\cdots n-2}}A_3(\widehat{P}^-, (n-1)^+, \widehat{n}^+).$$

At the pole,

$$0 = (p_{n-1} + \widehat{p}_n)^2 = \langle n-1, \widehat{n}\rangle[\widehat{n}, n-1],$$

and the anti-MHV three-point factor is supported on the branch $\langle n-1, \widehat{n}\rangle = 0$. Hence

$$z_* = \frac{\langle n-1, n\rangle}{\langle n-1, 1\rangle}, \qquad \widehat{\lambda}_n(z_*) = \frac{\langle n1\rangle}{\langle n-1, 1\rangle}\lambda_{n-1},$$

where the second identity is Schouten's identity applied to $(\lambda_{n-1}, \lambda_n, \lambda_1)$. Use the internal spinor frame for the left momentum

$$-\widehat{P} = \lambda_{n-1}\left(\widetilde{\lambda}_{n-1} + \frac{\langle n1\rangle}{\langle n-1, 1\rangle}\widetilde{\lambda}_n\right).$$

The induction hypothesis gives

$$A_{n-1} = \frac{\langle 12\rangle^4}{\langle 12\rangle\langle 23\rangle\cdots\langle n-2, n-1\rangle\langle n-1, 1\rangle}.$$

With the all-outgoing internal-line convention in the factorization residue, the three-point amplitude and the propagator combine to

$$\frac{1}{P^2_{1\cdots n-2}}A_3(\widehat{P}^-, (n-1)^+, \widehat{n}^+) = \frac{\langle n-1, 1\rangle}{\langle n-1, n\rangle\langle n1\rangle}.$$

Indeed $P^2_{1\cdots n-2} = \langle n-1, n\rangle[n, n-1]$, while the three-point formula evaluates to the displayed numerator factor times $[n, n-1]$; the relative sign is fixed by assigning the two internal momenta $\widehat{P}$ and $-\widehat{P}$ the opposite all-outgoing orientations in the factorization formula. Multiplying the last two displayed equations cancels $\langle n-1, 1\rangle$ and gives the claimed cyclic denominator with the same numerator $\langle 12\rangle^4$. $\square$

21.10 BCFW Recursion

Choose two external labels i and j. The BCFW deformation

$$\widehat{\widetilde{\lambda}}_i(z) = \widetilde{\lambda}_i + z\widetilde{\lambda}_j, \qquad \widehat{\lambda}_j(z) = \lambda_j - z\lambda_i, \tag{21.11}$$

leaves all other spinors fixed. It preserves $\widehat{p}_i(z)^2 = \widehat{p}_j(z)^2 = 0$ and total momentum:

$$\widehat{p}_i(z) + \widehat{p}_j(z) = p_i + p_j.$$

Let $q_{a\dot{a}} = \lambda_{i,a}\widetilde{\lambda}_{j,\dot{a}}$. Then $\widehat{p}_i = p_i + zq$, $\widehat{p}_j = p_j - zq$, and $q^2 = q\cdot p_i = q\cdot p_j = 0$.

The shifted momenta are

$$\widehat{p}_i(z) = \lambda_i(\widetilde{\lambda}_i + z\widetilde{\lambda}_j) = p_i + zq, \qquad \widehat{p}_j(z) = (\lambda_j - z\lambda_i)\widetilde{\lambda}_j = p_j - zq.$$

Each remains rank one, hence null. Their sum is unchanged. The vector $q = \lambda_i \widetilde{\lambda}_j$ is rank one and therefore null; moreover $\langle ii \rangle = 0$ and $[jj] = 0$, so $2q \cdot p_i = 2q \cdot p_j = 0$, with the mostly-plus sign understood through the spinor-invariant calculation above.

At tree level a color-ordered amplitude $A_n(z)$ is a rational function of z. Its finite poles occur when a cyclically adjacent momentum sum

$$P_I = \sum_{\ell \in I} p_\ell$$

contains exactly one of the shifted labels and becomes null:

$$\widehat{P}_I(z_I)^2 = 0. \tag{21.12}$$

Near such a pole, tree-level unitarity and locality give the factorization

$$A_n(z) \sim \sum_h A_L(z_I) \, \frac{1}{\widehat{P}_I(z)^2} \, A_R(z_I), \tag{21.13}$$

where the two lower-point amplitudes have an internal on-shell gluon of helicity h and $-h$, respectively. Applying Cauchy's theorem to $A_n(z)/z$ gives

$$A_n(0) = \sum_{I,h} A_L(z_I) \, \frac{1}{P_I^2} \, A_R(z_I) + B_\infty. \tag{21.14}$$

The boundary term B_∞ is the residue at $z = \infty$. For Yang–Mills tree amplitudes it vanishes for the standard good shifts used in the MHV construction, including the $(-,+)$ shift below. When a shift has nonzero boundary term, equation (21.14) remains true but is not a closed recursion until B_∞ is determined by other input.

BCFW residue formula with boundary term. Let $A_n(z)$ be a tree-level color-ordered Yang–Mills partial amplitude under a BCFW shift. Suppose its only finite singularities are simple factorization poles where an adjacent shifted momentum sum becomes null, and suppose the residues are the tree factorization products

$$\operatorname*{Res}_{z=z_I} A_n(z) = \sum_h A_L(z_I) \, \operatorname*{Res}_{z=z_I} \left(\frac{1}{\widehat{P}_I(z)^2} \right) A_R(z_I).$$

Then

$$A_n(0) = \sum_{I,h} A_L(z_I) \frac{1}{P_I^2} A_R(z_I) + B_\infty,$$

where B_∞ is minus the residue of $A_n(z)/z$ at infinity. If $A_n(z) \to 0$ as $z \to \infty$, then $B_\infty = 0$. The meromorphic one-form $A_n(z)\, dz/z$ on the Riemann sphere has total residue zero. Its residue at $z = 0$ is $A_n(0)$. A finite pole occurs when $\widehat{P}_I(z)^2 = P_I^2 + z\, 2P_I \cdot q$ vanishes, so

$$z_I = -\frac{P_I^2}{2P_I \cdot q}.$$

Near this point,

$$\frac{1}{\widehat{P}_I(z)^2} = \frac{1}{(z - z_I)\, 2P_I \cdot q} = \frac{z_I}{(z - z_I)(-P_I^2)}.$$

Therefore the contribution of this finite pole to the residue of $A_n(z)/z$ is $-A_L(z_I)A_R(z_I)/P_I^2$, summed over internal helicities. Moving all finite-pole residues and the residue at infinity to the other side gives the displayed recursion formula.

Figure 21.1 records the finite-pole factorization geometry used in the recursion formula: the shifted amplitude splits into left and right on-shell subamplitudes joined by the channel $\widehat{P}_I^2 = 0$.

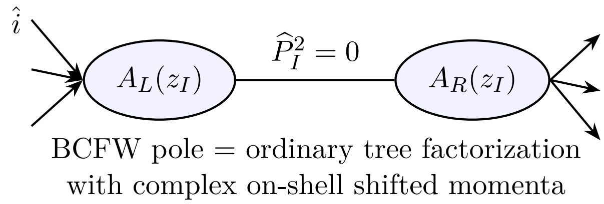


Figure 21.1: A pole in the complex BCFW parameter occurs when an adjacent momentum sum becomes null. The residue is the product of two lower-point on-shell amplitudes and the intermediate propagator.

21.11 Parke–Taylor from Recursion

Consider

$$A_n(1^-, 2^-, 3^+, \ldots, n^+).$$

Use the shift

$$\widehat{\widetilde{\lambda}}_1 = \widetilde{\lambda}_1 + z\widetilde{\lambda}_n, \qquad \widehat{\lambda}_n = \lambda_n - z\lambda_1. \tag{21.15}$$

This is a good $(-,+)$ Yang–Mills shift, so $B_\infty = 0$. The BCFW terms in which one side has fewer than two negative helicities vanish, except for the three-point anti-MHV factor allowed by complex kinematics. Inductively one obtains a single nonzero channel, consisting of an $(n-1)$-point MHV amplitude and a three-point amplitude. Substitution of (21.9) and the induction hypothesis gives

$$A_n(1^-, 2^-, 3^+, \ldots, n^+) = \frac{\langle 12\rangle^4}{\langle 12\rangle\langle 23\rangle \cdots \langle n1\rangle}.$$

This proves (21.10) for this placement of the two negative helicities. The nonadjacent (r, s) formula follows from the same BCFW recursion together with Schouten identities, but more than one channel can contribute; the adjacent proof above is the single-channel case needed for the worked example below.

For the first genuinely five-leg case,

$$A_5(1^-, 2^-, 3^+, 4^+, 5^+),$$

the shift (21.15) gives one nonzero recursive contribution:

$$A_5 = A_4(\widehat{1}^-, 2^-, 3^+, -\widehat{P}^+)\,\frac{1}{P_{123}^2}\,A_3(\widehat{P}^-, 4^+, \widehat{5}^+), \tag{21.16}$$

where $P_{123} = p_1 + p_2 + p_3$ and $\widehat{P} = \widehat{p}_1(z_*) + p_2 + p_3$ is null. The pole is determined by

$$\widehat{P}(z_*)^2 = 0.$$

Using the four-point Parke–Taylor amplitude on the left and the three-point amplitude (21.9) on the right, all dependence on the internal spinor representation of $\widehat{P}$ cancels. The result is

$$A_5(1^-, 2^-, 3^+, 4^+, 5^+) = \frac{\langle 12\rangle^4}{\langle 12\rangle\langle 23\rangle\langle 34\rangle\langle 45\rangle\langle 51\rangle}. \tag{21.17}$$

The calculation illustrates the conceptual point of BCFW recursion: tree amplitudes are determined by their on-shell factorization residues, helicity weights, and large-complex-momentum behavior, without introducing off-shell gauge-dependent subamplitudes.

The next chapter supplies the dynamics whose one-particle sector realizes these helicity states: Maxwell theory, its constraints, and the controlled introduction of gauge fixing.

Chapter 22

Haag–Ruelle Theory and Mathematical Scattering

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The source trace for the massive scattering construction is Haag's asymptotic condition and Ruelle's proof of scattering states [4, 5]. The LSZ interface later in the chapter is traced to [6]; the text keeps the Hilbert-space Haag–Ruelle construction logically prior to LSZ residues.

22.1 Vacuum Net and Isolated Mass Shell

Let $M = \mathbb{M}^D$ be Minkowski spacetime, and let

$$\mathcal{O} \longmapsto \mathcal{R}(\mathcal{O}) \subset \mathcal{B}(\mathcal{H})$$

be a Poincare-covariant vacuum net of von Neumann algebras. The standing data are a Hilbert space $\mathcal{H}$, a unit vector Ω, and a strongly continuous unitary representation U of the proper orthochronous Poincare group such that

$$U(a, \Lambda)\mathcal{R}(\mathcal{O})U(a, \Lambda)^{-1} = \mathcal{R}(\Lambda\mathcal{O} + a), \qquad U(a, \Lambda)\Omega = \Omega.$$

For translations alone we write

$$U(a) = U(a, \mathbf{1}) = \exp(\mathrm{i}a_\mu P^\mu),$$

where P^μ are the commuting self-adjoint energy-momentum generators. The scalar product in Fourier transforms is the same contraction $q\cdot x = q_\mu x^\mu$. This sign convention is part of the standing data: with the opposite convention for $U(a)$, every spectral-transfer formula below would contain $-\operatorname{supp}\widehat{f}$ instead of $\operatorname{supp}\widehat{f}$. The translation generators obey the spectrum condition

$$\mathrm{Spec}(P) \subset \overline{V}_+.$$

Let $E(\Delta)$ denote the joint spectral projection of P^μ for a Borel set $\Delta \subset \mathbb{R}^D$.

Fix $m > 0$. The positive mass shell is

$$\Sigma_m^+ = \{p \in \mathbb{R}^D : p^0 = \omega_{\vec{p}},\ p^2 = -m^2\}, \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^2 + m^2}.$$

The one-particle subspace for this stable species is

$$\mathcal{H}_1 = E(\Sigma_m^+)\mathcal{H}.$$

This notation carries an existence hypothesis: $\mathcal{H}_1 \neq \{0\}$. The projection onto the Borel set Σ_m^+ may be zero in a perfectly consistent Hilbert-space theory, or it may fail to be isolated from continuous spectral support. In either case the ordinary massive Haag–Ruelle theorem does not produce scattering states for that putative species. The relation between a one-particle shell and an atom in a Källén–Lehmann measure was spelled out in Remark 14.17. The Haag–Ruelle construction assumes that the shell is isolated in the energy-momentum spectrum: there is an open neighborhood N of Σ_m^+ such that

$$\mathrm{Spec}(P) \cap N = \Sigma_m^+.$$

This isolation is the spectral form of stability. The formulas below are written for a single bosonic species. If several stable species, spin multiplets, or fermionic particles are present, $\mathcal{H}_1$ is replaced by the appropriate direct sum of isolated one-particle representations and $\mathcal{F}_s(\mathcal{H}_1)$ by the corresponding graded asymptotic Fock space.

For a scalar multiplicity-one species, the one-particle Hilbert space is realized by the mass-shell spectral representation

$$W_1 : L^2(\Sigma_m^+, \mathrm{d}\mu_m) \xrightarrow{\sim} \mathcal{H}_1, \qquad \mathrm{d}\mu_m(p) = \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1} 2\omega_{\vec{p}}},$$

with

$$W_1 f = \int_{\Sigma_m^+} \mathrm{d}\mu_m(p)\, f(p) |p\rangle, \qquad U(a, \mathbf{1}) W_1 f = W_1\big(p \mapsto \mathrm{e}^{\mathrm{i} a_\mu p^\mu} f(p)\big).$$

The bosonic asymptotic Fock space is then the Hilbert direct sum

$$\mathcal{F}_s(\mathcal{H}_1) \simeq \mathbb{C}\Omega_F \oplus \bigoplus_{n\geq 1} L^2_{\mathrm{sym}}\big((\Sigma_m^+)^n, \mathrm{d}\mu_m^{\otimes n}\big).$$

Thus the wave operators below start from a constructed free many-particle Hilbert space whose momentum labels are coordinates in the spectral model.

22.2 Almost-Local Operators and Spectral Transfer

Almost-locality is the norm-approximation condition of Definition 17.3: an operator $B \in \mathcal{B}(\mathcal{H})$ is approximated by bounded local operators B_R localized in double cones of radius R such that, for every $N \geq 1$, some $C_N < \infty$ obeys

$$\|B - B_R\| \leq C_N R^{-N}.$$

Almost locality is the operator-algebraic substitute for using smeared local fields whose support is not strictly compact after energy-momentum filtering.

For a bounded local operator A, set

$$A(x) = U(x) A U(x)^{-1}, \qquad x \in \mathbb{R}^D.$$

For $f \in \mathcal{S}(\mathbb{R}^D)$, define

$$A(f) = \int \mathrm{d}^D x\, f(x) A(x), \qquad \widehat{f}(q) = \int \mathrm{d}^D x\, f(x) \mathrm{e}^{\mathrm{i} q \cdot x}.$$

With this convention, the energy-momentum transfer of $A(f)$ is contained in $\operatorname{supp} \widehat{f}$:

$$E(\Delta_1) A(f) E(\Delta_2) = 0 \quad \text{if} \quad \Delta_1 \cap \left(\Delta_2 + \operatorname{supp} \widehat{f}\right) = \emptyset. \tag{22.1}$$

Indeed, by the joint spectral theorem,

$$E(\mathrm{d}p)\, A(f)\, E(\mathrm{d}r) = \left(\int \mathrm{d}^D x\, f(x) \mathrm{e}^{\mathrm{i} x_\mu (p^\mu - r^\mu)} \right) E(\mathrm{d}p)\, A\, E(\mathrm{d}r) = \widehat{f}(p - r)\, E(\mathrm{d}p)\, A\, E(\mathrm{d}r).$$

After integrating $p \in \Delta_1$ and $r \in \Delta_2$, the operator can be nonzero only if $p - r \in \operatorname{supp} \widehat{f}$, equivalently $\Delta_1 \cap (\Delta_2 + \operatorname{supp} \widehat{f}) \neq \emptyset$. Equation (22.1) is the precise meaning of selecting a particle shell by smearing in spacetime.

Choose a compact set $K \subset \Sigma_m^+$. Let $\chi \in \mathcal{S}(\mathbb{R}^D)$ have $\operatorname{supp} \widehat{\chi} \subset N$, with $\widehat{\chi} = 1$ on a smaller neighborhood of K. For a local A, set

$$B = A(\chi).$$

Then B is almost local. Since the vacuum has momentum 0,

$$B\Omega = E(\operatorname{supp} \widehat{\chi}) B\Omega = P_1 B\Omega, \qquad P_1 = E(\Sigma_m^+),$$

provided the support of $\widehat{\chi}$ meets the spectrum only on the isolated shell. If $-\operatorname{supp} \widehat{\chi}$ is disjoint from the forward spectrum and $\operatorname{supp} \widehat{\chi}$ avoids 0, then

$$B^* \Omega = 0.$$

An almost-local operator satisfying these spectral support properties and $B\Omega \neq 0$ is a regular Haag–Ruelle creator for the shell.

Figure 22.1 displays the spectral-transfer condition for such a creator: the Fourier support meets the spectrum only on the isolated positive mass shell and avoids the vacuum and negative-energy regions.

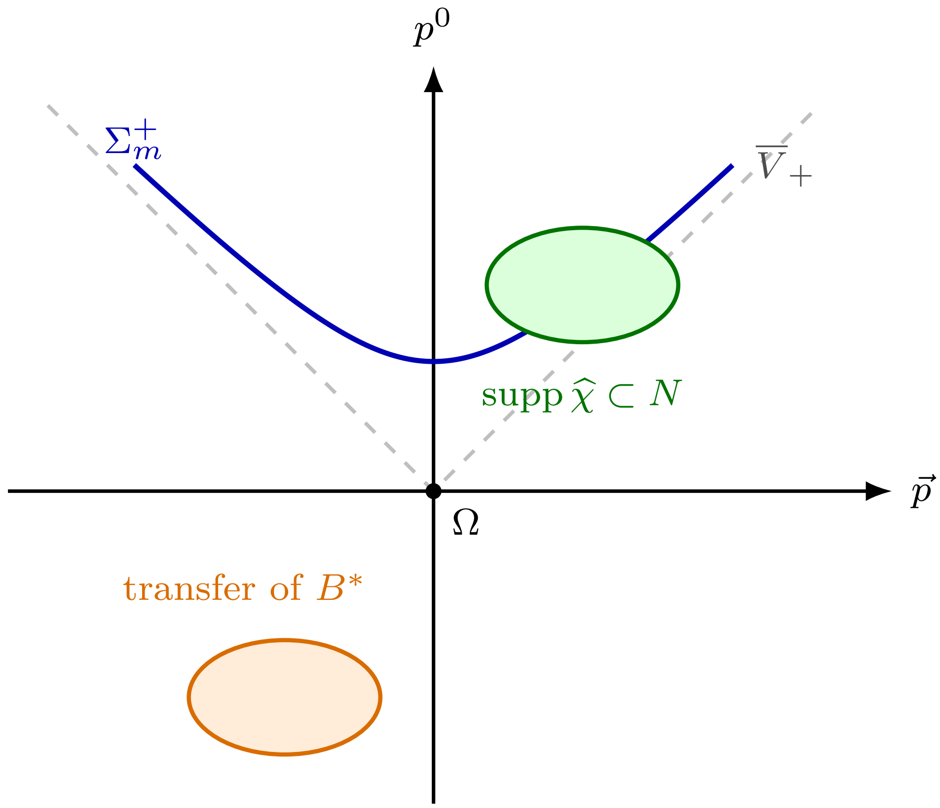

Figure 22.1: A spacetime smearing with χ restricts energy-momentum transfer to $\operatorname{supp}\widehat{\chi}$. The support is chosen inside the isolating neighborhood of the positive mass shell, while the reflected support controls the adjoint creator.

22.3 Wave Packets and Velocity Localization

Let B be a regular creator. For

$$h \in C_c^\infty(\mathbb{R}^{D-1}),$$

define the positive-energy Klein–Gordon packet

$$h_t(\vec{x}) = \int \frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}}\, h(\vec{p})\, \mathrm{e}^{\mathrm{i}\omega_{\vec{p}}t - \mathrm{i}\vec{p}\cdot\vec{x}}$$

and the time-dependent operator

$$B_t(h) = \int \mathrm{d}^{D-1}\vec{x}\, h_t(\vec{x}) B(t, \vec{x}).$$

The one-particle vector

$$\psi_h = P_1 B_t(h)\Omega$$

is independent of t; the phase in h_t cancels the free time evolution on the mass shell.

The velocity support of h is

$$V(h) = \left\{ \frac{\vec{p}}{\omega_{\vec{p}}} : \vec{p} \in \operatorname{supp} h \right\}.$$

Stationary phase says that $h_t(\vec{x})$ is rapidly decreasing away from the equal-time tube

$$\vec{x} \in t\,V(h) + O(|t|^0).$$

Thus packets with disjoint velocity supports become spacelike separated at large $|t|$. Combining this geometric separation with almost locality gives, for every $N \geq 1$,

$$\|[B_{i,t}(h_i), B_{j,t}(h_j)]\| \leq C_N(1+|t|)^{-N} \tag{22.2}$$

whenever $V(h_i) \cap V(h_j) = \emptyset$.

22.4 Haag–Ruelle Limits

Let $B_1, \ldots, B_n$ be regular creators and let

$$h_1, \ldots, h_n \in C_c^\infty(\mathbb{R}^{D-1})$$

have pairwise disjoint velocity supports. Define

$$\Psi_t = B_{1,t}(h_1) \cdots B_{n,t}(h_n)\Omega.$$

Theorem 22.1 (Haag–Ruelle scattering for a vacuum net)**.** *Assume locality, Poincare covariance, the spectrum condition, a unique vacuum, an isolated massive one-particle shell, and enough regular creators to generate a dense subspace of $\mathcal{H}_1$. Then the limits*

$$\Psi_{\text{out}} = \lim_{t\to+\infty} \Psi_t, \qquad \Psi_{\text{in}} = \lim_{t\to-\infty} \Psi_t$$

exist in Hilbert norm. They depend only on the one-particle vectors $\psi_{h_j} = P_1 B_{j,t}(h_j)\Omega$, and they define isometric wave operators from the symmetric Fock space $\mathcal{F}_s(\mathcal{H}_1)$ into $\mathcal{H}$.

Remark 22.2 (Physical scope of the isolated-shell hypothesis)*.* The nonzero isolated-shell assumption is a spectral theorem about the particular nonperturbative model, not a generic consequence of writing a formal Lagrangian. It is satisfied by free massive fields. It is also available in the massive stable sectors of constructive low-dimensional scalar models, such as $P(\phi)_2$ and massive $\lambda\phi_3^4$, in regimes where the Wightman theory, mass gap, and one-particle spectral gap have been established. For a four-dimensional $\lambda\phi^4$ Lagrangian treated only perturbatively, an isolated real pole in the formal two-point function is evidence for the intended particle interpretation, but it is not a nonperturbative theorem constructing an isolated shell in a Hilbert-space spectrum.

A Källén–Lehmann measure with no atom at m^2, even if its continuous support starts at m^2, supplies no normalizable one-particle vector of mass m for the corresponding local interpolating field. Haag–Ruelle then has no external particle of that species to scatter. The theorem exactly distinguishes a sharp stable particle from threshold spectral weight.

The hypothesis fails, or is the wrong hypothesis, in several central physical settings. In QED with long-range electromagnetic fields, charged sectors are expected to be infraparticle sectors: the energy-momentum spectrum has continuous soft-photon dressing attached to the charged state rather than a sharp Wigner mass hyperboloid. The photon is massless and belongs to a theory without the massive spectral gap used by the theorem. In QCD, colored quark and gluon shells are not expected to occur in the gauge-invariant observable Hilbert space; stable hadrons, when present below strong-decay thresholds, are the candidate isolated shells. Unstable particles and resonances do not give external Haag–Ruelle particles, because their spectral singularities are resonance poles on analytically continued sheets rather than point spectrum on the physical mass shell. Each of these cases requires a different asymptotic framework or a separate spectral theorem. The corresponding asymptotic-completeness problems for charged QED and physical QCD are stated as Open Problems 44.10 and 49.22.

22.4.1 The Cook Estimate and the Fock Inner Product

We now spell out the proof in a form that separates the analytic estimates from the algebraic conclusion. The estimates below are precisely the Haag–Ruelle estimates supplied by almost locality, spectral isolation, and stationary phase. Once they are known, the construction of scattering states and the Fock inner product is an elementary Hilbert-space argument.

Definition 22.3 (Haag–Ruelle estimate package)**.** For a finite family of regular creators B_j and smooth compactly supported packets h_j, write

$$B_{j,t} = B_{j,t}(h_j), \qquad \psi_j = B_{j,t}\Omega \in \mathcal{H}_1.$$

The family is said to satisfy the Haag–Ruelle estimate package on $|t| \geq T_0$ if the following hold.

1. The vectors $B_{j,t}\Omega = \psi_j$ are independent of t, and $B_{j,t}^{*}\Omega = 0$.
2. For every $N \geq 1$ and every pair with disjoint velocity supports,
$$\|[B_{i,t}^{\#}, B_{j,t}^{\#}]\| \leq C_N(1+|t|)^{-N}, \qquad B^{\#} \in \{B, B^*\}. \tag{22.3}$$
The same estimate holds on the finite-energy vectors obtained from the family when one entry is replaced by its strong time derivative. This derivative is the derivative of the smooth translation-smearing parameter; no norm differentiability of an unsmeared local operator is assumed.
3. For every pair of regular creators B, C with packets h, g,
$$B_t(h)^* C_t(g)\Omega = \langle B_t(h)\Omega, C_t(g)\Omega\rangle\, \Omega + r_t(B, h; C, g), \tag{22.4}$$
where for every $N \geq 1$, $\|r_t(B, h; C, g)\| \leq C_N(1+|t|)^{-N}$.
4. For two velocity-separated lists $B_1, \ldots, B_n$ and $C_1, \ldots, C_m$, the scalar products obey the recursive contraction estimate
$$\begin{aligned}&\langle B_{1,t}\cdots B_{n,t}\Omega, C_{1,t}\cdots C_{m,t}\Omega\rangle \\ &\quad = \sum_{\ell=1}^{m}\langle \psi_1, \varphi_\ell\rangle \left\langle B_{2,t}\cdots B_{n,t}\Omega, C_{1,t}\cdots \widehat{C_{\ell,t}}\cdots C_{m,t}\Omega\right\rangle + O_N((1+|t|)^{-N})\end{aligned} \tag{22.5}$$
for every $N \geq 1$, with the convention that the sum is empty when $m = 0$.
5. For each velocity-separated product $\Psi_t = B_{1,t}\cdots B_{n,t}\Omega$, there is an integrable nonnegative function $R(t)$ on $[T_0, \infty)$ and on $(-\infty, -T_0]$ such that
$$\left\|\frac{\mathrm{d}}{\mathrm{d}t}\Psi_t\right\| \leq R(t) \tag{22.6}$$
on the finite vector domain under discussion.

Proposition 22.4 (Estimate package implies Haag–Ruelle limits)**.** *Assume the estimate package Definition 22.3 for every finite velocity-separated family of regular creators. Then the limits in Theorem 22.1 exist, depend only on the one-particle vectors, and satisfy the bosonic Fock inner product formula*

$$\begin{aligned}&\big\langle \Psi^{\mathrm{out}}(\psi_1,\dots,\psi_n),\Phi^{\mathrm{out}}(\varphi_1,\dots,\varphi_m)\big\rangle\\ &\qquad=\delta_{nm}\sum_{\sigma\in S_n}\prod_{j=1}^{n}\langle\psi_j,\varphi_{\sigma(j)}\rangle_{\mathcal{H}_1}.\end{aligned}\tag{22.7}$$

The same statement holds for incoming limits. Hence the wave operators are isometries from $\mathcal{F}_s(\mathcal{H}_1)$ into $\mathcal{H}$.

Proof. We give the outgoing proof. The incoming proof is the same with $t\to-\infty$.

First, Cook's criterion gives existence. For $t'>t\geq T_0$,

$$\|\Psi_{t'}-\Psi_t\|\leq\int_t^{t'}\left\|\frac{\mathrm{d}}{\mathrm{d}s}\Psi_s\right\|\mathrm{d}s\leq\int_t^{t'}R(s)\,\mathrm{d}s.$$

Since $R\in L^1([T_0,\infty))$, the right side tends to zero as $t,t'\to+\infty$. Thus Ψ_t is Cauchy in the Hilbert norm and has an outgoing limit.

Second, compute the limiting scalar products. Let

$$\Psi_t=B_{1,t}\cdots B_{n,t}\Omega,\qquad\Phi_t=C_{1,t}\cdots C_{m,t}\Omega,$$

with both lists velocity-separated. Then

$$\langle\Psi_t,\Phi_t\rangle=\langle\Omega,B_{n,t}^*\cdots B_{1,t}^*C_{1,t}\cdots C_{m,t}\Omega\rangle.$$

The recursive contraction estimate (22.5) gives

$$\langle\Psi_t,\Phi_t\rangle=\sum_{\ell=1}^{m}\langle\psi_1,\varphi_\ell\rangle\,\langle B_{2,t}\cdots B_{n,t}\Omega,C_{1,t}\cdots\widehat{C_{\ell,t}}\cdots C_{m,t}\Omega\rangle+O_N(t^{-N}).$$

Induction on $n+m$, with the base cases following from $\langle\Omega,\Omega\rangle=1$ and $B_t^*\Omega=0$, gives (22.7). If $n\neq m$, the induction eventually leaves an annihilator acting on the vacuum, and the limit is zero.

The scalar product formula shows at once that changing an interpolating creator while keeping the one-particle vector fixed changes the limiting state by a vector of zero norm. It also identifies the norm of every finite linear combination of outgoing limits with the norm of the corresponding finite symmetric tensor in $\mathcal{F}_s(\mathcal{H}_1)$. Therefore the map from the algebraic velocity-separated Fock domain to $\mathcal{H}$ is isometric and extends uniquely to the Fock completion. Density of regular creators in $\mathcal{H}_1$ gives the stated domain of the wave operator. □

Lemma 22.5 (Stationary-phase velocity localization)**.** *Let $h\in C_c^\infty(\mathbb{R}^{D-1})$ and let*

$$h_t(\vec{x})=\int\frac{\mathrm{d}^{D-1}\vec{p}}{(2\pi)^{D-1}}\,h(\vec{p})\,\mathrm{e}^{\mathrm{i}\omega_{\vec{p}}t-\mathrm{i}\vec{p}\cdot\vec{x}}.$$

Let $V(h)=\{\vec{p}/\omega_{\vec{p}}:\vec{p}\in\operatorname{supp}h\}$. If $U\subset\mathbb{R}^{D-1}$ is an open neighborhood of $V(h)$, then for every $N\geq1$ there is C_N such that

$$|h_t(\vec{x})|\leq C_N(1+|t|+|\vec{x}|)^{-N}\qquad\textit{whenever }\vec{x}/t\notin U,\quad|t|\geq1.$$

Proof. On the compact support of h, the phase is

$$\Phi_t(\vec{p};\vec{x}) = \omega_{\vec{p}} t - \vec{p}\cdot\vec{x}.$$

Its gradient is

$$\nabla_{\vec{p}}\Phi_t = t\,\frac{\vec{p}}{\omega_{\vec{p}}} - \vec{x}.$$

If $\vec{x}/t \notin U$, compactness gives $|\nabla_{\vec{p}}\Phi_t| \ge c|t|$ on $\operatorname{supp} h$ for some $c > 0$. Apply repeatedly the integration-by-parts operator

$$L = \frac{1}{\mathrm{i}|\nabla_{\vec{p}}\Phi_t|^2}\nabla_{\vec{p}}\Phi_t\cdot\nabla_{\vec{p}}, \qquad L\mathrm{e}^{\mathrm{i}\Phi_t} = \mathrm{e}^{\mathrm{i}\Phi_t}.$$

Each integration by parts gains a factor $O(|t|^{-1})$, while derivatives of h and of the coefficients of L are bounded on the compact support. This gives $O(|t|^{-N})$. In the region $|\vec{x}| \gg |t|$, the same lower bound is $c(|t| + |\vec{x}|)$, giving the displayed estimate. □

Proposition 22.6 (Almost locality gives the commutator estimate)**.** *Let B_i and B_j be almost-local regular creators and let h_i, h_j have disjoint velocity supports. Then*

$$\|[B_{i,t}(h_i), B_{j,t}(h_j)]\| \le C_N(1+|t|)^{-N} \qquad (N \ge 1),$$

and the same estimate holds with either operator replaced by its adjoint.

Proof. Choose nested open neighborhoods

$$V(h_\ell) \subset U_\ell^0 \Subset U_\ell, \qquad \ell = i, j,$$

so that U_i and U_j have positive Euclidean distance

$$\delta = \operatorname{dist}(U_i, U_j) > 0.$$

Let χ_i^t, χ_j^t be smooth cutoffs equal to one on the smaller equal-time tubes $\vec{x}/t \in U_i^0$, $\vec{y}/t \in U_j^0$, and supported in the larger disjoint tubes $\vec{x}/t \in U_i$, $\vec{y}/t \in U_j$. Write

$$B_{i,t} = B_{i,t}^{\text{near}} + B_{i,t}^{\text{tail}}, \qquad B_{i,t}^{\text{near}} = \int \mathrm{d}^{D-1}\vec{x}\,\chi_i^t(\vec{x}) h_{i,t}(\vec{x}) B_i(t,\vec{x}),$$

and similarly for j. The stationary-phase lemma, used with an exponent larger than $N + D$, gives an L^1-tail estimate

$$\int_{\vec{x}/t\notin U_i^0} |h_{i,t}(\vec{x})|\,\mathrm{d}^{D-1}\vec{x} \le C_N(1+|t|)^{-N},$$

and the same for h_j. Since translations preserve operator norms,

$$\|B_{i,t}^{\text{tail}}\| \le \|B_i\| \int_{\vec{x}/t\notin U_i} |h_{i,t}(\vec{x})|\,\mathrm{d}^{D-1}\vec{x} = O_N(|t|^{-N}).$$

Every commutator containing at least one tail factor is therefore $O_N(|t|^{-N})$.

It remains to estimate the commutator of the near parts. For $\vec{x}/t \in U_i$ and $\vec{y}/t \in U_j$ the equal-time centers satisfy

$$|\vec{x} - \vec{y}| \ge \delta|t|.$$

Choose almost-local approximants $B_{\ell,R}$ localized in the double cone of radius R about the origin and obeying, for arbitrary K,

$$\|B_\ell - B_{\ell,R}\| \le C_K R^{-K}, \qquad \ell = i, j.$$

Set $R = \delta|t|/8$. A point in the translated localization region of $(B_{i,R})(t,\vec{x})$ has time coordinate within R of t and spatial coordinate within R of $\vec{x}$; likewise for j. Hence the absolute time separation of two points in the two translated double cones is at most $2R$, while their spatial separation is at least $\delta|t| - 2R$. With the chosen R,

$$\delta|t| - 2R = \frac{3}{4}\delta|t| > 2R,$$

so the two double cones are spacelike separated. Locality gives

$$[(B_{i,R})(t,\vec{x}), (B_{j,R})(t,\vec{y})] = 0$$

for all $\vec{x}, \vec{y}$ in the near supports, and hence the integrated commutator of the two approximated near parts vanishes.

The error made by replacing B_ℓ by $B_{\ell,R}$ is controlled in operator norm. The near-packet L^1-norm grows at most polynomially in $|t|$: inside a ball of radius $O(|t|)$ this is the trivial volume bound, while outside such a ball the same nonstationary-phase integration by parts gives rapid decay. Thus, for some fixed power M,

$$\|B_{\ell,t}^{\mathrm{near}} - (B_{\ell,R})_t^{\mathrm{near}}\| \le C(1+|t|)^M R^{-K}.$$

Since K is arbitrary in the almost-local approximation, choosing K larger than $M+N$ makes the replacement error $O_N(|t|^{-N})$. Combining the near-approximant commutator, the replacement errors, and the tail estimates proves the displayed commutator bound. The adjoint case is identical: B_R^* is localized in the same double cone as B_R, and $\|B^* - B_R^*\| = \|B - B_R\|$, so almost locality is preserved by taking adjoints. □

Proposition 22.7 (Origin of the remaining Haag–Ruelle estimates)**.** *For regular creators obtained by smooth spectral transfer inside the isolating neighborhood N, the one-particle contraction estimate* (22.4)*, the recursive contraction estimate* (22.5)*, and the Cook derivative estimate* (22.6) *follow from spectral isolation of Σ_m^+, the transfer relation* (22.1)*, and the commutator estimate of Proposition 22.6.*

Proof. The support of the spectral transfer of a regular creator meets the spectrum, when acting on the vacuum, only on Σ_m^+. Therefore $B_t(h)\Omega$ is exactly the one-particle vector determined by the mass-shell packet and is independent of t, while $B_t(h)^*\Omega = 0$ because the reflected transfer support is disjoint from $\overline{V}_+$. Acting with $B_t(h)^*C_t(g)$ on the vacuum, spectral transfer permits a vacuum component and separates all nonvacuum components from the isolated shell by a positive spectral distance fixed by the supports. Choose a smooth cutoff $\rho(P)$ that is 0 on a neighbourhood of the vacuum point and 1 on the separated nonvacuum spectral support. The oscillatory factors left after subtracting the vacuum component then have no stationary point on the relevant compact spectral support. Repeated integration by parts in the spectral variables, written equivalently as commuting powers of smooth functions of P through the translated smearing, gives the rapidly decreasing remainder in (22.4). The estimate is a strong finite-energy estimate; it is not a statement about an operator norm derivative of a pointlike field. Iterating this contraction after decomposing packet supports into finitely many small velocity cells gives (22.5); terms in which two uncontracted cells have separated velocity supports are estimated by Proposition 22.6, and the finite partition is removed by summing the finitely many cells.

For the Cook estimate, differentiate the product on the finite vector domain spanned by the vectors obtained by applying finitely many translated, spectrally smeared creators to the vacuum. The derivative of the k-th factor, after commuting it to the far right, annihilates the vacuum because the one-particle packet has been chosen to solve the free mass-shell evolution. Every commutation needed to move this derivative through later factors is controlled by the derivative version of Proposition 22.6; the derivative version is obtained by applying Lemma 22.5 to the differentiated packet. The differentiated packet only multiplies the compact momentum amplitude by a smooth polynomial expression in p, so it has the same velocity localization and rapid tube-tail estimates. The resulting bound is $C_N(1+|t|)^{-N}$ for arbitrary N, hence integrable. This is (22.6). □

Together, Propositions 22.4, 22.6, and 22.7 give the ordinary massive Haag–Ruelle theorem under the displayed vacuum-net, isolated-shell, and regular-creator hypotheses. No perturbative pole expansion or Lagrangian formalism enters this construction.

Proof of Theorem 22.1. Choose regular creators B_j whose one-particle projections are the desired wave packets and whose velocity supports are pairwise disjoint after the usual finite partition of momentum space. Spectral isolation of the mass shell gives $B_{j,t}\Omega = P_1 B_{j,t}\Omega$ independent of t, and excludes $B_{j,t}^*\Omega$ by the support condition against the forward spectrum. Lemma 22.5 and almost locality give the rapid commutator bound through Proposition 22.6. The remaining contraction and Cook bounds are supplied by Proposition 22.7; hence the family satisfies Definition 22.3. Applying Proposition 22.4 gives the outgoing and incoming Hilbert-norm limits and the Fock scalar product. The scalar product identifies vectors obtained from different interpolating creators with the same one-particle projection and extends the wave maps by completion from the algebraic symmetric Fock domain. The assumed density of regular creators in $\mathcal{H}_1$ gives the stated wave operators on $\mathcal{F}_s(\mathcal{H}_1)$. □

22.5 Gauge Charges and Nonlocal Charged Creators

The ordinary theorem uses local creators $B \in \mathcal{A}(\mathcal{O})$ whose vacuum vector $B\Omega$ has nonzero projection to an isolated one-particle shell. In a gauge theory with an unscreened Gauss-law charge, the existence of such a creator is a further dynamical and localization hypothesis. It is false for charged particles if the available local algebra is the gauge-invariant observable algebra.

Theorem 22.8 (Gauss-law obstruction to local charged creators)**.** *Let $\mathcal{A}$ be a gauge-invariant local observable net in a vacuum representation. Assume that an abelian charge Q is represented on a common invariant domain by the large-sphere Gauss-law limit*

$$Q = \lim_{R\to\infty} Q_R, \qquad Q_R = \int_{S_R} n_i E^i \, \mathrm{d}S,$$

and that locality holds between $\mathcal{A}(\mathcal{O})$ and electric-field operators localized spacelike to $\mathcal{O}$. If the vacuum is neutral, $Q\Omega = 0$, then every local gauge-invariant observable $A \in \mathcal{A}(\mathcal{O})$ creates a *neutral vector:*

$$Q\, A\Omega = 0.$$

Consequently a charged one-particle vector cannot be obtained by applying a bounded-region gauge-invariant observable to the vacuum.

Proof. The surface charge must be read as a limit of smeared operators. Choose a smooth function $\rho_R(r)$ supported in a shell $R < r < 2R$, normalized so that it represents the outward flux through a large sphere, and define the smeared Gauss operator $Q_R(\rho)$ on the common invariant domain. For R larger than the spatial diameter of $\mathcal{O}$, the support of the electric-field smearing is spacelike to $\mathcal{O}$ at the chosen time slice. Locality of the observable net with the electric-field algebra gives

$$[Q_R(\rho), A] = 0$$

on that domain. The statement is insensitive to the particular smooth representative of the large sphere: changing ρ_R inside the exterior region changes $Q_R(\rho)$ by an operator localized spacelike to $\mathcal{O}$, plus terms that vanish in the assumed Gauss-law limit.

By hypothesis the strong graph limit of $Q_R(\rho)$ on vectors generated from the vacuum by local observables exists and is the charge Q. Hence for every vector Φ in the common domain,

$$\langle \Phi, (QA - AQ)\Omega\rangle = \lim_{R\to\infty} \langle \Phi, [Q_R(\rho), A]\Omega\rangle = 0.$$

Thus $QA\Omega = AQ\Omega$ as a vector identity on the charge domain. Since the vacuum is neutral,

$$QA\Omega = AQ\Omega = 0.$$

If ψ has charge $q \neq 0$, so that $Q\psi = q\psi$, it cannot equal $A\Omega$ for such an A. □

This obstruction concerns localization and Gauss-law charge. It is distinct from the infraparticle obstruction in massless QED. The latter states that a charged sector with long-range electromagnetic flux does not contain an ordinary sharp Wigner mass-shell vector. The present theorem applies before asking whether the charged spectral distribution is an isolated shell or a soft-photon continuum: a bounded gauge-invariant observable cannot change the surface charge at infinity.

Almost-local closure. Under the hypotheses of Theorem 22.8, assume in addition that the charge operator Q is closed on a domain containing the vectors generated from Ω by local gauge-invariant observables. Let $B \in \mathcal{B}(\mathcal{H})$ be almost local with respect to the observable net: there are $B_R \in \mathcal{A}(\mathcal{O}_R)$, with $\mathcal{O}_R$ a cofinal family of bounded regions, such that

$$\|B - B_R\| \longrightarrow 0 \qquad (R \to \infty).$$

Then $B\Omega$ is neutral:

$$B\Omega \in \mathrm{Dom}(Q), \qquad QB\Omega = 0.$$

Consequently a vector with nonzero Gauss charge cannot be produced from the vacuum by an almost-local operator belonging to the gauge-invariant observable net.

For each R, Theorem 22.8 applied to the local observable B_R gives

$$B_R\Omega \in \mathrm{Dom}(Q), \qquad QB_R\Omega = 0.$$

The norm convergence $B_R \to B$ implies $B_R\Omega \to B\Omega$, while $QB_R\Omega \to 0$. Closedness of Q therefore gives

$$B\Omega \in \mathrm{Dom}(Q), \qquad QB\Omega = 0.$$

If $B\Omega$ had a nonzero component in a charge-q spectral subspace, $q \neq 0$, the self-adjoint spectral calculus for Q would give $QB\Omega \neq 0$ on that component. Hence no such component is present.

This almost-local extension is the exact point at which the ordinary Haag–Ruelle hypothesis fails. The obstruction is structural: the noncompact tail is forced by the charge superselection law. If an operator changes the Gauss-law flux at infinity, it cannot be approximated in norm, even rapidly, by bounded gauge-invariant observables localized in bounded regions.

Charged fields can be introduced in a larger field algebra, but they are not gauge-invariant local observables. A gauge-invariant charged insertion must carry flux to infinity. In an abelian convention

$$A \longmapsto A + \mathrm{d}\alpha, \qquad \psi_q(x) \longmapsto \mathrm{e}^{\mathrm{i}q\alpha(x)}\psi_q(x),$$

a path γ from x to spatial infinity gives the formal dressing

$$\Psi_{q,\gamma}(x) = \psi_q(x) \exp\left\{\mathrm{i}q \int_\gamma A\right\}. \tag{22.8}$$

For gauge functions with $\alpha(\infty) = 0$, the exponential transforms by $\mathrm{e}^{-\mathrm{i}q\alpha(x)}$, so $\Psi_{q,\gamma}(x)$ is gauge invariant. For a gauge function with nonzero boundary value, it transforms by the boundary phase and therefore carries the global charge. The price is noncompact localization: the localization region includes the curve γ reaching infinity, or a Coulombic dressing with equivalent asymptotic flux.

Hypothesis 22.9 (Nonconfining charged sector)**.** A charged sector is nonconfining, for the charged construction below, when it has the following objects and properties.

1. A vacuum observable net $\mathcal{A}$ with a positive-energy representation and a physical charged representation $(\mathcal{H}_q, U_q)$ of the observable net. The representation carries a self-adjoint boundary charge Q and, for each smooth angular test f on the sphere at spatial infinity, a Gauss-law flux operator $\Phi_\infty(f)$ obtained as the large-sphere limit of the corresponding electric-flux smearing on a common invariant domain.

2. Compactly localized gauge-invariant observables preserve the boundary charge and the angular flux sector in the large-sphere limit:

   $$[A, Q] = 0, \qquad [A, \Phi_\infty(f)] = 0$$

   on the common domain whenever A is localized in a bounded spacetime region. Thus the charged representation is labelled by data at infinity rather than by an operator in the bounded observable net.

3. The charged sector has finite-energy asymptotic content. In a massive screened or Coulomb-branch situation this means an isolated positive-energy mass hyperboloid

   $$\Sigma^+_{m,q} = \{p \in \mathbb{R}^{1,d} \mid p^2 = -m^2,\ p^0 > 0\}$$

   inside the joint spectrum of U_q, with finite-dimensional multiplicity space $E_{p,q}$ and spectral projection $P_{1,q}$. In a massless long-range abelian theory the corresponding spectral replacement is a charged threshold or infraparticle measure together with its flux-sector label; ordinary isolated-shell Haag–Ruelle estimates are then replaced by the modified asymptotic problem stated below.

4. There is a class of gauge-invariant noncompact charged creators $\Psi_{q,\Gamma}$, where Γ denotes a Wilson-line ray, Coulomb profile, or equivalent dressing geometry reaching infinity, such that their smeared vectors have a nonzero projection to the charged one-particle subspace, namely

$$P_{1,q}\Psi_{q,\Gamma}(f)\Omega \neq 0$$

in the isolated-shell case, or a nonzero threshold coefficient in the infraparticle case. The dressing geometry determines the angular flux label of the vector.

5. Truncated dressings must have a finite-energy limit after the local renormalizations belonging to the chosen charged operator. Let

$$\xi_{L,\varepsilon} = \frac{\Psi_{q,\Gamma;L,\varepsilon}(f)\Omega}{\|\Psi_{q,\Gamma;L,\varepsilon}(f)\Omega\|}$$

when the denominator is nonzero, and let $E_q(\Delta)$ be the spectral projection of the charged Hamiltonian H_q. The operational condition is spectral tightness:

$$\lim_{E\to\infty} \sup_{(L,\varepsilon)\in\mathcal{A}} \left\|(1 - E_q([0,E]))\xi_{L,\varepsilon}\right\| = 0 \tag{22.9}$$

for the admissible truncation schedules $\mathcal{A}$ used in the large-time construction. Uniform first-moment control,

$$\sup_{(L,\varepsilon)\in\mathcal{A}} \langle \xi_{L,\varepsilon}, H_q\xi_{L,\varepsilon}\rangle < \infty,$$

is a useful sufficient estimate by the spectral Markov inequality, but the scattering construction needs the tightness of the spectral measures themselves. The tightness condition is what permits extraction of finite-energy subsequential limits and makes the projection or threshold coefficient in the previous item meaningful.

The confining alternative is a spectral lower-bound statement for the declared class of gauge-invariant charged truncations. Let $\mathcal{D}_{q,L}$ be a class of normalized truncated charged vectors whose boundary flux reaches distance L. If there are $\sigma > 0$, L_0, and $c = o(L)$ such that every $\xi \in \mathcal{D}_{q,L}$, $L \geq L_0$, has spectral support above

$$E_{\text{vac}} + \sigma L - c(L), \tag{22.10}$$

or equivalently

$$\langle \xi, H_q\xi\rangle \geq E_{\text{vac}} + \sigma L - c(L),$$

then the family cannot satisfy (22.9). In that case the finite-energy charged asymptotic sector is absent and the scattering problem belongs to neutral composite sectors.

The word "nonconfining" in the rest of this section refers precisely to Hypothesis 22.9. The hypothesis does not solve the charged Haag–Ruelle problem. It states the minimum positive spectral and representation-theoretic data on which that problem can be posed. The subsequent LSZ and Dollard constructions explain what follows from these inputs and which large-time estimates still have to be proved.

Truncation topology for noncompact dressings. The symbol $\Psi_{q,\Gamma}$ in Hypothesis 22.9 is not an ordinary local operator-valued distribution with a hidden bounded localization region. For a Wilson-line ray or Coulomb dressing it must be defined as a renormalized limit of finite dressings. A precise charged construction must therefore fix, before any large-time scattering limit is taken, a family

$$\Psi_{q,\Gamma;L,\varepsilon}(f) = N_{\Gamma;L,\varepsilon}\,\psi_{q,\varepsilon}(f)\,W_{\Gamma;L,\varepsilon}$$

on a common finite-energy domain: L is the length or infrared truncation of the dressing, ε is the ultraviolet regulator at the charged endpoint and along cusps or corners, $W_{\Gamma;L,\varepsilon}$ is the finite Wilson-line or Coulombic factor, and $N_{\Gamma;L,\varepsilon}$ contains the endpoint, line, cusp, and local charged-field renormalizations belonging to the chosen scheme. The infinite dressing is a shorthand only after matrix elements against finite-energy vectors have limits, with the boundary charge and angular flux label held fixed:

$$\lim_{\varepsilon\downarrow 0}\lim_{L\to\infty}\langle \xi, \Psi_{q,\Gamma;L,\varepsilon}(f)\eta\rangle = \langle \xi, \Psi_{q,\Gamma}(f)\eta\rangle.$$

The order of limits may be replaced by a joint renormalization prescription, but the prescription is part of the operator datum.

For Haag–Ruelle purposes fixed-time convergence is not enough. The large-time approximants sample increasingly long pieces of the Gauss-law tail, so the theorem must specify admissible truncation schedules

$$L_i(t) \to \infty, \qquad \varepsilon_i(t) \downarrow 0, \qquad \sigma t \to +\infty,$$

for every charged external leg. Same-flux schedules and same-flux compact dressing changes should define the same asymptotic vector only if their modified comparison vectors obey a uniform tail condition on the scattering domain. In the notation used below this means that, for two admissible same-flux choices L and L',

$$\lim_{T\to\infty}\sup_{\sigma t\geq T}\left\|\mathcal{C}^{\sigma}_{I,L}(t) - \mathcal{C}^{\sigma}_{I,L'}(t)\right\| = 0, \tag{22.11}$$

and, whenever the norm derivative is used in Cook's argument,

$$\lim_{T\to\infty}\int_{\sigma t\geq T}\left\|\frac{\mathrm{d}}{\mathrm{d}t}\big(\mathcal{C}^{\sigma}_{I,L}(t) - \mathcal{C}^{\sigma}_{I,L'}(t)\big)\right\|\,\mathrm{d}t = 0. \tag{22.12}$$

Equations (22.11) and (22.12) are load-bearing estimates: they are the point where the formal infinite Wilson line becomes a legitimate asymptotic coordinate. A construction that only supplies $\Psi_{q,\Gamma;L,\varepsilon}(f)$ for each fixed L and then takes $L \to \infty$ at fixed time supplies a family of dressed matrix elements, while the charged Haag–Ruelle input requires control of the joint large-time/noncompact-tail limit.

Definition 22.10 (Dressed charged LSZ problem)**.** A dressed charged LSZ problem consists of:

1. a nonconfining charged sector in the sense of Hypothesis 22.9;
2. a family of gauge-invariant noncompact charged creators $\Psi_{q,\gamma}(x)$, or Coulombic variants with the same asymptotic flux;
3. a specification of the dressing geometry γ in terms of the asymptotic velocity or momentum labels;

4. a spectral statement for the vectors $\Psi_{q,\gamma}(f)\Omega$, either an isolated massive shell in an infrared-regulated or screened model, or the corresponding charged infraparticle threshold structure in massless QED;
5. a reduction prescription for Fourier-transformed dressed correlators

$$\langle\Omega|T\{\Psi_{q_1,\gamma_1}(x_1)\cdots\Psi^\dagger_{q_n,\gamma_n}(y_n)\,\mathcal{O}_1\cdots\mathcal{O}_k\}|\Omega\rangle$$

which extracts the same matrix elements as the large-time dressed wave operators.

This definition identifies the replacement for ordinary local-field LSZ in a charged gauge sector. The external residue, when an isolated charged shell is available after a regulator or screening deformation, is the residue of the dressed two-point function. It includes the short-distance renormalization of the matter field and the endpoint or cusp renormalization of the Wilson-line dressing. Different dressing geometries define different charged operators; showing that a physical on-shell answer is independent of the unobserved geometric choices is part of the reduction theorem, not an assumption inside the scalar LSZ formula.

22.5.1 Dressed Residues as Charged Coordinates

Before discussing the geometry of Wilson lines, it is useful to state the finite-dimensional algebra that any dressed LSZ theorem must implement. Fix, temporarily, an infrared regulator or screening deformation for which a charged isolated massive shell exists. Let

$$\{\Psi_a\}_{a=1}^r$$

be finitely many gauge-invariant dressed charged interpolating operators with the same charge, spin-statistics, mass, and asymptotic flux sector. Let E_p be the finite-dimensional one-particle multiplicity space over the mass shell point $p\in\Sigma_m^+$, and choose an orthonormal basis $\{|p,\lambda\rangle\}_{\lambda=1}^N$ of E_p. The one-particle matrix coefficients of the dressed coordinates are the numbers

$$z_a{}^\lambda(p)=\langle p,\lambda|\Psi_a(0)\Omega\rangle.$$

Equivalently, for a positive-frequency packet f supported in the isolating neighborhood of the shell,

$$P_1\Psi_a(f)\Omega=\int_{\Sigma_m^+}\mathrm{d}\mu_m(p)\,\widehat{f}(p)\sum_{\lambda=1}^N z_a{}^\lambda(p)|p,\lambda\rangle.$$

The singular part of the dressed two-point function is therefore the Gram matrix of these overlap vectors:

$$\lim_{p^2\to-m^2}(p^2+m^2-\mathrm{i}0)\widehat{G}_{ab}(p)=\mathrm{i}\sum_{\lambda=1}^N z_a{}^\lambda(p)\,\overline{z_b{}^\lambda(p)}\equiv\mathrm{i}Z_{ab}(p),\tag{22.13}$$

in the time-ordered convention used in the LSZ chapter. Thus the pole residue is not an intrinsic scalar attached to a raw noncompact operator; it is the coordinate Gram matrix of the physical one-particle shell in the chosen dressed operator coordinates.

The LSZ extraction of a normalized external charged state is possible from this family precisely when the overlap map

$$z(p):E_p\longrightarrow\mathbb{C}^r,\qquad \eta_\lambda|p,\lambda\rangle\longmapsto\left(\sum_\lambda z_a{}^\lambda(p)\eta_\lambda\right)_{a=1}^r$$

has full column rank. A choice of left inverse

$$L(p) : \mathbb{C}^r \longrightarrow E_p, \qquad L(p)z(p) = \mathbf{1}_{E_p},$$

then supplies the external charged residue coordinate. If

$$\widehat{H}_a(p;\Xi) = \frac{\mathrm{i}\sum_\lambda z_a{}^\lambda(p)\mathcal{A}_\lambda(p;\Xi)}{p^2+m^2-\mathrm{i}0} + \widehat{H}_a^{\text{less}}(p;\Xi)$$

is a Fourier-transformed dressed correlator with one external charged insertion and all other variables denoted by Ξ, then

$$\lim_{p^2\to -m^2}(p^2+m^2-\mathrm{i}0)\sum_a L^\rho{}_a(p)\,\widehat{H}_a(p;\Xi) = \mathrm{i}\,\mathcal{A}_\rho(p;\Xi). \tag{22.14}$$

The positive matrix $Z^{-1/2}$ in the finite-regulator theorem below is the special square-coordinate form of this left-inverse operation after the operator labels have been identified with an orthonormal multiplicity basis.

This algebra also gives the exact meaning of a harmless dressing change. If another family is related by a finite invertible change of dressed coordinates,

$$\Psi'_\alpha = \sum_a M_\alpha{}^a \Psi_a,$$

with the same charged shell and the same asymptotic flux sector, then

$$z' = Mz, \qquad Z' = MZM^\dagger, \qquad L' = LM^{-1}.$$

Equation (22.14) is unchanged. This is a coordinate statement on a fixed one-particle charged sector; it is not a path-independence theorem for arbitrary Wilson lines. A change of the asymptotic ray or Coulomb tail changes the Gauss-law flux at infinity in an unscreened theory and need not be represented by any finite invertible matrix on a common Hilbert-space shell. The soft-sector calculations below make this failure explicit.

22.5.2 Wilson-Line Covariance and Boundary Charge

The sign and orientation in (22.8) are fixed by gauge covariance. Let $\gamma_{x,\infty} : [0,\infty) \to M$ be a regulated curve with $\gamma(0) = x$ and endpoint tending to spatial infinity. With

$$A \mapsto A + \mathrm{d}\alpha, \qquad \psi_q(x) \mapsto \mathrm{e}^{\mathrm{i}q\alpha(x)}\psi_q(x),$$

the abelian Wilson factor

$$W_{q,\gamma}(x) = \exp\left\{\mathrm{i}q\int_{\gamma_{x,\infty}} A\right\}$$

transforms as

$$W_{q,\gamma}(x) \longmapsto \mathrm{e}^{\mathrm{i}q(\alpha(\infty)-\alpha(x))}W_{q,\gamma}(x).$$

Therefore

$$\Psi_{q,\gamma}(x) = \psi_q(x)W_{q,\gamma}(x) \longmapsto \mathrm{e}^{\mathrm{i}q\alpha(\infty)}\Psi_{q,\gamma}(x). \tag{22.15}$$

Equation (22.15) is the precise sense in which the operator is invariant under gauge transformations trivial at infinity and carries charge q under the boundary gauge transformation. The boundary phase is not a gauge redundancy; it is the global charge action in the charged sector.

For a nonabelian gauge field $A = A^a_\mu t^a_R \mathrm{d}x^\mu$ and a matter field $\psi_R(x)$ in representation R, choose the parallel transporter

$$U_R(\infty, x; \gamma) = P\exp\left\{\mathrm{i}\int_{\gamma_{x,\infty}} A^a_\mu t^a_R\, \mathrm{d}x^\mu\right\}.$$

Under a gauge transformation g,

$$U_R(\infty, x; \gamma) \longmapsto g(\infty) U_R(\infty, x; \gamma) g(x)^{-1}.$$

Thus $U_R(\infty, x; \gamma)\psi_R(x)$ transforms only by $g(\infty)$. In a sector where the boundary gauge group is treated as a global symmetry, this is a charged operator; in a confining theory with no colored asymptotic sectors, it is a noncompact string-like excitation rather than an external particle creator. This distinction is dynamical and cannot be read off from the formal gauge covariance alone.

Boundary-charge selection rule for dressed correlators. The endpoint transformation supplies the Ward identity that fixes which dressed correlators can enter an LSZ formula. Consider, with a fixed ultraviolet regulator and a fixed infrared endpoint prescription, a time-ordered vacuum distribution

$$G(x_1, \ldots, x_n; \Xi) = \langle\Omega| T\{\Psi^{\epsilon_1}_{q_1,\gamma_1}(x_1)\cdots\Psi^{\epsilon_n}_{q_n,\gamma_n}(x_n)\, \mathcal{O}(\Xi)\}|\Omega\rangle.$$

Here $\epsilon_a = +1$ means Ψ_{q_a,γ_a}, $\epsilon_a = -1$ means $\Psi^\dagger_{q_a,\gamma_a}$, and $\mathcal{O}(\Xi)$ is a product of neutral gauge-invariant local observables. Under a boundary gauge transformation with constant value α_∞, the vacuum and the neutral observables are invariant while

$$\Psi^{\epsilon_a}_{q_a,\gamma_a} \longmapsto \exp(\mathrm{i}\epsilon_a q_a \alpha_\infty)\Psi^{\epsilon_a}_{q_a,\gamma_a}.$$

Therefore, as an equality of regulated distributions,

$$G = \exp\left(\mathrm{i}\alpha_\infty \sum_{a=1}^{n} \epsilon_a q_a\right) G \qquad \text{for every } \alpha_\infty.$$

If the signed boundary charge does not vanish,

$$\sum_{a=1}^{n} \epsilon_a q_a \neq 0, \tag{22.16}$$

then $G = 0$. Equivalently, a nonzero vacuum correlator of dressed charged operators must be neutral after the charges carried by the endpoints at infinity are included. Matrix elements between charged superselection sectors obey the same rule with the right side of (22.16) replaced by the difference between the final and initial boundary charges. Thus the external charges in a dressed LSZ reduction form part of the boundary-charge bookkeeping of the correlator itself.

For a nonabelian boundary group, the same statement is representation theoretic. If the endpoints of the dressed insertions transform in boundary representations $R_1, \ldots, R_n$, then the vacuum correlator is an invariant tensor in

$$(R_1 \otimes \cdots \otimes R_n)^{G_\infty}.$$

If this invariant subspace is zero, the correlator vanishes. If it is nonzero, choosing a basis of invariant tensors is part of choosing the external charged channel. This is still separate from the dynamical question whether the corresponding charged sector has finite-energy asymptotic particles; in a confining phase the representation-theoretic singlet condition may be satisfied only by neutral composite operators, and ordinary Haag–Ruelle theory then applies to those composite particles rather than to individual colored endpoints.

22.5.3 Ray Dressings as Gauge-Slice Coordinates

The preceding covariance statement has a second, more computational, interpretation. A Wilson-line dressed charged coordinate is the ordinary charged coordinate written on a gauge slice adapted to the same ray. The statement below is elementary in abelian gauge theory, but it is a useful guardrail for perturbative calculations of dressed correlators.[1]

Let u^μ be a fixed nonzero vector and let the half-line from x be

$$\gamma_{x,u}(\tau) = x + \tau u, \qquad \tau \geq 0.$$

Work on a class of gauge potentials A and gauge functions α for which $u^\mu A_\mu(x+\tau u)$ and $u^\mu \partial_\mu \alpha(x+\tau u)$ are absolutely integrable on $[0, \infty)$ and for which

$$\alpha(x + \tau u) \longrightarrow 0, \qquad u^\mu A_\mu(x + \tau u) \longrightarrow 0 \qquad (\tau \to \infty)$$

along every ray under consideration. Define the line functional

$$\chi_u[A](x) = \int_0^\infty \mathrm{d}\tau \, u^\mu A_\mu(x + \tau u). \tag{22.17}$$

For the abelian gauge convention

$$A_\mu \longmapsto A_\mu + \partial_\mu \alpha, \qquad \psi_q \longmapsto \mathrm{e}^{\mathrm{i}q\alpha} \psi_q,$$

one has

$$\chi_u[A + \mathrm{d}\alpha](x) = \chi_u[A](x) - \alpha(x).$$

Hence

$$\Psi_{q,u}(x) = \mathrm{e}^{\mathrm{i}q\chi_u[A](x)} \psi_q(x) \tag{22.18}$$

is invariant under gauge transformations that are trivial at the ray endpoint.

[1] A recent perturbative study of finite-distance dressed observables in electrodynamics and perturbative gravity is C. Cheung, A. Sivaramakrishnan, J. Wilson-Gerow, and L. Zhou, *On Perturbatively Dressed Observables*, arXiv:2605.26077. The use made here is only the gauge-slice viewpoint; the abelian identities and denominators in this subsection are derived directly.

Ray dressing as an axial-gauge coordinate. For every A in the class above, set

$$A_\mu^{[u]}(x) = A_\mu(x) + \partial_\mu \chi_u[A](x), \qquad \psi_q^{[u]}(x) = \mathrm{e}^{\mathrm{i}q\chi_u[A](x)}\psi_q(x).$$

Then

$$u^\mu A_\mu^{[u]}(x) = 0, \qquad \psi_q^{[u]}(x) = \Psi_{q,u}(x). \tag{22.19}$$

Thus a dressed charged insertion may be computed, in any finite regularized perturbative path integral for which this gauge slice and the corresponding change of variables have been defined with their regulator and Faddeev–Popov factors, as the ordinary charged field inserted in the gauge $u^\mu A_\mu = 0$ with the same endpoint prescription. Indeed, differentiating (22.17) in the ray direction gives

$$\begin{aligned} u^\nu \partial_\nu \chi_u[A](x) &= \int_0^\infty \mathrm{d}\tau \, \frac{d}{d\tau}\big(u^\mu A_\mu(x+\tau u)\big) \\ &= \lim_{T\to\infty} u^\mu A_\mu(x+Tu) - u^\mu A_\mu(x) = -u^\mu A_\mu(x). \end{aligned}$$

Therefore

$$u^\mu A_\mu^{[u]}(x) = u^\mu A_\mu(x) + u^\mu \partial_\mu \chi_u[A](x) = 0.$$

The second identity in (22.19) is the definition of $\psi_q^{[u]}$ together with (22.18). The preceding transformation law for χ_u shows that this construction is constant on gauge orbits once the boundary gauge value has been fixed.

The perturbative singularities produced by the ray are also fixed at this elementary level. Insert an endpoint regulator

$$\chi_{u,\epsilon}[A](x) = \int_0^\infty \mathrm{d}\tau \, \mathrm{e}^{-\epsilon\tau} u^\mu A_\mu(x+\tau u), \qquad \epsilon > 0,$$

and use the Fourier convention

$$A_\mu(y) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \mathrm{e}^{-\mathrm{i}k\cdot y} \widehat{A}_\mu(k).$$

Then

$$\chi_{u,\epsilon}[A](x) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \mathrm{e}^{-\mathrm{i}k\cdot x} \frac{u^\mu \widehat{A}_\mu(k)}{k\cdot u - \mathrm{i}\epsilon}. \tag{22.20}$$

Indeed, substituting the Fourier transform gives

$$\chi_{u,\epsilon}[A](x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \mathrm{e}^{-\mathrm{i}k\cdot x} u^\mu \widehat{A}_\mu(k) \int_0^\infty \mathrm{d}\tau \, \mathrm{e}^{-(\epsilon + \mathrm{i}k\cdot u)\tau},$$

and the last integral is

$$\frac{1}{\epsilon + \mathrm{i}k\cdot u} = -\frac{\mathrm{i}}{k\cdot u - \mathrm{i}\epsilon}.$$

Expanding the exponential in (22.18) therefore inserts the distribution $(k\cdot u - \mathrm{i}0)^{-1}$ for every photon emitted from the line. These linear denominators are part of the nonlocal composite operator and of the corresponding axial-gauge coordinate system. They must be treated as additional singular hypersurfaces in loop integrals involving dressed finite-distance correlators. They do not, by themselves, supply the large-time Haag–Ruelle estimate or the infrared representation theory required for charged scattering; those are the separate problems formulated below and in Chapter 44.

22.5.4 The Missing Haag–Ruelle Estimate

Ordinary Haag–Ruelle theory uses two facts at large time: the one-particle part of $B_t(h)\Omega$ is time independent, and commutators of creators with disjoint velocity supports are rapidly decreasing because the creators are almost local. The almost-local closure of the Gauss-law obstruction above shows that, for an unscreened Gauss-law charge, a charged creator in the observable net cannot satisfy that localization hypothesis. A Wilson-line or Coulomb-dressed charged creator has noncompact localization for structural reasons, so the local commutator estimate must be replaced rather than reused.

The geometric replacement is not "large spacelike separation" of bounded double cones. Let V_h be the compact velocity support of the charged wave packet and let $\mathcal{C}_\Gamma$ denote the asymptotic cone, ray, or Coulomb coordinate carried by the dressing. A future charged theorem must separate two different pieces of the large-time operator. The compact core of $\Psi_{\Gamma,t}(h)$ is transported into the velocity tube $tV_h + O(1)$ and can be treated by the ordinary spacelike-separation argument when the velocity supports are disjoint. The Gauss-law tail attached to $\mathcal{C}_\Gamma$, however, remains noncompact and is not made harmless by separating the cores. Consequently the commutator estimate has to be a decomposition into the following three separately estimated contributions:

$$\text{core–core spacelike term} \quad + \quad \text{tail–tail flux pairing} \quad + \quad \text{integrable remainder.}$$

The second term is the part which becomes the Dollard or Faddeev–Kulish comparison phase below. Compact deformations of the dressing ray can change the operator by neutral field-strength insertions, as in (22.47), but they do not remove the asymptotic flux tail. Thus the analytic estimate to be proved is a cone/flux estimate, not a disguised application of ordinary almost locality.

The replacement has definite analytic content: a charged construction must separate the nonintegrable long-range part of the motion from the integrable remainder. For a charged packet h, write

$$\Psi_{\Gamma,t}(h)$$

for a dressed creator with datum $\Gamma = (q, \gamma, \mathcal{E}_\infty, \mathfrak{s})$: q is the boundary charge, γ is the geometric dressing or Coulomb coordinate, $\mathcal{E}_\infty$ is the limiting Gauss-law flux density, and $\mathfrak{s}$ records spin and internal multiplicity labels. A Haag–Ruelle replacement for a finite velocity-separated list

$$I = ((\Gamma_1, h_1), \ldots, (\Gamma_n, h_n))$$

must provide a real locally absolutely continuous comparison phase $\Theta_I(t)$ and vectors

$$\mathcal{C}_I(t) = \mathrm{e}^{-\mathrm{i}\Theta_I(t)}\Psi_{\Gamma_1,t}(h_1)\cdots\Psi_{\Gamma_n,t}(h_n)\Omega. \tag{22.21}$$

The desired estimates have the following precise content.

1. The one-particle or threshold coordinate of $\Psi_{\Gamma,t}(h)\Omega$ is independent of t after the chosen comparison dynamics is applied. In an infrared-regulated massive charged sector this is an ordinary isolated-shell projection. In massless QED it is instead a threshold or detector datum in a velocity/flux representation, not a Wigner one-particle vector in a single photon Fock space.

2. For two velocity-separated dressed creators, the large-time exchange relation on the finite-energy domain has the form

$$\Psi^{\#}_{\Gamma_i,t}(h_i)\Psi^{\#}_{\Gamma_j,t}(h_j) = \mathrm{e}^{\mathrm{i}\theta^{\#\#}_{ij}(t)}\Psi^{\#}_{\Gamma_j,t}(h_j)\Psi^{\#}_{\Gamma_i,t}(h_i) + R^{\#\#}_{ij}(t), \qquad \int_{T_0}^{\infty} \|R^{\#\#}_{ij}(t)\xi\|\,\mathrm{d}t < \infty, \tag{22.22}$$

for every vector ξ in the scattering domain and for each choice in which a superscript # denotes either the operator itself or its adjoint. The phase $\theta^{\#\#}_{ij}$, when present, is determined by the asymptotic flux data. In a local massive theory this phase is zero and the remainder is rapidly decreasing in operator norm. In a long-range charged theory a term with $\dot{\theta}_{ij}(t) \sim c_{ij}/t$ is not an error; it must be included in the comparison dynamics.

3. The comparison phase in (22.21) cancels all nonintegrable pair terms in the time derivative:

$$\left\|\frac{\mathrm{d}}{\mathrm{d}t}\mathcal{C}_I(t)\right\| \le R_I(t), \qquad R_I \in L^1([T_0,\infty)). \tag{22.23}$$

This is the charged analogue of Cook's estimate. It is the analytic heart of the missing theorem.

4. Scalar products of the modified vectors have limits computed in the appropriate asymptotic representation. For a screened theory with isolated massive charged shells this representation may be an ordinary charged Fock space. For massless QED it must be a representation carrying the velocity/flux labels discussed below; one cannot first form a single photon Fock space and then attach the flux by a limiting unitary.

5. Dressings with the same limiting flux and a finite Hilbert-space difference act as changes of interpolating coordinates. Dressings with different limiting fluxes define different charged sectors. The distinction is quantified below by the soft-norm and Weyl-implementation calculations.

Finite-dimensional Coulomb-tail comparison. The following elementary calculation fixes the normalization of the logarithmic comparison phase, but it is not a theorem about QFT. Let $u \in \mathbb{R}^3 \setminus \{0\}$, $b \in \mathbb{R}^3$, $a > 0$, and $\kappa \in \mathbb{R}$, and define

$$V(t) = \frac{\kappa}{\sqrt{a^2 + |b+ut|^2}}, \qquad \Phi(T) = \int_{T_0}^{T} V(t)\,\mathrm{d}t.$$

Introduce

$$\sigma = \frac{b\cdot u}{|u|^2}, \qquad b_\perp = b - \sigma u, \qquad \rho^2 = a^2 + |b_\perp|^2.$$

Then

$$a^2 + |b+ut|^2 = \rho^2 + |u|^2(t+\sigma)^2,$$

and the integral has the exact primitive

$$\Phi(T) = \frac{\kappa}{|u|}\left[\operatorname{arsinh}\left(\frac{|u|(t+\sigma)}{\rho}\right)\right]_{T_0}^{T}. \tag{22.24}$$

Using $\operatorname{arsinh} x = \log(2x) + O(x^{-2})$ as $x \to +\infty$, one obtains a finite constant $C(T_0, b, u, a, \kappa)$ with

$$\Phi(T) = \frac{\kappa}{|u|}\log T + C(T_0,b,u,a,\kappa) + O(T^{-1}) \qquad (T \to +\infty). \tag{22.25}$$

The same completed-square expression gives

$$V(t) = \frac{\kappa}{|u|}\frac{1}{t} + O(t^{-2}).$$

This finite-dimensional comparison calculation does not identify the coefficient κ in a QFT. Its role is to fix the logic of the missing charged Haag–Ruelle estimate. If the asymptotic flux-sector pairing of two charged packets produces an effective long-range pair term $V_{ij}(t)$ with leading coefficient $\kappa_{ij}/|u_{ij}|$, then the corresponding contribution to $\Theta_I(t)$ must contain

$$\frac{\kappa_{ij}}{|u_{ij}|}\log t.$$

Treating this logarithmic phase as an error would make the Cook derivative nonintegrable. The open QFT problem is precisely to derive the analogue of κ_{ij}, and the L^1 remainder after subtracting the resulting phase, from the noncompact Wilson-line or Coulomb-dressed charged creators.

Coefficient and residual estimate to be proved. The symbol κ_{ij} in the preceding comparison is not a free normalization. A nonperturbative charged Haag–Ruelle theorem must construct it from the asymptotic Gauss-law tail of the chosen charged coordinates. For two velocity-separated packet data (Γ_i, h_i), (Γ_j, h_j), and for each choice of creator or adjoint signs $\#\#$, the theorem must produce a scalar pair kernel $K_{ij}^{\#\#}(t)$ and a residual operator $\mathcal{R}_{ij}^{\#\#}(t)$ on the scattering domain. Denote by $\mathcal{D}_{ij}^{\#\#}(t)$ the pair component of the large-time exchange defect or Cook derivative in the chosen finite-regulator construction, and by $\mathcal{P}_{ij}^{\#\#}(t)$ the corresponding ordered product with the other dressed factors held fixed. The required decomposition is

$$\mathcal{D}_{ij}^{\#\#}(t)\xi = \mathrm{i}\, K_{ij}^{\#\#}(t)\, \mathcal{P}_{ij}^{\#\#}(t)\xi + \mathcal{R}_{ij}^{\#\#}(t)\xi, \tag{22.26}$$

with

$$\int_{T_0}^{\infty} \|\mathcal{R}_{ij}^{\#\#}(t)\xi\|\,\mathrm{d}t < \infty \qquad \text{for every scattering-domain vector } \xi. \tag{22.27}$$

The leading part of $K_{ij}^{\#\#}$ is fixed by a flux-pairing functional on the limiting tails:

$$K_{ij}^{\#\#}(t) = \eta_i\eta_j \frac{\kappa(\Gamma_i,\Gamma_j)}{\sqrt{a_{ij}^2 + |b_{ij} + u_{ij}t|^2}} + k_{ij}^{\#\#,\mathrm{rem}}(t), \qquad k_{ij}^{\#\#,\mathrm{rem}} \in L^1([T_0,\infty)). \tag{22.28}$$

Equivalently,

$$K_{ij}^{\#\#}(t) - \eta_i\eta_j \frac{\kappa(\Gamma_i,\Gamma_j)}{|u_{ij}|\,t} \in L^1([T_0,\infty)).$$

In an elementary abelian Coulomb normalization the functional $\kappa(\Gamma_i,\Gamma_j)$ reduces to the Coulomb constant times the product of the two scalar charges, after the velocity and angular-flux profiles defining Γ_i, Γ_j have been fixed. In a more general nonconfining gauge sector it is a matrix element, or sector label, of the asymptotic flux pairing; it is part of the representation-theoretic charged sector, not a parameter chosen after the scattering estimate is known.

This distinction is load-bearing. Replacing κ by $\kappa+\delta\kappa$ leaves an uncompensated $\delta\kappa/(|u_{ij}|t)$ term in the Cook derivative, and this term is not L^1. By contrast, a compact same-flux dressing change can only add an L^1 derivative to $K_{ij}^{\#\#}$, hence changes the comparison phase by a finite limit and does not change the logarithmic coefficient. Equal velocities are excluded from this pair estimate: when $u_{ij} = 0$, the pair must be treated as a charged cluster, threshold sector, or bound-state coordinate rather than as two separated Dollard legs.

The many-body comparison datum has the same pairwise form. For a velocity-separated list I, write v_i for a velocity in the support of h_i, $u_{ij} = v_i - v_j$, and let $\eta_i = +1$ for a charged creator and $\eta_i = -1$ for its adjoint. The sign convention records the fact that conjugating a dressed charged creator reverses its boundary charge and its asymptotic flux. Suppose that the finite-regulator charged dynamics, after all short-range terms have been separated, produces pair terms of the form

$$V_{ij}(t) = \eta_i \eta_j \frac{\kappa_{ij}}{\sqrt{a_{ij}^2 + |b_{ij} + u_{ij} t|^2}} + r_{ij}(t), \qquad r_{ij} \in L^1([T_0, \infty)). \tag{22.29}$$

Here $a_{ij} > 0$ is a regulator or transverse smearing scale, b_{ij} is the impact-parameter coordinate in the finite comparison model, and κ_{ij} is the flux-pairing coefficient that the actual QFT estimate must derive from the Wilson-line or Coulomb-tail data. The corresponding comparison phase must satisfy

$$\dot{\Theta}_I(t) = \sum_{i<j} \eta_i \eta_j \frac{\kappa_{ij}}{\sqrt{a_{ij}^2 + |b_{ij} + u_{ij} t|^2}} + \dot{\Theta}_I^{\mathrm{fin}}(t), \qquad \dot{\Theta}_I^{\mathrm{fin}} \in L^1([T_0, \infty)), \tag{22.30}$$

or, equivalently at the logarithmic level,

$$\Theta_I(T) = \sum_{i<j} \eta_i \eta_j \frac{\kappa_{ij}}{|u_{ij}|} \log T + O(1) \qquad (T \to +\infty). \tag{22.31}$$

The velocity-separation hypothesis is part of the datum: if $u_{ij} = 0$ the logarithmic coefficient is not defined, and the pair must be treated as a single charged cluster or as a separate infraparticle/bound-state sector. Equations (22.29)–(22.31) are not an independent scattering construction. They are the finite Dollard bookkeeping that the nonperturbative estimate must reproduce: all t^{-1} tails must be exhausted by oriented pair fluxes, and only the residual derivative is allowed to enter the Cook L^1 remainder.

Scalar-product Cauchy criterion. The comparison phase is useful only after it produces limits of scalar products in the charged asymptotic representation. Suppose that two velocity-separated lists I, J have modified comparison vectors $\mathcal{C}_I(t), \mathcal{C}_J(t)$ on the charged scattering domain and that, for $t \geq T_0$,

$$\|\mathcal{C}_I(t)\| \leq M_I, \qquad \|\mathcal{C}_J(t)\| \leq M_J, \qquad \left\| \frac{\mathrm{d}}{\mathrm{d}t} \mathcal{C}_I(t) \right\| \leq R_I(t), \qquad \left\| \frac{\mathrm{d}}{\mathrm{d}t} \mathcal{C}_J(t) \right\| \leq R_J(t),$$

with $R_I, R_J \in L^1([T_0, \infty))$. Then for $T > S \geq T_0$,

$$|\langle \mathcal{C}_I(T), \mathcal{C}_J(T) \rangle - \langle \mathcal{C}_I(S), \mathcal{C}_J(S) \rangle| \leq M_J \int_S^T R_I(t)\, \mathrm{d}t + M_I \int_S^T R_J(t)\, \mathrm{d}t. \tag{22.32}$$

Hence the scalar product has a limit once the modified Cook estimates are proved on a common domain and the comparison vectors are uniformly bounded. If the logarithmic coefficient in Θ_I is changed by $\delta \neq 0$, the model scalar product acquires the factor $\exp(\mathrm{i}\delta \log t)$. Along dyadic times this changes by $\exp(\mathrm{i}\delta \log 2)$, and the function $t \mapsto \exp(\mathrm{i}\delta \log t)$ has no large-time limit. Thus the scalar-product limit is another place where the flux-pairing coefficient is not a harmless convention: the same L^1 residual that makes Cook's estimate finite is also what makes the asymptotic inner product well defined.

Hypothesis 22.11 (Charged Dollard–Cook estimate package)**.** Fix a nonconfining charged sector and a dense set $\mathfrak{D}_{\mathrm{ch}}$ of charged packet data (Γ, h), where $\Gamma = (q, \gamma, \mathcal{E}_\infty, \mathfrak{s})$ records boundary charge, dressing geometry, limiting flux, and spin/internal labels, and where h has compact velocity support. For every finite velocity-separated ordered list

$$I = ((\Gamma_1, h_1), \ldots, (\Gamma_n, h_n))$$

and for each time direction $\sigma \in \{+, -\}$, assume the following data and estimates.

1. There are dressed approximants $\Psi^\sigma_{\Gamma_j,t}(h_j)$ acting on a common finite-energy domain containing Ω, and the product vector is defined there for all sufficiently large $\sigma t > 0$. These approximants are limits, in the truncation topology described above, of finite-length and ultraviolet regularized dressings; the estimates below are required to be stable under admissible same-flux truncation schedules.

2. There is a real locally absolutely continuous comparison phase $\Theta^\sigma_I(t)$, unique up to a finite large-time limit, whose nonintegrable part is the oriented pairwise Dollard logarithm (22.31) whenever the long-range tail is unscreened.

3. The modified vector

$$\mathcal{C}^\sigma_I(t) = \exp[-\mathrm{i}\Theta^\sigma_I(t)]\Psi^\sigma_{\Gamma_1,t}(h_1)\cdots\Psi^\sigma_{\Gamma_n,t}(h_n)\Omega$$

   is locally absolutely continuous in Hilbert norm and satisfies an integrable Cook bound

$$\left\| \frac{\mathrm{d}}{\mathrm{d}t}\mathcal{C}^\sigma_I(t) \right\| \le R^\sigma_I(t), \qquad R^\sigma_I \in L^1(\{t : \sigma t \ge T_0\}). \tag{22.33}$$

4. For every pair of velocity-separated lists I, J, the scalar products have limits

$$\langle J, I\rangle^\sigma_{\mathrm{as}} = \lim_{\sigma t\to+\infty} \langle \mathcal{C}^\sigma_J(t), \mathcal{C}^\sigma_I(t)\rangle, \tag{22.34}$$

   and these limits define a positive semidefinite sesquilinear form on the algebraic span of charged asymptotic symbols. The form is compatible with finite refinements of velocity partitions and with finite same-flux dressing coordinate changes.

5. If spacetime covariance is to be asserted, the approximants and phases obey the corresponding covariance law modulo vectors whose norms tend to zero in the same large-time limit.

Construction 22.12 (Charged wave maps from a Dollard–Cook package)**.** Assume Hypothesis 22.11. Let $\mathcal{H}^\sigma_{\mathrm{as},0}$ be the algebraic vector space generated by velocity-separated charged asymptotic symbols e^σ_I, modulo the finite linear relations imposed by packet refinement and same-flux coordinate changes. Equip it with the positive semidefinite form (22.34), quotient by its null space, and complete. The resulting Hilbert space is denoted $\mathcal{H}^{\sigma,\mathrm{ch}}_{\mathrm{as}}$.

For a generator e^σ_I, define

$$\Omega^{\mathrm{ch}}_\sigma e^\sigma_I = \lim_{\sigma t\to+\infty} \mathcal{C}^\sigma_I(t). \tag{22.35}$$

The limit exists because, for $\sigma t' > \sigma t \geq T_0$,

$$\|\mathcal{C}_I^\sigma(t') - \mathcal{C}_I^\sigma(t)\| \leq \int_{\sigma t}^{\sigma t'} R_I^\sigma(\sigma s)\,\mathrm{d}s$$

with the integral taken along the chosen time ray. The L^1 tail in (22.33) tends to zero, so $\mathcal{C}_I^\sigma(t)$ is Cauchy in $\mathcal{H}$.

The definition is independent of null asymptotic symbols. If $\xi = \sum_\alpha c_\alpha e_{I_\alpha}^\sigma$, then the corresponding physical approximant is

$$\mathcal{C}_\xi^\sigma(t) = \sum_\alpha c_\alpha \mathcal{C}_{I_\alpha}^\sigma(t),$$

and Hypothesis 22.11 gives

$$\lim_{\sigma t \to +\infty} \|\mathcal{C}_\xi^\sigma(t)\|^2 = \langle \xi, \xi \rangle_{\mathrm{as}}^\sigma. \tag{22.36}$$

Thus a null asymptotic vector has zero physical limit. For two algebraic vectors ξ, η, the same scalar-product limit gives

$$\langle \Omega_\sigma^{\mathrm{ch}} \eta, \Omega_\sigma^{\mathrm{ch}} \xi \rangle_{\mathcal{H}} = \langle \eta, \xi \rangle_{\mathrm{as}}^\sigma.$$

Therefore $\Omega_\sigma^{\mathrm{ch}}$ descends to an isometry from $\mathcal{H}_{\mathrm{as}}^{\sigma,\mathrm{ch}}$ into the physical Hilbert space. If the covariance clause in the hypothesis is included, the usual intertwining relation follows by applying the same norm-limit argument to the covariance defect.

Construction 22.12 is deliberately abstract. It proves that no additional Hilbert-space miracle is needed after the charged estimates have been established, but it does not establish those estimates. The remaining QFT problem is to derive (22.22) and (22.33), together with the scalar-product limit (22.34), from a nonperturbative construction of Wilson-line or Coulomb-dressed charged creators. If the gauge field is screened or massive, the long-range phase may be absent and ordinary massive scattering estimates can be recovered for gauge-invariant composite charged operators. For an unscreened Gauss-law charge, the flux tail is part of the asymptotic datum, so any theorem must include it from the start.

Finite null-quotient ledger. The quotient in Construction 22.12 is not a cosmetic step. It is the finite-dimensional algebra which lets packet refinements and same-flux coordinate redundancies coexist with a genuine asymptotic Hilbert space. Suppose three asymptotic symbols e_1, e_2, e_3 have physical large-time limits

$$\xi_1 = (1, 0), \qquad \xi_2 = (0, 1), \qquad \xi_3 = (1, 1)$$

in a two-dimensional Hilbert space. Their asymptotic scalar-product matrix is

$$G_{ab} = \langle \xi_a, \xi_b \rangle = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 2 \end{pmatrix}. \tag{22.37}$$

The matrix is positive semidefinite, not positive definite. Its null vector is

$$n = e_1 + e_2 - e_3, \qquad Gn = 0. \tag{22.38}$$

Thus e_3 is the same asymptotic vector as the refinement $e_1 + e_2$. For any coefficient vector $c = (c_1, c_2, c_3)$,

$$c^* G c = |c_1 + c_3|^2 + |c_2 + c_3|^2 = \|c_1\xi_1 + c_2\xi_2 + c_3\xi_3\|^2 .$$

Quotienting by the null relation is therefore exactly what makes the wave-map assignment $e_a \mapsto \xi_a$ well defined and isometric. If (c_1, c_2, c_3) is replaced by $(c_1 + c_3, c_2 + c_3, 0)$, the two coefficient vectors differ by a multiple of n and define the same asymptotic state. In the charged theorem this finite cell is replaced by the directed family of packet refinements and same-flux coordinate relations. The nontrivial analytic work is still the existence of the limits G_{ab} from Wilson-line or Coulomb-dressed creators; once those limits are supplied, the null quotient is ordinary Hilbert-space bookkeeping.

Proposition 22.13 (Same-flux schedule invariance of charged wave maps)**.** *Assume Hypothesis 22.11. Let $\mathcal{S}$ and $\mathcal{S}'$ be two admissible truncation schedules for the same charged packet data, with the same boundary charges and the same limiting angular fluxes. Write $\mathcal{C}^{\sigma}_{I,\mathcal{S}}(t)$ and $\mathcal{C}^{\sigma}_{I,\mathcal{S}'}(t)$ for the corresponding modified comparison vectors. Suppose that, for every generator e^{σ}_I, there is a real locally absolutely continuous function $\alpha^{\sigma}_I(t)$ with a finite limit $\alpha^{\sigma}_I(\infty)$ and*

$$d^{\sigma}_I(T) := \sup_{\sigma t \geq T} \left\| \mathcal{C}^{\sigma}_{I,\mathcal{S}}(t) - \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(t)} \mathcal{C}^{\sigma}_{I,\mathcal{S}'}(t) \right\| \longrightarrow 0 \qquad (T \to \infty). \tag{22.39}$$

Then the two schedules define the same physical charged wave map after the finite phase coordinate identification $e^{\sigma}_{I,\mathcal{S}} \sim \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(\infty)} e^{\sigma}_{I,\mathcal{S}'}$:

$$\Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}} e^{\sigma}_I = \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(\infty)} \Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}'} e^{\sigma}_I . \tag{22.40}$$

For two generators $e^{\sigma}_I, e^{\sigma}_J$, the asymptotic Gram forms obey

$$\langle J, I \rangle^{\sigma}_{\mathrm{as},\mathcal{S}} = \mathrm{e}^{\mathrm{i}\alpha^{\sigma}_J(\infty)} \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(\infty)} \langle J, I \rangle^{\sigma}_{\mathrm{as},\mathcal{S}'} . \tag{22.41}$$

Consequently same-flux schedule changes are quotient data, not new charged asymptotic sectors.

If the dressed-correlator interface of Hypothesis 22.14 is also available for the two schedules, and the external overlap maps on each finite coordinate frame are related by

$$z_{\ell,\mathcal{S}'}(p; t) = M_\ell(t) z_{\ell,\mathcal{S}}(p; t) + o(1), \qquad M_\ell(t) \longrightarrow M_\ell$$

with $M_\ell(t)$ invertible for all sufficiently large t and M_ℓ invertible on the chosen same-flux coordinate frame, then the left-inverse residue extraction gives the same coefficient $\mathcal{A}_{\boldsymbol{\lambda}}$ in the simultaneous external-shell limit.

Proof. The Cook bounds in (22.33) give Hilbert limits for both schedules and uniform large-time bounds for the comparison vectors. For σt large,

$$\begin{aligned} &\left\| \Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}} e^{\sigma}_I - \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(\infty)} \Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}'} e^{\sigma}_I \right\| \\ &\quad \leq \left\| \Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}} e^{\sigma}_I - \mathcal{C}^{\sigma}_{I,\mathcal{S}}(t) \right\| + d^{\sigma}_I(\sigma t) + \left| \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(t)} - \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_I(\infty)} \right| \left\| \mathcal{C}^{\sigma}_{I,\mathcal{S}'}(t) \right\| \\ &\qquad + \left\| \mathcal{C}^{\sigma}_{I,\mathcal{S}'}(t) - \Omega^{\mathrm{ch}}_{\sigma,\mathcal{S}'} e^{\sigma}_I \right\| . \end{aligned}$$

Every term on the right tends to zero. This proves (22.40).

The Gram statement is the same estimate before the last limit is taken. Put

$$\widetilde{\mathcal{C}}^{\sigma}_{I,\mathcal{S}'}(t) = \mathrm{e}^{-\mathrm{i}\alpha^{\sigma}_{I}(t)}\mathcal{C}^{\sigma}_{I,\mathcal{S}'}(t).$$

If M_I, M_J are large-time norm bounds for the corresponding comparison vectors, then

$$\begin{aligned}\Big|\langle \mathcal{C}^{\sigma}_{J,\mathcal{S}}(t), \mathcal{C}^{\sigma}_{I,\mathcal{S}}(t)\rangle - \langle \widetilde{\mathcal{C}}^{\sigma}_{J,\mathcal{S}'}(t), \widetilde{\mathcal{C}}^{\sigma}_{I,\mathcal{S}'}(t)\rangle\Big|& \\ \le M_I d^{\sigma}_{J}(\sigma t) + M_J d^{\sigma}_{I}(\sigma t).&\end{aligned}$$

Taking the large-time limit and then replacing $\alpha^{\sigma}_{I}(t), \alpha^{\sigma}_{J}(t)$ by their finite limits gives (22.41). The null quotient therefore identifies the two schedules by a finite coordinate phase.

For the residue statement, at finite regulator the singular tensor in (22.42) transforms on the ℓ-th external coordinate by $M_\ell(t)$, while the left inverse transforms by $L_{\ell,\mathcal{S}}(p;t)M_\ell(t)^{-1}$, for all sufficiently large t. Contracting the external coordinates gives

$$\bigotimes_{\ell}\big(L_{\ell,\mathcal{S}}M_\ell(t)^{-1}\big)\ \bigotimes_{\ell} M_\ell(t) = \bigotimes_{\ell} L_{\ell,\mathcal{S}}.$$

The $o(1)$ schedule errors are less singular in the declared shell topology and are killed by the same left-inverse contraction in the simultaneous external-shell limit. Hence the extracted coefficient is unchanged. □

22.5.5 Dressed Correlators and Wave-Map Matrix Elements

The wave-map construction above is formulated in Hilbert space. A Wilson-line LSZ theorem must also explain how it is read from time-ordered dressed correlators. This is a separate input: a pole in a formal gauge-fixed charged-field propagator is not a gauge-invariant observable, and a Wilson-line correlator is not automatically controlled by the ordinary local-field integration-by-parts proof. The object to be proved is the following interface between dressed correlators and the charged wave maps.

Hypothesis 22.14 (Dressed-correlator reduction interface)**.** Fix a nonconfining charged sector and assume the charged Dollard–Cook package of Hypothesis 22.11 for the packet data under consideration. For each external charged leg ℓ, choose a finite family of renormalized finite-truncation dressed coordinates

$$\Psi^{(\ell)}_{a_\ell;L_\ell,\varepsilon_\ell}(x), \qquad a_\ell = 1,\dots,r_\ell,$$

converging in the truncation topology described above to a noncompact dressing with fixed charge, asymptotic flux, and velocity support. In an infrared-regulated or screened setting with an isolated charged shell, let $E_\ell(p_\ell)$ be the corresponding one-particle multiplicity space, let

$$z_\ell(p_\ell) : E_\ell(p_\ell) \longrightarrow \mathbb{C}^{r_\ell}$$

be the dressed one-particle overlap map, and choose a left inverse $L_\ell(p_\ell)z_\ell(p_\ell) = \mathbf{1}_{E_\ell(p_\ell)}$. The dressed-correlator reduction interface consists of the following assertions, with estimates uniform over admissible same-flux truncation schedules.

1. The renormalized time-ordered correlators of the finite-truncation dressed coordinates have boundary values as tempered distributions in the external momenta after wave-packet smearing and after the declared endpoint, line, cusp, and local charged-field counterterms have been included.

2. Near the product of the isolated charged mass shells, their simultaneous external singular part has finite rank in the dressed coordinates:

$$\widehat{G}_{\mathbf{a}}(\mathbf{p};\Xi) = \frac{\mathrm{i}^N \sum_{\boldsymbol{\lambda}} \prod_{\ell=1}^N z_{\ell,a_\ell}{}^{\lambda_\ell}(p_\ell)\, \mathcal{A}_{\boldsymbol{\lambda}}(\mathbf{p};\Xi)}{\prod_{\ell=1}^N (p_\ell^2 + m_\ell^2 - \mathrm{i}0)} + \widehat{G}_{\mathbf{a}}^{\mathrm{less}}(\mathbf{p};\Xi). \tag{22.42}$$

   Here Ξ denotes compact gauge-invariant insertions or the remaining external variables, and "less" means that after multiplying by $\prod_\ell (p_\ell^2 + m_\ell^2 - \mathrm{i}0)$ and applying the left inverses, the term has zero simultaneous shell limit in the wave-packet topology being used. Partial shell singularities are assigned to the corresponding lower-particle disconnected or lower-channel matrix elements before the connected amplitude is read off.

3. The coefficient $\mathcal{A}_{\boldsymbol{\lambda}}$ obtained from (22.42) is the charged wave-map matrix element:

$$\mathcal{A}_{\boldsymbol{\lambda}}(\mathbf{p};\Xi) = \left\langle \Omega_+^{\mathrm{ch}} e_{\mathrm{out},\boldsymbol{\lambda}}, \mathcal{O}_\Xi\, \Omega_-^{\mathrm{ch}} e_{\mathrm{in},\boldsymbol{\lambda}} \right\rangle_{\mathrm{conn}}, \tag{22.43}$$

   with the total momentum delta distribution and the standard disconnected vacuum factors removed. The Dollard phases appearing in Hypothesis 22.11 are part of the definition of the asymptotic symbols $e_{\mathrm{in/out},\boldsymbol{\lambda}}$; without them a long-range charged correlator need not have a simple isolated-pole LSZ limit.

4. Endpoint and collision contact terms created by differentiating time-ordered Wilson-line insertions are either absorbed into the declared renormalized dressed coordinates, assigned to lower-channel contact coordinates, or shown to be less singular in the simultaneous external-shell sense above. They are not allowed to contribute an additional independent charged one-particle residue.

5. The extraction is covariant under finite same-flux coordinate changes: if z_ℓ is replaced by $M_\ell z_\ell$, with M_ℓ invertible on the chosen coordinate frame, then L_ℓ is replaced by $L_\ell M_\ell^{-1}$, the residue tensor is multiplied by M_ℓ on that external coordinate, and the coefficient $\mathcal{A}_{\boldsymbol{\lambda}}$ is unchanged.

This hypothesis is not a theorem about gauge theory. It names the analytic work that a Wilson-line LSZ theorem must do. One must construct the boundary-value distributions for the noncompact dressed insertions, prove uniformity in the truncation schedules $L_\ell(t)$ and $\varepsilon_\ell(t)$, identify the finite-rank external singular part, control contact terms from the endpoints and cusps of the lines, and match the resulting coefficient to the Dollard–Cook wave maps. In massless QED the isolated pole in (22.42) is expected to be replaced by a threshold coefficient in a velocity/flux representation; the same interface then has to be rewritten with the threshold functional in place of the mass-shell residue.

22.5.6 Finite-Regulator Dressed LSZ

There is nevertheless a precise finite-regulator statement. It is not the full massless charged scattering theorem; it is the part of the desired theory that follows from the usual LSZ argument once a dressed charged creator and an isolated charged shell have been supplied. Equivalently, it is the isolated-shell realization of Hypothesis 22.14 under the stronger regularity assumptions listed below.

Theorem 22.15 (Finite-regulator dressed LSZ)**.** *Fix a gauge theory with a regulator or screening deformation for which:*

1. *the physical Hilbert space contains an isolated massive charged one-particle shell Σ_m^+ in a charged sector;*
2. *for each external charged sector and mass there is a finite family of translation-covariant gauge-invariant dressed operators $\Psi_a(x)$ of the form (22.8), or Coulombic variants, whose smearings are defined on a common dense domain and whose one-particle overlap map has full rank on the chosen charged one-particle multiplicity space;*
3. *the dressed two-point distribution has, in a neighborhood of Σ_m^+, the pole decomposition*
$$\widehat{G}_{ab}(p) = \int \mathrm{d}^D x\, \mathrm{e}^{\mathrm{i}p\cdot x} \langle \Omega | T\{\Psi_a(x)\Psi_b^\dagger(0)\}|\Omega\rangle = \frac{\mathrm{i}Z_{ab}}{p^2+m^2-\mathrm{i}0} + \widehat{G}^{\mathrm{reg}}_{ab}(p), \tag{22.44}$$
where $Z = (Z_{ab})$ is the positive Gram matrix of those one-particle overlaps and $\widehat{G}^{\mathrm{reg}}$ is less singular at the shell;
4. *the large-time wave operators built from these dressed creators exist, and time-ordered dressed correlators have the usual boundary-value and wave-packet regularity needed for the LSZ integration by parts.*

For the displayed square-root formula choose, for each external charged one-particle multiplicity space, a square subfamily of dressed coordinates whose overlap matrix is invertible; equivalently restrict Z to the range spanned by that frame and regard it as a positive definite matrix there. If one keeps a rectangular overcomplete family, replace every $Z^{-1/2}$ below by a chosen left inverse of the overlap map as in (22.14). With the square-frame convention, let $Z^{-1/2}$ be the positive inverse square root of this positive definite Gram matrix. Then the simultaneous external residue of the dressed time-ordered $(m+n)$-point function equals the matrix element of the scattering operator between the dressed asymptotic charged states:

$$\begin{aligned}&\prod_{r=1}^{m}\big[(Z^{-1/2})_{a'_r b'_r}({p'_r}^2+m_r^2)\big]\prod_{s=1}^{n}\big[(p_s^2+m_s^2)(Z^{-1/2})_{b_s a_s}\big]\,\widehat{G}^{\,b'_1\cdots b'_m}{}_{b_1\cdots b_n}(p'_1,\ldots;p_1,\ldots)\\ &\qquad\longrightarrow \langle p'_1,a'_1;\ldots;p'_m,a'_m,\mathrm{out}|S|p_1,a_1;\ldots;p_n,a_n,\mathrm{in}\rangle_{\mathrm{conn}},\end{aligned} \tag{22.45}$$

after wave-packet smearing and removal of the total momentum-conservation delta distribution, with the same connected/disconnected convention as in the ordinary LSZ chapter.

Proof. The hypotheses put the dressed fields in exactly the analytic position in which LSZ is a residue calculation on the one-particle spectral summand. We spell out the reduction because the fields Ψ_a are not assumed to be localized in bounded spacetime regions. Choose a positive-frequency Klein–Gordon wave packet f whose Fourier transform is supported in the isolating neighborhood of the shell $p^2+m^2=0$. The pole decomposition (22.44) says that the distribution $\langle\Omega|\Psi_b^\dagger(g)\Psi_a(f)|\Omega\rangle$ has one-particle part

$$\sum_{c,d}\langle g,c|f,d\rangle\, Z_{ad}\,\delta_{cb},$$

in the mass-shell representation, with the regular part contributing a smooth function of the external invariant. Equivalently,

$$P_1\Psi_a(f)\Omega = \sum_b (Z^{1/2})_a{}^b\,|f,b\rangle, \tag{22.46}$$

after choosing the positive square root on the finite multiplicity space.

For one incoming external leg, multiplication of the Fourier transform by (p^2+m^2) is the Fourier transform of $(-\Box+m^2)$ in the corresponding coordinate, in the present mostly-plus Lorentzian convention. Pair this differentiated coordinate with the wave packet f and integrate over the time slab $[-T,T]$. On every open time ordering chamber the differentiated time-ordered correlator is the Klein–Gordon operator applied to the corresponding distributional matrix element. The spectral regularity assumption implies that the part orthogonal to the isolated one-particle summand remains regular at the shell; after the external factor (p^2+m^2) is taken to the shell, that regular part gives zero. The integrations by parts therefore leave only the slab boundaries and the standard equal-time contact terms. The latter are local in the external time variable and are again regular functions of the external invariant after wave-packet smearing, so they disappear in the simultaneous mass-shell residue.

The boundary term at $t=-T$ is, by the assumed existence of the dressed Haag–Ruelle limit, the incoming wave operator applied to the one-particle vector (22.46); the boundary term at $t=+T$ gives the outgoing wave operator. Repeating the argument for all external legs, with the usual induction over time orderings and with disconnected vacuum components subtracted after the total momentum delta distribution is removed, gives the scattering matrix element written in the dressed one-particle coordinates. Multiplication by $Z^{-1/2}$ on every external multiplicity index converts those coordinates to the orthonormal mass-shell basis, and yields (22.45). No step requires Ψ_a to be a bounded-region local observable; the required substitute for locality is exactly the assumed existence and regularity of the dressed large-time limits. $\Box$

The theorem is useful because it isolates what is known from what remains open. At finite infrared regulator or in a screened phase, the formal dressed-correlator residue has a precise Hilbert-space meaning if the listed hypotheses hold. Removing the regulator in four-dimensional QED is a different operation: the pole in (22.44) is expected to be replaced by charged threshold behavior, and the asymptotic Hilbert space must remember the angular electric-flux sector.

22.5.7 Dressing Dependence as Coordinate Dependence

Path dependence has two different meanings. A deformation that changes the field at infinity changes the charged sector. A compact deformation, or a replacement of one short-distance dressing by another with the same asymptotic flux, changes the interpolating coordinate used to reach the same charged state.

Compact dressing changes as LSZ-coordinate changes. In the finite-regulator setting of Theorem 22.15, let Ψ_a and Ψ'_a be two families of dressed charged interpolating operators with the same charge, spin, mass, and asymptotic flux. Suppose their one-particle matrix elements are related by an invertible matrix M,

$$P_1\Psi'_a(f)\Omega = M_a{}^b\,P_1\Psi_b(f)\Omega + \text{terms orthogonal to } \mathcal{H}_1$$

for all wave packets f supported near the shell. Then the LSZ residues computed with Ψ' give the same scattering matrix after the external normalization matrix $Z'^{-1/2}$ is used. The singular part of the two-point function transforms as

$$Z' = MZM^{\dagger}.$$

The amputated external coordinates obtained from Ψ' are therefore related to those obtained from Ψ by the unitary polar part of $MZ^{1/2}$ acting inside the one-particle multiplicity space. LSZ computes matrix elements between orthonormal one-particle vectors, not between the raw operator labels. After multiplying by $Z'^{-1/2}$, this coordinate change is removed on every external leg. Contributions orthogonal to $\mathcal{H}_1$ are regular at the isolated shell and vanish in the external residue.

For abelian Wilson lines this statement has a concrete finite-regulator meaning. Let γ and γ' be two oriented paths beginning at x and sharing the same asymptotic ray. Truncate both paths at a large radius and use the same endpoint cap at the truncation surface. If the difference of the truncated paths is the boundary of an oriented compact surface $S_{\gamma',\gamma}$,

$$\partial S_{\gamma',\gamma} = \gamma'_R - \gamma_R,$$

then, for a smooth regulated connection A with curvature $F = \mathrm{d}A$, Stokes' identity gives

$$\int_{\gamma'_R} A - \int_{\gamma_R} A = \int_{S_{\gamma',\gamma}} F. \tag{22.47}$$

Hence

$$\Psi_{q,\gamma'}(x) = \Psi_{q,\gamma}(x)\, \exp\left\{ \mathrm{i}q \int_{S_{\gamma',\gamma}} F \right\}$$

in the abelian regulated theory, with the same short-distance prescription at the common starting point. The extra factor is gauge invariant, neutral, and localized in the compact region swept out by the deformation. It can change the overlap vector $P_1\Psi_{q,\gamma}(f)\Omega$ by a finite amount, but it does not change the Gauss-law boundary charge or the asymptotic flux label. This is the precise setting in which the preceding LSZ coordinate calculation applies.

For a nonabelian connection the corresponding infinitesimal statement is a curvature-insertion formula rather than an ordinary scalar Stokes identity. With $U_\gamma(s_2, s_1)$ defined by

$$\partial_{s_2} U_\gamma(s_2, s_1) = -\dot{\gamma}^\mu(s_2) A_\mu(\gamma(s_2)) U_\gamma(s_2, s_1), \qquad U_\gamma(s_1, s_1) = 1,$$

and with a compact path variation $\eta^\nu(s)$ that vanishes at the endpoint and on the asymptotic tail, one has

$$\delta U_\gamma(\infty, 0) = \int_0^\infty \mathrm{d}s\, U_\gamma(\infty, s)\, F_{\mu\nu}(\gamma(s)) \dot{\gamma}^\mu(s) \eta^\nu(s)\, U_\gamma(s, 0),$$

in the same sign convention as the preceding differential equation. Thus a compact nonabelian deformation inserts covariantly transported curvature along the finite strip between the two dressings; it is not a change of the endpoint representation at infinity. None of these identities proves independence under changes of the asymptotic ray, because such changes are not compact: they modify the electric flux at infinity. In massless QED the asymptotic ray or Coulomb profile is tied to the charged velocity, and changing it changes the infrared representation rather than merely the interpolating coordinate.

22.5.8 Asymptotic Wilson Lines, Flux, and Eikonal Data

The preceding definitions identify a charged dressing as part of the asymptotic datum. We now spell out the elementary calculation behind this statement. Work in four spacetime dimensions with an abelian gauge field, and let a massive charged particle have charge q, momentum p^μ, mass $m > 0$, and four-velocity

$$u^\mu = \frac{p^\mu}{m}, \qquad u_\mu u^\mu = -1, \qquad p^0 > 0.$$

The future-directed straight dressing from x is represented, before the infrared limit is taken, by the regulated current

$$J^\mu_{q,u,\epsilon}(y;x) = q\int_0^\infty \mathrm{d}\tau\, \mathrm{e}^{-\epsilon\tau} u^\mu \delta^{(4)}(y - x - u\tau), \qquad \epsilon > 0. \tag{22.48}$$

The corresponding Wilson factor is the exponential of $\mathrm{i}\int A_\mu J^\mu$. The factor ϵ is not a physical photon mass; it is an adiabatic endpoint regulator used to define the half-line Fourier transform. The endpoint at $\tau = 0$ is the charged field insertion, and the endpoint at $\tau = \infty$ is the boundary charge recorded by (22.15).

Worldline dressing and the soft eikonal denominator. With the Fourier convention

$$\widehat{J}^\mu(k) = \int \mathrm{d}^4 y\, \mathrm{e}^{\mathrm{i}k\cdot y} J^\mu(y),$$

the regulated current (22.48) has

$$\widehat{J}^\mu_{q,u,\epsilon}(k;x) = q\, u^\mu\, \mathrm{e}^{\mathrm{i}k\cdot x} \frac{1}{\epsilon - \mathrm{i}k\cdot u}. \tag{22.49}$$

For an on-shell soft photon of momentum k and physical polarization $e_h(k)$, the homogeneous soft factor carried by the dressing is therefore

$$f^h_{p,\epsilon}(k) = q\, \frac{p\cdot e^*_h(k)}{\epsilon m - \mathrm{i}p\cdot k}\, \mathrm{e}^{\mathrm{i}k\cdot x}. \tag{22.50}$$

After the endpoint prescription is fixed, this is the same eikonal denominator that appears in the leading Faddeev–Kulish soft cloud and in the leading soft-photon theorem. Substituting (22.48) gives

$$\begin{aligned}\widehat{J}^\mu_{q,u,\epsilon}(k;x) &= qu^\mu \int_0^\infty \mathrm{d}\tau\, \mathrm{e}^{-\epsilon\tau} \mathrm{e}^{\mathrm{i}k\cdot(x+u\tau)} \\ &= qu^\mu \mathrm{e}^{\mathrm{i}k\cdot x} \int_0^\infty \mathrm{d}\tau\, \mathrm{e}^{-(\epsilon - \mathrm{i}k\cdot u)\tau} = qu^\mu \mathrm{e}^{\mathrm{i}k\cdot x} \frac{1}{\epsilon - \mathrm{i}k\cdot u}.\end{aligned}$$

Since $p^\mu = mu^\mu$, contraction with $e^*_h(k)$ gives (22.50). The sign of the infinitesimal imaginary part depends on whether the half-line is future or past directed and on the incoming/outgoing convention. The load-bearing structure is the homogeneous denominator $p\cdot k$, not the regulator sign.

The same charged sector can be described at spacelike infinity by its electric flux. If $\mathbf{v} = \mathbf{p}/p^0$ and $\mathbf{n} \in S^2$, the boosted Coulomb radial flux density is

$$\mathcal{E}_{q,\mathbf{v}}(\mathbf{n}) = \frac{q}{4\pi} \frac{1 - |\mathbf{v}|^2}{(1 - \mathbf{v}\cdot\mathbf{n})^2}. \tag{22.51}$$

It defines the value of the limiting flux functional

$$\Phi_\infty(f) = \int_{S^2} \mathrm{d}\Omega(\mathbf{n})\, f(\mathbf{n})\mathcal{E}_{q,\mathbf{v}}(\mathbf{n})$$

on a one-particle charged asymptotic datum with velocity $\mathbf{v}$.

Velocity-labelled flux sectors. For $|\mathbf{v}| < 1$,

$$\int_{S^2} \mathrm{d}\Omega(\mathbf{n})\, \mathcal{E}_{q,\mathbf{v}}(\mathbf{n}) = q. \tag{22.52}$$

If $q \neq 0$, the function $\mathcal{E}_{q,\mathbf{v}}(\mathbf{n})$ determines $\mathbf{v}$. Thus different charged velocities carry different sharp angular flux data. Rotate coordinates so that $\mathbf{v} = \beta \mathbf{e}_3$. Then

$$\begin{aligned}\int_{S^2} \mathrm{d}\Omega\, \frac{1-\beta^2}{(1-\beta\cos\theta)^2} &= 2\pi(1-\beta^2)\int_{-1}^{1} \frac{\mathrm{d}z}{(1-\beta z)^2} \\ &= 2\pi(1-\beta^2)\left[\frac{1}{\beta(1-\beta z)}\right]_{z=-1}^{z=1} = 4\pi,\end{aligned}$$

which proves (22.52). For $q \neq 0$, the maximum of $\mathcal{E}_{q,\mathbf{v}}$ occurs in the direction of $\mathbf{v}$ when $\mathbf{v} \neq 0$, while the ratio of the maximum to the minimum is

$$\left(\frac{1+|\mathbf{v}|}{1-|\mathbf{v}|}\right)^2.$$

This ratio determines $|\mathbf{v}|$, and the direction of the maximum determines the direction of $\mathbf{v}$. The case $\mathbf{v} = 0$ is the unique rotationally invariant density.

Neutral boundary charge versus angular flux sector. The boundary-charge condition (22.16) is the zero-mode of a sharper asymptotic datum. For an oriented list of charged asymptotic coordinates

$$I = ((\epsilon_1, q_1, \mathbf{v}_1), \ldots, (\epsilon_N, q_N, \mathbf{v}_N)), \qquad \epsilon_a = \pm 1,$$

define the signed angular flux profile

$$\mathcal{E}_I(\mathbf{n}) = \sum_{a=1}^{N} \epsilon_a\, \mathcal{E}_{q_a,\mathbf{v}_a}(\mathbf{n}). \tag{22.53}$$

By (22.52),

$$\int_{S^2} \mathrm{d}\Omega(\mathbf{n})\, \mathcal{E}_I(\mathbf{n}) = \sum_{a=1}^{N} \epsilon_a q_a.$$

Thus a vacuum dressed correlator can obey the ordinary boundary-charge Ward identity while still having nonzero angle-dependent flux data. For instance, two opposite charges with the same velocity have $\mathcal{E}_I(\mathbf{n}) = 0$ pointwise. Two opposite charges with distinct velocities have zero total boundary charge but, unless the velocity labels coincide, the profile $\mathcal{E}_I$ is not the zero function. The charged LSZ datum therefore contains more information than the integer or real total charge: it contains the limiting angular Gauss-law profile, or an equivalent large-gauge-charge functional. A same-flux dressing change is a finite coordinate change of the type described above; a change of $\mathcal{E}_I$ changes the asymptotic charged sector and belongs to the open Haag–Ruelle problem, not to a harmless path-independence argument.

22.5.9 Soft Coherent Norm and Velocity Superselection

The preceding flux density is visible already in the finite-cutoff soft photon Fock calculation. The calculation is not a construction of massless QED scattering; it is a precise diagnostic of why a single ordinary photon Fock representation cannot contain sharp charged particles of all velocities as normal vectors after the infrared cutoff is removed.

Fix $0 < \lambda < \Lambda < \infty$. The finite soft-photon one-particle space is

$$\mathfrak{h}_{\lambda,\Lambda} = L^2\left([\lambda,\Lambda] \times S^2, \frac{r\,\mathrm{d}r\,\mathrm{d}\Omega(\mathbf{n})}{2(2\pi)^3}; \mathbb{C}^2\right),$$

where $k = (r, r\mathbf{n})$ is null and the two complex components label a measurable orthonormal transverse polarization frame $\epsilon_h(\mathbf{n})$, $h = 1, 2$, satisfying $\mathbf{n} \cdot \epsilon_h(\mathbf{n}) = 0$. The polarization frame is a coordinate choice; the sum over h below is the transverse projector

$$P_{\mathbf{n}}^{ij} = \delta^{ij} - n^i n^j.$$

For a massive charge q with velocity $\mathbf{v}$, $|\mathbf{v}| < 1$, the homogeneous soft part of the worldline dressing (22.50) is represented by

$$F^h_{q,\mathbf{v},\lambda,\Lambda}(r,\mathbf{n}) = -q\,\frac{\mathbf{v} \cdot \epsilon_h(\mathbf{n})}{r(1 - \mathbf{v} \cdot \mathbf{n})}\mathbf{1}_{\lambda<r<\Lambda}. \tag{22.54}$$

The mass and Lorentz factor cancel because

$$\frac{p \cdot e_h(k)}{p \cdot k} = -\frac{\mathbf{v} \cdot \epsilon_h(\mathbf{n})}{r(1 - \mathbf{v} \cdot \mathbf{n})}$$

for $e^0_h = 0$, $p^\mu = m\gamma(1, \mathbf{v})$, and the mostly-plus Minkowski product.

Proposition 22.16 (Velocity separation in the soft coherent norm)**.** *For two velocities $\mathbf{v}, \mathbf{w} \in B_1(0) \subset \mathbb{R}^3$ and the same nonzero charge q,*

$$\|F_{q,\mathbf{v},\lambda,\Lambda} - F_{q,\mathbf{w},\lambda,\Lambda}\|^2_{\mathfrak{h}_{\lambda,\Lambda}} = \frac{q^2}{2(2\pi)^3}\log\frac{\Lambda}{\lambda}\,\mathcal{A}(\mathbf{v},\mathbf{w}), \tag{22.55}$$

where

$$\mathcal{A}(\mathbf{v},\mathbf{w}) = \int_{S^2} \mathrm{d}\Omega(\mathbf{n}) \left| P_{\mathbf{n}}\left(\frac{\mathbf{v}}{1 - \mathbf{v} \cdot \mathbf{n}} - \frac{\mathbf{w}}{1 - \mathbf{w} \cdot \mathbf{n}}\right)\right|^2. \tag{22.56}$$

The coefficient obeys $\mathcal{A}(\mathbf{v},\mathbf{w}) \geq 0$, and $\mathcal{A}(\mathbf{v},\mathbf{w}) = 0$ if and only if $\mathbf{v} = \mathbf{w}$.

Proof. The radial dependence of (22.54) is r^{-1}. Therefore the measure $r\,\mathrm{d}r\,\mathrm{d}\Omega/(2(2\pi)^3)$ gives the logarithm

$$\int_\lambda^\Lambda \frac{\mathrm{d}r}{r} = \log\frac{\Lambda}{\lambda}.$$

After summing over the two physical polarizations,

$$\sum_{h=1}^{2}\left|\left(\frac{\mathbf{v}}{1 - \mathbf{v} \cdot \mathbf{n}} - \frac{\mathbf{w}}{1 - \mathbf{w} \cdot \mathbf{n}}\right) \cdot \epsilon_h(\mathbf{n})\right|^2 = \left|P_{\mathbf{n}}\left(\frac{\mathbf{v}}{1 - \mathbf{v} \cdot \mathbf{n}} - \frac{\mathbf{w}}{1 - \mathbf{w} \cdot \mathbf{n}}\right)\right|^2,$$

which proves (22.55). The integrand in $\mathcal{A}(\mathbf{v},\mathbf{w})$ is the squared norm of a transverse vector for each $\mathbf{n}$, and the sphere measure is positive, so $\mathcal{A}(\mathbf{v},\mathbf{w}) \geq 0$.

It remains to characterize the zero set. If $\mathcal{A}(\mathbf{v},\mathbf{w}) = 0$, continuity implies that the displayed transverse projection vanishes for every $\mathbf{n}$. Suppose first that $\mathbf{v} \neq 0$. Put $\mathbf{n} = \mathbf{v}/|\mathbf{v}|$. The projection of $\mathbf{v}$ onto the plane orthogonal to $\mathbf{n}$ is zero, hence the projection of $\mathbf{w}$ onto that plane must also vanish; $\mathbf{w}$ is parallel to $\mathbf{v}$. Writing $\mathbf{v} = \beta\mathbf{e}_3$ and $\mathbf{w} = \alpha\mathbf{e}_3$, and choosing any $\mathbf{n}$ not parallel to $\mathbf{e}_3$, the vanishing condition becomes

$$\frac{\beta}{1-\beta n_3} = \frac{\alpha}{1-\alpha n_3}.$$

Thus $\beta = \alpha$. If $\mathbf{v} = 0$, the same condition says that the transverse projection of $\mathbf{w}$ vanishes for every $\mathbf{n}$; this forces $\mathbf{w} = 0$. Hence the coefficient vanishes exactly on the diagonal $\mathbf{v} = \mathbf{w}$. □

Let $\mathcal{E}(F)$ denote the normalized bosonic coherent vector in the finite-cutoff photon Fock space,

$$\mathcal{E}(F) = \mathrm{e}^{-\|F\|^2/2} \bigoplus_{n\geq 0} \frac{F^{\otimes_s n}}{\sqrt{n!}}.$$

Summing the Fock inner products gives

$$|\langle \mathcal{E}(F), \mathcal{E}(G)\rangle| = \exp\left\{-\frac{1}{2}\|F-G\|^2\right\}.$$

Therefore Proposition 22.16 implies that, for $\mathbf{v} \neq \mathbf{w}$,

$$|\langle \mathcal{E}(F_{q,\mathbf{v},\lambda,\Lambda}), \mathcal{E}(F_{q,\mathbf{w},\lambda,\Lambda})\rangle| = \exp\left\{-\frac{q^2}{4(2\pi)^3}\log\frac{\Lambda}{\lambda}\,\mathcal{A}(\mathbf{v},\mathbf{w})\right\} \longrightarrow 0 \qquad (\lambda \downarrow 0).$$

This is the finite-Fock-space calculation behind velocity-labelled charged sectors. It is stronger than saying that a bare electron emits many soft photons: different charged velocities determine different infrared coherent directions. A Haag–Ruelle replacement for massless charged sectors must therefore build its asymptotic representation with the charged velocity and flux label included from the start.

22.5.10 Weyl Implementation and the Failure of a Common Photon Fock Space

The preceding norm calculation has an operator-algebraic meaning. For $0 < \Lambda < \infty$, let $\mathfrak{h}_{0,\Lambda}$ be the photon one-particle space obtained by replacing the interval $[\lambda,\Lambda]$ in $\mathfrak{h}_{\lambda,\Lambda}$ by $(0,\Lambda]$. For each $\lambda > 0$, $\mathfrak{h}_{\lambda,\Lambda}$ is a closed subspace of $\mathfrak{h}_{0,\Lambda}$ by extension by zero on $(0,\lambda]$. Let

$$\mathcal{F}_{0,\Lambda} = \mathcal{F}_s(\mathfrak{h}_{0,\Lambda})$$

be the corresponding fixed photon Fock space, and let

$$W(f) = \exp\Big(a^\dagger(f) - a(f)\Big), \qquad f \in \mathfrak{h}_{0,\Lambda},$$

be the Weyl operator. With the real symplectic form

$$\sigma(f,g) = 2\,\mathrm{Im}\langle f,g\rangle_{\mathfrak{h}},$$

the Weyl relations are

$$W(f)W(g) = \exp\left(-\frac{\mathrm{i}}{2}\sigma(f,g)\right)W(f+g), \qquad W(f)^* = W(-f), \tag{22.57}$$

and the Fock vacuum state is

$$\omega_0(W(f)) = \langle \Omega, W(f)\Omega\rangle = \exp\left(-\frac{1}{2}\|f\|_{\mathfrak{h}}^2\right).$$

The coherent state with soft profile F is

$$\omega_F(A) = \langle \mathcal{E}(F), A\mathcal{E}(F)\rangle = \langle W(F)\Omega, AW(F)\Omega\rangle.$$

On Weyl generators this gives

$$\omega_F(W(f)) = \exp(\mathrm{i}\sigma(F,f))\exp\left(-\frac{1}{2}\|f\|_{\mathfrak{h}}^2\right). \tag{22.58}$$

Thus the soft cloud changes the representation by adding a linear phase on the Weyl algebra. At finite cutoff this phase is inner, implemented by the unitary $W(F)$. The infrared question is whether the implementing unitaries have a limit on one fixed Fock representation as $\lambda \downarrow 0$.

Proposition 22.17 (No common Fock implementer for distinct charged velocities)**.** *Fix $q \neq 0$, $0 < \Lambda < \infty$, and two distinct velocities $\mathbf{v}, \mathbf{w} \in B_1(0)$. Put*

$$D_{\lambda,\Lambda} = F_{q,\mathbf{v},\lambda,\Lambda} - F_{q,\mathbf{w},\lambda,\Lambda}.$$

Then $\|D_{\lambda,\Lambda}\| \to \infty$ as $\lambda \downarrow 0$. Consequently the finite-cutoff Weyl implementers $W(D_{\lambda,\Lambda})$ have no strong operator limit, and no nonzero weak operator limit, on the fixed photon Fock representation.

Proof. The divergence of $\|D_{\lambda,\Lambda}\|$ is exactly Proposition 22.16: for $\mathbf{v} \neq \mathbf{w}$,

$$\|D_{\lambda,\Lambda}\|^2 = \frac{q^2}{2(2\pi)^3}\log\frac{\Lambda}{\lambda}\,\mathcal{A}(\mathbf{v},\mathbf{w}), \qquad \mathcal{A}(\mathbf{v},\mathbf{w}) > 0.$$

It remains to translate this divergence into an operator statement. Let $\mathcal{D}_{\text{fin}}$ be the dense subspace of finite-particle vectors. Matrix elements of $W(D)$ between vectors in $\mathcal{D}_{\text{fin}}$ are finite sums of polynomials in the finitely many inner products $\langle f_i, D\rangle$ and their complex conjugates, multiplied by the vacuum Gaussian factor

$$\langle \Omega, W(D)\Omega\rangle = \exp\left(-\frac{1}{2}\|D\|^2\right).$$

This follows by commuting $a(f)$ and $a^\dagger(f)$ through $W(D)$, or equivalently by differentiating the Weyl relation (22.57) with respect to finite test directions. Polynomial growth cannot compensate the Gaussian decay. Hence for every $\xi, \eta \in \mathcal{D}_{\text{fin}}$,

$$\langle \xi, W(D_{\lambda,\Lambda})\eta\rangle \longrightarrow 0 \qquad (\lambda \downarrow 0).$$

The operators $W(D_{\lambda,\Lambda})$ are unitary and therefore uniformly bounded, so density of $\mathcal{D}_{\text{fin}}$ gives weak convergence to zero on all Fock vectors. A strong limit of unitaries, if it existed, would have the same weak limit and would therefore be the zero operator; but a strong limit of unitaries is an isometry on every vector whose norm limit exists:

$$\|U\eta\| = \lim_{\lambda\downarrow 0}\|W(D_{\lambda,\Lambda})\eta\| = \|\eta\|.$$

The zero operator is not an isometry. Thus no strong limit exists. ∎

Definition 22.18 (Hilbert-equivalent soft dressings)**.** Fix the ultraviolet cutoff Λ and use the photon one-particle space $\mathfrak{h}_{0,\Lambda}$ introduced above. Let

$$F_\lambda, G_\lambda \in \mathfrak{h}_{\lambda,\Lambda} \subset \mathfrak{h}_{0,\Lambda}, \qquad 0 < \lambda < \Lambda,$$

be two infrared-regulated soft profiles for the same charged insertion. They are called Hilbert-equivalent at the cutoff Λ if there exists a vector $\Delta \in \mathfrak{h}_{0,\Lambda}$ such that

$$\lim_{\lambda \downarrow 0} \|G_\lambda - F_\lambda - \Delta\|_{\mathfrak{h}_{0,\Lambda}} = 0. \tag{22.59}$$

The vector Δ is the finite soft-coordinate change between the two dressings. This definition is deliberately a Hilbert-space definition: it does not identify dressings whose difference changes the limiting Gauss-law flux, because such a difference is not represented by a vector of $\mathfrak{h}_{0,\Lambda}$.

Proposition 22.19 (Hilbert soft changes are inner Weyl coordinate changes)**.** *Let F_λ and G_λ be Hilbert-equivalent soft profiles in the sense of Definition 22.18, and put*

$$\Delta_\lambda = G_\lambda - F_\lambda.$$

For every finite Weyl polynomial A in the generators $W(f)$, $f \in \mathfrak{h}_{0,\Lambda}$,

$$\omega_{G_\lambda}(A) - \omega_{F_\lambda}(W(\Delta_\lambda)^* A W(\Delta_\lambda)) = 0, \tag{22.60}$$

and the implementing unitaries have the strong limit

$$W(\Delta_\lambda) \longrightarrow W(\Delta) \qquad \text{on } \mathcal{F}_{0,\Lambda}.$$

Consequently

$$|\langle \mathcal{E}(F_\lambda), \mathcal{E}(G_\lambda)\rangle| = \exp\left(-\frac{1}{2}\|\Delta_\lambda\|^2\right) \longrightarrow \exp\left(-\frac{1}{2}\|\Delta\|^2\right) > 0.$$

Thus a Hilbert-equivalent soft change is a finite reparametrization of the same infrared representation, not a change of charged sector. The velocity change in Proposition 22.17 fails this criterion because $\|F_{q,\mathbf{v},\lambda,\Lambda} - F_{q,\mathbf{w},\lambda,\Lambda}\| \to \infty$ for $\mathbf{v} \neq \mathbf{w}$.

Proof. The equality (22.60) is first checked on one Weyl generator. The Weyl relations give

$$W(\Delta_\lambda)^* W(f) W(\Delta_\lambda) = \exp(\mathrm{i}\sigma(\Delta_\lambda, f))\, W(f),$$

and hence, using (22.58),

$$\begin{aligned}\omega_{F_\lambda}(W(\Delta_\lambda)^* W(f) W(\Delta_\lambda)) &= \exp(\mathrm{i}\sigma(\Delta_\lambda, f)) \exp(\mathrm{i}\sigma(F_\lambda, f)) \exp\left(-\frac{1}{2}\|f\|^2\right) \\ &= \exp(\mathrm{i}\sigma(G_\lambda, f)) \exp\left(-\frac{1}{2}\|f\|^2\right) = \omega_{G_\lambda}(W(f)).\end{aligned}$$

Linearity and multiplication by the Weyl relations extend this identity to finite Weyl polynomials.

It remains to prove the strong convergence of the implementers. The coherent vectors

$$\mathcal{E}(K) = \mathrm{e}^{-\|K\|^2/2} \bigoplus_{n \geq 0} \frac{K^{\otimes_s n}}{\sqrt{n!}}, \qquad K \in \mathfrak{h}_{0,\Lambda},$$

span a dense subspace of $\mathcal{F}_{0,\Lambda}$. On such vectors,

$$W(H)\mathcal{E}(K) = \exp\left(-\frac{\mathrm{i}}{2}\sigma(H,K)\right)\mathcal{E}(K+H),$$

because $\mathcal{E}(K) = W(K)\Omega$ and (22.57) gives $W(H)W(K) = \exp[-\mathrm{i}\sigma(H,K)/2]W(H+K)$. If $H_n \to H$ in $\mathfrak{h}_{0,\Lambda}$, the displayed formula and the coherent-vector inner product

$$\langle \mathcal{E}(K_1), \mathcal{E}(K_2)\rangle = \exp\left(-\frac{1}{2}\|K_1\|^2 - \frac{1}{2}\|K_2\|^2 + \langle K_1, K_2\rangle\right)$$

show that $W(H_n)\mathcal{E}(K) \to W(H)\mathcal{E}(K)$ in norm. Since all $W(H_n)$ and $W(H)$ are unitary, density upgrades convergence on coherent vectors to strong convergence on the whole Fock space. Applying this to $H_n = \Delta_{\lambda_n}$ along every sequence $\lambda_n \downarrow 0$ proves

$$W(\Delta_\lambda) \to W(\Delta) \quad \text{strongly.}$$

The overlap formula follows by summing the Fock inner products of coherent vectors, and the limiting overlap is nonzero because $\Delta \in \mathfrak{h}_{0,\Lambda}$ has finite norm. The last assertion is then exactly Proposition 22.17. □

Proposition 22.17 is a precise version of the representation-theoretic obstruction. At every positive infrared cutoff, changing the soft cloud is an ordinary Weyl displacement on Fock space. Removing the cutoff separates two cases. A Hilbert-equivalent change remains an inner coordinate change by Proposition 22.19. A change of charged velocity escapes to infinity in the one-particle norm and is not implemented on the original Fock representation. Therefore a charged asymptotic Hilbert space must be organized as a direct integral or measurable field of infrared representations labelled by the limiting flux data, not as a single photon Fock space tensored with a Wigner one-particle electron space. This is still not the missing Haag–Ruelle theorem, but it is one of the structural inputs that theorem must contain.

The flux statement and the eikonal statement are two aspects of the same nonlocal charged datum. The Wilson line fixes how the charged insertion transforms under boundary gauge transformations; the boosted Coulomb field records the corresponding Gauss-law flux at spacelike infinity; the half-line Fourier transform gives the soft denominator used by perturbative dressed-state constructions. A local observable cannot change $\Phi_\infty(f)$, so a local observable cannot replace this noncompact dressing in a Haag–Ruelle construction. Conversely, specifying only the formal denominator $p \cdot k$ is not yet a scattering theorem: a full charged-sector Haag–Ruelle theory must still construct large-time limits in the representation labelled by the flux density (22.51).

22.5.11 Velocity-Fibered Soft Representations

The preceding propositions rule out one tempting but incorrect construction: one cannot keep a single photon Fock representation and implement all charged velocity changes by limiting Weyl unitaries. The minimal replacement is a fibered infrared representation. A scattering theory must still construct large-time limits, while this representation gives the correct representation-theoretic target for such a construction in a nonconfining charged sector.

This qualification is essential. The charged-sector construction discussed here is not a proposed scattering theory for colored quarks in a confining four-dimensional Yang–Mills theory. It applies only when the theory has physical charged superselection sectors with charged asymptotic data: for example electric charge in a nonconfining abelian gauge theory, or suitable unconfined charges on a Coulomb branch or in a deconfined regime after the infrared and representation-theoretic hypotheses have been stated. In a confining theory the gauge-invariant Wilson-line operator ending at infinity creates a state with a macroscopic flux string or fails to have a finite-energy charged-particle limit; the physical massive one-particle states, if present, are instead neutral hadrons or glueballs created by local gauge-invariant operators. Ordinary Haag–Ruelle theory is then the correct starting point for those neutral particles.

Fix $q \neq 0$ and $0 < \Lambda < \infty$. Let $\mathfrak{h}_{\mathrm{reg}} \subset \mathfrak{h}_{0,\Lambda}$ be a complex linear subspace of infrared-regular photon test functions such that, for every $\mathbf{v} \in B_1(0)$, the limit

$$\ell_{\mathbf{v}}(f) = \lim_{\lambda \downarrow 0} \sigma(F_{q,\mathbf{v},\lambda,\Lambda}, f) \tag{22.61}$$

exists for all $f \in \mathfrak{h}_{\mathrm{reg}}$. For example, the condition is satisfied on smooth compactly supported one-photon wave packets whose radial support is bounded away from $r = 0$. Larger infrared test spaces require an explicit condition on the radial behavior of f; the definition above records exactly the condition needed for the soft phase to be a finite functional.

Let $\mathfrak{W}_{\mathrm{reg}}$ be the Weyl $*$-algebra generated by $W(f)$, $f \in \mathfrak{h}_{\mathrm{reg}}$, with relations (22.57). The charged velocity $\mathbf{v}$ defines the state

$$\omega_{\mathbf{v}}(W(f)) = \exp(\mathrm{i}\ell_{\mathbf{v}}(f)) \exp\left(-\frac{1}{2}\|f\|^2_{\mathfrak{h}_{0,\Lambda}}\right), \qquad f \in \mathfrak{h}_{\mathrm{reg}}. \tag{22.62}$$

Let $(\mathcal{H}_{\mathbf{v}}, \pi_{\mathbf{v}}, \Omega_{\mathbf{v}})$ be the GNS representation of $\omega_{\mathbf{v}}$. If ν is a Borel measure on $B_1(0)$ for which the field $\mathbf{v} \mapsto (\mathcal{H}_{\mathbf{v}}, \pi_{\mathbf{v}})$ has been given a measurable structure, define

$$\mathcal{H}^{\mathrm{soft}}_{q,\nu} = \int^{\oplus}_{B_1(0)} \mathcal{H}_{\mathbf{v}}\, \mathrm{d}\nu(\mathbf{v}), \qquad \big(\pi_{q,\nu}(A)\Psi\big)(\mathbf{v}) = \pi_{\mathbf{v}}(A)\Psi(\mathbf{v}). \tag{22.63}$$

Remark 22.20 (Soft photon algebra preserves the velocity fibers). In the direct-integral representation (22.63), let P_E be multiplication by the characteristic function of a Borel set $E \subset B_1(0)$. Then

$$[P_E, \pi_{q,\nu}(A)] = 0 \qquad \text{for all } A \in \mathfrak{W}_{\mathrm{reg}}. \tag{22.64}$$

Consequently, if $E \cap E' = \varnothing$, then

$$\langle P_E\xi, \pi_{q,\nu}(A) P_{E'}\eta\rangle = 0 \qquad \text{for all } \xi, \eta \in \mathcal{H}^{\mathrm{soft}}_{q,\nu}, \quad A \in \mathfrak{W}_{\mathrm{reg}}. \tag{22.65}$$

Thus the soft photon Weyl algebra is diagonal in the charged velocity label. Any charged scattering operator that changes the massive particle momentum must include additional charged-sector dynamics supplied by operators beyond the soft photon algebra alone. Indeed, by the definition of the direct-integral action, for $\Psi \in \mathcal{H}^{\mathrm{soft}}_{q,\nu}$,

$$(P_E \pi_{q,\nu}(A)\Psi)(\mathbf{v}) = \mathbf{1}_E(\mathbf{v})\pi_{\mathbf{v}}(A)\Psi(\mathbf{v}) = (\pi_{q,\nu}(A) P_E \Psi)(\mathbf{v})$$

for ν-almost every $\mathbf{v}$. If $E \cap E' = \varnothing$, then $P_E P_{E'} = 0$, and therefore

$$\langle P_E\xi, \pi_{q,\nu}(A) P_{E'}\eta\rangle = \langle \xi, P_E \pi_{q,\nu}(A) P_{E'}\eta\rangle = \langle \xi, \pi_{q,\nu}(A) P_E P_{E'}\eta\rangle = 0.$$

This fibered construction is the algebraic form of the velocity superselection conclusion. It also states a precise target for the still missing charged Haag–Ruelle theorem: the theorem must construct incoming and outgoing charged wave operators whose asymptotic photon part lives in a measurable field of infrared representations labelled by the Gauss-law flux, and whose hard charged part supplies the off-diagonal momentum-changing dynamics. Treating the charged soft cloud as a removable unitary dressing on one Fock space would erase exactly the sector information proved above.

Open Problem 22.21 (Haag–Ruelle and LSZ for nonconfining dressed charged sectors). Construct a large-time scattering theory for nonconfining gauge-theory charged sectors using noncompact gauge-invariant charged creators. The construction should prove the analogue of Haag–Ruelle limits for the chosen dressing class, identify the asymptotic flux labels, and prove a dressed-correlator reduction formula whose external factors are the residues or threshold coefficients of the corresponding dressed two-point functions. The hypothesis "nonconfining" means that the charged sector is a genuine finite-energy physical sector with asymptotic charged data; it excludes colored charges in a confining phase, for which the physical scattering problem is the neutral hadron or glueball scattering problem. In massless QED this problem must be combined with the infraparticle flux-sector analysis of Chapter 44.

22.6 Wave Operators, Scattering Operator, and Completeness

Let

$$\Omega_{\mathrm{in}}, \Omega_{\mathrm{out}} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{H}$$

be the Haag–Ruelle wave operators, in the terminology introduced in Chapter 17, produced by Haag–Ruelle limits. They are isometric maps. Their construction has two equivalent topological descriptions. First, for each finite velocity-separated Fock vector

$$F = \psi_1 \odot \cdots \odot \psi_n$$

represented by regular creators B_j and packets h_j, the vector family

$$\Omega^{\mathrm{HR}}_{\mathrm{out},t} F = B_{1,t}(h_1) \cdots B_{n,t}(h_n)\Omega$$

converges in the Hilbert norm of $\mathcal{H}$. Second, after these vector limits are packaged as maps from the algebraic velocity-separated Fock domain to $\mathcal{H}$, the same assertion is strong convergence of the approximating maps:

$$\Omega^{\mathrm{HR}}_{\mathrm{out},t} F \longrightarrow \Omega_{\mathrm{out}} F \quad \text{in } \mathcal{H} \quad \text{for every fixed } F. \tag{22.66}$$

The incoming map is obtained by the same statement with $t \to -\infty$. Weak convergence of matrix elements follows from this norm convergence for each F, while weak convergence alone would not determine the isometric identification. No operator-norm limit over the unit sphere of $\mathcal{F}_s(\mathcal{H}_1)$ is part of the theorem. Their ranges

$$\mathcal{H}_{\mathrm{in}} = \operatorname{Ran} \Omega_{\mathrm{in}}, \qquad \mathcal{H}_{\mathrm{out}} = \operatorname{Ran} \Omega_{\mathrm{out}}$$

are the incoming and outgoing scattering subspaces. The comparison operator

$$S = \Omega^*_{\mathrm{out}} \Omega_{\mathrm{in}} \quad \text{on} \quad \mathcal{F}_s(\mathcal{H}_1)$$

is unitary on the sector when $\mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}}$. Its wave-packet matrix elements are

$$\begin{aligned}&\langle \varphi_1 \odot \cdots \odot \varphi_m,\, S(\psi_1 \odot \cdots \odot \psi_n)\rangle_{\mathcal{F}_s(\mathcal{H}_1)} \\ &\qquad = \langle \Omega_{\text{out}}(\varphi_1 \odot \cdots \odot \varphi_m),\, \Omega_{\text{in}}(\psi_1 \odot \cdots \odot \psi_n)\rangle_{\mathcal{H}}\,.\end{aligned}$$

This is the nonperturbative definition of the scattering matrix element in the massive isolated-shell sector.

Asymptotic completeness is a further assertion:

$$\mathcal{H}_{\text{sector}} = \mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}}.$$

It is a dynamical property of the model or sector. For nontrivial interacting massive local Wightman theories in four spacetime dimensions, full asymptotic completeness is presently an open problem rather than a theorem following from the axioms. Existing proofs are confined to restricted model classes, notably constructive or integrable models in lower spacetime dimensions and related weakened-locality settings. Bound states require additional isolated shells. Confinement can remove charged or colored one-particle shells from the observable spectrum while retaining hadronic shells. Long-range gauge forces and infraparticle spectra require modified asymptotic state spaces or detector observables; the charged-QED and physical-QCD versions are the open asymptotic-completeness problems formulated in Open Problems 44.10 and 49.22. Each case changes the large-time construction rather than the meaning of the massive theorem above.

22.7 Interface With LSZ and Perturbation Theory

The Haag–Ruelle construction defines the Hilbert-space target of LSZ. If a local field or local observable has a nonzero vacuum-to-one-particle matrix element on the isolated shell, then its two-point function contains the corresponding one-particle pole or spectral atom. LSZ extracts those external singularities from time-ordered correlation functions and thereby computes matrix elements of the scattering operator already defined by wave operators.

The logical dependencies are

$$\text{local net and spectrum} \longrightarrow \text{Haag–Ruelle wave operators} \longrightarrow S,$$

$$\text{time-ordered Green functions} \xrightarrow{\text{LSZ external residues}} \langle \text{out}|S|\text{in}\rangle,$$

$$\text{renormalized perturbation theory} \longrightarrow \text{Green-function expansion} \longrightarrow \text{expansion of } \langle \text{out}|S|\text{in}\rangle.$$

Thus Feynman graphs for Green functions acquire a scattering interpretation only after the asymptotic Hilbert-space data and the reduction theorem are in place. The same order applies whether the theory is presented by a Lagrangian, a Euclidean construction satisfying reconstruction hypotheses, a local net, or another nonperturbative definition.

Chapter 23

Local Data and Kernel Conventions

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

23.1 Purpose of This Chapter

The preceding part constructed the local Hilbert-space frameworks, the Källén–Lehmann spectral representation, Haag–Ruelle scattering states, and LSZ reduction. This chapter does not rederive those constructions. Its role is to fix the notation used in the analytic scattering chapters: Poincare-action conventions, one-particle normalizations, spectral-threshold symbols, and Green-function boundary-value conventions.

23.2 Status of Scalar Model Examples

Definition 23.1 (Three uses of scalar Lagrangian notation)**.** Scalar Lagrangian densities appear in this part at three logically different levels. First, at finite ultraviolet cutoff they define regulated Green functions and perturbative kernels. Second, in low spacetime dimensions, certain scalar models have constructive non-Gaussian continuum realizations, as catalogued in Table 11.2 and recalled in Chapter 15. Third, a four-dimensional $\lambda\phi^4$ expression may be used as a renormalized perturbative or effective-field-theory model below a cutoff, or as a conditional notation for an exact massive local QFT if such a theory has been separately constructed.

Remark 23.2 (Four-dimensional scalar status). For the standard reflection-positive lattice $\lambda\phi^4$

family in four Euclidean dimensions with $\lambda \geq 0$, the known triviality theorems apply to the usual critical or near-critical continuum scaling limits: the resulting continuum limits are Gaussian, so the interacting connected correlations vanish after the continuum field normalization. This is a theorem about that specified constructive scaling-limit problem. It is a different statement from the broader open question whether an ultraviolet-complete four-dimensional QFT could have a small-coupling expansion agreeing with formal ϕ_4^4 perturbation theory to all orders while differing nonperturbatively. The latter possibility would require its own construction and verification of locality, positivity, spectrum, and scattering hypotheses.

Consequently, when the following chapters use $D = 4$ scalar amplitudes, they are to be read either as finite-cutoff perturbative or effective descriptions, or as conditional consequences of the stated Hilbert-space and analytic hypotheses. The scattering machinery derives consequences from a massive local QFT with stable particles; it does not prove that a particular bare four-dimensional scalar polynomial supplies such a QFT after removing the cutoff. The corresponding Wilsonian cutoff-removal assertion is stated later as the finite-coordinate cutoff-removal estimate in Chapter 36. There the retained-coordinate limit is derived from explicit tuning, semigroup, and generated-integral convergence hypotheses, rather than being imported as informal renormalizability lore.

23.3 Poincare and Field Conventions

Convention 23.3 (Poincare action, metric, and field covariance)**.** The unitary representation is written

$$U(a, \Lambda), \qquad U(a, \mathbf{1}) = \exp(\mathrm{i}a_\mu P^\mu) = \exp(\mathrm{i}a^\mu P_\mu),$$

with group law

$$U(a', \Lambda')U(a, \Lambda) = U(a' + \Lambda' a, \Lambda'\Lambda).$$

The metric is mostly plus,

$$\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +), \qquad p^2 = \eta_{\mu\nu} p^\mu p^\nu,$$

and the spectrum condition is

$$\mathrm{Spec}(P) \subset \overline{V}_+ = \{p : p^0 \geq 0,\ p^2 \leq 0\}.$$

Here P in the spectrum condition denotes the contravariant energy-momentum P^μ, while $P_\mu = \eta_{\mu\nu}P^\nu$ is used in the exponent when the translation parameter is written with an upper index. The vacuum vector is denoted by Ω and satisfies

$$U(a, \Lambda)\Omega = \Omega.$$

For a local field transforming in a finite-dimensional Lorentz representation R,

$$U(a, \Lambda)^{-1}\widehat{\Phi}_\alpha(x)U(a, \Lambda) = R(\Lambda)_\alpha{}^\beta \widehat{\Phi}_\beta(\Lambda x + a).$$

Thus translations give

$$\widehat{\Phi}_\alpha(x) = \mathrm{e}^{-\mathrm{i}x^\mu P_\mu}\widehat{\Phi}_\alpha(0)\mathrm{e}^{\mathrm{i}x^\mu P_\mu}.$$

All such identities are identities of smeared operator-valued distributions on the stated common domains.

23.4 One-Particle Normalization

Definition 23.4 (One-particle normalization and spectral threshold)**.** For a stable scalar species of mass $m > 0$,

$$\Sigma_m^+ = \{(\omega_{\vec{p}}, \vec{p}) : \omega_{\vec{p}} = (\vec{p}^2 + m^2)^{1/2}\}$$

is the positive mass shell. Delta-normalized vectors and covariantly normalized vectors are related by

$$|\vec{p}\rangle = \left((2\pi)^d 2\omega_{\vec{p}}\right)^{1/2} |\vec{p}\rangle_\delta,$$

with

$${}_\delta\langle\vec{q} \mid \vec{p}\rangle_\delta = \delta^{(d)}(\vec{q} - \vec{p}), \qquad \langle\vec{q} \mid \vec{p}\rangle = (2\pi)^d 2\omega_{\vec{p}} \delta^{(d)}(\vec{q} - \vec{p}).$$

The invariant mass-shell measure is

$$\mathrm{d}\mu_m(\vec{p}) = \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d 2\omega_{\vec{p}}}.$$

If a scalar interpolating field $\widehat{\phi}$ creates the species, its one-particle residue is fixed by

$$\langle\Omega|\widehat{\phi}(0)|\vec{p}\rangle = Z_\phi^{1/2}, \qquad Z_\phi > 0.$$

This Z_ϕ is the atom of the Källén–Lehmann measure at $\mu^2 = m^2$, as derived in Chapter 14. The symbol M_{cont} denotes the lowest invariant mass in the continuous spectral support with the same quantum numbers. When the first continuum consists of two particles of the same mass m, $M_{\text{cont}} = 2m$.

23.5 Green-Function Boundary Values

Definition 23.5 (Time-ordered Green functions and boundary-value kernels)**.** For local fields $\widehat{\Phi}_{a_1}, \ldots, \widehat{\Phi}_{a_N}$, the time-ordered distribution is

$$G_{a_1 \cdots a_N}(x_1, \ldots, x_N) = \langle\Omega|\,\mathrm{T}\{\widehat{\Phi}_{a_1}(x_1) \cdots \widehat{\Phi}_{a_N}(x_N)\}|\Omega\rangle.$$

Products at coincident points require a specified time-ordering prescription or a renormalized composite-operator convention.

For a scalar two-point function, the positive spectral measure gives the boundary-value formula

$$G_2(x) = \int_0^\infty \mathrm{d}\rho_\phi(\mu^2)\, \Delta_F(x; \mu^2),$$

where

$$\Delta_F(x; \mu^2) = -\mathrm{i} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k \cdot x}}{k^2 + \mu^2 - \mathrm{i}0}.$$

The Euclidean two-point Schwinger function, when OS reconstruction hypotheses are satisfied, is

$$S_2(x_E) = \int_0^\infty \mathrm{d}\rho_\phi(\mu^2) \int \frac{\mathrm{d}^D k_E}{(2\pi)^D} \frac{\mathrm{e}^{\mathrm{i}k_E \cdot x_E}}{k_E^2 + \mu^2}.$$

The passage among Wightman, time-ordered, and Euclidean functions is governed by the tube-domain and OS hypotheses stated in the foundational chapters. In the present part these formulas serve only as notation and as inputs to LSZ, dispersion theory, and threshold analysis.

23.6 Regulated Functional Integrals as Downstream Data

Definition 23.6 (Regulated functional integral notation)**.** Regulated path integrals are used later to compute Green functions and their renormalized limits. If Λ is a regulator and J is a source, the notation

$$Z_\Lambda[J] = \int_{\mathcal{C}_\Lambda} D_\Lambda\varphi \, \exp\left(-S_{\Lambda,E}[\varphi; g_I(\Lambda)] + \int \mathrm{d}^D x_E \, J(x_E)\varphi(x_E)\right)$$

means the finite-dimensional or otherwise regulated integral specified by the chosen cutoff. For a finite-dimensional bosonic scalar regulator, $D_\Lambda\varphi$ is the reference density $D_\Lambda^{\mathrm{ref}}\varphi$ of Definition 11.3. If the quadratic part has been absorbed into a Gaussian reference measure, the same regulated integral is written with $\mathrm{d}\mu_{C_\Lambda}$ and an interaction weight. For gauge, fermionic, oscillatory, BV, or algebraic regularizations, $D_\Lambda\varphi$ names the regulated integration object supplied by that construction and must be specified before use. A continuum Schwinger function is a distributional limit of source derivatives of Z_Λ, after the cutoff dependence of the coefficients $g_I(\Lambda)$ has been chosen. Existence of such a limit requires a renormalization or construction theorem: the notation records the regulated objects and the topology of the intended limit. The systematic renormalized-source treatment begins in the renormalization and effective-action chapters.

Chapter 24

Scattering Kernels, LSZ, and Cluster Decomposition

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \dots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Definition 24.1 (Status of time-ordered correlators in the scattering chapters)**.** The time-ordered distributions used in this part have a fixed status. In an exact scattering statement, G_N^{c} denotes the connected time-ordered distribution associated with local Hilbert-space fields $\widehat{\phi}(x)$, obtained from the Wightman distributions by the specified ordering and boundary-value prescription. The input needed for LSZ is then spectral: the two-point function has an isolated one-particle pole of mass m and residue $Z_\phi > 0$, and the N-point time-ordered distribution has the corresponding external pole boundary values after smearing. No path integral is part of the definition of the scattering operator in this case; S remains $\Omega_{\mathrm{out}}^* \Omega_{\mathrm{in}}$ from Haag–Ruelle theory.

In perturbative examples, Feynman graphs, Feynman parameters, and loop integrals denote coefficientwise contributions to a regulated source functional $Z[J]$. Its connected functional is the coefficientwise logarithm of $Z[J]$, with the Lorentzian or Euclidean factor fixed by the chosen regulator convention; the full source-functional status declaration is given in Chapter 30, and the BPHZ status declaration is given in Chapter 32. These are formal or regulated calculations of the time-ordered distributions whose pole residues may then be inserted into the LSZ formula. Such graph calculations do not define S and do not assert the existence of an unregulated continuum path-integral measure.

If a Euclidean construction is used instead, the time-ordered Lorentzian distributions are obtained only after the stated Osterwalder–Schrader reconstruction or analytic-continuation hypotheses have been verified. Thus a symbol such as G^{c}_N, Z_ϕ, or a Feynman-parameter integral always carries one of these statuses: exact Hilbert-space distribution, Euclidean reconstructed distribution, or formal/regulator-dependent perturbative coefficient.

Definition 24.2 (Mostly-plus Mandelstam variables)**.** Throughout the scattering and analyticity chapters, physical $2 \to 2$ momenta are written as incoming positive-energy momenta p_1, p_2 and outgoing positive-energy momenta p_3, p_4, with

$$p_i^2 = -m_i^2, \qquad p_1 + p_2 = p_3 + p_4$$

in the mostly-plus metric. The Mandelstam variables are

$$s = -(p_1 + p_2)^2, \qquad t = -(p_1 - p_3)^2, \qquad u = -(p_1 - p_4)^2.$$

They obey

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2.$$

For equal masses $m_i = m$, in the center-of-mass frame,

$$s = E_{\mathrm{cm}}^2, \qquad t = -2|\vec{p}_*|^2(1 - \cos\theta), \qquad u = -2|\vec{p}_*|^2(1 + \cos\theta),$$

so physical s-channel scattering has $s \geq 4m^2$ and

$$-(s - 4m^2) \leq t \leq 0, \qquad -(s - 4m^2) \leq u \leq 0.$$

Positive real t or u in later fixed-t and crossing discussions is therefore a crossed-channel timelike invariant, not a physical s-channel scattering angle.

24.1 Cross-Volume Scattering Architecture

The scattering chapters use several inequivalent objects. This section is a routing convention for those objects before the detailed chapters branch apart. Its main rule is that an amplitude, an inclusive rate, a detector distribution, and a resonance pole are different outputs of different hypotheses. A formula may connect two of them only after the hypotheses on both sides have been stated.

Definition 24.3 (Status labels for scattering constructions)**.** In this part the following labels have fixed meanings.

1. A *theorem* is a statement proved from the stated Hilbert-space, locality, spectral, and domain hypotheses.
2. A *conditional theorem* is a theorem after additional analytic hypotheses have been supplied, for example a factorization, asymptotic completeness, or convergence assumption.
3. A *regulated construction* is a finite-cutoff or perturbative object with a specified regulator and subtraction prescription.
4. *Numerical evidence* is a finite-volume, lattice, bootstrap, or Monte Carlo datum that supports but does not replace the continuum construction.
5. An *open problem* is a required bridge whose hypotheses, convergence, or physical state-space construction are not supplied in this monograph.

Framework matrix.

Massive Haag–Ruelle/LSZ. The primary objects are the in/out maps, the scattering operator, and the external residues used to extract amplitudes. The input is a mass gap or isolated shell, local fields or almost-local creators, velocity separation, and distributional time ordering. Under those hypotheses this is a theorem producing wave-packet S-matrix elements and invariant amplitudes. It stops when charged sectors, confinement, or massless thresholds remove the isolated particle shell.

Charged QED and long-range sectors. The primary objects are dressed hard states, the soft photon cloud, and an inclusive detector resolution. The input is Gauss-law flux, the massless photon spectrum, an infrared cutoff or detector resolution, and a dressing or inclusive prescription. This gives conditional perturbative and algebraic constructions. The exact charged electron is not an ordinary LSZ particle of the massless theory; inclusive rates or dressed matrix elements replace bare charged S-matrix kernels.

Detector and event-shape observables. The primary observables are event-shape distributions and energy-flow measures. Light-ray detector products give one operator realization. The input is an outgoing physical state space, a positive detector measure, a contact convention, and either IRC safety or a declared nonperturbative function. The output is an observable distribution rather than an amplitude. Perturbative kernels enter only after matching, subtraction, and detector limits have been fixed.

Analytic S-matrix and resonances. The primary objects are partial waves, dispersion relations, and the sheet structure in which poles, cuts, and other singularities can be characterized. The input is a previously constructed amplitude, unitarity, crossing domain, spectral condition, and analyticity assumptions. This gives a conditional analytic continuation of amplitudes. A particular resonance pole is additional dynamical information, for example a zero of a continued inverse partial wave or a finite-volume/spectral analysis that fixes the continued singularity; it is not produced by analyticity alone. Resonance poles encode unstable states; they are not normalizable asymptotic particles.

Confining gauge theory and QCD factorization. The primary objects are hadronic cross sections, PDFs, TMDs, jets, and energy correlators. The input is color-singlet external states, operator definitions, factorization, Glauber status, power counting, and a detector or parton-density scheme. The output is a conditional factorized observable. Colored partonic amplitudes are short-distance coordinates, not physical external S-matrix elements.

Integrable two-dimensional scattering. The primary objects are factorized scattering functions, form factors, and TBA data. The input is elastic factorization, Yang–Baxter constraints, locality axioms for form factors, convergence, and completeness assumptions. The output is exact algebraic and thermodynamic data. Reconstruction of local observables and local algebras is a separate analytic bridge.

Massive route. In a massive theory with a stable isolated one-particle shell, the route is: local fields and spectrum; Haag–Ruelle wave operators $\Omega_{\text{in/out}}$; the scattering operator S; the invariant amplitude $\mathcal{M}$; and finally the cross section σ. The first arrow is Haag–Ruelle theory (Chapters 17 and 22). The second is the definition of the scattering operator. The third is LSZ residue extraction (Chapter 18 and this chapter). The fourth is phase-space integration with the flux and normalization conventions of Chapter 19. Analytic continuation, partial waves, and resonance poles may then be studied in Chapters 26 and 29, but those analytic objects start from the amplitude already obtained on the physical sheet.

Charged QED route. In massless QED the charged sector does not satisfy the massive LSZ input. Gauss-law flux and arbitrarily soft photons change the spectral support of a charged state, so the bare electron Green-function residue is not an exact one-particle S-matrix coordinate of the full theory. The route is instead: a hard charged process; soft dressing or an inclusive sum; and a detector-resolved rate. Chapter 42 fixes external-state conventions for regulated perturbative calculations. Chapter 44 then supplies the inclusive and dressed replacements. A perturbative hard amplitude remains useful, but only as an ingredient in the resolution dependent observable after the soft sector has been attached.

Detector and QCD route. For QCD event shapes and energy correlators the physical object is a color-singlet detector distribution. The route is: a current or hadron source; factorized operator data; jet, soft, or parton-density functions; and the detector measure. Chapter 49 gives the QCD operator and factorization layers, Chapter 50 develops event shapes, track functions, and hadronization coordinates, and Chapter 65 supplies the conformal light-ray and detector-algebra comparison. A partonic amplitude or splitting kernel is a short-distance coordinate inside this route. It becomes a physical prediction only after the observable, subtraction scheme, Glauber status, endpoint/contact convention, and nonperturbative inputs have been declared.

Map and non-map ledger. The following implications are used in later chapters.

1. Haag–Ruelle plus LSZ hypotheses give massive wave-packet amplitudes.
2. Massive amplitudes plus unitarity, boundedness, and analyticity hypotheses give partial-wave and dispersion-relation machinery, together with a continuation framework in which resonance poles, cuts, and other singularities can be characterized if present. The existence and location of a resonance pole require separate channel-specific dynamical or spectral evidence.
3. A charged hard process plus soft or inclusive data gives infrared-safe charged rates.
4. QCD operator definitions plus factorization data give detector and event-shape distributions.

The converse arrows are absent without extra hypotheses. A detector distribution does not determine a unique amplitude; a resonance pole does not produce an asymptotic particle vector; an inclusive QED rate does not restore a bare charged LSZ state; a finite partonic or lattice check does not supply the continuum factorization or reconstruction theorem. This ledger is the cross-volume convention used whenever the later chapters compare these languages.

24.2 Scattering Operator and Kernel Notation

This chapter fixes the distributional kernel notation used in the analytic chapters. The nonperturbative construction of S by Haag–Ruelle wave operators was given in Chapters 17 and 22; it is not being redefined here.

Work in one massive Haag–Ruelle scattering sector satisfying the hypotheses of Theorem 22.1, with the scalar point-field construction and Cook estimates reviewed in Proposition 17.8. Fix a stable scalar species of mass $m > 0$. Its positive mass shell is

$$\Sigma_m^+ = \{(\omega_{\vec{p}}, \vec{p}) : \vec{p} \in \mathbb{R}^d\}, \qquad \omega_{\vec{p}} = \sqrt{\vec{p}^2 + m^2}.$$

The corresponding one-particle Hilbert space is denoted by $\mathcal{H}_1$. In the scalar case it is represented as $L^2(\Sigma_m^+, \mathrm{d}\mu_m)$, where

$$\mathrm{d}\mu_m(\vec{p}) = \frac{\mathrm{d}^d\vec{p}}{(2\pi)^d 2\omega_{\vec{p}}}.$$

The symmetric Fock space over $\mathcal{H}_1$ is

$$\mathcal{F}_s(\mathcal{H}_1) = \bigoplus_{n=0}^{\infty} \mathcal{H}_1^{\odot n}.$$

The Haag–Ruelle wave operators from the preceding theorem layers are isometries

$$\Omega_{\mathrm{in/out}} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{H}.$$

On a scattering sector for which the incoming and outgoing ranges coincide, the scattering operator is

$$S = \Omega_{\mathrm{out}}^* \Omega_{\mathrm{in}} : \mathcal{F}_s(\mathcal{H}_1) \longrightarrow \mathcal{F}_s(\mathcal{H}_1).$$

This is the object whose kernels will be studied throughout this part.

Generalized momentum states on Σ_m^+ are normalized by

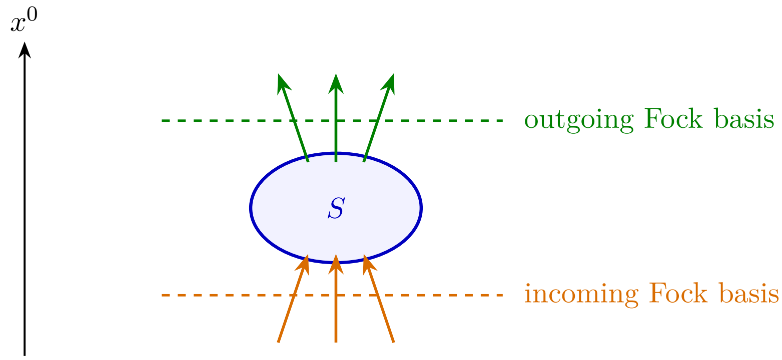
$$\langle \vec{q} | \vec{p} \rangle = (2\pi)^d 2\omega_{\vec{p}}\, \delta^{(d)}(\vec{q} - \vec{p}).$$

For outgoing momenta $q_i = (\omega_{\vec{q}_i}, \vec{q}_i)$ and incoming momenta $p_j = (\omega_{\vec{p}_j}, \vec{p}_j)$, write

$$S(q_1, \ldots, q_m | p_1, \ldots, p_n) = {}_{\mathrm{out}}\langle \vec{q}_1, \ldots, \vec{q}_m | \vec{p}_1, \ldots, \vec{p}_n \rangle_{\mathrm{in}}.$$

This notation denotes a distributional kernel. Its value on wave packets $f_i, g_j \in C_c^\infty(\mathbb{R}^d)$ is

$$\begin{aligned} &S[f_1, \ldots, f_m; g_1, \ldots, g_n] \\ &= \int \prod_{i=1}^{m} \mathrm{d}\mu_m(\vec{q}_i)\, f_i(\vec{q}_i)^* \prod_{j=1}^{n} \mathrm{d}\mu_m(\vec{p}_j)\, g_j(\vec{p}_j) S(q_1, \ldots, q_m | p_1, \ldots, p_n). \end{aligned}$$



24.3 Connected Kernels and Invariant Amplitudes

Let

$$P_{\text{out}} = \sum_{i=1}^{m} q_i, \qquad P_{\text{in}} = \sum_{j=1}^{n} p_j.$$

Translation invariance implies that the non-identity part of every connected scattering kernel is supported on $P_{\text{out}} = P_{\text{in}}$. The phase convention is fixed once and for all by distinguishing the connected S-kernel from the connected T-kernel. With

$$S = \mathbf{1} + \mathrm{i}T,$$

write

$$\begin{aligned} &S^{\mathrm{c}}(q_1, \ldots, q_m | p_1, \ldots, p_n) \\ &\qquad = I^{\mathrm{c}}(q_1, \ldots, q_m | p_1, \ldots, p_n) + \mathrm{i}\, T^{\mathrm{c}}(q_1, \ldots, q_m | p_1, \ldots, p_n), \end{aligned}$$

where I^{c} is zero except for one incoming and one outgoing particle of the same species, in which case

$$I^{\mathrm{c}}(q|p) = (2\pi)^d 2\omega_{\vec{p}} \delta^{(d)}(\vec{q} - \vec{p}).$$

The invariant amplitude $\mathcal{M}$ is the reduced connected T-kernel:

$$\begin{aligned} &T^{\mathrm{c}}(q_1, \ldots, q_m | p_1, \ldots, p_n) \\ &\qquad = (2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) \mathcal{M}(q_1, \ldots, q_m | p_1, \ldots, p_n). \end{aligned}$$

Equivalently, the transition part of the connected S-kernel is

$$S^{\mathrm{c}} - I^{\mathrm{c}} = \mathrm{i}(2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) \mathcal{M}.$$

The connected T-matrix kernel is therefore

$${}_{\text{out}}\langle q|T|p\rangle_{\mathrm{c}} = (2\pi)^D \delta^{(D)}(P_{\text{out}} - P_{\text{in}}) \mathcal{M}(q|p).$$

The word connected has a recursive distributional meaning. If the full process splits into independent subprocesses, the full kernel is the product of the kernels of those subprocesses, with separate momentum conservation in each component. The connected kernel is the part that remains after subtracting all such products.

24.4 LSZ as Pole Extraction

The pole-extraction theorem is Theorem 18.5 of Chapter 18; it is not restated here. In this chapter we use only its kernel consequence: after wave-packet smearing, a connected time-ordered distribution whose external variables have isolated one-particle poles of residue Z_ϕ gives the connected scattering kernel by multiplying each external leg by $Z_\phi^{-1/2}\mathrm{i}(k_a^2 + m^2)$, taking the simultaneous external pole boundary value, and then setting outgoing variables $k_i = q_i$ and incoming variables $k_{m+j} = -p_j$ on Σ_m^+. The resulting distribution is a matrix element of the already-defined Haag–Ruelle operator $S = \Omega_{\text{out}}^* \Omega_{\text{in}}$; in perturbative sections the same operation is applied coefficientwise to regulated time-ordered kernels.

24.5 Cluster Decomposition

Let $\alpha = \{p_1, \dots, p_n\}$ be the incoming labels and $\beta = \{q_1, \dots, q_m\}$ the outgoing labels. A process partition Π is a finite set of nonempty blocks B, where each block contains a subset $\alpha_B \subset \alpha$ and a subset $\beta_B \subset \beta$, and the blocks partition all incoming and outgoing labels. Define

$$S_B^{\mathrm{c}} = S^{\mathrm{c}}(\beta_B|\alpha_B).$$

Connected scattering kernels. For fixed incoming and outgoing labels, the full scattering kernel has a unique expansion

$$S(\beta|\alpha) = \sum_{\Pi} \prod_{B\in\Pi} S^{\mathrm{c}}(\beta_B|\alpha_B), \tag{24.1}$$

where the sum is over process partitions. Equivalently, the connected kernel is determined recursively by

$$S^{\mathrm{c}}(\beta|\alpha) = S(\beta|\alpha) - \sum_{\Pi\neq\{\alpha\cup\beta\}} \prod_{B\in\Pi} S^{\mathrm{c}}(\beta_B|\alpha_B). \tag{24.2}$$

The one-particle identity kernel I^{c} introduced above is included as the connected kernel for a block with one incoming and one outgoing label:

$$\begin{aligned} S^{\mathrm{c}}(q|p) &= I^{\mathrm{c}}(q|p) + \mathrm{i}(2\pi)^D \delta^{(D)}(q-p)\mathcal{M}(q|p) \\ &= (2\pi)^d 2\omega_{\vec{p}}\delta^{(d)}(\vec{q}-\vec{p}) + \mathrm{i}(2\pi)^D\delta^{(D)}(q-p)\mathcal{M}(q|p). \end{aligned} \tag{24.3}$$

In a translationally invariant vacuum without external backgrounds, the nontrivial one-particle amplitude vanishes for a stable isolated species, and the identity term remains.

Order the finite label sets by their total number of external labels. For one block the statement defines S^{c}. Suppose the connected kernels have been defined for every proper subcollection. Then (24.2) defines the connected kernel for the given collection by subtracting all factorizations into proper subprocesses. Substituting this definition back into the right-hand side of (24.1) gives $S(\beta|\alpha)$; uniqueness follows because every other solution would have a difference whose highest-size nonzero component appears only in the one-block term and hence must vanish. This is the moment-cumulant recursion for scattering kernels, with process partitions replacing ordinary set partitions.

This recursion is algebraic: it defines connected kernels once the full kernel is known. The physical cluster property is the large-separation theorem below. Its hypotheses are additional Hilbert-space and locality hypotheses, not consequences of the recursion.

Theorem 24.4 (Cluster decomposition for scattering kernels)**.** *Assume a Haag–Ruelle scattering theory with a unique translation-invariant vacuum, a mass gap above the vacuum, local commutativity, and the following quantitative clustering estimate for the almost-local Haag–Ruelle approximants used to construct the scattering states. If F_T and G_T are finite products of such approximants at fixed time parameter T, and if $G_T(a) = U(a)G_TU(a)^*$, then for every N there are constants C_N, M_N, R_N, depending on the chosen operator families and wave packets but independent of T and a, such that*

$$|\langle\Omega|F_TG_T(a)|\Omega\rangle - \langle\Omega|F_T|\Omega\rangle\langle\Omega|G_T|\Omega\rangle| \leq C_N(1+|T|)^{M_N}(1+\rho(a,T))^{-N}. \tag{24.4}$$

Here $\rho(a,T)$ is the spacelike separation of the two localization tubes after replacing the almost-local operators by local approximants; for velocity supports separated from the light cone of the relative translation, $\rho(a,T) \geq c|a| - R_N(1+|T|)$ for some $c > 0$. Let $\Psi_A^{\mathrm{in/out}}$ and $\Psi_B^{\mathrm{in/out}}$ be two groups of wave-packet scattering states whose velocity supports stay disjoint after a relative spacelike translation a, with $a^2 > 0$ and $|a| \to \infty$. Then the full scattering matrix element factorizes:

$$\left\langle \Psi_A^{\mathrm{out}} \otimes U(a)\Psi_B^{\mathrm{out}}, S\, \Psi_A^{\mathrm{in}} \otimes U(a)\Psi_B^{\mathrm{in}} \right\rangle \longrightarrow \left\langle \Psi_A^{\mathrm{out}}, S\Psi_A^{\mathrm{in}} \right\rangle \left\langle \Psi_B^{\mathrm{out}}, S\Psi_B^{\mathrm{in}} \right\rangle.$$

Equivalently, the connected kernel $S^{\mathrm{c}}(\beta|\alpha)$ has no distributional component carrying separate momentum conservation for a proper subprocess; it carries only the total conservation law of the connected process.

Proof. Choose Haag–Ruelle approximants

$$\Psi_{A,T}^{\mathrm{out}} = A_T^{\mathrm{out}}\Omega, \qquad \Psi_{A,T}^{\mathrm{in}} = A_{-T}^{\mathrm{in}}\Omega, \qquad \Psi_{B,T}^{\mathrm{out}} = B_T^{\mathrm{out}}\Omega, \qquad \Psi_{B,T}^{\mathrm{in}} = B_{-T}^{\mathrm{in}}\Omega$$

for the four scattering states. The Haag–Ruelle theorem gives norm convergence as $T \to +\infty$ for the outgoing approximants and as $T \to +\infty$ for the incoming approximants written at time $-T$. Translation by $U(a)$ is unitary, so these norm errors are independent of the relative translation a. Hence, for every $\varepsilon > 0$, there exists T_ε such that for $T \geq T_\varepsilon$ the exact matrix element differs by at most ε, uniformly in a, from the finite-time expression

$$M_T(a) = \langle \Omega | (A_T^{\mathrm{out}})^* (B_T^{\mathrm{out}}(a))^* A_{-T}^{\mathrm{in}} B_{-T}^{\mathrm{in}}(a) | \Omega \rangle.$$

Almost-locality permits replacement of each approximant by a local operator localized in its Haag–Ruelle tube, with an error decreasing faster than any power of the tube size. For the fixed T chosen above, large spacelike a makes the A-tube spacelike separated from the translated B-tube. Local commutativity then orders the two groups, up to the almost-local tail estimate, into

$$M_T(a) = \langle \Omega | F_T G_T(a) | \Omega \rangle + O_N((1+|a|)^{-N}), \qquad F_T = (A_T^{\mathrm{out}})^* A_{-T}^{\mathrm{in}}, \quad G_T = (B_T^{\mathrm{out}})^* B_{-T}^{\mathrm{in}}.$$

Applying (24.4) gives

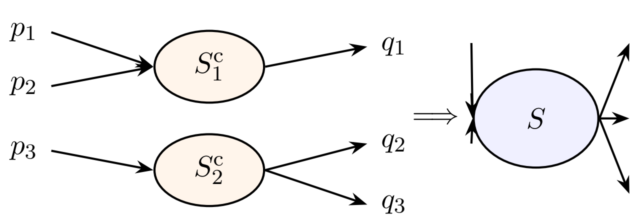
$$\lim_{|a| \to \infty} M_T(a) = \langle \Omega | F_T | \Omega \rangle \langle \Omega | G_T | \Omega \rangle.$$

Finally take $T \to \infty$ in the two factors. The same norm convergence gives

$$\langle \Omega | F_T | \Omega \rangle \longrightarrow \left\langle \Psi_A^{\mathrm{out}}, S\Psi_A^{\mathrm{in}} \right\rangle, \qquad \langle \Omega | G_T | \Omega \rangle \longrightarrow \left\langle \Psi_B^{\mathrm{out}}, S\Psi_B^{\mathrm{in}} \right\rangle.$$

Since ε was arbitrary, the scattering matrix element factorizes in the stated large-$|a|$ limit.

The kernel statement follows by testing the distributional kernel against wave packets whose velocity supports realize the two translated clusters. If the connected kernel contained a component with separate momentum conservation inside a proper subprocess, its wave-packet pairing would survive the large-separation limit as a product contribution. The recursion defining connected scattering kernels subtracts exactly those proper-subprocess products. Therefore only the total momentum-conservation delta distribution remains in S^{c}. $\square$



The same decomposition appears in connected Green functions. Since LSZ acts on external pole residues, it maps the connected part of a time-ordered Green function to the connected part of the scattering kernel with the same external labels.

24.6 Preparation for Analytic Structure

The object carried forward is the connected invariant amplitude

$$\mathcal{M}(q_1, \ldots, q_m | p_1, \ldots, p_n)$$

as a distributional boundary value on the physical mass shells. Bound states will appear as poles of this object in an appropriate channel. Resonances will appear as poles reached by analytic continuation through a continuum cut. Renormalization will be formulated as the construction of finite Green functions and finite amplitudes while preserving the local form of the counterterms.

For sectors with massless long-range forces, confinement, or infraparticle spectra, the asymptotic data require modified observables or modified state spaces. The later chapters return to those domains after the massive scattering and renormalization structures have been developed. In particular, one must not identify the charged electron labels used in perturbative QED hard kernels with exact on-shell LSZ external particles of massless QED. The ordinary LSZ formula requires an isolated charged one-particle pole; the QED infrared chapters instead construct resolution-inclusive probabilities and softly dressed charged asymptotic data.

Chapter 25

Bound States from Exchange Amplitudes

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\dots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

25.1 Exchange Model

Consider two real scalar fields in four spacetime dimensions with Lorentzian Lagrangian density

$$\mathcal{L} = -\frac{1}{2}\partial_\mu\phi_1\partial^\mu\phi_1 - \frac{1}{2}m_1^2\phi_1^2 - \frac{1}{2}\partial_\mu\phi_2\partial^\mu\phi_2 - \frac{1}{2}m_2^2\phi_2^2 - \frac{1}{2}g\phi_1^2\phi_2.$$

The masses m_1, m_2 are positive, and g is a real coupling. Use the same mostly-plus convention as before. The scalar propagators and cubic vertex are

$$\phi_i: \quad \frac{-\mathrm{i}}{k^2 + m_i^2 - \mathrm{i}0}, \qquad \phi_1\phi_1\phi_2: \quad -\mathrm{i}g.$$

This Lagrangian is used as a perturbative exchange model in the sense of Section 23.2. The pole criterion derived below is a statement about any exact massive local theory whose amplitude has the displayed analytic structure; the polynomial scalar density by itself is only the finite-cutoff or effective description from which the tree kernel is computed.

The connected $\phi_1\phi_1 \to \phi_1\phi_1$ tree amplitude receives s-, t-, and u-channel exchange contributions. The three routings and the solid/dashed line convention are fixed in Figure 25.1. With all external

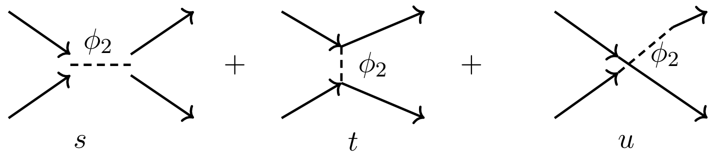


Figure 25.1: Tree exchange routings in the cubic scalar model. Solid directed lines are external ϕ_1 legs and the dashed internal line is the exchanged ϕ_2 field. The labels s, t, u specify which Mandelstam invariant flows through the internal denominator.

momenta on the ϕ_1 mass shell, define

$$s = -(k_1 + k_2)^2, \qquad t = -(k_1 - k_3)^2, \qquad u = -(k_1 - k_4)^2.$$

Here the metric is mostly plus, $k_i^2 = -m_1^2$, k_1, k_2 are incoming, and k_3, k_4 are outgoing, as in Definition 24.2. Momentum conservation gives the Mandelstam constraint

$$s + t + u = 4m_1^2.$$

The tree-level invariant amplitude is

$$\mathcal{M}_{\text{tree}}(s,t,u) = g^2 \left(\frac{1}{m_2^2 - s - \mathrm{i}0} + \frac{1}{m_2^2 - t - \mathrm{i}0} + \frac{1}{m_2^2 - u - \mathrm{i}0} \right).$$

In the center-of-mass frame for equal incoming masses m_1,

$$s = E^2, \qquad t = -\frac{E^2 - 4m_1^2}{2}(1 - z), \qquad u = -\frac{E^2 - 4m_1^2}{2}(1 + z),$$

where E is the total energy and $z = \cos\theta$. The two-ϕ_1 threshold is

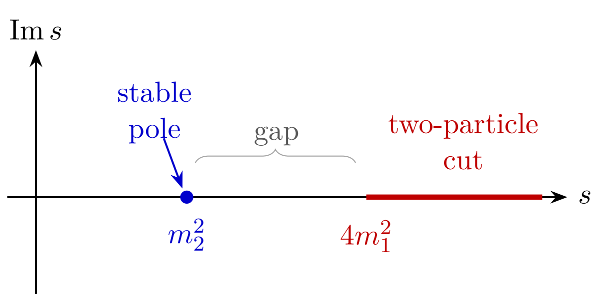
$$s = 4m_1^2.$$

25.2 Pole Below a Two-Particle Threshold

Assume

$$0 < m_2 < 2m_1.$$

Then the s-channel pole $s = m_2^2$ lies below the two-ϕ_1 threshold. It is outside the physical two-ϕ_1 scattering region $s \geq 4m_1^2$, but it is reached by analytic continuation in the invariant energy variable.



The scattering conclusion is precise: the two-ϕ_1 channel couples to a stable one-particle state of invariant mass m_2. In the present model that state is represented explicitly by the field ϕ_2. In a theory where no elementary field for that state is introduced, the same below-threshold pole is the scattering signature of a stable bound state. The pole criterion and the microscopic origin of the state are separate statements.

Definition 25.1 (Stable-channel sheets)**.** Fix a connected stable-channel scattering amplitude, with the identity term and the overall momentum-conservation delta function removed, and let s be the invariant energy variable for a two-particle channel whose threshold is s_{th}. The *first sheet*, or physical sheet, is the analytic germ reached from the Feynman boundary prescription whose physical value on the open two-particle interval is the upper-edge boundary value $\mathcal{M}^{\mathrm{I}}(s+\mathrm{i}0)$, $s > s_{\mathrm{th}}$. A real point below that threshold is on the first sheet when it is reached inside this same germ without crossing the threshold cut. Near an ordinary square-root threshold, one may use a local variable such as

$$\beta(s) = \sqrt{1 - \frac{s_{\mathrm{th}}}{s}},$$

with the branch fixed by $\beta(s+\mathrm{i}0) > 0$ on the physical interval. Continuing through the threshold cut to the adjacent germ changes the sign of this local square root. That adjacent germ is called the *second sheet* relative to the specified channel. With several open channels, a sheet is not specified by the word "second" alone: one must say which channel cuts have been crossed, or equivalently which local threshold variables have had their branches changed.

In this terminology, a stable bound state coupled to the channel appears as an isolated pole on the first sheet below the corresponding threshold. A resonance is instead a pole of an analytically continued stable-channel amplitude on an adjacent nonphysical sheet, not a pole of the physical real-axis boundary value. The resonance chapter constructs this second-sheet continuation explicitly in an exchange model, and the analyticity chapter later develops the same terminology for general $2 \to 2$ amplitudes.

Remark 25.2 (Existence is dynamical input)*.* The exchange model above contains the state at $s = m_2^2$ because the Lagrangian already contains the stable field ϕ_2 and the chosen masses place its pole below the two-ϕ_1 threshold. In a theory without such an elementary field, the existence of a below-threshold composite pole is a nonperturbative fact about the spectrum and the connected four-point function, requiring dynamical spectral input beyond locality, unitarity, and the local action. The rest of this chapter uses the conditional statement: if an isolated stable pole is present in a two-particle channel, then its position, spin, and factorized residue have the scattering consequences derived below. For a Bethe–Salpeter kernel, the corresponding converse requires the analytic Fredholm hypotheses stated later in Theorem 27.3; a below-threshold eigenvalue of an unspecified or truncated kernel is not, by itself, a theorem that the exact QFT contains a stable particle.

Remark 25.3 (Near-threshold and unitary-limit caveat)*.* The inequality $M_B < 2m_1$ is the physical location statement: the state lies below the two-particle continuum. The pole statement used in this chapter is stronger. It assumes an isolated one-particle spectral point of finite multiplicity, separated from the continuum and from other singularities by a nonzero gap, with nonzero overlap with the two-particle channel. Under those hypotheses the amplitude has a simple first-sheet pole and a factorized residue.

This hypothesis is not uniform as the binding energy tends to zero. In a two-body channel with equal masses, write the relative momentum by

$$s = 4(m_1^2 + k^2), \qquad k = \mathrm{i}\kappa, \qquad \kappa > 0$$

for a below-threshold bound state. The threshold is $k = 0$. The effective range expansion of an s-wave amplitude has the low-energy denominator

$$-a^{-1} + \frac{1}{2} r_e k^2 - \mathrm{i}k + \cdots,$$

so a shallow bound state has $\kappa \sim a^{-1}$ when the effective range is finite. As $a^{-1} \to 0^+$, the pole reaches the branch point at threshold: there is no fixed neighborhood of the pole disjoint from the two-particle cut, and the simple-pole expansion in the invariant s-plane ceases to be the right local description. Depending on the side of the continuation one may obtain a threshold bound state, a virtual state, or a resonance pole on another sheet. In three-body unitary physics, Efimov spectra give an even sharper warning: infinitely many poles may accumulate at threshold, so the isolated finite-rank pole hypothesis fails outright.

Near-threshold molecular states and unitary-limit systems therefore require a separate threshold expansion, usually in the momentum variable k and with the branch point kept explicit. The pole factorization below applies to an isolated stable bound state before this degeneration has occurred; it is not a claim that every attractive channel near threshold is described by a single simple pole in s.

Theorem 25.4 (Isolated spectral atom gives a first-sheet pole)**.** *Let $A(x)$ and $B(x)$ be local or smeared composite operators whose Fourier transforms carry the same conserved quantum numbers. Assume that, in the corresponding translation-invariant Hilbert space, the joint energy-momentum spectrum contains an isolated finite-multiplicity one-particle mass shell of mass M_B, with spectral projection Π_B, and that this shell is separated by a positive gap from the continuum in a neighborhood of total momentum P. Assume also that the matrix elements of A and B on this shell are nonzero, that their finite-rank product admits a holomorphic local off-shell extension in the complexified total momentum variables, and that the remaining spectral measure is locally finite across $P^2 = -M_B^2$. Then the Fourier transform of the connected time-ordered two-point function*

$$G_{AB}(P) = \int \mathrm{d}^4x \, \mathrm{e}^{-\mathrm{i}P\cdot x} \langle \Omega | \, \mathrm{T} \, A(x) B(0) | \Omega \rangle_{\mathrm{conn}}$$

has, in the mostly-plus Feynman convention of this volume, the local form

$$G_{AB}(P) = \frac{-\mathrm{i}\, R_{AB}(P)}{P^2 + M_B^2 - \mathrm{i}0} + G_{AB}^{\mathrm{reg}}(P), \tag{25.1}$$

where G_{AB}^{reg} is analytic in a sufficiently small first-sheet neighborhood of the pole. The numerator $R_{AB}(P)$ is any local holomorphic off-shell extension of the on-shell finite-rank matrix

$$R_{AB}(P) = \sum_{\lambda=1}^{d_B} \langle \Omega | A(0) | B, P, \lambda \rangle \langle B, P, \lambda | B(0) | \Omega \rangle. \tag{25.2}$$

defined for $P^2 = -M_B^2$, $P^0 > 0$. Here λ labels an orthonormal basis of the finite spin/internal degeneracy space of the isolated shell. The pole residue is independent of the chosen holomorphic off-shell extension; changing the extension changes only the analytic term in (25.1).

Proof. Let $U(a)$ be the translation representation and let $E(\mathrm{d}q)$ be the joint projection-valued spectral measure of its self-adjoint generators, in the mostly-plus convention $q^2 = -(q^0)^2 + |\vec{q}|^2$. Translation covariance gives

$$\langle\Omega|A(x)B(0)|\Omega\rangle = \int_{\overline{V}_+} \mathrm{e}^{\mathrm{i}q\cdot x}\,\mathrm{d}\mu_{AB}(q), \qquad \mathrm{d}\mu_{AB}(q) := \langle\Omega|A(0)E(\mathrm{d}q)B(0)|\Omega\rangle.$$

The connected subtraction removes only the vacuum atom at $q = 0$, so it does not affect a positive-mass shell with $M_B > 0$. On the isolated shell the spectral measure has the finite-rank form

$$\sum_\lambda \int \frac{\mathrm{d}^3\vec{p}}{(2\pi)^3\,2E_{\vec{p}}}\,\mathrm{e}^{\mathrm{i}p\cdot x}\langle\Omega|A(0)|B,p,\lambda\rangle\langle B,p,\lambda|B(0)|\Omega\rangle, \qquad E_{\vec{p}} = \sqrt{|\vec{p}|^2 + M_B^2}.$$

This is the restriction of $E(\mathrm{d}q)$ to the finite-dimensional range of Π_B, written in the standard covariant normalization of one-particle vectors.

The time-ordered distribution contributed by this shell is obtained by adding the reversed ordering for $x^0 < 0$. The scalar contour identity in the present convention is

$$\int \frac{\mathrm{d}P^0}{2\pi}\,\mathrm{e}^{-\mathrm{i}P^0 t}\frac{-\mathrm{i}}{P^2 + M_B^2 - \mathrm{i}0} = \frac{1}{2E_{\vec{P}}}\big[\theta(t)\mathrm{e}^{-\mathrm{i}E_{\vec{P}}t} + \theta(-t)\mathrm{e}^{\mathrm{i}E_{\vec{P}}t}\big], \qquad E_{\vec{P}} = (|\vec{P}|^2 + M_B^2)^{1/2}.$$

Indeed $P^2 + M_B^2 - \mathrm{i}0 = -((P^0)^2 - E_{\vec{P}}^2 + \mathrm{i}0)$, so the poles in the P^0-plane lie at $E_{\vec{P}} - \mathrm{i}0$ and $-E_{\vec{P}} + \mathrm{i}0$. Closing the contour below for $t > 0$ and above for $t < 0$ gives the two displayed boundary values. Fourier transformation of the shell part of the time-ordered correlator therefore gives

$$G^B_{AB}(P) = \frac{-\mathrm{i}\,R_{AB}(P)}{P^2 + M_B^2 - \mathrm{i}0}$$

in a neighborhood of the chosen shell, where the numerator is the finite sum of matrix elements displayed in (25.2). If R_{AB} is extended off the mass shell in two different holomorphic ways, their difference vanishes on the complex hypersurface $P^2 + M_B^2 = 0$. Since the differential of $P \mapsto P^2 + M_B^2$ is nonzero on the positive-energy mass shell, this function may be used as one local holomorphic coordinate. The difference of the two extensions is therefore $(P^2 + M_B^2)$ times a holomorphic function, and after division by the Feynman denominator it changes only the analytic remainder. The pole residue is the on-shell class.

It remains to check that the rest of the spectral measure cannot create a singularity at the same first-sheet point. By hypothesis there is a neighborhood $\mathcal{U}$ of the chosen real mass-shell point such that the support of $E(\mathrm{d}q)(1 - \Pi_B)$ is separated from $\{P \in \mathcal{U} : P^2 = -M_B^2,\ P^0 > 0\}$ by a positive spectral gap. For complex P in a smaller first-sheet neighborhood, the denominators arising from the contour representation of the time-ordered distribution are then bounded away from zero on this remaining support. Local finiteness of $\mathrm{d}\mu_{AB}$ permits differentiation under the spectral integral against compactly supported test functions, so the continuum contribution is holomorphic there. This holomorphic contribution, together with the off-shell-extension ambiguity just described, is G^{reg}_{AB}. □

Theorem 25.5 (LSZ factorization of an isolated bound-state pole)**.** *Consider a connected $2 \to 2$ amplitude between stable scalar external particles, and let $P = k_1 + k_2 = k_3 + k_4$ be the total momentum in the s-channel, $s = -P^2$. Assume the external one-particle LSZ hypotheses of Chapter 18, and assume that the connected four-point function has an isolated spectral atom of* *mass $M_B < 2m$ in this channel satisfying the hypotheses of Theorem 25.4. Then, in a first-sheet neighborhood of $s = M_B^2$ disjoint from the two-particle cut, the invariant amplitude has the factorized form*

$$\mathcal{M}_{fi}(s, z) = \frac{\sum_{\lambda=1}^{d_B} \Gamma_\lambda^{\text{out}}(k_3, k_4)\, \Gamma_\lambda^{\text{in}}(k_1, k_2)}{M_B^2 - s - \mathrm{i}0} + \mathcal{M}_{fi}^{\text{reg}}(s, z). \tag{25.3}$$

The functions $\Gamma_\lambda^{\text{in/out}}$ are the LSZ-amputated matrix elements coupling the two external particles to the one-particle vector $|B, P, \lambda\rangle$. They depend on the external channel, normalization of one-particle states, and finite choice of interpolating fields, but the pole position M_B^2, the finite-rank factorization, and the spin content of the residue are invariant scattering data.

Proof. Write the connected four-point function in the s-channel as a time-ordered two-point function of two composite channel operators. For test functions $f_{\text{in/out}}$ of compact support in the relative coordinates, define

$$A_{\text{out}}(X) = \int \mathrm{d}^4 r\, f_{\text{out}}(r)\, O_3\Big(X + \frac{r}{2}\Big)\, O_4\Big(X - \frac{r}{2}\Big),$$
$$A_{\text{in}}(Y) = \int \mathrm{d}^4 r\, f_{\text{in}}(r)\, O_1\Big(Y + \frac{r}{2}\Big)\, O_2\Big(Y - \frac{r}{2}\Big).$$

LSZ amputation is applied after the external one-particle Fourier variables are restored and the test functions are removed in the usual distributional order. Theorem 25.4 gives the isolated denominator $(P^2 + M_B^2 - \mathrm{i}0)^{-1}$ and a finite-rank residue equal to the product of matrix elements through the spectral projection Π_B.

The LSZ operation multiplies the four external legs by the inverse external two-point denominators and then puts each external momentum on the stable mass shell. By assumption the external LSZ residues are finite and nonzero, and M_B^2 is separated from the external one-particle poles and from the two-particle threshold. Thus LSZ changes only the numerator factors: it amputates the external legs in the two matrix elements and leaves the internal denominator $P^2 + M_B^2 - \mathrm{i}0 = M_B^2 - s - \mathrm{i}0$ untouched. The finite rank of Π_B gives the displayed sum over λ, and all remaining spectral contributions are regular in the chosen first-sheet neighborhood. □

25.3 One-Dimensional Pole Criterion as Orientation

The elementary one-dimensional Schrödinger model is useful here only as an orientation for the bound-state pole criterion. Its Hilbert-space conventions belong to the general discussion of continuous spectra in Section 5.2, and its unitary Schrödinger evolution is part of the quantum-mechanical setup of Chapter 7. The detailed one-dimensional analytic continuation, including outgoing resonance poles and the two-sheeted energy plane, is treated in Section 26.2.

For the present stable-bound-state purpose, take a short-range Hamiltonian

$$H = -\frac{1}{2\mu}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + V(x), \qquad E_{\text{nr}} = \frac{k^2}{2\mu},$$

with V real. After fixing the real-k scattering normalization, an outgoing solution has the asymptotic form

$$\psi_k^{\text{out}}(x) \sim S(k)^{-1} \mathrm{e}^{-\mathrm{i}kx} + \mathrm{e}^{\mathrm{i}kx} \qquad (x \to +\infty).$$

Analytic continuation to $k = \mathrm{i}\alpha$, $\alpha > 0$, gives

$$\psi_{\mathrm{i}\alpha}^{\mathrm{out}}(x) \sim S(\mathrm{i}\alpha)^{-1}\mathrm{e}^{\alpha x} + \mathrm{e}^{-\alpha x}.$$

An L^2 bound-state wave function cannot contain the growing term $\mathrm{e}^{\alpha x}$. Thus normalizability requires

$$S(\mathrm{i}\alpha)^{-1} = 0, \qquad E_{\mathrm{nr}} = -\frac{\alpha^2}{2\mu},$$

or equivalently a pole of $S(k)$ at $k = \mathrm{i}\alpha$ on the positive imaginary k-axis. In the relativistic amplitude this statement becomes: a stable bound state below a two-particle threshold appears as a first-sheet pole below the corresponding branch cut, with the sheet convention of Definition 25.1.

25.4 Partial Waves

For an equal-mass scalar elastic channel in four dimensions, write

$$z = \cos\theta, \qquad s = E^2.$$

The underlying partial waves are generalized two-particle asymptotic states. In the center-of-mass frame, with the δ-normalized sharp-momentum basis,

$$\langle \vec{k}_1, \vec{k}_2 | E, \vec{P} = \vec{0}, \ell, m_\ell\rangle_\delta = \delta^{(3)}(\vec{k}_1 + \vec{k}_2)\,\delta(\omega_1 + \omega_2 - E)\,\mathcal{N}(E) Y_{\ell m_\ell}(\widehat{k}_1),$$

where

$$\omega_i = \sqrt{|\vec{k}_i|^2 + m^2}, \qquad |\vec{k}_1| = |\vec{k}_2| = k, \qquad E = 2\sqrt{k^2 + m^2}.$$

For identical scalar bosons,

$$\mathcal{N}(E) = \left(\frac{2E}{k\,\omega_1\omega_2}\right)^{1/2}, \qquad \ell \in 2\mathbb{Z}_{\geq 0}.$$

For a distinguishable equal-mass pair, such as a charged scalar and its antiparticle, the factor of 2 under the square root is absent and both even and odd ℓ occur. The ordered-particle invariant amplitude below uses the 16π normalization fixed in Chapter 19; for an unordered identical-boson channel, the same physical information is obtained after Bose symmetrization and restriction to even partial waves, with the 32π normalization in Equation (29.2).

Rotational invariance diagonalizes the elastic single-channel matrix element,

$$|E, \ell, m_\ell\rangle^{\mathrm{in}} = S_\ell(E)|E, \ell, m_\ell\rangle^{\mathrm{out}} \quad \text{in the elastic sector.} \tag{25.4}$$

When additional channels with the same conserved quantum numbers are open, Equation (25.4) is the elastic component of a larger unitary matrix and gives $|S_\ell(E)| \leq 1$.

In the elastic region, define partial-wave amplitudes by

$$\mathcal{M}(s, z) = 16\pi \sum_{\ell=0}^{\infty} (2\ell + 1) a_\ell(s) P_\ell(z), \tag{25.5}$$

equivalently

$$a_\ell(s) = \frac{1}{32\pi}\int_{-1}^{1} \mathrm{d}z\, P_\ell(z)\mathcal{M}(s,z). \tag{25.6}$$

This is the ordered 16π convention fixed in Chapter 19; the coefficient $a_\ell(s)$ here is the same partial-wave amplitude used there. The letter a is deliberate: M_δ remains reserved for the $\delta^{(d)}$-normalized sharp-momentum kernel of Chapter 19, whereas a_ℓ is a scalar coordinate of the invariant amplitude in a fixed angular-momentum channel. The elastic partial-wave S-matrix eigenvalue is written

$$S_\ell(s) = 1 + 2\mathrm{i}\,\beta(s)a_\ell(s), \qquad \beta(s) = \sqrt{1-\frac{4m^2}{s}},$$

with the branch chosen by $\beta(s) > 0$ for $s > 4m^2$. Elastic unitarity is

$$|S_\ell(s)| = 1$$

on the physical elastic interval.

Spin from the angular residue. Let the external particles be spinless and work in the center-of-mass frame. Suppose the isolated bound-state shell in Theorem 25.5 transforms as an irreducible spin-J representation of spatial rotations and that the channel coupling is rotationally covariant. Then the pole residue in the scalar $2 \to 2$ amplitude is proportional to $P_J(z)$, with $z = \widehat{k}_{\mathrm{out}} \cdot \widehat{k}_{\mathrm{in}}$, and only the partial wave $\ell = J$ contains the simple pole. More precisely,

$$\sum_{m=-J}^{J} \Gamma^{\mathrm{out}}_{Jm}(\widehat{k}_{\mathrm{out}})\Gamma^{\mathrm{in}}_{Jm}(\widehat{k}_{\mathrm{in}}) = g_{\mathrm{out}}g_{\mathrm{in}}\,\frac{2J+1}{4\pi}\,P_J(\widehat{k}_{\mathrm{out}}\cdot\widehat{k}_{\mathrm{in}}) \tag{25.7}$$

after the conventional normalization of spherical harmonics is absorbed into the constants $g_{\mathrm{in/out}}$. For spinless external particles, the angular dependence of a coupling to a spin-J intermediate state is an intertwiner from functions on the sphere to the spin-J representation. Rotational covariance fixes this intertwiner, up to an overall constant, to the spherical harmonics

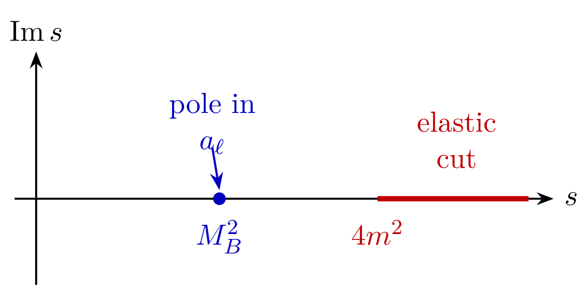
$$\Gamma^{\mathrm{in}}_{Jm}(\widehat{k}) = g_{\mathrm{in}}Y_{Jm}(\widehat{k}), \qquad \Gamma^{\mathrm{out}}_{Jm}(\widehat{k}) = g_{\mathrm{out}}\overline{Y_{Jm}(\widehat{k})}$$

with the conjugation convention determined by in/out orientation. Summing over the magnetic quantum number and using the spherical-harmonic addition theorem gives (25.7). Orthogonality of Legendre polynomials in (25.6) then projects this residue only onto the $\ell = J$ partial wave.

A stable spin-ℓ state of mass $M_B < 2m$ coupled to the two-particle channel therefore gives

$$a_\ell(s) = \frac{r_\ell}{M_B^2 - s} + \text{regular terms},$$

where the residue r_ℓ is determined by the squared coupling of the state to the two-particle channel with angular momentum ℓ.



For the exchange model, the s-channel term is independent of z. Its below-threshold pole therefore appears in the $\ell = 0$ partial wave. Higher spin bound states arise when the pole residue has the angular dependence of $P_\ell(z)$, or more generally the corresponding spin-ℓ tensor structure.

The spin carried by a channel pole can be read directly from this angular dependence. As an algebraic illustration, consider the numerator structure of scalar QED, developed later in the gauge-theory chapters; here only the Lorentz-contracted photon-exchange numerator is used, not the full gauge theory. The charged scalar-antiscalar annihilation channel has an s-channel exchange numerator proportional to

$$(p_1 - p_2)^\mu (p_3 - p_4)_\mu.$$

In the center-of-mass frame this numerator is

$$4k^2 \cos\theta = 4k^2 P_1(\cos\theta),$$

up to the overall sign fixed by momentum routing and metric conventions. The massless pole is therefore an $\ell = 1$ pole in this channel. The invariant statement is the pole position and spin-one residue in the scalar-antiscalar scattering amplitude; the microscopic description of the corresponding one-particle state is additional data of the theory.

25.5 Operator Interpretation

Let $O_B(x)$ be a local or suitably smeared composite operator with nonzero overlap with a stable state B,

$$\langle \Omega | O_B(0) | B(P) \rangle \neq 0, \qquad P^2 = -M_B^2.$$

Then the spectral representation of a two-point function of O_B contains an atom at M_B^2. The same state appears in four-point functions through a factorizing pole. For external operators O_1, O_2, O_3, O_4, and P the momentum flowing through the channel,

$$\widetilde{G}_4(P; \cdots) \sim \frac{\langle \Omega | O_3 O_4 | B(P) \rangle \langle B(P) | O_1 O_2 | \Omega \rangle}{P^2 + M_B^2 - \mathrm{i}0} + \text{regular terms}.$$

After LSZ reduction on the external stable particles, this factorization becomes the bound-state pole of the scattering amplitude.

The particle content of a theory is therefore read from spectral and asymptotic data. A field appearing in a Lagrangian can interpolate a stable state, and a composite operator can interpolate a stable state. The analytic pole and its residue state the channel coupling; additional structural data state how the corresponding state is represented inside the theory.

Chapter 26

Resonances and Dressed Propagators

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-,+,\ldots,+)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

26.1 Above-Threshold Exchange

Continue the two-scalar model of the preceding chapter,

$$\mathcal{L} = -\frac{1}{2}\partial_\mu\phi_1\partial^\mu\phi_1 - \frac{1}{2}m_1^2\phi_1^2 - \frac{1}{2}\partial_\mu\phi_2\partial^\mu\phi_2 - \frac{1}{2}m_2^2\phi_2^2 - \frac{1}{2}g\phi_1^2\phi_2,$$

with $m_1, m_2 > 0$ and $g \in \mathbb{R}$.

Definition 26.1 (Above-threshold scalar exchange datum)**.** The above-threshold exchange datum consists of the preceding two-scalar local Lagrangian, stable external ϕ_1 one-particle states, the mass inequality

$$m_2 > 2m_1,$$

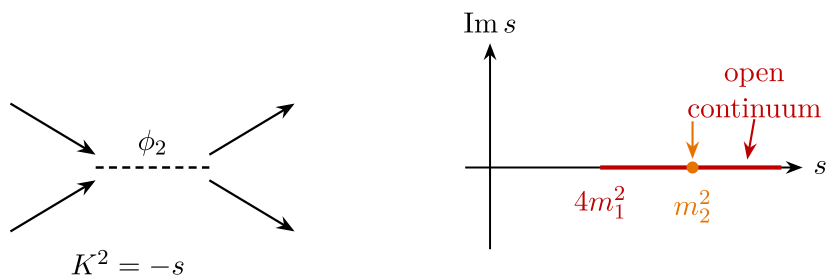
and the mostly-plus Mandelstam invariant

$$K = k_1 + k_2, \qquad s = -K^2,$$

where k_1, k_2 are the incoming ϕ_1 momenta, in the convention of Definition 24.2. The s-channel tree contribution to the connected invariant amplitude is

$$\mathcal{M}_s^{\mathrm{tree}}(s) = \frac{g^2}{m_2^2 - s - \mathrm{i}0}.$$

For the datum of Definition 26.1, the value $s = m_2^2$ lies in the two-ϕ_1 scattering region $s \geq 4m_1^2$. The relevant scattering problem is therefore a problem with stable external ϕ_1 states and an open two-particle continuum in the same channel as the exchanged ϕ_2 line. The exact physical-axis S-matrix is a bounded unitary boundary value; the pole suggested by the tree graph is the lowest-order expansion of an analytic structure reorganized by the exact two-point function of ϕ_2.



The partial-wave normalization used below is the unordered identical-boson convention for the physical $\phi_1\phi_1 \to \phi_1\phi_1$ channel:

$$\mathcal{M}(s, z) = 32\pi \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)a_\ell(s)P_\ell(z), \qquad z = \cos\theta, \tag{26.1}$$

This is the 32π, even-ℓ convention of Equation (29.2). The ordered 16π convention may still be used as an intermediate labelled-leg bookkeeping device, but the elastic S_ℓ below acts on the symmetric two-ϕ_1 Hilbert-space channel, so the physical partial-wave coordinate is a_ℓ. In an elastic one-channel interval,

$$S_\ell(s) = 1 + 2\mathrm{i}\,\rho_1(s)a_\ell(s), \qquad \rho_1(s) = \sqrt{1 - \frac{4m_1^2}{s}}. \tag{26.2}$$

The branch of ρ_1 is chosen by $\rho_1(s) > 0$ for $s > 4m_1^2$ on the physical upper boundary of the first sheet, in the terminology of Definition 25.1. Elastic unitarity gives

$$|S_\ell(s)| = 1. \tag{26.3}$$

With inelastic channels included on the same Hilbert space, the elastic matrix element instead obeys $|S_\ell(s)| \leq 1$. Thus the exact physical-axis partial wave is finite. The divergence of $\mathcal{M}_s^{\text{tree}}$ at $s = m_2^2$ records that the perturbative description has expanded around a stable reference line in a region where the state couples to an open decay channel. The exact object is a resonance: a nearby pole of the continuation of $S_\ell(s)$, or equivalently of $a_\ell(s)$, through the threshold cut. On the physical sheet the same channel is represented by the continuum part of the spectral measure; an isolated real mass atom occurs only for a stable one-particle state.

Physical-axis boundedness and resonance-sheet location. Let $I \subset (4m_1^2, \infty)$ be an elastic interval away from the threshold endpoint, and assume that the exact stable-channel partial-wave boundary value exists on I. If $S_\ell(s)$ is unitary on I, or if it is the elastic matrix element of a larger unitary channel matrix, then

$$|a_\ell(s)| \leq \frac{1}{\rho_1(s)} \qquad (s \in I).$$

Consequently a resonance associated with this channel is not a pole of the physical upper-edge boundary value $a_\ell(s+\mathrm{i}0)$. It is a pole of the analytic continuation through the channel cut.

Indeed, Equation (26.2) gives

$$a_\ell(s) = \frac{S_\ell(s)-1}{2\mathrm{i}\rho_1(s)}.$$

On I, $\rho_1(s) > 0$. If S_ℓ is elastic unitary, then $|S_\ell| = 1$, while if it is the elastic component of a larger unitary matrix, then $|S_\ell| \le 1$. In both cases

$$|a_\ell(s)| \le \frac{|S_\ell(s)|+1}{2\rho_1(s)} \le \frac{1}{\rho_1(s)}.$$

The bound is finite on compact subintervals away from threshold. Hence a simple divergence on the physical boundary is incompatible with exact stable-channel unitarity; the tree pole is a perturbative signal of a nearby singularity on an analytically continued sheet, not a physical-axis pole.

26.2 Outgoing Poles in a One-Dimensional Model

This section is the detailed one-dimensional model promised in Section 25.3. It extends the bound-state pole criterion to outgoing resonance poles; the underlying Hilbert-space interpretation of generalized scattering states is the one fixed in Section 5.2. Let

$$H = -\frac{1}{2\mu}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + V(x),$$

where V is real and short range. For $x \to +\infty$, use the outgoing solution

$$\psi_k^{\mathrm{out}}(x,t) \sim S(k)^{-1}\mathrm{e}^{-\mathrm{i}kx-\mathrm{i}Et} + \mathrm{e}^{\mathrm{i}kx-\mathrm{i}Et}, \qquad E = \frac{k^2}{2\mu}.$$

Definition 26.2 (Outgoing one-dimensional resonance pole)**.** For the one-dimensional short-range Hamiltonian above, an outgoing resonance pole is a pole k_* of the meromorphic continuation of $S(k)$ with

$$\operatorname{Re} k_* > 0, \qquad \operatorname{Im} k_* < 0,$$

for which the corresponding continued solution satisfies the outgoing boundary condition at spatial infinity. Its complex energy is

$$E_* = \frac{k_*^2}{2\mu}.$$

If $S(k)$ has a pole at $k = k_*$, then the incoming coefficient vanishes at that analytically continued value and the asymptotic solution is purely outgoing. Write

$$E_* = \frac{k_*^2}{2\mu} = \omega - \mathrm{i}\gamma, \qquad \gamma > 0.$$

Then

$$\psi_{k_*}^{\mathrm{out}}(x,t) \sim \mathrm{e}^{\mathrm{i}k_*x-\mathrm{i}\omega t-\gamma t}.$$

The negative imaginary part of E_* is the exponential decay rate of the time dependence. The same wave grows in space along the outgoing direction. This spatial growth is forced by probability conservation for a state with only outgoing flux: a uniformly decaying packet cannot also be a normalizable stationary eigenvector of a self-adjoint Hamiltonian. The pole therefore defines a singular outgoing functional, a resonance or Gamow functional, associated with the analytically continued scattering function.

At a simple pole of $S(k)$, the coefficient $S(k)^{-1}$ of the incoming wave in the displayed outgoing solution vanishes. The continued asymptotic solution is therefore proportional to $\exp(\mathrm{i}k_*x - \mathrm{i}E_*t)$. Write

$$k_* = a - \mathrm{i}b, \qquad a > 0, \quad b > 0.$$

Then

$$E_* = \frac{a^2 - b^2}{2\mu} - \mathrm{i}\frac{ab}{\mu} = \omega - \mathrm{i}\gamma, \qquad \gamma = \frac{ab}{\mu} > 0.$$

The time factor is $\exp(-\mathrm{i}\omega t)\exp(-\gamma t)$, while the spatial factor for $x \to +\infty$ contains $\exp(bx)$. Thus the same analytic continuation that gives decay for $t > 0$ gives exponential growth in the outgoing spatial direction. Such a function is not in $L^2(\mathbb{R})$, so it is not an eigenvector of the self-adjoint Hamiltonian on the Hilbert space.

The spatial growth and temporal decay described above are summarized in Figure 26.1.

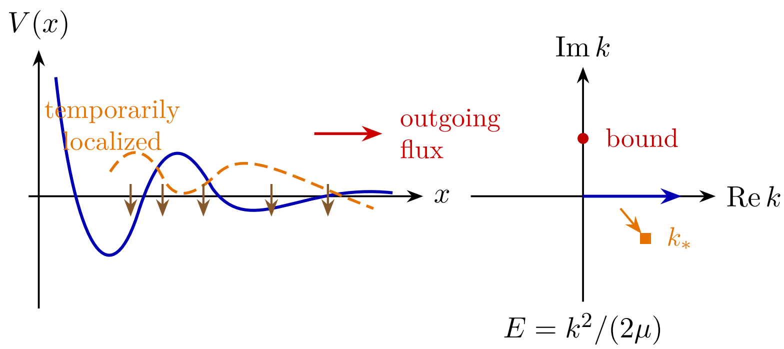


Figure 26.1: Outgoing Gamow behavior and the k-plane location of poles in the one-dimensional resonance model. The dashed packet in the left panel marks temporary localization and the arrow marks outward flux. In the right panel a circular marker denotes a bound-state pole on the positive imaginary k-axis, while a square marker denotes a resonance pole with $\mathrm{Im}\, k_* < 0$.

Because $E = k^2/(2\mu)$, the energy plane is a two-sheeted cover of the k-plane. Bound-state poles lie on the positive imaginary k-axis and map to negative real energies on the physical sheet. Resonance poles with $\mathrm{Re}\, k_* > 0$ and $\mathrm{Im}\, k_* < 0$ map to complex energies below the positive real axis on the sheet reached by continuing through the scattering cut. The continuation through the cut is shown explicitly in Figure 26.2.

26.3 The Dressed Propagator

Return to the relativistic exchange model.

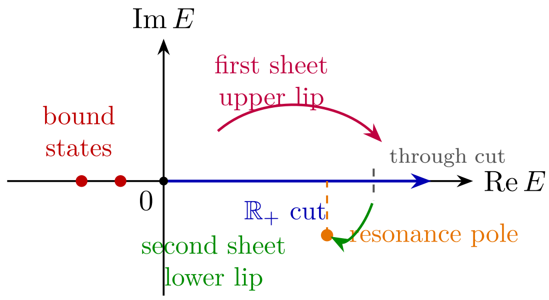

Figure 26.2: Energy-plane branch structure for a resonance pole. The first sheet is reached from the upper edge of the positive real cut; crossing the cut gives the second-sheet lower-edge branch on which the resonance pole appears.

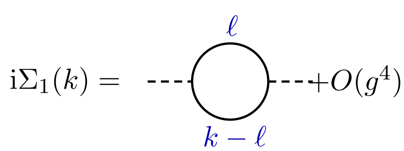
Definition 26.3 (Dressed propagator and self-energy convention)**.** The exact time-ordered two-point function of ϕ_2 in momentum space is

$$D_2(k) = \int \mathrm{d}^4x\, \mathrm{e}^{-\mathrm{i}k\cdot x} \langle \Omega | T\phi_2(x)\phi_2(0)|\Omega\rangle.$$

Let $\Sigma(k)$ be the sum of amputated one-particle-irreducible two-point insertions for the ϕ_2 line, with the convention

$$D_2(k) = \frac{-\mathrm{i}}{k^2 + m_{2,\Lambda}^2 - \mathrm{i}0 - \Sigma(k)}.$$

This is the geometric series obtained by inserting 1PI two-point kernels into the regulated reference propagator.



At one loop,

$$\mathrm{i}\Sigma_1(k) = \frac{(-\mathrm{i}g)^2}{2} \int \frac{\mathrm{d}^D\ell}{(2\pi)^D} \frac{-\mathrm{i}}{\ell^2 + m_1^2 - \mathrm{i}0} \frac{-\mathrm{i}}{(k-\ell)^2 + m_1^2 - \mathrm{i}0}.$$

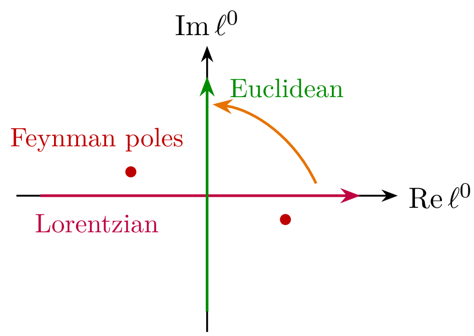
The factor $1/2$ is the symmetry factor for the two identical ϕ_1 lines in the loop. Combining denominators gives

$$\mathrm{i}\Sigma_1(k) = \frac{g^2}{2} \int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^D\ell}{(2\pi)^D} \frac{1}{\left[\ell^2(1-x) + (k-\ell)^2 x + m_1^2 - \mathrm{i}0\right]^2}.$$

Shift $\ell^\mu \mapsto \ell^\mu + xk^\mu$, then rotate the shifted energy contour according to the Feynman prescription. The Euclidean expression is

$$\mathrm{i}\Sigma_1(k) = \mathrm{i}\frac{g^2}{2} \int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^D\ell_E}{(2\pi)^D} \frac{1}{\left[\ell_E^2 + k^2x(1-x) + m_1^2\right]^2}.$$

The rotation is a contour statement, not a change of notation: for the shifted loop variable the pole displacements prescribed by $-\mathrm{i}0$ leave a sector through which the ℓ^0-contour can be moved to the Euclidean axis without crossing singularities. After the contour has been rotated, the Euclidean denominator is an ordinary real denominator. Its boundary value on a timelike cut is obtained by analytically continuing the resulting function with the original Feynman prescription; it is not encoded by leaving a residual $-\mathrm{i}0$ in the Euclidean integrand. When the answer is later written as a Lorentzian boundary value, a notation such as $k^2x(1-x)+m_1^2-\mathrm{i}0$, or $1-sx(1-x)/m_1^2-\mathrm{i}0$ with $k^2=-s$, refers to the boundary-value choice of the external invariant k^2 only. It is not a pole prescription for the already rotated Euclidean loop variable ℓ_E.



In four dimensions, with a Euclidean cutoff $|\ell_E|<\Lambda$ and with k in the domain reached by the contour rotation,

$$\Sigma_1(k)=\frac{g^2}{32\pi^2}\int_0^1 \mathrm{d}x\left[\log\frac{\Lambda^2}{k^2x(1-x)+m_1^2}-1+O(\Lambda^{-2})\right].$$

The divergent part is independent of k. Introduce

$$m_{2,\Lambda}^2=(m_2^R)^2+\delta m_2^2,\qquad \Sigma_1(k)=\Sigma_1^R(k)+\delta m_2^2,$$

where the counterterm cancels the cutoff-dependent constant. One convenient subtraction is

$$\Sigma_1^R(k)=-\frac{g^2}{32\pi^2}\int_0^1 \mathrm{d}x\,\log\frac{k^2x(1-x)+m_1^2}{m_1^2}.$$

This is first an analytic function on the Euclidean side of the cut. The physical boundary value is specified only after the external invariant is continued to a timelike value.

26.4 The Threshold Cut and the Cut Width

For the s-channel exchange, $k=K=k_1+k_2$ and $K^2=-s$. The dressed contribution is

$$\mathcal{M}_s(s)=\frac{g^2}{F(s)},\qquad F(s)=-s+(m_2^R)^2-\mathrm{i}0-\Sigma_1^R(K).$$

Equivalently,

$$F(s)=-s+(m_2^R)^2-\mathrm{i}0+\frac{g^2}{32\pi^2}\int_0^1 \mathrm{d}x\,\log\left[1-\frac{s\,x(1-x)}{m_1^2}-\mathrm{i}0\right].$$

Since

$$0 \le x(1-x) \le \frac{1}{4},$$

the logarithm develops a discontinuity precisely for

$$s \ge 4m_1^2.$$

For real $s > 4m_1^2$, define

$$\rho_1(s) = \sqrt{1 - \frac{4m_1^2}{s}}, \qquad x_\pm = \frac{1}{2}\left(1 \pm \rho_1(s)\right).$$

The argument of the logarithm is negative for $x \in [x_-, x_+]$. On the physical upper boundary the prescription gives

$$\log(-|a| - \mathrm{i}0) = \log|a| - \mathrm{i}\pi,$$

and therefore

$$\operatorname{Im} \Sigma_1^R(K)\big|_{s+\mathrm{i}0} = \frac{g^2}{32\pi}\rho_1(s).$$

This boundary value is fixed by the same Wick-rotation prescription that relates the Euclidean Green function to the Lorentzian time-ordered Green function. For real positive energy above the two-particle threshold, k^0 is reached by analytic continuation from the imaginary k^0-axis to the positive real axis through the upper half-plane.

Threshold discontinuity of the one-loop self-energy. For $s > 4m_1^2$, with the physical upper-edge boundary value specified above,

$$\operatorname{Im} \Sigma_1^R(K)\big|_{K^2=-s+\mathrm{i}0} = \frac{g^2}{32\pi}\rho_1(s), \qquad \rho_1(s) = \sqrt{1 - \frac{4m_1^2}{s}}.$$

Equivalently, the imaginary part of the dressed inverse denominator on the first sheet is

$$\operatorname{Im} F_{\mathrm{I}}(s + \mathrm{i}0) = -\frac{g^2}{32\pi}\rho_1(s) + O(0^+).$$

The logarithm in $F(s)$ is

$$\log\left[1 - \frac{s\,x(1-x)}{m_1^2} - \mathrm{i}0\right].$$

Its argument is negative precisely when $x \in [x_-, x_+]$, where

$$x_\pm = \frac{1}{2}(1 \pm \rho_1(s)).$$

The interval length is $x_+ - x_- = \rho_1(s)$. On the physical upper edge,

$$\log(-|a| - \mathrm{i}0) = \log|a| - \mathrm{i}\pi.$$

Since

$$\Sigma_1^R(K) = -\frac{g^2}{32\pi^2}\int_0^1 \mathrm{d}x\, \log\left[1 - \frac{s\,x(1-x)}{m_1^2} - \mathrm{i}0\right],$$

the imaginary part is

$$-\frac{g^2}{32\pi^2}(-\pi)\,(x_+ - x_-) = \frac{g^2}{32\pi}\rho_1(s).$$

The denominator $F_{\mathrm{I}} = m_R^2 - s - \mathrm{i}0 - \Sigma_1^R$ therefore has the opposite imaginary part, up to the infinitesimal boundary prescription.

Figure 26.3 records the two analytic continuations used in the self-energy computation: the k^0 contour deformation and the corresponding discontinuity across the s-channel cut.

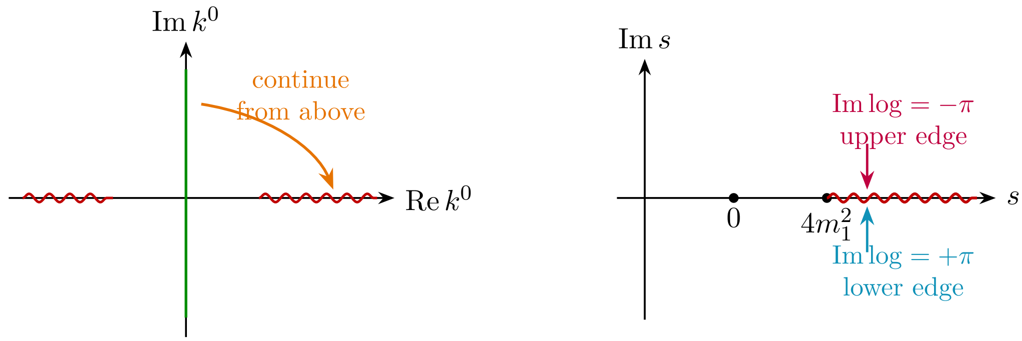


Figure 26.3: Cut continuation for the one-loop self-energy. The left panel shows the k^0 continuation from the upper edge past the on-shell singularities. The right panel records the sign convention for the logarithm on the two sides of the s-channel cut beginning at $4m_1^2$.

Choose a real resonance mass parameter M_R by the condition that the real part of the denominator vanishes at $s = M_R^2$,

$$\operatorname{Re} F(M_R^2 + \mathrm{i}0) = 0.$$

At weak coupling, and to leading order in the variation of the real part of Σ_1^R, the amplitude near this point is

$$\mathcal{M}_s(s) \simeq \frac{g^2}{M_R^2 - s - \mathrm{i}M_R\Gamma_{\mathrm{cut}}(M_R)},$$

where

$$M_R\Gamma_{\mathrm{cut}}(M_R) = \frac{g^2}{32\pi}\sqrt{1 - \frac{4m_1^2}{M_R^2}} + O(g^4).$$

The subscript “cut” is deliberate. The number above is extracted from the absorptive part of the two-point function on the physical cut. It is the quantity computed by the inclusive cut, or Fermi golden rule, calculation at the real energy M_R. The underlying discontinuity is the two-point specialization of Hilbert-space unitarity; the line-replacement calculation is its perturbative expansion, in the sense explained in Remark 28.18. It is not, by itself, a definition of every resonance width.

26.5 Width Parameters and Their Comparison

There are several operationally different quantities that are often denoted by the same letter Γ. In a narrow isolated resonance they agree to the order at which the local Breit–Wigner approximation is meaningful, but their definitions are distinct.

Definition 26.4 (Width coordinates for an isolated resonance)**.** Let a stable-channel amplitude have an isolated simple resonance pole s_* on a specified nonphysical sheet, and assume that a real energy window containing the corresponding line shape has been fixed. The following four quantities are different coordinates on different data.

1. The cut width $\Gamma_{\text{cut}}(M)$ is defined at a real energy M by the inclusive transition rate obtained from the discontinuity of the self-energy at that real energy. For a scalar resonance coupled to stable final channels X, the perturbative expression has the form

$$\Gamma_{\text{cut}}(M) = \frac{1}{2M}\sum_X \int \mathrm{d}\Phi_X(P)\ |\mathcal{A}(R(P)\to X)|^2, \qquad P^2 = -M^2, \quad P^0 > 0,$$

with the symmetry factors included in the invariant phase-space measure $\mathrm{d}\Phi_X(P)$ and in the amplitude $\mathcal{A}$. This formula should be read as a weak-coupling construction using the stable state R of the decoupled or lower-order theory as an interpolating state. Once the channel is open, the exact theory has stable asymptotic states in the final channels, not an exact external one-resonance state.

2. The line-shape width Γ_{line} is an observable extracted from a specified physical inclusive cross section or event distribution. After a specified smooth background subtraction and a specified resolution function, one may define it as the full width at half maximum in the energy variable $E = \sqrt{s}$ of the resonant contribution. This definition depends on the chosen process, on the observable used to form the inclusive distribution, and on how nonresonant background is separated from the pole term. It is therefore not an invariant analytic datum for a broad resonance.

3. The Gamow time width, or complex-energy pole width, is defined from the second-sheet pole after choosing an energy square root. If s_* is a simple resonance pole and the square-root branch is chosen so that $\mathrm{Re}\sqrt{s_*} > 0$ near the resonance, write

$$E_* = \sqrt{s_*} = M_{\text{pole}} - \frac{\mathrm{i}}{2}\Gamma_{\text{pole}}, \qquad M_{\text{pole}} > 0, \quad \Gamma_{\text{pole}} > 0.$$

Equivalently,

$$s_* = M_{\text{pole}}^2 - \mathrm{i}M_{\text{pole}}\Gamma_{\text{pole}} - \frac{1}{4}\Gamma_{\text{pole}}^2.$$

This definition is independent of a particular production process once the pole and sheet have been specified. The associated outgoing Gamow functional evolves as

$$\mathrm{e}^{-\mathrm{i}E_* t} = \mathrm{e}^{-\mathrm{i}M_{\text{pole}}t}\,\mathrm{e}^{-\Gamma_{\text{pole}}t/2},$$

so its probability norm, in the formal Gamow description, decays as $\mathrm{e}^{-\Gamma_{\text{pole}}t}$. This is the time-decay width of the pole functional. The statement concerns the pole contribution in the rigged-Hilbert analytic continuation; an exact normalizable state in a self-adjoint Hamiltonian does not have a purely exponential survival law for all times.

4. The s-plane pole-imaginary width is defined by

$$M_s = \sqrt{\mathrm{Re}\, s_*}, \qquad \Gamma_s = -\frac{\mathrm{Im}\, s_*}{M_s}.$$

This convention uses the imaginary part of the pole in the s-plane rather than the imaginary part of the energy $E = \sqrt{s}$. It agrees with Γ_{pole} only up to the kinematic conversion

$$\Gamma_s = \Gamma_{\text{pole}} \left[1 + O\left(\frac{\Gamma_{\text{pole}}^2}{M_{\text{pole}}^2} \right) \right].$$

Controlled Approximation 26.5 (Narrow-resonance comparison of widths)**.** Suppose that, in the energy window $|E - M_{\text{pole}}| = O(\Gamma_{\text{pole}})$, the continued stable-channel amplitude is dominated by a single simple pole, the residue and the nonresonant background are holomorphic and vary only on a scale of order M_{pole}, and the pole is separated from thresholds and other singularities by a squared-mass distance much larger than $M_{\text{pole}}\Gamma_{\text{pole}}$. Then the ideal resonant line shape obtained from the pole term, with the smooth residue replaced by its value at the pole and with the smooth background removed, has

$$\Gamma_{\text{line}} = \Gamma_{\text{pole}} \left[1 + O\left(\frac{\Gamma_{\text{pole}}^2}{M_{\text{pole}}^2} \right) \right],$$

as follows. Keeping only the pole term and writing $E = M_{\text{pole}} + x$,

$$|s_* - E^2|^2 = \left(2M_{\text{pole}}x + x^2 + \frac{1}{4}\Gamma_{\text{pole}}^2 \right)^2 + M_{\text{pole}}^2 \Gamma_{\text{pole}}^2.$$

The half-maximum points of the pole term, measured in the energy variable, are therefore

$$x_{\pm} = \pm\frac{1}{2}\Gamma_{\text{pole}} - \frac{1}{4M_{\text{pole}}}\Gamma_{\text{pole}}^2 + O\left(\frac{\Gamma_{\text{pole}}^3}{M_{\text{pole}}^2} \right),$$

so $x_+ - x_- = \Gamma_{\text{pole}}[1 + O(\Gamma_{\text{pole}}^2/M_{\text{pole}}^2)]$. The common shift of the two half-maximum points records that the peak in E is not centered exactly at M_{pole} once the quadratic relation $s = E^2$ is retained. If the residue, phase space, detector resolution, or subtracted background varies appreciably over the same energy interval, the measured line-shape width receives additional process-dependent corrections. That is precisely why Γ_{line} is not an invariant analytic datum for a broad resonance.

The cut calculation at the real resonance energy gives

$$M_{\text{pole}}\Gamma_{\text{pole}} = M_R \Gamma_{\text{cut}}(M_R) + O(g^4)$$

in the weak-coupling scalar model above. Indeed, on the second sheet the discontinuity computation gives

$$F_{\text{II}}(M_R^2) = -\mathrm{i} M_R \Gamma_{\text{cut}}(M_R) + O(g^4), \qquad F'_{\text{II}}(M_R^2) = -1 + O(g^2).$$

Solving $F_{\text{II}}(s_*) = 0$ by one Newton step therefore gives

$$s_* - M_R^2 = -\mathrm{i} M_R \Gamma_{\text{cut}}(M_R) + O(g^4).$$

Thus the common symbol Γ_R is justified only after these hypotheses and approximations have been stated. For a broad resonance, for an overlapping pair of poles, or near a threshold branch point, Γ_{line}, Γ_{cut}, Γ_{pole}, and Γ_s need not coincide.

26.6 Elastic Phase Motion

The preceding weak-coupling discussion defines a single-channel elastic resonance model after three choices have been made: retain the resonant s-channel exchange, discard smooth background and crossed-channel pieces, and replace the absorptive part by the width function

$$W(s) = \frac{g^2}{32\pi}\rho_1(s)$$

on the elastic real interval. These choices are the approximation. Once they have been made, the corresponding Breit–Wigner elastic S-matrix element is a definite rational function and its elastic unitarity is exact in the model.

Only the $\ell = 0$ partial wave carries the retained scalar exchange. Since the resonant s-channel term is independent of z, Equation (26.1) gives

$$a_0^{(s)}(s) = \frac{\mathcal{M}_s(s)}{32\pi}, \qquad S_0(s) - 1 = 2\mathrm{i}\rho_1(s)a_0^{(s)}(s) = \frac{\mathrm{i}\rho_1(s)}{16\pi}\mathcal{M}_s(s).$$

Equivalently,

$$\mathcal{M}_s(s) = -16\pi\mathrm{i}\sqrt{\frac{s}{s-4m_1^2}}\,\big(S_0(s) - 1\big),$$

for the angle-independent elastic partial wave in this normalization. The Breit–Wigner elastic approximant is therefore

$$S_0^{\mathrm{BW}}(s) := 1 + \frac{\mathrm{i}\rho_1(s)}{16\pi}\frac{g^2}{M_R^2 - s - \mathrm{i}W(s)} = \frac{M_R^2 - s + \mathrm{i}W(s)}{M_R^2 - s - \mathrm{i}W(s)}, \qquad W(s) = \frac{g^2}{32\pi}\rho_1(s).$$

Elastic unitarity of the Breit–Wigner factor. On a real interval where only the elastic $\phi_1\phi_1$ channel is retained and $W(s) \in \mathbb{R}$, the model S-matrix element

$$S_0^{\mathrm{BW}}(s) = \frac{M_R^2 - s + \mathrm{i}W(s)}{M_R^2 - s - \mathrm{i}W(s)}$$

obeys

$$|S_0^{\mathrm{BW}}(s)| = 1$$

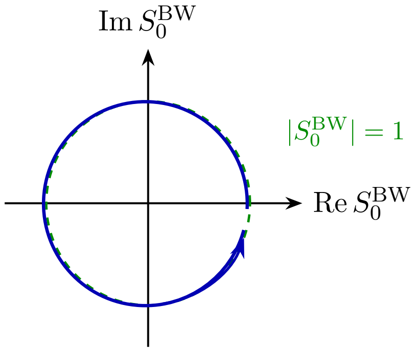
wherever the denominator is nonzero. For real s, the number $A(s) = M_R^2 - s$ is real and, by hypothesis, $W(s)$ is real. Hence $A(s)+\mathrm{i}W(s)$ is the complex conjugate of $A(s)-\mathrm{i}W(s)$. Therefore

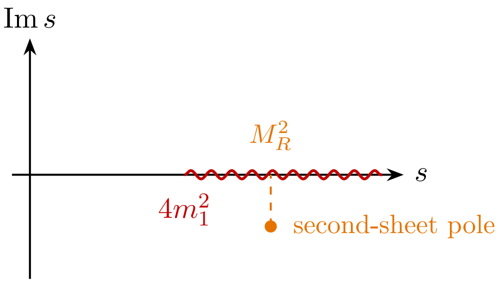
$$|S_0^{\mathrm{BW}}(s)|^2 = \frac{(A+\mathrm{i}W)(A-\mathrm{i}W)}{(A-\mathrm{i}W)(A+\mathrm{i}W)} = 1.$$

The physical partial wave differs from S_0^{BW} by the omitted background, crossed-channel, inelastic, and higher-order corrections; these are corrections to the model, not violations of the algebraic unitarity of the Breit–Wigner factor itself. The resonance is expressed as rapid phase motion. If

$$S_0^{\mathrm{BW}}(s) = \mathrm{e}^{2\mathrm{i}\delta_0^{\mathrm{BW}}(s)},$$

then the phase shift δ_0^{BW} changes rapidly through the point where $\operatorname{Re} F_{\mathrm{II}}(s)$ vanishes in the same local second-sheet approximation.





26.7 The Second Sheet

The sheet convention was fixed in Definition 25.1. Here it is made explicit for the above-threshold exchange model. The terminology applies to connected stable-channel scattering kernels.

Definition 26.6 (Adjacent second sheet in a single stable channel)**.** After the identity term and the overall momentum-conservation delta function have been removed, let

$$\mathcal{M}^{\mathrm{I}}_{ab}(s)$$

denote a connected invariant amplitude or partial-wave coordinate between stable channels a and b on the first sheet. Let $I \subset (4m_1^2, \infty)$ be an open interval on which the only cut being crossed is the $\phi_1\phi_1$ threshold cut and on which the upper and lower first-sheet boundary values exist as distributions or as ordinary functions after smearing in the remaining variables. The physical value on I is the upper-edge boundary value $\mathcal{M}^{\mathrm{I}}_{ab}(s + \mathrm{i}0)$.

The adjacent second-sheet germ relative to the $\phi_1\phi_1$ channel is the analytic germ obtained by continuing $\mathcal{M}^{\mathrm{I}}_{ab}$ from the upper edge of I through the cut once. Equivalently, in a local logarithmic coordinate for the cut, the second-sheet continuation replaces the lower first-sheet boundary value

$$\log(-r + \mathrm{i}0) = \log r + \mathrm{i}\pi, \qquad r > 0,$$

by the continued value

$$\log_{\mathrm{II}}(-r) = \log r - \mathrm{i}\pi.$$

For a square-root channel variable this is the same operation as changing the sign of the phase-space square root ρ_1 relative to the first sheet. A resonance in this channel is a pole of this adjacent germ, not a pole of the physical upper-edge boundary value and not an additional normalizable asymptotic state.

For the scalar model above the first-sheet exchange amplitude is $\mathcal{M}^{\mathrm{I}}_s(s) = g^2/F_{\mathrm{I}}(s)$, with F_{I} given by the Feynman boundary prescription in the preceding section. The first sheet contains the physical branch cut beginning at $4m_1^2$. The denominator F_{II} denotes the continuation of F_{I} through this cut in the sense of Definition 26.6. On a real point of the cut, the logarithmic discontinuity is

$$\log(-|a| - \mathrm{i}0) - \log(-|a| + \mathrm{i}0) = -2\pi\mathrm{i}.$$

Therefore the lower second-sheet boundary differs from the lower first-sheet boundary by the finite discontinuity generated by this logarithm. Near $s = M_R^2$, the branch inherited by F_{II} has

$$F_{\mathrm{II}}(s) = M_R^2 - s - \mathrm{i}W(s) + O(g^4, g^2(s - M_R^2)),$$

where $W(s) = g^2\rho_1(s)/(32\pi)$. This is the local analytic reason a pole can occur below the real axis on the adjacent sheet while no first-sheet pole appears at the same point.

Proposition 26.7 (No first-sheet resonance zero in the scalar model)**.** *Use the first-sheet branch of*

$$F_{\mathrm{I}}(s) = -s + (m_2^R)^2 + \frac{g^2}{32\pi^2}\int_0^1 \mathrm{d}x \,\log\left(1 - \frac{s\,x(1-x)}{m_1^2}\right)$$

defined by continuation from the real interval $s < 4m_1^2$, with the cut placed along $s \geq 4m_1^2$. Then F_{I} has no zero in the upper half of the first sheet and no zero in the lower half of the first sheet.

Proof. Let $s = u + \mathrm{i}v$ with $v > 0$. For $0 < x < 1$, set $\alpha = x(1-x)/m_1^2 > 0$. The logarithm has argument

$$1 - \alpha s = (1 - \alpha u) - \mathrm{i}\alpha v,$$

whose imaginary part is strictly negative. On the branch reached from $s < 4m_1^2$, its argument lies in $(-\pi, 0)$; hence

$$\operatorname{Im}\log(1 - \alpha s) < 0.$$

At the endpoints $x = 0, 1$ the logarithm is zero; they do not affect the integral. Also

$$\operatorname{Im}(-s) = -v < 0.$$

Since $g^2/(32\pi^2) > 0$, every nonconstant contribution to $\operatorname{Im} F_{\mathrm{I}}(s)$ has negative sign, and the integral is strictly negative. Therefore $\operatorname{Im} F_{\mathrm{I}}(s) < 0$ in the upper half-plane, so $F_{\mathrm{I}}(s) \neq 0$ there. If $v < 0$, the argument of $1 - \alpha s = (1 - \alpha u) - \mathrm{i}\alpha v$ lies in $(0, \pi)$ on the same first-sheet branch, and $\operatorname{Im}(-s) = -v > 0$. The two terms then have positive imaginary parts, so $\operatorname{Im} F_{\mathrm{I}}(s) > 0$ in the lower half-plane. Thus the zero associated with the resonance cannot lie on either half of the first sheet. □

Proposition 26.8 (Narrow pole on the adjacent sheet)**.** *Let*

$$W_R = M_R\Gamma_{\mathrm{cut}}(M_R) = \frac{g^2}{32\pi}\sqrt{1 - \frac{4m_1^2}{M_R^2}} + O(g^4),$$

and assume $M_R^2 > 4m_1^2$ is separated from the threshold by a fixed positive amount. Suppose that in a fixed neighborhood of M_R^2 the second-sheet denominator has the weak-coupling expansion

$$F_{\mathrm{II}}(s) = M_R^2 - s - \mathrm{i}W_R + (s - M_R^2)R_1(s, g) + R_0(g), \qquad R_1 = O(g^2), \quad R_0 = O(g^4),$$

with R_1 holomorphic and uniformly bounded with its first derivative. Then, for sufficiently small g, there is a unique zero of F_{II} in a disk $|s - M_R^2| \leq Cg^2$, and it is

$$s_* = M_R^2 - \mathrm{i}M_R\Gamma_{\mathrm{cut}}(M_R) + O(g^4).$$

Proof. Write $s = M_R^2 + \delta$. The equation $F_{\mathrm{II}}(s) = 0$ is

$$\delta = -\mathrm{i}W_R + \delta R_1(M_R^2 + \delta, g) + R_0(g).$$

For $|\delta| \le Cg^2$ and C large enough, the right-hand side maps the disk to itself for all sufficiently small g, because $W_R = O(g^2)$, $\delta R_1 = O(g^4)$, and $R_0 = O(g^4)$. Its derivative with respect to δ is

$$R_1(M_R^2 + \delta, g) + \delta\, \partial_s R_1(M_R^2 + \delta, g),$$

which is $O(g^2)$ uniformly on the disk. Thus the map is a contraction, and it has a unique fixed point. The fixed-point equation immediately gives

$$\delta = -\mathrm{i}W_R + O(g^4),$$

which is the stated pole location. Equivalently, $F_{\mathrm{II}}(M_R^2) = -\mathrm{i}W_R + O(g^4)$ and $F'_{\mathrm{II}}(M_R^2) = -1 + O(g^2)$, so the same result is the controlled one-step Newton approximation. $\square$

Equivalently, the pole width defined by $E_* = \sqrt{s_*} = M_{\mathrm{pole}} - \mathrm{i}\Gamma_{\mathrm{pole}}/2$ obeys

$$M_{\mathrm{pole}}\Gamma_{\mathrm{pole}} = M_R\Gamma_{\mathrm{cut}}(M_R) + O(g^4).$$

More invariantly, s_* is defined by the denominator obtained by continuing the first-sheet F_{I} through the elastic cut:

$$F_{\mathrm{II}}(s_*) = 0.$$

The number s_* is an analytic datum of the stable-particle scattering amplitude. Its position sets the resonance location and the pole lifetime scale in the narrow-width regime; it is not the same kind of object as a physical-axis line-shape width unless the narrow-resonance hypotheses of the preceding section hold.

The same distinction is visible in the spectral representation. A stable one-particle state gives an atom in the spectral measure and supplies a Haag–Ruelle asymptotic sector. An open channel gives continuous spectral measure beginning at threshold. A narrow resonance is a pronounced analytic feature of that continuum: it can appear as a peak in the spectral density and as a pole after analytic continuation, while the external scattering states remain the stable states used in the construction of the S-matrix.

26.8 Unstable Resonances and External-Leg Reduction

The LSZ theorem applies to an external particle only when the theory supplies an isolated real mass shell in the physical Hilbert space. In the notation of Chapter 18, this means an orthogonal projection

$$P_1 = E(\Sigma_m^+)$$

onto a Wigner one-particle subspace, a positive pole residue in a local-field two-point function, and Haag–Ruelle incoming and outgoing states built from that subspace. A resonance pole $s_* = M_{\mathrm{pole}}^2 - \mathrm{i}M_{\mathrm{pole}}\Gamma_{\mathrm{pole}} - \Gamma_{\mathrm{pole}}^2/4$ has none of these properties. It is a pole of an analytically continued stable scattering amplitude on a nonphysical sheet; the associated outgoing Gamow functional is not a normalizable vector in $\mathcal{H}$, and there is no projection-valued spectral atom $E(\{p : p^2 = -s_*\})$.

Therefore a residue at $s = s_*$ is not an LSZ external-leg residue. Physical S-matrix elements with a resonance are matrix elements between stable asymptotic states. Near an isolated resonance pole the meromorphic continuation of such a stable-particle amplitude may have the local form

$$\mathcal{M}_{a\to b}(s,\alpha,\beta) = \frac{r_a(\alpha)\, r_b(\beta)}{s_* - s} + \mathcal{M}_{\mathrm{reg}}(s,\alpha,\beta),$$

where a, b label stable channels and α, β denote the remaining kinematic variables. The functions r_a, r_b are pole residues of the continued stable-channel amplitude. They can be used to describe production and decay through the resonance, but they do not define an incoming or outgoing one-resonance Hilbert-space state.

Perturbation theory often packages this pole information in a Stueckelberg–Veltman, or complex-mass-shell, prescription. One analytically continues the inverse dressed propagator to the pole,

$$F_{\mathrm{II}}(s_*) = 0, \qquad Z_*^{-1} = -F'_{\mathrm{II}}(s_*),$$

and replaces the resonant propagator near the pole by

$$\frac{g^2}{F_{\mathrm{II}}(s)} = \frac{g^2 Z_*}{s_* - s} + \text{terms holomorphic near } s_*.$$

This is a pole-scheme parametrization of the stable-channel amplitude, not a new LSZ theorem. Its usefulness requires a controlled narrow-resonance regime: the pole must be isolated from other nearby poles and branch points, the width scale $M_{\mathrm{pole}}\Gamma_{\mathrm{pole}}$ must be small compared with the squared-mass distance to thresholds or singularities whose variation is being neglected, and the nonresonant background must be slowly varying on the same scale. If the pole lies close to a threshold, or if several channels produce nearby singularities, the simple Breit–Wigner or complex-mass-shell description is replaced by the corresponding multi-channel analytic line shape. The external states remain the stable states in all cases.

26.9 Pole-Factorized Resonance Objects

The preceding discussion leaves a precise mathematical problem. Stable external particles are vectors in asymptotic Hilbert spaces. Resonances are singularities of analytic continuations of matrix elements between such vectors. A candidate "amplitude with an external resonance" must therefore be extracted from stable-channel amplitudes by pole residues.

Definition 26.9 (Local pole neighborhood)**.** Fix stable channels a, b and kinematic variables (s, α, β), where s is the invariant mass squared of a channel whose analytic continuation has a pole. A local pole neighborhood consists of a sheet $\mathfrak{s}$ of the analytically continued amplitude $\mathcal{M}^{\mathfrak{s}}_{a\to b}(s,\alpha,\beta)$, an open set $U \subset \mathbb{C}$ containing s_*, and open real or complex neighborhoods V_a, V_b of α, β, such that the only singularity in $(U \setminus \{s_*\}) \times V_a \times V_b$ is a simple pole at $s = s_*$.

Definition 26.10 (Pole-factorized resonance object)**.** In a local pole neighborhood, the pole-residue kernel is

$$R_{ab}(\alpha,\beta) = \lim_{s\to s_*} (s_* - s)\, \mathcal{M}^{\mathfrak{s}}_{a\to b}(s,\alpha,\beta). \tag{26.4}$$

If the residue kernel has rank one in the channel variables, a pole-factorized resonance object is an equivalence class of factorizations

$$R_{ab}(\alpha,\beta) = r_b(\beta)\, r_a(\alpha), \qquad (r_a, r_b) \sim (\lambda r_a, \lambda^{-1} r_b), \qquad \lambda \in \mathbb{C}^\times.$$

The functions r_a, r_b are production and decay residue functionals. The equivalence class, rather than either factor separately, is the invariant object in the one-pole problem.

For a resonance in a spin-j channel, the residue kernel carries the indices of the corresponding partial wave or covariant tensor structure. After projecting to the irreducible spin component at the pole, rank one means rank one in the remaining channel space. In gauge theory this projection must be performed on the gauge-invariant stable-channel amplitude, or equivalently on BRST cohomology representatives whose pole residue is independent of the chosen gauge-fixing representatives. Pole position and full stable-channel residues are the primary objects; a split into "production" and "decay" factors is meaningful only after the normalization equivalence in Definition 26.10 has been imposed.

The same construction extends to several resonance variables only under a strong isolation hypothesis. Suppose a stable-channel amplitude depends on complex variables $s_1, \ldots, s_N$, and the chosen sheet contains simple poles at $s_i = s_{*i}$. If there is a polydisc $\prod_i U_i$ in which the only singular divisors are these N simple pole hyperplanes, define the nested residue

$$R^{(N)} = \lim_{s_N \to s_{*N}} \cdots \lim_{s_1 \to s_{*1}} \left(\prod_{i=1}^{N} (s_{*i} - s_i) \right) \mathcal{M}^{\mathfrak{s}}(s_1, \ldots, s_N, \gamma). \tag{26.5}$$

The order of residues is then immaterial by meromorphy in the polydisc. This object is the mathematical candidate for an amplitude with N external resonance slots and any remaining stable external data γ. The definition collapses when a threshold branch point, an anomalous threshold, or another pole intersects the same neighborhood.

Remark 26.11 (Properties inherited from stable-channel scattering). Assume the stable-channel S-matrix is unitary on the physical boundary, Poincare covariant, and obtained from local fields satisfying the analyticity hypotheses used in the preceding chapters. Let R_{ab} be the pole-residue kernel in a local pole neighborhood. Then:

1. s_* and R_{ab} are invariant under changes of interpolating fields that preserve the stable-channel S-matrix.

2. covariance of the stable amplitude induces covariance of R_{ab} in the little-group or partial-wave representation labeling the pole.

3. physical unitarity gives reality and conjugation constraints relating the pole on the chosen sheet to the conjugate singularity on the reflected sheet, and it fixes the positive inclusive decay rate in the narrow isolated regime through the discontinuity of the stable-channel amplitude.

4. in a gauge theory, if the stable-channel amplitude is represented by BRST-closed external operators, the residue kernel is independent of BRST-exact changes of those representatives.

The residue kernel is obtained by applying the linear functional $\mathrm{Res}_{s=s_*}$ to a meromorphic continuation of a stable-channel matrix element. Field redefinitions that leave the stable-channel S-matrix unchanged leave this meromorphic germ unchanged, and hence leave its residue unchanged. Poincare transformations act on the stable amplitude before continuation; since analytic continuation and taking a simple residue commute with the finite-dimensional tensor or partial-wave projection, the residue transforms in the corresponding representation.

On the physical boundary, unitarity gives $S^\dagger S = 1$, or equivalently the discontinuity relation for $T = S - 1$ derived from stable-channel unitarity. Continuing this relation through the cut relates the pole on one sheet to the conjugate analytic structure on the reflected sheet. In the narrow isolated regime, projecting the discontinuity onto the pole term gives the same inclusive rate as the self-energy cut calculation of the previous section. Finally, a BRST-exact change of a stable external representative changes a physical stable-channel matrix element by zero; applying the residue functional to zero gives zero.

26.10 Gamow Functionals and the Boundary of the Construction

A rigged-Hilbert formulation packages the pole residue into generalized vectors. Choose dense test spaces

$$\Phi_- \subset \mathcal{H} \subset \Phi_-^\times, \qquad \Phi_+ \subset \mathcal{H} \subset \Phi_+^\times$$

whose energy wavefunctions have the analyticity needed to continue the incoming and outgoing scattering amplitudes to the pole. A decaying Gamow functional associated with s_* is an element of one dual space whose pairing with test vectors reproduces the pole residue. In the rest frame, with $E_* = M_{\text{pole}} - \mathrm{i}\Gamma_{\text{pole}}/2$, its time evolution is a semigroup:

$$\mathrm{e}^{-\mathrm{i}Ht}|G_*\rangle = \mathrm{e}^{-\mathrm{i}M_{\text{pole}}t}\mathrm{e}^{-\Gamma_{\text{pole}}t/2}|G_*\rangle, \qquad t \geq 0,$$

as a statement about pairings with the chosen test space. The restriction $t \geq 0$ is part of the analytic test-space construction; a self-adjoint Hamiltonian on $\mathcal{H}$ still generates a unitary group on normalizable vectors.

This rigged-Hilbert language is useful because it records the decaying pole term without pretending that the resonance is a vector in $\mathcal{H}$. It is also additional structure. Different choices of test spaces can represent the same pole residue, and a general local QFT does not come equipped with a canonical Hardy-space rigging for every multiparticle channel. For this monograph the invariant data remain the pole position, sheet, and residue kernels of stable-channel amplitudes; Gamow functionals are a representation of those data when the required analytic rigging has been supplied.

26.11 Obstructions to External-Resonance Amplitudes

The pole-residue construction has sharp failure modes.

1. **Threshold collision.** If s_* lies at a distance comparable to its width from a branch point, there is no neighborhood in which the amplitude is a single simple pole plus a holomorphic remainder. The observable line shape is controlled by the pole and the branch point together.
2. **Coupled channels.** With several open channels, the analytic continuation lives on a multi-sheeted surface. A pole may be close on one sheet and absent or shadowed on another. The residue is then a matrix in channel space, and rank-one factorization can fail.
3. **Overlapping resonances.** If two poles lie in the same local domain, the residue decomposition depends on the chosen basis in the finite-dimensional pole subspace unless the pole projectors are separated by contours.

4. **Gauge and line-shape conventions.** A complex pole of the full stable-channel amplitude is invariant, but masses, widths, branching fractions, and production factors extracted from a fitted real-axis line shape depend on the convention used to separate pole and background terms.
5. **Long-range and massless effects.** If the stable channels have infraparticle behavior or uncancelled soft radiation, the stable-channel amplitude itself must be replaced by an inclusive or dressed observable before any resonance residue is defined.

Open Problem 26.12 (External resonances). The local construction above gives a candidate object in the isolated simple-pole regime. The open problem is to promote these local residues to a general theory of amplitudes with resonance slots. Such a theory must specify the class of local QFTs and channels for which the required analytic continuations exist, define the allowed rigged-Hilbert test spaces or avoid them in favor of purely meromorphic residue data, prove compatibility with stable-channel unitarity, formulate covariance for spin and gauge theories, and give precise replacement rules when thresholds, overlapping poles, massless sectors, or coupled-channel sheets obstruct rank-one pole factorization. Perturbative complex-mass and pole schemes are calculational realizations of the isolated-pole part of this problem; they are not a nonperturbative external-state construction.

Chapter 27

Composite Bound States and Bethe–Salpeter Amplitudes

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The time-ordered four-point functions, residues, and perturbative bubble integrals in this chapter are understood with the status convention of Definition 24.1. Exact bound-state pole statements use Hilbert-space spectral and LSZ data; the bubble-chain calculation is a formal regulated graph calculation of the corresponding time-ordered kernel.

27.1 Composite Particles as Poles

Let ϕ be a real scalar field whose stable one-particle states have mass m. A stable two-particle composite species B of mass M_B is an isolated one-particle sector whose wavepacket states are normalizable and whose mass satisfies

$$0 < M_B < 2m.$$

The inequality places the state below the two-ϕ continuum threshold.

Assumption 27.1 (Bound-state pole hypothesis)**.** The existence of B is an input in this chapter. More explicitly, assume that the Hilbert space contains an isolated positive-energy one-particle subrepresentation of mass M_B, separated from the two-ϕ continuum, and that at least one operator in the two-ϕ channel has nonzero matrix element with this state. The following sections derive the consequences of that spectral hypothesis for four-point functions, scattering amplitudes, and Bethe–Salpeter residues. They do not give a general proof that an arbitrary Lagrangian with attractive interactions has such a state.

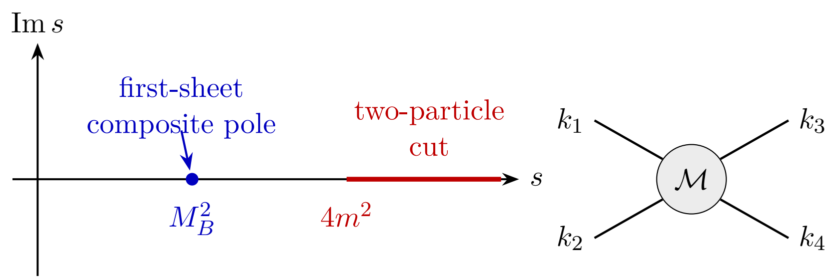
It is then represented, on the first sheet in the sense of Definition 25.1, by a pole of the appropriate four-point function at

$$s = M_B^2, \qquad s = -(k_1 + k_2)^2.$$

Equivalently, for the $2 \to 2$ invariant amplitude $\mathcal{M}(s,t)$, whose connected S-kernel transition part is $\mathrm{i}\mathcal{M}(s,t)$ after the overall momentum-conservation delta function is removed, with

$$t = -(k_1 - k_3)^2, \qquad u = -(k_1 - k_4)^2, \qquad s + t + u = 4m^2,$$

the same state appears as a pole in s, at fixed quantum numbers in the (12)-channel. After LSZ reduction of the external stable ϕ particles, the pole is present in the connected scattering amplitude; the external one-particle residues multiply the amplitude and do not determine the position of the pole. These are the mostly-plus Mandelstam variables of Definition 24.2 for on-shell external momenta: $k_i^2 = -m^2$, with k_1, k_2 incoming and k_3, k_4 outgoing.



This statement is independent of whether the Lagrangian contains a field named B. What matters is the spectral state and the residue with which operators in the two-particle channel create it.

27.2 A Bubble-Chain Example

The explicit calculation in this section is a $D = 2$ spacetime-dimensional model. The purpose is to exhibit, in a finite elementary integral, how a geometric sum of connected four-point kernels can generate a stable pole below the two-particle threshold. In $D = 4$ the same channel has a different threshold behavior and the pole condition involves the renormalized contact interaction at threshold; the numerical estimate for M_B below is therefore not a dimension-independent formula. The word generate in this paragraph refers to the specified bubble-chain approximation. A zero of the resummed denominator is a pole of that approximate kernel. Promoting it to an exact particle statement for a complete model requires additional nonperturbative control of the spectrum and of the analytic continuation of the exact four-point function.

Consider the scalar theory

$$\mathcal{L} = -\frac{1}{2}(\partial_\mu \phi)^2 - \frac{1}{2}m^2\phi^2 - \frac{g}{4!}\phi^4.$$

The four-point vertex is $-\mathrm{i}g$. Before specializing the integral, the s-channel bubble-chain approximation to $2 \to 2$ scattering contains the one-loop bubble

$$\frac{(-\mathrm{i}g)^2}{2}\int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\,\frac{-\mathrm{i}}{\ell^2+m^2-\mathrm{i}0}\,\frac{-\mathrm{i}}{(k_1+k_2-\ell)^2+m^2-\mathrm{i}0}.$$

The factor $1/2$ is the symmetry factor of the two identical internal lines. Feynman parametrization and Wick rotation give

$$\frac{\mathrm{i}g^2}{2}\int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^D\ell_E}{(2\pi)^D}\,\frac{1}{\left[\ell_E^2 - sx(1-x)+m^2\right]^2}.$$

As in the self-energy calculation, the Wick-rotated denominator is real on the Euclidean side; the $-\mathrm{i}0$ prescription enters only when the resulting function is continued back to a Lorentzian boundary value.

Specializing now to $D=2$, this becomes

$$\frac{\mathrm{i}g^2}{8\pi}f(s), \qquad f(s) = \int_0^1 \mathrm{d}x\,\frac{1}{m^2 - sx(1-x)-\mathrm{i}0}.$$

With the convention of Chapter 24, the geometric bubble chain gives the connected S-kernel transition part

$$\mathrm{i}\mathcal{M}^{(s)}_{\mathrm{chain}}(s) = -\mathrm{i}g\sum_{L=0}^{\infty}\left(-\frac{g}{8\pi}f(s)\right)^L = \frac{-\mathrm{i}g}{1+\dfrac{g}{8\pi}f(s)}.$$

External wavefunction factors multiply the expression and do not move the zeros of the denominator.

For a real scalar field the external particles are identical, so the physical amplitude is Bose symmetric. The displayed chain is the contribution in the (12)-channel. The crossed chains obtained by applying the same truncated geometric construction in the (13)- and (14)-channels give functions $\mathcal{M}^{(t)}_{\mathrm{chain}}(t)$ and $\mathcal{M}^{(u)}_{\mathrm{chain}}(u)$, and the full identical-boson amplitude in this additive channel truncation is decomposed as

$$\mathcal{M}_{\mathrm{Bose}}(s,z) = \mathcal{M}^{(s)}_{\mathrm{chain}}(s) + \mathcal{M}^{(t)}_{\mathrm{chain}}(t(s,z)) + \mathcal{M}^{(u)}_{\mathrm{chain}}(u(s,z)) + \mathcal{M}_{\mathrm{rest}}(s,z),$$

where $\mathcal{M}_{\mathrm{rest}}$ denotes kernels not included in the single-channel bubble-chain truncation. In a four-dimensional partial-wave normalization the identical-boson s-wave coordinate would be

$$a_0^{\mathrm{Bose}}(s) = \frac{1}{64\pi}\int_{-1}^{1}\mathrm{d}z\,\mathcal{M}_{\mathrm{Bose}}(s,z) = \frac{\mathcal{M}^{(s)}_{\mathrm{chain}}(s)}{32\pi} + a_{0,\mathrm{cross}}(s).$$

Here, for center-of-mass momentum $p_*^2 = (s-4m^2)/4$,

$$t(s,z) = -2p_*^2(1-z), \qquad u(s,z) = -2p_*^2(1+z).$$

As s approaches the s-channel threshold $4m^2$, the crossed invariants t and u remain in a neighborhood of 0, whereas the (12)-channel invariant approaches its two-particle threshold. Therefore the crossed chains and $\mathcal{M}_{\mathrm{rest}}$, insofar as they are regular in this local neighborhood, contribute to $a_{0,\mathrm{cross}}$ as analytic background terms. They do not contain the $f(s) \sim \pi/(m\sqrt{4m^2-s})$ threshold

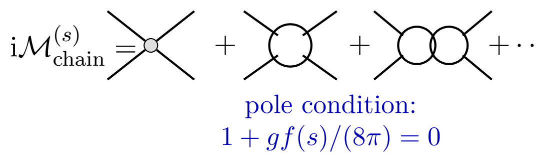


Figure 27.1: Single-channel bubble-chain contribution to the invariant amplitude. The gray vertex denotes the contact kernel in the selected channel, while the successive two-particle bubbles generate the denominator whose zero is the leading pole criterion $1 + gf(s)/(8\pi) = 0$.

enhancement that drives the denominator displayed above. Including the crossed and omitted kernels in a more complete Bethe–Salpeter kernel can change the numerical pole position; the calculation below is the leading single-channel statement. The channel separation and the pole denominator are organized in Figure 27.1.

Near the two-particle threshold from below, write

$$s = 4m^2 - \delta, \qquad \delta \to 0^+.$$

The integral is dominated by $x = 1/2$. Setting $x = 1/2 + y$, one obtains

$$m^2 - sx(1-x) = \frac{\delta}{4} + 4m^2y^2 + O(\delta y^2),$$

and hence

$$f(4m^2 - \delta) \simeq \frac{\pi}{m\sqrt{\delta}}.$$

The denominator can vanish for attractive coupling $g < 0$. At weak coupling,

$$\delta \simeq \left(\frac{g}{8m}\right)^2, \qquad M_B = \sqrt{4m^2 - \delta} \simeq 2m - \frac{g^2}{256m^3}.$$

Thus, within the $D = 2$ bubble-chain approximation and for attractive weak coupling, the resummed denominator has a stable-pole zero slightly below the two-particle threshold.

The calculation uses the local expansion around a perturbative vacuum. A complete scalar model with an attractive quartic term must specify the large-field behavior of the potential. For example,

$$V(\phi) = \frac{m^2}{\beta^2}(1 - \cos\beta\phi) = \frac{1}{2}m^2\phi^2 - \frac{m^2\beta^2}{4!}\phi^4 + O(\phi^6)$$

has an attractive quartic term in its local expansion, with local quartic coefficient $g_{\text{local}} = -m^2\beta^2$, while retaining a potential bounded from below. The bubble-chain computation should therefore be read as a statement about the local interaction coefficients around the chosen vacuum, not as a nonperturbative definition of an unstable negative-quartic polynomial theory.

27.3 Bethe–Salpeter Amplitude

Let $|B(P)\rangle$ be a stable composite one-particle state of mass M_B, with

$$P^2 = -M_B^2, \qquad P^0 > 0.$$

We use the covariant plane-wave normalization

$$\langle B(\vec{P}\,')|B(\vec{P})\rangle = (2\pi)^{D-1} 2\omega_{\vec{P}}\,\delta^{(D-1)}(\vec{P}-\vec{P}\,'), \qquad \omega_{\vec{P}} = \sqrt{\vec{P}^{\,2}+M_B^2}.$$

The momentum eigenstate is distributional; physical Hilbert-space states are obtained by smearing it with square-integrable wavepackets. The Bethe–Salpeter amplitude associated with the scalar local field $\widehat{\phi}$ is the time-ordered matrix element

$$\Phi_B(x_1,x_2;P) = \langle\Omega|T\widehat{\phi}(x_1)\widehat{\phi}(x_2)|B(P)\rangle.$$

Here Φ_B names a c-number bound-state amplitude, not a field operator. Translation covariance gives

$$\Phi_B(x_1+a,x_2+a;P) = \mathrm{e}^{\mathrm{i}P\cdot a}\Phi_B(x_1,x_2;P),$$

with the Fourier convention used below. Therefore its Fourier transform has support on total momentum P:

$$\Phi_B(x_1,x_2;P) = \int \frac{\mathrm{d}^D k_1}{(2\pi)^D}\frac{\mathrm{d}^D k_2}{(2\pi)^D}\,\mathrm{e}^{\mathrm{i}k_1\cdot x_1+\mathrm{i}k_2\cdot x_2}(2\pi)^D\delta^{(D)}(k_1+k_2-P)\widetilde{\Phi}_B(k_1,k_2;P).$$

If instead one uses unit-normalized momentum kets, a factor $\left[(2\pi)^{D-1}2\omega_{\vec{P}}\right]^{-1/2}$ appears on the right-hand side; here that factor is absorbed into the definition of $\widetilde{\Phi}_B$. The invariant normalization of $\widetilde{\Phi}_B$ is fixed by the four-point pole residue. No constituent LSZ factors are divided out in this definition. If the scalar field has one-particle residue

$$\langle\Omega|\widehat{\phi}(0)|\vec{p}\rangle = Z_\phi^{1/2},$$

then $\widetilde{\Phi}_B$ is the unamputated, field-normalized Bethe–Salpeter amplitude and contains the $Z_\phi^{1/2}$ normalization associated with each constituent field. A convention using LSZ-normalized constituent fields would instead use

$$\widetilde{\Phi}_B^{\mathrm{LSZ}} = Z_\phi^{-1}\widetilde{\Phi}_B$$

for two identical scalar constituents. In this chapter the inverse LSZ factors $Z_\phi^{-1/2}$ are not part of $\widetilde{\Phi}_B$; they are inserted only when a four-point Green function is converted to an invariant scattering amplitude.

Now consider the momentum-space time-ordered four-point function

$$\widetilde{G}_4(k_1,k_2,k_3,k_4) = \int \prod_{j=1}^{4}\mathrm{d}^D x_j\,\exp\left[-\mathrm{i}\sum_{j=1}^{4}k_j\cdot x_j\right] \times \langle\Omega|T\phi(x_1)\phi(x_2)\phi(x_3)\phi(x_4)|\Omega\rangle.$$

All four momenta are taken incoming, so translation invariance supplies $(2\pi)^D\delta^{(D)}(k_1+k_2+k_3+k_4)$.

Theorem 27.2 (Bethe–Salpeter pole factorization)**.** *Assume that the* (12)*-channel contains an isolated stable scalar bound state* B *of mass* M_B*, separated from the multiparticle continuum, and that after smearing the relative coordinates of the pairs* (12) *and* (34)*, the resulting pair operators admit a channel spectral decomposition with this isolated one-particle subspace. With*

$$P = k_1+k_2, \qquad P^2 \to -M_B^2,$$

the pole part of the Fourier-transformed four-point function is

$$\widetilde{G}_4(k_1,k_2,k_3,k_4) \sim (2\pi)^D\delta^{(D)}(k_1+k_2+k_3+k_4) \times \frac{-\mathrm{i}\,\widetilde{\Phi}_B(k_1,k_2;P)\,\widetilde{\Phi}_B^*(-k_3,-k_4;P)}{P^2+M_B^2-\mathrm{i}0} + \textit{terms regular at } P^2=-M_B^2. \tag{27.1}$$

Proof. First prove the pole statement after smearing the relative coordinates. Let $\xi = x_1 - x_2$, $\eta = x_3 - x_4$, $X = (x_1+x_2)/2$, and $Y = (x_3+x_4)/2$. For test functions f, g in the relative variables set

$$\mathcal{O}_f(X) = \int \mathrm{d}^D\xi\, f(\xi)\, T\{\phi(X+\xi/2)\phi(X-\xi/2)\},$$

and define $\mathcal{O}_g(Y)$ similarly for the (34) pair. The singularity in the total momentum P is controlled by the Fourier transform in the cluster separation $R = X - Y$. Terms in which the two pairs are not separated by arbitrarily large positive or negative R^0 have compact support, or rapid decrease after the relative smearing, in the R^0 direction and therefore give functions regular at $P^2 = -M_B^2$. The pole comes from the two cluster time orderings

$$\theta(R^0)\langle\Omega|\mathcal{O}_f(X)\mathcal{O}_g(Y)|\Omega\rangle + \theta(-R^0)\langle\Omega|\mathcal{O}_g(Y)\mathcal{O}_f(X)|\Omega\rangle.$$

Insert the spectral resolution between the two pair operators. The isolated one-particle bound-state subspace contributes

$$\int \frac{\mathrm{d}^{D-1}\vec{Q}}{(2\pi)^{D-1}2\omega_{\vec{Q}}}\,|B(\vec{Q})\rangle\langle B(\vec{Q})|, \qquad \omega_{\vec{Q}} = \sqrt{\vec{Q}^{\,2}+M_B^2},$$

with the invariant one-particle normalization used throughout the scattering chapters. Translation covariance gives

$$\langle\Omega|\mathcal{O}_f(X)|B(\vec{Q})\rangle = \mathrm{e}^{\mathrm{i}Q\cdot X}F_f(\vec{Q}), \qquad \langle B(\vec{Q})|\mathcal{O}_g(Y)|\Omega\rangle = \mathrm{e}^{-\mathrm{i}Q\cdot Y}F_g(\vec{Q})^*,$$

where $Q^0 = \omega_{\vec{Q}}$, and F_f, F_g are the relative-coordinate smearings of the Bethe–Salpeter amplitudes. The bound-state part of the cluster-ordered correlator is therefore

$$\int \frac{\mathrm{d}^{D-1}\vec{Q}}{(2\pi)^{D-1}2\omega_{\vec{Q}}}\,F_f(\vec{Q})F_g(\vec{Q})^*\left[\theta(R^0)\mathrm{e}^{\mathrm{i}Q\cdot R} + \theta(-R^0)\mathrm{e}^{-\mathrm{i}Q\cdot R}\right],$$

with the second term obtained from the reversed ordering. Fourier transform the cluster separation with total momentum P. The time integral uses

$$\int_{-\infty}^{\infty}\mathrm{d}\tau\,\mathrm{e}^{\mathrm{i}E\tau}\left[\theta(\tau)\mathrm{e}^{-\mathrm{i}\omega\tau}+\theta(-\tau)\mathrm{e}^{\mathrm{i}\omega\tau}\right] = \frac{\mathrm{i}}{E-\omega+\mathrm{i}0} - \frac{\mathrm{i}}{E+\omega-\mathrm{i}0} = \frac{2\mathrm{i}\omega}{E^2-\omega^2+\mathrm{i}0}. \tag{27.2}$$

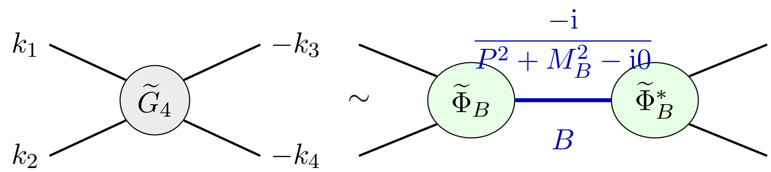
Combining this with the invariant measure $1/(2\omega_{\vec{Q}})$ gives

$$\frac{\mathrm{i}}{(P^0)^2-\omega_{\vec{P}}^2+\mathrm{i}0} = \frac{-\mathrm{i}}{P^2+M_B^2-\mathrm{i}0}$$

in the mostly-plus metric. This is the origin of the displayed Feynman prescription. The spatial Fourier transform fixes $\vec{Q}=\vec{P}$, and the remaining common translation gives $(2\pi)^D\delta^{(D)}(k_1+k_2+k_3+k_4)$.

Removing the relative-coordinate test functions gives the distributional kernel statement. The two matrix elements F_f and F_g^* unsmear to $\widetilde{\Phi}_B(k_1, k_2; P)$ and $\widetilde{\Phi}_B^*(-k_3, -k_4; P)$. The continuum spectral integral begins at invariant mass above M_B, so its denominator has no singularity at $P^2 = -M_B^2$ and contributes the terms regular at the pole. □

Equation (27.1) is the four-point analogue of the spectral pole in a two-point function. The residue is the product of the amplitudes for two fields to create and annihilate the stable composite state.



27.4 The Homogeneous Equation

Let p and q denote relative momenta at fixed total momentum P. For equal constituent masses one may write the two internal momenta as

$$\frac{P}{2} + q, \qquad \frac{P}{2} - q.$$

Let $D(k)$ be the exact time-ordered propagator of the constituent field, and define the two-particle propagator

$$\mathcal{G}_P(q) = D\left(\frac{P}{2} + q\right) D\left(\frac{P}{2} - q\right).$$

Let $\mathcal{K}_P(p, q)$ be the amputated two-particle irreducible kernel in the chosen channel: by definition, it cannot be separated into two pieces by cutting the two constituent lines carrying total momentum P. Contact vertices, crossed exchanges, and self-energy insertions on a constituent line may be part of this kernel after the constituent propagator convention has been fixed; an iteration of two kernels connected by the two constituent lines is not part of the kernel, because that iteration is precisely what the Bethe–Salpeter equation resums.

This definition is an operator statement once the relative-momentum variables are smeared. Let $\mathcal{X}$ be a chosen test-function or Hilbert space of amputated relative wavefunctions, for instance a weighted Sobolev space on a Euclidean relative-momentum contour in a massive model. The distribution $\mathcal{K}_P(p, q)$ represents a kernel only if it induces a continuous map from $\mathcal{X}$ to its dual, or, after the factors of $\mathcal{G}_P$ are included, a densely defined operator on $\mathcal{X}$. Equivalently, in a regulated theory one may define $\mathcal{K}_P$ by the exact four-point block $\mathcal{T}_P$ through

$$\mathcal{K}_P = \mathcal{T}_P(\mathbf{1} + \mathcal{G}_P\mathcal{T}_P)^{-1},$$

on any open P^2-domain where the inverse exists on the chosen space. The continuum kernel is then the limit of this regulated kernel in the same operator topology. The present chapter assumes this analytic operator realization when it writes $\mathcal{K}_P\mathcal{G}_P$ as an integral operator. Without such a realization the displayed Bethe–Salpeter equation is only distributional notation for a desired decomposition of the four-point function.

The amputated four-point scattering block $\mathcal{T}_P(p,p')$ obeys the operator equation

$$\mathcal{T}_P = \mathcal{K}_P + \mathcal{K}_P \mathcal{G}_P \mathcal{T}_P, \tag{27.3}$$

or explicitly

$$\begin{aligned} \mathcal{T}_P(p,p') &= \mathcal{K}_P(p,p') \\ &\quad + \int \frac{\mathrm{d}^D q}{(2\pi)^D}\, \mathcal{K}_P(p,q)\mathcal{G}_P(q)\mathcal{T}_P(q,p'). \end{aligned} \tag{27.4}$$

A bound-state pole at $P^2 = -M_B^2$ has the form

$$\mathcal{T}_P(p,p') \sim \frac{\Psi_B(p;P)\,\overline{\Psi}_B(p';P)}{P^2 + M_B^2 - \mathrm{i}0} + \text{regular terms}. \tag{27.5}$$

Here $\overline{\Psi}_B$ denotes the residue on the right side of the four-point function; for scalar constituents it is the complex conjugate with the momenta reversed, up to the same convention choices already present in $\widetilde{\Phi}_B^*(-k_3,-k_4;P)$. Substituting this pole form into the integral equation and equating residues gives the homogeneous Bethe–Salpeter equation

$$\Psi_B(p;P) = \int \frac{\mathrm{d}^D q}{(2\pi)^D}\, \mathcal{K}_P(p,q)\mathcal{G}_P(q)\Psi_B(q;P), \qquad P^2 = -M_B^2. \tag{27.6}$$

Equivalently, define the integral operator

$$(\widehat{V}_P F)(p) = \int \frac{\mathrm{d}^D q}{(2\pi)^D}\, \mathcal{K}_P(p,q)\mathcal{G}_P(q)F(q).$$

Then a bound state is a nonzero vector Ψ_B in the domain of this operator for which

$$(\mathbf{1} - \widehat{V}_P)\Psi_B = 0.$$

The pole condition is thus an eigenvalue-one condition for the repeated two-particle propagation at $P^2 = -M_B^2$. This statement has the logical status of a residue equation unless the operator problem is supplied with enough analytic structure. The following theorem records the standard Fredholm form of the missing structure. It is not a general existence theorem for bound states in arbitrary Lagrangians; it is the precise local theorem that converts an eigenvalue-one Bethe–Salpeter condition into a pole of the represented four-point block, and conversely, when the exact kernel has been realized as an analytic compact-operator family.

Theorem 27.3 (Analytic Fredholm Bethe–Salpeter pole criterion)**.** *Let $z = P^2$, and let $U \subset \mathbb{C}$ be a connected open neighborhood of $z_B = -M_B^2$ whose closure is separated from the two-constituent threshold and from every other singular locus of the chosen first-sheet continuation. Let $\mathcal{X}$ be the Banach space of amputated relative-momentum test functions used to realize the exact two-particle irreducible kernel. Assume that*

$$\widehat{V}(z) = \mathcal{K}_z \mathcal{G}_z : \mathcal{X} \to \mathcal{X}$$

is analytic in z as a family of compact operators, and that $\mathbf{1} - \widehat{V}(z_0)$ is invertible for at least one $z_0 \in U$. Assume also that the part of the amputated four-point block seen by the external two-field channel has an operator representation

$$\mathcal{T}_z^{\mathrm{rep}} = \mathcal{R}_z + \mathcal{F}_z\big(\mathbf{1} - \widehat{V}(z)\big)^{-1}\mathcal{E}_z, \tag{27.7}$$

where $\mathcal{E}_z : \mathcal{Y} \to \mathcal{X}$, $\mathcal{F}_z : \mathcal{X} \to \mathcal{Y}'$, and $\mathcal{R}_z : \mathcal{Y} \to \mathcal{Y}'$ are analytic bounded-operator families for the selected external test space $\mathcal{Y}$.

Then $(\mathbf{1} - \widehat{V}(z))^{-1}$, initially defined where the inverse exists, extends to a meromorphic family on U, and each coefficient in its principal part has finite rank. Therefore $\mathcal{T}_z^{\mathrm{rep}}$ is meromorphic on U. It has a pole at z_B precisely when the finite-rank principal part of $(\mathbf{1} - \widehat{V}(z))^{-1}$ at z_B is not annihilated by the channel maps $\mathcal{F}_z$ and $\mathcal{E}_z$. In particular, if $\ker(\mathbf{1} - \widehat{V}(z_B)) \neq 0$ and the corresponding root subspace has nonzero external overlap, then z_B is a pole of the represented four-point block. Conversely, any pole of $\mathcal{T}_z^{\mathrm{rep}}$ whose singular part is represented through (27.7) comes from a nonzero root vector of $\mathbf{1} - \widehat{V}(z_B)$.

If the root space is simple, so that $\ker(\mathbf{1}-\widehat{V}(z_B)) = \mathbb{C}\psi$, $\ker(\mathbf{1}-\widehat{V}(z_B))^* = \mathbb{C}\chi$, $\chi(\psi) = 1$, and the corresponding analytic eigenvalue $\lambda(z)$ of $\widehat{V}(z)$ satisfies $\lambda(z_B) = 1$, $\lambda'(z_B) \neq 0$, then the singular part is

$$\mathcal{T}_z^{\mathrm{rep}} = -\frac{(\mathcal{F}_{z_B}\psi) \otimes (\chi\mathcal{E}_{z_B})}{\lambda'(z_B)(z - z_B)} + \text{holomorphic terms}. \tag{27.8}$$

The pole is visible in the chosen channel if and only if $\mathcal{F}_{z_B}\psi \neq 0$ and $\chi\mathcal{E}_{z_B} \neq 0$. When, in addition, z_B lies on the first sheet below threshold and the exact Hilbert-space spectral representation has positive one-particle residue there, this pole is the scattering signature of a stable bound state.

Proof. The analytic Fredholm theorem applies because $\widehat{V}(z)$ is analytic and compact and because $\mathbf{1}-\widehat{V}(z_0)$ is invertible at one point of the connected domain U. Hence $(\mathbf{1}-\widehat{V}(z))^{-1}$ is meromorphic on U, with singular coefficients of finite rank supported on the finite-dimensional generalized root spaces of $\widehat{V}(z_B)$ at eigenvalue 1. Multiplication on the left and right by analytic bounded families $\mathcal{F}_z$ and $\mathcal{E}_z$, and addition of the analytic background $\mathcal{R}_z$, preserve meromorphicity and can only remove a singularity by annihilating its finite-rank principal part. This proves the pole criterion in (27.7).

For the simple-root formula, choose analytic right and left eigenvectors $\psi(z)$, $\chi(z)$ near z_B with $\chi(z)\psi(z) = 1$. On the rank-one spectral subspace, $\mathbf{1} - \widehat{V}(z)$ acts by multiplication by $1 - \lambda(z)$. Since

$$1 - \lambda(z) = -\lambda'(z_B)(z - z_B) + O\big((z - z_B)^2\big),$$

the inverse has principal part

$$-\frac{\psi \otimes \chi}{\lambda'(z_B)(z - z_B)}.$$

Substitution into (27.7) gives (27.8). The final sentence is not a Fredholm consequence: it is the separate spectral identification supplied by the exact Hilbert-space theory, namely a first-sheet isolated pole below the continuum with positive residue in a physical channel. □

Remark 27.4 (What the homogeneous equation proves). The homogeneous Bethe–Salpeter equation is therefore an existence theorem only relative to the hypotheses of Theorem 27.3: exact kernel, specified Banach space, compact analytic dependence on P^2, invertibility somewhere in the analytic neighborhood, nonzero external overlap, and spectral positivity for the first-sheet below-threshold pole. In a ladder or other truncated kernel, a nonzero solution of $(\mathbf{1} - \widehat{V}_P)\Psi = 0$ is a self-consistency condition inside that approximation. A derivation of a normalizable positive-energy bound state in the exact QFT requires control of the approximation and of the corresponding spectral subspace of the full theory.

The unamputated Bethe–Salpeter amplitude is related to the amputated vertex by

$$\widetilde{\Phi}_B(p;P) = \mathcal{G}_P(p)\Psi_B(p;P),$$

with the same field normalization used in (27.1). Here $D(k)$ is the exact propagator of the local field ϕ, including its pole residue Z_ϕ. Thus no extra Z_ϕ factor is hidden in Ψ_B. Changing to LSZ-normalized constituent fields sends

$$\widetilde{\Phi}_B \mapsto Z_\phi^{-1}\widetilde{\Phi}_B, \qquad D \mapsto Z_\phi^{-1}D, \qquad \Psi_B \mapsto Z_\phi\,\Psi_B$$

for two identical scalar constituents, so the convention can be translated without changing the pole condition. In unamputated form the equation reads

$$\widetilde{\Phi}_B(p;P) = \mathcal{G}_P(p)\int \frac{\mathrm{d}^D q}{(2\pi)^D}\,\mathcal{K}_P(p,q)\widetilde{\Phi}_B(q;P), \qquad P^2 = -M_B^2.$$

This operator formulation is the pole data used later in analytic and dispersive arguments. When a stable composite state appears in a crossed channel, crossing transports the pole $P^2 = -M_B^2$ to the corresponding Mandelstam location, while Theorem 27.2 supplies the residue as a product of Bethe–Salpeter amplitudes. In a two-constituent channel the mass of the pole is equivalently the value of P^2 for which the integral operator $\widehat{V}_P$ has eigenvalue one. Thus the bound-state pole terms added in fixed-t dispersion formulae are not independent terms in a meromorphic ansatz: their positions and residues are the spectral and Bethe–Salpeter data of the stable one-particle sector.

Figure 27.2 collects the three operator statements used in this paragraph: the definition of the two-particle irreducible kernel, its iteration into the scattering operator, and the homogeneous eigenvalue equation for a stable bound-state amplitude.

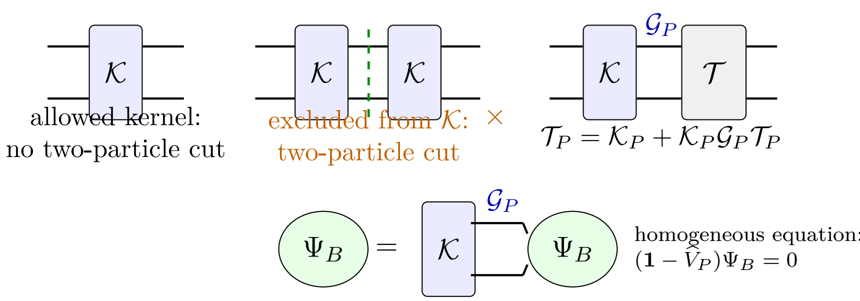


Figure 27.2: Bethe–Salpeter kernel, scattering equation, and homogeneous bound-state equation. The dashed cut marks a two-particle reducible contribution, which is excluded from $\mathcal{K}_P$ and generated instead by iterating $\mathcal{K}_P\mathcal{G}_P$.

27.5 Ladder Limit

The kernel $\mathcal{K}_P$ is exact when it contains all two-particle irreducible contributions in the chosen channel. A ladder approximation keeps only a selected low-order kernel and iterates it through $\mathcal{G}_P$. For example, a single exchanged scalar particle produces the model kernel

$$\mathcal{K}_P(p,q) \approx \frac{g_{\rm ex}^2}{(p-q)^2 + \mu^2 - \mathrm{i}0},$$

with μ the exchanged mass and with numerator factors determined by the spins and couplings of the fields.

The ladder sum has a controlled meaning only after the same operator topology has been fixed. For a selected kernel $\mathcal{K}_P^{(0)}$, set

$$\widehat{V}_P^{(0)} = \mathcal{K}_P^{(0)} \mathcal{G}_P.$$

If $\|\widehat{V}_P^{(0)}\|_{\mathcal{B}(\mathcal{X})} < 1$ in a region of complex P^2, the Neumann series

$$\mathcal{T}_P^{\mathrm{lad}} = \sum_{n=0}^{\infty} (\widehat{V}_P^{(0)})^n \mathcal{K}_P^{(0)} = (\mathbf{1} - \widehat{V}_P^{(0)})^{-1} \mathcal{K}_P^{(0)}$$

converges in operator norm there. At a bound-state pole the relevant eigenvalue reaches 1, so the Neumann series itself is no longer a convergent expansion at the pole; the pole is obtained by the meromorphic Fredholm continuation of the resolvent. Thus a ladder Bethe–Salpeter eigenvalue is a theorem inside a specified compact-operator approximation, and becomes a statement about the exact QFT only when the omitted two-particle irreducible kernels are controlled in the same topology.

In a weakly bound massive system, let

$$P^0 = 2m + E_{\mathrm{nr}}, \qquad |E_{\mathrm{nr}}| \ll m, \qquad |\vec{p}| \ll m.$$

If the kernel is instantaneous to leading order, the relative-energy integral through the two constituent propagators reduces the Bethe–Salpeter equation to a Schrödinger eigenvalue problem for the equal-time wavefunction. This nonrelativistic limit is a derived approximation to the four-point pole condition. The relativistic equation retains the full dependence on relative time, energy flow, and field-theoretic kernel structure.

Chapter 28

Analyticity, Crossing, and Landau Singularities

Conventions in this chapter.

- **Signature.** Lorentzian $\mathbb{M}^D$.
- **Metric sign.** $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$.
- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

The analytic amplitudes in this chapter are boundary values of exact Hilbert-space time-ordered or Wightman distributions when the stated spectral, locality, and LSZ hypotheses are being used. The Landau and Feynman-parameter discussions are instead coefficientwise perturbative graph analyses of regulated time-ordered kernels. This is the standing convention of Definition 24.1.

28.1 Physical Region and First Sheet

Definition 25.1 introduced the sheet terminology at the first point where bound-state and resonance poles required it. This section develops the same convention for the general identical massive $2 \to 2$ amplitude and fixes the physical s-channel region used in the analyticity discussion.

Consider $2 \to 2$ scattering of identical stable scalar particles of mass m. The metric is mostly plus, so a physical mass-m momentum k obeys $k^2 = -m^2$. Let the connected invariant amplitude be denoted by

$$\mathcal{M}(s, t),$$

where

$$s = -(k_1 + k_2)^2, \qquad t = -(k_1 - k_3)^2, \qquad u = -(k_1 - k_4)^2 = 4m^2 - s - t.$$

Here k_1, k_2 are incoming and k_3, k_4 are outgoing physical momenta, in the convention of Definition 24.2. Equivalently, all four external momenta may be taken incoming after replacing outgoing momenta by their negatives; the above definitions are the physical scattering convention. With $k_i^2 = -m^2$, the mostly-plus Mandelstam identity is

$$s + t + u = 4m^2.$$

In the center-of-mass frame,

$$s = E^2 = 4(k^2 + m^2), \qquad t = -2k^2(1 - \cos\theta), \qquad u = -2k^2(1 + \cos\theta).$$

Thus the physical s-channel region is

$$t \le 0, \qquad u \le 0, \qquad s \ge 4m^2 - t.$$

The last inequality is the statement $-t \le s - 4m^2$. For fixed $s \ge 4m^2$, the allowed physical interval is

$$-(s - 4m^2) \le t \le 0.$$

For fixed real $t < 0$, the physical upper edge begins at

$$s = 4m^2 - t,$$

because this is the value for which $u = 0$. The analytic function whose boundary value is the physical amplitude also has the lower s-channel threshold at $s = 4m^2$; for $4m^2 < s < 4m^2 - t$ the point is on the same right-hand cut but outside the physical s-channel scattering interval for that fixed t. Figure 28.1 fixes the corresponding s-plane branch conventions.

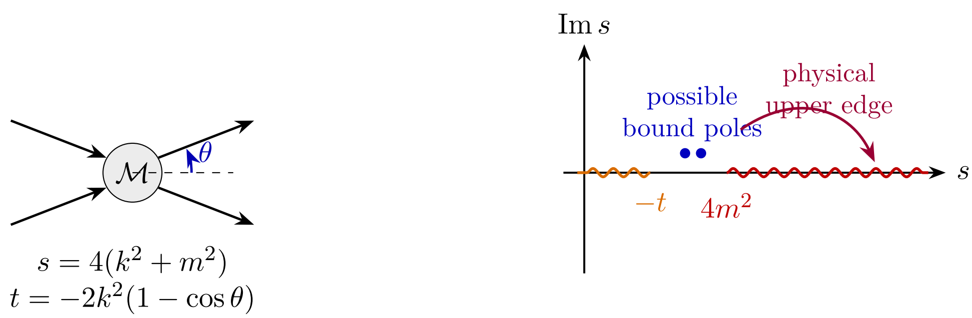

Figure 28.1: Fixed-t physical edge and cuts in the s-plane. The left panel fixes the center-of-mass kinematics and the angular variable. The right panel shows the first-sheet right-hand cut, the crossed cut, possible stable poles, and the upper-edge boundary value used for the physical amplitude.

For fixed real $t < 0$, the physical amplitude is the upper-edge boundary value

$$\lim_{\epsilon \to 0^+} \mathcal{M}(s + \mathrm{i}\epsilon, t)$$

on the first sheet. In this monograph the terms *first sheet* and *physical sheet* mean the same analytic branch: the germ reached from the Euclidean or Feynman domain by the prescribed $+\mathrm{i}0$ continuation without passing through any unitarity cut. This is a statement about a branch of the complexified invariant variables, not a synonym for the physical region of real external momenta. In the fixed-t s-plane this branch has the right-hand s-channel cut

$$C_s = [4m^2, \infty),$$

and, because $u = 4m^2 - s - t$, the crossed u-channel cut

$$C_u = (-\infty, -t].$$

A stable state of mass $M_B < 2m$ coupled to the two external scalars gives a first-sheet pole at $s = M_B^2$ in the corresponding channel. In the crossed channel this same statement appears as a pole at

$$s = 4m^2 - t - M_B^2.$$

If the stable state is composite, this pole is the same spectral pole whose four-point residue is factorized in Theorem 27.2. In a two-constituent description its mass is equivalently determined by the homogeneous Bethe–Salpeter condition (27.6), or by $(\mathbf{1} - \widehat{V}_P)\Psi_B = 0$ at $P^2 = -M_B^2$. Crossing changes the Mandelstam coordinate in which the pole is seen; it does not change the Hilbert space state or the residue matrix element from which the pole term is built. For the purposes used here, the first-sheet data consist of this cut plane together with the possible pole data and with any additional first-sheet singularities allowed by the full spectral problem.

A *second sheet* is always defined relative to a specified cut. It is the adjacent analytic germ obtained by continuing the first-sheet germ through that cut. Near a single two-particle threshold, with

$$\beta(s) = \sqrt{1 - \frac{s_{\mathrm{th}}}{s}}$$

chosen so that $\beta(s) > 0$ on the physical upper edge $s > s_{\mathrm{th}}$, the continuation through the corresponding unitarity cut sends $\beta \mapsto -\beta$. With several thresholds there is no cut-independent meaning of “the” second sheet; the sheet is labelled by the set of cuts through which the analytic germ has been continued, or equivalently by the monodromy choices for the associated channel momenta.

28.2 Real Analyticity and Crossing

For the analytic discussion in this chapter assume a mass gap, Poincare invariance, locality, unitarity, and the existence of stable one-particle external states to which LSZ applies. These assumptions specify the structural input used here, while the maximal analytic domain remains an additional problem. The continuation used in this chapter is an on-shell continuation in the invariant variables. The external legs remain on the complexified mass shell; the variables s, t, u are complex coordinates on the algebraic surface

$$\mathfrak{S}_m = \{(s, t, u) \in \mathbb{C}^3 : \ s + t + u = 4m^2\},$$

with $u = 4m^2 - s - t$. The starting object on a real physical edge is the connected LSZ amplitude as a tempered distribution in wave-packet momenta, after the overall momentum-conserving delta function and external pole residues have been extracted. Away from thresholds, stable-particle poles, and other singular loci, this distribution is represented by boundary values of holomorphic functions on tube-like domains in $\mathfrak{S}_m$.

Definition 28.1 (Tempered holomorphic amplitude germ)**.** Let $\mathcal{D} \subset \mathfrak{S}_m$ be a connected open set and let $\mathcal{D}_{\mathbb{R}}$ be a real edge of $\mathcal{D}$. A holomorphic amplitude germ on $\mathcal{D}$ is an element

$$F \in \mathcal{O}_{\text{poly}}(\mathcal{D})$$

with the following local polynomial-growth property: for every relatively compact $K \Subset \mathcal{D}$ that approaches $\mathcal{D}_{\mathbb{R}}$ inside a fixed open cone of imaginary directions, there are constants C_K, N_K such that

$$|F(z)| \le C_K(1 + |z|)^{N_K} \operatorname{dist}(z, \partial\mathcal{D})^{-N_K}.$$

Its boundary value on an open real set $U \subset \mathcal{D}_{\mathbb{R}}$ is the distribution

$$\operatorname{bv} F \in \mathcal{D}'(U)$$

defined by

$$\langle \operatorname{bv} F, \varphi\rangle = \lim_{\lambda \downarrow 0} \int_U F(x + \mathrm{i}\lambda\eta)\varphi(x)\, \mathrm{d}x, \qquad \varphi \in C_c^\infty(U),$$

whenever the limit exists and is independent of η inside the chosen cone. On noncompact real edges the same polynomial-growth condition permits Schwartz test functions and gives a tempered boundary value in $\mathcal{S}'$ in the chosen real coordinate chart. Equality of two physical amplitudes on U means equality of these boundary values in the strong dual topology of $\mathcal{D}'(U)$, or of $\mathcal{S}'$ when the noncompact tempered version is used.

28.2.1 Primitive Tube Domains from Wightman Data

We now isolate the first domain theorem used in scattering analyticity. It is not a perturbative statement. It is the theorem that converts the spectral condition and locality of Wightman fields into holomorphic domains for correlation functions. The later Lehmann–Martin and Jin–Martin arguments start from this primitive domain and add the further retarded-commutator, partial-wave, and unitarity input needed for fixed-t dispersion theory.

Let $\Phi_a(x)$, $a \in A$, be scalar Wightman fields for simplicity of notation. Spin and finite-dimensional internal labels only insert the corresponding covariance matrices and do not change the domain argument. For an ordering $\sigma \in S_n$, define the ordered n-point distribution

$$W_\sigma(x_1, \dots, x_n) = \langle \Omega, \Phi_{\sigma(1)}(x_{\sigma(1)}) \cdots \Phi_{\sigma(n)}(x_{\sigma(n)})\Omega\rangle.$$

Translation invariance allows one to remove the center-of-mass variable. For the displayed ordering, put

$$\xi_j = x_{\sigma(j)} - x_{\sigma(j+1)}, \qquad j = 1, \dots, n-1,$$

and write the reduced distribution as $w_\sigma(\xi_1, \dots, \xi_{n-1})$. Let P^μ be the self-adjoint generators of spacetime translations and let $\overline{V}_+$ denote the closed future light cone in momentum space, with the mostly-plus mass convention fixed in Volume I.

Theorem 28.2 (Primitive Wightman tube-domain theorem)**.** *Assume the Wightman hypotheses for the fields appearing above: a translation-invariant vacuum, strong continuity of translations, the spectrum condition*

$$\operatorname{Spec}(P) \subset \overline{V}_+,$$

and temperedness of all vacuum matrix elements. Then, for every ordering σ,

$$\operatorname{supp} \widehat{w}_\sigma \subset (\overline{V}_+)^{n-1} \tag{28.1}$$

in the reduced Fourier variables conjugate to $(\xi_1, \dots, \xi_{n-1})$. Consequently w_σ is the tempered boundary value of a holomorphic function

$$\mathcal{W}_\sigma(z_1, \dots, z_{n-1}), \qquad z_j = \xi_j - \mathrm{i}\eta_j,$$

on the tube

$$T_{n-1} = \{(\xi_j - \mathrm{i}\eta_j)_{j=1}^{n-1} \mid \eta_j \in V_+^\circ,\ j = 1, \dots, n-1\}, \tag{28.2}$$

with the same damping convention as the Wightman tube construction of Chapter 16: for $p, \eta \in \overline{V}_+$ the mostly-plus pairing satisfies $p \cdot \eta \leq 0$, so the factor $\exp(p \cdot \eta)$ is damping. Equivalently, it is Proposition 12.13 after the identification of its positive dual variable with $-\eta$ in the Lorentzian pairing. More precisely, for every closed subcone $K \Subset (V_+^\circ)^{n-1}$ the tested functions

$$f \longmapsto \int \mathcal{W}_\sigma(\xi - \mathrm{i}\eta) f(\xi)\, \mathrm{d}^{D(n-1)}\xi$$

are bounded by finitely many Schwartz seminorms of f, with constants polynomial in the reciprocal distance of η from the boundary of the cone, and converge in $\mathcal{S}'$ to w_σ as $\eta \to 0$ inside K.

Proof. We first prove the support statement. It is enough to test $\widehat{w}_\sigma$ against a compactly supported smooth function $\widehat{f}(p_1, \dots, p_{n-1})$ whose support is disjoint from $(\overline{V}_+)^{n-1}$. Choose Schwartz functions

$$f(\xi_1, \dots, \xi_{n-1}) = \int \mathrm{e}^{-\mathrm{i}\sum_j p_j \cdot \xi_j} \widehat{f}(p_1, \dots, p_{n-1}) \prod_j \frac{\mathrm{d}^D p_j}{(2\pi)^D}.$$

The smeared reduced Wightman distribution is obtained by inserting the joint spectral resolution of the translation representation between adjacent fields. On the common invariant domain this gives the weak identity

$$\langle \widehat{w}_\sigma, \widehat{f} \rangle = \int \widehat{f}(p_1, \dots, p_{n-1})\, \mathrm{d}\mu_\sigma(p_1, \dots, p_{n-1}), \tag{28.3}$$

where the scalar distributional measure μ_σ is built from the successive spectral projections of the translation representation applied to the vectors generated by the ordered fields. The j-th momentum p_j is the total momentum carried by the state between the j-th and $(j+1)$-st inserted fields. By the spectrum condition each such intermediate momentum lies in $\overline{V}_+$. Therefore the right hand side of (28.3) vanishes whenever $\operatorname{supp} \widehat{f} \cap (\overline{V}_+)^{n-1} = \varnothing$, which is exactly (28.1).

For completeness we spell out why the preceding spectral-resolution formula is legitimate for distributional fields. First smear each field with a Schwartz function and use the spectral theorem for the strongly continuous unitary translation group between the smeared field operators. The translation covariance relation

$$U(a)\Phi_b(h)U(a)^{-1} = \Phi_b(h_a), \qquad h_a(x) = h(x - a),$$

turns translations of adjacent insertions into the Fourier factors in (28.3). The Wightman temperedness hypothesis gives continuity in the Schwartz topology, so the identity extends from tensor-product test functions to all Schwartz tests in the reduced variables and then by density to the displayed $\widehat{f}$.

The holomorphic continuation is now the Fourier–Laplace theorem for tempered distributions carried by a closed convex cone, applied to the cone $(\overline{V}_+)^{n-1}$. The exponential damping in the imaginary directions $\eta_j \in V_+^\circ$ makes the Fourier transform into a holomorphic function of $z_j = \xi_j - \mathrm{i}\eta_j$. The finite-order Schwartz-seminorm estimate for $\widehat{w}_\sigma$ gives the displayed polynomial tube bounds after differentiating the exponential multiplier. The same estimate, with the exponential multiplier tending to 1 in the Schwartz topology after testing, gives the boundary value $\mathcal{W}_\sigma(\cdot - \mathrm{i}\eta) \to w_\sigma$ in $\mathcal{S}'$. This is precisely the construction written abstractly in Proposition 12.13. $\square$

The primitive tube is only the first part of the domain. Locality determines how different ordered tubes are glued. The relevant real edge is the Jost set. In the reduced variables of an ordering, define

$$C(\xi) = \left\{ \sum_{j=1}^{n-1} \lambda_j \xi_j \,\middle|\, \lambda_j \geq 0 \right\}.$$

A real reduced configuration ξ is a Jost configuration if every nonzero vector in $C(\xi)$ is spacelike. With the mostly-plus convention, this means $v^2 > 0$ for all $0 \neq v \in C(\xi)$. In particular, every difference $x_{\sigma(i)} - x_{\sigma(k)} = \xi_i + \cdots + \xi_{k-1}$ between two ordered insertion points is spacelike.

Theorem 28.3 (Jost-edge gluing of primitive tubes)**.** *Assume, in addition to the hypotheses of Theorem 28.2, graded local commutativity on the common Wightman domain:*

$$\Phi_a(f)\Phi_b(g) = (-1)^{|a||b|}\Phi_b(g)\Phi_a(f)$$

whenever the supports of f and g are spacelike separated. Let σ' be obtained from σ by one adjacent transposition of field labels whose two insertion points are spacelike throughout an open Jost neighbourhood U_J. Then the two boundary distributions $\operatorname{bv}\mathcal{W}_\sigma$ and $\operatorname{bv}\mathcal{W}_{\sigma'}$, expressed in the same real coordinates on U_J, agree there up to the Koszul sign of the transposition. Hence the distributional edge-of-the-wedge theorem gives a single holomorphic function on the envelope of holomorphy of the union of the two adjacent primitive tubes and the common Jost edge. Iterating adjacent transpositions gives a well-defined holomorphic germ on the primitive Bros–Epstein–Glaser envelope generated by all ordered Wightman tubes and their Jost-edge identifications.

Proof. Choose test functions supported in a coordinate neighbourhood of U_J. For the adjacent pair being transposed, every point in the product support has spacelike separation. Graded local commutativity therefore permits the two smeared fields to be exchanged on the common invariant domain, with the factor $(-1)^{|a||b|}$. Leaving all other insertions fixed gives equality of the two ordered Wightman distributions on U_J, again with the same Koszul factor. This proves equality of the real boundary values on the Jost edge.

By Theorem 28.2, each ordered distribution is the boundary value of a holomorphic function with polynomial tube bounds. The distributional edge-of-the-wedge theorem applies exactly to such a pair: holomorphic functions in two opposite or adjacent wedges with equal distributional boundary values on a common real edge extend to the envelope of holomorphy of their union. The extension is unique because a holomorphic function with zero distributional boundary value on an open edge vanishes in the connected envelope. Applying this step to a sequence of adjacent transpositions gives the asserted primitive envelope. If two different transposition sequences relate the same orderings, uniqueness on the overlaps makes the resulting germs identical; thus the iterated continuation is path independent inside the generated envelope. □

Remark 28.4 (Output of the primitive domain theorem for four-point scattering). For a massive Wightman theory with stable scalar external particles, the connected four-point Wightman distributions possess a crossing-symmetric primitive analytic germ obtained from Theorems 28.2 and 28.3. After separating the connected part and the external one-particle poles, LSZ boundary values in the physical s-, t-, and u-channel regions are boundary values of this germ on the corresponding real edges whenever those LSZ limits exist. Indeed, for $n = 4$, the preceding two theorems apply to each ordering and glue the ordered tubes along Jost edges. Passing to the connected part removes finite sums of products of lower-point distributions with the same spectral support and locality properties. The statement about scattering is not an additional analyticity theorem: it is the conditional transfer of this connected four-point germ through the already defined LSZ boundary operation, with wave-packet smearing, removal of the external one-particle pole factors, and the mass-shell limit taken only on edges where that limit exists.

28.2.2 Causal Commutators and the Dyson Representation

The next domain theorem uses the commutator rather than the ordered Wightman functions. It is the analytic reason that a coincidence region in momentum space can be converted into a representation by mass hyperboloids. This is the Jost–Lehmann–Dyson mechanism in the form needed for scattering amplitudes.

Let $C(x) \in \mathcal{S}'(\mathbb{M}^4)$ be a scalar tempered distribution whose support is contained in the closed causal cone

$$\overline{V}_{\text{caus}} = \{x \in \mathbb{M}^4 \mid x^2 \leq 0\}$$

in the mostly-plus convention. In QFT applications

$$C(x) = \langle Q_f, [J_1(x/2), J_2(-x/2)]Q_i\rangle \tag{28.4}$$

with J_i local current operators and with Q_i, Q_f finite-energy vectors. Local commutativity gives the support condition. Let

$$\widehat{C}(q) = \langle C(x), \mathrm{e}^{\mathrm{i}q\cdot x}\rangle$$

be its Fourier transform, again as a tempered distribution.

The representation also uses a momentum-space coincidence region. Let

$$R = \{q \in \mathbb{R}^4 \mid h_-(\vec{q}) < q^0 < h_+(\vec{q})\} \tag{28.5}$$

where $h_\pm : \mathbb{R}^3 \to \mathbb{R}$ are continuous functions satisfying

$$|h_\pm(\vec{q}) - h_\pm(\vec{q}\,')| \leq |\vec{q} - \vec{q}\,'|$$

and $h_-(\vec{q}) < h_+(\vec{q})$. Thus the boundary graphs are spacelike or null. Assume

$$\widehat{C}(q) = 0 \qquad q \in R \tag{28.6}$$

as a distributional restriction to R. For $u \in \mathbb{R}^4$ and $\mu \geq 0$, define the two mass-hyperboloid sheets

$$H_\pm(u, \mu) = \{q \in \mathbb{R}^4 \mid (q - u)^2 = -\mu^2,\ \pm(q^0 - u^0) > 0\}.$$

The pair (u,μ) is called R-admissible if

$$q \in H_+(u,\mu) \Rightarrow q^0 \geq h_+(\vec{q}), \qquad q \in H_-(u,\mu) \Rightarrow q^0 \leq h_-(\vec{q}). \tag{28.7}$$

Let $S_R \subset \mathbb{R}^4 \times [0,\infty)$ be the closed set of R-admissible pairs.

Lemma 28.5 (Distributional Cauchy formula for the six-dimensional wave equation)**.** *Let $Y = (\tau, \mathbf{y}) \in \mathbb{R}^{1,5}$, with $\mathbf{y} \in \mathbb{R}^5$, and let*

$$\Box_{1,5} = \partial_\tau^2 - \Delta_{\mathbf{y}}.$$

Let $F \in \mathcal{S}'(\mathbb{R}^{1,5})$ solve

$$\Box_{1,5} F = 0$$

in the distributional sense. Fix an affine spacelike hyperplane $\Sigma_{\tau_*} = \{\tau = \tau_*\}$, and suppose the Cauchy traces

$$f = F|_{\Sigma_{\tau_*}}, \qquad g = \partial_\tau F|_{\Sigma_{\tau_*}}$$

exist as tempered distributions on $\mathbb{R}^5$. Let D_6 be the odd fundamental solution of the six-dimensional wave equation, normalized by

$$\mathcal{F}_{\mathbf{y}} D_6(t,\cdot)(\mathbf{k}) = \frac{\sin(|\mathbf{k}|t)}{|\mathbf{k}|}, \qquad \partial_t D_6(0,\mathbf{y}) = \delta(\mathbf{y}), \qquad D_6(0,\mathbf{y}) = 0. \tag{28.8}$$

Then, as a tempered distribution in $Y_0 = (\tau_0, \mathbf{y}_0)$,

$$F(Y_0) = \langle f(\mathbf{y}), \partial_\tau D_6(\tau_* - \tau_0, \mathbf{y} - \mathbf{y}_0)\rangle_{\mathbf{y}} - \langle g(\mathbf{y}), D_6(\tau_* - \tau_0, \mathbf{y} - \mathbf{y}_0)\rangle_{\mathbf{y}}. \tag{28.9}$$

Equivalently, for an affine spacelike hyperplane $\Sigma \subset \mathbb{R}^{1,5}$ with future unit normal n,

$$F(Y_0) = \int_\Sigma \left(F(Y)\,\partial_{n_Y} D_6(Y - Y_0) - D_6(Y - Y_0)\,\partial_{n_Y} F(Y)\right) \mathrm{d}\Sigma(Y), \tag{28.10}$$

where the displayed integral denotes the distributional pairing of the Cauchy traces with the kernel.

Proof. It is enough to prove the formula for $\tau_* = 0$; translating τ gives the general case. Taking the Fourier transform in the five spatial variables converts the wave equation into

$$\partial_\tau^2 \widehat{F}(\tau,\mathbf{k}) + |\mathbf{k}|^2 \widehat{F}(\tau,\mathbf{k}) = 0 \tag{28.11}$$

in $\mathcal{S}'(\mathbb{R}_\tau \times \mathbb{R}^5_{\mathbf{k}})$. A distributional solution of this constant-coefficient ordinary differential equation is uniquely determined by

$$\widehat{F}(0,\mathbf{k}) = \widehat{f}(\mathbf{k}), \qquad \partial_\tau \widehat{F}(0,\mathbf{k}) = \widehat{g}(\mathbf{k}),$$

because the difference of two such solutions has zero Cauchy data and therefore pairs to zero with every compactly supported test function after solving the adjoint final-value problem. The solution is

$$\widehat{F}(\tau,\mathbf{k}) = \cos(|\mathbf{k}|\tau)\widehat{f}(\mathbf{k}) + \frac{\sin(|\mathbf{k}|\tau)}{|\mathbf{k}|}\widehat{g}(\mathbf{k}), \tag{28.12}$$

with the quotient interpreted by its smooth value τ at $\mathbf{k} = 0$. Inverse Fourier transformation and the normalization (28.8) give (28.9). The geometric form follows by applying a real Lorentz transformation carrying the chosen affine spacelike hyperplane to a constant-τ hyperplane; the wave operator, D_6, the normal derivative, and the distributional pairing are invariant under that transformation. $\square$

Lemma 28.6 (Auxiliary pushforward and the $p = 0$ momentum trace). *Let*

$$U \in \mathcal{S}'(\mathbb{R}^4_x \times \mathbb{R}^2_y)$$

and define its Fourier transform by duality from the convention

$$\Psi^\vee(x, y) = \int_{\mathbb{R}^4 \times \mathbb{R}^2} \Psi(q, p) \mathrm{e}^{\mathrm{i}q\cdot x + \mathrm{i}p\cdot y} \,\mathrm{d}^4 q \,\mathrm{d}^2 p, \qquad \langle \widehat{U}, \Psi \rangle = \langle U, \Psi^\vee \rangle. \tag{28.13}$$

Choose $\rho \in \mathcal{S}(\mathbb{R}^2_p)$ with $\int \rho(p) \,\mathrm{d}^2 p = 1$, set

$$\rho_\epsilon(p) = \epsilon^{-2} \rho(p/\epsilon), \qquad m_\epsilon(y) = \int_{\mathbb{R}^2} \rho_\epsilon(p) \mathrm{e}^{\mathrm{i}p\cdot y} \,\mathrm{d}^2 p. \tag{28.14}$$

Suppose that for every $\varphi \in \mathcal{S}(\mathbb{R}^4_x)$ the limit

$$\langle \pi_{y*} U, \varphi \rangle := \lim_{\epsilon \downarrow 0} \langle U, \varphi(x) m_\epsilon(y) \rangle \tag{28.15}$$

exists and is independent of the normalized approximate identity ρ. Then $\pi_{y*}U \in \mathcal{S}'(\mathbb{R}^4_x)$, and the trace of $\widehat{U}$ at $p = 0$, defined by

$$\left\langle \iota^* \widehat{U}, \psi \right\rangle := \lim_{\epsilon \downarrow 0} \left\langle \widehat{U}(q, p), \psi(q) \rho_\epsilon(p) \right\rangle, \qquad \iota(q) = (q, 0), \tag{28.16}$$

exists for every $\psi \in \mathcal{S}(\mathbb{R}^4_q)$ and obeys

$$\iota^* \widehat{U} = \widehat{\pi_{y*} U}. \tag{28.17}$$

Conversely, if the limits in (28.16) exist for every ψ and are continuous in the Schwartz topology, then (28.15) defines a tempered y-pushforward and (28.17) holds.

Proof. For $\psi \in \mathcal{S}(\mathbb{R}^4_q)$, define

$$\psi^\vee(x) = \int_{\mathbb{R}^4} \psi(q) \mathrm{e}^{\mathrm{i}q\cdot x} \,\mathrm{d}^4 q. \tag{28.18}$$

With the convention (28.13), the definition of the Fourier transform of a tempered distribution gives

$$\left\langle \widehat{U}(q, p), \psi(q) \rho_\epsilon(p) \right\rangle = \left\langle U(x, y), \psi^\vee(x) m_\epsilon(y) \right\rangle. \tag{28.19}$$

If the pushforward limit exists, the right side tends to

$$\langle \pi_{y*} U, \psi^\vee \rangle = \langle \widehat{\pi_{y*} U}, \psi \rangle,$$

which proves existence of the trace and (28.17). Continuity follows because the pointwise limit of the continuous functionals $\varphi \mapsto \langle U, \varphi(x) m_\epsilon(y) \rangle$ on the Schwartz space is continuous by the uniform boundedness principle for Frechet spaces; the Fourier transform is a topological automorphism of the Schwartz space.

Conversely, the map $\psi \mapsto \psi^\vee$ is a topological automorphism of $\mathcal{S}(\mathbb{R}^4)$. Given $\varphi \in \mathcal{S}(\mathbb{R}^4)$, choose ψ with $\psi^\vee = \varphi$. If the limits in (28.16) exist continuously, then (28.19) defines the limit in (28.15); the resulting functional on φ is tempered, and its Fourier transform is precisely $\iota^* \widehat{U}$. This proves the converse and the identity. $\square$

Definition 28.7 (Dyson-regular causal commutator)**.** A causal commutator distribution $C \in \mathcal{S}'(\mathbb{M}^4)$ is Dyson-regular if its Fourier transform is the restriction to the plane $p_1 = p_2 = 0$ of a rotationally invariant distribution

$$F(q, p_1, p_2) \in \mathcal{S}'(\mathbb{R}^{1,5})$$

with the following properties:

1. F solves the six-dimensional wave equation

$$\Box_{1,5} F = 0$$

   in the distributional sense.

2. On every affine spacelike hyperplane used in the Dyson argument, the traces $F|_\Sigma$ and $\partial_n F|_\Sigma$ exist as tempered distributions, and the distributional Cauchy formula (28.10) holds.

3. If U is the inverse Fourier transform of F, then U is supported on the six-dimensional light cone, the auxiliary y-pushforward $\pi_{y*}U$ exists in the sense of Lemma 28.6, and

$$\pi_{y*}U = \kappa C$$

   for a fixed nonzero normalization κ. Equivalently, after absorbing κ into the definition of the lift,

$$\iota^* F = \widehat{C}, \qquad \iota(q) = (q, 0, 0).$$

For a sufficiently regular function $C(x)$ with causal support this lift is represented by Dyson's formula

$$\widetilde{C}(x, y) = 4\pi C(x)\delta(x_D^2 - |y|^2), \qquad y \in \mathbb{R}^2,$$

in the temporary mostly-minus notation $x_D^2 = (x^0)^2 - |\vec{x}|^2$. This display is not a definition for an arbitrary Wightman distribution: multiplying an arbitrary distribution by the light-cone delta is a microlocal operation and requires a transversality or regularization argument. The definition records exactly the regularity datum needed for the Dyson proof; verifying it for a specified class of unsmeared QFT matrix coefficients is a separate theorem, not a notational convention.

Definition 28.8 (Support-pruned Dyson data in a coincidence slab)**.** Let R be the coincidence slab in (28.5), and let S_R be the corresponding closed set of admissible hyperboloids. For a distribution

$$\Psi \in \mathcal{D}'(\mathbb{R}^4_u \times [0, \infty)_\mu)$$

for which the pairing is defined, write

$$(\mathcal{H}\Psi)(q) = \big\langle \Psi(u, \mu), \varepsilon(q^0 - u^0)\delta\big((q-u)^2 + \mu^2\big)\big\rangle_{u,\mu} \tag{28.20}$$

for the Dyson hyperboloid transform. A Dyson-regular commutator has support-pruned Dyson data relative to R if the Cauchy-data distribution Ψ_Σ produced from its six-dimensional wave lift can be replaced, modulo the kernel of $\mathcal{H}$, by a distribution Ψ_R satisfying

$$\operatorname{supp} \Psi_R \subset S_R, \qquad \mathcal{H}\Psi_R = \mathcal{H}\Psi_\Sigma. \tag{28.21}$$

The condition is independent of the chosen affine Cauchy hyperplane in the following sense: changing the hyperplane changes Ψ_Σ by a distribution in the kernel of $\mathcal{H}$, because both Cauchy surfaces reconstruct the same six-dimensional wave solution by Lemma 28.5.

Proposition 28.9 (Axis trace nonuniqueness)**.** *Let the six-dimensional wave operator be written in affine coordinates*

$$Y = (\tau, \xi, p) \in \mathbb{R}_\tau \times \mathbb{R}^3_\xi \times \mathbb{R}^2_p, \qquad \Box_{1,5} = \partial_\tau^2 - \Delta_\xi - \Delta_p.$$

There exists a nonzero $O(2)$-invariant tempered smooth solution

$$F \in C^\infty(\mathbb{R}^{1,5})$$

of $\Box_{1,5} F = 0$ such that

$$F(\tau, \xi, 0) = 0 \qquad \textit{for } |\tau| < 1,\ \xi \in \mathbb{R}^3. \tag{28.22}$$

Thus vanishing of the auxiliary-momentum trace on a coincidence slab does not by itself imply that the six-dimensional Cauchy data vanish in the region of Cauchy-data space whose hyperboloids meet that slab.

Proof. Choose a nonzero function

$$a \in C_c^\infty((2,3))$$

and define radial Cauchy data on the auxiliary p-plane by

$$f(p) = a(|p|), \qquad g(p) = 0.$$

Let $F_0(\tau, p)$ be the solution of the $1+2$-dimensional wave equation

$$(\partial_\tau^2 - \Delta_p) F_0 = 0, \qquad F_0(0,p) = f(p), \qquad \partial_\tau F_0(0,p) = g(p).$$

The Cauchy problem with smooth compactly supported data has a unique smooth solution, obtained for instance by Fourier transform in p. Rotational invariance of the operator and uniqueness imply that $F_0(\tau, p)$ is $O(2)$-invariant. The finite-propagation estimate follows from the local energy identity. For a solution u of $(\partial_\tau^2 - \Delta_p)u = 0$, the stress tensor

$$e = \frac{1}{2}\big((\partial_\tau u)^2 + |\nabla_p u|^2\big), \qquad j = -\partial_\tau u \, \nabla_p u$$

satisfies $\partial_\tau e + \nabla_p \cdot j = 0$. Integrating this identity over a truncated backward cone with vertex (τ_0, p_0) gives

$$E(s_2) + \int_{\text{null side}} \frac{1}{2}\big(\partial_\tau u + \hat{n} \cdot \nabla_p u\big)^2 \, \mathrm{d}\sigma = E(s_1),$$

where $E(s)$ is the energy on the disk $|p - p_0| \le \tau_0 - s$ at time s and $\hat{n}$ is the outward radial unit vector on the side of the cone. The side flux is nonnegative, so zero Cauchy data on the base disk force u to vanish in the cone. Hence the value at (τ, p_0) depends only on the data in

$$\{p \in \mathbb{R}^2 : |p - p_0| \le |\tau|\}.$$

For $p_0 = 0$ and $|\tau| < 1$, this disk is disjoint from $\operatorname{supp} f \subset \{|p| > 2\}$ and from $\operatorname{supp} g$. Hence $F_0(\tau, 0) = 0$ for $|\tau| < 1$. On the other hand $F_0(0,p) = a(|p|)$ is not identically zero.

Define

$$F(\tau, \xi, p) = F_0(\tau, p).$$

Then F is independent of ξ, solves $\partial_\tau^2 F - \Delta_\xi F - \Delta_p F = 0$, is $O(2)$-invariant in the auxiliary variables, and satisfies (28.22). Since F_0 is smooth and has at most polynomial growth as a distribution under the Fourier-transform solution formula, its pullback constant in ξ is tempered on $\mathbb{R}^{1,5}$. This proves the claim. $\square$

Definition 28.10 (Dyson regularity modulo contact terms)**.** A causal commutator $C \in \mathcal{S}'(\mathbb{M}^4)$ is Dyson-regular modulo contact terms if there is a finite-order distribution L supported at $x = 0$ such that $C - L$ is Dyson-regular in the sense of Definition 28.7. Equivalently, $\widehat{C}$ has the Dyson hyperboloid representation of Theorem 28.15 plus a polynomial in q. This is the form actually used after source-current reduction, because applying differential wave operators to time-ordered products can produce local terms at coincident points.

Definition 28.11 (Local scaling degree)**.** Let $T \in \mathcal{D}'(\mathbb{R}^n \setminus \{0\})$. For $\varphi \in C_c^\infty(\mathbb{R}^n)$, set

$$\varphi_\lambda(z) = \lambda^{-n}\varphi(z/\lambda), \qquad 0 < \lambda < 1.$$

The scaling degree of T at the origin is

$$\mathrm{sd}_0(T) = \inf\left\{\omega \in \mathbb{R} \;\middle|\; \lambda^{\omega+\epsilon}\langle T, \varphi_\lambda\rangle \to 0 \text{ for every } \epsilon > 0 \text{ and every } \varphi\right\}. \tag{28.23}$$

Finite scaling degree means $\mathrm{sd}_0(T) < \infty$. With this normalization a smooth function has scaling degree 0, while $\partial^\alpha\delta_0$ in $\mathbb{R}^n$ has scaling degree $n + |\alpha|$.

Proposition 28.12 (Microlocal status of the Dyson light-cone lift)**.** *Let*

$$X^\circ = (\mathbb{M}^4 \times \mathbb{R}^2) \setminus \{(0,0)\}, \qquad g(x,y) = x_D^2 - |y|^2, \qquad \pi(x,y) = x,$$

where $x_D^2 = (x^0)^2 - |\vec{x}|^2$*. Let*

$$\mathcal{N}_{\mathrm{lc}} = \{(x; \lambda\,\mathrm{d}_x x_D^2) \mid x \neq 0,\ x_D^2 = 0,\ \lambda \in \mathbb{R}^\times\} \subset T^*\mathbb{M}^4 \setminus 0$$

be the conormal bundle of the punctured four-dimensional light cone. If $C \in \mathcal{D}'(\mathbb{M}^4)$ *satisfies*

$$\mathrm{WF}(C) \cap \mathcal{N}_{\mathrm{lc}} = \varnothing, \tag{28.24}$$

then the product

$$U^\circ = \pi^* C \cdot \delta(g) \tag{28.25}$$

is a well-defined distribution on X°*. If* $\operatorname{supp} C \subset \overline{V}_{\mathrm{caus}}$*, then*

$$\operatorname{supp} U^\circ \subset \{(x,y) \in X^\circ \mid x \in \overline{V}_{\mathrm{caus}},\ x_D^2 = |y|^2\}.$$

Any two extensions of U° *to* $\mathbb{M}^4 \times \mathbb{R}^2$ *differ by a distribution supported at* $(0,0)$*. Hence their six-dimensional Fourier transforms differ by a polynomial in the six dual momenta, and their restrictions to* $p_1 = p_2 = 0$ *differ by a polynomial in* q*.*

Consequently, if $\mathrm{WF}(C)$ *contains a nonzero covector conormal to the punctured light cone, Dyson's displayed product*

$$C(x)\delta(x_D^2 - |y|^2)$$

is not canonically defined by the standard product of distributions. In that case a Dyson lift, if it exists, contains extra renormalized extension data; that data is invisible away from the light-cone vertex only after one proves the corresponding finite-contact ambiguity and the six-dimensional wave equation.

Proof. The projection $\pi : X^\circ \to \mathbb{M}^4$ is a submersion, so the pullback π^*C is always defined and

$$\mathrm{WF}(\pi^*C) \subset \{(x, y; \xi, 0) \mid (x; \xi) \in \mathrm{WF}(C)\}. \tag{28.26}$$

On X°, the hypersurface $g = 0$ is smooth: the only zero of $\mathrm{d}g$ is $(0, 0)$, which has been removed. Therefore

$$\mathrm{WF}(\delta(g)) = \{(x, y; \lambda\, \mathrm{d}_x g, \lambda\, \mathrm{d}_y g) \mid g(x, y) = 0,\ \lambda \in \mathbb{R}^\times\}. \tag{28.27}$$

Hormander's product criterion says that the product of two distributions is defined if their wavefront sets contain no pair of opposite covectors over the same base point. A possible obstruction to multiplying π^*C by $\delta(g)$ would therefore require

$$(\xi, 0) + (\lambda\, \mathrm{d}_x g, \lambda\, \mathrm{d}_y g) = 0.$$

If $y \neq 0$, then $\mathrm{d}_y g = -2y \cdot \mathrm{d}y \neq 0$, and the second component cannot vanish for $\lambda \neq 0$. Hence the only obstruction can occur at $y = 0$. On $g = 0$, this forces $x_D^2 = 0$, and the remaining obstruction is precisely

$$(x; \xi) = (x; -\lambda\, \mathrm{d}_x x_D^2) \in \mathcal{N}_{\mathrm{lc}}.$$

The transversality condition (28.24) excludes this case and proves that (28.25) is a well-defined distribution on X°.

The support statement follows from the elementary support rule for a defined product of distributions:

$$\mathrm{supp}(\pi^*C \cdot \delta(g)) \subset \pi^{-1}(\mathrm{supp}\, C) \cap \{g = 0\}.$$

If U_1 and U_2 are two extensions to the full six-dimensional space, then $U_1 - U_2$ vanishes on X°, so its support is contained in the single point $(0, 0)$. A distribution supported at one point is a finite linear combination of derivatives of the delta distribution at that point:

$$U_1 - U_2 = \sum_{|\alpha|+|\beta| \leq N} c_{\alpha\beta}\, \partial_x^\alpha \partial_y^\beta \delta(x)\delta(y).$$

Fourier transformation sends this finite sum to a polynomial in (q, p_1, p_2), and restriction to $p_1 = p_2 = 0$ gives a polynomial in q. This is exactly the local-contact ambiguity recorded in the Dyson representation. □

Theorem 28.13 (Punctured Dyson lift and finite scaling degree)**.** *Let $C \in \mathcal{S}'(\mathbb{M}^4)$ be supported in $\overline{V}_{\mathrm{caus}}$ and suppose that the wavefront transversality condition*

$$\mathrm{WF}(C) \cap \mathcal{N}_{\mathrm{lc}} = \varnothing$$

holds on the punctured four-dimensional light cone. Let

$$U^\circ = \kappa\, \pi^*C \cdot \delta(x_D^2 - |y|^2) \qquad \text{on } X^\circ = (\mathbb{M}^4 \times \mathbb{R}^2) \setminus \{0\}, \tag{28.28}$$

where $\kappa \neq 0$ is a fixed normalization. Assume that U° has finite scaling degree at the origin in $\mathbb{R}^6$, and that it admits a tempered $O(2)$-invariant extension

$$U \in \mathcal{S}'(\mathbb{R}^6)$$

with the following three further properties:

$$\mathrm{supp}\, U \subset \{(x, y) \mid x \in \overline{V}_{\mathrm{caus}},\ x_D^2 = |y|^2\}. \tag{28.29}$$

$$(x_D^2 - |y|^2)\, U = 0, \tag{28.30}$$

and the y-pushforward of U, with the chosen normalization κ, equals C modulo a distribution supported at $x = 0$. Then the Fourier transform

$$F(q, p_1, p_2) = \widehat{U}(q, p_1, p_2)$$

is rotationally invariant in (p_1, p_2) and solves

$$\Box_{1,5} F = 0 \tag{28.31}$$

in the distributional sense. The restriction of F to $p_1 = p_2 = 0$, if defined by the chosen extension, equals $\widehat{C}(q)$ up to a polynomial in q. Hence C is Dyson-regular modulo contact terms once the restriction and Cauchy-data requirements in Definition 28.7 are satisfied by F.

Moreover, if U_1 and U_2 are two such finite-scaling-degree extensions, then

$$U_1 - U_2 = \sum_{|\alpha|+|\beta| \le N} c_{\alpha\beta}\, \partial_x^\alpha \partial_y^\beta \delta(x)\delta(y) \tag{28.32}$$

for some N. Thus the induced ambiguity in $F(q, 0, 0)$ is a finite polynomial in q, and no cut, threshold, or hyperboloid support is changed by choosing a different extension.

Proof. The product U° on X° is well-defined by Proposition 28.12. We first recall the extension mechanism because it is the local analytic part of the argument. Let $n = 6$ and let $T^\circ \in \mathcal{D}'(\mathbb{R}^n \setminus \{0\})$ have finite scaling degree s at the origin. Put

$$m = \lfloor s \rfloor - n$$

when $s \ge n$, and $m = -1$ otherwise. Choose $\chi \in C_c^\infty(\mathbb{R}^n)$ equal to 1 near the origin. For a test function φ, define

$$R_m\varphi(z) = \varphi(z) - \chi(z) \sum_{|\alpha| \le m} \frac{z^\alpha}{\alpha!} \partial^\alpha \varphi(0) \tag{28.33}$$

with the sum omitted when $m = -1$. The function $R_m\varphi$ vanishes at the origin to order $m+1$. Let $\chi_\epsilon(z) = \chi(z/\epsilon)$. The finite-scaling-degree bound makes the limit

$$T_0(\varphi) = \lim_{\epsilon \downarrow 0} T^\circ\big((1 - \chi_\epsilon) R_m \varphi\big)$$

finite and continuous in the test-function topology: the Taylor remainder removes precisely the jets whose scaling would make the punctured distribution divergent at the origin. The possible values of an extension on the finite jet removed in (28.33) are exactly the constants multiplying $\partial^\alpha \delta_0$ for $|\alpha| \le m$. This gives an extension of T°, preserves the scaling degree, and shows that two extensions with the same punctured distribution differ by a finite sum of derivatives of δ_0. If T° is supported in a closed cone with vertex at the origin, the same construction applied after restricting test functions supported away from that cone gives an extension with support in the closed cone; the only new support allowed by extension is the vertex itself.

Applying this statement to $T^\circ = U^\circ$ gives the asserted local ambiguity (28.32). The additional condition (28.30) is essential: support on the cone alone would still allow derivatives of the delta distribution in the normal direction at the vertex, and multiplication by the quadratic equation need not annihilate such terms. Fourier transformation converts multiplication by $x_D^2 - |y|^2$ into the six-dimensional wave operator in momentum space, up to the sign fixed by the Fourier convention. Therefore $\square_{1,5} F = 0$. Rotational invariance in the two auxiliary momenta is one of the stated extension requirements. Equivalently, if a non-invariant extension satisfying the other conditions has been constructed, averaging it over $O(2)$ preserves the punctured value, support, (28.30), and the pushforward normalization.

It remains to identify the four-dimensional restriction. On X°, the y-pushforward of the punctured expression is the intended four-dimensional commutator with the normalization κ. The theorem therefore requires the extension to preserve this pushforward modulo a distribution supported at $x = 0$. By Lemma 28.6, Fourier transformation of this y-pushforward is precisely the $p = 0$ trace of $\widehat{U}(q, p)$, when either side exists in the stated distributional sense. Hence the distribution obtained by restricting $\widehat{U}(q, p)$ to $p = 0$ differs from $\widehat{C}(q)$ by the Fourier transform of a distribution supported at $x = 0$, namely by a polynomial in q. The same conclusion follows directly from (28.32): setting $p = 0$ turns the Fourier transform of every $\partial_x^\alpha \partial_y^\beta \delta(x)\delta(y)$ into a polynomial in q, with the p-powers evaluated at zero.

The theorem has not proved the physical source-current kernels to be Dyson-regular. It proves the exact local construction that remains once the punctured wavefront condition, finite scaling degree, cone equation, pushforward normalization, temperedness, and Cauchy-data trace hypotheses have been verified for those kernels. Under those hypotheses the difference between the constructed lift and a strict Dyson lift is only a contact term, so Definition 28.10 applies. □

Proposition 28.14 (Source-current differentials preserve the punctured input)**.** *Let Φ_b, Φ_c be local scalar fields and let Ψ_i, Ψ_f be normalizable finite-energy vectors. Define the relative-coordinate commutator matrix element*

$$C_{bc}^{\Phi}(x) = \langle \Psi_f, [\Phi_b(x/2), \Phi_c(-x/2)]\Psi_i \rangle \in \mathcal{S}'(\mathbb{M}^4). \tag{28.34}$$

Let $\mathcal{K}_b(\partial_{x_b})$ and $\mathcal{K}_c(\partial_{x_c})$ be the mostly-plus Klein–Gordon LSZ operators used to define source currents

$$J_b = \mathcal{K}_b \Phi_b, \qquad J_c = \mathcal{K}_c \Phi_c.$$

Set

$$P_{bc}(\partial_x) = \mathcal{K}_b(2\partial_x)\mathcal{K}_c(-2\partial_x), \qquad r = \operatorname{ord} P_{bc}. \tag{28.35}$$

Then

$$C_{bc}^{J}(x) = \langle \Psi_f, [J_b(x/2), J_c(-x/2)]\Psi_i \rangle = P_{bc}(\partial_x) C_{bc}^{\Phi}(x) \tag{28.36}$$

as tempered distributions. Consequently:

1. *If* $\operatorname{supp} C_{bc}^{\Phi} \subset \overline{V}_{\text{caus}}$, *then*
$$\operatorname{supp} C_{bc}^{J} \subset \overline{V}_{\text{caus}}.$$

2. *If*
$$\mathrm{WF}(C_{bc}^{\Phi}) \cap \mathcal{N}_{\text{lc}} = \varnothing,$$
then
$$\mathrm{WF}(C_{bc}^{J}) \cap \mathcal{N}_{\text{lc}} = \varnothing.$$

3. *If C_{bc}^{Φ} has finite scaling degree s at $x = 0$, then C_{bc}^{J} has finite scaling degree at most $s + r$.*

4. Under the preceding wavefront and scaling assumptions, the punctured Dyson product

$$U_{bc}^{J,\circ} = \kappa\, \pi^* C_{bc}^J \cdot \delta(x_D^2 - |y|^2) \qquad \text{on } X^\circ \tag{28.37}$$

is well-defined and has finite scaling degree at the six-dimensional origin, bounded by $s+r+2$.

Thus replacing interpolating fields by LSZ source currents supplies no new punctured light-cone obstruction beyond finite-order differentiation. The remaining, genuinely nonlocal input for Theorem 28.13 is the existence of a tempered $O(2)$-invariant extension satisfying the cone equation, pushforward normalization, and Cauchy-data trace requirements.

Proof. The coordinate $x_b = x/2$ gives

$$\partial_{x_b^\mu} = 2\partial_{x^\mu},$$

whereas $x_c = -x/2$ gives

$$\partial_{x_c^\mu} = -2\partial_{x^\mu}.$$

Since the LSZ source currents are obtained by constant-coefficient differential operators acting on the corresponding field variable, the commutator matrix element is obtained from (28.34) by the operator (28.35). This proves (28.36).

Differentiation cannot enlarge support, so causal support is preserved. For wavefront sets, every constant-coefficient differential operator P satisfies

$$\mathrm{WF}(PT) \subset \mathrm{WF}(T). \tag{28.38}$$

Indeed, after multiplying by a cutoff χ equal to one near a point, the Fourier transform of χPT is a polynomial in the Fourier variable times the Fourier transform of χT, plus lower-order terms with cutoffs supported in the same neighbourhood; polynomial multiplication cannot destroy rapid decay in a conic neighbourhood where χT already has rapid decay. This proves the wavefront assertion.

The scaling-degree estimate is equally direct. For a multi-index α,

$$\langle \partial^\alpha T, \varphi_\lambda \rangle = (-1)^{|\alpha|} \lambda^{-|\alpha|} \langle T, (\partial^\alpha \varphi)_\lambda \rangle. \tag{28.39}$$

Thus $\mathrm{sd}_0(\partial^\alpha T) \le \mathrm{sd}_0(T) + |\alpha|$. Applying this to every derivative in P_{bc} gives $\mathrm{sd}_0(C_{bc}^J) \le s + r$.

The punctured product (28.37) is defined by Proposition 28.12, because the source-current commutator has the same conormal avoidance. It remains only to record finite scaling degree in six dimensions. The pullback $\pi^* C_{bc}^J$ has the same local scaling degree as C_{bc}^J: when a six-dimensional test function is scaled, integration over the two auxiliary y-variables produces a scaled four-dimensional test function with the same power of λ relevant to the x-distribution. The distribution $\delta(x_D^2 - |y|^2)$ is homogeneous of degree -2, hence has scaling degree 2 in $\mathbb{R}^6$. The product is a continuous microlocal product on the conic wavefront neighbourhoods fixed in the previous proposition, and the defining seminorm estimates give the standard subadditivity bound

$$\mathrm{sd}_0\big(\pi^* C_{bc}^J \cdot \delta(x_D^2 - |y|^2)\big) \le \mathrm{sd}_0(C_{bc}^J) + 2 \le s + r + 2. \tag{28.40}$$

This proves the final assertion. $\square$

Theorem 28.15 (Dyson representation of a causal commutator)**.** *Let $C \in \mathcal{S}'(\mathbb{M}^4)$ be Dyson-regular in the sense of Definition 28.7. Assume* $\operatorname{supp} C \subset \overline{V}_{\text{caus}}$*. Then there is a distribution*

$$\Psi \in \mathcal{D}'(\mathbb{R}^4_u \times [0,\infty)_\mu)$$

such that, in $\mathcal{D}'(\mathbb{R}^4_q)$,

$$\widehat{C}(q) = \big\langle \Psi(u,\mu), \varepsilon(q^0 - u^0)\,\delta\big((q-u)^2 + \mu^2\big)\big\rangle_{u,\mu}. \tag{28.41}$$

Here $\varepsilon(t) = 1$ for $t > 0$ and $\varepsilon(t) = -1$ for $t < 0$. If, in addition, $\widehat{C}$ vanishes in the slab R of (28.5) and the Dyson data are support-pruned relative to R in the sense of Definition 28.8, then Ψ can be chosen with

$$\operatorname{supp}\Psi \subset S_R.$$

If a later source-current or retarded-product reduction adds local terms supported at $x = 0$, their Fourier transforms are finite polynomials in q. Such local-contact polynomials are recorded separately; they do not change the hyperboloid support or the holomorphic domain away from infinity.

Proof. The proof is a hyperbolic Cauchy problem in disguise. We give it because the support statement is the part that carries the QFT locality information into the analytic domain. The Dyson-regularity hypothesis supplies the six-dimensional wave-equation solution F; without that hypothesis, the formal product $C(x)\delta(x_D^2 - |y|^2)$ at the light cone would not be a legitimate operation for an arbitrary tempered distribution.

Temporarily write the scalar product in Dyson's mostly-minus convention

$$x_D^2 = (x^0)^2 - |\vec{x}|^2 = -x^2.$$

The causal support hypothesis becomes $C(x) = 0$ for $x_D^2 < 0$. Add two auxiliary spacelike coordinates $y = (y_1, y_2)$ and set

$$Z = (x,y) \in \mathbb{R}^{1,5}, \qquad Z_D^2 = x_D^2 - y_1^2 - y_2^2.$$

Let $R_6 = (q, p_1, p_2)$ be the six-dimensional momentum dual to Z. By Dyson regularity there is a rotationally invariant distribution $F(R_6)$ such that

$$\Box_{1,5} F = 0. \tag{28.42}$$

and the original Fourier transform is recovered as the boundary value

$$\widehat{C}(q) = F(q,0,0)$$

after absorbing the fixed normalization constant in the definition of the lift. In the regular-function case this F is the Fourier transform of $4\pi C(x)\delta(Z_D^2)$, which explains the geometry of the construction.

For solutions of (28.42) with the Dyson-regular Cauchy traces, Lemma 28.5 gives, on every affine spacelike hyperplane $\Sigma \subset \mathbb{R}^{1,5}$,

$$F(R_0) = \int_\Sigma \big(F(R)\,\partial_{n_R} D_6(R - R_0) - D_6(R - R_0)\,\partial_{n_R} F(R)\big)\,\mathrm{d}\Sigma(R), \tag{28.43}$$

where D_6 is the odd fundamental solution of the six-dimensional wave operator and n_R is the future unit normal to Σ. This is a theorem about the linear wave equation and its distributional Cauchy data; no QFT input enters it after Dyson regularity has supplied the traces.

Take $R_0 = (q, 0, 0)$. Because D_6 is supported on the six-dimensional light cone, and because F is rotation-invariant in the last two momenta, the angular integral over the (p_1, p_2)-plane rewrites (28.43) as a superposition of four-dimensional mass hyperboloids:

$$F(q, 0, 0) = \left\langle \Psi_\Sigma(u, \mu), \varepsilon(q_D^0 - u_D^0)\delta\big((q_D - u_D)^2 - \mu^2\big) \right\rangle. \tag{28.44}$$

Here u is the four-momentum part of the point $R \in \Sigma$, while $\mu = (p_1^2 + p_2^2)^{1/2}$; the distribution Ψ_Σ is the push forward of the Cauchy data $(F|_\Sigma, \partial_n F|_\Sigma)$ with the differential operator that comes from $\partial_n D_6$. Returning to the mostly-plus convention changes $(q_D - u_D)^2 - \mu^2 = 0$ into $(q-u)^2 + \mu^2 = 0$, giving the kernel in (28.41).

The support-restricted conclusion is now exactly the content of Definition 28.8. If the commutator vanishes in the slab R and its Dyson data are support-pruned relative to R, choose Ψ_R satisfying (28.21). Since $\mathcal{H}\Psi_R = \mathcal{H}\Psi_\Sigma = \widehat{C}$, the same hyperboloid representation holds with $\operatorname{supp}\Psi_R \subset S_R$.

The geometric reason for the support-pruning condition is the following. If $(u, \mu) \notin S_R$, at least one sheet of the hyperboloid $(q-u)^2 = -\mu^2$ enters the coincidence slab. Since the slab boundaries are spacelike or null graphs, a small double cone in momentum space adapted to that sheet lies inside R. The classical Jost–Lehmann–Dyson proof uses the six-dimensional wave equation and domain-of-dependence uniqueness to remove the corresponding Cauchy-data component. In this monograph that removal is recorded as the support-pruning theorem still to be proved for the LSZ source-current kernels; it is not identified with the simpler statement that the trace $F(q, 0, 0)$ vanishes in R.

The statement about finite contact polynomials follows from differentiating the commutator or from derivatives of step functions in retarded products: Fourier transformation changes local distributions supported at $x = 0$ into polynomials in q. Such terms have no cut or hyperboloid support and are separated as subtraction/contact terms in dispersion formulae. □

Proposition 28.16 (Coincidence regions from the spectral condition)**.** *Let J_b, J_c be local source-current fields whose matrix elements with the states below define tempered distributions. Let Ψ_i, Ψ_f be normalizable vectors whose joint energy-momentum spectral supports are compact sets $B_i, B_f \subset \operatorname{Spec}(P)$, and let $E(\cdot)$ be the joint spectral measure of P^μ. Define the intermediate spectral matrix distributions*

$$\begin{aligned} \mathrm{d}\nu_{bc}^+(r_f, p, r_i) &= \langle E(\mathrm{d}r_f)\Psi_f, J_b(0)E(\mathrm{d}p)J_c(0)E(\mathrm{d}r_i)\Psi_i\rangle, \\ \mathrm{d}\nu_{bc}^-(r_f, p, r_i) &= \langle E(\mathrm{d}r_f)\Psi_f, J_c(0)E(\mathrm{d}p)J_b(0)E(\mathrm{d}r_i)\Psi_i\rangle. \end{aligned} \tag{28.45}$$

Let $\mathfrak{S}_{bc}^+$ and $\mathfrak{S}_{bc}^-$ be their supports in

$$B_f \times \operatorname{Spec}(P) \times B_i.$$

With the Fourier convention

$$\widehat{f}(q) = \int \mathrm{e}^{\mathrm{i}q\cdot x} f(x)\,\mathrm{d}^4x,$$

the two ordered matrix elements

$$C_{bc}^+(x) = \langle \Psi_f, J_b(x/2)J_c(-x/2)\Psi_i\rangle, \qquad C_{bc}^-(x) = \langle \Psi_f, J_c(-x/2)J_b(x/2)\Psi_i\rangle$$

obey

$$\operatorname{supp}\widehat{C}^{+}_{bc} \subset \left\{ p - \frac{1}{2}(r_f + r_i) \;\middle|\; (r_f, p, r_i) \in \mathfrak{S}^{+}_{bc} \right\},$$
$$\operatorname{supp}\widehat{C}^{-}_{bc} \subset \left\{ \frac{1}{2}(r_f + r_i) - p \;\middle|\; (r_f, p, r_i) \in \mathfrak{S}^{-}_{bc} \right\}. \tag{28.46}$$

Hence the commutator distribution

$$C_{bc} = C^{+}_{bc} - C^{-}_{bc}$$

has Fourier transform supported in the union of the two displayed sets. Every open set R disjoint from this union is a coincidence region:

$$\widehat{C}_{bc}(q) = 0 \qquad (q \in R). \tag{28.47}$$

The coarser but often sufficient replacement

$$\mathfrak{S}^{\pm}_{bc} \subset B_f \times \overline{V}_{+} \times B_i$$

uses

$$K_{fi} = \frac{1}{2}(B_f + B_i) = \left\{ \frac{1}{2}(r_f + r_i) \;\middle|\; r_f \in B_f,\ r_i \in B_i \right\}$$

and gives the model coincidence region between the two shifted spectral cones

$$\overline{V}_{+} - K_{fi}, \qquad K_{fi} - \overline{V}_{+}.$$

For generalized sharp external momenta Q_i, Q_f, one recovers the familiar shorthand by setting $K = (Q_f + Q_i)/2$ and

$$\Sigma^{fi}_{bc} = \operatorname{supp}\langle J_b(0)^{*}\Psi_f, E(\mathrm{d}p) J_c(0)\Psi_i\rangle, \qquad \Sigma^{fi}_{cb} = \operatorname{supp}\langle J_c(0)^{*}\Psi_f, E(\mathrm{d}p) J_b(0)\Psi_i\rangle,$$

so that the two ordered supports are contained in

$$\Sigma^{fi}_{bc} - K, \qquad K - \Sigma^{fi}_{cb}.$$

Proof. Translation covariance gives

$$J_b(x/2) = \mathrm{e}^{\mathrm{i}P\cdot x/2} J_b(0) \mathrm{e}^{-\mathrm{i}P\cdot x/2}, \qquad J_c(-x/2) = \mathrm{e}^{-\mathrm{i}P\cdot x/2} J_c(0) \mathrm{e}^{\mathrm{i}P\cdot x/2}.$$

Insert the spectral resolution of P on the external vectors and between the two currents. The first ordered matrix element becomes

$$\begin{aligned} C^{+}_{bc}(x) &= \int \mathrm{e}^{\mathrm{i}(r_f + r_i)\cdot x/2} \mathrm{e}^{-\mathrm{i}p\cdot x}\, \mathrm{d}\nu^{+}_{bc}(r_f, p, r_i) \\ &= \int \mathrm{e}^{\mathrm{i}((r_f + r_i)/2 - p)\cdot x}\, \mathrm{d}\nu^{+}_{bc}(r_f, p, r_i), \end{aligned} \tag{28.48}$$

where the equality is first read after smearing all fields and then extended to the matrix-element distribution by Wightman temperedness. Pairing against a test function in x and using the Fourier convention in the statement shows that $\widehat{C}^{+}_{bc}$ is supported where

$$q + \frac{1}{2}(r_f + r_i) - p = 0.$$

Thus $q = p - \frac{1}{2}(r_f + r_i)$ with $(r_f, p, r_i) \in \mathfrak{S}^+_{bc}$. This is the first inclusion in (28.46).

The second ordered product is

$$\begin{aligned} C^-_{bc}(x) &= \int e^{-i(r_f+r_i)\cdot x/2} e^{ip\cdot x}\, d\nu^-_{bc}(r_f, p, r_i) \\ &= \int e^{i(p-(r_f+r_i)/2)\cdot x}\, d\nu^-_{bc}(r_f, p, r_i). \end{aligned} \tag{28.49}$$

Therefore its Fourier transform is supported where

$$q + p - \frac{1}{2}(r_f + r_i) = 0,$$

or $q = \frac{1}{2}(r_f + r_i) - p$, proving the second inclusion. Taking the difference of the two ordered products proves the support inclusion for the commutator. A distribution whose Fourier support is contained in a closed set vanishes on every open set disjoint from that support, which proves (28.47). □

Remark 28.17 (JLD input for the LSZ retarded commutator). Let

$$J_b = \mathcal{K}_b \Phi_b, \qquad J_c = \mathcal{K}_c \Phi_c$$

denote the source currents obtained by applying the mostly-plus Klein–Gordon operators $\mathcal{K}_b, \mathcal{K}_c$ used in the LSZ reduction formula. For finite-energy states $|Q_i\rangle, |Q_f\rangle$, assume that the distribution

$$C_{bc}(x) = \langle Q_f, [J_b(x/2), J_c(-x/2)] Q_i\rangle$$

is Dyson-regular modulo contact terms in the sense of Definition 28.10. Then the nonlocal part of C_{bc} has a Dyson representation of the form (28.41), plus a finite polynomial in q from contact terms. In a coincidence slab R where the intermediate-state spectral condition makes the nonlocal part of $\widehat{C}_{bc}$ vanish, this representation is support-restricted to S_R if and only if the corresponding Dyson data are support-pruned relative to R in the sense of Definition 28.8. The associated retarded and advanced Fourier transforms

$$C^R_{bc}(q) = \int e^{iq\cdot x} \theta(x^0) C_{bc}(x)\, d^4x, \qquad C^A_{bc}(q) = -\int e^{iq\cdot x} \theta(-x^0) C_{bc}(x)\, d^4x$$

are boundary values of the same analytic continuation across that coincidence region, up to the finite contact polynomials generated by the source-current reduction. The justification is exactly the chain of hypotheses now separated above. Locality gives causal support; Proposition 28.16 gives the spectral coincidence regions; Dyson regularity is the extra six-dimensional wave-equation input needed to use Theorem 28.15; support restriction inside a slab is a property of the Cauchy-data class modulo $\ker \mathcal{H}$, together with the separate datum that $\widehat{C}_{bc} = 0$ on the slab. Local source-current terms supported at $x = 0$ transform to finite polynomials in q. The edge-of-the-wedge continuation of retarded and advanced boundary values is therefore a conditional analytic consequence of these inputs, with theorem status supplied only after the hypotheses are verified.

Remark 28.4 is the rigorous crossing-domain input supplied directly by the Wightman locality and spectrum axioms, while Proposition 28.16 supplies the spectral coincidence regions for the LSZ source-current commutator. Theorem 28.15 then supplies the causal-commutator representation used to enlarge domains from those coincidence regions, provided the commutator is Dyson-regular modulo contact terms; the S_R-support-restricted version additionally requires support-pruned Dyson data relative to the coincidence slab. The stronger fixed-t cut-plane theorem used in dispersion relations still requires the Dyson-regularity and support-pruning verification for the relevant LSZ source-current matrix coefficients. Proposition 28.12 shows the precise microlocal obstruction to treating Dyson's light-cone lift as an ordinary product of distributions, and identifies the finite local ambiguity of any renormalized lift. Theorem 28.13 then proves the local finite-scaling-degree extension mechanism, including the cone equation, pushforward normalization, and the fact that all remaining extension ambiguity is polynomial after Fourier transformation. Proposition 28.14 checks that passing from interpolating fields to LSZ source currents preserves the punctured wavefront and finite-scaling-degree inputs by finite-order differentiation, with the correct $x/2$ and $-x/2$ factors. What remains is not the differential source-current step, but the actual QFT theorem constructing the required extension, Cauchy data, and support-pruning for the source-current kernel. After that regularity problem one still needs the Bros–Epstein–Glaser analytic-completion step and the LSZ pole-separation transfer hypotheses. The analytic LSZ transfer itself is proved in Theorem 29.17: once an off-shell fixed-t domain has normal-crossing external one-particle poles with uniform boundary growth, restricting the LSZ-amputated germ to the external mass shells preserves holomorphy and tempered discontinuities. What remains here is to prove that the primitive four-point germ and the causal-commutator Dyson representation extend far enough to give such an off-shell first-sheet s-plane domain at fixed t, with only the stated right- and left-hand cuts and with controlled boundary growth. That additional step is the Lehmann–Martin/Jin–Martin domain theorem, not a restatement of primitive tube analyticity.

The same symbol $\mathcal{M}(s,t)$ will denote the holomorphic germ $F(s,t,4m^2-s-t)$ on whichever connected domain is under discussion, and its physical value will always mean the specified tempered boundary value. Analytic continuation is continuation of this germ through overlapping domains in $\mathcal{O}_{\text{poly}}$. If two such germs have the same tempered boundary value on a nonempty real open edge, the edge-of-the-wedge theorem gives a common continuation to the envelope generated by the adjacent tubes; inside a connected holomorphic domain the ordinary identity theorem then gives uniqueness. No perturbative Borel summation procedure is part of this definition. The polynomial growth in $\mathcal{O}_{\text{poly}}$ is the local growth condition needed for distributional boundary values; polynomial boundedness in high-energy directions is a stronger global estimate and is introduced only in the dispersion-relation chapter.

Hermiticity of the theory and the Feynman boundary prescription imply real analyticity on conjugate domains:

$$\mathcal{M}(s^*,t^*) = \mathcal{M}(s,t)^*$$

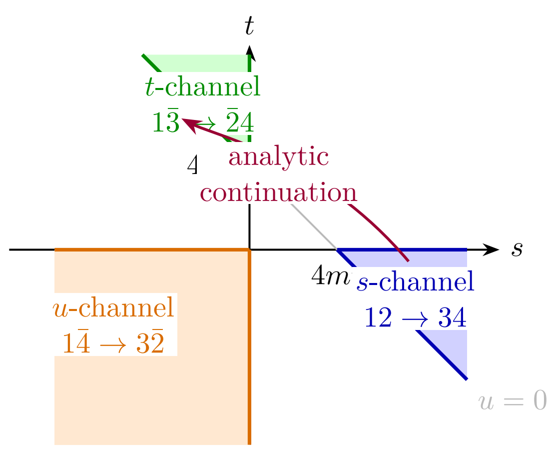
where both sides are evaluated on corresponding branches. On a real segment not lying on a cut, this says that the first-sheet value is real up to pole singularities. On a cut, it relates the lower-edge and upper-edge boundary values. In perturbation theory the same property is visible graph by graph when the couplings are real.

Crossing states that the s-, t-, and u-channel physical amplitudes are boundary values of the same analytically continued four-point function in different real regions, with the external representation conjugated when an outgoing particle is moved to the incoming side or conversely. On the real (s,t)-plane these regions are separated by thresholds and cuts. The locality-and-spectrum argument gives a common analytic germ in the Bros–Epstein–Glaser envelope generated by the relevant tube domains and spacelike edge identifications. A stronger statement, namely that full physical s- and crossed-channel regions can be joined by a path on a specified first-sheet domain, requires an analyticity domain large enough to contain that path. In four spacetime dimensions this larger Mandelstam-type domain requires input beyond the edge-of-the-wedge argument alone.

The Mandelstam representation is a stronger conjectural statement about this same four-point function. For equal external masses, with $u = 4m^2 - s - t$, it would assert that, after all first-sheet pole terms and a specified finite polynomial subtraction have been separated, the remaining amplitude admits a simultaneous two-variable dispersion representation of the form

$$\mathcal{M}_{\mathrm{reg}}(s,t) = \sum_{\chi=s,t,u} \int_{\chi_0}^{\infty} \frac{\rho_\chi(\sigma)}{\sigma - \chi}\,\mathrm{d}\sigma + \sum_{(\chi,\chi')=(s,t),(s,u),(t,u)} \int_{\chi_0}^{\infty} \mathrm{d}\sigma \int_{\chi_0'}^{\infty} \mathrm{d}\tau\, \frac{\rho_{\chi\chi'}(\sigma,\tau)}{(\sigma-\chi)(\tau-\chi')},$$

with $i0$ boundary prescriptions assigned when a physical edge of a cut is approached. Here ρ_χ and $\rho_{\chi\chi'}$ are single and double discontinuity distributions, and the support restrictions on the double spectral distributions are part of the conjectural content. This simultaneous-cut representation is stronger than the single-variable Cauchy representation at fixed t. No derivation is presently available for general interacting four-dimensional Wightman theories with a mass gap. The arguments in this monograph use fixed-t or fixed-crossed-variable dispersion relations together with crossing and angular analyticity; the Mandelstam representation is not assumed in those deductions.



28.3 Unitarity on the Physical Cut

Crossing and real analyticity constrain how different boundary values fit together. On the physical s-channel cut there is also the Hilbert-space constraint from the unitary scattering operator. Let $S_\ell(s)$ denote the angular-momentum-ℓ partial-wave scattering eigenvalue in the identical-scalar two-particle sector, with the normalization fixed earlier. The elastic $2 \to 2$ amplitude is

$$\mathcal{M}(s,t) = -16\pi \mathrm{i} \sqrt{\frac{s}{s-4m^2}} \sum_{\ell=0}^{\infty} (2\ell+1) P_\ell(\cos\theta) \big(S_\ell(s) - 1\big),$$

where

$$\cos\theta = 1 + \frac{2t}{s-4m^2}.$$

Unitarity of S implies, for $s \geq 4m^2$,

$$|S_\ell(s)| \leq 1.$$

If no inelastic channel is open, namely for

$$4m^2 \leq s \leq M_{\text{inel}}^2,$$

the partial wave is a phase and

$$|S_\ell(s)| = 1.$$

Here M_{inel} is the invariant mass threshold of the lightest state outside the two-particle elastic channel. These inequalities are boundary conditions on the upper edge of the physical cut; they are not by themselves an analytic continuation principle. They will combine with angular analyticity in the following chapter.

28.4 Perturbative Discontinuities and Cut Rules

The Hilbert-space unitarity statement determines the physical-cut discontinuity of exact on-shell amplitudes whenever the relevant upper and lower boundary values exist as distributions and the intermediate-state resolution is complete in the scattering sector under consideration. Its perturbative expansion gives the graph-level cut rules. Write

$$S = \mathbf{1} + \mathrm{i}T, \qquad \operatorname{Disc}_s \mathcal{M} = \mathcal{M}(s + \mathrm{i}0, t) - \mathcal{M}(s - \mathrm{i}0, t).$$

From $S^\dagger S = \mathbf{1}$ one obtains

$$-\mathrm{i}(T - T^\dagger) = T^\dagger T.$$

Taking connected matrix elements and removing the common momentum-conserving delta function gives, on the s-channel physical cut,

$$\operatorname{Disc}_s \mathcal{M}_{\beta\alpha} = \mathrm{i} \sum_X \int \mathrm{d}\Phi_X \, \mathcal{M}_{X\alpha} \, \mathcal{M}_{X\beta}^*. \tag{28.50}$$

Here X runs over on-shell intermediate states with total momentum P_α, and $\mathrm{d}\Phi_X$ is the Lorentz-invariant phase-space measure, including the factor $1/N!$ for N identical particles when the state sum is over unordered particles. The subscript convention is $\mathcal{M}_{\gamma\delta} = \mathcal{M}(\gamma|\delta)$, so the conjugated factor is the amplitude $\beta \to X$, complex conjugated. It is not, in a generic theory, the complex conjugate of the reversed process $X \to \beta$. Writing $\mathcal{M}_{\beta X}^*$ in this exact Hilbert-space identity would add a reciprocity assumption, such as time-reversal invariance with specified antiunitary phase conventions. The forward case $\beta = \alpha$ then reduces to the positive optical-theorem sum.

Remark 28.18 (Unitarity discontinuity and perturbative cut rules). Equation (28.50) is the non-perturbative on-shell unitarity identity: it relates boundary values of the exact amplitude to a sum over exact on-shell intermediate states and exact lower-point amplitudes. Its hypotheses are Hilbert-space unitarity, the existence of the relevant scattering states and boundary values, and the completeness of the state sum used in the channel. The Cutkosky rule is the perturbative refinement obtained after choosing a regulator and expansion, writing $T = \sum_r T^{(r)}$, representing the terms by Feynman graphs, and identifying the contribution of a specified graph cut with on-shell propagator replacements. Thus the full discontinuity formula and the graph-by-graph replacement theorem have different logical status, even though the latter is obtained by expanding the former.

Proposition 28.19 (Largest-time identity for a scalar graph)**.** *Consider a regularized scalar Feynman graph G with vertices $x_1, \dots, x_V$, local Hermitian interaction vertices, and internal lines of masses m_e. For each mass set*

$$\Delta_m^+(x) = \int \frac{\mathrm{d}^D q}{(2\pi)^D} (2\pi)\theta(q^0)\delta(q^2 + m^2)\, \mathrm{e}^{\mathrm{i}q\cdot x}, \qquad \Delta_m^-(x) = \Delta_m^+(-x),$$

and decompose the Feynman boundary value as

$$\Delta_{F,m}(x) = \theta(x^0)\Delta_m^+(x) + \theta(-x^0)\Delta_m^-(x), \qquad \Delta_{F,m}(x)^* = \theta(x^0)\Delta_m^-(x) + \theta(-x^0)\Delta_m^+(x).$$

For a circling $\sigma : \{1, \dots, V\} \to \{0, 1\}$, define G_σ by using ordinary vertex factors and Feynman propagators inside the uncircled set, complex-conjugated vertex factors and anti-Feynman propagators inside the circled set, and Wightman propagators on mixed lines. A mixed line oriented from the uncircled side to the circled side carries Δ^+; the reverse orientation carries Δ^-. Circled vertices carry the minus sign associated with complex conjugating the perturbative i-weighted vertex. Then

$$\sum_{\sigma\in\{0,1\}^V} G_\sigma(x_1, \dots, x_V) = 0. \tag{28.51}$$

Proof. First smear the vertex variables with a test function whose support avoids all equal-time hyperplanes $x_a^0 = x_b^0$. The complement is a finite union of open time-ordering chambers, so it suffices to prove the identity on one such chamber. The general smeared distribution is then obtained by a finite partition of unity and by taking the limit as the partition is refined; the equal-time hyperplanes have no independent contribution because the regularized boundary values are distributions and the displayed theta decomposition is used only after smearing.

Fix a chamber and let k be the unique vertex with largest time. Split the sum over circlings into pairs $(\sigma, \sigma^{(k)})$, where $\sigma^{(k)}$ differs from σ only at k. Lines not incident on k have identical factors in the two paired graphs. If a line joins x_k to an earlier vertex x_j, then $x_k^0 - x_j^0 > 0$. The four possible circling assignments give

circling at k, j	line factor from k to j
$0, 0$	$\Delta_F(x_k - x_j) = \Delta^+(x_k - x_j)$
$1, 1$	$\Delta_F(x_k - x_j)^* = \Delta^-(x_k - x_j)$
$0, 1$	$\Delta^+(x_k - x_j)$
$1, 0$	$\Delta^-(x_k - x_j)$.

Thus changing only the circling of the largest-time vertex leaves every incident line factor fixed: the factor is Δ^+ if the earlier vertex is uncircled and Δ^- if it is circled. The local interaction factor at x_k, however, is multiplied by -1 when x_k is circled, because complex conjugation of the perturbative i-weighted Hermitian vertex changes $i\mathcal{L}_{\text{int}}$ to $-i\mathcal{L}_{\text{int}}$. Each pair $(G_\sigma, G_{\sigma^{(k)}})$ therefore cancels. Summing the pairs over all circlings proves (28.51) on the chamber, and hence as the regularized distribution. □

Subtract from (28.51) the all-uncircled and all-circled terms. The former is the original Feynman graph. The latter is the complex-conjugated graph with the opposite boundary prescription. Every remaining term contains at least one mixed line, and each mixed line has the Fourier representation

$$\frac{\mathrm{d}^D q}{(2\pi)^D} (2\pi)\theta(q^0)\delta(q^2 + m^2)$$

after orienting q from the uncircled side to the circled side. Thus the largest-time identity expresses the difference between the two boundary values of a graph as a sum of cut graphs. A physical s-channel cut is the subsum of those circlings for which the mixed lines separate the external legs into the chosen left and right subprocesses and carry total momentum P_α across the cut. Circlings whose mixed-line energy support belongs to another channel contribute to the corresponding channel discontinuity instead.

Theorem 28.20 (Cutkosky cut rule for a perturbative physical cut). *Consider a perturbative contribution to a connected amplitude whose s-channel discontinuity is produced by putting a set C of internal lines on shell so that the graph separates into a left subamplitude and a right subamplitude. With the amplitude normalization fixed by $S = \mathbf{1} + \mathrm{i}T$, the discontinuity contribution of this cut is obtained by replacing each cut propagating line of mass m_i by the on-shell measure*

$$\frac{\mathrm{d}^D q_i}{(2\pi)^D}\,(2\pi)\theta(q_i^0)\delta(q_i^2 + m_i^2),$$

multiplying the left and right lower-order amplitudes, complex conjugating the amplitude on the lower-edge side, and integrating over the common on-shell phase space. Equivalently, the graph contribution is the corresponding term in (28.50).

Proof. There are two statements to match. The first is the Hilbert-space discontinuity. Expand $T = \sum_r T^{(r)}$ in the chosen interaction order. The order-N part of $-\mathrm{i}(T - T^\dagger) = T^\dagger T$ is

$$-\mathrm{i}\big(T^{(N)} - T^{(N)\dagger}\big) = \sum_{r=1}^{N-1} T^{(r)\dagger} T^{(N-r)}.$$

Insert the spectral resolution of the identity on the physical Hilbert space between the two factors on the right. For a sector of n stable particles of masses m_i, this resolution contains

$$\frac{1}{n!}\prod_{i=1}^{n}\left[\int \frac{\mathrm{d}^D q_i}{(2\pi)^{D-1}}\,\theta(q_i^0)\delta(q_i^2 + m_i^2)\right](2\pi)^D\delta^{(D)}\left(P_\alpha - \sum_i q_i\right).$$

After the external LSZ residues and the overall momentum-conserving delta function are removed, this is precisely the phase-space integral in (28.50).

The second statement identifies the same term inside a fixed Feynman graph. Apply Proposition 28.19 to the graph. The difference between its two physical boundary values is the sum of mixed circlings. For the chosen s-channel discontinuity, retain the circlings whose mixed lines separate the graph into the ordinary subamplitude $\alpha \to X$ and the adjoint subamplitude whose unconjugated orientation is $\beta \to X$. The mixed propagator on each separating line is exactly

$$\frac{\mathrm{d}^D q_i}{(2\pi)^D}(2\pi)\theta(q_i^0)\delta(q_i^2 + m_i^2),$$

with q_i oriented from the lower-order amplitude to its conjugate across the cut. The uncircled side contains the ordinary Feynman rules for one lower-order amplitude, while the circled side contains the complex-conjugated rules for the lower-edge amplitude. The product of the mixed-line distributions supplies the on-shell phase-space measure and the residual momentum delta function enforces $P_X = P_\alpha$. This is the graph-level line-replacement rule stated in the theorem, with the overall factor fixed by the $S = \mathbf{1} + \mathrm{i}T$ convention used in (28.50). □

For the two-particle equal-mass cut, the phase-space factor appearing in (28.50) is explicit. Let $P^2 = -s$ and

$$\mathrm{d}\Phi_2(P) = \int \frac{\mathrm{d}^4 q}{(2\pi)^3}\theta(q^0)\delta(q^2+m^2)\,\frac{\mathrm{d}^4 r}{(2\pi)^3}\theta(r^0)\delta(r^2+m^2)\,(2\pi)^4\delta^{(4)}(P-q-r).$$

In the center-of-mass frame $P = (\sqrt{s}, \vec{0})$ this becomes

$$\mathrm{d}\Phi_2(P) = \frac{\mathrm{d}^3\vec{q}}{(2\pi)^2\, 4\omega_{\vec{q}}^2}\,\delta(\sqrt{s}-2\omega_{\vec{q}}).$$

Using $\omega_{\vec{q}} = \sqrt{\vec{q}^{\,2}+m^2}$, the radial delta function fixes

$$|\vec{q}| = \frac{1}{2}\sqrt{s-4m^2},$$

and hence

$$\int \mathrm{d}\Phi_2(P) = \frac{1}{8\pi}\sqrt{1-\frac{4m^2}{s}}\,\theta(s-4m^2). \tag{28.52}$$

For identical intermediate particles this is multiplied by $1/2!$ if the state sum is over unordered two-particle states. Thus a one-loop bubble cut has discontinuity equal to i times the product of the two tree subamplitudes times (28.52), with this symmetry factor when appropriate. The square-root branch point is the same threshold that the Landau equations identify below.

28.5 Crossing From Locality and Tube Analyticity

The structural origin of crossing is the same analytic mechanism used for Wightman functions. For four scalar fields, the vacuum distribution

$$W_4(x_1,x_2,x_3,x_4) = \langle\Omega|\widehat{\phi}(x_1)\widehat{\phi}(x_2)\widehat{\phi}(x_3)\widehat{\phi}(x_4)|\Omega\rangle$$

has Fourier support fixed by the spectrum condition in relative variables. It is therefore the boundary value of a holomorphic function in a tube domain. More explicitly, after removing the center-of-mass coordinate, the Fourier transform has support in products of closed forward lightcones for appropriate partial sums of momenta. This support condition is the input which makes the imaginary spacetime variables point into forward tubes.

Local commutativity says that, at real configurations where adjacent insertions are spacelike separated,

$$W_4(\ldots,x_i,x_{i+1},\ldots) = W_4(\ldots,x_{i+1},x_i,\ldots)$$

for identical scalar fields. The edge-of-the-wedge theorem then identifies the analytic continuations attached to the two orderings in the domain generated from such spacelike configurations.

LSZ reduction is applied to the time-ordered or Wightman boundary values after isolating the one-particle poles of the external legs. Different assignments of external legs as incoming or outgoing particles correspond to different real boundary components of the same analytically continued four-point function. The s-channel process

$$1+2\to 3+4$$

and the crossed process

$$1 + \bar{3} \to \bar{2} + 4$$

are therefore boundary values of one analytic object in the domain obtained from permuted Wightman tubes by edge-of-the-wedge continuation. For a self-conjugate scalar $\bar{2} = 2$ and $\bar{3} = 3$; for charged fields the bars indicate the conjugate particle associated with the adjoint field.

The statement is local on the analytic domain. It does not erase the singularities separating physical regions. Threshold cuts, bound-state poles, and anomalous thresholds specify how the analytic continuation must be routed and which boundary value is obtained at the end. Crossing is the assertion of common analytic origin; the singularity analysis below describes the obstructions and boundary prescriptions encountered along particular continuations.

Warning 28.21 (BEG crossing versus a Mandelstam domain). The edge-of-the-wedge argument used here is the rigorous Bros–Epstein–Glaser mechanism. It proves that permuted Wightman boundary values and their LSZ residues have a common analytic continuation on the envelope generated by the corresponding tube domains. A path connecting the s-channel physical region to a crossed physical region on the same first-sheet branch, while avoiding all singularities, is additional analytic data. That physical-region-to-physical-region crossing statement is therefore a stronger analyticity assertion. In perturbation theory it is studied by tracking graph singularities and sheets; in nonperturbative four-dimensional QFT it is usually formulated as a Mandelstam-type domain hypothesis rather than as a theorem following solely from locality, spectrum, and LSZ.

28.6 Edge-of-the-Wedge Form

The analytic gluing used above is the distributional edge-of-the-wedge theorem quoted in Theorem 16.6, applied in local kinematic coordinates. Let F_+ and F_- be holomorphic functions in two domains

$$\mathcal{D}_+, \qquad \mathcal{D}_-$$

of the complexified kinematic variables. Suppose both domains have boundary values on a common real open set U, in the sense of distributional limits against test functions supported in U. Suppose these boundary values agree:

$$F_+|_U = F_-|_U.$$

The edge-of-the-wedge theorem gives a holomorphic function F on a domain containing $\mathcal{D}_+ \cup U \cup \mathcal{D}_-$ in its envelope of holomorphy, with $F = F_+$ on $\mathcal{D}_+$ and $F = F_-$ on $\mathcal{D}_-$.

In local QFT, the real set U is supplied by spacelike configurations where local commutativity equates two Wightman orderings. The domains $\mathcal{D}_\pm$ are the corresponding forward-tube domains selected by the spectrum condition. The theorem then produces a single analytic function whose different real boundary components give differently ordered correlators. LSZ reduction transfers this analytic relation from correlators to scattering amplitudes whenever the external one-particle pole hypotheses hold.

28.7 Pinches

On the first sheet one finds stable one-particle poles, ordinary thresholds, and anomalous thresholds. In perturbative graph analysis an anomalous threshold is a contour-pinch singularity on the physical sheet, caused by several internal lines going on shell in a spacetime arrangement satisfying the positive Coleman–Norton orientation condition stated in (28.53). Its invariant location is determined by the Landau configuration of those internal lines.

The singularities of perturbative amplitudes arise when an integration contour is forced against singularities of the integrand. Consider a scalar graph with internal momenta

$$q_i = q_i(\ell_1, \ldots, \ell_L; p_1, \ldots, p_n),$$

where the q_i are affine functions of the loop momenta ℓ_a and external momenta p_j. A typical denominator is

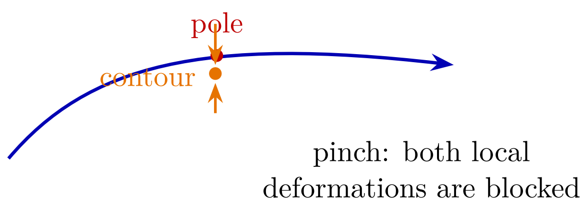
$$q_i^2 + m_i^2 - \mathrm{i}0.$$

After Feynman parametrization, a product of N denominators has the form

$$\int_{\alpha_i \geq 0} \prod_{i=1}^{N} \mathrm{d}\alpha_i\, \delta\left(\sum_{i=1}^{N} \alpha_i - 1\right) \frac{\text{numerator}}{\left[\sum_{i=1}^{N} \alpha_i (q_i^2 + m_i^2) - \mathrm{i}0\right]^N}.$$

Numerator factors and ultraviolet subtractions can change the degree or even remove a candidate singularity, but they do not change the necessary pinch conditions for the scalar denominator.

As external momenta move in the complex domain, the loop contours can be deformed as long as no singularity traps them. A necessary condition for a singularity is that the denominator vanish at a point where its first variation in every loop-momentum direction also vanishes. If the first variation were nonzero, the contour could be displaced locally away from the zero. At a stationary zero, nearby singular hypersurfaces can pinch the original real contour, and local deformations cannot remove the obstruction.



This stationary-pinch condition is the source of the Landau equations. The equations are necessary conditions for a singularity of a graph. To decide whether a singularity is actually present one must also check the sheet, the orientation of the pinch, and whether the numerator cancels the local singular term.

28.8 Landau Equations

Let

$$\mathcal{D}(\ell, \alpha; p) = \sum_{i=1}^{N} \alpha_i (q_i^2 + m_i^2).$$

A Landau singularity can occur only if there are Feynman parameters $\alpha_i \geq 0$, not all zero, such that

$$\alpha_i(q_i^2 + m_i^2) = 0 \qquad \text{for every internal line } i,$$

and, for every loop momentum ℓ_a^μ,

$$\frac{\partial \mathcal{D}}{\partial \ell_a^\mu} = 0.$$

Equivalently,

$$\sum_{i=1}^{N} \alpha_i q_{i\nu} \frac{\partial q_i^\nu}{\partial \ell_a^\mu} = 0, \qquad a = 1, \ldots, L.$$

The omitted factor of 2 is irrelevant because the right hand side is zero.

For a one-loop graph with all internal momenta oriented around the loop, this reduces to

$$\sum_i \alpha_i q_i^\mu = 0.$$

The first equation says that every line with $\alpha_i > 0$ is on shell:

$$q_i^2 = -m_i^2.$$

The second equation says that the corresponding on-shell momenta form a stationary configuration around each loop. Solutions with some $\alpha_i = 0$ describe singularities of reduced graphs in which the inactive lines have been contracted. Solutions with all relevant $\alpha_i > 0$ are the leading Landau singularities of that graph.

With the terminology fixed in Section 28.1, the physical sheet is selected by the sign of the Feynman prescription together with positive Feynman parameters. Positivity of the Feynman parameters distinguishes a first-sheet threshold from the same algebraic locus reached only after continuation through a cut.

28.9 Spacetime Interpretation of Positive Landau Solutions

The sign condition on the parameters has a spacetime meaning. Consider a Landau solution in a real physical region and keep only the active internal lines, namely those with $\alpha_i > 0$. Let the graph vertices be labelled by v, and orient each active edge i from a tail $v_-(i)$ to a head $v_+(i)$. The momentum q_i is the momentum assigned to this oriented edge by the chosen loop-momentum routing. The loop-stationarity equations say that, for every oriented cycle C of the active graph,

$$\sum_{i \in C} \sigma_{Ci} \alpha_i q_i = 0, \qquad \sigma_{Ci} = \begin{cases} +1, & \text{if the edge orientation agrees with the orientation of } C, \\ -1, & \text{if it is opposite.} \end{cases}$$

Equivalently, the vector assigned to an active edge by $\alpha_i q_i$ has zero sum around every closed path. Hence, on each connected component, there are vertex positions x_v, unique up to a common translation, such that

$$x_{v_+(i)} - x_{v_-(i)} = \lambda_i q_i, \qquad \lambda_i \geq 0,$$

with λ_i proportional to α_i. The proportionality constant depends only on the convention used for the quadratic form in the parametrized denominator.

The positive-energy condition is an additional orientation condition. Choose a time orientation in Minkowski space. A positive Coleman–Norton realization of the Landau solution consists of an orientation of every active edge in its classical direction of propagation and momenta k_i on those oriented edges such that

$$k_i^2 = -m_i^2, \qquad k_i^0 > 0, \qquad x_{v_+(i)} - x_{v_-(i)} = \lambda_i k_i, \qquad \lambda_i \geq 0. \tag{28.53}$$

If the loop-momentum routing originally assigned the opposite orientation to that edge, then $k_i = -q_i$ and the tail and head used in the spacetime equation are interchanged. Equivalently, one may reorient the active graph so that $q_i = k_i$ on every active edge. Thus the compatibility condition is precisely that each active internal momentum be a future-directed positive-energy on-shell momentum in the direction in which the corresponding edge is traversed in spacetime.

For $m_i > 0$, this is the worldline equation for a classical massive particle propagating for nonnegative proper time, with $\lambda_i m_i$ proportional to that proper time. For $m_i = 0$, it is the corresponding future-directed null geodesic equation with nonnegative affine parameter. Momentum conservation at each vertex is the graph momentum conservation for the same oriented momenta, with the external momenta assigned to that vertex. Thus a real leading Landau solution satisfying the positive Coleman–Norton orientation condition is a classical spacetime process: all active internal particles go on shell, carry positive energy in their direction of propagation, and meet at the vertices with energy and momentum conserved. This is the Coleman–Norton interpretation. It is a criterion for first-sheet physical singularities that must be combined with the pinch analysis: a formal algebraic solution contributes to the physical singularity only on the relevant sheet, with the integration contour trapped, and with a numerator that leaves a nonzero local singular term.

Warning 28.22 (Scope of the Coleman–Norton converse). The implication just proved is the geometric interpretation of a real positive Landau solution: such a solution is a classical spacetime process. The converse statement, often phrased as “every allowed classical process gives a singularity,” has a narrower status. For a fixed perturbative Feynman graph, a nondegenerate positive pinch on the relevant sheet produces a local singularity of the scalar integral; numerator factors, symmetry factors, subtractions, or sums of graphs may cancel the leading local term. Thus the perturbative converse is a theorem only after the pinch orientation, nondegeneracy, and non-cancellation hypotheses have been checked. In an exact nonperturbative QFT there is no general theorem that every such classical spacetime picture produces a singularity of the full S-matrix. There it should be regarded as a diagnostic expectation, to be justified from the spectral and locality structure of the theory in each setting.

Subleading Landau solutions have some $\alpha_i = 0$. Geometrically, the corresponding internal lines are contracted, and the classical propagation picture applies to the reduced graph. Ordinary thresholds are reduced classical processes in which a set of particles can be produced on shell with the total external energy-momentum supplied to the subgraph.

28.10 Two-Particle Threshold

For the equal-mass two-propagator loop, take internal momenta

$$q_1 = \ell, \qquad q_2 = \ell + P.$$

The Landau equations with $0 < \alpha < 1$ are

$$\ell^2 + m^2 = 0, \qquad (\ell + P)^2 + m^2 = 0,$$

and

$$(1-\alpha)\ell + \alpha(\ell + P) = 0.$$

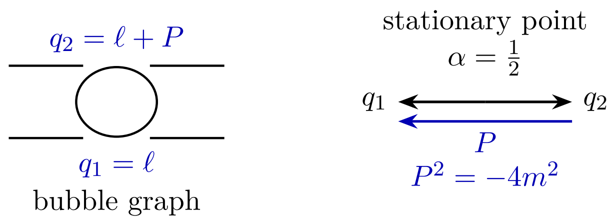
The stationary equation gives

$$\ell = -\alpha P.$$

Substitution into the two on-shell equations gives

$$\alpha = \frac{1}{2}, \qquad \ell = -\frac{P}{2}, \qquad P^2 = -4m^2.$$

Thus the ordinary two-particle threshold is a Landau singularity. In terms of the invariant $s = -P^2$, this is $s = 4m^2$.



For unequal masses, the same equations give

$$\ell = -\alpha P, \qquad \alpha^2 P^2 = -m_1^2, \qquad (1-\alpha)^2 P^2 = -m_2^2.$$

The positive-parameter solution with $0 < \alpha < 1$ is

$$\alpha = \frac{m_1}{m_1 + m_2}, \qquad P^2 = -(m_1 + m_2)^2.$$

This is the ordinary threshold: the two on-shell internal particles propagate with zero relative spatial momentum in the center-of-mass frame. The algebraic equations also contain the pseudo-threshold

$$P^2 = -(m_1 - m_2)^2,$$

but its parameter signs do not describe the same first-sheet physical production process.

28.11 Triangle Singularities

The triangle graph is the first elementary example of a first-sheet singularity produced by a genuine on-shell contour pinch rather than by a pole or endpoint threshold. Let the three external momenta be

$$P_1^2 = -M_1^2, \qquad P_2^2 = -M_2^2, \qquad P_3^2 = -M_3^2,$$

with $P_1 + P_2 + P_3 = 0$. The three internal lines are required to be on shell, and the positive-parameter stationary condition requires their momentum vectors to close consistently around the loop. For one choice of loop orientation this means

$$q_i^2 = -m_i^2, \qquad \alpha_1 q_1 + \alpha_2 q_2 + \alpha_3 q_3 = 0, \qquad \alpha_i > 0.$$

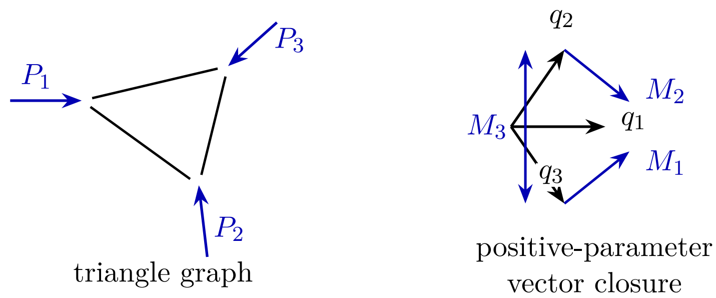


Figure 28.2: Triangle Landau data. The left panel labels the external momentum flow in the triangle graph. The right panel shows the positive-parameter closure condition $\alpha_1 q_1 + \alpha_2 q_2 + \alpha_3 q_3 = 0$ for oriented on-shell internal momenta.

Together with momentum conservation at the vertices, these equations define the candidate singular locus in the external invariants. Equivalently, the Gram matrix $G_{ij} = q_i \cdot q_j$ has a null vector $(\alpha_1, \alpha_2, \alpha_3)$ with strictly positive entries. Thus the condition is not only $\det G = 0$, but the existence of a positive null vector for the oriented on-shell momenta. The graph and vector-closure data are shown in Figure 28.2.

In the equal-internal-mass planar example, the Euclideanized internal momentum vectors in the sketch all have length m. The external invariant M_a is the length of the chord between two such vectors, so

$$M_a^2 = 2m^2(1 - \cos\varphi_a),$$

where φ_a is the angle between the corresponding internal on-shell vectors. Thus $M_a = \sqrt{2}\,m$ is the right-angle value. If $M_1, M_2 < \sqrt{2}\,m$, the relevant vectors lie in an open half-plane in the configuration shown, and no positive relation $\alpha_1 q_1 + \alpha_2 q_2 + \alpha_3 q_3 = 0$ exists. If $M_1, M_2 > \sqrt{2}\,m$, the vectors can be arranged with the origin in their convex hull; the positive-parameter Landau equation can then be satisfied. The remaining invariant is fixed by this geometry, giving a singularity at the corresponding value $P_3^2 = -M_3^2$. The convex-hull distinction is drawn in Figure 28.3.

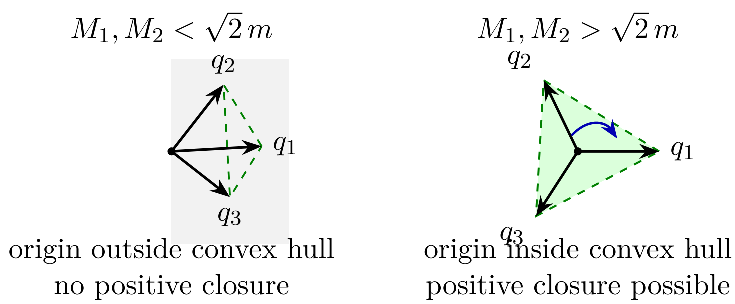

Figure 28.3: Convex-hull form of the positive-parameter Landau condition in the equal-internal-mass triangle example. When the origin lies outside the hull of the oriented on-shell vectors no positive closure exists; when it lies inside, the stationary equation can be solved with $\alpha_i > 0$.

The vector sketch represents the Coleman–Norton condition. The actual singular locus is obtained by solving the three on-shell equations together with the positive-parameter stationary equation. A solution gives a first-sheet anomalous threshold at the determined value of $P_3^2 = -M_3^2$ only when the active edges can be oriented with momenta $k_i^0 > 0$ and separations $x_{v_+(i)} - x_{v_-(i)} = \lambda_i k_i$, $\lambda_i \geq 0$. A solution requiring reversed time ordering or a negative proper-time segment lies on a continued sheet, even if it solves the same algebraic Landau equations.

Such a singularity is an anomalous threshold: a first-sheet singularity of the amplitude produced by on-shell internal propagation and contour pinching. Its local data are the masses, momentum routing, and positive Feynman parameters of the Landau solution. Ordinary endpoint thresholds are the reduced-graph case in which the on-shell process begins at the boundary of the integration domain; the triangle is the first elementary interior-pinch case. Coleman–Thun singularities in two-dimensional factorized scattering give a nonperturbative setting in which the same on-shell propagation and contour pinching mechanism appears.

28.12 Use of Landau Analysis

Landau equations are derived graph by graph. Their role here is diagnostic: they identify the local analytic mechanisms by which thresholds and more subtle first-sheet singularities arise in perturbation theory. In an exact massive theory, the singularities of amplitudes are expected to be governed by the same spectral and locality principles, with internal on-shell lines replaced by actual stable particles or by spectral continua of the theory.

Within existing axiomatic frameworks, only parts of this analytic picture are presently theorems. The terminology used here is precise, but its logical status is not uniform: stable particles appear as first-sheet poles below thresholds under the one-particle spectral hypotheses, resonances are continued-sheet pole data, ordinary thresholds are tied to multi-particle spectral continua, and anomalous thresholds are perturbative on-shell propagation patterns encoded by the Landau equations. Beyond perturbation theory the last statement is a conjectural guide unless a separate nonperturbative analytic construction is supplied. This classification will be used in the following chapter only at the level needed for angular analyticity: the nearest first-sheet crossed-channel singularity fixes the distance from the physical angular interval to the edge of the Lehmann ellipse. Landau analysis supplies a concrete perturbative mechanism for such singularities. The nonperturbative construction of the S-operator and the spectral assumptions stated earlier remain the structural input for the exact scattering problem.

- **Generator convention.** $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$, hence $[P_\mu, \widehat{\Phi}(x)] = \mathrm{i}\partial_\mu \widehat{\Phi}(x)$ when the field is translation covariant.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

29.1 Hypotheses and Angular Analyticity

Work in $D = 4$ for the detailed Lehmann-ellipse and Legendre-polynomial derivation. The higher-dimensional logarithmic-power estimate is separated near Theorem 29.25 as an additional Gegenbauer/angular-tube hypothesis. Consider scattering of the lightest stable identical scalar particle of mass m. The connected invariant amplitude is denoted by

$$\mathcal{M}(s,t).$$

The Mandelstam variables are the mostly-plus physical scattering variables

$$s = -(k_1 + k_2)^2, \qquad t = -(k_1 - k_3)^2, \qquad u = -(k_1 - k_4)^2, \qquad k_i^2 = -m^2,$$

where k_1, k_2 are incoming and k_3, k_4 are outgoing. Hence

$$s + t + u = 4m^2.$$

This is the convention of Definition 24.2; in the physical s-channel interval $t \leq 0$, while positive t below denotes the crossed-channel timelike variable that controls the nearest angular singularity.

The normalization of $\mathcal{M}$ is the identical-particle normalization fixed in Chapter 19. The forward optical theorem is rederived below in this normalization, because the unordered two-particle convention, the even-partial-wave projection, and the $1/2$ from the symmetric two-particle identity resolution must be kept together.

The hypotheses used in this chapter are the following. The theory has a mass gap above the vacuum, the external scalar is stable and is the lightest one-particle species in the sector under consideration, the S-operator on the relevant asymptotic space is unitary, and the amplitude is the boundary value of an analytic first-sheet function with the crossing properties described in Section 28.1 and Chapter 28. Whenever a displayed dispersion formula omits bound-state pole terms, those poles are assumed absent in the displayed kinematic range. If they are present, their residues are added explicitly; for a stable composite pole these residues are the Bethe–Salpeter pole-factorization data of Theorem 27.2, transported to the channel under discussion by crossing.

The results in this chapter are therefore conditional statements. They are deductions from specified analyticity, crossing, unitarity, and boundedness hypotheses, not a claim that all such hypotheses are presently derivable from one universally accepted axiom system for interacting quantum field theory. Only restricted versions of the analyticity and boundedness inputs are known as theorems under robust assumptions. This distinction matters: the mathematical content below is the implication from the hypotheses to the high-energy bound, with every hypothesis stated before it is used. The fixed-t dispersion hypotheses used here are the single-variable hypotheses described in Chapter 28; the simultaneous two-variable Mandelstam representation is not assumed. The notation $\mathcal{M}(s,t)$ is used in the function-space sense of Definition 28.1: it is a holomorphic germ with local polynomial boundary growth on the complexified on-shell invariant surface, with physical values obtained as tempered distributional boundary values. At fixed real t, the one-variable function of complex s is the corresponding restriction of that germ after possible pole loci have been separated. Cut discontinuities in the dispersion formulae below are boundary-value differences in $\mathcal{D}'$ locally, and in $\mathcal{S}'$ on noncompact real edges when the stated high-energy polynomial-growth estimates are imposed.

For a fixed physical value $s > 4m^2$, introduce

$$x = \cos\theta = 1 + \frac{2t}{s - 4m^2}.$$

The physical s-channel scattering angles give the interval

$$-1 \leq x \leq 1.$$

At the t-channel two-particle threshold $t = 4m^2$,

$$x = x_t(s) \equiv \frac{s + 4m^2}{s - 4m^2} > 1,$$

and the t-channel cut maps to $x \in [x_t, \infty)$. The u-channel threshold gives the symmetric cut $x \in (-\infty, -x_t]$. If a crossed channel contains a stable bound state of mass $M_B < 2m$, its pole appears at

$$x_B = 1 + \frac{2M_B^2}{s - 4m^2}$$

or at the corresponding point on the left. Let $t_0 > 0$ be the infimum of positive real t-values at which the crossed-channel first sheet has a singularity, including stable poles and multiparticle thresholds. If the infimum is realized by a pole, the following estimates are applied at $0 < t < t_0$ and the limit $t \to t_0^-$ is taken only at the end. For large s, the nearest right singularity is approached at

$$x_0(s) = 1 + \frac{2t_0}{s - 4m^2}.$$

In the simplest equal-mass case with no crossed-channel bound state, $t_0 = 4m^2$. If there is a stable crossed-channel bound-state pole of mass $M_B < 2m$ and no closer singularity, then $t_0 = M_B^2$. In the elementary single-pole situation this is summarized as

$$t_0 = \min\{4m^2, M_B^2\},$$

with the convention that M_B^2 is omitted when no such pole exists. When B is composite, M_B is not an additional kinematic parameter chosen independently of the dynamics. It is the invariant mass of an isolated spectral state, and in a two-constituent description it is characterized by the eigenvalue-one condition $(\mathbf{1} - \widehat{V}_P)\Psi_B = 0$ of Section 27.4. The high-energy estimate below depends on the nearest singular location t_0; the associated residue becomes relevant when the fixed-t dispersion relation is written with explicit pole terms. Figure 29.1 shows how this nearest singularity fixes the available Lehmann ellipse.

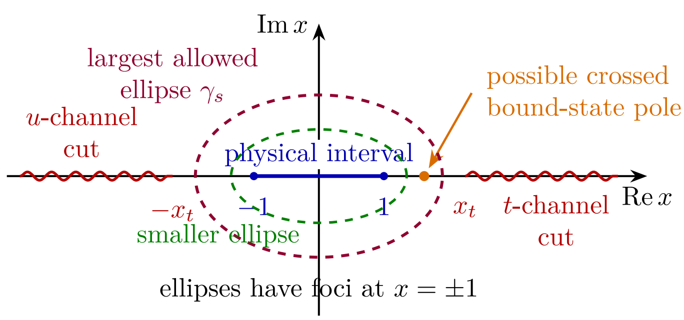

Figure 29.1: Lehmann ellipses in the angular variable $x = \cos\theta$. The physical interval has foci at $x = \pm 1$. The nearest crossed-channel singularity fixes the largest available ellipse γ_s; smaller ellipses with positive distance from the singular set are used in the estimates.

The angular analyticity hypothesis used below is this precise statement: for each such s, the boundary value $\mathcal{M}(s+\mathrm{i}0, x)$, continued in the angular variable x, is analytic in a domain containing the physical interval $[-1, 1]$. For every ellipse with foci at ± 1 whose closure lies in this domain, the amplitude is bounded on the ellipse. The largest ellipse of this type, when it exists, is called the Lehmann ellipse at energy s. The estimates use only smaller ellipses whose closures stay a positive distance from the singular set.

It is useful to parametrize these ellipses before using them. Write

$$R = \mathrm{e}^{\eta}, \qquad \eta > 0,$$

and define the ellipse E_R by $|\zeta(x)| = R$, where

$$\zeta(z) = z + \sqrt{z^2 - 1}, \qquad \zeta(z) \sim 2z \quad (z \to \infty), \tag{29.1}$$

with branch cut on $[-1, 1]$. Its right endpoint is

$$x_R = \frac{1}{2}(R + R^{-1}) = \cosh\eta.$$

Thus the point corresponding to a crossed-channel value t_* has

$$x_*(s) = 1 + \frac{2t_*}{s - 4m^2} = \cosh \eta_*(s), \qquad \eta_*(s) = 2\sqrt{\frac{t_*}{s}} + O(s^{-3/2})$$

at fixed $t_* > 0$ and large s. The singular value t_0 determines the limiting ellipse in the same way, but estimates are made at $0 < t_* < t_0$ and only then is t_* allowed to approach t_0.

29.2 Expansion Inside the Lehmann Ellipse

Let γ_s be a counterclockwise contour inside the angular analytic domain and enclosing $[-1, 1]$. For x inside γ_s,

$$\mathcal{M}(s, x) = \oint_{\gamma_s} \frac{\mathrm{d}z}{2\pi\mathrm{i}} \frac{\mathcal{M}(s, z)}{z - x}.$$

Use the branch (29.1). The level sets $|\zeta(z)| = R > 1$ are ellipses with foci at $z = \pm 1$, and the physical interval is the degenerate ellipse $R = 1$. On the level set $R = \mathrm{e}^{\eta}$ one may write

$$z = \frac{1}{2}\left(R\mathrm{e}^{\mathrm{i}\varphi} + R^{-1}\mathrm{e}^{-\mathrm{i}\varphi}\right), \qquad 0 \le \varphi < 2\pi,$$

and hence

$$\operatorname{Re} z = \frac{R + R^{-1}}{2}\cos\varphi = \cosh\eta\,\cos\varphi, \qquad \operatorname{Im} z = \frac{R - R^{-1}}{2}\sin\varphi = \sinh\eta\,\sin\varphi.$$

Thus

$$\frac{(\operatorname{Re} z)^2}{\cosh^2\eta} + \frac{(\operatorname{Im} z)^2}{\sinh^2\eta} = 1.$$

The semimajor and semiminor axes are therefore $\cosh\eta$ and $\sinh\eta$, and the focal distance is $\sqrt{\cosh^2\eta - \sinh^2\eta} = 1$, so the foci are at $z = \pm 1$.

The kernel has the Legendre expansion

$$\frac{1}{z - x} = \sum_{\ell=0}^{\infty}(2\ell + 1)P_\ell(x)Q_\ell(z),$$

where

$$Q_\ell(z) = \frac{1}{2}\int_{-1}^{1} \mathrm{d}y\, \frac{P_\ell(y)}{z - y}.$$

With the same branch choice for $\sqrt{z^2 - 1}$, the Legendre function of the second kind also has the useful representation

$$Q_\ell(z) = \int_{\zeta(z)}^{\infty} \frac{\mathrm{d}\xi}{\xi^{\ell+1}\sqrt{1 - 2z\xi + \xi^2}}, \qquad \zeta(z) = z + \sqrt{z^2 - 1},$$

where the integration path is taken in the ξ-plane with the square-root branch obtained by continuation from large positive z. This form makes the exponential large-ℓ decay transparent: the leading suppression is controlled by the lower endpoint $\zeta(z)$. This expansion converges when

$$\left|z + \sqrt{z^2 - 1}\right| > \left|x + \sqrt{x^2 - 1}\right|.$$

Indeed, at large ℓ,

$$P_\ell(x) \sim \left(x + \sqrt{x^2 - 1}\right)^\ell, \qquad Q_\ell(z) \sim \left(z + \sqrt{z^2 - 1}\right)^{-\ell},$$

where the omitted prefactors are powers of ℓ and algebraic functions of x or z that do not change the exponential rate. Thus angular analyticity implies convergence of the partial-wave expansion throughout every smaller ellipse inside the Lehmann ellipse. More quantitatively, if $\mathcal{M}(s, z)$ is bounded by $B_s(R)$ on $|\zeta(z)| = R$, and if $|\zeta(x)| \le r < R$, then the Legendre expansion inside the contour is bounded term by term by

$$C(R, r)\, B_s(R) \left(\frac{r}{R}\right)^\ell.$$

In particular, the partial-wave coefficients obtained from the contour have exponential decay $O(B_s(R) R^{-\ell})$. This is the analytic input later combined with unitarity: high angular momentum is exponentially suppressed inside an ellipse, while the physical partial-wave weights are bounded by unitarity.

29.3 Partial-Wave Normalization

Let $\mathcal{M}_{\mathrm{ord}}(s, x)$ denote the ordered two-particle amplitude with distinguishable external labels and expansion

$$\mathcal{M}_{\mathrm{ord}}(s, x) = 16\pi \sum_{\ell=0}^{\infty} (2\ell + 1) a_\ell(s) P_\ell(x).$$

The physical amplitude on the two-particle space of identical scalar bosons is Bose symmetric. With the convention fixed in Chapter 19, it is

$$\mathcal{M}(s, x) = \mathcal{M}_{\mathrm{ord}}(s, x) + \mathcal{M}_{\mathrm{ord}}(s, -x) = 32\pi \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1) a_\ell(s) P_\ell(x). \tag{29.2}$$

Equation (29.2) is the conversion between the ordered 16π convention and the unordered identical-boson convention. Only even ℓ occur, and the factor 32π is tied to the final-state factor $1/2$ in the symmetric two-particle resolution of the identity used in the identical-particle cross section. No additional symmetry factor will be inserted later.

Using

$$S_\ell(s) = 1 + 2\mathrm{i}\, \beta(s) a_\ell(s), \qquad \beta(s) = \sqrt{1 - \frac{4m^2}{s}},$$

this becomes the convention

$$\mathcal{M}(s, x) = -16\pi\mathrm{i}\, \beta(s)^{-1} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)\big(S_\ell(s) - 1\big) P_\ell(x).$$

Here $S_\ell(s)$ is the partial-wave matrix element of the full S-operator in the elastic identical-particle channel. If no inelastic channel is open in this angular momentum, it is an eigenvalue of modulus one. With inelastic channels present, it is the elastic matrix element of a unitary matrix on the channel space, hence

$$|S_\ell(s)| \le 1.$$

For real x inside the Lehmann ellipse, the partial-wave series for the physical upper-edge boundary value gives

$$\operatorname{Im} \mathcal{M}(s, x) = 16\pi\, \beta(s)^{-1} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1) P_\ell(x)\, w_\ell(s),$$

where

$$w_\ell(s) = 1 - \operatorname{Re} S_\ell(s).$$

The inequality $|S_\ell| \le 1$ implies the pointwise bound

$$0 \le w_\ell(s) \le 2.$$

The lower bound is simply $\operatorname{Re} S_\ell \le |S_\ell| \le 1$; the upper bound follows from $\operatorname{Re} S_\ell \ge -|S_\ell| \ge -1$.

We now derive the forward optical theorem in the same convention. In the center-of-mass frame put

$$p = |\vec{p}_*| = \frac{1}{2}\sqrt{s - 4m^2}, \qquad \beta(s) = \frac{2p}{\sqrt{s}}.$$

The unordered identical-boson two-particle space contains only the even orbital partial waves in this scalar channel. The same normalization that produces (29.2) gives the elastic partial-wave cross section

$$\sigma_{\text{el}} = \frac{2\pi}{p^2} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)|S_\ell(s) - 1|^2.$$

The coefficient $2\pi/p^2$ is the place where the identical final-state factor has already entered: the full labeled solid-angle integral carries the symmetric identity-resolution factor $1/2$, while the Bose-symmetrized amplitude contains only the even angular momenta. Equivalently, since $p^2 = (s - 4m^2)/4$,

$$\sigma_{\text{el}} = \frac{8\pi}{s - 4m^2} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)|S_\ell(s) - 1|^2.$$

The loss of probability from the elastic two-particle channel in the same partial wave gives

$$\sigma_{\text{inel}} = \frac{2\pi}{p^2} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)\big(1 - |S_\ell(s)|^2\big) = \frac{8\pi}{s - 4m^2} \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell + 1)\big(1 - |S_\ell(s)|^2\big).$$

Both formulas have the same prefactor because they are projections of the same unitary partial-wave channel decomposition. In the elastic term the factor

$$\frac{2\pi}{|\vec{p}_*|^2} \sum_{\ell \text{ even}} (2\ell + 1)|S_\ell - 1|^2$$

is just the identical-boson formula of Chapter 19; in the inelastic term it is the same incoming-flux normalization multiplied by the deficit $1 - |S_\ell|^2$ of elastic probability. Adding the two expressions gives

$$|S_\ell - 1|^2 + 1 - |S_\ell|^2 = 2(1 - \operatorname{Re} S_\ell) = 2w_\ell.$$

Adding them gives

$$\sigma_{\rm tot} = \frac{16\pi}{s-4m^2} \sum_{\substack{\ell=0\\ \ell \text{ even}}}^{\infty} (2\ell+1) w_\ell(s).$$

On the other hand, the forward absorptive part follows directly from the symmetrized amplitude. Setting $x = 1$, using $P_\ell(1) = 1$, and writing $S_\ell = 1 + 2\mathrm{i}\beta a_\ell$, one obtains

$$\mathcal{M}(s,1) = 32\pi \sum_{\substack{\ell=0\\ \ell \text{ even}}}^{\infty} (2\ell+1) \frac{S_\ell(s)-1}{2\mathrm{i}\beta(s)} = -16\pi\mathrm{i}\,\beta(s)^{-1} \sum_{\substack{\ell=0\\ \ell \text{ even}}}^{\infty} (2\ell+1)\big(S_\ell(s)-1\big).$$

Therefore

$$\operatorname{Im}\mathcal{M}(s,1) = 16\pi\,\beta(s)^{-1} \sum_{\substack{\ell=0\\ \ell \text{ even}}}^{\infty} (2\ell+1) w_\ell(s).$$

Since $\beta(s) = 2p/\sqrt{s} = \sqrt{s-4m^2}/\sqrt{s}$, the preceding two displays imply

$$\sigma_{\rm tot} = \frac{\beta(s)}{s-4m^2} \operatorname{Im}\mathcal{M}(s,1) = \frac{1}{\sqrt{s(s-4m^2)}} \operatorname{Im}\mathcal{M}(s,1).$$

This is the optical theorem in the present normalization. The identity-resolution factor 1/2 has already been used in the partial-wave cross-section prefactor, while the forward amplitude appearing here is the Bose-symmetrized amplitude with the 32π expansion in (29.2). Here $\sigma_{\rm tot}$ is the ideal complete-sum cross section of Chapter 19. A detector-level observable with finite angular, energy, jet, or soft-radiation resolution is obtained by replacing the outgoing identity operator in the unitarity sum by the corresponding positive detector effect. In massless theories this replacement is part of the infrared definition of the observable.

29.4 Elastic Form Factors and Watson's Theorem

The same partial-wave unitarity that fixes the phase of an elastic two-particle scattering amplitude also fixes the phase of a form factor into that two-particle channel. This statement is useful only after the channel and the boundary-value convention have been specified.

Fix a two-particle channel A. In examples A may include isospin, charge conjugation, parity, and angular momentum labels; for the identical scalar channel above it is just the even angular momentum ℓ. Suppose that on an open interval

$$s_{\rm th} < s < s_{\rm inel}$$

the only asymptotic states with the quantum numbers A and invariant mass $\sqrt{s}$ are the two particles in this channel. The elastic partial-wave S-matrix is then a scalar phase,

$$S_A(s) = 1 + 2\mathrm{i}\,\beta(s) a_A(s) = \mathrm{e}^{2\mathrm{i}\delta_A(s)}, \qquad s_{\rm th} < s < s_{\rm inel}, \tag{29.3}$$

where $a_A(s)$ is normalized by the same convention as the partial waves in Section 29.3. Equivalently,

$$a_A(s) = \frac{\mathrm{e}^{\mathrm{i}\delta_A(s)} \sin\delta_A(s)}{\beta(s)}.$$

Let $\mathcal{O}_A(x)$ be a Hermitian local operator whose vacuum quantum numbers allow it to create the channel A. Its two-particle partial-wave form factor is the boundary value of a function $\mathcal{F}_A(s)$ on the first sheet:

$$\mathcal{F}_A^+(s) = \lim_{\epsilon\downarrow 0} \mathcal{F}_A(s + \mathrm{i}\epsilon), \qquad \mathcal{F}_A^-(s) = \lim_{\epsilon\downarrow 0} \mathcal{F}_A(s - \mathrm{i}\epsilon).$$

The $+$ boundary value is the form factor with the outgoing two-particle boundary condition, while the $-$ boundary value is the corresponding incoming one. The phase convention for the one-particle states is chosen real, and Hermiticity of $\mathcal{O}_A$, together with real analyticity of the first-sheet form factor, gives

$$\mathcal{F}_A^-(s) = \mathcal{F}_A^+(s)^* \qquad (s_{\text{th}} < s < s_{\text{inel}}). \tag{29.4}$$

Figure 29.2 keeps track of the two boundary values on the elastic cut and the two operations used in Watson's theorem: real analytic conjugation and multiplication by the elastic two-body phase.

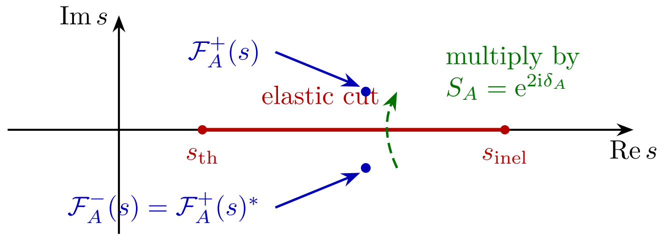

Figure 29.2: On a one-channel elastic cut, real analyticity relates the two boundary values by complex conjugation, while unitarity relates them by the dashed phase-multiplication arrow. Together they imply Watson's theorem.

Proposition 29.1 (Watson theorem in a one-channel elastic interval)**.** *Under the hypotheses above, the two boundary values of the form factor obey*

$$\mathcal{F}_A^+(s) = S_A(s)\mathcal{F}_A^-(s) = \mathrm{e}^{2\mathrm{i}\delta_A(s)}\mathcal{F}_A^-(s). \tag{29.5}$$

Consequently,

$$\mathrm{e}^{-\mathrm{i}\delta_A(s)}\mathcal{F}_A^+(s) \in \mathbb{R}. \tag{29.6}$$

At a point where $\mathcal{F}_A^+(s) \neq 0$, its phase is therefore

$$\operatorname{Arg} \mathcal{F}_A^+(s) = \delta_A(s) \mod \pi.$$

Proof. The discontinuity of the form factor across the two-particle cut is obtained by applying $S^\dagger S = 1$, or equivalently $T - T^\dagger = \mathrm{i}T^\dagger T$ for $S = 1 + \mathrm{i}T$, between the state $\mathcal{O}_A(0)|0\rangle$ and the two-particle channel A, and then projecting to the partial wave A. The LSZ reduction of this Hilbert-space identity gives, in the normalization of (29.3),

$$\mathcal{F}_A^+(s) - \mathcal{F}_A^-(s) = 2\mathrm{i}\,\beta(s)a_A(s)^*\,\mathcal{F}_A^+(s), \qquad s_{\text{th}} < s < s_{\text{inel}}. \tag{29.7}$$

There is only one intermediate state in this interval, so no channel sum is present. The coefficient is the same two-body phase-space coefficient that gives $\operatorname{disc} a_A = 2\mathrm{i}\,\beta|a_A|^2$ for elastic scattering; one side of the cut carries the complex-conjugated scattering amplitude, and the other carries the production form factor.

Using $a_A = \mathrm{e}^{\mathrm{i}\delta_A} \sin\delta_A/\beta$,

$$2\mathrm{i}\,\beta a_A^* = 2\mathrm{i}\,\mathrm{e}^{-\mathrm{i}\delta_A}\sin\delta_A = 1 - \mathrm{e}^{-2\mathrm{i}\delta_A}.$$

Thus (29.7) becomes

$$\mathcal{F}_A^+ - \mathcal{F}_A^- = (1 - \mathrm{e}^{-2\mathrm{i}\delta_A})\mathcal{F}_A^+,$$

or

$$\mathcal{F}_A^- = \mathrm{e}^{-2\mathrm{i}\delta_A}\mathcal{F}_A^+.$$

This is (29.5). Combining it with real analyticity (29.4) gives

$$\mathcal{F}_A^+(s) = \mathrm{e}^{2\mathrm{i}\delta_A(s)}\mathcal{F}_A^+(s)^*,$$

which is equivalent to (29.6). □

For the standard two-pion examples, ignore weak and electromagnetic interactions and work in the isospin limit of QCD. The isovector vector current has

$$\langle \pi^b(p_1)\pi^c(p_2), \mathrm{out}|J_a^\mu(0)|0\rangle = \mathrm{i}\epsilon^{abc}(p_1 - p_2)^\mu F_V^+(s), \qquad s = -(p_1 + p_2)^2,$$

so the two-pion state has $I = 1$ and $\ell = 1$. In the elastic interval, Watson's theorem gives

$$\operatorname{Arg} F_V^+(s) = \delta_1^1(s) \quad \mod \pi.$$

Similarly, for the isoscalar scalar source $\mathcal{S} = \widehat{m}(\bar{u}u + \bar{d}d)$,

$$\langle \pi^a(p_1)\pi^b(p_2), \mathrm{out}|\mathcal{S}(0)|0\rangle = \delta^{ab}F_S^+(s),$$

and the elastic phase is the $I = 0, \ell = 0$ pion-pion phase shift,

$$\operatorname{Arg} F_S^+(s) = \delta_0^0(s) \quad \mod \pi,$$

up to the first inelastic threshold in that channel.

The theorem has a matrix form once more than one channel is open. If $\mathbf{F}^\pm$ is the vector of form factors into all open channels with the same conserved quantum numbers, unitarity gives

$$\mathbf{F}^+(s) = S_A(s)\mathbf{F}^-(s),$$

where now $S_A(s)$ is a unitary matrix. A single form factor component then does not have a phase equal to a single elastic phase shift unless the source couples to an eigenchannel and the channel basis has been diagonalized. In general the phases are determined by the coupled-channel unitary matrix, not by one scalar function $\delta_A(s)$.

Watson's theorem is also the local input for the Omnès construction. Given a phase function on a cut and an integer N large enough for convergence, define

$$\Omega_A(s) = \exp\left\{ \frac{s^N}{\pi} \int_{s_{\mathrm{th}}}^{\infty} \frac{\delta_A(s')\,\mathrm{d}s'}{(s')^N(s' - s)} \right\}. \tag{29.8}$$

Its boundary values obey $\Omega_A^+(s) = \mathrm{e}^{2\mathrm{i}\delta_A(s)}\Omega_A^-(s)$ on the part of the cut where the phase input is valid. Hence the quotient

$$G_A(s) = \mathcal{F}_A(s)/\Omega_A(s)$$

has no discontinuity on that part of the cut. If the phase relation holds on the whole right cut, if all zeros and pole factors of $\mathcal{F}_A$ in the domain have been divided out or inserted explicitly, and if the resulting quotient is polynomially bounded on the cut plane, then the edge-of-the-wedge continuation and the usual one-variable growth theorem give

$$\mathcal{F}_A(s) = P_{N-1}(s)\,\Omega_A(s) \quad \text{up to the displayed zero and pole factors.} \tag{29.9}$$

The degree of the real polynomial P_{N-1} is fixed by the subtraction and growth hypotheses, not by Watson's theorem alone. If the phase is known only below s_{inel}, then (29.9) is not a theorem-level representation of the full form factor; the part of the cut above s_{inel}, zeros of $\mathcal{F}_A$, and possible pole factors must be included as additional input. What Watson's theorem fixes without such additional input is precisely the elastic-cut phase relation (29.5).

29.5 Eikonal Small-Angle Scattering and Regge Singularities

The Froissart–Martin argument uses partial waves to bound the total amount of probability that can be carried by large angular momenta. There is a second, more differential high-energy limit of the same partial-wave representation. It keeps the momentum transfer fixed while $s \to \infty$, so that the scattering angle tends to zero and the angular momentum becomes a transverse impact parameter. This limit is the natural setting for eikonal exponentiation and for the Regge description of fixed-t high-energy scattering.

We formulate the small-angle limit first for an ordered distinguishable amplitude. The identical-particle amplitude in (29.2) is obtained by adding the crossed backward contribution; in the forward high-energy region the ordered direct amplitude is the local object whose partial waves become impact-parameter waves. With the same $S_\ell = 1 + 2\mathrm{i}\beta a_\ell$ convention as above,

$$\mathcal{M}_{\text{ord}}(s,x) = -8\pi\mathrm{i}\,\beta(s)^{-1}\sum_{\ell=0}^{\infty}(2\ell+1)\big(S_\ell(s)-1\big)P_\ell(x).$$

Let

$$p = \frac{1}{2}\sqrt{s-4m^2}, \qquad q = \sqrt{-t} = 2p\sin\frac{\theta}{2}, \qquad b = \frac{\ell+\frac{1}{2}}{p}.$$

The high-energy small-angle scaling is

$$s \to \infty, \qquad q \text{ fixed}, \qquad \ell \to \infty, \qquad b = \frac{\ell+\frac{1}{2}}{p} \text{ fixed}.$$

In this scaling,

$$P_\ell(\cos\theta) = J_0(bq) + O(p^{-1})$$

uniformly on compact bq-intervals; this is the Mehler–Heine limit of the Legendre polynomials. If the elastic partial-wave matrix elements have a weak Riemann-sum limit

$$S_\ell(s) \longrightarrow S(s,b)$$

against smooth compactly supported test functions of b, then the partial-wave sum becomes

$$\mathcal{M}_{\text{ord}}(s,-q^2) = 2\mathrm{i}s\int_{\mathbb{R}^2}\mathrm{d}^2b\,\mathrm{e}^{\mathrm{i}q\cdot b}\,\Gamma(s,b) + o(s), \qquad \Gamma(s,b) = 1 - S(s,b). \tag{29.10}$$

Indeed,

$$\sum_{\ell}(2\ell+1)F\left(\frac{\ell+\frac{1}{2}}{p}\right) = 2p^2\int_0^\infty b\,\mathrm{d}b\,F(b) + o(p^2),$$

and

$$2\pi\int_0^\infty b\,\mathrm{d}b\,J_0(bq)F(b) = \int_{\mathbb{R}^2}\mathrm{d}^2b\,\mathrm{e}^{\mathrm{i}q\cdot b}F(b).$$

Since $4p^2 = s - 4m^2$, the coefficient in (29.10) is $2\mathrm{i}s$ at leading order. The formula is therefore not a new normalization of the S-matrix: it is the continuum large-ℓ form of the partial-wave normalization already fixed above.

At fixed b, unitarity of the partial-wave channel gives

$$|S(s,b)| \le 1$$

in the same weak limiting sense. Thus the profile $\Gamma = 1 - S$ obeys

$$2\,\mathrm{Re}\,\Gamma(s,b) = |\Gamma(s,b)|^2 + \big(1 - |S(s,b)|^2\big). \tag{29.11}$$

Consequently the high-energy limits of the total, elastic, and inelastic cross sections are

$$\sigma_{\mathrm{tot}}(s) = 2\int \mathrm{d}^2b\;\mathrm{Re}\,\Gamma(s,b), \qquad \sigma_{\mathrm{el}}(s) = \int \mathrm{d}^2b\,|\Gamma(s,b)|^2, \tag{29.12}$$

and

$$\sigma_{\mathrm{inel}}(s) = \int \mathrm{d}^2b\,\big(1 - |S(s,b)|^2\big).$$

The identity (29.11) is the continuum version of partial-wave probability conservation. The limiting profile is often parametrized by an eikonal phase

$$S(s,b) = \exp\{\mathrm{i}\chi(s,b)\}, \qquad \mathrm{Im}\,\chi(s,b) \ge 0,$$

so that

$$\mathcal{M}_{\mathrm{eik}}(s,-q^2) = 2\mathrm{i}s\int \mathrm{d}^2b\,\mathrm{e}^{\mathrm{i}q\cdot b}\left(1 - \mathrm{e}^{\mathrm{i}\chi(s,b)}\right). \tag{29.13}$$

The condition $\mathrm{Im}\,\chi \ge 0$ is precisely the statement $|S| \le 1$. A purely real χ describes elastic phase shift without absorption; a positive imaginary part describes loss of probability into inelastic channels at the same impact parameter.

The first term in the eikonal phase is fixed by the Born amplitude. Expanding (29.13) to first order gives

$$\mathcal{M}_{\mathrm{Born}}(s,-q^2) = 2s\int \mathrm{d}^2b\,\mathrm{e}^{\mathrm{i}q\cdot b}\chi_1(s,b),$$

hence

$$\chi_1(s,b) = \frac{1}{2s}\int \frac{\mathrm{d}^2Q}{(2\pi)^2}\,\mathrm{e}^{-\mathrm{i}Q\cdot b}\,\mathcal{M}_{\mathrm{Born}}(s,-Q^2). \tag{29.14}$$

For example, if a massive exchanged field of mass μ gives

$$\mathcal{M}_{\mathrm{Born}}(s,-Q^2) = \frac{g_1 g_2}{Q^2+\mu^2}$$

in the high-energy normalization used here, then

$$\chi_1(s,b) = \frac{g_1 g_2}{4\pi s} K_0(\mu b).$$

For exchange of spin J, the Born numerator may grow as s^J, so the same Fourier formula gives $\chi_1 = O(s^{J-1})$ at fixed b. The eikonal representation is then a unitarization of the repeated exchange at fixed impact parameter, not a proof that the Born approximation remains small.

Figure 29.3 identifies the impact parameter variable used in this limit and displays the exponentiation of ladder exchanges into the eikonal phase $\chi(s,b)$.

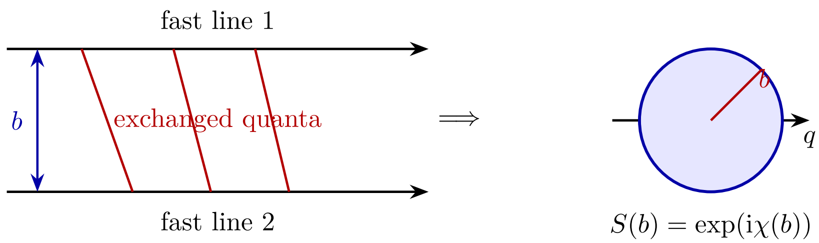

Figure 29.3: In the high-energy small-angle limit, the large angular momentum label becomes an impact parameter $b = (\ell + \frac{1}{2})/p$. The sum of ladder and crossed-ladder exchanges is encoded by the eikonal phase $\chi(s,b)$, while unitarity is the pointwise condition $|S(s,b)| \le 1$.

Controlled Approximation 29.2 (Eikonal exponentiation of repeated exchange)**.** Fix a perturbative regularization and consider two heavy or high-energy external particles whose momentum transfer remains transverse and finite as $s \to \infty$. Assume that, at each fixed order n, the hard external propagators in the ladder and crossed-ladder graphs may be replaced by their eikonal denominators with an integrable remainder. Let $\chi_1(s,b)$ be the Born phase defined by (29.14). Then the leading contribution of all n-exchange ladder and crossed-ladder graphs to the ordered amplitude is

$$\mathcal{M}^{(n)}_{\mathrm{ladd}}(s,-q^2) = 2\mathrm{i}s \int \mathrm{d}^2 b\, \mathrm{e}^{\mathrm{i}q\cdot b} \left[-\frac{(\mathrm{i}\chi_1(s,b))^n}{n!} \right] + o(s) \tag{29.15}$$

in the high-energy small-angle scaling. Summing over $n \ge 1$ gives (29.13) with $\chi = \chi_1$ at leading eikonal order.

The derivation starts from the singular part of a hard line after it absorbs momenta k_r whose transverse components are fixed and whose longitudinal components are small compared with the hard energy. For an on-shell scalar line with momentum p, the regulated propagator after a partial momentum K has flowed through the line is

$$\frac{\mathrm{i}}{(p+K)^2 + m^2 - \mathrm{i}0} = \frac{\mathrm{i}}{2p\cdot K + K^2 - \mathrm{i}0}.$$

In the eikonal scaling $K^2/(p\cdot K) \to 0$ on the leading pinch surface, so the propagator is replaced by

$$\frac{\mathrm{i}}{2p\cdot K - \mathrm{i}0}.$$

The numerator of a spinor or vector external line reduces at the same order to the matrix element of the charge or color generator transported along the classical line; spin-dependent corrections carry at least one additional power of the small momentum transfer divided by the hard energy.

The sum over all ladder and crossed-ladder orderings is exactly the perturbative expansion of two ordered exponentials along the two classical trajectories. In an abelian scalar-exchange model this statement is literal: the hard-line factor is

$$\exp\left\{ \mathrm{i}g_1 \int_{-\infty}^{\infty} \mathrm{d}\tau\, \varphi(b_1 + v_1\tau) \right\} \exp\left\{ \mathrm{i}g_2 \int_{-\infty}^{\infty} \mathrm{d}\tau\, \varphi(b_2 + v_2\tau) \right\}.$$

Contracting the exchanged field between the two lines gives the connected two-line cumulant

$$\mathrm{i}\chi_1(s,b) = -g_1 g_2 \int \mathrm{d}\tau_1 \mathrm{d}\tau_2\, D_F(b + v_1\tau_1 - v_2\tau_2),$$

with the same Feynman prescription as the original graphs. Fourier transforming the transverse separation gives (29.14). Since the exchanged field is Gaussian at this order, the exponential cumulant formula gives the coefficient $(\mathrm{i}\chi_1)^n/n!$. The connected amplitude is proportional to $1 - \exp(\mathrm{i}\chi_1)$, which supplies the sign in (29.15).

For nonabelian gauge exchange the ordered exponentials are Wilson lines, and the exponent contains color matrices ordered along the hard trajectories. Only in a color channel where the Wilson-line product is diagonal does the result reduce to a scalar phase χ. In general the impact-parameter $S(s,b)$ is a matrix on the finite-dimensional internal channel space, and (29.11) is replaced by the positive operator identity

$$(1-S) + (1-S)^\dagger = (1-S)^\dagger(1-S) + (1 - S^\dagger S).$$

Regge theory is a different organization of the same high-energy fixed-t regime. It analytically continues angular momentum rather than taking the large-ℓ continuum limit at fixed b. The continuation is not a consequence of the partial-wave expansion alone; it is an additional analyticity and growth hypothesis in the complex angular-momentum plane. The simultaneous Mandelstam representation, when available, controls the locations and discontinuities of first-sheet singularities in the invariant variables. It does not by itself assert that the partial-wave sequence has a unique meromorphic interpolation in J, nor that such an interpolation has only pole singularities. Regge poles therefore enter below only after the complex-J interpolation and its growth class have been declared.

To state the construction, use the crossed t-channel scattering angle

$$z_t = 1 + \frac{2s}{t - 4m^2}.$$

At fixed physical $t < 0$ and $s \to +\infty$, one has $-z_t \sim 2s/(4m^2 - t) > 0$. Let $a_\ell(t)$ be the t-channel partial-wave coefficient, normalized so that

$$\mathcal{M}_t(t, z_t) = 16\pi \sum_{\ell=0}^{\infty} (2\ell+1) a_\ell(t) P_\ell(z_t)$$

in the t-channel physical region. The signature components are

$$\mathcal{M}_\tau(s,t) = \frac{1}{2}\big(\mathcal{M}(s,t) + \tau\, \mathcal{M}(u,t)\big), \qquad \tau = \pm 1, \qquad u = 4m^2 - s - t.$$

Theorem 29.3 (Carlson uniqueness in the half-plane)**.** *Let F be holomorphic in $\operatorname{Re} J > 0$, continuous on $\operatorname{Re} J \geq 0$, and suppose that it has strict exponential type smaller than π in the closed right half-plane: there is a number $\kappa < \pi$ such that, for every $\delta > 0$,*

$$|F(J)| \leq C_\delta \exp\big((\kappa + \delta)|J|\big), \qquad \operatorname{Re} J \geq 0.$$

Assume also that the boundary function on the imaginary axis has strict type smaller than π: for some $\sigma < \pi$ and every $\delta > 0$,

$$|F(\mathrm{i}y)| \leq C'_\delta \exp\big((\sigma + \delta)|y|\big), \qquad y \in \mathbb{R}.$$

If

$$F(n) = 0, \qquad n = 0, 1, 2, \ldots,$$

then $F \equiv 0$ in the half-plane. Equivalently, within this growth class the values on the nonnegative integers determine the holomorphic interpolation uniquely.

Proof. The number π is the density threshold set by the model zero set $\mathbb{Z}_{\geq 0}$. The Carleman–Jensen formula in the right half-plane turns the boundary exponential type into a bound on the logarithmic density of positive real zeros. Let F be nonzero and let

$$N_F(R) = \#\{a : \ F(a) = 0, \ 0 < a < R, \ a \in \mathbb{R}\}$$

count positive real zeros with multiplicity; the possible boundary zero at $J = 0$ is irrelevant to this density estimate. Applying the half-plane Jensen formula to the half-disc

$$H_R = \{J : \operatorname{Re} J > 0, \ |J| < R\}$$

and using the growth bounds on the semicircle and on the imaginary diameter gives the zero-density estimate

$$\int_1^R \frac{N_F(r)}{r^2}\,\mathrm{d}r \leq \frac{\sigma + \delta}{\pi} \log R + O_\delta(1), \qquad R \to \infty. \tag{29.16}$$

Indeed, the zero term in Carleman's formula is $\sum_{0<a<R}(a^{-1} - aR^{-2})$, which is equivalent to $\int_1^R N_F(r) r^{-2} \mathrm{d}r$ up to $O(1)$. The logarithmic term comes from the imaginary diameter, where $\log|F(\mathrm{i}y)F(-\mathrm{i}y)| \leq 2(\sigma + \delta)|y| + O_\delta(1)$; the semicircle term is only $O_{\kappa,\delta}(1)$, since it carries the prefactor $(\pi R)^{-1} \int_{-\pi/2}^{\pi/2} \cos\theta\,\mathrm{d}\theta$. Polynomial boundary factors and small endpoint losses are removed by the standard Phragmen–Lindelof smoothing $F(J) \mapsto F(J)\mathrm{e}^{-\delta J}(1 + \epsilon J)^{-m}$, with m chosen large enough to remove polynomial boundary factors before $\epsilon \downarrow 0$.

If $F(n) = 0$ for every positive integer n, then

$$N_F(r) \geq \lfloor r \rfloor$$

and therefore

$$\int_1^R \frac{N_F(r)}{r^2}\,\mathrm{d}r \geq \log R + O(1).$$

Combining this with (29.16) gives

$$1 \leq \frac{\sigma + \delta}{\pi}$$

for every $\delta > 0$, contradicting $\sigma < \pi$. Hence a nonzero function in the stated class has too small a boundary type to vanish at every positive integer, and the theorem follows. The threshold is sharp: $\sin \pi J$ vanishes at all integers and has type exactly π on the imaginary axis. Thus the growth hypothesis is the datum that makes the complex-J interpolation unique. $\square$

Carlson uniqueness application. Fix t and a signature τ. Suppose two proposed continuations $a_{\tau,1}(J,t)$ and $a_{\tau,2}(J,t)$ of the same partial-wave sequence $a_{\tau,\ell}(t)$ are holomorphic in a right half-plane after separating the same declared Regge-pole set, have the same pole principal parts there, and obey the Carlson growth class of Theorem 29.3 on the pole-subtracted difference. Then the two continuations agree in that half-plane.

Subtract the common pole principal parts and define

$$F(J) = a_{\tau,1}(J,t) - a_{\tau,2}(J,t).$$

The hypotheses make F holomorphic in the right half-plane and put it in the Carlson growth class. Since both continuations reproduce the same integer-spin partial waves, $F(n) = 0$ for every $n \in \mathbb{Z}_{\geq 0}$. Theorem 29.3 gives $F \equiv 0$. Adding back the common pole principal parts proves the claim.

This uniqueness application has existence content only after a continuation with the stated growth has been constructed. It shows why a Regge analysis must state the vertical-strip or half-plane growth bound of the complex-J continuation: outside such a growth class, functions may agree at every integer J and differ away from the integers. The pole assumptions used below are therefore part of the analytic input rather than consequences of the physical partial-wave series alone.

Assume that, for fixed t in a domain of interest, the signature-projected partial waves admit an analytic continuation $a_\tau(J,t)$ from nonnegative integer J to a meromorphic function in a right half-plane, with sufficient decrease in vertical strips to justify the contour deformation below. Let C be a counterclockwise contour encircling the nonnegative integers and no other singularities. Then the Sommerfeld–Watson representation is

$$\mathcal{M}_\tau(s,t) = 8\pi \int_C \frac{\mathrm{d}J}{2\mathrm{i}} \, \frac{(2J+1)\big(1+\tau \mathrm{e}^{-\mathrm{i}\pi J}\big) a_\tau(J,t) P_J(-z_t)}{\sin \pi J}. \tag{29.17}$$

The normalization is fixed by residues at $J = \ell$: since

$$P_\ell(-z_t) = (-1)^\ell P_\ell(z_t), \qquad \sin \pi J = \pi(-1)^\ell (J-\ell) + O((J-\ell)^2),$$

the residue of (29.17) at $J = \ell$ is

$$16\pi \, \frac{1+\tau(-1)^\ell}{2} \, (2\ell+1) a_\ell(t) P_\ell(z_t).$$

Thus $\tau = +1$ keeps the even-spin part and $\tau = -1$ keeps the odd-spin part.

Suppose that $a_\tau(J,t)$ has a simple Regge pole

$$a_\tau(J,t) = \frac{r_\tau(t)}{J-\alpha(t)} + a_\tau^{\mathrm{reg}}(J,t), \tag{29.18}$$

and that the contour in (29.17) may be moved past this pole, with the remaining background contour lying to the left of $\operatorname{Re}\alpha(t)$. The pole contribution is then

$$\mathcal{M}_\tau^{\mathrm{pole}}(s,t) = \eta_\tau(\alpha(t)) \, \mathfrak{r}_\tau(t) \left(\frac{s}{s_0(t)}\right)^{\alpha(t)} \big(1 + O(s^{-1})\big), \tag{29.19}$$

where

$$\eta_\tau(\alpha) = \frac{1+\tau \mathrm{e}^{-\mathrm{i}\pi\alpha}}{\sin \pi\alpha}$$

is the signature factor, $s_0(t)$ is a positive kinematic scale such as $(4m^2 - t)/2$, and the Regge residue $\mathfrak{r}_\tau(t)$ includes $8\pi(2\alpha+1)r_\tau(t)$ together with the leading large-$(-z_t)$ coefficient of $P_\alpha(-z_t)$. Explicitly, for fixed complex α away from negative integers,

$$P_\alpha(Z) = \frac{\Gamma(2\alpha+1)}{\Gamma(\alpha+1)^2}\left(\frac{Z}{2}\right)^\alpha \left(1 + O(Z^{-2})\right), \qquad |Z| \to \infty$$

in any sector avoiding the negative real axis, and the branch used in (29.19) is inherited from the first-sheet continuation of z_t.

Figure 29.4 records the Sommerfeld–Watson deformation: the integer-spin contour is moved past a Regge pole, and the pole residue gives the $s^{\alpha(t)}$ fixed-t high-energy term.

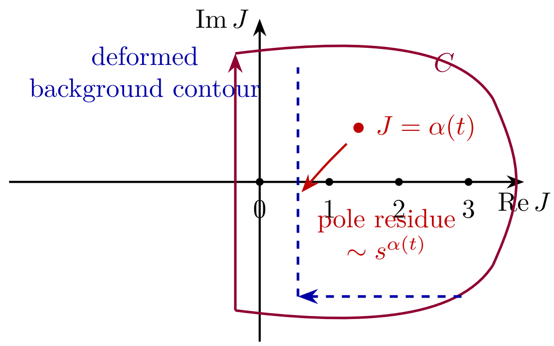

Figure 29.4: The Sommerfeld–Watson contour converts the integer-spin partial-wave sum into a complex-J integral. Deforming the contour past a Regge pole $J = \alpha(t)$ produces the fixed-t high-energy power $s^{\alpha(t)}$, while the displaced contour gives the remaining background.

The pole has a particle interpretation when its trajectory passes through an allowed integer spin. If

$$\alpha(M_n^2) = n, \qquad \tau = (-1)^n, \qquad \alpha'(M_n^2) \neq 0,$$

then the signature factor in (29.19) has the same pole as $(\alpha(t)-n)^{-1}$, and the Regge contribution contains

$$\frac{\text{const.}}{n - \alpha(t)} = \frac{\text{const.}}{-\alpha'(M_n^2)(t - M_n^2)} + \text{regular terms.}$$

This is the usual spin-n exchanged-particle pole in the crossed channel. The Regge trajectory is therefore a statement about analytic organization of a family of exchanged singularities, not an independent replacement for the spectral condition or for LSZ.

Definition 29.4 (Regge trajectory and daughter data)**.** Fix a signature τ, a t-domain, and a meromorphic continuation $a_\tau(J,t)$ satisfying the vertical-strip hypotheses needed for (29.17). A Regge trajectory system is a collection of pole curves

$$J = \alpha_r(t) - n, \qquad n \in \mathbb{Z}_{\geq 0},$$

together with residues $r_{\tau,r,n}(t)$ and a statement of the background contour. The curve $n = 0$ is called the leading trajectory and $n > 0$ curves are daughter trajectories. This terminology is only meaningful after the complex-J continuation and its growth conditions have been specified.

Daughters are not optional decorations if the amplitude is expected to encode an infinite family of crossed-channel resonances while retaining crossing symmetry and polynomial boundedness. A daughter pole contributes

$$\mathcal{M}^{\text{pole}}_{\tau,r,n}(s,t) \sim \eta_\tau(\alpha_r(t)-n)\, \mathfrak{r}_{\tau,r,n}(t) \left(\frac{s}{s_0(t)}\right)^{\alpha_r(t)-n}.$$

It is therefore suppressed at fixed t and large s relative to the leading pole, but it can carry the crossed-channel particle poles required by the finite-spin spectrum. The statement that a hadron family lies on a Regge trajectory means that the corresponding scattering amplitude has such a pole organization and that the trajectory passes through the physical pole positions. It is not a statement about a constituent potential.

Let

$$A(s,t) = g^2 \frac{\Gamma(-\alpha(s))\Gamma(-\alpha(t))}{\Gamma(-\alpha(s)-\alpha(t))}, \qquad \alpha(x) = \alpha_0 + \alpha' x, \quad \alpha' > 0. \tag{29.20}$$

At $\alpha(s) = n \in \mathbb{Z}_{\geq 0}$, $A(s,t)$ has a simple pole whose residue is a polynomial of degree n in $\alpha(t)$. Explicitly,

$$A(s,t) = -\frac{g^2}{n!} \frac{\prod_{r=1}^{n}\big(\alpha(t)+r\big)}{\alpha(s)-n} + O(1). \tag{29.21}$$

Thus the n-th pole contains crossed-channel angular dependence no higher than spin n, in the same sense that a polynomial of degree n in the crossed scattering variable decomposes into partial waves with $\ell \leq n$. Near $\alpha(s) = n$, write $\epsilon = \alpha(s) - n$. Since

$$\Gamma(-n-\epsilon) = \frac{(-1)^{n+1}}{n!\,\epsilon} + O(1),$$

one has

$$A(s,t) = \frac{g^2(-1)^{n+1}}{n!\,(\alpha(s)-n)} \frac{\Gamma(-\alpha(t))}{\Gamma(-n-\alpha(t))} + O(1).$$

Using

$$\frac{\Gamma(z)}{\Gamma(z-n)} = \prod_{r=1}^{n}(z-r)$$

with $z = -\alpha(t)$ gives

$$\frac{\Gamma(-\alpha(t))}{\Gamma(-n-\alpha(t))} = (-1)^n \prod_{r=1}^{n}(\alpha(t)+r),$$

which proves (29.21).

Controlled Approximation 29.5 (Flux-tube slope and Regge phenomenology)**.** If a highly excited mesonic state is approximated by a long rotating open flux tube of tension σ with endpoint masses neglected, the classical relations

$$E = \frac{\pi\sigma}{\omega}, \qquad J = \frac{\pi\sigma}{2\omega^2}$$

give

$$J = \frac{E^2}{2\pi\sigma}. \tag{29.22}$$

This explains the frequently quoted slope $\alpha'_{\text{open}} = 1/(2\pi\sigma)$ as a long-string approximation. It is not a nonperturbative derivation of the QCD hadron spectrum. Endpoint masses, spin, string breaking, mixing with multi-hadron channels, and the fact that most physical resonances are second-sheet poles must be supplied before (29.22) becomes a quantitative QCD statement.

The leading even-signature vacuum singularity is called the Pomeron. In a pure pole model with

$$\alpha_P(0) > 1,$$

the forward optical theorem would give

$$\sigma_{\text{tot}}(s) \sim s^{\alpha_P(0)-1}$$

up to phases and logarithms. Such a single uncompensated pole cannot be the complete asymptotic answer in a massive theory satisfying the Froissart–Martin hypotheses. Eikonalization gives the mechanism by which a growing exchange may be compatible with impact-parameter unitarity. If the leading eikonal phase has large-b behavior

$$\chi_1(s,b) \sim C\, s^{\Delta} \mathrm{e}^{-\mu b}, \qquad \Delta > 0, \quad \mu > 0,$$

then the region where $|\chi_1| \gtrsim 1$ has radius

$$R(s) \sim \frac{\Delta}{\mu} \log s.$$

After the eikonal exponential has saturated $|S(b)| \le 1$ inside this region, the total cross section grows like an area,

$$\sigma_{\text{tot}}(s) \lesssim 2\pi R(s)^2 = O(\log^2 s).$$

The precise coefficient requires the same analyticity and nearest-singularity input as the Froissart–Martin theorem; the eikonal estimate explains the impact-parameter dynamics behind saturation but does not replace the axiomatic bound.

Definition 29.6 (Inclusive triple-Regge kinematics)**.** For an inclusive reaction

$$a(p_a) + b(p_b) \longrightarrow c(p_c) + X,$$

write

$$s = (p_a + p_b)^2, \qquad t = (p_a - p_c)^2, \qquad M_X^2 = (p_a + p_b - p_c)^2.$$

The triple-Regge limit is the limiting regime

$$s \to \infty, \qquad M_X^2 \to \infty, \qquad t \text{ fixed}, \qquad \xi := \frac{M_X^2}{s} \to 0. \tag{29.23}$$

The particle c is separated from the unobserved system X by the large rapidity interval $\log(s/M_X^2)$, while the internal energy available to the inclusive subsystem X grows like M_X. Choose once and for all a positive mass scale s_0 and define the dimensionless inclusive density

$$\mathcal{D}_{ab\to cX}(s, M_X^2, t) := s_0^2 \, \frac{\mathrm{d}^2\sigma(ab \to cX)}{\mathrm{d}t\, \mathrm{d}M_X^2}. \tag{29.24}$$

Hypothesis 29.7 (Triple-Regge factorization system)**.** For the inclusive density in (29.24), a triple-Regge system on a domain $t \in U$ consists of:

1. Regge trajectories $\alpha_i(t)$ for the two t-channel exchanges adjacent to the measured transition $a \to c$;
2. Regge trajectories $\alpha_k(0)$ for the forward singularities governing the inclusive b-to-X discontinuity;
3. coefficient functions $G_{ijk}(t)$, including the two external Regge residues and a local triple-Regge vertex, in a stated phase and signature convention;
4. a background term $B(s, M_X^2, t)$ whose growth in the variables s/M_X^2 and M_X^2/s_0 is bounded by exponents strictly below the retained trajectories on the chosen domain.

The system asserts the asymptotic representation

$$\mathcal{D}_{ab\to cX}(s, M_X^2, t) = \sum_{i,j,k} G_{ijk}(t) \left(\frac{s}{M_X^2}\right)^{\alpha_i(t)+\alpha_j(t)-2} \left(\frac{M_X^2}{s_0}\right)^{\alpha_k(0)-1} + B(s, M_X^2, t) \tag{29.25}$$

in the limit (29.23). Equation (29.25) is a precise factorization hypothesis about a six-point discontinuity. A derivation from local QFT requires the corresponding six-point analyticity, complex angular-momentum continuation, signature, and discontinuity hypotheses in addition to the two-body Sommerfeld–Watson representation.

Exponent bookkeeping in a triple-Regge system. Assume the system of Hypothesis 29.7 and fix a single term (i, j, k). In the variables

$$Y := \log \frac{s}{M_X^2}, \qquad Y_X := \log \frac{M_X^2}{s_0},$$

the contribution of that term to the dimensionless density is

$$G_{ijk}(t) \exp\bigl[\bigl(\alpha_i(t) + \alpha_j(t) - 2\bigr)Y + \bigl(\alpha_k(0) - 1\bigr)Y_X\bigr]. \tag{29.26}$$

For the diffractive PPP contribution, where the same even-signature vacuum trajectory appears on all three Reggeon lines,

$$\mathcal{D}^{PPP} = G_{PPP}(t) \left(\frac{s}{M_X^2}\right)^{2\alpha_P(t)-2} \left(\frac{M_X^2}{s_0}\right)^{\alpha_P(0)-1} \tag{29.27}$$

up to the declared background and lower trajectories. If $\alpha_P(t) = 1 + \Delta + \alpha_P' t + O(t^2)$, then at small fixed t the dependence on the rapidity gap is

$$\exp\bigl[2(\Delta + \alpha_P' t + O(t^2))Y\bigr].$$

Indeed, taking logarithms of the two dimensionless ratios in (29.25) gives

$$\left(\frac{s}{M_X^2}\right)^{\alpha_i(t)+\alpha_j(t)-2} \left(\frac{M_X^2}{s_0}\right)^{\alpha_k(0)-1} = \exp\bigl[\bigl(\alpha_i(t) + \alpha_j(t) - 2\bigr)Y + \bigl(\alpha_k(0) - 1\bigr)Y_X\bigr].$$

The PPP specialization is obtained by setting $i = j = k = P$. Expanding $\alpha_P(t)$ near $t = 0$ gives the final displayed expression.

Remark 29.8 (AGK rules and what the eikonal argument proves). Abramovsky–Gribov–Kancheli cutting rules are statements about discontinuities of multi-Reggeon exchange diagrams after a definite Reggeon-field-theory or eikonal representation has been specified. The minimal result that follows from the absorptive one-channel eikonal used above is the Poisson law for cut elementary exchanges at fixed impact parameter:

$$S(b) = \mathrm{e}^{-\Omega(b)/2} \quad\Longrightarrow\quad P_n(b) = \mathrm{e}^{-\Omega(b)}\,\frac{\Omega(b)^n}{n!}, \qquad \sum_{n=0}^{\infty} P_n(b) = 1. \tag{29.28}$$

This identity is a consequence of unitarity for that eikonal model. The full AGK cancellation pattern for general Reggeon diagrams requires additional analytic continuation, signature, and cutting hypotheses; in this monograph it will be used only after those hypotheses have been declared.

Definition 29.9 (Minimal Reggeon field-theory model)**.** Fix a high-energy regime in which a single even-signature vacuum Regge singularity is retained. A minimal Reggeon field-theory model consists of:

(i) a rapidity variable Y and an impact parameter $b \in \mathbb{R}^2$;

(ii) two fields $\phi(Y,b)$ and $\widetilde{\phi}(Y,b)$, where $\widetilde{\phi}$ is the response field used to write a retarded evolution problem;

(iii) a quadratic action

$$S_0[\widetilde{\phi},\phi] = \int \mathrm{d}Y\,\mathrm{d}^2b\,\widetilde{\phi}\big(\partial_Y - \alpha'_P\nabla_b^2 - \Delta_P\big)\phi, \qquad \alpha'_P > 0, \tag{29.29}$$

with retarded boundary condition in Y;

(iv) a list of interaction vertices, for example a triple-Reggeon vertex $g_{3P}\int \mathrm{d}Y\,\mathrm{d}^2b\,(\widetilde{\phi}\phi^2 - \widetilde{\phi}^2\phi)$, together with a declared cutting prescription.

This model is not a definition of QCD. It is an effective high-energy description of a selected complex-angular-momentum singularity after a Reggeon basis, signature convention, and unitarity/cutting rules have been declared.

Free Reggeon diffusion kernel. The retarded Green kernel of

$$\big(\partial_Y - \alpha'_P\nabla_b^2 - \Delta_P\big)G(Y,b) = \delta(Y)\delta^{(2)}(b) \tag{29.30}$$

is

$$G(Y,b) = \Theta(Y)\,\frac{\exp(\Delta_P Y)}{4\pi\alpha'_P Y}\,\exp\!\left(-\frac{|b|^2}{4\alpha'_P Y}\right). \tag{29.31}$$

Equivalently, in transverse momentum q,

$$\widehat{G}(Y,q) = \Theta(Y)\exp\!\big((\Delta_P - \alpha'_P q^2)Y\big). \tag{29.32}$$

Thus a pole contribution generated by the quadratic model has trajectory

$$\alpha_P(t) = 1 + \Delta_P + \alpha'_P t \tag{29.33}$$

when $t = -q^2$.

Fourier transform in b:

$$\widehat{G}(Y,q) = \int \mathrm{d}^2 b\, \mathrm{e}^{-\mathrm{i}q\cdot b} G(Y,b).$$

For $Y > 0$, (29.30) becomes

$$\partial_Y \widehat{G}(Y,q) = (\Delta_P - \alpha'_P q^2)\widehat{G}(Y,q).$$

The retarded delta-function normalization gives $\widehat{G}(0^+,q) = 1$, hence (29.32). The inverse two-dimensional Fourier transform of $\exp(-\alpha'_P q^2 Y)$ is the heat kernel $(4\pi\alpha'_P Y)^{-1}\exp[-|b|^2/(4\alpha'_P Y)]$, giving (29.31). Since $\widehat{G} \sim \exp[(\alpha_P(t)-1)Y]$ in Regge notation and $t = -q^2$, the trajectory is (29.33).

Two-Reggeon cut in the free diffusion model. In the quadratic model of Definition 29.9, the exchange of two independent Reggeons with total transverse momentum q has the rapidity kernel

$$I_2(Y,q) = \int \frac{\mathrm{d}^2 k}{(2\pi)^2}\, \widehat{G}(Y,k)\widehat{G}(Y,q-k) = \Theta(Y)\, \frac{\exp\left[\left(2\Delta_P - \frac{\alpha'_P q^2}{2}\right) Y\right]}{8\pi\alpha'_P Y}. \tag{29.34}$$

Consequently its Mellin transform in rapidity has a logarithmic branch point at

$$J_{\mathrm{cut}}(t) = 1 + 2\Delta_P + \frac{\alpha'_P}{2} t, \qquad t = -q^2, \tag{29.35}$$

rather than a simple Regge pole. The corresponding n-Reggeon free convolution has leading exponent

$$n\Delta_P - \frac{\alpha'_P q^2}{n} = n\Delta_P + \frac{\alpha'_P}{n} t \tag{29.36}$$

up to the power of Y generated by the transverse Gaussian integral.

Insert (29.32):

$$I_2(Y,q) = \Theta(Y)\mathrm{e}^{2\Delta_P Y} \int \frac{\mathrm{d}^2 k}{(2\pi)^2} \exp[-\alpha'_P Y (k^2 + (q-k)^2)].$$

Completing the square gives

$$k^2 + (q-k)^2 = 2\left(k - \frac{q}{2}\right)^2 + \frac{q^2}{2}.$$

The two-dimensional Gaussian integral

$$\int \frac{\mathrm{d}^2 \ell}{(2\pi)^2} \mathrm{e}^{-2\alpha'_P Y \ell^2} = \frac{1}{8\pi\alpha'_P Y}$$

proves (29.34). Let $\omega = J - 1$. Up to factors analytic in ω near the singularity, the rapidity Mellin transform contains

$$\int_0^\infty \frac{\mathrm{d}Y}{Y} \exp\left[-\left(\omega - 2\Delta_P + \frac{\alpha'_P q^2}{2}\right) Y\right].$$

After an infrared subtraction at small Y, this integral equals

$$-\log\left(\omega - 2\Delta_P + \frac{\alpha'_P q^2}{2}\right) + \text{analytic terms},$$

so the singularity is a branch point at $\omega = 2\Delta_P - \alpha'_P q^2/2$, which is (29.35). For n independent Reggeons with momenta k_i and $\sum_i k_i = q$, the identity

$$\sum_{i=1}^{n} k_i^2 = \sum_{i=1}^{n} \left(k_i - \frac{q}{n}\right)^2 + \frac{q^2}{n}$$

gives (29.36); the remaining constrained Gaussian integration changes only the power of Y, not the displayed exponential trajectory.

Remark 29.10 (Regge cuts as singularity data). Once more than one exchanged Reggeon is retained, complex angular momentum singularities can become branch cuts. The elementary computation above already produces a cut whose intercept and slope are determined by the two-particle diffusion saddle. Interactions, signature factors, and unitarity constraints change the singularity structure. A pole-only parametrization is therefore a restricted approximation whose scope must be declared. A QCD use of the word Pomeron must specify whether it is describing an isolated pole, a cut, or an effective fit to a restricted energy window.

Definition 29.11 (Absorptive eikonal cut generator)**.** At fixed impact parameter b, let $\Omega(s,b) \geq 0$ be the opacity of a one-channel absorptive eikonal model and write

$$S(s,b) = \exp\left[-\frac{1}{2}\Omega(s,b)\right]. \tag{29.37}$$

The cut-exchange generating function is

$$Z_b(z) = \exp[-\Omega(s,b)(1-z)]. \tag{29.38}$$

The coefficient of z^n,

$$P_n(s,b) = [z^n]Z_b(z) = \mathrm{e}^{-\Omega(s,b)} \frac{\Omega(s,b)^n}{n!}, \tag{29.39}$$

is the fixed-b topological weight for n cut elementary exchanges in this model.

Eikonal AGK cancellation as a factorial-moment identity. For the cut generator of Definition 29.11,

$$\sum_{n=0}^{\infty} P_n(s,b) = 1, \qquad \sum_{n=0}^{\infty} n\, P_n(s,b) = \Omega(s,b). \tag{29.40}$$

More generally, for the falling factorial

$$(n)_r = n(n-1)\cdots(n-r+1), \qquad r \geq 1, \tag{29.41}$$

one has

$$\sum_{n=0}^{\infty} (n)_r P_n(s,b) = \Omega(s,b)^r. \tag{29.42}$$

Equivalently, if every P_n is expanded in powers of Ω, the coefficient of Ω^m in the r-th factorial moment is

$$\sum_{n=r}^{m} \frac{(n)_r(-1)^{m-n}}{n!\,(m-n)!} = \begin{cases} 1, & m = r, \\ 0, & m \neq r. \end{cases} \tag{29.43}$$

This is the precise cancellation supplied by the one-channel absorptive eikonal. It is an AGK-type cancellation for inclusive factorial moments, not a theorem about arbitrary Reggeon-field-theory diagrams. Normalization is $Z_b(1) = 1$. Differentiating $Z_b(z)$ gives

$$\left.\frac{\partial^r Z_b}{\partial z^r}\right|_{z=1} = \Omega(s,b)^r,$$

while the same derivative of the power series

$$Z_b(z) = \sum_{n=0}^{\infty} P_n(s,b) z^n$$

is $\sum_n (n)_r P_n(s,b)$. This proves (29.42); the case $r = 1$ gives the mean.

For the coefficient form, expand

$$P_n = \sum_{q=0}^{\infty} \frac{(-1)^q}{q!\,n!} \Omega^{q+n}. \tag{29.44}$$

The coefficient of Ω^m in the factorial moment is therefore

$$\sum_{n=r}^{m} \frac{n!}{(n-r)!} \frac{(-1)^{m-n}}{(m-n)!\,n!} = \sum_{j=0}^{m-r} \frac{(-1)^{m-r-j}}{j!\,(m-r-j)!}. \tag{29.45}$$

This is the coefficient of x^{m-r} in $\mathrm{e}^x \mathrm{e}^{-x} = 1$. It is one when $m = r$ and zero otherwise.

Remark 29.12 (Soft and hard Pomeron language). The words "soft Pomeron" and "hard Pomeron" are not definitions. In this chapter a Pomeron means a declared even-signature vacuum singularity in a specified amplitude or effective high-energy datum. A phenomenological intercept fitted from hadron cross sections, a BFKL cut or pole in a perturbative color-dipole regime, and the intercept Δ_P in (29.29) are different coordinates unless a matching argument relates them. The BFKL construction in Chapter 49 is therefore a short-distance high-energy datum; it is not automatically the same object as the soft vacuum singularity used to organize low-energy hadron scattering.

29.6 The Froissart–Martin Mechanism

Define the positive total weight

$$\bar{L}^2(s) = \sum_{\substack{\ell=0 \\ \ell \text{ even}}}^{\infty} (2\ell+1) w_\ell(s) = \frac{s-4m^2}{16\pi}\,\sigma_{\mathrm{tot}}(s).$$

For real $x > 1$, the Legendre polynomial $P_\ell(x)$ is positive and strictly increases with ℓ. Consider all even-ℓ weights obeying

$$0 \le w_\ell \le 2, \qquad \sum_{\ell \text{ even}} (2\ell+1) w_\ell = \bar{L}^2.$$

Among these weights, the smallest possible value of

$$\sum_{\ell \text{ even}} (2\ell+1) P_\ell(x) w_\ell$$

is obtained by filling the lowest allowed angular momenta to height 2, with at most one partially filled endpoint. This is the elementary rearrangement inequality: if weight is moved from a larger ℓ to a smaller ℓ, the constraint is unchanged while the sum decreases. Denote this minimizing profile by b_ℓ. If L is the largest filled angular momentum, then

$$\sum_{\substack{0\le \ell \le L\\ \ell \text{ even}}} 2(2\ell+1) = L^2 + O(L), \qquad L^2 = \bar{L}^2 + O(\bar{L}).$$

The rearrangement step and the angular-analyticity domain are illustrated in Figure 29.5.

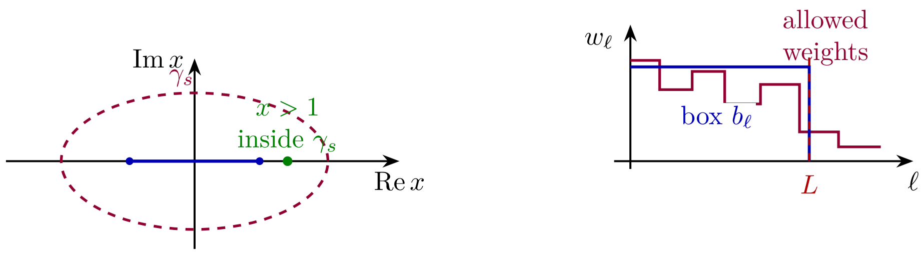

Figure 29.5: Angular point inside the Lehmann ellipse and the minimizing partial-wave weight profile. For $x > 1$ inside γ_s, positivity of $P_\ell(x)$ makes the extremal lower-bound profile a filled box b_ℓ up to the endpoint angular momentum L.

For $x > 1$, write $x = \cosh\eta$, $\eta > 0$. The integral representation

$$P_\ell(\cosh\eta) = \frac{1}{\pi}\int_0^\pi (\cosh\eta + \cos\alpha\,\sinh\eta)^\ell \, d\alpha$$

implies the following lower bound. For every fixed small $\delta > 0$ there is a constant $C_\delta > 0$, independent of s and ℓ in the large-energy regime used below, such that

$$P_\ell(\cosh\eta) \ge C_\delta \left(1 + (1-\delta)\sinh\eta\right)^\ell \equiv C_\delta y^\ell.$$

Indeed, restrict the integral to an interval of α on which $\cos\alpha \ge 1-\delta$; on that interval the integrand is bounded below by the displayed base.

The actual weighted sum is bounded below by the same sum evaluated on the minimizing box profile. Therefore, for $x > 1$ inside the angular analytic domain,

$$\operatorname{Im}\mathcal{M}(s,x) \ge C\,\beta(s)^{-1} \sum_{\substack{0\le \ell \le L\\ \ell \text{ even}}} (2\ell+1) y^\ell \ge C'\,\beta(s)^{-1} L\,\frac{y^L}{y-1}, \tag{29.46}$$

whenever $L(y-1) \ge 1$. If $L(y-1) < 1$, then $L^2 \lesssim (y-1)^{-2}$, and the relation between L^2 and σ_{tot} already gives a high-energy bound stronger than a logarithmic-square estimate. Hence the displayed lower bound covers the only case in which the Froissart estimate is nontrivial. The constants are independent of s at sufficiently large energy, for fixed δ and fixed t away from the singularity.

Now choose a number t_* with

$$0 < t_* < t_0$$

and evaluate the amplitude at

$$x_*(s) = 1 + \frac{2t_*}{s - 4m^2}.$$

This point lies strictly inside the Lehmann ellipse for sufficiently large s. At large s,

$$y - 1 = (1-\delta)\sqrt{x_*^2 - 1} + O(s^{-1}) = 2(1-\delta)\sqrt{\frac{t_*}{s}} + O(s^{-1}), \tag{29.47}$$

and

$$L \simeq \sqrt{\frac{s\,\sigma_{\rm tot}}{16\pi}}.$$

Therefore the exponential factor obeys

$$y^L \simeq \exp\left[(1-\delta)\sqrt{\frac{t_*\,\sigma_{\rm tot}}{4\pi}}\right]. \tag{29.48}$$

Definition 29.13 (Polynomial bounds used in dispersion theory)**.** For the on-shell amplitude $\mathcal{M}(s,t)$, three polynomial estimates occur in distinct domains.

1. A *physical-region bound* controls $\mathcal{M}(s+\mathrm{i}0,t)$ for real physical scattering angles $-(s-4m^2) \leq t \leq 0$.
2. A *fixed-t cut-plane bound* controls the first-sheet function of complex s at a fixed real $t < 0$, on the contours used for a fixed-t dispersion relation.
3. An *angular-tube bound* controls the analytically continued amplitude at $0 < t < t_0$, equivalently at $x = 1 + 2t/(s-4m^2) > 1$ inside a Lehmann ellipse or its higher-dimensional angular-tube replacement.

The Froissart comparison below uses the third estimate. The Jin–Martin fixed-t theorem supplies the second estimate, while the angular-tube estimate is an additional input unless it has been derived from a stronger Lehmann–Martin domain theorem in the theory under study.

Assume the angular-tube polynomial bound at the chosen nonphysical point:

$$|\mathcal{M}(s, x_*(s))| \leq C_N s^N \qquad (s \to \infty),$$

for some fixed integer N. The lower bound contains the prefactor $\beta^{-1}L/(y-1)$, which is of order $s\sqrt{\sigma_{\rm tot}}$ up to fixed constants. Hence compatibility with the polynomial upper bound implies

$$\sigma_{\rm tot}(s) \leq \frac{(N-1)^2}{(1-\delta)^2}\,\frac{4\pi}{t_*}\left(\log\frac{s}{M_0^2}\right)^2$$

for sufficiently large s. The scale M_0 changes only subleading terms in the logarithm. Taking $t_* \to t_0^-$ after the estimate gives the coefficient governed by the nearest crossed-channel singularity. This is the Froissart–Martin mechanism: angular analyticity converts polynomial boundedness into a bound on the number of strongly contributing partial waves, and unitarity bounds the weight carried by each such partial wave.

29.7 Polynomial Boundedness

The first polynomial-growth statement supplied directly by the Wightman framework is distributional. It is weaker than the pointwise high-energy estimate used at the edge of the Lehmann ellipse in the Froissart comparison, but it is the correct starting point: Wightman functions and LSZ boundary values are tempered distributions before they are functions.

Let

$$\langle s\rangle = (1+s^2)^{1/2}.$$

For $r, N \in \mathbb{Z}_{\geq 0}$, define the Schwartz seminorm

$$p_{r,N}(\varphi) = \max_{0\leq j\leq r} \sup_{s\in\mathbb{R}} \langle s\rangle^N |\partial_s^j \varphi(s)|. \tag{29.49}$$

Let $T \in \mathcal{S}'(\mathbb{R})$ be a tempered distribution. By definition, the topology on $\mathcal{S}(\mathbb{R})$ is generated by the seminorms

$$\varphi \mapsto \sup_s \langle s\rangle^a |\partial_s^b \varphi(s)|, \qquad a, b \in \mathbb{Z}_{\geq 0},$$

and continuity of T means that T is bounded by a finite linear combination of them. Increasing the two indices if necessary gives constants $C > 0$, $r \in \mathbb{Z}_{\geq 0}$, and $N \in \mathbb{Z}_{\geq 0}$ such that

$$|\langle T, \varphi\rangle| \leq C\, p_{r,N}(\varphi) \qquad \text{for all } \varphi \in \mathcal{S}(\mathbb{R}). \tag{29.50}$$

If $\varphi \in \mathcal{S}(\mathbb{R})$ is fixed and

$$\varphi_{R,\Delta}(s) = \Delta^{-1}\varphi\left(\frac{s-R}{\Delta}\right), \qquad R \in \mathbb{R}, \quad \Delta \geq 1, \tag{29.51}$$

then

$$|\langle T, \varphi_{R,\Delta}\rangle| \leq C_\varphi\,(1+|R|+\Delta)^N. \tag{29.52}$$

The estimate follows directly from

$$\partial_s^j \varphi_{R,\Delta}(s) = \Delta^{-1-j}\varphi^{(j)}\left(\frac{s-R}{\Delta}\right).$$

Writing $s = R + \Delta y$ gives

$$\langle s\rangle^N |\partial_s^j \varphi_{R,\Delta}(s)| \leq C_N (1+|R|+\Delta)^N \Delta^{-1-j} \langle y\rangle^N |\varphi^{(j)}(y)|.$$

Since $\Delta \geq 1$, the factors Δ^{-1-j} are bounded by one; taking the supremum over y and over $0 \leq j \leq r$ gives (29.52).

Remark 29.14 (Fixed-t LSZ boundary values after smearing). Fix real $t < 0$ in a fixed-t analyticity domain and separate any first-sheet stable-particle pole terms explicitly. Suppose the connected LSZ amplitude has a boundary value

$$\mathcal{M}_t(s + \mathrm{i}0) \in \mathcal{S}'(\mathbb{R}_s)$$

on the remaining real edge. Then every family of high-energy wave-packet smearings of the form (29.51) obeys a polynomial bound in the central energy R:

$$|\langle \mathcal{M}_t, \varphi_{R,\Delta}\rangle| \leq C_{\varphi,t}\,(1+|R|+\Delta)^{N_t}. \tag{29.53}$$

This is exactly the preceding translated-packet estimate applied to the tempered distribution $\mathcal{M}_t(s+\mathrm{i}0)$. The exponent N_t and the constant $C_{\varphi,t}$ are determined by a finite list of Schwartz seminorms controlling this fixed-t boundary distribution. The constants may depend on the chosen fixed-t edge and on the pole terms that were removed before forming the cut distribution; those pole contributions are handled explicitly by their Cauchy residues in the dispersion formula.

Proposition 29.15 (Subtracted Cauchy transform of a tempered cut)**.** *Let $T \in \mathcal{S}'(\mathbb{R}_\sigma)$, and choose C_T, r_T, N_T such that*

$$|\langle T, \psi\rangle| \le C_T \max_{0\le j\le r_T} \sup_{\sigma\in\mathbb{R}} \langle\sigma\rangle^{N_T} |\partial_\sigma^j \psi(\sigma)| \tag{29.54}$$

for all $\psi \in \mathcal{S}(\mathbb{R})$. Fix $z_0 \in \mathbb{C}\setminus\mathbb{R}$ and an integer $q > N_T$. For $z \in \mathbb{C}\setminus\mathbb{R}$, set

$$K_q(\sigma; z, z_0) = \frac{(z-z_0)^q}{(\sigma-z)(\sigma-z_0)^q}, \qquad F_q(z) = \langle T, K_q(\cdot; z, z_0)\rangle. \tag{29.55}$$

Then F_q is holomorphic in the upper and lower half-planes, and for $y = |\operatorname{Im} z| > 0$,

$$|F_q(z)| \le C_{T,q,z_0}\,(1+|z|)^q\, y^{-r_T-1}. \tag{29.56}$$

Consequently, if a fixed-t amplitude with pole terms removed admits a q-subtracted Cauchy representation whose right- and left-cut discontinuities are tempered distributions of finite orders, then the amplitude is pointwise polynomially bounded on every fixed contour staying a positive distance from the cuts, up to the subtraction polynomial of degree at most $q-1$.

Proof. For real σ, the denominator $\sigma - z$ never vanishes. Since $q > N_T$, the function $K_q(\cdot; z, z_0)$ is a Schwartz function of σ: at large $|\sigma|$ it decays as $|\sigma|^{-q-1}$, and every σ-derivative decays at least as fast. Thus $F_q(z)$ is well-defined. Differentiating K_q with respect to z again gives a Schwartz function of σ, locally uniformly for z in either open half-plane, so differentiation may be passed through the continuous functional T. Hence F_q is holomorphic separately in the upper and lower half-planes.

It remains to prove the displayed bound. By Leibniz' rule, $\partial_\sigma^j K_q$ is a finite sum of terms

$$(z-z_0)^q \frac{c_{a,b}}{(\sigma-z)^{a+1}(\sigma-z_0)^{q+b}}, \qquad a+b=j, \qquad c_{a,b}\in\mathbb{Z}. \tag{29.57}$$

Because $z_0 \notin \mathbb{R}$, and because $q > N_T$,

$$\sup_{\sigma\in\mathbb{R}} \langle\sigma\rangle^{N_T} |\sigma - z_0|^{-q-b} \le C_{q,z_0,N_T}. \tag{29.58}$$

Also $|\sigma - z|^{-a-1} \le y^{-a-1} \le y^{-r_T-1}$ for $0 \le a \le j \le r_T$. Therefore

$$\max_{0\le j\le r_T} \sup_{\sigma\in\mathbb{R}} \langle\sigma\rangle^{N_T} |\partial_\sigma^j K_q(\sigma; z, z_0)| \le C_{q,z_0,N_T,r_T}\, |z-z_0|^q\, y^{-r_T-1}. \tag{29.59}$$

Combining this with (29.54) and $|z - z_0| \le C_{z_0}(1+|z|)$ gives (29.56).

For the final assertion, apply the same estimate to each cut distribution after translating the cut coordinate to σ. A q-subtracted Cauchy representation has the form

$$\mathcal{M}_{\mathrm{reg}}(z,t) = P_{q-1}(z;t) + \sum_{\mathrm{cuts}} \left\langle T_{\mathrm{cut}}(\sigma;t), \frac{(z-z_0)^q}{(\sigma-z)(\sigma-z_0)^q} \right\rangle. \tag{29.60}$$

On a contour whose distance from all cuts is bounded below by a positive number, the factor y^{-r_T-1} and its translated analogues are bounded by contour-dependent constants. The subtraction polynomial and the finite sum of Cauchy-transform bounds are therefore bounded by a power of $1+|z|$. ☐

Remark 29.16 (Where the Jin–Martin input enters). In a massive Wightman theory with stable external scalar particles, tempered LSZ boundary values and the subtracted-Cauchy Proposition 29.15 prove only the following conditional implication:

$$\begin{gathered}\text{fixed-}t\text{ first-sheet cut plane} + \text{ finite-subtraction Cauchy formula}\\ + \text{ tempered discontinuities} \Longrightarrow \text{pointwise cut-plane polynomial growth.}\end{gathered} \tag{29.61}$$

The genuinely QFT-specific theorem is the preceding line's input: locality, the spectrum condition, LSZ pole separation, and the Jost–Lehmann–Dyson/Bros–Epstein–Glaser domain analysis must supply the fixed-t first-sheet domain, the pointwise large-contour growth estimate, and the tempered cut distributions. Once those inputs are known, the finite-subtraction Cauchy formula itself follows from Theorem 29.19. This is the Jin–Martin proof layer. It is a proof obligation for the analytic-scattering part of this monograph and requires more data than Wightman temperedness alone. The implication (29.61) is the final statement of Proposition 29.15. The construction of the first-sheet fixed-t domain is an analytic-continuation theorem for Wightman functions and LSZ limits, not a consequence of the topological definition of $\mathcal{S}'$. Similarly, the pointwise large-contour bound is not a theorem about all tempered boundary values. The global Cauchy formula is proved below, but it needs those domain and growth hypotheses before it can be applied to a QFT amplitude.

Theorem 29.17 (LSZ transfer of a fixed-t holomorphic domain)**.** *Fix a real $t<0$. Let $D_t \subset \mathbb{C}_s$ be a connected one-variable first-sheet domain whose boundary contains a real open edge, and let*

$$\kappa_a = k_a^2 + m^2, \qquad a = 1, \dots, 4,$$

be local holomorphic normal coordinates to the four external mass shells in an off-shell neighbourhood of the relevant on-shell configurations. Suppose an off-shell connected four-point time-ordered germ

$$G_t(s, \kappa_1, \dots, \kappa_4)$$

is holomorphic for $s \in D_t$ and $0 < |\kappa_a| < \epsilon_a$, and has at most normal-crossing simple external one-particle poles in the following strong sense: the LSZ-amputated germ

$$H_t(s,\kappa) = \left[\prod_{a=1}^{4} Z_a^{-1/2}\, \mathrm{i}\, \kappa_a\right] G_t(s,\kappa) \tag{29.62}$$

extends holomorphically to the full polydisc

$$D_t \times \{|\kappa_a| < \epsilon_a,\ a = 1, \dots, 4\}.$$

Assume also that H_t has local polynomial boundary growth in s, uniformly for κ on compact subpolydiscs. Define

$$\mathcal{M}_t(s) = H_t(s,0,0,0,0). \tag{29.63}$$

Then $\mathcal{M}_t$ is holomorphic on D_t, has local polynomial boundary growth on every real edge inherited from H_t, and its distributional discontinuities across cuts are the external-mass-shell restrictions *of the discontinuities of H_t. In particular, if the off-shell discontinuity on a noncompact real edge is tempered in s, with the seminorm orders uniform for $|\kappa_a| \le \epsilon'_a < \epsilon_a$, then the on-shell discontinuity of $\mathcal{M}_t$ is tempered in s.*

Proof. The first assertion is the restriction theorem for holomorphic functions: because H_t is holomorphic on a neighbourhood of the complex submanifold $\kappa = 0$, its restriction $\mathcal{M}_t(s) = H_t(s, 0)$ is holomorphic in $s \in D_t$. The Cauchy formula in the normal variables gives the explicit restriction map. Choose radii $0 < r_a < \epsilon_a$. Then

$$H_t(s,0) = \frac{1}{(2\pi \mathrm{i})^4} \int_{|\zeta_1|=r_1} \cdots \int_{|\zeta_4|=r_4} \frac{H_t(s,\zeta_1,\ldots,\zeta_4)}{\zeta_1\zeta_2\zeta_3\zeta_4} \,\mathrm{d}\zeta_1 \cdots \mathrm{d}\zeta_4. \tag{29.64}$$

The integrand is holomorphic in s, and the integration tori are compact, so the integral is holomorphic in s.

The same formula transfers polynomial boundary growth. Let $K \Subset D_t$ be a subdomain whose boundary approach to a real edge is controlled in the usual tempered-holomorphic sense, and assume

$$|H_t(s,\zeta)| \le C_K (1+|s|)^N d(s, \partial D_t)^{-M}$$

for $s \in K$ and $|\zeta_a| = r_a$. Taking absolute values in (29.64) gives the same type of bound for $H_t(s,0)$, with the constant multiplied by $\prod_a r_a^{-1}$. Thus the LSZ mass-shell restriction does not create a new high-energy growth mechanism; it only changes constants and keeps the finite polynomial order.

For boundary values, test against a compactly supported smooth function $\varphi(s)$ on a real edge. The polynomial-growth hypothesis permits the boundary-value map to commute with the compact Cauchy integrals:

$$\langle \mathrm{bv}\, \mathcal{M}_t, \varphi \rangle = \frac{1}{(2\pi \mathrm{i})^4} \int_{|\zeta_1|=r_1} \cdots \int_{|\zeta_4|=r_4} \langle \mathrm{bv}\, H_t(\cdot,\zeta), \varphi \rangle \frac{\mathrm{d}^4\zeta}{\zeta_1\zeta_2\zeta_3\zeta_4}. \tag{29.65}$$

Taking the difference of the upper and lower boundary values gives the same formula for the discontinuity. If the off-shell discontinuities are tempered with seminorm orders independent of ζ on the chosen tori, the right side is bounded by the same finite Schwartz seminorms of φ, again up to the compact-torus constant. This proves temperedness of the on-shell discontinuity.

Finally, the normalization in (29.62) is exactly the external one-particle pole extraction of the LSZ theorem in Chapter 18. The theorem here does not prove that a particular Wightman theory supplies the off-shell domain and uniform normal-crossing extension; it proves that once those hypotheses are supplied by the locality, spectrum, Jost–Lehmann–Dyson, and Bros–Epstein–Glaser construction, the passage to the on-shell fixed-t amplitude is a legitimate holomorphic and distributional operation. □

Definition 29.18 (Admissible fixed-t two-cut exhaustion)**.** Let $b < a$ be real numbers and set

$$C_R = [a,\infty), \qquad C_L = (-\infty, b], \qquad \Omega = \mathbb{C} \setminus (C_R \cup C_L).$$

An admissible exhaustion of Ω is a family of bounded domains $\Omega_{\mathcal{R},\epsilon} \Subset \Omega$, indexed by $\mathcal{R} \to \infty$ and $\epsilon \downarrow 0$, whose positively oriented boundaries are piecewise C^1 and have the following structure. For each fixed $\epsilon > 0$ and all sufficiently large $\mathcal{R}$, the boundary decomposes as

$$\partial\Omega_{\mathcal{R},\epsilon} = \Gamma^{\infty}_{\mathcal{R},\epsilon} \cup \Gamma^{R,+}_{\mathcal{R},\epsilon} \cup \Gamma^{R,-}_{\mathcal{R},\epsilon} \cup \Gamma^{L,+}_{\mathcal{R},\epsilon} \cup \Gamma^{L,-}_{\mathcal{R},\epsilon} \cup E_{\mathcal{R},\epsilon}. \tag{29.66}$$

The large part $\Gamma^{\infty}_{\mathcal{R},\epsilon}$ lies in the annulus $\mathcal{R} - c_\epsilon \le |w| \le \mathcal{R} + c_\epsilon$ and obeys

$$\operatorname{length} \Gamma^{\infty}_{\mathcal{R},\epsilon} \le c_\epsilon \mathcal{R}. \tag{29.67}$$

The right lips are parameterized, up to endpoint smoothings contained in $E_{\mathcal{R},\epsilon}$, by

$$w = \sigma + \mathrm{i}\epsilon, \qquad w = \sigma - \mathrm{i}\epsilon, \qquad a + \epsilon \le \sigma \le \mathcal{R}, \tag{29.68}$$

with the induced orientation upper minus lower. The left lips are similarly parameterized by

$$w = \sigma + \mathrm{i}\epsilon, \qquad w = \sigma - \mathrm{i}\epsilon, \qquad -\mathcal{R} \le \sigma \le b - \epsilon, \tag{29.69}$$

again with upper-minus-lower orientation after writing the integral in the increasing real variable σ. The connector set $E_{\mathcal{R},\epsilon}$ consists of finitely many smooth arcs joining the lips to the large part and to small circles around the finite endpoints a and b. Its finite-endpoint components have length $O_\epsilon(1)$ and shrink to the endpoints as $\epsilon \downarrow 0$; its large-end components lie in the same annulus as $\Gamma^{\infty}_{\mathcal{R},\epsilon}$ and have total length $O_\epsilon(1)$. Finally, for every compact $K \Subset \Omega$, one has

$$K \subset \Omega_{\mathcal{R},\epsilon}$$

for all sufficiently large $\mathcal{R}$ and sufficiently small ϵ.

The definition is intentionally invariant under smoothing of the corners. If two admissible exhaustions have the same parameters, the difference of their boundaries is the boundary of a compact subset of Ω, together with connector arcs whose limits are either zero by the large-$\mathcal{R}$ estimate or are included in the endpoint boundary distributions. Therefore Cauchy's theorem gives the same limiting formula for every admissible choice.

Theorem 29.19 (Finite-subtraction Cauchy formula in a fixed-t cut plane)**.** *Let $b < a$ be real numbers and set*

$$C_R = [a, \infty), \qquad C_L = (-\infty, b], \qquad \Omega = \mathbb{C} \setminus (C_R \cup C_L).$$

Let F be meromorphic in Ω, with only finitely many simple poles $p_\nu \in \Omega$, and write its local pole part as

$$F(w) = \frac{A_\nu}{p_\nu - w} + \textit{holomorphic near } p_\nu. \tag{29.70}$$

Assume that F has polynomial boundary growth at the two cuts, so that the upper and lower boundary values on each cut exist as tempered distributions, and denote the discontinuities by

$$T_R = F(\sigma + \mathrm{i}0) - F(\sigma - \mathrm{i}0) \quad (\sigma \in C_R), \qquad T_L = F(\sigma + \mathrm{i}0) - F(\sigma - \mathrm{i}0) \quad (\sigma \in C_L).$$

Choose temperedness data N_R, N_L for the weight orders of T_R and T_L, in the sense of (29.54) after translating each cut coordinate to the real line. Suppose also that, for some $A \ge 0$, the large circular parts $\Gamma^{\infty}_{\mathcal{R},\epsilon}$ of an admissible two-cut exhaustion in the sense of Definition 29.18 obey

$$\sup_{w \in \Gamma^{\infty}_{\mathcal{R},\epsilon}} |F(w)| \le C_\epsilon \mathcal{R}^A \qquad (\mathcal{R} \to \infty) \tag{29.71}$$

for every fixed slit-opening regulator $\epsilon > 0$, with constants independent of $\mathcal{R}$. Choose distinct subtraction points $s_1, \ldots, s_q \in \Omega$, away from z and from the poles p_ν, with

$$q > \max\{A, N_R, N_L\}.$$

Define

$$B_q(w,z) = \prod_{j=1}^{q} \frac{z-s_j}{w-s_j}, \qquad L_j(z) = \prod_{k\neq j} \frac{z-s_k}{s_j-s_k}. \tag{29.72}$$

Then, for $z \in \Omega$ not equal to a pole,

$$\begin{aligned} F(z) = P_{q-1}(z) &+ \sum_{\nu} \frac{A_\nu}{p_\nu - z} B_q(p_\nu, z) \\ &+ \frac{1}{2\pi \mathrm{i}} \left\langle T_R(\sigma), \frac{B_q(\sigma,z)}{\sigma - z} \right\rangle_{C_R} + \frac{1}{2\pi \mathrm{i}} \left\langle T_L(\sigma), \frac{B_q(\sigma,z)}{\sigma - z} \right\rangle_{C_L}, \end{aligned} \tag{29.73}$$

where

$$P_{q-1}(z) = \sum_{j=1}^{q} F(s_j) L_j(z) \tag{29.74}$$

is the degree at most $q-1$ interpolation polynomial at the subtraction points. Endpoint singularities at a or b, if present as boundary distributions, are included in T_R or T_L. Thus no separate "threshold circle" term is present once the discontinuities are understood distributionally.

Proof. For fixed $z \in \Omega$, consider

$$\Phi(w;z) = \frac{F(w)}{w-z} B_q(w,z). \tag{29.75}$$

Write

$$K_z(w) = \frac{B_q(w,z)}{w-z}. \tag{29.76}$$

On a large circle $|w| = \mathcal{R}$, away from the slit regulators,

$$|\Phi(w;z)| \leq C_z \mathcal{R}^A \mathcal{R}^{-1} \mathcal{R}^{-q} = C_z \mathcal{R}^{A-q-1}.$$

By (29.67), the large circular part has length $O_\epsilon(\mathcal{R})$, hence its contribution is $O_\epsilon(\mathcal{R}^{A-q})$, which tends to zero because $q > A$. The large-end connector arcs in Definition 29.18 have $O_\epsilon(1)$ total length in the same annulus, so their contribution is $O_\epsilon(\mathcal{R}^{A-q-1})$ and also tends to zero.

The residues of Φ inside the cut-plane contour are the residue at $w = z$, the residues at the subtraction points s_j, and the residues at the poles p_ν of F. They are

$$\begin{aligned} \operatorname*{Res}_{w=z} \Phi(w;z) &= F(z), \\ \operatorname*{Res}_{w=s_j} \Phi(w;z) &= -F(s_j) L_j(z), \end{aligned} \tag{29.77}$$

and, using the pole convention (29.70),

$$\operatorname*{Res}_{w=p_\nu} \Phi(w;z) = -\frac{A_\nu}{p_\nu - z} B_q(p_\nu, z). \tag{29.78}$$

The admissible boundary has the standard upper-minus-lower orientation on each cut by (29.68) and (29.69). For fixed $(\mathcal{R}, \epsilon)$, before taking boundary values, the lip part is

$$\begin{aligned} I^{\mathrm{lip}}_{\mathcal{R},\epsilon}(z) = \frac{1}{2\pi \mathrm{i}} &\int_{a+\epsilon}^{\mathcal{R}} \mathrm{d}\sigma \, \left(F(\sigma + \mathrm{i}\epsilon) K_z(\sigma + \mathrm{i}\epsilon) - F(\sigma - \mathrm{i}\epsilon) K_z(\sigma - \mathrm{i}\epsilon)\right) \\ &+ \frac{1}{2\pi \mathrm{i}} \int_{-\mathcal{R}}^{b-\epsilon} \mathrm{d}\sigma \, \left(F(\sigma + \mathrm{i}\epsilon) K_z(\sigma + \mathrm{i}\epsilon) - F(\sigma - \mathrm{i}\epsilon) K_z(\sigma - \mathrm{i}\epsilon)\right) \end{aligned} \tag{29.79}$$

up to the connector arcs already described. After the limits $\mathcal{R} \to \infty$ and $\epsilon \downarrow 0$, this lip contribution becomes

$$\frac{1}{2\pi \mathrm{i}} \left[\int_{C_R} \mathrm{d}\sigma \, \frac{F(\sigma + \mathrm{i}0) - F(\sigma - \mathrm{i}0)}{\sigma - z} B_q(\sigma, z) + \int_{C_L} \mathrm{d}\sigma \, \frac{F(\sigma + \mathrm{i}0) - F(\sigma - \mathrm{i}0)}{\sigma - z} B_q(\sigma, z) \right]. \tag{29.80}$$

The finite-endpoint connector arcs are small circles around a and b. They are not discarded pointwise; their limits are part of the distributional boundary values at threshold. Thus any threshold-supported terms produced by endpoint singularities are represented inside T_R or T_L. The residue theorem applied before the limits says that the finite lip integral plus connector and large-contour terms equals the sum of the residues just displayed. Passing to the limits removes the large terms and absorbs the finite-endpoint limits into T_R, T_L. Solving for $F(z)$ gives (29.73).

It remains to pass from lip integrals to distributional boundary values and to justify the pairings. On C_R, for large σ,

$$\frac{B_q(\sigma, z)}{\sigma - z} = O(|\sigma|^{-q-1}),$$

and every σ-derivative has at least the same leading decay improved by one further power, up to constants depending on z and the subtraction points. The same estimate holds on C_L. Because q is larger than the tempered weight orders of T_R and T_L, the two kernels define Schwartz test functions on the cut coordinates after a smooth extension across the finite endpoints. Polynomial boundary growth is exactly the hypothesis that the lip values of F converge to the tempered boundary distributions $F(\sigma \pm \mathrm{i}0)$. Testing those convergent boundary values against the displayed kernels gives the distributional limit of (29.80); endpoint contributions, if any, are included in the same distributional limit. This limit is precisely the pairing displayed in (29.73). □

The domain theorem to be proved is therefore not the elementary estimate above, but the construction of its hypotheses from the Wightman data. Its logical pieces are: the primitive Wightman tube theorem from the spectrum condition; local commutativity at Jost configurations and the edge-of-the-wedge enlargement of the primitive tubes; the Jost–Lehmann–Dyson representation for the relevant retarded commutator matrix element; the Bros–Epstein–Glaser enlargement that gives the fixed-t Lehmann–Martin domain; and the verification that this off-shell domain satisfies the normal-crossing hypotheses of Theorem 29.17. Once those hypotheses hold, that theorem carries the domain and tempered-discontinuity bounds to the on-shell amplitude after stable-particle pole terms have been separated. The first two QFT-specific steps are proved in Theorems 28.2 and 28.3; the causal-commutator spectral coincidence regions are proved in Proposition 28.16; and the Jost–Lehmann–Dyson input is proved for Dyson-regular commutator distributions in Theorem 28.15 and Remark 28.17. The microlocal meaning and obstruction of the Dyson light-cone lift are isolated in Proposition 28.12: away from the light-cone vertex the ordinary product construction is valid under an explicit wavefront transversality condition, and any extension ambiguity is a finite contact polynomial after Fourier transform. The local finite-scaling-degree extension mechanism is proved in Theorem 28.13; it states the additional cone-equation, pushforward-normalization, temperedness, and Cauchy-data conditions that must hold before the source-current commutator is Dyson-regular modulo contact terms. Proposition 28.14 proves that the LSZ source-current differentials themselves preserve causal support, the punctured conormal wavefront avoidance, and finite scaling degree, with the correct relative-coordinate factors. The remaining steps are the Dyson-regularity verification for the actual LSZ source-current matrix coefficients and the Bros–Epstein–Glaser fixed-t enlargement with the uniform normal-coordinate control required for Theorem 29.17, together with the large-contour polynomial estimate needed in Theorem 29.19. These are needed before the Jin–Martin polynomial bound and the corresponding finite-subtraction dispersion formula can be promoted from conditional inputs to derived scattering theorems. Complex-analysis results such as the edge-of-the-wedge theorem are tools in this construction; they do not replace the field-theoretic support, locality, and LSZ arguments.

Example 29.20 (Tempered distribution with an unbounded representative)**.** There is a smooth nonnegative function $f \in L^1(\mathbb{R})$, hence a tempered distribution by

$$\langle T_f, \varphi \rangle = \int_{\mathbb{R}} f(s)\varphi(s)\,\mathrm{d}s,$$

such that $f(n) \geq e^{n^2}$ for all positive integers n. Consequently, no pointwise polynomial bound for a chosen boundary-value representative can be inferred from temperedness alone.

Choose $\psi \in C_c^\infty((-1/4, 1/4))$ with $\psi \geq 0$ and $\psi(0) = 1$. Define

$$f(s) = \sum_{n=1}^{\infty} e^{n^2} \psi\Big(e^{3n^2}(s-n)\Big).$$

The supports are contained in intervals

$$\left(n - \frac{1}{4}e^{-3n^2},\, n + \frac{1}{4}e^{-3n^2}\right),$$

which are pairwise disjoint. On every compact subset of $\mathbb{R}$, only finitely many summands are present, so f is smooth. Moreover

$$\int_{\mathbb{R}} f(s)\,\mathrm{d}s = \sum_{n=1}^{\infty} e^{n^2} e^{-3n^2} \int_{\mathbb{R}} \psi(u)\,\mathrm{d}u = \left(\int_{\mathbb{R}} \psi(u)\,\mathrm{d}u\right) \sum_{n=1}^{\infty} e^{-2n^2} < \infty.$$

Thus $f \in L^1(\mathbb{R})$, and

$$|\langle T_f, \varphi \rangle| \leq \|f\|_{L^1} \sup_s |\varphi(s)| \leq \|f\|_{L^1} p_{0,0}(\varphi),$$

so $T_f \in \mathcal{S}'(\mathbb{R})$. At the center of the n-th spike,

$$f(n) \geq e^{n^2}\psi(0) = e^{n^2}.$$

This exceeds $C(1+n)^N$ for every fixed C, N. Hence distributional temperedness is compatible with super-polynomial pointwise values of a smooth representative.

Remark 29.14 is the polynomial boundedness that follows immediately from temperedness. It says that smooth high-energy packet matrix elements with fixed energy resolution cannot grow faster than a power of the central energy. It does not by itself give a pointwise bound for a chosen boundary-value representative, nor does it control the large semicircle in a complex s-plane Cauchy deformation. The obstruction is substantive: Example 29.20 shows that the distributional statement is logically too weak even for smooth functions. Those stronger statements use additional analyticity and boundary-regularity input. The Jin–Martin fixed-t theorem is precisely such an additional theorem-level upgrade in the massive Wightman setting: it turns the locality, spectral, edge-of-the-wedge, Lehmann-domain, and LSZ hypotheses into a pointwise cut-plane polynomial estimate at fixed $t < 0$. The angular-tube estimate at positive $t < t_0$, used in the Froissart comparison above, is a still different boundedness statement and must be supplied separately when it is used.

The polynomial boundedness assumption has a causal interpretation. A one-dimensional model isolates the relevant analytic structure. Let

$$f_{\mathrm{out}}(t) = \int \mathrm{d}t'\, K(t-t') f_{\mathrm{in}}(t'), \qquad \widetilde{K}(\omega) = \int \mathrm{d}t\, \mathrm{e}^{\mathrm{i}\omega t} K(t).$$

If the kernel has retarded support,

$$K(t) = 0 \qquad (t < 0),$$

then $\widetilde{K}(\omega)$ is analytic for $\mathrm{Im}\,\omega > 0$. Moreover a growth like $\exp(c\,\mathrm{Im}\,\omega)$ in the upper half plane would correspond to support at negative time. For relativistic scattering the hypothesis is formulated directly for the invariant amplitude: locality and causal propagation are reflected in analyticity and in the absence of exponential growth in complex energy directions.

Remark 29.21 (Jin–Martin fixed-t theorem)*.* There is a theorem-level fixed-t result in the Wightman framework. The Lehmann ellipse analysis, its Bros–Epstein–Glaser extension, and the Jin–Martin theorem imply the following kind of statement for massive two-particle scattering: for each fixed real $t < 0$ in the fixed-t analyticity domain, there are constants $C_t > 0$, $R_t > 0$, and an integer N_t such that the first-sheet amplitude in the cut s-plane obeys

$$|\mathcal{M}(s,t)| \le C_t(1+|s|)^{N_t}, \qquad |s| > R_t,$$

on the contours used for the fixed-t dispersion relation. This is the derivable polynomial boundedness input: it gives a finite number of subtractions at fixed negative t. It is narrower than the additional boundedness used in the Froissart–Martin mechanism at nonphysical positive t inside the Lehmann–Martin ellipse, and narrower than a simultaneous Mandelstam-domain polynomial bound. Those stronger bounds are stated as hypotheses whenever they are used below.

For the invariant amplitude, fix real $t < 0$ and continue s to the complex plane. Theorem 29.19 is the precise one-variable Cauchy statement behind the following physics notation. The displayed dispersion formula records the cut terms in a kinematic situation where bound-state pole terms and anomalous first-sheet terms are absent; when such terms are present, their residues are added explicitly. More concretely, if the first sheet contains simple stable-particle poles with local behavior

$$\mathcal{M}(s,t) \sim \frac{R_B^{(s)}(t)}{M_B^2 - s} \qquad \text{or} \qquad \mathcal{M}(s,t) \sim \frac{R_B^{(u)}(t)}{4m^2 - t - M_B^2 - s},$$

where $R_B^{(u)}(t)$ is defined with respect to the s-plane local coordinate $4m^2 - t - M_B^2 - s$. Equivalently, it includes the sign relating this coordinate to $M_B^2 - u$. Then the subtracted dispersion relation contains the corresponding Cauchy residue terms

$$\frac{R_B^{(s)}(t)}{M_B^2 - s} \prod_{j=1}^{N} \frac{s - s_j}{M_B^2 - s_j}, \qquad \frac{R_B^{(u)}(t)}{4m^2 - t - M_B^2 - s} \prod_{j=1}^{N} \frac{s - s_j}{4m^2 - t - M_B^2 - s_j}.$$

For a composite stable state the functions $R_B^{(s)}(t)$ and $R_B^{(u)}(t)$ are the crossed forms of the four-point pole residue described in Theorem 27.2; the homogeneous Bethe–Salpeter equation fixes the corresponding pole location when the two-constituent description is valid. Assume that for some integer N,

$$\lim_{|s|\to\infty}\left|\frac{\mathcal{M}(s,t)}{s^N}\right|=0$$

in the domain used to deform the contour. Choose subtraction points

$$s_1,\ldots,s_N$$

away from the cuts and from the evaluation point s. Then

$$\frac{\mathcal{M}(s',t)}{\prod_{j=1}^{N}(s'-s_j)}$$

has sufficient decay for the large circle to be removed in Cauchy's theorem. Equivalently,

$$\mathcal{M}(s,t)=\oint_\gamma\frac{\mathrm{d}s'}{2\pi\mathrm{i}}\,\frac{\mathcal{M}(s',t)}{s'-s}\prod_{j=1}^{N}\frac{s-s_j}{s'-s_j},$$

where γ encloses s and the subtraction points before deformation.

Figure 29.6 shows the contour deformation used in the subtracted fixed-t dispersion formula.

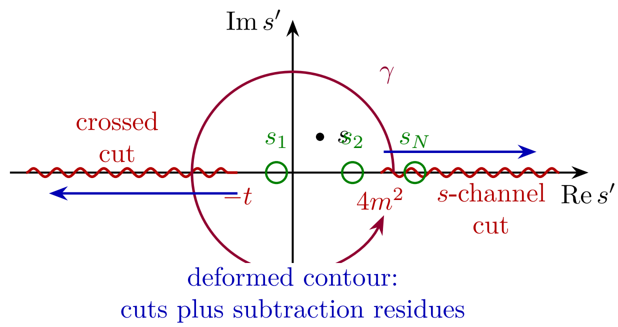

Figure 29.6: Subtracted fixed-t Cauchy contour. The original contour γ encloses the evaluation point and subtraction points; after deformation it is replaced by integrals along the right- and left-hand cuts, with the subtraction factors suppressing the large-circle contribution.

Let

$$\operatorname{disc}\mathcal{M}(s,t)=\mathcal{M}(s+\mathrm{i}0,t)-\mathcal{M}(s-\mathrm{i}0,t).$$

After deforming γ onto the right and left cuts, one obtains

$$\mathcal{M}(s,t)=P_{N-1}(s;t)+\frac{1}{2\pi\mathrm{i}}\int_{C_s\cup C_u}\mathrm{d}s'\,\operatorname{disc}\mathcal{M}(s',t)\,\frac{1}{s'-s}\prod_{j=1}^{N}\frac{s-s_j}{s'-s_j}.$$

Here $C_s=[4m^2,\infty)$ is the right cut, $C_u=(-\infty,-t]$ is the crossed cut in the s'-plane, and $P_{N-1}(s;t)$ is the polynomial of degree at most $N-1$ produced by the small circles around the subtraction points. On a real cut where real analyticity holds,

$$\operatorname{disc}\mathcal{M}(s,t)=2\mathrm{i}\,\operatorname{Im}\mathcal{M}(s+\mathrm{i}0,t).$$

The formula is an N-subtracted fixed-t dispersion relation.

Equivalently, parametrize the left cut by the positive crossed-channel variable

$$u' = 4m^2 - s' - t, \qquad u = 4m^2 - s - t, \qquad u_j = 4m^2 - s_j - t.$$

For an amplitude whose crossing convention identifies the left-cut discontinuity with the absorptive part in the u-channel, the same dispersion relation may be written as

$$\mathcal{M}(s,t) = P_{N-1}(s;t) + \int_{4m^2}^{\infty} \frac{\mathrm{d}s'}{\pi} \frac{\operatorname{Im}\mathcal{M}(s'+\mathrm{i}0,t)}{s'-s} \prod_{j=1}^{N} \frac{s-s_j}{s'-s_j}$$
$$+ \int_{4m^2}^{\infty} \frac{\mathrm{d}u'}{\pi} \frac{\operatorname{Im}\mathcal{M}_u(u'+\mathrm{i}0,t)}{u'-u} \prod_{j=1}^{N} \frac{u-u_j}{u'-u_j}.$$

Here $\mathcal{M}_u$ denotes the amplitude in the crossed channel, with external labels crossed as appropriate. For identical scalar scattering $\mathcal{M}_u$ is the same analytic function with s replaced by u; for general external species this displayed formula must be read with the corresponding crossed process.

29.8 Two Subtractions

The previous derivation used a complex-plane polynomial bound. A useful refinement is that a real-axis bound on the absorptive part controls the number of subtractions. The form needed here is the following conditional statement. Fix $t < 0$, assume a fixed-t dispersion representation with some finite number of subtractions exists, and suppose

$$|\operatorname{Im}\mathcal{M}(s,t)| \le C s^{N-\epsilon} \qquad (s \to +\infty)$$

for some $\epsilon > 0$, uniformly for t in a small real interval, with the same power bound also available at the forward endpoint $t = 0$. If a larger subtraction number $N' \ge N+1$ were genuinely required, the subtraction polynomial would contain a nonzero term

$$C_{N'-1}(t) s^{N'-1}.$$

If the coefficient $C_{N'-1}(t)$ is not identically zero, analyticity in t gives an interval of real $t < 0$ on which its magnitude is bounded below. On the physical interval for elastic scattering,

$$-(s - 4m^2) \le t \le 0,$$

write

$$k^2 = \frac{s - 4m^2}{4}, \qquad t = 2k^2(x-1).$$

Unitarity gives a positive estimate for the forward absorptive part:

$$\operatorname{Im}\mathcal{M}(s,0) = \sqrt{s(s-4m^2)}\,\sigma_{\mathrm{tot}}(s) \ge \sqrt{s(s-4m^2)}\,\sigma_{\mathrm{el}}(s).$$

The elastic term is then evaluated in the same partial-wave normalization:

$$\begin{aligned}\sqrt{s(s-4m^2)}\,\sigma_{\rm el}(s) &= 8\pi\sqrt{\frac{s}{s-4m^2}}\sum_{\substack{\ell=0\\ \ell\ \text{even}}}^{\infty}(2\ell+1)|S_\ell(s)-1|^2\\ &= \frac{1}{64\pi}\sqrt{\frac{s-4m^2}{s}}\int_{-1}^{1}\mathrm{d}x\,|\mathcal{M}(s,2k^2(x-1))|^2\\ &= \frac{1}{32\pi\sqrt{s(s-4m^2)}}\int_{-(s-4m^2)}^{0}\mathrm{d}t\,|\mathcal{M}(s,t)|^2.\end{aligned}$$

Consequently,

$$\operatorname{Im}\mathcal{M}(s,0)\geq\frac{1}{32\pi\sqrt{s(s-4m^2)}}\int_{-(s-4m^2)}^{0}\mathrm{d}t\,|\mathcal{M}(s,t)|^2.$$

The last equality in the elastic chain is the change of variables from x to t. If the nonzero polynomial coefficient $C_{N'-1}(t)$ is bounded below on a fixed real t-interval inside $(-\infty,0)$, this estimate gives, along a high-energy sequence,

$$\operatorname{Im}\mathcal{M}(s,0)\geq c\,s^{2N'-3}$$

for some $c>0$. This fixed-t version is the only estimate needed here: since $N'\geq N+1$, it contradicts the assumed bound $|\operatorname{Im}\mathcal{M}(s,0)|\leq Cs^{N-\epsilon}$ at the forward point. A stronger estimate is obtained if the leading behavior persists on a subinterval of scattering angles of nonzero length, because the corresponding t-interval has length of order s; the fixed-t estimate avoids assuming such uniformity. Therefore the real-axis absorptive bound fixes the subtraction number, apart from polynomial terms whose leading coefficients vanish identically and hence were not genuine subtractions.

The preceding Froissart mechanism, applied with any finite initial polynomial bound, gives at forward scattering

$$\operatorname{Im}\mathcal{M}(s,0)\leq C\,s(\log s)^2.$$

For fixed real $t<0$ and sufficiently large s, the corresponding angular variable satisfies $-1<x<1$. In this range $|P_\ell(x)|\leq 1$, while $P_\ell(1)=1$. Using the positive weights w_ℓ,

$$|\operatorname{Im}\mathcal{M}(s,t)|\leq\operatorname{Im}\mathcal{M}(s,0)$$

for the absorptive partial-wave sum. Thus, for every $0<\epsilon<1$,

$$|\operatorname{Im}\mathcal{M}(s,t)|\leq C_\epsilon s^{2-\epsilon}\qquad(s\to+\infty)$$

at fixed real $t<0$. Applying the preceding conditional subtraction-count argument with $N=2$ rules out genuine subtraction terms of degree two or higher. Under the finite-subtraction hypothesis stated at the beginning of this section, two subtractions are therefore sufficient in the massive scalar setting, and the twice-subtracted representation has $\mathcal{M}(s,t)/s^2\to 0$ at fixed real $t<0$ in the dispersion domain.

This conclusion is conditional in exactly the sense stated: the argument starts from the existence of a fixed-t dispersion representation with some finite subtraction number. It is not a proof, by itself, that the axioms of massive local QFT imply a two-subtracted representation without first knowing that a finite-subtracted representation exists.

Remark 29.22 (Two-subtraction theorem). There is a stronger theorem-level input in the axiomatic analyticity-unitarity program: for massive two-particle scattering satisfying the Wightman hypotheses and the usual mass-gap assumptions used in the Lehmann–Martin analysis, fixed-t dispersion theory can be brought to the two-subtraction form without assuming a finite number of subtractions as an independent premise.[1] The conditional proof above supplies a useful internal mechanism: once a finite subtraction number is available, positivity and the Froissart absorptive bound remove all genuine higher subtraction coefficients. The cited theorem supplies the additional axiomatic step. In later uses, these two inputs must not be conflated.

The extension from real $t < 0$ to complex t inside the disk set by the nearest t-plane singularity uses positivity of the Taylor coefficients of the absorptive part at $t = 0$:

$$\frac{\partial^n}{\partial t^n} \operatorname{Im} \mathcal{M}(s,t)\bigg|_{t=0} \geq 0.$$

This positivity follows from the same partial-wave expansion: derivatives of $P_\ell(1 + 2t/(s - 4m^2))$ at $t = 0$ are nonnegative, since

$$\frac{\mathrm{d}^n}{\mathrm{d}x^n} P_\ell(x)\bigg|_{x=1} = \frac{(\ell+n)!}{2^n n!(\ell-n)!} \geq 0$$

for $n \leq \ell$, and the derivative is zero for $n > \ell$. This positivity allows the Taylor expansion in t to commute with the dispersive integral inside its convergence disk.

Hypothesis 29.23 (Higher-dimensional angular tube)**.** Let $D \geq 4$ be the spacetime dimension and set

$$\lambda = \frac{D-3}{2}.$$

For scalar $2 \to 2$ scattering in the center-of-mass frame, the angular variable is a point on S^{D-2}. For an $SO(D-1)$-invariant scalar amplitude this dependence is through $x = \cos\theta$, and the partial-wave basis is the Gegenbauer basis $C_\ell^\lambda(x)$. The degeneracy of degree-ℓ spherical harmonics on S^{D-2} is

$$g_\ell^{(D)} = \frac{(2\ell + D - 3)(\ell + D - 4)!}{\ell!(D-3)!} = O(\ell^{D-3}).$$

Assume that the D-dimensional analogue of the Lehmann ellipse is available in the following form. For every $0 < t_* < t_0$ and all sufficiently large s, the amplitude has an $SO(D-1)$-invariant holomorphic continuation to a complex angular tube containing the point

$$x_*(s) = 1 + \frac{2t_*}{s - 4m^2} = \cosh \eta_*(s), \qquad \eta_*(s) = 2\sqrt{\frac{t_*}{s}} + O(s^{-3/2}),$$

and its Gegenbauer coefficients obey the Cauchy-type large-ℓ estimate

$$|a_\ell(s)| \leq A\, s^N\, \ell^q\, \mathrm{e}^{-\ell\eta_*(s)}$$

for constants A, N, q depending on the chosen tube margin but not on ℓ or large s. This hypothesis is the higher-dimensional replacement for the $D = 4$ Lehmann ellipse and Legendre-coefficient estimate; it is an additional angular-domain input beyond the displayed four-dimensional ellipse.

[1] See L. Łukaszuk and A. Martin, "Absolute upper bounds for $\pi\pi$ scattering," *Nuovo Cimento A* **52** (1967) 122–145, doi:10.1007/BF02739279; and F. J. Ynduráin, "Rigorous constraints, bounds, and relations for scattering amplitudes," *Rev. Mod. Phys.* **44** (1972) 645–667, doi:10.1103/RevModPhys.44.645.

Proposition 29.24 (Conditional angular counting in D spacetime dimensions)**.** *Assume Hypothesis 29.23, partial-wave unitarity, a two-subtraction input giving the required polynomial bound at fixed nonphysical* $0 < t_* < t_0$*, and the usual massive scalar kinematics. Then*

$$\sigma_{\text{tot}}(s) \le C_D(\log s)^{D-2}$$

for sufficiently large s*, with* C_D *depending on the normalization,* t_0*, and the angular-tube constants.*

Proof. With the normalization convention absorbed into $\mathcal{N}_D(s)$, the D-dimensional scalar partial-wave expansion has the form

$$\mathcal{M}_D(s,x) = \mathcal{N}_D(s)\sum_{\ell=0}^{\infty} g_\ell^{(D)} a_\ell(s)\frac{C_\ell^\lambda(x)}{C_\ell^\lambda(1)},$$

with only even ℓ in the identical-boson channel. Omitting the odd partial waves changes constants but not powers. Unitarity bounds the physical weights $w_\ell(s) = 1 - \operatorname{Re} S_\ell(s)$ by a constant independent of s and ℓ. The total cross section has the high-energy form

$$\sigma_{\text{tot}}(s) \le C'_D\, s^{-(D-2)/2}\sum_{\ell\ge 0} g_\ell^{(D)} w_\ell(s),$$

where C'_D records the normalization convention and the $(1+O(m^2/s))$ phase-space factor.

The angular-tube estimate gives exponential suppression of partial-wave coefficients up to powers of ℓ. More explicitly, after changing the constants to match the optical-theorem normalization, the physical absorptive weights obey a bound of the form

$$w_\ell(s) \le B\min\{1,\, s^N(1+\ell)^q \mathrm{e}^{-\ell\eta_*(s)}\}, \tag{29.81}$$

where the first entry is unitarity and the second entry is the Cauchy estimate in Hypothesis 29.23. Put

$$\eta = \eta_*(s), \qquad L(s) = \alpha\,\eta^{-1}\log s,$$

with α larger than $N + (D-2+q)/2$. Since $\eta_*(s) = 2\sqrt{t_*/s} + O(s^{-3/2})$, this is the same scale as $C\sqrt{s}\log s$. The contribution below L is controlled only by unitarity:

$$\sum_{\ell\le L(s)} g_\ell^{(D)} w_\ell(s) \le C\sum_{\ell\le L(s)}(1+\ell)^{D-3} = O(L(s)^{D-2}).$$

For the tail, set $r = D-3+q$. The same two estimates give

$$\sum_{\ell>L(s)} g_\ell^{(D)} w_\ell(s) \le C\, s^N \sum_{\ell>L(s)}(1+\ell)^r \mathrm{e}^{-\ell\eta}.$$

For large s, $L(s)\eta = \alpha\log s$ and $\eta \to 0$. Splitting the sum into unit intervals, or equivalently using a geometric comparison after observing that $(1+\ell+1)^r\mathrm{e}^{-(\ell+1)\eta}/((1+\ell)^r\mathrm{e}^{-\ell\eta}) \le \mathrm{e}^{-\eta/2}$ for $\ell \ge L(s)$, gives

$$\sum_{\ell>L(s)}(1+\ell)^r\mathrm{e}^{-\ell\eta} \le C_r\,(1+L(s))^r\,\mathrm{e}^{-L(s)\eta}\,(1-\mathrm{e}^{-\eta})^{-1}.$$

Thus

$$\sum_{\ell>L(s)} g_\ell^{(D)} w_\ell(s) \le C\, s^{N-\alpha}\,\eta^{-(r+1)}(\log s)^r = O\Big(s^{N-\alpha+(D-2+q)/2}(\log s)^{D-3+q}\Big).$$

The choice of α makes this tail $O(1)$, hence subordinate to the leading angular count. Combining the low-angular-momentum estimate with the tail estimate gives

$$\sum_{\ell \geq 0} g_\ell^{(D)} w_\ell(s) = O(L(s)^{D-2}),$$

because $g_\ell^{(D)} = O(\ell^{D-3})$. Substituting this into the preceding cross-section estimate gives

$$\sigma_{\text{tot}}(s) \leq C''_D s^{-(D-2)/2} \big(\sqrt{s} \log s\big)^{D-2} = C_D (\log s)^{D-2}.$$

□

Theorem 29.25 (Froissart–Martin high-energy bound)**.** *Consider massive $2 \to 2$ scalar scattering with mass gap and no massless exchange. Assume:*

1. *partial-wave unitarity in the physical s-channel;*
2. *analyticity in the Lehmann–Martin ellipse with nearest t-channel singularity at $t = t_0 > 0$;*
3. *crossing symmetry and a fixed-t dispersion representation;*
4. *a two-subtraction input, obtained either from the conditional finite-subtraction hypothesis together with the real-axis absorptive bound used above, or from the Łukaszuk–Martin/Ynduŕáin theorem as an additional axiomatic input;*
5. *the angular-tube polynomial bound of Definition 29.13 at $0 < t < t_0$, with the exponent $N = 2$ supplied by the two-subtraction input.*

Then, in four spacetime dimensions, for every fixed $0 < \delta < 1$ there are constants M_0 and s_0 such that

$$\sigma_{\text{tot}}(s) \leq \frac{1}{(1-\delta)^2} \frac{4\pi}{t_0} \left(\log \frac{s}{M_0^2} \right)^2, \qquad s \geq s_0. \tag{29.82}$$

In D spacetime dimensions, after replacing the $D = 4$ Lehmann-ellipse input by Hypothesis 29.23, the corresponding conditional estimate is

$$\sigma_{\text{tot}}(s) \leq C\,(\log s)^{D-2}. \tag{29.83}$$

Proof. Fix $0 < t_* < t_0$. To prove the theorem with the displayed margin δ, choose an auxiliary margin δ_0 with

$$0 < \delta_0 < \delta.$$

The Legendre lower bound below will use δ_0, leaving the remaining margin $\delta - \delta_0$ to absorb constants and lower-order logarithmic terms without changing the stated coefficient. By the Lehmann–Martin angular-domain hypothesis, the point

$$x_*(s) = 1 + \frac{2t_*}{s - 4m^2}$$

lies inside the allowed angular domain for all sufficiently large s. The angular-tube polynomial bound with exponent N gives

$$|\mathcal{M}(s, x_*(s))| \leq C_N s^N. \tag{29.84}$$

The absorptive part at this point is nonnegative in the partial-wave representation used above, so $\operatorname{Im}\mathcal{M}(s, x_*(s)) \le |\mathcal{M}(s, x_*(s))|$.

Let

$$W(s) := \sum_{\ell \text{ even}} (2\ell+1) w_\ell(s).$$

The optical-theorem normalization derived in Section 29.3 gives

$$W(s) = \frac{s-4m^2}{16\pi}\,\sigma_{\text{tot}}(s).$$

The box-profile minimization in the Froissart comparison chooses

$$L = W(s)^{1/2} + O(1) = \left(\frac{s-4m^2}{16\pi}\sigma_{\text{tot}}(s)\right)^{1/2} + O(1). \tag{29.85}$$

For $x_*(s) = \cosh\eta_*(s)$, the Legendre lower bound with margin δ_0 gives the base $y = 1 + (1-\delta_0)\sinh\eta_*(s)$. The same expansion as in (29.47), with δ replaced by δ_0, gives

$$y - 1 = 2(1-\delta_0)\sqrt{\frac{t_*}{s}} + O(s^{-1}). \tag{29.86}$$

Combining this with (29.85) yields

$$L(y-1) = (1-\delta_0)\sqrt{\frac{t_*\,\sigma_{\text{tot}}(s)}{4\pi}} + o(1). \tag{29.87}$$

The factor 4π in this expression is the coefficient produced by the partial-wave normalization $W = (s-4m^2)\sigma_{\text{tot}}/(16\pi)$ together with the angular-distance estimate $\sinh\eta_*(s) \sim 2\sqrt{t_*/s}$.

If $L(y-1) < 1$ along a high-energy subsequence, then (29.87) already gives

$$\sigma_{\text{tot}}(s) \le \frac{4\pi}{(1-\delta_0)^2 t_*} + o(1),$$

which is stronger than the logarithmic-square estimate for large s. We therefore consider the case $L(y-1) \ge 1$, where (29.46) applies. Using (29.86), the algebraic prefactor in (29.46) is bounded below by a fixed positive constant times $s\,\sigma_{\text{tot}}(s)^{1/2}$. Hence (29.84) can hold only if, for every $\varepsilon > 0$ and all sufficiently large s,

$$(1-\delta_0)\sqrt{\frac{t_*\,\sigma_{\text{tot}}(s)}{4\pi}} \le (N-1+\varepsilon)\log\frac{s}{M_0^2}. \tag{29.88}$$

Indeed, if the left side exceeded the right side along a high-energy subsequence, the exponential y^L in (29.46) would grow faster than $(s/M_0^2)^{N-1+\varepsilon}$; multiplying by the prefactor of order $s\,\sigma_{\text{tot}}^{1/2}$ would contradict (29.84).

Solving (29.88) for σ_{tot} gives

$$\sigma_{\text{tot}}(s) \le \frac{(N-1+\varepsilon)^2}{(1-\delta_0)^2}\frac{4\pi}{t_*}\left(\log\frac{s}{M_0^2}\right)^2.$$

Since $\delta_0 < \delta$, choose $\varepsilon > 0$ small enough that

$$\frac{N-1+\varepsilon}{1-\delta_0} \leq \frac{N-1}{1-\delta}.$$

This proves the same estimate with the displayed $(N-1)^2(1-\delta)^{-2}$ coefficient after increasing s_0. The two-subtraction input in the theorem supplies $N = 2$. Finally take $t_* \to t_0^-$, after the estimate has been established at fixed $t_* < t_0$, to obtain (29.82). The factor $(1-\delta)^{-2}$ is therefore the square of the final reserved margin in the Legendre lower bound, and $4\pi/t_0$ is the coefficient obtained from the optical-theorem normalization and the nearest crossed-channel angular distance.

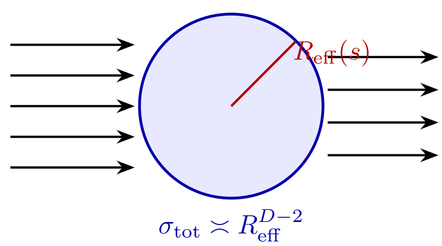
The displayed D-dimensional estimate is the separate conditional Gegenbauer/angular-counting result of Proposition 29.24. □

Equation (29.83) may be restated through an effective transverse radius whenever the higher-dimensional angular-tube hypothesis has been assumed. If one defines $R_{\text{eff}}(s)$ by the geometric scaling relation

$$\sigma_{\text{tot}}(s) \asymp R_{\text{eff}}(s)^{D-2},$$

then the massive high-energy bound implies $R_{\text{eff}}(s) = O(\log s)$. This is only a translation of the cross-section estimate, not an additional dynamical assumption.

$R_{\text{eff}}(s) = O(\log s)$ under the stated massive hypotheses



29.9 Scope of the Bound

The bound is a theorem about amplitudes satisfying the stated massive analyticity, unitarity, crossing, and boundedness hypotheses. The mass gap is part of the statement. When massless particles are present, the total cross section may diverge because arbitrarily small scattering angles or collinear emissions are experimentally unresolved. The corresponding observable is then an inclusive or angularly cut cross section, while the quantity bounded above is the total cross section of the massive problem.

For a confining gauge theory, the external particles in such a statement are gauge-invariant one-particle states in the physical Hilbert space: glueballs in pure Yang–Mills theory, and mesons or baryons in theories with matter fields when the relevant stable isolated masses exist. The scalar particle used in the preceding derivation is therefore a stand-in for a chosen stable hadron or glueball created by a local gauge-invariant operator and normalized by the Haag–Ruelle–LSZ construction. The analyticity and unitarity statements then refer to the hadronic amplitude between these physical states. In four-dimensional pure Yang–Mills theory, the existence of a positive mass gap and of the corresponding massive local quantum field theory is a separate open construction problem; the present high-energy bound uses that gap as an input. For QCD-like theories with massless pions or massless partons, the massive hypotheses must be replaced by the appropriate inclusive or gapped-channel statement before a Froissart-type conclusion is asserted.

Gravity also lies outside the same massive-QFT hypothesis. In D spacetime dimensions, a black hole of energy E has Schwarzschild radius

$$r_H \sim (G_N E)^{1/(D-3)},$$

so the effective interaction size grows as a power of energy. This is a different high-energy problem governed by long-range gravitational dynamics rather than the massive Froissart–Martin hypotheses.

Part III

Renormalization, Effective Field Theory, and Critical Phenomena

Chapter 30

Generating Functionals and the One-Particle-Irreducible Effective Action

Conventions in this chapter.

- **Signature.** Lorentzian formulas use $\mathbb{M}^D$; Euclidean formulas use $\mathbb{R}^D$.
- **Metric sign.** Lorentzian $\eta_{\mu\nu} = \mathrm{diag}(-, +, \ldots, +)$; Euclidean $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ for Hilbert-space vacuum matrix elements; functional averages are named separately.
- **Generator convention.** Lorentzian translations use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

Notation for Z-Factors in This Part

Several unrelated objects traditionally use the letter Z. The renormalization part keeps them distinct as follows.

symbol	meaning
$Z[J]$	source or partition functional. Its logarithm generates connected correlators after a regulator and a branch or formal logarithm have been specified. This Z is not a field-strength factor.
Z_ϕ^{pole}	one-particle Källén–Lehmann/LSZ residue of a chosen interpolating field: $\mathrm{d}\rho_\phi(s) = Z_\phi^{\mathrm{pole}}\delta_{m^2}(\mathrm{d}s) + \cdots$. Earlier scattering chapters often write this residue simply as Z_ϕ, or as Z when only one scalar field is present. Once the field normalization is fixed, it is a physical pole coefficient for that interpolating field and has no renormalization-scale argument.
$Z_{\mathrm{MOM}}(\mu)$	finite momentum-subtraction field rescaling at Euclidean subtraction scale μ, for example $[\phi]_\mu = Z_{\mathrm{MOM}}(\mu)^{-1/2}\phi_R^{\mathrm{ref}}$. It is a coordinate choice in the renormalized 1PI chart, not the Källén–Lehmann pole residue. Only after analytic continuation to an isolated physical pole and the imposition of an on-shell residue condition can a finite field factor be identified with the pole-residue normalization.
$Z_\phi^{\mathrm{chart}}(\lambda(\mu), \mu, \Lambda)$	total cutoff-dependent bare-to-renormalized field factor in a chosen renormalization chart. In the Callan–Symanzik equation this factor carries the anomalous dimension through $\gamma_\phi = \frac{1}{2}\,\mathrm{d}\log Z_\phi^{\mathrm{chart}}/\mathrm{d}\log\mu$ at fixed bare data.
$Z_\phi^{\mathrm{MS}}(\lambda_{\mathrm{MS}}, \epsilon)$	minimal-subtraction field renormalization constant. It contains pole counterterms in ϵ and no finite residue normalization; it is not the LSZ residue.
$\mathcal{Z}^I{}_{A_1\cdots A_r}$	operator/source mixing distribution for composite insertions. This is a local contact-term renormalization matrix and is unrelated to either the source functional $Z[J]$ or a one-particle pole residue.

When a later formula suppresses a superscript, the surrounding chart specifies which row of this table is meant. In particular, the notation Z_ϕ in LSZ statements means Z_ϕ^{pole}, while Z_ϕ inside a Callan–Symanzik derivation means the chart field factor Z_ϕ^{chart}.

30.1 Sources and Connected Functionals

Definition 30.1 (Regulated scalar source functional)**.** Fix a quantum field theory with a specified ultraviolet regulator and a specified prescription for Lorentzian correlation functions. Let ϕ denote a real scalar field in this section; the definitions extend to several bosonic fields by adding indices, and to fermionic fields by replacing ordinary sources with Grassmann sources. Since a quantum field is a distribution, a c-number source is a real test function, for instance a smooth compactly supported function or a Schwartz function,

$$J\colon \mathbb{R}^{1,D-1} \longrightarrow \mathbb{R}$$

coupled linearly to ϕ through the pairing

$$\langle J, \phi \rangle = \int \mathrm{d}^D x \, J(x) \phi(x).$$

At finite regulator this pairing is replaced by the corresponding finite sum, finite-mode pairing, or regulated distributional pairing. The regulated source functional is

$$Z[J] = \int D_\Lambda^{\mathrm{ref}} \phi \, \exp\{\mathrm{i} S_\Lambda[\phi] + \mathrm{i} \langle J, \phi \rangle\} \, .$$

The sign in the Lorentzian source exponent must not be compared directly with a Euclidean positive-measure convention until the source coordinate has been continued. With the lower-half-plane convention of Chapter 16, $x^0 = -\mathrm{i}\tau$ and $\mathrm{d}x^0 = -\mathrm{i}\mathrm{d}\tau$, the formal chain for scalar insertions is

$$\mathrm{i} S_L[\phi] + \mathrm{i} \langle J_L, \phi \rangle_L \longmapsto -S_E[\phi_E] + \langle J_L^{\mathrm{W}}, \phi_E \rangle_E, \qquad J_L^{\mathrm{W}}(\tau, \vec{x}) := J_L(-\mathrm{i}\tau, \vec{x}).$$

Thus a Euclidean source functional written with a plus source term uses $J_E^+ = J_L^{\mathrm{W}}$, while the positive-measure/free-energy convention used later in this chapter,

$$Z_E[J_E] = \int [D\phi] \, \exp\{-S_E[\phi] - \langle J_E, \phi \rangle_E\},$$

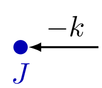
uses $J_E = -J_L^{\mathrm{W}}$. This is a change of source coordinate, not a new Green function. The derivative normalizations and the corresponding connected-log conventions are collected in Definition 30.11. With the Fourier convention

$$\phi(x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \mathrm{e}^{\mathrm{i}k \cdot x} \, \widetilde{\phi}(k),$$

the source pairing is

$$\langle J, \phi \rangle = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \widetilde{J}(k) \widetilde{\phi}(-k).$$

Perturbatively, the source is therefore a one-valent vertex with factor $\mathrm{i}\widetilde{J}(k)$:



$= \quad \mathrm{i}\widetilde{J}(k).$

Here $D_\Lambda^{\mathrm{ref}} \phi$ is the reference integration density of Definition 11.3 in a finite-dimensional bosonic scalar regulator, and S_Λ is the regulated action placed in the exponential. If a chapter instead uses a Gaussian reference measure, it writes $\mathrm{d}\mu_{C_\Lambda}$ and moves the quadratic kinetic term into that measure. Other regulators, such as fermionic, gauge, BV, Lorentzian oscillatory, or dimensional-regularization prescriptions, must specify their own regulated integration object. The notation suppresses Λ after this paragraph. All functional derivatives in this chapter are first derivatives of the regulated source functional; continuum statements are obtained only after the chosen renormalization prescription gives a distributional limit.

Definition 30.2 (Status of $\log Z$)**.** The symbol $\log Z[J]$ has one of the following meanings, fixed by the regulator and limiting prescription.

1. *Formal perturbation theory.* Let g denote the interaction couplings and work in a formal power-series ring in g, with coefficients that are regulated source distributions. If $Z[0]$ is invertible, write
$$Z[J] = Z[0]\big(1 + A[J]\big), \qquad A[0] = 0.$$
Then
$$\log Z[J] = \log Z[0] + \sum_{n\geq 1} \frac{(-1)^{n+1}}{n} A[J]^n$$
is the algebraic logarithm in that completed ring. The first term is a vacuum functional; source derivatives of positive order depend only on the second term. This is the interpretation used by dimensional regularization, minimal subtraction, and graph-by-graph perturbative constructions unless an actual positive measure or oscillatory integral has also been supplied.

2. *Positive Euclidean construction.* If $Z_E[J]$ is defined by a positive finite Euclidean measure on a real source domain and $0 < Z_E[J] < \infty$, then $\log Z_E[J]$ is the ordinary real logarithm. Convexity and Legendre–Fenchel statements in the later Euclidean section use this meaning and require the positivity and finiteness hypotheses stated there.

3. *Lorentzian oscillatory or phase construction.* If a finite Lorentzian regulator gives a complex-valued source functional $Z_L[J]$, then $\log Z_L[J]$ is defined only on a source neighborhood on which $Z_L[J] \neq 0$ and a branch has been chosen from a base source. A principal branch is a possible convention only when the image of that neighborhood avoids its branch cut. Changing the branch on a connected zero-free neighborhood changes $\log Z_L$ by an additive constant in $2\pi\mathrm{i}\mathbb{Z}$, hence changes $W_L = -\mathrm{i}\log Z_L$ by a source- independent constant and leaves connected correlators of positive order unchanged.

No statement in this chapter uses an unclassified logarithm. Every later Legendre transform or connected-kernel formula is to be read in the corresponding one of these three senses.

Definition 30.3 (Connected functional and source-dependent field)**.** For the source functional of Definition 30.1, define the Lorentzian connected functional W by
$$Z[J] = \mathrm{e}^{\mathrm{i}W[J]}, \qquad W[J] = -\mathrm{i}\log Z[J],$$
with the meaning of $\log Z$ supplied by Definition 30.2. In the Lorentzian complex-valued case this includes the choice of a zero-free source neighborhood and a logarithm branch on it; in the formal case it is the algebraic logarithm and no analytic branch is involved. The constant $W[0]$ is the vacuum functional; subtracting it removes vacuum bubbles and leaves all source derivatives of positive order unchanged. The functional $W[J]$, with this harmless constant suppressed, generates connected Green functions with the Lorentzian phase factor
$$G_{\mathrm{c}}^{(n)}(x_1, \ldots, x_n) = \mathrm{i}^{1-n} \frac{\delta^n W[J]}{\delta J(x_1)\cdots\delta J(x_n)}\bigg|_{J=0}.$$
The full Green functions are generated by $Z[J]$:
$$G^{(n)}(x_1, \ldots, x_n) = \frac{1}{Z[0]} \frac{\delta}{\mathrm{i}\delta J(x_1)} \cdots \frac{\delta}{\mathrm{i}\delta J(x_n)}\, Z[J]\bigg|_{J=0}.$$
The correlation-ordering prescription is the one built into the path integral. With the Feynman boundary prescription specified by the $+\mathrm{i}0$ deformation of quadratic denominators, these are time-ordered Lorentzian Green functions.

The source-dependent one-point function is

$$\varphi_J(x) = \frac{\delta W[J]}{\delta J(x)} = \frac{1}{Z[J]} \int D_\Lambda^{\mathrm{ref}}\phi\, \phi(x)\, \exp\{\mathrm{i}S_\Lambda[\phi] + \mathrm{i}\langle J, \phi\rangle\}\,.$$

At $J = 0$, this is the vacuum expectation value of $\phi(x)$ in the chosen state and prescription:

$$\varphi_0(x) = \langle \phi(x) \rangle.$$

Figure 30.1 records the source-to-field map used in the Legendre transform: differentiating $W_\Lambda[J]$ inserts one field, and solving for J as a function of φ defines the 1PI coordinate.

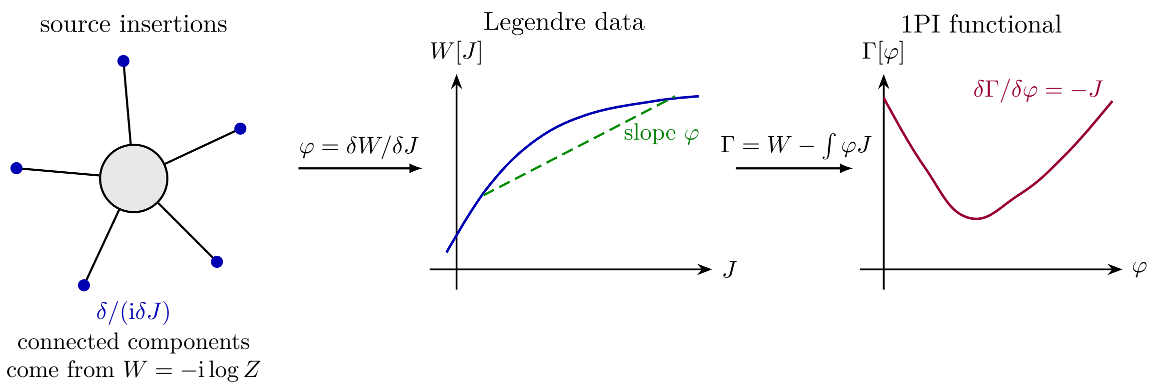


Figure 30.1: The logarithm of the source functional generates connected diagrams. The source-dependent field φ_J is the slope of $W[J]$, and the Legendre transform exchanges the source J for the field φ.

30.2 Legendre Transform

Definition 30.4 (Local one-particle-irreducible Legendre transform)**.** Assume that, in a neighborhood of the source configurations under discussion, the map

$$J \longmapsto \varphi_J = \frac{\delta W[J]}{\delta J}$$

is locally invertible. Denote the inverse by J_φ, so that

$$\varphi(x) = \left.\frac{\delta W[J]}{\delta J(x)}\right|_{J=J_\varphi}.$$

The one-particle-irreducible effective action is the Legendre transform

$$\Gamma[\varphi] = W[J_\varphi] - \langle J_\varphi, \varphi\rangle.$$

This is a local differentiable Legendre transform in the chosen source-coordinate system. It is the definition used by perturbative 1PI diagrammatics: W and Γ may be formal power series, and J_φ is obtained coefficient by coefficient by inverting $\varphi = \delta W/\delta J$. This formal operation does not require a positive measure and does not imply convexity. In particular, in dimensional regularization with minimal subtraction the regulated functional integral is not a positive finite measure on field configurations; it is a prescription for formal amplitudes. Whenever later perturbative MS or BPHZ discussions use the 1PI effective action, this local formal 1PI functional is the operative object unless a positive Euclidean regulator and the convex Legendre–Fenchel construction are explicitly invoked.

Lemma 30.5 (1PI source equation and inverse two-point kernel)**.** *For the local Legendre transform of Definition 30.4,*

$$\frac{\delta\Gamma[\varphi]}{\delta\varphi(x)} = -J_\varphi(x),$$

and the connected two-point kernel is the inverse of the 1PI two-point kernel with the Lorentzian sign

$$\int \mathrm{d}^D z\, W^{(2)}(x,z)\Gamma^{(2)}(z,y) = -\delta^{(D)}(x-y).$$

Proof. Varying the definition of Γ gives

$$\delta\Gamma[\varphi] = \int \mathrm{d}^D x\, \frac{\delta W[J_\varphi]}{\delta J_\varphi(x)}\delta J_\varphi(x) - \int \mathrm{d}^D x\, \delta\varphi(x)J_\varphi(x) \\ - \int \mathrm{d}^D x\, \varphi(x)\delta J_\varphi(x).$$

The first and third terms cancel by the defining relation $\delta W/\delta J = \varphi$. Therefore

$$\frac{\delta\Gamma[\varphi]}{\delta\varphi(x)} = -J_\varphi(x).$$

At zero source, the physical vacuum expectation value is an extremum of the effective action:

$$\left.\frac{\delta\Gamma[\varphi]}{\delta\varphi(x)}\right|_{\varphi=\langle\phi\rangle} = 0.$$

The second derivative records the inverse relation between the connected two-point function and the 1PI two-point kernel. Define

$$W^{(2)}(x,y) = \frac{\delta^2 W[J]}{\delta J(x)\delta J(y)}, \qquad \Gamma^{(2)}(x,y) = \frac{\delta^2\Gamma[\varphi]}{\delta\varphi(x)\delta\varphi(y)}.$$

Differentiating $\varphi(x) = \delta W/\delta J(x)$ with respect to $\varphi(y)$ gives

$$\delta^{(D)}(x-y) = \int \mathrm{d}^D z\, W^{(2)}(x,z)\frac{\delta J(z)}{\delta\varphi(y)}.$$

Differentiating $\delta\Gamma/\delta\varphi = -J$ gives

$$\Gamma^{(2)}(z,y) = -\frac{\delta J(z)}{\delta\varphi(y)}.$$

Combining the two identities,

$$\int \mathrm{d}^D z\, W^{(2)}(x,z)\Gamma^{(2)}(z,y) = -\delta^{(D)}(x-y).$$

The sign is a consequence of the Lorentzian convention $\Gamma = W - \int \varphi J$. In momentum space, for a translation-invariant vacuum,

$$W^{(2)}(k)\Gamma^{(2)}(k) = -1.$$

With the same Feynman $+\mathrm{i}0$ boundary prescription, $W^{(2)}$ is related to the connected propagator by the same factors of i that appear in the source-derivative definition above. □

30.3 Background Split and One-Particle-Irreducible Kernels

Shifted representation and tadpole condition. Fix a field configuration φ, set $J = J_\varphi$, and write

$$\phi = \varphi + \xi.$$

The local 1PI functional has the shifted representation

$$\begin{aligned} e^{i\Gamma[\varphi]} &= e^{iW[J]-i\langle J,\varphi\rangle} \\ &= \int [D\xi]\ \exp\{iS[\varphi+\xi] + i\langle J,\xi\rangle\}_{J=J_\varphi}. \end{aligned}$$

In this shifted functional integral,

$$\langle \xi(x)\rangle_\varphi = 0,$$

so the linear source term is chosen exactly to cancel the quantum tadpole in the background φ.

The first equality is the Legendre definition $\Gamma[\varphi] = W[J_\varphi] - \langle J_\varphi, \varphi\rangle$. In the regulated integral for $Z[J_\varphi]$, make the affine change of variables $\phi = \varphi + \xi$. The symbol $[D\xi]$ denotes the pushforward of the specified regulated integration object under this change of variables; if the chosen regulator produces a nontrivial Jacobian or density term, its logarithm is part of the shifted action. The source term $\langle J_\varphi, \phi\rangle$ becomes $\langle J_\varphi, \varphi\rangle + \langle J_\varphi, \xi\rangle$, and the first part is precisely removed by the Legendre factor. Finally,

$$\langle \xi(x)\rangle_\varphi = \langle \phi(x)\rangle_{J_\varphi} - \varphi(x) = \left.\frac{\delta W[J]}{\delta J(x)}\right|_{J=J_\varphi} - \varphi(x) = 0.$$

Expand the action around the background:

$$S[\varphi+\xi] = S[\varphi] + \int d^D x\, S^{(1)}_\varphi(x)\xi(x) + \frac{1}{2}\int d^D x\, d^D y\, \xi(x) S^{(2)}_\varphi(x,y)\xi(y) + \cdots.$$

The vertices in the shifted theory may carry two types of legs: quantum ξ-legs that are contracted in loops, and background φ-legs that remain external. The source term supplies an additional linear vertex

$$i\langle J_\varphi, \xi\rangle.$$

For example, if the microscopic action contains a cubic interaction, then the polynomial identity after the split is

$$\phi^3 = \varphi^3 + 3\varphi^2\xi + 3\varphi\xi^2 + \xi^3.$$

Thus a single local interaction produces vertices with zero, one, two, or three quantum fluctuation legs. The first term is a purely background contribution to the zero-loop effective action; the terms with ξ-legs are contracted in the shifted functional integral; and the source supplies one more one-point quantum vertex. The shifted-vertex bookkeeping is displayed in Figure 30.2. Since J_φ is fixed by $\langle\xi\rangle = 0$, all tadpole subdiagrams in the shifted theory cancel in the sum.

Remark 30.6 (One-particle-reducible graphs are Legendre trees). A connected diagram is one-particle reducible if cutting one internal ξ propagator separates it into two connected diagrams, each with at least one external background leg. In the Legendre transform, such single-propagator reducible contributions are generated by solving the stationary equation for φ_J and joining lower kernels by exact propagators. They are therefore part of the tree reconstruction of connected

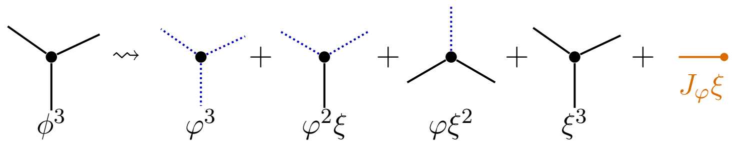

Figure 30.2: Cubic interaction after the background-field split $\phi = \varphi + \xi$. Dotted blue legs are background fields, solid legs are quantum fluctuations, and the orange one-point vertex is the source term fixed by the condition $\langle\xi\rangle_\varphi = 0$.

functions from Γ, rather than new kernels in Γ itself. The new kernels in Γ are the one-particle-irreducible ones. Equivalently, in a shifted connected vacuum diagram, cut an internal quantum propagator. Each side becomes a connected subdiagram with one open quantum leg and any number of background legs. When all graphs with the same external background data are summed, either side is precisely the source-dependent tadpole functional; it vanishes by $\langle\xi\rangle_\varphi = 0$. This is the diagrammatic content of the Legendre transform, not an additional dynamical assumption.

Figure 30.3 shows the diagrammatic content of this argument: cutting a quantum propagator in a shifted connected vacuum graph produces tadpole subgraphs, which vanish at the Legendre-transform background.

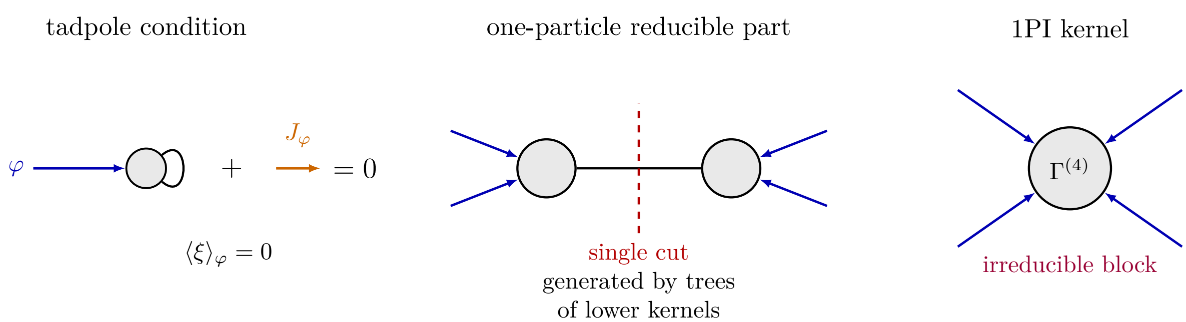

Figure 30.3: The source J_φ in the shifted functional integral is fixed by the condition that the quantum fluctuation has zero one-point function. With this condition imposed, the Legendre transform is represented by one-particle-irreducible kernels.

Perturbatively, one may write

$$\mathrm{i}\Gamma[\varphi] = \mathrm{i}S[\varphi] + \{\text{sum of connected 1PI vacuum graphs in the shifted theory}\}\,.$$

The position-space 1PI kernels are the functional derivatives

$$\Gamma^{(n)}(x_1,\ldots,x_n) = \left.\frac{\delta^n\Gamma[\varphi]}{\delta\varphi(x_1)\cdots\delta\varphi(x_n)}\right|_{\varphi=\varphi_0},$$

where φ_0 is the background about which the expansion is made. In a translation-invariant vacuum with vanishing one-point function, the expansion point is $\varphi_0 = 0$; if the one-point function is nonzero, one first shifts the field and then expands around the shifted stationary background. Equivalently, after expanding in powers of the background, $\mathrm{i}\Gamma^{(n)}$ is computed by amputated 1PI n-point diagrams whose external lines carry the background field. The momenta on these external legs range over the off-shell momentum space of the vertex function. Scattering kinematics enter only after LSZ and the corresponding on-shell limits.

30.4 Vertex Expansion

Definition 30.7 (Momentum-space 1PI vertices)**.** In a translation-invariant vacuum, the effective action has a momentum-space expansion

$$\Gamma[\varphi] = \sum_{n=0}^{\infty} \frac{1}{n!} \int \prod_{r=1}^{n} \frac{\mathrm{d}^D k_r}{(2\pi)^D} \, (2\pi)^D \delta^{(D)}\!\left(\sum_{r=1}^{n} k_r\right) \Gamma^{(n)}(k_1, \ldots, k_n) \, \widetilde{\varphi}(k_1) \cdots \widetilde{\varphi}(k_n).$$

The delta function expresses translation invariance, so only $n-1$ of the momenta are independent. With this normalization,

$$\Gamma^{(n)}(k_1, \ldots, k_n) = \left. \frac{\delta^n \Gamma}{\delta\widetilde{\varphi}(k_1) \cdots \delta\widetilde{\varphi}(k_n)} \right|_{\varphi=0}$$

after removing the overall momentum-conserving delta function.

For $n = 2$, the exact two-point 1PI kernel is the inverse propagator in the Legendre sense. For a scalar field with tree-level action

$$S_0[\phi] = -\frac{1}{2} \int \frac{\mathrm{d}^D k}{(2\pi)^D} \, \widetilde{\phi}(k)(k^2 + m^2)\widetilde{\phi}(-k),$$

one writes

$$\mathrm{i}\Gamma^{(2)}(k) = -\mathrm{i}(k^2 + m^2) + \Pi_{\mathrm{1PI}}(k),$$

where $\Pi_{\mathrm{1PI}}(k)$ is the sum of 1PI self-energy diagrams in the same normalization. The exact connected propagator is obtained by inverting this kernel with the $i\epsilon$ prescription fixed by the underlying Lorentzian functional integral.

Definition 30.8 (Local derivative expansion of a 1PI branch)**.** When the kernels are analytic near zero momentum, their Taylor expansion gives a local derivative expansion. For a single scalar field,

$$\Gamma[\varphi] = \int \mathrm{d}^D x \left[-V_{\mathrm{eff}}(\varphi) - \frac{1}{2} Z_{\mathrm{eff}}(\varphi) \partial_\mu \varphi \, \partial^\mu \varphi + \sum_{r \geq 2} \mathcal{C}_r(\varphi, \partial\varphi, \ldots) \right],$$

where each $\mathcal{C}_r$ contains operators with higher numbers of derivatives. The coefficients are determined by derivatives of the kernels $\Gamma^{(n)}(k_1, \ldots, k_n)$ at small momenta. The expansion has to be used with its analytic domain stated: loops of massless fields commonly produce terms such as logarithms and threshold branch points at small momentum, and these terms are part of the exact 1PI action.

30.5 One-Loop Effective Potential and Dimensional Transmutation

The effective potential is the zero-derivative part of the local formal 1PI effective action. It is not, by definition, the exact convex Legendre–Fenchel effective action of a positive Euclidean measure. The latter is discussed later in this chapter. In perturbation theory one chooses a background branch, computes the local 1PI functional around that branch, and only then asks whether the branch is stable and whether the logarithms are under perturbative control.

Work in four dimensions with one real scalar field and Euclidean action

$$S_E[\phi] = \int \mathrm{d}^4x \left[\frac{1}{2}\partial_\mu\phi\,\partial_\mu\phi + V_0(\phi)\right], \qquad V_0(\phi) = \frac{\lambda}{4!}\phi^4.$$

The regulated path-integral Lagrangian contains the counterterm part needed by the chosen subtraction prescription; those terms are part of the regulated Lagrangian, not a separate physical theory. Let the background be constant, $\phi(x) = \varphi + \xi(x)$. The quadratic fluctuation operator is

$$\Delta_\varphi = -\partial^2 + M^2(\varphi), \qquad M^2(\varphi) = V_0''(\varphi) = \frac{\lambda}{2}\varphi^2.$$

In a finite box of volume Vol, the formal one-loop contribution to the 1PI effective action is

$$\Gamma_E^{(1)}[\varphi] = \frac{1}{2}\operatorname{Tr}\log\Delta_\varphi, \qquad V_1(\varphi) = \frac{1}{2\,\mathrm{Vol}}\operatorname{Tr}\log\Delta_\varphi.$$

After passing to momentum space and subtracting the φ-independent vacuum term,

$$V_1(\varphi) = \frac{1}{2}\mu^\epsilon \int \frac{\mathrm{d}^{4-\epsilon}p}{(2\pi)^{4-\epsilon}}\,\log\!\big(p^2 + M^2(\varphi)\big) + V_{\mathrm{ct}}^{(1)}(\varphi). \tag{30.1}$$

The scale μ is the dimensional-regularization scale in the selected subtraction chart. To evaluate the determinant without hiding constants, differentiate with respect to M^2:

$$\frac{\partial V_1}{\partial M^2} = \frac{1}{2}\mu^\epsilon \int \frac{\mathrm{d}^{4-\epsilon}p}{(2\pi)^{4-\epsilon}}\,\frac{1}{p^2+M^2} = \frac{1}{2}\frac{\mu^\epsilon}{(4\pi)^{2-\epsilon/2}}\Gamma\Big(-1+\frac{\epsilon}{2}\Big)\,(M^2)^{1-\epsilon/2}.$$

Integrating back in M^2 and choosing the additive constant so that $V_1(0) = 0$ gives

$$V_1^{\mathrm{reg}} = -\frac{1}{2}\frac{\mu^\epsilon}{(4\pi)^{2-\epsilon/2}}\Gamma\Big(-2+\frac{\epsilon}{2}\Big)\,(M^2)^{2-\epsilon/2} + V_{\mathrm{ct}}^{(1)}.$$

In the $\overline{\mathrm{MS}}$ chart, after subtracting the pole and the associated $\log 4\pi - \gamma_E$ convention terms, this becomes

$$V_1^{\overline{\mathrm{MS}}}(\varphi) = \frac{M^4(\varphi)}{64\pi^2}\left[\log\frac{M^2(\varphi)}{\mu^2} - \frac{3}{2}\right]. \tag{30.2}$$

Thus the one-loop formal 1PI effective potential in massless $\lambda\phi^4$ theory is

$$V_{\mathrm{eff}}^{\overline{\mathrm{MS}}}(\varphi) = \frac{\lambda(\mu)}{4!}\varphi^4 + \frac{\lambda(\mu)^2\varphi^4}{256\pi^2}\left[\log\frac{\lambda(\mu)\varphi^2}{2\mu^2} - \frac{3}{2}\right] + O(\lambda^3). \tag{30.3}$$

The logarithm is the first explicit signal that the classical scale-invariant polynomial has become a renormalized family depending on a subtraction scale. The dependence on μ is not physical by itself; it is compensated by the running coupling. To this order the field anomalous dimension starts only at higher loop order, while

$$\beta_\lambda(\lambda) = \mu\frac{\mathrm{d}\lambda}{\mathrm{d}\mu} = \frac{3\lambda^2}{16\pi^2} + O(\lambda^3).$$

Indeed,

$$\mu\frac{\partial}{\partial\mu}\left[\frac{\lambda^2\varphi^4}{256\pi^2}\log\frac{\lambda\varphi^2}{2\mu^2}\right] = -\frac{\lambda^2\varphi^4}{128\pi^2},$$

whereas

$$\beta_\lambda\frac{\partial}{\partial\lambda}\left(\frac{\lambda\varphi^4}{24}\right) = \frac{\lambda^2\varphi^4}{128\pi^2}.$$

Thus

$$\left(\mu\frac{\partial}{\partial\mu} + \beta_\lambda\frac{\partial}{\partial\lambda} - \gamma_\phi\varphi\frac{\partial}{\partial\varphi}\right)V_{\text{eff}} = 0$$

holds through order λ^2, with $\gamma_\phi = O(\lambda^2)$ contributing only at the next order in this single-scalar example.

Coleman–Weinberg often uses a finite subtraction condition at a nonzero field value M, because the fourth derivative of $\varphi^4\log\varphi^2$ is singular at $\varphi = 0$. Define λ_{CW} by

$$\left.\frac{\mathrm{d}^4V_{\text{eff}}}{\mathrm{d}\varphi^4}\right|_{\varphi=M} = \lambda_{\text{CW}}.$$

After the corresponding finite change of quartic coordinate, the one-loop potential is

$$V_{\text{CW}}(\varphi) = \frac{\lambda_{\text{CW}}}{24}\varphi^4 + \frac{\lambda_{\text{CW}}^2}{256\pi^2}\varphi^4\left[\log\frac{\varphi^2}{M^2} - \frac{25}{6}\right] + O(\lambda_{\text{CW}}^3). \tag{30.4}$$

The constant $-25/6$ is fixed by the displayed fourth-derivative condition:

$$\frac{\mathrm{d}^4}{\mathrm{d}\varphi^4}\left[\varphi^4\log\frac{\varphi^2}{M^2}\right]\Bigg|_{\varphi=M} = 100, \qquad \frac{\mathrm{d}^4}{\mathrm{d}\varphi^4}\varphi^4 = 24.$$

The nonzero stationary points of the one-loop branch satisfy

$$0 = \frac{1}{\varphi^3}\frac{\mathrm{d}V_{\text{CW}}}{\mathrm{d}\varphi} = \frac{\lambda_{\text{CW}}}{6} + \frac{\lambda_{\text{CW}}^2}{64\pi^2}\left[\log\frac{\varphi^2}{M^2} - \frac{11}{3}\right] + O(\lambda_{\text{CW}}^3). \tag{30.5}$$

At the one-loop level this gives the formal scale

$$v = M\exp\left[\frac{11}{6} - \frac{16\pi^2}{3\lambda_{\text{CW}}(M)}\right]. \tag{30.6}$$

At such a stationary point,

$$\left.\frac{\mathrm{d}^2V_{\text{CW}}}{\mathrm{d}\varphi^2}\right|_{\varphi=v} = \frac{\lambda_{\text{CW}}^2}{32\pi^2}v^2 + O(\lambda_{\text{CW}}^3v^2).$$

Equations (30.5) and (30.6) display the algebraic mechanism called dimensional transmutation: a dimensionless coupling specified at the subtraction point is exchanged for a dimensionful scale on a chosen renormalized trajectory.

This statement has an important perturbative qualification. In the single real scalar theory, taking $M = v$ in (30.5) gives

$$\lambda_{\text{CW}}(v) = \frac{32\pi^2}{11},$$

which is not a small coupling. If instead $\lambda_{\mathrm{CW}}(M)$ is small, then $\log(v/M) = O(1/\lambda_{\mathrm{CW}})$, so higher leading logarithms are not parametrically smaller than the one-loop logarithm. The one-loop massless-scalar potential therefore demonstrates the structure of the calculation and the scale-generating relation, but it does not by itself give a controlled weak-coupling proof of a radiatively generated vacuum in pure $\lambda\phi^4$ theory.

The renormalization-group form of dimensional transmutation is independent of this particular one-loop branch. For a dimensionless coupling g with $\beta(g) \neq 0$, choosing $g(\mu)$ at a subtraction scale is equivalent, on a one-dimensional RG trajectory, to choosing the scale Λ_{g_*} at which the running coupling reaches a reference value g_*:

$$\log \frac{\Lambda_{g_*}}{\mu} = \int_{g(\mu)}^{g_*} \frac{\mathrm{d}g}{\beta(g)}. \tag{30.7}$$

For the one-loop scalar beta function $\beta_\lambda = b\lambda^2$, $b = 3/(16\pi^2)$, this gives

$$\Lambda_{\lambda_*} = \mu \exp\left[\frac{1}{b\lambda(\mu)} - \frac{1}{b\lambda_*}\right].$$

Because $b > 0$, this scale is the scale of increasing coupling toward the ultraviolet rather than an asymptotically free strong scale. In gauge theories with a negative one-loop beta function the same formula produces the familiar infrared strong scale.

A controlled Coleman–Weinberg minimum can occur in a multi-coupling theory where the tree quartic coupling is of the same order as a one-loop effect. For example, in massless scalar electrodynamics on a chosen perturbative branch and in the conventional radial-field normalization, the gauge-boson one-loop term gives

$$V_{\mathrm{eff}}(\varphi) = \frac{\lambda}{24}\varphi^4 + \frac{3e^4}{64\pi^2}\varphi^4\left[\log\frac{\varphi^2}{M^2} - \frac{25}{6}\right] + \cdots,$$

after the same type of nonzero-field quartic subtraction. Then a stationary point at $M = v$ requires $\lambda = 33e^4/(8\pi^2) + O(e^6)$, which is compatible with weak coupling when e is small. This is the controlled version of radiative breaking; the single-scalar computation above is the minimal determinant calculation and the clearest place to see how the subtraction scale enters the formal 1PI potential.

30.6 Connected Functions from Exact 1PI Vertices

The Legendre transform can be inverted. Given $\Gamma[\varphi]$, the connected functional $W[J]$ is obtained by solving

$$\frac{\delta\Gamma[\varphi]}{\delta\varphi(x)} = -J(x)$$

for $\varphi = \varphi_J$, and then setting

$$W[J] = \Gamma[\varphi_J] + \langle J, \varphi_J\rangle.$$

Equivalently, the inversion can be written as the stationary value

$$W[J] = \underset{\varphi}{\mathrm{stationary}}\left(\Gamma[\varphi] + \langle J, \varphi\rangle\right).$$

This identity is exact at the level of the Legendre transform. It also has a diagrammatic interpretation: connected Green functions are obtained as tree diagrams whose vertices are exact 1PI kernels and whose internal lines are the exact connected propagator.

Proposition 30.9 (Exact 1PI tree reconstruction of connected kernels)**.** *Work in DeWitt notation, with repeated indices summed and integrated, and set*

$$W^{i_1\cdots i_n} = \frac{\delta^n W}{\delta J_{i_1}\cdots\delta J_{i_n}}, \qquad \Gamma_{i_1\cdots i_n} = \frac{\delta^n \Gamma}{\delta\varphi^{i_1}\cdots\delta\varphi^{i_n}}$$

at the paired configurations J and φ_J. Let

$$G^{ij} = W^{ij} = \frac{\delta\varphi_J^i}{\delta J_j}$$

be the exact connected two-point kernel. Then

$$\Gamma_{ia}G^{aj} = -\delta_i^{\ j}, \tag{30.8}$$

$$W^{ijk} = G^{ia}G^{jb}G^{kc}\Gamma_{abc}, \tag{30.9}$$

and

$$\begin{aligned} W^{ijkl} &= G^{ia}G^{jb}G^{kc}G^{ld}\Gamma_{abcd} \\ &\quad + G^{ia}G^{jb}\Gamma_{abe}G^{ef}\Gamma_{fcd}G^{kc}G^{ld} \\ &\quad + G^{ia}G^{kc}\Gamma_{ace}G^{ef}\Gamma_{fbd}G^{jb}G^{ld} \\ &\quad + G^{ia}G^{ld}\Gamma_{ade}G^{ef}\Gamma_{fbc}G^{jb}G^{kc}. \end{aligned} \tag{30.10}$$

In general, every connected kernel $W^{i_1\cdots i_n}$ is obtained by a finite sum over trees whose vertices are exact 1PI kernels Γ_r with $r \geq 3$, whose internal edges are G, and whose external half-edges are attached to the external labels by G. No loop is created in this reconstruction; all loop information is already contained in the exact kernels Γ_r and the exact propagator G.

Proof. The stationarity equation is

$$\Gamma_i[\varphi_J] + J_i = 0.$$

Differentiating once with respect to J_j gives

$$\Gamma_{ia}G^{aj} + \delta_i^{\ j} = 0,$$

which proves (30.8). Differentiating this identity with respect to J_k gives

$$\Gamma_{iab}G^{bk}G^{aj} + \Gamma_{ia}W^{ajk} = 0.$$

Multiplying by $G^{\ell i}$ and using $G^{\ell i}\Gamma_{ia} = -\delta^{\ell}{}_a$, which is the same inverse relation with the two factors interchanged, gives

$$W^{\ell jk} = G^{\ell i}\Gamma_{iab}G^{aj}G^{bk}.$$

Renaming dummy indices proves (30.9).

Differentiate the preceding second-derivative identity once more:

$$\begin{aligned} 0 = {}& \Gamma_{iabc}G^{c\ell}G^{bk}G^{aj} + \Gamma_{iab}W^{bk\ell}G^{aj} + \Gamma_{iab}G^{bk}W^{aj\ell} \\ & + \Gamma_{iab}G^{b\ell}W^{ajk} + \Gamma_{ia}W^{ajk\ell}. \end{aligned}$$

Multiplication by G^{mi} solves for $W^{mjk\ell}$. The first term gives the single four-point vertex in (30.10); substituting (30.9) into the other three terms gives the three pairings of two exact three-point vertices joined by one exact propagator. This proves (30.10).

The recursive tree statement follows by induction. Suppose every source derivative of φ_J of order less than n is a sum of trees. The $(n-1)$st derivative of $\Gamma_i[\varphi_J] + J_i = 0$ is a finite Faà di Bruno sum: one differentiates some Γ_r and distributes the source derivatives among the factors $\delta^m \varphi_J / \delta J^m$. By the induction hypothesis those factors are trees. Multiplying once by G solves the remaining Γ_{ia}-factor and attaches one additional external propagator. This operation glues trees at a new exact 1PI vertex and cannot form a cycle. Therefore the result is a sum over trees only. Translating from derivatives of W to Lorentzian Green functions uses the same powers of i as in the source-derivative definitions at the beginning of the chapter. $\square$

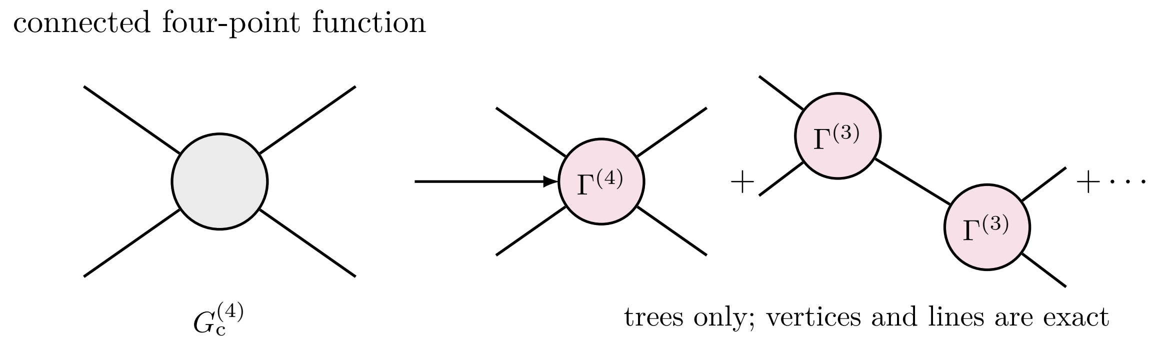

Figure 30.4: Connected Green functions are reconstructed from the exact 1PI action by forming trees. The internal lines are exact propagators, and the vertices are exact kernels $\Gamma^{(n)}$.

One can express the same statement with a bookkeeping parameter $\hbar$:

$$\mathrm{i}W[J] = \lim_{\hbar \to 0} \hbar \log \int [D\varphi]\, \exp\left\{ \frac{\mathrm{i}}{\hbar} \left(\Gamma[\varphi] + \langle J, \varphi \rangle \right) \right\}.$$

The limit keeps only tree diagrams built from Γ. Since Γ already contains the full loop information of the original theory, this tree expansion is the tree-level representation of the exact Legendre inverse.

30.7 Schwinger–Dyson Identities and the 1PI Hierarchy

The Legendre transform organizes exact kernels, but it does not by itself use the equation of motion of the integration variable. The latter information is contained in the Schwinger–Dyson identities. These identities are exact only after their hypotheses are stated: at the regulator under discussion the reference integration density must be translation invariant in the integration coordinate, or else its logarithmic derivative must be included; the contour or domain must have no boundary contribution for the variation being made; and any Jacobian from a nontrivial change of variables must be recorded as an additional insertion. Gauge theories replace the naive field translation by gauge-fixed BRST/BV identities. In this scalar section we assume the translation-invariant regulated scalar density introduced at the beginning of the chapter.

Use condensed DeWitt notation in this section. A single index i denotes both a discrete field label and a spacetime point, repeated indices are summed and integrated, and

$$J_i\phi^i = \langle J, \phi\rangle.$$

Write

$$S_i[\phi] = \frac{\delta S[\phi]}{\delta\phi^i}, \qquad S_{ij}[\phi] = \frac{\delta^2 S[\phi]}{\delta\phi^i\delta\phi^j},$$

and similarly for higher field derivatives of the regulated action.

Functional Schwinger–Dyson identity. For every regulated test functional $\mathcal{O}[\phi]$ for which the following integration by parts is legitimate,

$$\big\langle \big(S_i[\phi] + J_i\big)\mathcal{O}[\phi]\big\rangle_J = \mathrm{i}\left\langle \frac{\delta\mathcal{O}[\phi]}{\delta\phi^i}\right\rangle_J. \tag{30.11}$$

Equivalently, at the level of the source functional,

$$\left[S_i\left(\frac{1}{\mathrm{i}}\frac{\delta}{\delta J}\right) + J_i\right] Z[J] = 0. \tag{30.12}$$

At finite regulator, integrate the total derivative

$$0 = \int D_\Lambda^{\mathrm{ref}}\phi\, \frac{\delta}{\delta\phi^i}\left[\mathcal{O}[\phi]\, \exp\{\mathrm{i}S[\phi] + \mathrm{i}J_j\phi^j\}\right].$$

Expanding the derivative gives

$$0 = \left\langle \frac{\delta\mathcal{O}}{\delta\phi^i}\right\rangle_J + \mathrm{i}\,\langle \mathcal{O}(S_i + J_i)\rangle_J\,.$$

Since $-1/\mathrm{i} = \mathrm{i}$, this is (30.11). Taking $\mathcal{O} = 1$ and replacing each field insertion by $(1/\mathrm{i})\delta/\delta J$ gives (30.12). If the reference density has logarithmic derivative $R_i[\phi]$, the left side is modified by $S_i + J_i - \mathrm{i}R_i$; that is the measure contribution which, in symmetry variations, becomes the anomaly term.

The case $\mathcal{O} = 1$ gives the quantum equation of motion

$$\langle S_i[\phi]\rangle_J + J_i = 0.$$

Using $\Gamma_i[\varphi] = \delta\Gamma/\delta\varphi^i = -J_i$, this becomes

$$\Gamma_i[\varphi] = \langle S_i[\phi]\rangle_{J_\varphi}\,. \tag{30.13}$$

Thus the 1PI equation of motion is not the classical equation $S_i[\varphi] = 0$. It is the expectation value of the microscopic equation of motion in the source ensemble whose mean field is φ.

Equation (30.12) may be written directly in connected variables. Since

$$Z^{-1}\frac{1}{\mathrm{i}}\frac{\delta Z}{\delta J_i} = \frac{\delta W}{\delta J_i} = \varphi^i,$$

one has the operator identity

$$Z[J]^{-1}F\left(\frac{1}{\mathrm{i}}\frac{\delta}{\delta J}\right)Z[J] = F\left(\varphi + \frac{1}{\mathrm{i}}\frac{\delta}{\delta J}\right)1 \tag{30.14}$$

for every polynomial functional F, with the functional derivatives on the right acting on all source-dependent quantities to their right before setting them on 1. Therefore

$$S_i\left(\varphi + \frac{1}{\mathrm{i}}\frac{\delta}{\delta J}\right)1 + J_i = 0. \tag{30.15}$$

This formula is the compact exact Schwinger–Dyson equation for W. Its Legendre form is obtained by substituting $J_i = -\Gamma_i[\varphi]$ and using $W^{(2)}\Gamma^{(2)} = -1$ to convert source derivatives into field derivatives when desired.

Quartic scalar example

For a single scalar field with a quartic interaction, write the regulated action in condensed notation as

$$S[\phi] = \frac{1}{2}K_{ij}\phi^i\phi^j + \frac{\lambda}{4!}V_{ijkl}\phi^i\phi^j\phi^k\phi^l,$$

where $K_{ij} = K_{ji}$ is the regulated quadratic kernel and V_{ijkl} is totally symmetric. The sign of λV is the sign chosen in the Lorentzian action; no Euclidean positivity is being assumed in this formal identity. Since

$$S_i[\phi] = K_{ij}\phi^j + \frac{\lambda}{3!}V_{ijkl}\phi^j\phi^k\phi^l,$$

the connected Schwinger–Dyson equation becomes

$$\begin{aligned}\Gamma_i[\varphi] = K_{ij}\varphi^j + \frac{\lambda}{3!}V_{ijkl}\Big[&\varphi^j\varphi^k\varphi^l \\ &+ \frac{1}{\mathrm{i}}\big(W^{jk}\varphi^l + W^{jl}\varphi^k + W^{kl}\varphi^j\big) + \frac{1}{\mathrm{i}^2}W^{jkl}\Big]_{J=J_\varphi}.\end{aligned} \tag{30.16}$$

Here

$$W^{i_1\cdots i_n} = \frac{\delta^n W[J]}{\delta J_{i_1}\cdots\delta J_{i_n}}$$

is the connected-kernel convention already used in this chapter. The powers of 1/i in (30.16) are not optional: they come from the Lorentzian source factor $\exp(\mathrm{i}J_i\phi^i)$.

Full propagator member

Assume for this paragraph that the vacuum is translation invariant and $\phi \mapsto -\phi$ symmetric, so that $\varphi = 0$ and odd connected functions vanish at $J = 0$. Differentiate the field equation with respect to J_m and set $J = 0$. The exact two-point member of the hierarchy is

$$0 = K_{ij}W^{jm} + \frac{\lambda}{3!}V_{ijkl}\Big[\frac{1}{\mathrm{i}}\big(W^{jk}W^{lm} + W^{jl}W^{km} + W^{jm}W^{kl}\big) + \frac{1}{\mathrm{i}^2}W^{jklm}\Big] + \delta_i{}^m. \tag{30.17}$$

This is the full propagator Schwinger–Dyson equation in connected form. It is not a one-loop formula: W^{jm} is the exact connected two-point kernel and W^{jklm} is the exact connected four-point kernel. Multiplying (30.17) by the exact inverse kernel $\Gamma^{(2)}$, using

$$W^{im}\Gamma^{(2)}_{mn} = -\delta^i{}_n,$$

gives the corresponding inverse-propagator form

$$\Gamma^{(2)}_{in} = K_{in} + \frac{\lambda}{2\mathrm{i}} V_{inkl} W^{kl} - \frac{\lambda}{3!\,\mathrm{i}^2} V_{ijkl} W^{jklm} \Gamma^{(2)}_{mn}. \tag{30.18}$$

The second term is the exact tadpole contraction. The last term is the amputated contribution of the exact connected four-point kernel. A common "gap" or Hartree approximation drops the connected four-point term and then solves the remaining equation self-consistently for $W^{(2)}$. That operation is a truncation of the exact hierarchy, not a derivation from the Schwinger–Dyson identity.

Full vertex member

The next nontrivial member is obtained from (30.11) with $\mathcal{O} = \phi^a\phi^b\phi^c$, or equivalently by differentiating (30.16) three times with respect to the source. First, the insertion form gives

$$\begin{aligned} K_{ij} \left\langle \phi^j \phi^a \phi^b \phi^c \right\rangle + \frac{\lambda}{3!} V_{ijkl} \left\langle \phi^j \phi^k \phi^l \phi^a \phi^b \phi^c \right\rangle \\ = \mathrm{i}\Big(\delta_i{}^a \left\langle \phi^b \phi^c \right\rangle + \delta_i{}^b \left\langle \phi^a \phi^c \right\rangle + \delta_i{}^c \left\langle \phi^a \phi^b \right\rangle\Big). \end{aligned} \tag{30.19}$$

This equation contains disconnected pair products. They are not an ambiguity: they are removed by the lower two-point Schwinger–Dyson member. The same statement is obtained without mentioning disconnected moments by differentiating the connected equation. Let Sym_{abc} denote summation over all distinct permutations of the displayed labels a, b, c, and let $\mathrm{Sym}^{2,1}_{abc}$ denote the three splittings $(ab|c), (ac|b), (bc|a)$. In the symmetric vacuum,

$$\begin{aligned} 0 = K_{ij} W^{jabc} + \frac{\lambda}{3!} V_{ijkl} \Big[\mathrm{Sym}_{abc}\, W^{ja} W^{kb} W^{lc} \\ + \frac{3}{\mathrm{i}} \Big(W^{jk} W^{labc} + \mathrm{Sym}^{2,1}_{abc}\, W^{jkab} W^{lc} \Big) + \frac{1}{\mathrm{i}^2} W^{jklabc} \Big]. \end{aligned} \tag{30.20}$$

Equation (30.20) is often the cleanest form of the full vertex hierarchy: every term is connected, and the first term is the kinetic operator acting on the exact connected four-point kernel. The 1PI version is obtained by substituting the Legendre identities between connected kernels and exact 1PI kernels. In the $\phi \mapsto -\phi$ symmetric case,

$$W^{abcd} = W^{aa'} W^{bb'} W^{cc'} W^{dd'} \Gamma^{(4)}_{a'b'c'd'}, \tag{30.21}$$

because the exact three-point vertex vanishes. The connected six-point kernel decomposes as

$$\begin{aligned} W^{abcdef} = W^{aa'} W^{bb'} W^{cc'} W^{dd'} W^{ee'} W^{ff'} \Gamma^{(6)}_{a'b'c'd'e'f'} \\ + \sum_{\mathcal{P}_3} \left(\prod_{r \in A} W^{rr'} \right) \left(\prod_{s \in B} W^{ss'} \right) \Gamma^{(4)}_{A'u} W^{uv} \Gamma^{(4)}_{vB'}. \end{aligned} \tag{30.22}$$

Here $\mathcal{P}_3$ is the set of the ten unordered partitions $\{a, b, c, d, e, f\} = A \sqcup B$ with $|A| = |B| = 3$; A' and B' denote the primed external indices attached to the labels in the corresponding block. The signs in (30.21) and (30.22) follow from the convention $W^{im}\Gamma^{(2)}_{mn} = -\delta^i{}_n$. Substituting (30.21) and (30.22) into (30.20), and multiplying by exact inverse two-point kernels on the external labels, gives the full four-point 1PI Schwinger–Dyson equation. It relates $\Gamma^{(4)}$ to the exact propagator, the exact six-point vertex $\Gamma^{(6)}$, and the two $\Gamma^{(4)}$-vertices joined by one exact propagator in (30.22). Without the $\phi \mapsto -\phi$ symmetry, the same construction contains the additional tree terms built from exact three-point vertices described in Figure 30.4. A vertex truncation is the choice to keep only a specified subset of these terms, for example to model $\Gamma^{(4)}$ while discarding the connected six-point kernel. The exact Schwinger–Dyson hierarchy itself does not justify that closure; the closure must be supplied by a small parameter, a controlled kinematic limit, a renormalization condition plus error estimate, or an explicit nonperturbative ansatz.

30.8 Euclidean Convexity

The convexity statement is a theorem only after the Euclidean functional integral has been given positive measure-theoretic meaning. The analytic input used in the proof is isolated in the following assumption.

Assumption 30.10 (Positive finite Euclidean regulator for convexity)**.** Fix a regulator Λ. There is a measurable regulated configuration space $(\mathcal{C}_\Lambda, \mathcal{A}_\Lambda)$, a positive finite measure μ_Λ on it, and a real vector space $\mathcal{S}_\Lambda$ of regulated sources paired with the regulated field by a measurable real functional

$$(J, \phi) \longmapsto \langle J, \phi \rangle_\Lambda.$$

There is a nonempty convex source domain $\mathcal{D}_\Lambda \subset \mathcal{S}_\Lambda$ such that, for every $J \in \mathcal{D}_\Lambda$,

$$0 < Z_{E,\Lambda}[J] := \int_{\mathcal{C}_\Lambda} \exp\{-\langle J, \phi \rangle_\Lambda\} \, \mathrm{d}\mu_\Lambda(\phi) < \infty. \tag{30.23}$$

In the scalar finite-dimensional convention this positive measure may be represented as a density

$$\mathrm{d}\mu_\Lambda(\phi) = Z_\Lambda^{-1} \mathrm{e}^{-S_E[\phi]} \, D_\Lambda^{\mathrm{ref}} \phi,$$

where the normalization is optional in unnormalized source functionals. In the Gaussian-reference convention the same object is written $\mathrm{e}^{-L_\Lambda[\phi]} \mathrm{d}\mu_{C_\Lambda}(\phi)$, with the relation to $D_\Lambda^{\mathrm{ref}}\phi$ given by (11.1).

Under Assumption 30.10 define

$$Z_E[J] = Z_{E,\Lambda}[J] = \mathrm{e}^{-W_E[J]}.$$

Any continuum limit $\Lambda \to \infty$ of the statements below requires an additional existence theorem for the limiting Schwinger functional. The finite-regulator argument by itself does not prove such a limit for a proposed model.

Definition 30.11 (Lorentzian–Euclidean source-convention bridge)**.** Write the Lorentzian logarithm as

$$\mathcal{W}_L[J_L] = \log Z_L[J_L] = \mathrm{i} W_L[J_L], \qquad Z_L[J_L] = \int [D\phi] \, \exp\{\mathrm{i} S_L[\phi] + \mathrm{i}\langle J_L, \phi \rangle_L\}\,.$$

Write the Euclidean logarithm in the convention used in this and the following Euclidean chapters as

$$\mathcal{W}_E[J_E] = \log Z_E[J_E] = -W_E[J_E], \qquad Z_E[J_E] = \int [D\phi]\, \exp\{-S_E[\phi] - \langle J_E, \phi\rangle_E\}\,.$$

In this definition $[D\phi]$ is only compact continuum notation for the regulated integration object already specified earlier in the chapter. In a finite-dimensional bosonic scalar regulator, the Euclidean line is represented by $D^{\mathrm{ref}}_\Lambda \phi\, \mathrm{e}^{-S_{E,\Lambda}[\phi]}$; after splitting $S_{E,\Lambda} = S_{\mathrm{kin},\Lambda} + L_\Lambda$, the same object is $\mathrm{d}\mu_{C_\Lambda}(\phi)\, \mathrm{e}^{-L_\Lambda[\phi]}$. The Lorentzian line is the corresponding oscillatory notation and carries its own regulator and boundary-value prescription. For scalar insertions with no tensor time indices, the analytic continuation from Lorentzian time-ordered connected distributions to Euclidean connected Schwinger distributions is recorded by the derivative identities

$$G_n^{L,\mathrm{c}} = \mathrm{i}^{-n} \frac{\delta^n \mathcal{W}_L}{\delta J_L(x_1)\cdots\delta J_L(x_n)}\bigg|_{J_L=0} = \mathrm{i}^{1-n} \frac{\delta^n W_L}{\delta J_L(x_1)\cdots\delta J_L(x_n)}\bigg|_{J_L=0}, \tag{30.24}$$

and

$$G_n^{E,\mathrm{c}} = (-1)^n \frac{\delta^n \mathcal{W}_E}{\delta J_E(x_1)\cdots\delta J_E(x_n)}\bigg|_{J_E=0} = (-1)^{n+1} \frac{\delta^n W_E}{\delta J_E(x_1)\cdots\delta J_E(x_n)}\bigg|_{J_E=0}. \tag{30.25}$$

The source signs in the exponents are related as follows. Under the formal coordinate rotation $t = -\mathrm{i}\tau$, the Lorentzian pairing satisfies

$$\mathrm{i}\langle J_L, \phi\rangle_L \longmapsto +\langle J_L^{\mathrm{W}}, \phi_E\rangle_E, \qquad J_L^{\mathrm{W}}(\tau, \vec{x}) = J_L(-\mathrm{i}\tau, \vec{x}),$$

whereas the Euclidean convention above uses $-\langle J_E, \phi_E\rangle_E$. Therefore the Euclidean source variable of this chapter is

$$J_E = -J_L^{\mathrm{W}} \tag{30.26}$$

when one translates a formal source insertion from the Lorentzian convention to the Euclidean convention. Equations (30.24) and (30.25), together with the analytic continuation of the connected distributions, are the matching rule used by the later Euclidean path-integral and RG chapters. For operators with Lorentz indices, spinor indices, or time derivatives, the usual Wick-rotation matrix for those indices must also be applied.

In particular, the Euclidean free-energy convention $W_E = -\log Z_E$ is opposite to the connected-log convention $\mathcal{W}_E = \log Z_E$. The source derivative of W_E has the sign displayed in (30.25); this is the sign used in the convex Legendre transform below.

Lemma 30.12 (Euclidean convexity at finite regulator)**.** *Assume Assumption 30.10. Define*

$$K[J] = \log Z_E[J], \qquad W_E[J] = -K[J].$$

Thus W_E is the Euclidean free energy. It is the negative of the connected-log functional K. Functional derivative signs are therefore fixed by two independent choices: whether one differentiates K or $-K$, and the sign with which the source is placed in the exponent. For the present source term $-\langle J, \phi\rangle$, one has $\delta W_E/\delta J = \langle\phi\rangle_J$. For a source term $+\langle J, \mathcal{O}\rangle$, the same free-energy convention gives $\delta W/\delta J = -\langle\mathcal{O}\rangle_J$. Then K is convex on $\mathcal{D}_\Lambda$, and W_E is concave on $\mathcal{D}_\Lambda$. The finite-regulator Euclidean effective action

$$\Gamma_E[\varphi] = \sup_{J\in\mathcal{D}_\Lambda} \{W_E[J] - \langle J, \varphi\rangle\}$$

is a convex functional of φ. At a differentiability point where the supremum is attained by a locally unique source J_φ satisfying

$$\varphi(x) = \left.\frac{\delta W_E[J]}{\delta J(x)}\right|_{J=J_\varphi},$$

this definition reduces to the local Legendre transform

$$\Gamma_E[\varphi] = W_E[J_\varphi] - \langle J_\varphi, \varphi\rangle, \qquad \frac{\delta \Gamma_E[\varphi]}{\delta\varphi(x)} = -J_\varphi(x),$$

and its second variation is nonnegative on the subspace where the source-field map is nonsingular.

Proof. For $J_1, J_2 \in \mathcal{D}_\Lambda$ and $0 \le t \le 1$, Holder's inequality with respect to the positive measure μ_Λ gives

$$\begin{aligned} Z_E[tJ_1 + (1-t)J_2] &= \int_{\mathcal{C}_\Lambda} \left(\mathrm{e}^{-\langle J_1,\phi\rangle_\Lambda}\right)^t \left(\mathrm{e}^{-\langle J_2,\phi\rangle_\Lambda}\right)^{1-t} \mathrm{d}\mu_\Lambda(\phi) \\ &\le Z_E[J_1]^t Z_E[J_2]^{1-t}. \end{aligned}$$

Taking the logarithm yields

$$K[tJ_1 + (1-t)J_2] \le tK[J_1] + (1-t)K[J_2],$$

so K is convex. Equivalently,

$$W_E[tJ_1 + (1-t)J_2] \ge tW_E[J_1] + (1-t)W_E[J_2].$$

For each fixed source J, the map $\varphi \mapsto W_E[J] - \langle J, \varphi\rangle$ is affine. The supremum of affine functionals is convex, proving convexity of Γ_E. If the supremum is attained at a locally unique differentiability point, its stationarity condition is $\varphi = \delta W_E/\delta J|_{J=J_\varphi}$. Differentiating $W_E[J_\varphi] - \langle J_\varphi, \varphi\rangle$ then cancels the δJ_φ terms and gives $\delta\Gamma_E/\delta\varphi = -J_\varphi$. Convexity gives, in any nonsingular local chart,

$$\int \mathrm{d}^D x\, \mathrm{d}^D y\, f(x)\Gamma_E^{(2)}(x,y) f(y) \ge 0$$

for every real test function f in the corresponding tangent subspace. □

30.9 Legendre–Fenchel Form at Finite Regulator

This section remains in the positive-measure setting of Lemma 30.12. It supplies the positive-measure finite-regulator construction. The perturbative 1PI definition used in dimensional regularization, or in any other regulator whose "path integral" is a formal algebraic prescription, is a separate construction. The two constructions agree only in a domain where both are defined and the convex conjugate is differentiable with a locally invertible source-field map.

The local inverse J_φ used above is a convenient notation. Lemma 30.12 identifies the exact finite-regulator definition as a convex-conjugate formula. At finite regulator, the source space is a finite-dimensional vector space or a specified space of test functions, depending on the regulator. Its dual is the space in which the regulated mean field φ lives, and the pairing is

$$\langle J, \varphi\rangle = \int \mathrm{d}^D x\, J(x)\varphi(x)$$

with the corresponding finite sum on a lattice.

Let

$$K[J] = \log Z_E[J], \qquad W_E[J] = -K[J].$$

Under the positivity assumption of Lemma 30.12, K is convex. The exact Euclidean effective action is the convex conjugate with the sign convention fixed by the source term $-\langle J, \phi\rangle$:

$$\Gamma_E[\varphi] = \sup_J \{-K[J] - \langle J, \varphi\rangle\} = \sup_J \{W_E[J] - \langle J, \varphi\rangle\}.$$

This formula covers cases in which the map $J \mapsto \varphi_J$ has multiple preimages or the supremum is attained by more than one source. It is also meaningful at boundary points of the domain where the supremum is represented by a limiting sequence of sources. If K is differentiable and the supremum is attained at J_φ, the stationarity condition is

$$0 = -\frac{\delta K[J_\varphi]}{\delta J(x)} - \varphi(x), \qquad \varphi(x) = \frac{\delta W_E[J_\varphi]}{\delta J(x)}.$$

Thus the earlier Legendre transform is the differentiable local form of the Legendre–Fenchel definition.

The subgradient statement is the coordinate-free replacement for the inverse source map. A source J maximizes the displayed variational expression at φ precisely when

$$-\varphi \in \partial K[J],$$

where $\partial K[J]$ is the convex subdifferential of K at J. If K is twice differentiable and its Hessian has a kernel at a source J, the source-field map is locally degenerate there. The convex-conjugate formula remains the definition. It records the supporting hyperplanes of K: an admissible mean field φ is one for which $-\varphi$ is a subgradient of K at some source, or a limit of such subgradients at a boundary point of the domain.

A finite-dimensional model displays the same logic without functional analysis. Let $\phi \in \mathbb{R}$ and

$$Z_E(J) = \int_{\mathbb{R}} \mathrm{d}\phi\, \mathrm{e}^{-S(\phi)-J\phi} = \mathrm{e}^{-W_E(J)}$$

with $S(\phi)$ a confining function. The source-dependent mean is

$$\varphi(J) = \frac{\mathrm{d}W_E}{\mathrm{d}J}.$$

In the small-fluctuation limit, $W_E(J)$ is obtained by minimizing $S(\phi) + J\phi$ with respect to ϕ. The corresponding $\Gamma_E(\varphi)$ is the convex Legendre transform. If $S(\phi)$ has more than one local minimum, different ranges of J select different stationary branches, and the exact Legendre transform produces a convex function of φ. A perturbative expansion around a chosen branch is valid where the quadratic fluctuation operator at that branch is positive.

The last clause is an analytic condition, not a matter of terminology. Choose a point ϕ_0 on a stationary branch and choose the source

$$J_0 = -S'(\phi_0).$$

The Euclidean background representation of the effective action is

$$e^{-\Gamma_E(\phi_0)} = \int d\xi \, \exp\{-S(\phi_0+\xi) - J_0\xi\}\Big|_{\langle\xi\rangle_{\phi_0,J_0}=0}.$$

The exponent is obtained by subtracting the tangent line to S at ϕ_0. Its expansion begins

$$S(\phi_0+\xi) + J_0\xi = S(\phi_0) + \frac{1}{2}S''(\phi_0)\xi^2 + O(\xi^3).$$

If $S''(\phi_0) < 0$, the Gaussian integral around this point is not a positive quadratic approximation to the finite-dimensional Euclidean integral. The exact Γ_E is then determined by the global supporting line data encoded in the Legendre–Fenchel transform, while the coefficientwise stationary-phase expansion around that branch computes only a local branch functional. This is the finite-dimensional form of the distinction between the exact convex effective action and a perturbative effective potential computed around a specified saddle.

Figure 30.5 records the local branch condition for the finite-dimensional model: perturbation theory around a chosen saddle uses a positive quadratic part, while the exact Legendre–Fenchel transform uses global supporting lines.

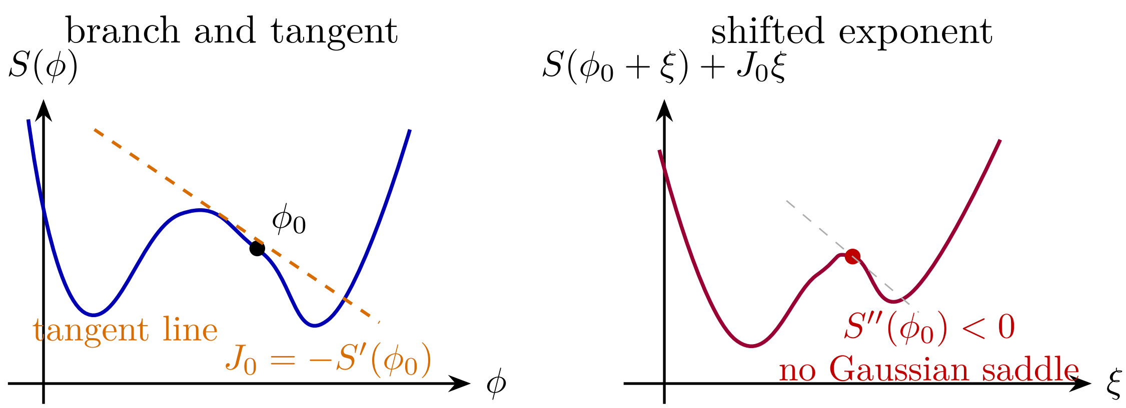

Figure 30.5: In the finite-dimensional model, the source subtracts the tangent line at the chosen mean field. Perturbation theory around that point requires the shifted exponent to have a positive quadratic part. The exact Legendre–Fenchel effective action instead uses the global supporting-line structure and is convex.

Figure 30.6 displays the convex Euclidean effective action obtained from the exact Legendre–Fenchel construction, in contrast to the nonconvex local branch just described.

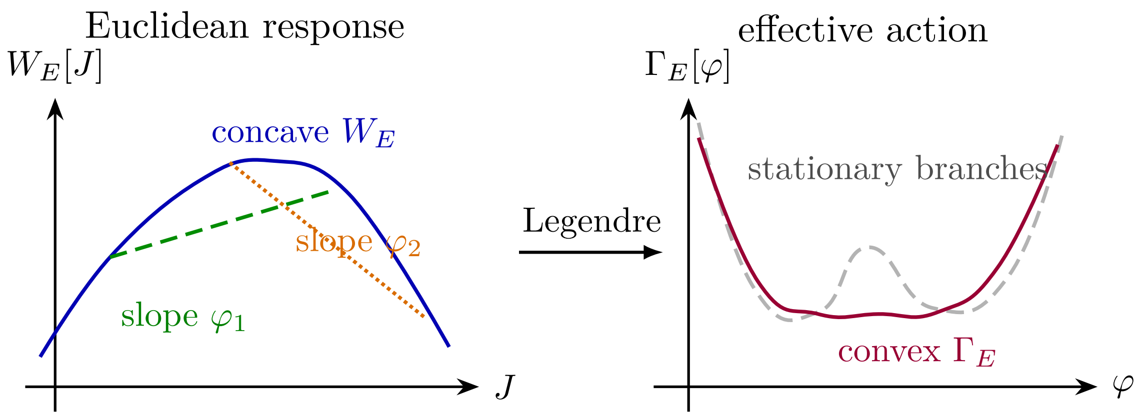

Figure 30.6: For a positive Euclidean measure and the convention $Z_E[J] = \mathrm{e}^{-W_E[J]}$, the response functional W_E is concave and the effective action Γ_E is convex. Dashed and dotted support lines distinguish two source values, while the dashed nonconvex branches are not the exact effective action. In a finite-dimensional double-well model, the exact Legendre transform connects the stable branches by the convex segment.

The Euclidean convexity theorem is a statement about the exact Legendre–Fenchel transform of a positive finite-measure source functional. A Wilsonian action at a finite cutoff scale, the regulated action that appears in the Euclidean measure, the local formal perturbative 1PI effective action, and a perturbative effective potential computed around one stationary branch are distinct functionals with distinct definitions. The next chapter uses the local formal 1PI functional as the arena in which perturbative local counterterms are identified and organized.

Chapter 31

Renormalizability and Local Counterterms

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

31.1 Regulated Euclidean Actions

Let ϕ be a real scalar field on D-dimensional Euclidean space. Fix a regulator, denoted collectively by Λ. At finite regulator the field is an element of a regulated field space $\mathcal{F}_\Lambda$: for example a finite lattice field, a finite collection of Fourier modes, or a field paired only with test functions after a smoothing kernel has been inserted. The regulated functional integral has the form

$$Z_\Lambda = \int D_\Lambda^{\mathrm{ref}}\phi \, \exp\left[-\int \mathrm{d}^D x \, \mathcal{L}_{E,\Lambda}\right],$$

where $D_\Lambda^{\mathrm{ref}}\phi$ is the finite-regulator reference density of Definition 11.3. In the alternative Gaussian-reference convention, the quadratic part of $\mathcal{L}_{E,\Lambda}$ is absorbed into $\mathrm{d}\mu_{C_\Lambda}$, and the remaining interaction is integrated with density $\exp\{-L_\Lambda[\phi]\}\mathrm{d}\mu_{C_\Lambda}(\phi)$. The Euclidean Lagrangian appearing in the path integral is written as

$$\mathcal{L}_{E,\Lambda} = \frac{1}{2}\partial_\mu\phi\,\partial_\mu\phi + \frac{1}{2}m^2\phi^2 + \sum_I g_I\,\mathcal{O}_I(\phi).$$

Each $\mathcal{O}_I$ is a local polynomial, or more generally a local function, of $\phi(x)$ and finitely many derivatives $\partial_\mu\phi(x), \partial_\mu\partial_\nu\phi(x), \ldots$. The index I includes all discrete labels required to specify the monomial: the number of fields, the derivative multi-indices, and the internal symmetry contraction when such indices are present. Operators that differ by a total derivative or by a chosen integration-by-parts convention are represented once. The coefficient g_I is a regulated local coordinate. The collection of regulated coordinates includes the parameters chosen as finite inputs and the regulator-dependent coordinates later called counterterms.

Two regulator languages will be used repeatedly. A momentum cutoff restricts Fourier modes to

$$p^2 < \Lambda^2$$

in a Euclidean invariant notation, or to a corresponding finite Brillouin zone on a lattice. Dimensional regularization assigns analytic meaning to momentum integrals in

$$D = d - \varepsilon$$

and removes the regulator by taking $\varepsilon \to 0$ after a subtraction prescription has been specified. These two languages belong to different rows of Table 11.1. The cutoff language denotes a finite-regulator field integral only after the regulated field space and density have been supplied. Dimensional regularization is not a measure on $\mathcal{F}_\Lambda$; it is a meromorphic assignment to the formal perturbative graph distributions and their tensor algebra. In both languages the regulated coordinates are allowed to depend on the regulator or analytic continuation parameter.

Definition 31.1 (Finite-parameter renormalized family)**.** Choose an open set $U \subset \mathbb{R}^N$ with coordinates

$$\lambda = (\lambda_1, \ldots, \lambda_N),$$

and choose, for each regulator value, a map from U to the regulated coordinate space,

$$b_\Lambda \colon U \longrightarrow \{g_I\}_{I\in\mathcal{I}}, \qquad \lambda \longmapsto g_I(\lambda, \Lambda),$$

or, in dimensional regularization,

$$b_\varepsilon \colon U \longrightarrow \{g_I\}_{I\in\mathcal{I}}, \qquad \lambda \longmapsto g_I(\lambda, \varepsilon).$$

The coordinates λ_a are renormalized coordinates if they are fixed by finite conditions on regulated correlation functions or 1PI kernels and if, after inserting the corresponding map b_Λ or b_ε, the chosen class of renormalized observables has a regulator-independent limit.

Definition 31.2 (Counterterm coordinates and insertion regularization)**.** For a fixed regulator and a fixed renormalized coordinate chart $\lambda \mapsto b_\Lambda(\lambda)$, there is one regulated action in the path integral,

$$S_\Lambda[\phi;\lambda] = \int \mathrm{d}^D x\, \mathcal{L}_{E,\Lambda}\big(\phi; \{g_I(\lambda,\Lambda)\}\big).$$

A *counterterm* is not a second Lagrangian added to this action from outside. It is the regulator-dependent part of the same local coordinate map b_Λ, described relative to a chosen finite reference chart λ. Thus the split into finite reference terms and counterterm terms is a bookkeeping split of $S_\Lambda[\phi;\lambda]$.

An *insertion regularization* is separate data. Before operator mixing or continuum matching is discussed, an inserted operator is represented by a regulated functional

$$\mathcal{O}^{\mathrm{ins}}_{a,\Lambda}(x;\phi)$$

or equivalently by a derivative with respect to a regulated local source. A lattice representative, a smeared functional, a point-split expression, a heat-kernel expression, a dimensional-regularization graph rule, and a source-derivative prescription are different insertion regularizations. A renormalized operator $[O_A]_\lambda$ is the finite source coordinate or finite linear combination obtained after the regulator-dependent insertion map and the action-coordinate map have been fixed and the chosen continuum limit exists. Regularization supplies finite or meromorphic objects before the limit; renormalization is the coordinate choice that produces finite matched observables and operator insertions.

Thus a perturbatively renormalizable family consists of a finite-dimensional family of coordinate maps into regulated Lagrangians. Masses, residues, and specified 1PI vertex values at Euclidean subtraction momenta are common choices of the coordinates λ_a, but the definition only requires the chosen conditions to be finite and locally independent. Local counterterms are the regulator-dependent local coordinates in b_Λ or b_ε that make these finite conditions compatible with the existence of the continuum limit. The phrase "existence of the continuum limit" denotes a theorem or hypothesis about a specified regulator family; selected rigorous scalar and gauge examples, together with scalar triviality regimes, are catalogued in Table 11.2.

31.2 Renormalized Fields and Effective Couplings

Let $\Gamma_{E,\Lambda}$ be the regulated Euclidean 1PI effective action, defined by the Euclidean Legendre construction of the preceding chapter. A field normalization is a regulator-dependent nonzero scalar $Z_R(\lambda, \Lambda)$, or a matrix in a theory with several fields. For a single scalar we write

$$\phi_R(x) = Z_R^{-1/2}\phi(x).$$

The normalization condition can be imposed, for instance, by requiring the coefficient of p^2 in the renormalized two-point 1PI kernel at a chosen Euclidean subtraction point to equal a prescribed finite value. The precise condition is part of the coordinate choice λ.

The Green-function finiteness criterion is distributional. For every n in the chosen class and every test function $f \in C_c^\infty((\mathbb{R}^D)^n)$, require

$$\lim_{\Lambda\to\infty} \int \prod_{a=1}^{n} \mathrm{d}^D x_a\, f(x_1, \ldots, x_n)\langle \phi_R(x_1)\cdots\phi_R(x_n)\rangle_{E,\Lambda;\lambda}$$

to exist. The same statement in dimensional regularization is the existence of the $\varepsilon \to 0$ limit after the prescribed subtractions. This is a criterion for the correlation distributions themselves; it is stronger than the statement that a finite number of Taylor coefficients is finite.

On a Euclidean momentum domain where the two-point kernel is invertible and no infrared singularity is being tested, the connected Green functions are reconstructed from the exact 1PI kernels by trees. Therefore, order by order in perturbation theory, finiteness of the renormalized 1PI kernels

$$\Gamma^{(n)}_{E,R,\Lambda}(p_1, \ldots, p_n; \lambda) = Z_R^{n/2}\Gamma^{(n)}_{E,\Lambda}(p_1, \ldots, p_n; b_\Lambda(\lambda))$$

as distributions on such momentum domains is equivalent to finiteness of the connected functions on the corresponding domains. This equivalence uses the Legendre relation and the inverse two-point kernel.

For local counterterm classification one extracts only the local Taylor coefficients of the renormalized 1PI action. Define

$$\widetilde{\Gamma}_{E,\Lambda}[\phi_R] = \Gamma_{E,\Lambda}[Z_R^{1/2}\phi_R].$$

Near a subtraction point at which the relevant kernels are analytic, write the local part as

$$\widetilde{\Gamma}^{\mathrm{loc}}_{E,\Lambda}[\phi_R] = S_{\mathrm{kin}}[\phi_R] + \int \mathrm{d}^D x \sum_I g^{\mathrm{eff}}_{I,\Lambda}(\lambda)\, \mathcal{O}_I(\phi_R).$$

Here S_{kin} is the chosen finite quadratic reference action and $\widetilde{\Gamma}^{\mathrm{loc}}$ denotes the Taylor-polynomial part in external momenta. The local 1PI finiteness condition is

$$\lim_{\Lambda\to\infty} g^{\mathrm{eff}}_{I,\Lambda}(\lambda) \qquad \text{finite}$$

for every local operator coefficient included in the finite-list renormalized description. Nonlocal terms in the exact 1PI action, such as threshold logarithms, belong to the finite continuum correlation functions.

The same structure appears directly in the regulated action. Suppose the cutoff-dependent quadratic coordinate is represented by

$$S_{\mathrm{quad}}[\phi] = \frac{1}{2}\int \mathrm{d}^D x\, \phi(-\partial^2 + m_0^2)\phi.$$

After $\phi = Z_R^{1/2}\phi_R$, choose a finite mass parameter m_R and write

$$\begin{aligned} S_{\mathrm{quad}}[Z_R^{1/2}\phi_R] = \frac{1}{2}\int \mathrm{d}^D x\, \phi_R(-\partial^2 + m_R^2)\phi_R \\ + \frac{Z_R - 1}{2}\int \mathrm{d}^D x\, \phi_R(-\partial^2 + m_R^2)\phi_R + \frac{1}{2}\delta m^2 \int \mathrm{d}^D x\, \phi_R^2. \end{aligned}$$

The first line is the finite quadratic reference action. The second line is local and is treated perturbatively as the wavefunction and mass counterterm part of the interaction.

Thus perturbation theory is organized by writing

$$\widetilde{S}_\Lambda[\phi_R] = S_{\mathrm{ref}}[\phi_R] + S_{\mathrm{int}}[\phi_R;\lambda] + S_{\mathrm{ct}}[\phi_R;\lambda,\Lambda],$$

where S_{ct} is local and regulator dependent. The finite parts of the counterterms are part of the renormalization prescription: changing them changes the coordinate system λ on the same perturbative family. The displayed split is a split of the single regulated action $\widetilde{S}_\Lambda[\phi_R]$, not a division into a physical action and an external local functional.

31.3 Locality as Extension of Distributions

The locality of counterterms has an intrinsic position-space formulation. In position space, a Feynman graph with vertices

$$x_1, \ldots, x_r$$

defines a distribution on the configuration space where no ultraviolet collision has occurred. Ultraviolet renormalization extends this distribution across the collision diagonals, such as

$$x_{i_1} = \cdots = x_{i_k}.$$

The possible ambiguities in the extension are local distributions supported on those diagonals.

Definition 31.3 (Scaling degree)**.** Let $T \in \mathcal{D}'(\mathbb{R}^n \setminus \{0\})$. For $\lambda > 0$, define the scaled distribution T_λ by

$$\langle T_\lambda, f \rangle = \lambda^{-n} \left\langle T, f(\lambda^{-1} \cdot) \right\rangle, \qquad f \in C_c^\infty(\mathbb{R}^n \setminus \{0\}).$$

The scaling degree of T at the origin is

$$\mathrm{sd}_0(T) = \inf \left\{ \delta \in \mathbb{R} : \lambda^\delta T_\lambda \to 0 \text{ in } \mathcal{D}'(\mathbb{R}^n \setminus \{0\}) \text{ as } \lambda \to 0^+ \right\}.$$

The extension theorem is the distribution-theoretic core of perturbative locality.

Theorem 31.4 (Extension at a diagonal)**.** *Let $T \in \mathcal{D}'(\mathbb{R}^n \setminus \{0\})$ have finite scaling degree $s = \mathrm{sd}_0(T)$. There exists an extension $\overline{T} \in \mathcal{D}'(\mathbb{R}^n)$ whose restriction to $\mathbb{R}^n \setminus \{0\}$ is T and whose scaling degree is still s. If $s < n$, this extension is unique. If $s \geq n$, any two extensions of scaling degree s differ by*

$$\sum_{|\alpha| \leq \lfloor s \rfloor - n} c_\alpha \, \partial^\alpha \delta^{(n)}(x),$$

with constants c_α.

Proof. We give the proof in the one-diagonal model; the general diagonal is reduced to this model by separating center-of-mass and relative coordinates. Let $m = \lfloor s \rfloor - n$. If $s < n$, choose a smooth cutoff χ that is equal to 1 near 0, and set $\chi_\epsilon(x) = \chi(x/\epsilon)$. For $f \in C_c^\infty(\mathbb{R}^n)$, define

$$\langle \overline{T}, f \rangle = \lim_{\epsilon \to 0^+} \langle T, (1 - \chi_\epsilon) f \rangle.$$

The scaling-degree hypothesis with $s < n$ implies that the contribution from the annulus $\epsilon < |x| < 2\epsilon$ is $O(\epsilon^{n-s-\eta})$ for every $\eta > 0$ small enough; hence the limit exists and is independent of the cutoff. This defines an extension with the same scaling degree. If two such extensions existed, their difference would be supported at 0. A distribution supported at 0 is a finite sum $\sum c_\alpha \partial^\alpha \delta$, and $\mathrm{sd}_0(\partial^\alpha \delta) = n + |\alpha| \geq n$. Since $s < n$, no nonzero supported-at-zero difference is allowed. This proves existence and uniqueness in the convergent case.

Assume now $s \geq n$. Choose test functions $w_\alpha \in C_c^\infty(\mathbb{R}^n)$, indexed by $|\alpha| \leq m$, such that

$$\partial^\beta w_\alpha(0) = \delta_{\alpha\beta} \qquad (|\alpha|, |\beta| \leq m).$$

Define the Taylor-subtraction projector

$$Wf = f - \sum_{|\alpha| \leq m} (\partial^\alpha f)(0) \, w_\alpha.$$

Then all derivatives of Wf at the origin through order m vanish. This vanishing improves the small-scale behavior exactly enough that the same cutoff limit

$$\langle \overline{T}_0, f \rangle = \lim_{\epsilon \to 0^+} \langle T, (1 - \chi_\epsilon) Wf \rangle$$

exists and has scaling degree s. The functional $\overline{T}_0$ agrees with T on test functions supported away from 0, because then the subtraction terms may be chosen away from the support and the cutoff is eventually zero on the support.

The choice of w_α and the values assigned to the Taylor coefficients at the origin are not canonical. Adding

$$\sum_{|\alpha|\le m} c_\alpha\, \partial^\alpha \delta^{(n)}$$

keeps the restriction to $\mathbb{R}^n \setminus \{0\}$ and has scaling degree at most $n+m \le s$. Conversely, if $\overline{T}_1$ and $\overline{T}_2$ are two extensions with scaling degree s, their difference is supported at 0, so it is a finite sum of derivatives of δ. The scaling-degree bound excludes all terms with $n+|\alpha| > s$, hence $|\alpha| \le \lfloor s \rfloor - n = m$. This is exactly the displayed ambiguity. □

Remark 31.5 (Ultraviolet content of the scaling-degree theorem). This theorem is local at the diagonal. Its hypotheses already assume that a distribution T is defined on the punctured configuration space $\mathbb{R}^n \setminus \{0\}$, and the conclusion controls only the missing ultraviolet point 0. It does not assert that a massless graph or Schwinger function exists as a global distribution before infrared renormalization, nor does it control large-distance behavior, zero-momentum limits, or exceptional momentum configurations.

For example, a massless Euclidean propagator may have finite scaling degree at the origin as a distribution on compactly supported test functions, while an integrated graph containing it may fail to have an infrared-finite meaning without an additional prescription. If an amplitude is already infrared divergent before the collision point is restored, then the assumption $T \in \mathcal{D}'(\mathbb{R}^n \setminus \{0\})$ has failed. In massless critical applications the extension theorem is therefore used only after an infrared-safe setup has been specified: nonexceptional external momenta, a finite-volume or small-mass limit, a Wilsonian cutoff construction, BPHZL subtractions, or an equivalent prescription. With that extra datum in place, the scaling degree classifies the local ultraviolet ambiguity, not the infrared existence problem.

For a graph subconfiguration collapsing to a diagonal, translation invariance removes the center-of-mass coordinate, so $n = D(k-1)$ for k colliding vertices. The integer

$$\omega = \lfloor \mathrm{sd}_0(T) \rfloor - n$$

is the degree of local ambiguity. A derivative $\partial^\alpha \delta^{(n)}(x)$ supported on the diagonal is, after Fourier transform, a polynomial of degree $|\alpha|$ in the momenta entering the collapsed subgraph. Thus the extension theorem gives exactly the local Taylor polynomial counterterms used in momentum-space renormalization.

Multiple collision diagonals meet along smaller diagonals. Choosing extensions compatibly over this stratified configuration space is the position-space form of the subdivergence problem. The forest formulas in the next chapter organize the same compatibility in momentum space: each divergent subgraph corresponds to one collision diagonal, and each counterterm is the allowed derivative-of-delta ambiguity on that diagonal.

31.4 First Counterterm Census in Four Dimensions

The local nature of the required terms is visible in low-order scalar examples. Vacuum-energy terms are omitted from the census because they affect only the zero-point functional. Linear tadpole terms are fixed by the chosen expansion point; in a theory without a symmetry forbidding them, their counterterms are included among the local coordinates. In the following diagrams, a shaded disk labelled 1PI denotes the full one-particle-irreducible vertex being tested after this vacuum and tadpole bookkeeping has been imposed.

First take a $D = 4$ scalar theory with a cubic vertex $\int g_3\phi^3$, expanded about a point at which the one-point function has been fixed by a tadpole condition. The one-loop two-point graph contains the integral

$$g_3^2 \int^\Lambda \frac{\mathrm{d}^4 q}{(2\pi)^4} \frac{1}{(q^2+m^2)^2} \sim g_3^2 \log \Lambda.$$

It contributes to the local operator ϕ^2, and is canceled by a mass counterterm. The corresponding one-loop triangle and box integrals are ultraviolet finite in four dimensions.

For a $D = 4$ scalar theory with a quartic vertex $\int g_4\phi^4$, the one-loop two-point 1PI graph is a tadpole. Up to the normalization chosen for the quartic vertex, it has the form

$$\Sigma^{(1)}(p) = C_4 g_4 \int^\Lambda \frac{\mathrm{d}^4 q}{(2\pi)^4} \frac{1}{q^2+m^2},$$

where C_4 is a numerical combinatorial constant. This expression is independent of the external momentum p. It therefore contributes to the local operator ϕ^2, but not to $\partial_\mu\phi\,\partial_\mu\phi$; equivalently the one-loop coefficient of the wavefunction counterterm is

$$\delta Z^{(1)}_{\phi^4} = 0.$$

The first logarithmically divergent momentum-dependent two-point contribution in ϕ^4_4 is the two-loop sunset graph, whose Taylor coefficient at order p^2 is local and is canceled by δZ. The vanishing of $\delta Z^{(1)}_{\phi^4}$ is only a one-loop census result; it is not a criterion for excluding the kinetic counterterm from the local chart. The four-point 1PI function already has a logarithmic divergence at one loop. The candidate $D = 4$, ϕ^4 local chart therefore contains

$$\delta m^2\phi^2, \qquad \delta Z\,\partial_\mu\phi\,\partial_\mu\phi, \qquad \delta g_4\phi^4.$$

The power-counting argument in the next section then proves that this candidate list is closed: higher n-point 1PI functions with $n \geq 6$ have negative superficial degree of divergence.

For $D = 4$ scalar theory with a sextic vertex $\int g_6\phi^6$, the first tests already generate both a cutoff-dependent correction to the sextic coupling and higher local terms. The six-point 1PI kernel receives a quadratically divergent local contribution of the form

$$\delta g_6\,\phi^6, \qquad \delta g_6 = O(g_6^2\Lambda^2)$$

up to logarithms and finite prescription-dependent terms. The eight-point 1PI kernel has logarithmic behavior,

$$\delta g_8\,\phi^8, \qquad \delta g_8 = O(g_6^2 \log \Lambda).$$

At the next stages, the same local-subgraph mechanism generates

$$\delta g_{10}\phi^{10}, \qquad \delta g_{12}\phi^{12}, \qquad \ldots.$$

The cutoff-removal limit then requires an unbounded sequence of independent local coefficients.

Figure 31.1 summarizes this first counterterm census: the finite local list for renormalizable scalar interactions in four dimensions and the proliferation generated by a sextic interaction.

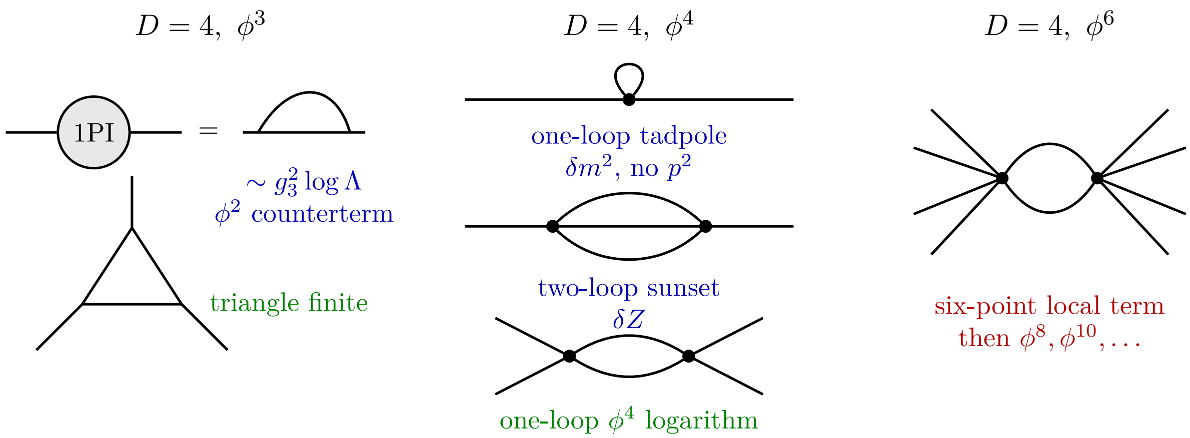

Figure 31.1: A first counterterm census in four dimensions, after vacuum-energy and tadpole bookkeeping has been fixed. Cubic and quartic scalar interactions require local terms from a finite operator list. In the quartic theory the one-loop tadpole fixes only the mass counterterm, while the field-strength counterterm first appears through the two-loop sunset. A sextic interaction generates higher local operators under loop corrections.

31.5 Engineering Dimensions and the Finite List

The preceding examples are organized by engineering dimension. Assign dimension $[x] = -1$ and $[\partial_\mu] = 1$. The Euclidean action is dimensionless. Since the kinetic term is

$$\frac{1}{2}\int \mathrm{d}^D x\, \partial_\mu\phi\, \partial_\mu\phi,$$

the field has engineering dimension

$$[\phi] = \frac{D-2}{2}.$$

Let $\mathcal{O}_I$ contain n_I fields and ℓ_I derivatives. Its engineering dimension is

$$d_I = \ell_I + n_I\frac{D-2}{2},$$

and the coupling multiplying it has dimension

$$[g_I] = D - d_I.$$

Lemma 31.6 (Power-counting finite-list criterion)**.** *Let G be a graph contributing to the coefficient of a local operator $\mathcal{O}_I$ in the 1PI effective action. Denote by $V(G)$ the multiset of interaction vertices in the graph, and let d_v be the engineering dimension of the local operator at v. After the external momentum derivatives that extract $\mathcal{O}_I$ have been taken, the superficial ultraviolet scaling has the form*

$$\left(\prod_{v\in V(G)} g_v\right)\Lambda^{(D-d_I)-\sum_{v\in V(G)}(D-d_v)}\big(\log\Lambda\big)^r, \qquad 0 \le r \le L,$$

where L is the loop number. An overall local counterterm for $\mathcal{O}_I$ can be required only when

$$D - d_I - \sum_{v \in V(G)} (D - d_v) \geq 0. \tag{31.1}$$

If all interaction vertices present in the regulated local chart have $d_v \leq D$, then every superficially required overall local counterterm has $d_I \leq D$. For scalar polynomial interactions with finitely many derivatives at fixed D, after imposing the chosen symmetries and integration-by-parts conventions, the space of such local operators is finite dimensional.

Proof. The coefficient g_I^{eff} of $\mathcal{O}_I$ in the 1PI effective action is extracted by differentiating an n_I-point 1PI vertex with respect to the appropriate external momenta and then setting those momenta to zero, or to a specified Euclidean subtraction point, provided the chosen point is infrared regular. Under the ultraviolet rescaling of all loop momenta by Λ, the coefficient of a dimension-d_I local operator must have engineering dimension $D - d_I$. The product of vertices contributes the dimension $\sum_v (D - d_v)$. Therefore the remaining cutoff dependence has the power displayed in the statement; logarithms can occur only when homogeneous powers collide or after nested integrations, and their degree is bounded at fixed loop order. This is a statement about the overall ultraviolet scaling after subdivergences have either been absent or treated recursively by the next chapter's forest formula.

If every coupling appearing in the action has $d_v \leq D$, then $D - d_v \geq 0$. Inequality (31.1) implies $d_I \leq D$. For scalar polynomial interactions with finitely many derivatives at fixed D, after imposing the chosen symmetries and integration-by-parts conventions there are only finitely many local operators with $d_I \leq D$. This is the power-counting finite-list criterion for perturbative renormalizability: every local ambiguity allowed by superficial ultraviolet scaling lies in a fixed finite-dimensional local operator space. □

If an interaction with $d_J > D$ is included and its coefficient is allowed to participate in the cutoff-removal problem on the same footing, repeated insertions can satisfy the inequality for operators of arbitrarily large dimension. Such a Lagrangian is still a valid low-energy effective description at finite cutoff. Its cutoff-removal problem, with that interaction iterated to all orders on the same footing as marginal or relevant couplings, requires an unbounded sequence of independent local coordinates by this power-counting criterion.

31.6 A Renormalizable Model in Six Dimensions

The scalar cubic interaction is marginal in $D = 6$. Use the Euclidean Lagrangian, written in terms of the renormalized field,

$$\begin{aligned}\mathcal{L}_E = \frac{1}{2}\partial_\mu\phi\,\partial_\mu\phi + \frac{1}{2}m_R^2\phi^2 + \delta Z\left(\frac{1}{2}\partial_\mu\phi\,\partial_\mu\phi + \frac{1}{2}m_R^2\phi^2\right) \\ + \frac{1}{2}\delta m^2\phi^2 + \frac{1}{3!}(g_R + \delta g)\phi^3.\end{aligned}$$

In dimensional regularization with $D = 6 - \varepsilon$, the last term is understood as

$$\frac{\mu^{\varepsilon/2}}{3!}(g_R + \delta g)\phi^3,$$

so that g_R is dimensionless and μ is the subtraction scale. The finite parameters are m_R, g_R, and the normalization convention for ϕ. The counterterm coordinates are

$$\delta Z, \qquad \delta m^2, \qquad \delta g.$$

They are functions of m_R, g_R, μ and of the regulator.

Lemma 31.7 (One-loop local poles in six-dimensional cubic theory)**.** *In the $D = 6 - \varepsilon$ scalar cubic model above, the order-g_R^2 self-energy pole is a local polynomial*

$$\Sigma_2(k)\big|_{\text{pole}} = -\frac{g_R^2}{6(4\pi)^3}\frac{k^2}{\varepsilon} - \frac{g_R^2}{(4\pi)^3}\frac{m_R^2}{\varepsilon} + O(\varepsilon^0).$$

It is canceled by δZ and δm^2. The order-g_R^3 one-loop three-point pole is local in the cubic vertex and is canceled by δg, while the one-loop four-point box is ultraviolet finite by power counting.

Proof. At order g_R^2, the one-loop self-energy is

$$\Sigma_2(k) = \frac{1}{2}g_R^2 \int \frac{\mathrm{d}^D\ell}{(2\pi)^D} \frac{1}{(\ell^2 + m_R^2)((k-\ell)^2 + m_R^2)}.$$

Combining denominators gives

$$\Sigma_2(k) = \frac{1}{2}g_R^2 \int_0^1 \mathrm{d}x \int \frac{\mathrm{d}^D\ell}{(2\pi)^D} \frac{1}{\left(\ell^2 + x(1-x)k^2 + m_R^2\right)^2}.$$

In dimensional regularization,

$$\int \frac{\mathrm{d}^D\ell}{(2\pi)^D} \frac{1}{(\ell^2 + \Delta)^n} = \frac{1}{(4\pi)^{D/2}} \frac{\Gamma(n - D/2)}{\Gamma(n)} \Delta^{D/2-n}.$$

For $D = 6 - \varepsilon$, this gives

$$\Sigma_2(k) = \frac{1}{2}g_R^2 \frac{\Gamma(-1+\varepsilon/2)}{(4\pi)^{3-\varepsilon/2}} \int_0^1 \mathrm{d}x \left(m_R^2 + x(1-x)k^2\right)^{1-\varepsilon/2}.$$

The pole part is therefore a local polynomial

$$\Sigma_2(k)\big|_{\text{pole}} = A_1(\varepsilon)\, k^2 + B_1(\varepsilon)\, m_R^2,$$

where A_1 and B_1 have simple $1/\varepsilon$ poles in minimal subtraction. In the normalization of the displayed integral,

$$A_1(\varepsilon) = -\frac{g_R^2}{6(4\pi)^3}\frac{1}{\varepsilon} + O(\varepsilon^0), \qquad B_1(\varepsilon) = -\frac{g_R^2}{(4\pi)^3}\frac{1}{\varepsilon} + O(\varepsilon^0),$$

where the finite parts depend on the subtraction prescription. The finite renormalized self-energy has the large-momentum form

$$\Sigma_{2,R}(k) = (\alpha k^2 + \beta m_R^2)\log\frac{k^2}{\mu^2} + c_1 k^2 + c_0 m_R^2 + O(m_R^4/k^2) \qquad (k^2 \gg m_R^2)$$

for finite constants α, β, c_0, c_1 fixed by the chosen finite renormalization. The counterterms δZ and δm^2 are chosen so that the pole part is canceled and $\Sigma_{2,R}$ is finite at the subtraction point.

At order g_R^3, the one-loop three-point triangle has a logarithmic ultraviolet divergence. Write the corresponding scalar kernel, with the overall graph symmetry and sign convention suppressed because they do not affect locality, as

$$I_3(p_1, p_2, p_3) = \int \frac{\mathrm{d}^D \ell}{(2\pi)^D} \frac{1}{(\ell^2 + m_R^2)((\ell + p_1)^2 + m_R^2)((\ell - p_3)^2 + m_R^2)}, \qquad p_1 + p_2 + p_3 = 0. \tag{31.2}$$

Feynman parameters give

$$\begin{aligned} I_3(p_1, p_2, p_3) = 2 \int_{\Delta_2} & \mathrm{d}x_1 \mathrm{d}x_2 \mathrm{d}x_3 \, \delta(1 - x_1 - x_2 - x_3) \\ & \times \int \frac{\mathrm{d}^D L}{(2\pi)^D} \frac{1}{(L^2 + \Delta_3(x, p, m_R))^3}, \end{aligned} \tag{31.3}$$

where the shifted loop momentum L removes the linear term and Δ_3 is a polynomial in m_R^2 and the pairwise external invariants. Using the same dimensional-regularization formula as above,

$$\int \frac{\mathrm{d}^D L}{(2\pi)^D} \frac{1}{(L^2 + \Delta)^3} = \frac{1}{(4\pi)^{D/2}} \frac{\Gamma(3 - D/2)}{2} \Delta^{D/2 - 3}.$$

For $D = 6 - \varepsilon$,

$$\frac{\Gamma(3 - D/2)}{2} \Delta^{D/2 - 3} = \frac{1}{\varepsilon} + O(\varepsilon^0),$$

and the simplex volume, including the prefactor 2 in (31.3), is one. Hence the triangle pole is independent of p_1, p_2, p_3:

$$I_3(p_1, p_2, p_3)\big|_{\text{pole}} = \frac{1}{(4\pi)^3} \frac{1}{\varepsilon} + O(\varepsilon^0). \tag{31.4}$$

Equivalently, write the difference from $I_3(0, 0, 0)$ as an integral of the first derivative of the integrand along the straight line from zero external momenta to (p_1, p_2, p_3). That derivative has large-ℓ behavior $O(|\ell|^{-7})$, so the six-dimensional radial integral is convergent at infinity. The pole therefore multiplies exactly the local cubic vertex and is canceled by δg. The one-loop four-point box in $D = 6$ is ultraviolet finite by power counting: four propagators give large-ℓ behavior $\mathrm{d}^6 \ell \, \ell^{-8}$. □

Figure 31.2 displays the two one-loop kernels used in this six-dimensional ϕ^3 check: the two-point kernel with mass and kinetic local parts, and the local three-point vertex subtraction.

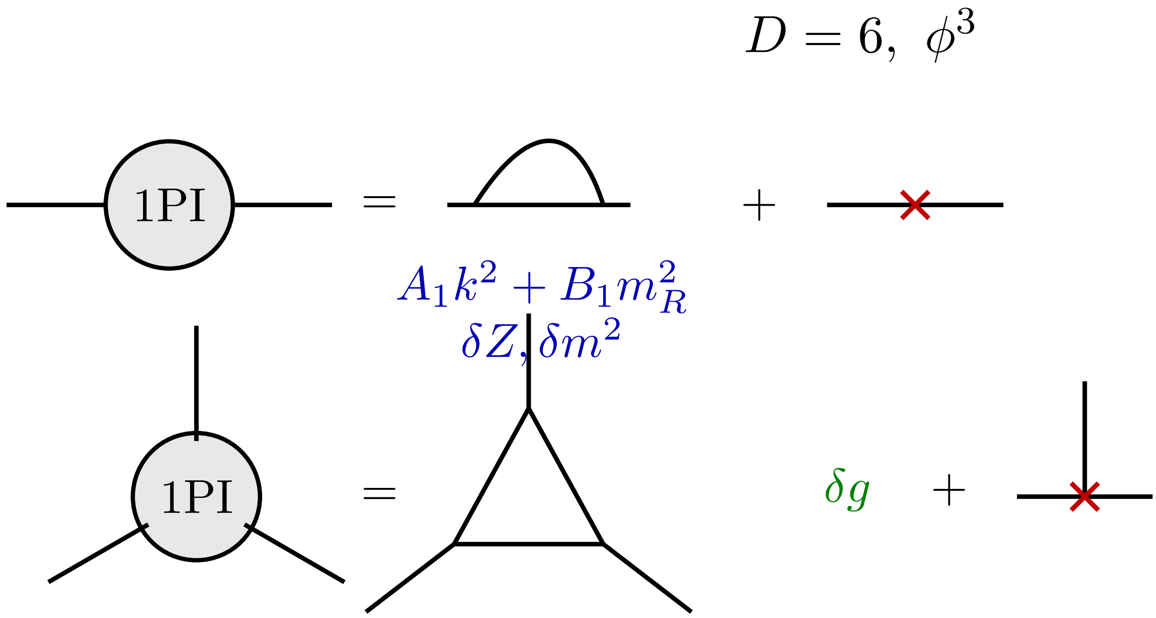

Figure 31.2: In six-dimensional ϕ^3 theory, the one-loop two-point divergence is local in k^2 and m_R^2, and the one-loop three-point divergence is local in the cubic vertex.

31.7 Locality at Higher Order

The one-loop renormalized self-energy in the six-dimensional cubic theory has large Euclidean momentum behavior

$$\Sigma_R(q) \sim (\alpha q^2 + \beta m_R^2) \log \frac{q^2}{\mu^2}, \qquad q^2 \gg m_R^2,$$

for finite constants α, β determined by the subtraction scheme. When this renormalized subgraph is inserted into a larger self-energy graph, the ultraviolet region of the remaining integral is represented by

$$\int \frac{\mathrm{d}^6 q}{(2\pi)^6} \frac{\Sigma_R(q)}{(q^2 + m_R^2)^2((k-q)^2 + m_R^2)}.$$

The external momentum dependence is isolated by expanding

$$\frac{1}{(k-q)^2 + m_R^2} = \frac{1}{q^2 + m_R^2} - \frac{k^2 - 2k \cdot q}{(q^2 + m_R^2)^2} + \frac{4(k \cdot q)^2}{(q^2 + m_R^2)^3} + R_3(q, k),$$

where Taylor's formula gives $R_3(q,k) = O(|k|^3 |q|^{-5})$ for $|q| \gg |k|, m_R$. Because

$$\frac{\Sigma_R(q)}{(q^2 + m_R^2)^2} = O\left(\frac{\log q^2}{q^2}\right), \qquad |q| \to \infty,$$

the remainder contributes an integrand

$$\mathrm{d}^6 q \; O\left(\frac{\log q^2}{|q|^7}\right),$$

which is ultraviolet convergent. The displayed Taylor terms are local in the external momentum through order k^2. After angular integration, odd powers of q vanish and $(k \cdot q)^2$ becomes proportional to $k^2 q^2$. Thus the divergent part contributes only to the ϕ^2 and $(\partial\phi)^2$ counterterms.

Dimensional regularization expresses the same fact algebraically. Integrals of the form

$$\int \frac{\mathrm{d}^D q}{(2\pi)^D} \frac{\log(q^2+\Delta)}{(q^2+\Delta)^n} = -\frac{\partial}{\partial n}\left[\frac{1}{(4\pi)^{D/2}} \frac{\Gamma(n-D/2)}{\Gamma(n)} \Delta^{D/2-n}\right]$$

produce double and single poles in ε. For the self-energy insertion, the pole part has the local form

$$\Sigma_{\text{insertion}}(k)\big|_{\text{pole}} = A_\varepsilon k^2 + B_\varepsilon m_R^2, \qquad A_\varepsilon = \frac{a_2}{\varepsilon^2} + \frac{a_1}{\varepsilon}, \qquad B_\varepsilon = \frac{b_2}{\varepsilon^2} + \frac{b_1}{\varepsilon}.$$

The coefficients a_i, b_i are finite constants depending on the finite renormalization prescription. The pole part is polynomial in the external momentum, so it is represented by local counterterms already present in the six-dimensional cubic Lagrangian. The absence of a pole of the form

$$\frac{1}{\varepsilon} \log k^2$$

is essential: such a term would be nonlocal in position space and could not be canceled by a local Lagrangian counterterm. The reason it is absent is visible before integration over Feynman parameters. For $D = 6 - \varepsilon$ and $n = 2, 3$,

$$\frac{1}{(4\pi)^{D/2}} \frac{\Gamma(n-D/2)}{\Gamma(n)} \Delta^{D/2-n} = \left(\frac{c_n}{\varepsilon} + c_n' \log \Delta\right) \Delta^{3-n} + O(\varepsilon^0),$$

with constants c_n, c_n'. Differentiating with respect to n, as in the logarithmic integral above, produces

$$\left(\frac{c_{n,2}}{\varepsilon^2} + \frac{c_{n,1}}{\varepsilon}\right) \Delta^{3-n} + O(\varepsilon^0),$$

because the $\varepsilon^{-1} \log \Delta$ pieces cancel between the derivative of the gamma function and the derivative of $\Delta^{D/2-n}$.

Figure 31.3 isolates the local k^0 and k^2 terms left by a renormalized self-energy insertion before the remaining large-momentum integral is made convergent.

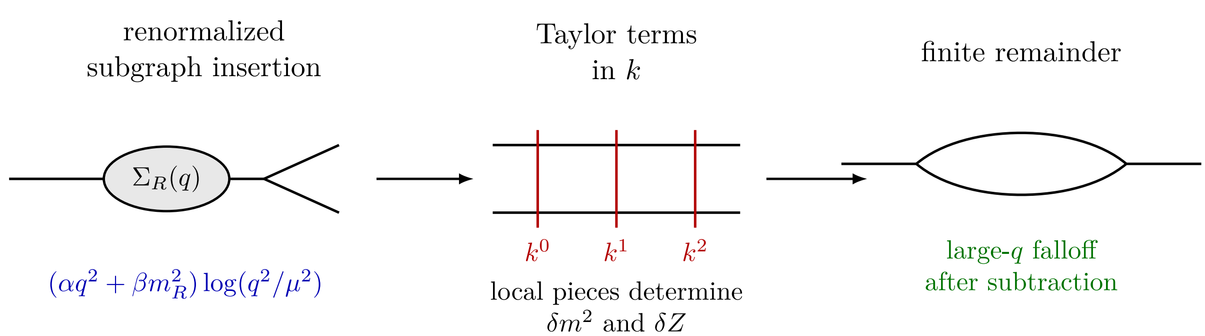

Figure 31.3: A renormalized subgraph can leave logarithmic large-momentum behavior. Expanding the remaining propagator in the external momentum separates the local k^0 and k^2 terms from a convergent remainder.

31.8 Schwinger Parameters and Subdivergent Regions

The same mechanism appears geometrically in Schwinger parameters. Consider the two-loop self-energy graph in $D = 6$ cubic theory with two loop momenta ℓ_1, ℓ_2:

$$\frac{g_R^4}{2} \int \frac{\mathrm{d}^6 \ell_1}{(2\pi)^6} \frac{\mathrm{d}^6 \ell_2}{(2\pi)^6} P(\ell_1) P(k - \ell_1) P(\ell_2) P(k - \ell_2) P(\ell_1 - \ell_2),$$

where

$$P(\ell) = \frac{1}{\ell^2 + m_R^2}.$$

Using

$$P(\ell) = \int_0^\infty \mathrm{d}\alpha \, \mathrm{e}^{-\alpha(\ell^2 + m_R^2)},$$

the Gaussian loop integrations produce an integrand of the form

$$\frac{1}{(4\pi)^6} \int_0^\infty \prod_{i=1}^5 \mathrm{d}\alpha_i \, \frac{\mathrm{e}^{-m_R^2 \sum_i \alpha_i - k^2 Q(\alpha)}}{(\det A)^3},$$

with

$$A = \begin{pmatrix} \alpha_1 + \alpha_2 + \alpha_5 & -\alpha_5 \\ -\alpha_5 & \alpha_3 + \alpha_4 + \alpha_5 \end{pmatrix}.$$

The function $Q(\alpha)$ is nonnegative. Ultraviolet regions are boundary regions in which Schwinger parameters of a subgraph go to zero. Explicitly,

$$Q(\alpha) = \alpha_2 + \alpha_4 - (\alpha_2, \alpha_4) A^{-1} \begin{pmatrix} \alpha_2 \\ \alpha_4 \end{pmatrix} \geq 0.$$

Writing

$$F(k^2; \alpha_1, \ldots, \alpha_5) = \frac{\exp[-k^2 Q(\alpha)]}{(\det A)^3},$$

one has the homogeneous scaling relation

$$\rho^6 F\left(\frac{k^2}{\rho}; \rho\alpha_1, \ldots, \rho\alpha_5\right) = F(k^2; \alpha_1, \ldots, \alpha_5).$$

There are two one-loop subdivergent regions:

$$\alpha_1, \alpha_2, \alpha_5 \to 0, \qquad \alpha_3, \alpha_4, \alpha_5 \to 0.$$

They correspond to shrinking the left or right one-loop self-energy subgraph. The counterterm insertions for the one-loop self-energy subtract the limiting functions associated with these boundary regions. At the level of the Schwinger-parameter integrand this replacement is

$$\begin{aligned} \widetilde{F} = F &- \lim_{\rho \to 0} \rho^3 F(k^2; \rho\alpha_1, \rho\alpha_2, \alpha_3, \alpha_4, \rho\alpha_5) \\ &- \lim_{\rho \to 0} \rho^3 F(k^2; \alpha_1, \alpha_2, \rho\alpha_3, \rho\alpha_4, \rho\alpha_5). \end{aligned}$$

After these subtractions, the remaining overall ultraviolet region is the simultaneous scaling

$$\alpha_1, \dots, \alpha_5 \to 0.$$

Power counting then says that its dependence on the external momentum is at most quadratic. Subtracting the k^0 and k^2 Taylor terms leaves a finite parameter integral. The overall counterterm is therefore again a linear combination of ϕ^2 and $(\partial\phi)^2$. Equivalently, the finite remainder may be represented by replacing $\widetilde{F}$ with

$$\widetilde{F}_R(k^2;\alpha) = \widetilde{F}(k^2;\alpha) - \widetilde{F}(0;\alpha) - \left.\frac{\partial \widetilde{F}}{\partial k^2}\right|_{k^2=0} k^2.$$

Figure 31.4 translates the same locality statement into Schwinger parameters: one-loop boundary faces are subtracted first, and the overall boundary face then supplies the remaining local terms.

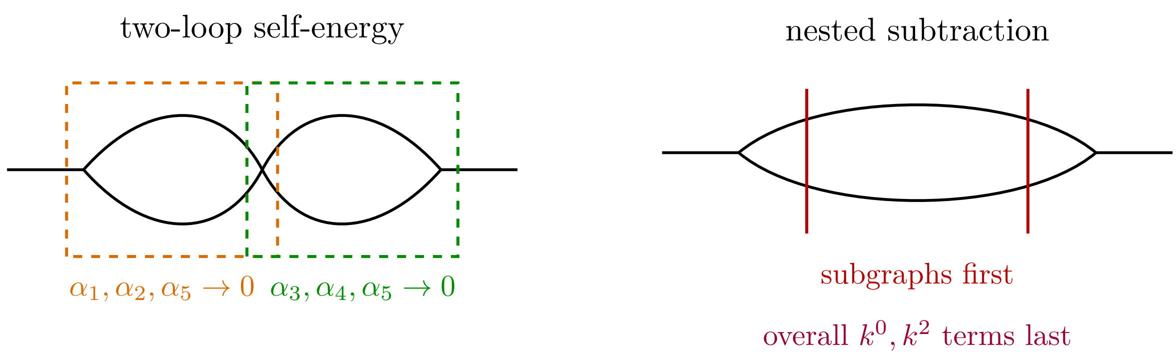

Figure 31.4: In Schwinger parameters, ultraviolet divergences are boundary regions. Subdivergent one-loop regions are subtracted before the remaining overall boundary region is expanded in local external-momentum terms.

The preceding analysis is the local core of perturbative renormalizability for power-counting finite-list theories. At all orders, the same nested structure is organized by the Bogoliubov–Parasiuk–Hepp–Zimmermann theorem: subtract local Taylor polynomials for divergent subgraphs in a compatible nested order, and the remaining integrals are finite. The next chapter develops this subtraction structure as a systematic forest formula.

32.1 Path-Integral Status: Formal Coefficientwise Renormalization

The construction in this chapter is a perturbative construction extracted from a regulated Euclidean source functional. Let $\langle - \rangle_{0,\Lambda}$ be a specified ultraviolet-regulated Gaussian expectation and let V_Λ be a finite linear combination of regulated local interaction functionals with couplings

$$g = (g_1, \ldots, g_r), \qquad V_\Lambda[\phi] = \sum_{\alpha=1}^{r} g_\alpha O_{\alpha,\Lambda}[\phi],$$

where the subscript Λ denotes the ultraviolet regulator used to define both the covariance and the inserted local functionals. The normalized source functional is

$$Z_{\Lambda,g}[J] = \frac{\big\langle \exp\big(\langle J, \phi \rangle - V_\Lambda[\phi]\big)\big\rangle_{0,\Lambda}}{\big\langle \exp\big(-V_\Lambda[\phi]\big)\big\rangle_{0,\Lambda}},$$

understood as an identity in the formal power-series ring $\mathbb{C}[[g_1, \ldots, g_r]]$. Its correlation functions are expanded as formal power series in g:

$$\big\langle \phi(x_1) \cdots \phi(x_n) \big\rangle_{\Lambda,g} = \sum_{\nu \in \mathbb{N}^r} g^\nu\, G^{(\nu)}_{\Lambda,n}(x_1, \ldots, x_n), \qquad g^\nu = \prod_{\alpha=1}^{r} g_\alpha^{\nu_\alpha}.$$

Each coefficient $G^{(\nu)}_{\Lambda,n}$ is a finite sum of graph distributions, or equivalently of momentum-space graph integrals after a choice of momentum routing and test functions. BPHZ renormalization acts on these coefficient distributions graph by graph. For a graph Γ, the forest formula constructs a renormalized coefficient $R_\Gamma I_\Gamma$ by subtracting Taylor polynomials in the external momenta of divergent subgraphs. Only after this coefficientwise operation has been performed does one assemble the formal series again.

Thus BPHZ, as used here, is not an assertion that the formal symbol $\mathcal{D}\phi$ denotes a countably additive measure on an unregulated continuum field space, and it is not a nonperturbative construction of the theory. It is a precise local subtraction scheme for the formal perturbative expansion of regulated Euclidean Green functions and 1PI kernels. Its comparison with Wilsonian effective actions is therefore an order-by-order comparison between two coordinate systems on perturbative coefficient data, not an equality of nonperturbative path integrals.

32.2 Graphs and Ultraviolet Subgraphs

Work in a massive Euclidean scalar theory in D dimensions, with local polynomial interactions and a fixed choice of momentum routing. The massive assumption isolates ultraviolet questions from infrared ones; the subtraction points will also be chosen away from exceptional momentum configurations. The graphs in this chapter represent 1PI kernels; connected Green functions are reconstructed from 1PI kernels by the Legendre tree expansion discussed earlier. A connected one-particle-irreducible Feynman graph Γ has a finite set $E(\Gamma)$ of internal lines, a finite set $V(\Gamma)$ of vertices, and external momenta

$$p = (p_1, \dots, p_N), \qquad \sum_{a=1}^{N} p_a = 0.$$

Choose independent loop momenta $\ell = (\ell_1, \dots, \ell_{L(\Gamma)})$, where

$$L(\Gamma) = |E(\Gamma)| - |V(\Gamma)| + 1.$$

With polynomial numerator $N_\Gamma(\ell, p)$ and propagator masses $m_e > 0$, the Euclidean momentum-space integrand has the form

$$I_\Gamma(\ell, p) = \frac{N_\Gamma(\ell, p)}{\prod_{e \in E(\Gamma)} \left(q_e(\ell, p)^2 + m_e^2\right)}.$$

Here $q_e(\ell, p)$ is the momentum carried by the line e, determined by the chosen momentum routing. Coupling constants, symmetry factors, and overall powers of 2π are suppressed in this chapter because they do not affect the ultraviolet degree or locality of the subtraction.

Definition 32.1 (Momentum subgraph)**.**

A momentum subgraph $\gamma \subseteq \Gamma$ is specified by a nonempty subset $E(\gamma) \subseteq E(\Gamma)$, together with all vertices incident to those internal lines. Its connected components are formed with the incidence relation inherited from Γ. The loop number of γ is

$$L(\gamma) = |E(\gamma)| - |V(\gamma)| + c(\gamma),$$

where $c(\gamma)$ is the number of connected components of γ. The external half-lines of γ are all half-lines incident to $V(\gamma)$ that are not internal lines of γ. They include original external half-lines of Γ and the half-lines obtained by cutting internal lines of $\Gamma \setminus \gamma$ at vertices of γ. The momenta on these half-lines are denoted p_γ, with momentum conservation imposed separately on each connected component. The contracted graph Γ/γ is obtained by replacing every connected component of γ by a single vertex carrying the total external momentum of that component.

The ultraviolet scaling associated with γ scales independent loop momenta internal to γ by a common parameter ρ and keeps p_γ fixed. The momenta p_γ may include loop momenta of the contracted graph; during the test of γ they are treated as external parameters. If the leading homogeneous scaling of I_γ together with the internal loop measure is

$$\mathrm{d}^{DL(\gamma)}\ell_\gamma \, I_\gamma(\rho\ell_\gamma, p_\gamma) = O(\rho^{\omega(\gamma)})\mathrm{d}^{DL(\gamma)}\ell_\gamma \qquad (\rho \to \infty),$$

then $\omega(\gamma)$ is the superficial degree of divergence. For a scalar graph with numerator degree $r(\gamma)$,

$$\omega(\gamma) = DL(\gamma) + r(\gamma) - 2|E(\gamma)|.$$

Equivalently, $\omega(\gamma)$ is the mass dimension of the local polynomial that can be produced when γ is shrunk to a point. A connected subgraph is one-particle-irreducible if it remains connected after any one of its internal lines is removed. A proper connected one-particle-irreducible subgraph with $\omega(\gamma) \geq 0$ is called a divergent subgraph; proper means $\gamma \neq \Gamma$. A disconnected subgraph is divergent when each of its connected components is divergent. In that case its local counterterm is the product of the counterterms of its connected components.

32.3 Taylor Operators and Local Vertices

Fix for each divergent subgraph γ a subtraction point p^*_γ in the space of independent external momenta of γ. The point is chosen away from infrared singularities; for massive Euclidean graphs, zero momentum is allowed when the relevant Green function is infrared regular. Let $a = (a_1, \dots, a_M)$ be affine coordinates for the independent components of $p_\gamma - p^*_\gamma$, after imposing momentum conservation. The Taylor operator of degree $\omega(\gamma)$ is

$$(t_\gamma f)(p_\gamma) = \sum_{|\alpha| \leq \omega(\gamma)} \frac{a^\alpha}{\alpha!} \, \partial_a^\alpha f(p^*_\gamma + a)\big|_{a=0}.$$

It acts on the dependence of the integrand on the external momenta of γ, while all loop momenta internal to γ remain integration variables and all momenta belonging to the contracted graph are held fixed. For a disconnected divergent subgraph, t_γ is the product of the Taylor operators for its connected components.

The image $t_\gamma I_\Gamma$ is polynomial in p_γ of degree at most $\omega(\gamma)$, with coefficients depending on the loop variables internal to γ and on the remaining variables of the contracted graph. After the internal variables of γ have been integrated or recursively prepared, this polynomial becomes a vertex factor in Γ/γ. In position space, a polynomial in the momentum entering a contracted vertex is a finite linear combination of derivatives acting at that vertex. Therefore $t_\gamma I_\Gamma$ represents a local insertion in Γ/γ. This is the graph-level form of the locality statement established in the preceding chapter.

Figure 32.1 shows this graph-level operation explicitly: Taylor expansion in the external variables of γ becomes a polynomial counterterm vertex in the contracted graph Γ/γ.

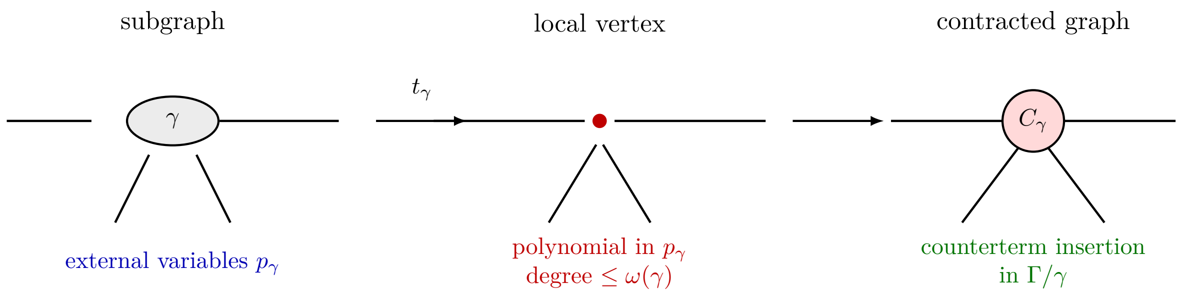

Figure 32.1: The Taylor operator t_γ extracts the polynomial part of a divergent subgraph in its external variables. The polynomial is represented in the contracted graph by a local counterterm vertex.

32.4 Spinneys, Forests, and the Recursive R-Operation

Definition 32.2 (Spinneys and forests)**.** A spinney S of Γ is a finite set of mutually disjoint connected divergent proper subgraphs of Γ. Mutually disjoint means that no internal line or vertex is shared. The empty set is allowed. A forest F of Γ is a finite set of connected divergent subgraphs such that any two elements of F are either disjoint or nested:

$$\gamma_1 \cap \gamma_2 = \emptyset, \qquad \gamma_1 \subset \gamma_2, \qquad \text{or} \qquad \gamma_2 \subset \gamma_1.$$

The full graph Γ is included among the possible forest elements when Γ is one-particle-irreducible and $\omega(\Gamma) \geq 0$. The empty forest is allowed.

Figure 32.2 fixes the compatibility relation used in the forest sum: divergent subgraphs may be disjoint or nested, whereas overlapping subgraphs appear in separate forest terms.

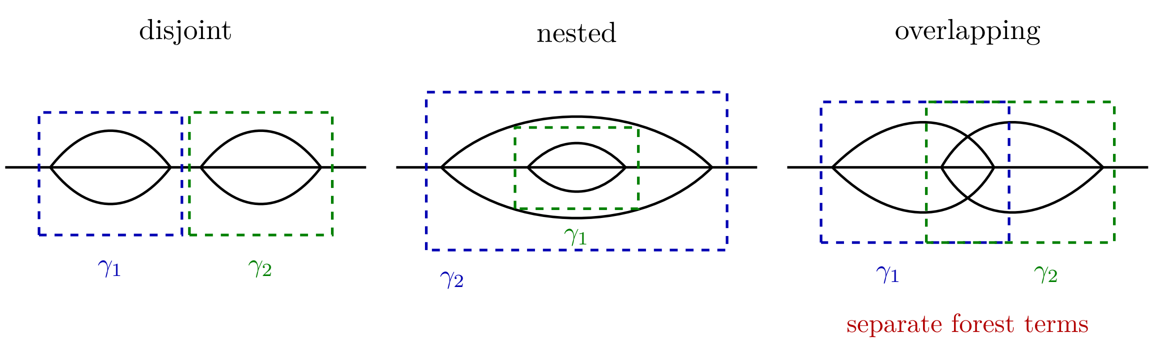

Figure 32.2: A forest contains compatible divergent subgraphs: disjoint or nested collections are compatible. Overlapping subgraphs are handled by separate forest terms.

The recursive construction is most transparent when written in two steps. First define the prepared integrand

$$\overline{R}_\Gamma I_\Gamma = I_\Gamma + \sum_{\substack{S \text{ spinney of } \Gamma \\ S \neq \emptyset}} \left(\prod_{\gamma \in S} C_\gamma \right) I_\Gamma.$$

The product of C_γ's means: for each disjoint component $\gamma \in S$, replace the prepared subgraph by its local counterterm vertex and insert the resulting product of local vertices into the contracted graph Γ/S. Since the elements of a spinney are disjoint, these replacements can be made simultaneously. The counterterm attached to a connected divergent graph is defined recursively by

$$C_\gamma I_\gamma = -\, t_\gamma \, \overline{R}_\gamma I_\gamma.$$

Thus the counterterm of γ is the negative Taylor polynomial of the subgraph after its own proper subdivergences have already been prepared. The recursion starts at divergent graphs with no proper divergent subgraphs, for which $\overline{R}_\gamma I_\gamma = I_\gamma$. For disconnected divergent subgraphs, C_γ is the product over connected components.

The full R-operation is

$$R_\Gamma I_\Gamma = \begin{cases} (1 - t_\Gamma)\, \overline{R}_\Gamma I_\Gamma, & \omega(\Gamma) \geq 0, \\ \overline{R}_\Gamma I_\Gamma, & \omega(\Gamma) < 0. \end{cases}$$

This formula enforces the order of operations: proper subdivergences are subtracted inside $\overline{R}_\Gamma$, and the overall Taylor subtraction is applied afterward when the whole graph is superficially divergent.

Proposition 32.3 (Bogoliubov preparation recursion)**.** *Fix the subtraction points and Taylor degrees described above. For every connected 1PI graph Γ, the recursive definitions of $\overline{R}_\Gamma$, C_γ, and R_Γ determine a finite linear combination of integrands obtained from Γ by replacing divergent connected subgraphs by local polynomial vertices. If γ is connected and divergent, then $C_\gamma I_\gamma$ is a polynomial in the external momenta p_γ of degree at most $\omega(\gamma)$, with coefficients that are finite linear combinations of prepared lower-loop or lower-line graph integrands.*

Proof. Order connected graphs by the number of internal lines. A proper connected subgraph of Γ has strictly fewer internal lines than Γ, so the recursion is well founded. For graphs with no proper divergent connected subgraphs, $\overline{R}_\Gamma I_\Gamma = I_\Gamma$, and, if Γ is divergent, $C_\Gamma I_\Gamma = -t_\Gamma I_\Gamma$, which is a polynomial in the external variables by the definition of t_Γ.

Assume the claim for all proper connected divergent subgraphs of Γ. A spinney is a finite set of mutually disjoint such subgraphs, so the product $\prod_{\gamma \in S} C_\gamma$ can be inserted simultaneously: each factor has already been constructed by the induction hypothesis, and disjoint replacements affect disjoint vertex and line sets. The number of spinneys is finite because Γ has finitely many internal lines. Hence $\overline{R}_\Gamma I_\Gamma$ is a finite linear combination of integrands on contracted graphs with local polynomial vertices.

If Γ itself is divergent, $C_\Gamma I_\Gamma$ is defined as $-t_\Gamma \overline{R}_\Gamma I_\Gamma$. The Taylor operator acts only on the external variables of Γ and truncates at degree $\omega(\Gamma)$; local vertices produced inside $\overline{R}_\Gamma$ are polynomial factors in slower external variables and remain local after the Taylor extraction. Thus the new counterterm is again a local polynomial vertex of the stated degree. This completes the induction. ∎

32.5 The Forest Formula

Let $\mathfrak{F}(\Gamma)$ be the set of forests whose elements are connected divergent subgraphs of Γ, including Γ itself when Γ is one-particle-irreducible and $\omega(\Gamma) \geq 0$. For $F \in \mathfrak{F}(\Gamma)$, define t_F by applying t_γ from smaller subgraphs to larger subgraphs, with each smaller subtraction regarded as a local vertex before the larger Taylor operator is applied. If two elements are disjoint, their operators commute. The forest formula is the following identity.

Theorem 32.4 (Zimmermann forest formula)**.** *For the BPHZ recursion of Proposition 32.3,*

$$R_\Gamma I_\Gamma = \sum_{F \in \mathfrak{F}(\Gamma)} (-1)^{|F|}\, t_F I_\Gamma, \tag{$*$}$$

with $t_\emptyset = 1$. The identity is an identity of formal graph integrands before loop integrations are performed. In a nested chain, Taylor operators are ordered from smaller subgraphs to larger subgraphs; for disjoint subgraphs the order is immaterial.

Proof. We prove the identity by induction on the number of internal lines. For a graph with no proper divergent connected subgraphs, the spinney sum contains only the empty spinney. If Γ is superficially convergent then $R_\Gamma I_\Gamma = I_\Gamma$, which is the forest formula with only the empty forest. If Γ is superficially divergent then

$$R_\Gamma I_\Gamma = (1 - t_\Gamma) I_\Gamma = I_\Gamma - t_\Gamma I_\Gamma,$$

which is the sum over the two forests $\emptyset$ and $\{\Gamma\}$.

Assume the statement for every proper connected divergent subgraph of Γ. Expanding the counterterm of a proper connected divergent subgraph γ gives

$$C_\gamma I_\gamma = -t_\gamma \overline{R}_\gamma I_\gamma = \sum_{\substack{F_\gamma \in \mathfrak{F}(\gamma) \\ \gamma \in F_\gamma}} (-1)^{|F_\gamma|} t_{F_\gamma} I_\gamma. \tag{32.1}$$

Indeed, by the induction hypothesis, $\overline{R}_\gamma$ is the forest sum over forests of γ not containing γ; multiplying by $-t_\gamma$ appends γ as the largest element and changes the sign.

Now expand the spinney sum in $\overline{R}_\Gamma$. A nonempty spinney S is a set of pairwise disjoint proper connected divergent subgraphs. For each $\gamma \in S$, choose a forest F_γ of γ whose largest element is γ, as in (32.1). The union

$$F = \bigcup_{\gamma \in S} F_\gamma$$

is a forest of Γ that does not contain Γ, because different members of S are disjoint and all further elements lie inside those members. Conversely, every forest of Γ not containing Γ has a unique set of maximal elements; these maximal elements form a spinney, and the portions lying below each maximal element are precisely the corresponding F_γ's. The product of the signs in the spinney expansion is $(-1)^{\sum_{\gamma \in S} |F_\gamma|} = (-1)^{|F|}$. Therefore

$$\overline{R}_\Gamma I_\Gamma = \sum_{\substack{F \in \mathfrak{F}(\Gamma) \\ \Gamma \notin F}} (-1)^{|F|} t_F I_\Gamma. \tag{32.2}$$

If Γ is superficially convergent, $R_\Gamma = \overline{R}_\Gamma$ and this is the desired formula. If Γ is superficially divergent, then

$$R_\Gamma I_\Gamma = (1 - t_\Gamma)\overline{R}_\Gamma I_\Gamma.$$

The first term is (32.2). The second term appends Γ as the unique largest element to every forest not already containing Γ, with one extra minus sign. This gives exactly the remaining forests, namely those containing Γ, and proves ($*$). $\square$

The inclusion-exclusion structure can be seen directly in a graph with one proper divergent subgraph γ and a divergent overall graph Γ. The possible forests are

$$\emptyset, \qquad \{\gamma\}, \qquad \{\Gamma\}, \qquad \{\gamma, \Gamma\}.$$

The corresponding operator is

$$R_\Gamma = 1 - t_\gamma - t_\Gamma + t_\Gamma t_\gamma = (1 - t_\Gamma)(1 - t_\gamma),$$

where t_γ acts before t_Γ. The last term restores the part counted twice at the boundary where the subgraph and the whole graph shrink in a nested way.

32.6 Order of Subtractions and Scale Hierarchies

The prescription that t_γ acts before t_Γ for $\gamma \subset \Gamma$ is determined by the geometry of ultraviolet limits. A nested forest represents a hierarchy of large internal momenta. For example, if loop momenta internal to γ are of size $\rho\sigma$ and the remaining loop momenta of Γ/γ are of size ρ, with $\sigma \to \infty$ before $\rho \to \infty$, then the innermost singular region is the subgraph γ. Its Taylor polynomial is first converted into a local vertex of the contracted graph. After that replacement, the overall Taylor operator acts on the local integrand of the larger graph.

This ordering can be expressed algebraically. If

$$C_\gamma I_\gamma = -t_\gamma \overline{R}_\gamma I_\gamma,$$

then the term $t_\Gamma t_\gamma I_\Gamma$ in a forest is interpreted as

$$t_\Gamma\big((t_\gamma I_\gamma)\, I_{\Gamma/\gamma}\big),$$

where $t_\gamma I_\gamma$ is a polynomial in the external momenta entering γ. The polynomial is part of the local vertex data of Γ/γ, so the overall subtraction is again a Taylor polynomial in the external momenta of Γ. This is the mechanism by which nested subtractions preserve locality.

Overlapping divergent subgraphs are not disjoint and neither contains the other, so they are not placed in the same forest. Their common ultraviolet region is represented by the sum over compatible forests together with the overall subtraction. The forest sum is the inclusion-exclusion expression that subtracts all ultraviolet boundary regions while assigning counterterms only to local contracted subgraphs.

32.7 The Two-Loop Self-Energy Forest

Return to the two-loop self-energy graph in the six-dimensional cubic theory. Let Γ be the full graph and let γ_L, γ_R denote the left and right one-loop self-energy subgraphs. These two subgraphs overlap: they share the central propagator. Therefore the forest set is

$$\emptyset, \quad \{\gamma_L\}, \quad \{\gamma_R\}, \quad \{\Gamma\}, \quad \{\gamma_L, \Gamma\}, \quad \{\gamma_R, \Gamma\}.$$

The overlap of γ_L and γ_R is represented by the two separate one-subgraph forests $\{\gamma_L\}$ and $\{\gamma_R\}$, together with their nested overall forests.

For this graph the R-operation is

$$\begin{aligned} R_\Gamma I_\Gamma = I_\Gamma - t_{\gamma_L} I_\Gamma - t_{\gamma_R} I_\Gamma - t_\Gamma I_\Gamma \\ + t_\Gamma t_{\gamma_L} I_\Gamma + t_\Gamma t_{\gamma_R} I_\Gamma. \end{aligned}$$

The first two subgraph subtraction terms remove the two Schwinger-parameter boundary regions

$$\alpha_1, \alpha_2, \alpha_5 \to 0, \qquad \alpha_3, \alpha_4, \alpha_5 \to 0.$$

After these subtractions, the remaining overall boundary $\alpha_1, \ldots, \alpha_5 \to 0$ is subtracted by t_Γ. Since $\omega(\Gamma) = 2$ for the self-energy in $D = 6$, t_Γ extracts the constant and quadratic terms in the external momentum. The final counterterm is therefore a linear combination of the local operators ϕ^2 and $\partial_\mu \phi \, \partial_\mu \phi$.

Figure 32.3 displays the diamond graph in which the two one-loop subdivergences overlap; the forest formula subtracts each compatible option and then the remaining overall divergence.

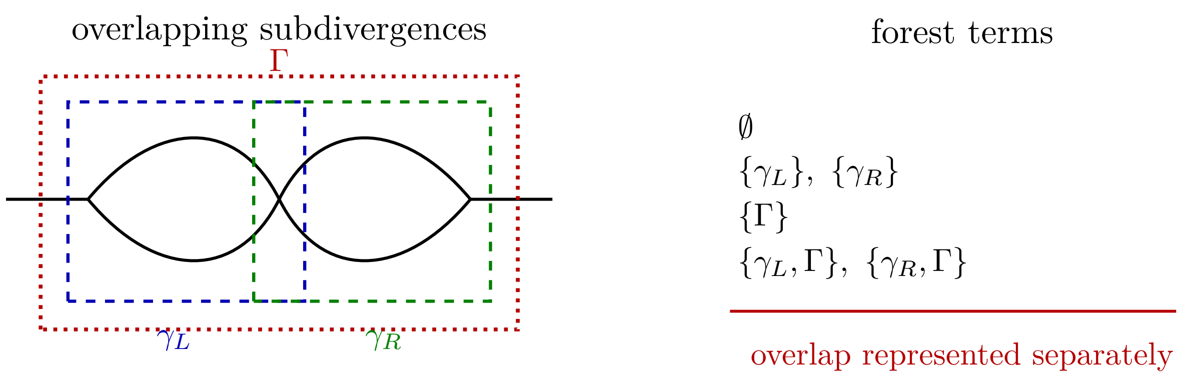

Figure 32.3: The two one-loop subdivergences of the diamond graph overlap along one internal line. The forest formula treats them in separate compatible forests, while the overall graph is subtracted after either one-loop subgraph subtraction.

32.8 Finiteness and Locality

Lemma 32.5 (Hepp-sector forest associated to an ultraviolet hierarchy)**.** *Fix a smooth Hepp-sector partition of the noncompact loop-momentum region of a graph Γ, so that in each sector the magnitudes of the line momenta are ordered up to bounded ratios. In one sector, the ultraviolet* *boundary strata determine a finite forest F_S as follows: for each threshold in the ordered list of large line momenta, form the subgraph spanned by lines above the threshold, decompose it into connected components, keep the one-particle-irreducible components that contain loops, and then discard components with negative superficial degree. The retained components are pairwise disjoint or nested. Moreover, every superficially divergent ultraviolet boundary of that sector is represented by a member of this forest, or by a quotient graph obtained after members of the forest have been contracted.*

Proof. Label the distinct momentum-size thresholds in the sector by

$$\rho_1 \gg \rho_2 \gg \cdots \gg \rho_N$$

after subdividing the partition of unity if necessary so that the ratios ρ_{j+1}/ρ_j are the sector coordinates. Let H_j be the subgraph spanned by the internal lines whose momenta have size at least ρ_j. Then

$$H_1 \subset H_2 \subset \cdots \subset H_N.$$

For two indices $i < j$, every connected component of H_i is either contained in a connected component of H_j or disjoint from it, because the edge set of H_i is a subset of the edge set of H_j.

It remains to check that passing from connected components to 1PI loop-containing components does not introduce a crossing overlap. Use the block decomposition of a connected graph into maximal one-particle-irreducible blocks, bridges, and tree attachments. If B is a 1PI block of a smaller threshold graph H_i, then any two lines of B lie on a common cycle in H_i, hence still lie on a common cycle in the larger graph H_j. Thus B is contained in a unique maximal 1PI block of the connected component of H_j that contains it. Adding further high-momentum lines can merge old 1PI blocks, but it cannot split an old 1PI block. Consequently two retained 1PI loop subgraphs obtained from different thresholds are either edge-disjoint, or one is contained in the other after the obvious inclusion of edge sets. Discarding components with negative superficial degree removes vertices from this partially ordered set and therefore preserves the forest property.

Now consider a boundary stratum of the sector at which a subset of sector ratios tends to zero, equivalently a nested collection of high-momentum scales is sent to infinity relative to the slower scales. At the first nontrivial ratio the large lines form one of the components of some H_j. If its superficial degree is negative, the Taylor-subtracted integrand has a convergent power-counting exponent at that boundary, so the boundary is not superficially divergent. If its degree is nonnegative, the corresponding 1PI loop block is one of the retained elements of F_S. For the next larger scale separation, the lines already represented by retained blocks are replaced by local vertices; the remaining divergent large-line configuration is therefore a divergent component of the quotient graph. An induction over the ordered ratios gives a nested sequence of retained subgraphs and quotient divergences. This is precisely the forest associated to the ultraviolet hierarchy in the Hepp sector. □

Theorem 32.6 (BPHZ finiteness for massive Euclidean scalar graphs)**.** *Let Γ be a connected one-particle-irreducible Euclidean Feynman graph in a massive scalar theory. Assume that all external momenta and subtraction points are chosen away from infrared singularities, that the numerator of every graph is polynomial in loop and external momenta, and that t_γ subtracts every divergent one-particle-irreducible subgraph γ through degree $\omega(\gamma)$. Then*

$$\int \prod_{i=1}^{L(\Gamma)} \mathrm{d}^D \ell_i \, R_\Gamma I_\Gamma(\ell, p)$$

is ultraviolet finite. The counterterm produced by each connected divergent subgraph is a polynomial in p_γ of degree at most $\omega(\gamma)$.

Proof. The proof is local on loop-momentum space. Choose a smooth partition of unity subordinate to one compact region and to finitely many conic Hepp sectors. Lemma 32.5 attaches to each sector S a forest F_S containing the superficially divergent boundary components of that sector. It is enough to prove absolute convergence on each sector, since the partition has finitely many sectors and the compact region is harmless for massive Euclidean propagators.

The elementary estimate is the following Taylor-remainder bound. Let γ be a connected divergent subgraph, and let $\rho \geq 1$ scale loop momenta internal to γ while the external variables p_γ of γ are kept on a slower scale. Write $p_\gamma = p_\gamma^* + a$. Taylor's formula with integral remainder gives

$$f(p_\gamma) - t_\gamma f(p_\gamma) = \sum_{|\alpha|=\omega(\gamma)+1} \frac{a^\alpha}{\alpha!} \int_0^1 (1-u)^{\omega(\gamma)} \big(\partial_a^\alpha f\big)(p_\gamma^* + ua)\, \mathrm{d}u. \tag{32.3}$$

Here f denotes the prepared integrand of γ, with all proper subdivergences already replaced by their renormalized expressions or local counterterm vertices. A derivative with respect to an external momentum of γ differentiates either a polynomial numerator or a propagator whose momentum is affine in p_γ. For a propagator,

$$\partial_{p_\mu} \frac{1}{q(\ell,p)^2 + m^2} = -\frac{2q_\nu(\ell,p)\, \partial_{p_\mu} q_\nu(\ell,p)}{(q(\ell,p)^2 + m^2)^2},$$

which has one less power under the large internal scaling than the original propagator. Derivatives of the polynomial numerator are bounded by the same rule because differentiating a polynomial lowers its degree, and derivatives falling on counterterm vertices only differentiate polynomials in slower external variables. Consequently, including the internal loop measure of γ,

$$\mathrm{d}^{DL(\gamma)}\ell_\gamma\, \partial_a^\alpha f(\rho\ell_\gamma, p_\gamma) = O\Big(\rho^{\omega(\gamma)-|\alpha|}\Big)\, \mathrm{d}^{DL(\gamma)}\ell_\gamma. \tag{32.4}$$

For $|\alpha| = \omega(\gamma)+1$, the γ-scale exponent is at most -1. In radial sector coordinates this means that the corresponding boundary integral is bounded by

$$C \int_R^\infty \rho^{-1}\, \frac{\mathrm{d}\rho}{\rho} < \infty. \tag{32.5}$$

If γ has negative superficial degree, the same estimate holds without applying $1 - t_\gamma$, because then the exponent is already at most -1.

Now fix a Hepp sector S. Let $\gamma_1, \ldots, \gamma_r$ be a chain in F_S, ordered from smaller to larger subgraph. If the forest has disjoint branches, introduce one such ordered scale chain on each branch; the sector coordinates factor into the product of these branch variables because disjoint subgraphs use disjoint sets of internal momenta. Introduce scale ratios $\rho_j \geq 1$ so that the momenta internal to γ_j but not to the previous members of the chain are of order $\rho_1 \cdots \rho_j$, while the external momenta of γ_j are on the slower scale $\rho_1 \cdots \rho_{j-1}$. The forest formula acts in precisely this order: smaller Taylor operators are applied before the larger ones, and the counterterm produced by a smaller member is viewed as a local vertex in the quotient graph. Applying (32.3) successively from the innermost members outward gives, on the sector S, a bound of the form

$$|R_\Gamma I_\Gamma(\ell,p)|\, \mathrm{d}^{DL(\Gamma)}\ell \leq C_S \prod_{j=1}^{r} \rho_j^{-1} \frac{\mathrm{d}\rho_j}{\rho_j} \prod_b \sigma_b^{-1} \frac{\mathrm{d}\sigma_b}{\sigma_b} \mathrm{d}\Omega_S. \tag{32.6}$$

The additional variables σ_b correspond to superficially convergent subgraphs or quotient subgraphs; their exponents are already negative by power counting. The angular variables Ω_S range over a compact part of the sector after the radial ratios have been extracted. Thus the right hand side is integrable in every noncompact sector variable.

It remains to explain why the estimate just obtained for a sector is the estimate of the actual forest formula, not of a sector-dependent subtraction prescription. In the sector S, the ultraviolet boundary strata are labelled by nested or disjoint components as above. Expanding the product of the corresponding Taylor remainders gives the alternating sum over all subforests of F_S. Zimmermann's forest formula is the global inclusion-exclusion sum over all compatible forests of Γ; restricted to the sector S, the terms that meet the boundary strata of S are exactly the terms in this sector product, while terms corresponding to extra subtractions are Taylor polynomials of already integrable remainders and obey the same or better estimates. Overlapping divergent subgraphs are handled by the sector decomposition: a single sector resolves the hierarchy into compatible nested or disjoint components, and the sum over sectors restores the sector-independent forest expression.

The mass and nonexceptional-momentum assumptions remove the remaining noncompact possibilities. In the compact part of loop-momentum space the integrand is smooth. Away from compact sets, the only boundaries are the ultraviolet scaling boundaries estimated above; massive denominators are bounded away from zero on the real Euclidean integration contour. Hence the renormalized integral is absolutely ultraviolet finite.

The locality assertion is algebraic and occurs before integration. By definition,

$$C_\gamma I_\gamma = -\, t_\gamma \, \overline{R}_\gamma I_\gamma,$$

and t_γ is a Taylor polynomial in the external variables p_γ of degree at most $\omega(\gamma)$. After integrating the internal variables of γ, or after inserting the recursively defined prepared counterterm, this polynomial is a local vertex in Γ/γ. Thus every connected divergent subgraph produces a counterterm polynomial of degree at most $\omega(\gamma)$. In a theory whose power-counting counterterms belong to a finite local operator space, the recursive operation remains inside that finite space, giving perturbative renormalizability in the finite-list sense used in the preceding chapter. $\square$

Remark 32.7 (Massless graphs and the BPHZL extension). The theorem just stated is a massive, nonexceptional-momentum theorem. Its proof uses the fact that the only remaining noncompact regions after subtraction are ultraviolet regions. For a massless graph, a Taylor subtraction at zero external momentum can change the small-loop-momentum behavior of the integrand. Thus the ultraviolet forest formula alone does not control the infrared boundary in which a massless subgraph momentum goes to zero.

The Lowenstein–Zimmermann extension, usually called BPHZL, augments the subtraction data so that ultraviolet and infrared degrees are controlled simultaneously.[1] In one standard formulation, each massless propagator is temporarily replaced by an s-dependent massive propagator, so that $s = 1$ gives the desired massless graph while another value of s supplies an auxiliary infrared mass.

[1] See J. H. Lowenstein and W. Zimmermann, "On the formulation of theories with zero mass propagators," *Nucl. Phys. B* **86** (1975) 77–103, doi:10.1016/0550-3213(75)90075-9; and J. H. Lowenstein and W. Zimmermann, "The power counting theorem for Feynman integrals with massless propagators," *Commun. Math. Phys.* **44** (1975) 73–86, doi:10.1007/BF01609059. For the scalar critical model see also J. H. Lowenstein and W. Zimmermann, "Infrared convergence of Feynman integrals for the massless ϕ^4-model," *Commun. Math. Phys.* **46** (1976) 105–118, doi:10.1007/BF01608491.

The subtraction operators are then Taylor operators in the external momenta together with the auxiliary parameter, with degrees chosen from both ultraviolet and infrared power counting. The resulting forest formula is local in the ultraviolet variables and has enough additional subtraction at the infrared boundary to possess a distributional $s \to 1$ massless limit.

This is the momentum-subtraction counterpart of the Wilsonian statement used in the critical chapters. The Wilson–Fisher and Ising discussions work on a massless critical surface, where zero-momentum Green functions and composite insertions must be interpreted through an infrared-safe prescription: nonexceptional external momenta, finite volume, a small mass followed by a scaling limit, BPHZL, or an equivalent Wilsonian exact-RG construction. The massive BPHZ theorem above supplies the ultraviolet locality mechanism; it is not, by itself, the full renormalization theorem for the massless critical regime.

32.9 Oversubtractions and Zimmermann Normal Products

Composite operators are renormalized by the same forest mechanism, with one distinguished local insertion. Let $O(x)$ be a local monomial in the fields and derivatives, and let

$$\Gamma_O$$

be a graph with one vertex marked as the insertion of O. Divergent subgraphs may contain the marked vertex or may be ordinary subgraphs away from it. The Taylor degree assigned to a subgraph containing the insertion is chosen at least as large as the engineering degree of O, and may be chosen larger. The resulting renormalized insertion is denoted

$$N_\delta[O](x),$$

where δ is the subtraction degree at the marked vertex.

It fixes a BPHZ subtraction scheme for insertions of O.

Increasing δ is an oversubtraction.

Proposition 32.8 (Zimmermann identity for oversubtracted normal products)**.** *Let $\delta' \geq \delta$. Fix a finite basis $\{O_A\}$ of local monomials, with the same exact global and spacetime quantum numbers as O, and with engineering degree at most δ', modulo total derivatives and field relations already chosen as part of the operator basis. For every graph with one insertion of O, the difference between the BPHZ-renormalized insertion with subtraction degree δ' and the one with subtraction degree δ is a finite sum of BPHZ-renormalized insertions of the O_A's:*

$$N_{\delta'}[O](x) = N_\delta[O](x) + \sum_A c_A\, N_{\delta'}[O_A](x). \tag{32.7}$$

The coefficients c_A are finite functions of the subtraction points, finite subtraction prescription, masses, and renormalized couplings. They are local scheme-change coordinates; they are not new nonlocal dynamical data.

Proof. Work graph by graph. For a marked subgraph γ containing the insertion vertex, write $t_\gamma^{(\delta)}$ and $t_\gamma^{(\delta')}$ for the two Taylor operators. Their difference is the finite Taylor polynomial

$$t_\gamma^{(\delta')} - t_\gamma^{(\delta)} = \sum_{\delta < |\alpha| \leq \delta'} \frac{a^\alpha}{\alpha!}\, \partial_a^\alpha|_{a=0} \tag{32.8}$$

in the external variables of the marked subgraph, with all lower subdivergences prepared in the same forest order as above. After the marked subgraph is contracted, each monomial a^α is a local derivative operator at the insertion point. By the chosen local operator basis, the resulting local insertion is a finite linear combination of the O_A's.

Unmarked divergent subgraphs are subtracted in the same way in both normal products. Hence their forest sums cancel in the difference except insofar as they prepare the coefficients multiplying the finite Taylor polynomial (32.8). The BPHZ finiteness theorem applied to graphs with the corresponding local insertion shows that these coefficients are finite after the remaining loop integrations. Regrouping the finite local insertions in the common oversubtracted scheme δ' gives (32.7). □

This is the BPHZ form of the operator mixing matrix used later in the renormalized-operator chapter.

32.10 Finite Parts and Subtraction Coordinates

The Taylor operator includes a choice of subtraction point. In addition, one may add finite local polynomial terms compatible with the same subtraction degree. Changing these choices replaces C_γ by

$$C_\gamma + \Delta C_\gamma,$$

where ΔC_γ is again a local polynomial in p_γ of degree at most $\omega(\gamma)$. Hence a change of subtraction prescription is a local redefinition of the parameters multiplying local operators. The renormalized amplitudes expressed in one set of renormalized coordinates can be re-expressed in another by a finite local change of coordinates.

The next chapter uses this freedom actively. A family of subtraction conditions indexed by a Euclidean momentum scale μ gives scale-dependent renormalized couplings. The differential comparison of neighboring values of μ is the 1PI renormalization group. Chapter 36 compares the same finite local freedom with Wilsonian local coordinates: the Taylor polynomial assigned to a divergent subgraph is a local vertex, and changing its finite part changes the corresponding coordinate on the local Wilsonian chart.

33.1 Scale-Dependent Coordinates on the 1PI Effective Action

The previous chapters constructed local counterterms and organized subdivergence subtractions. We now use that construction to compare renormalized 1PI data at different Euclidean momentum scales.

Work in a Euclidean perturbative quantum field theory on $\mathbb{R}^D$, with a UV regulator denoted by Λ. The symbol Λ refers to a cutoff class in Table 11.1; if the calculation is instead made in dimensional regularization, the corresponding object is a meromorphic formal graph assignment in $D = d - \varepsilon$, not a finite-regulator measure. Let $\Gamma_\Lambda[\varphi]$ be the regulated 1PI effective action, expressed as a functional of a classical field φ. Its momentum-space expansion has the form

$$\Gamma_\Lambda[\varphi] = \sum_{n\geq 0} \frac{1}{n!} \int \prod_{a=1}^{n} \frac{\mathrm{d}^D k_a}{(2\pi)^D} (2\pi)^D \delta\left(\sum_{a=1}^{n} k_a\right) \Gamma_\Lambda^{(n)}(k_1, \ldots, k_n) \widetilde{\varphi}(k_1) \cdots \widetilde{\varphi}(k_n).$$

The distribution $\Gamma_\Lambda^{(n)}$ is the regulated 1PI n-point vertex. Momentum conservation allows one momentum argument to be suppressed when convenient.

A scale-dependent 1PI coordinate is obtained by specifying:

- a finite list of local operators $\mathcal{O}_I$, each with a number n_I of fields and a derivative tensor structure;
- a Euclidean subtraction configuration $\mathcal{S}_{I,\mu}$ whose momenta have size $O(\mu)$;
- a field normalization convention at the same scale;
- a linear projector Π_I extracting the Taylor coefficient of the 1PI vertex with the tensor structure of $\mathcal{O}_I$.

The resulting coordinate is denoted $g_I(\mu)$. Its precise value depends on the chosen subtraction configuration and projector; once these choices are fixed, $g_I(\mu)$ is a finite renormalized coordinate on the family of theories under consideration.

The 1PI renormalization group is the differential comparison of these coordinates at nearby scales:

$$\frac{\mathrm{d}g_I(\mu)}{\mathrm{d}\log\mu} = \beta_I(\{g_J(\mu)\};\mu).$$

The right-hand side is the beta function in the selected coordinate system. When all dimensionful quantities have been replaced by dimensionless ratios and included among the coordinates, the vector field on this enlarged coordinate space has no separate explicit μ-argument.

The finite-cutoff Wilsonian effective action uses another construction. In that construction one defines an action at cutoff Λ by integrating over field modes between two cutoffs and studies the dependence of that action on Λ. That construction will be developed later. The present chapter uses the 1PI effective action and subtraction conditions on its vertices.

At the level of perturbative graphs, the scale comparison is a precise reuse of lower-order subgraph data. A one-loop subgraph that determines the variation of a 1PI coordinate reappears inside higher-order 1PI graphs. The renormalization-group equation records this reuse as a differential equation for the finite coordinate, after the local counterterms have removed the cutoff dependence.

Figure 33.1 records the graph-theoretic source of the perturbative RG equation: lower-order local subgraph data reappear inside higher-order 1PI graphs and therefore control the scale derivative of a finite coordinate.

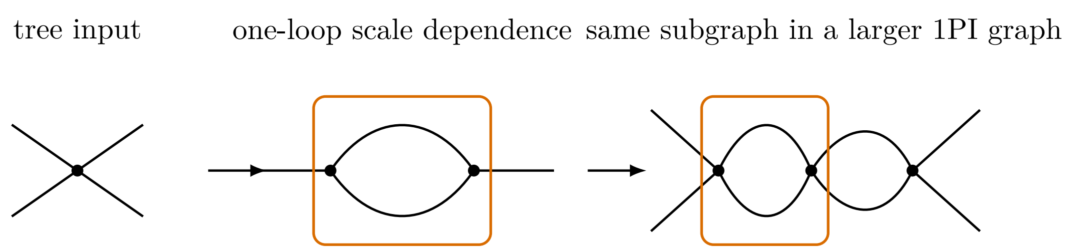

Figure 33.1: The scale derivative of a 1PI coordinate is local in perturbation theory because the scale-dependent part of a lower-order 1PI subgraph is reused inside larger graphs. The differential equation is written only after the subgraph counterterms of the previous chapters have made the coordinate comparison finite.

Figure 33.2 then identifies the coordinate comparison itself: a field normalization and a vertex subtraction condition at scale μ define the finite 1PI coordinates transported by the RG vector field.

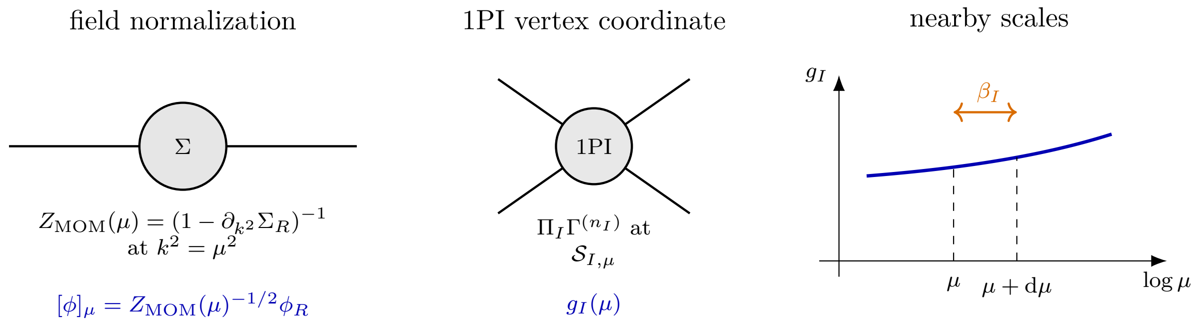

Figure 33.2: The 1PI renormalization group compares coordinate systems on renormalized 1PI vertices. A field normalization is fixed at the same scale as the vertex subtraction, and nearby scales are compared by a differential equation.

33.2 Scalar Quartic Theory in Four Euclidean Dimensions

Let $D = 4$, and consider a real scalar theory with bare Euclidean Lagrangian

$$\mathcal{L}_E = \frac{1}{2}(\partial_\mu\phi)(\partial_\mu\phi) + \frac{1}{2}m_0^2\phi^2 + \frac{1}{4!}g_0\phi^4.$$

Choose a renormalized field $\phi_R = Z_R^{-1/2}\phi$, a renormalized mass m_R, and a renormalized quartic coupling g_R. The same bare Lagrangian can be written as

$$\begin{aligned}\mathcal{L}_E = {}& \frac{1}{2}(\partial_\mu\phi_R)(\partial_\mu\phi_R) + \frac{1}{2}m_R^2\phi_R^2 \\ & + (Z_R - 1)\left[\frac{1}{2}(\partial_\mu\phi_R)(\partial_\mu\phi_R) + \frac{1}{2}m_R^2\phi_R^2\right] + \frac{1}{2}\delta m^2\phi_R^2 + \frac{1}{4!}(g_R + \delta g)\phi_R^4.\end{aligned}$$

Here Z_R, δm^2, and δg depend on the regulator and on the chosen renormalization conditions.

Let $\Gamma_R^{(4)}(k_1, k_2, k_3)$ be the renormalized 1PI four-point vertex, with $k_4 = -k_1 - k_2 - k_3$. A zero-momentum definition such as

$$g_R = -\Gamma_R^{(4)}(0, 0, 0)$$

is one possible coordinate. To compare physics at a Euclidean momentum scale μ, it is better to define a coordinate using external momenta of size μ and to normalize the external field at the same scale.

The connected two-point function is written in the form

$$G_R(k) = \frac{1}{k^2 + m_R^2 - \Sigma_R(k)},$$

which defines the self-energy $\Sigma_R(k)$ in this convention. The scale-dependent normalization is

$$Z_{\mathrm{MOM}}(\mu) = \left(1 - \frac{\partial\Sigma_R}{\partial k^2}\right)^{-1}_{k^2=\mu^2}, \qquad [\phi]_\mu = Z_{\mathrm{MOM}}(\mu)^{-1/2}\phi_R.$$

Thus the 1PI effective action, when viewed as a functional of $[\phi]_\mu$, has a canonically normalized quadratic term at momenta $k^2 = \mu^2$.

For the four-point coordinate, use the symmetric Euclidean subtraction point

$$k_i^2 = \mu^2, \qquad s = t = u = -\frac{4}{3}\mu^2,$$

where

$$s = -(k_1 + k_2)^2, \qquad t = -(k_1 + k_3)^2, \qquad u = -(k_1 + k_4)^2.$$

These are Euclidean subtraction variables obtained by analytic continuation from the mostly-plus Mandelstam convention. With all four Euclidean momenta taken incoming and $k_1+k_2+k_3+k_4 = 0$, the identity fixing the common channel value is

$$\begin{aligned} s + t + u &= -\sum_{j=2}^{4}(k_1 + k_j)^2 \\ &= -\left(3k_1^2 + \sum_{j=2}^{4} k_j^2 + 2k_1 \cdot \sum_{j=2}^{4} k_j\right) \\ &= -\sum_{i=1}^{4} k_i^2. \end{aligned}$$

At $k_i^2 = \mu^2$ this gives $s + t + u = -4\mu^2$; imposing the symmetric subtraction condition $s = t = u$ therefore gives $s = t = u = -4\mu^2/3$. After continuing to Lorentzian on-shell scattering and crossing two momenta back to the physical outgoing convention, the same algebraic relation becomes $s + t + u = \sum_i m_i^2$. Explicitly, if p_i are mostly-plus Lorentzian momenta and the Euclidean momenta are continued as $k_i = (\mathrm{i}p_i^0, \vec{p}_i)$, then

$$(k_i + k_j)^2_{\mathrm{E}} = (p_i + p_j)^2_{\mathrm{L}}, \qquad s_{\mathrm{E}} := -(k_1 + k_2)^2_{\mathrm{E}} = s_{\mathrm{L}} := -(p_1 + p_2)^2_{\mathrm{L}}.$$

The sign flip is between s_{E} and the bare mostly-plus Lorentzian quadratic form $(p_1 + p_2)^2_{\mathrm{L}}$, not between the Euclidean subtraction variable and the mostly-plus Mandelstam variable used in the scattering chapters. The running quartic coupling in this momentum-subtraction scheme is

$$g(\mu) = -Z_{\mathrm{MOM}}(\mu)^2 \Gamma_R^{(4)}(k_1, k_2, k_3)\bigg|_{k_i^2=\mu^2,\ s=t=u=-\frac{4}{3}\mu^2}.$$

Definition 33.1 (Momentum-subtraction quartic coordinate)**.** For the four-dimensional Euclidean scalar theory above, the momentum- subtraction quartic coordinate $g(\mu)$ is the negative of the four-point 1PI vertex at the symmetric Euclidean point, expressed in the field normalization $[\phi]_\mu$. The subtraction scheme consists of the renormalized field convention, the symmetric point, and the sign convention in the displayed formula.

In the 1PI vertex convention used here, the tree-level quartic vertex is $\Gamma^{(4)}_{\text{tree}} = -g_R$. The explicit minus sign in the definition of $g(\mu)$ therefore makes the coordinate agree at tree level with the positive coefficient multiplying $\phi^4/4!$ in the Euclidean action. In Section 34.9 the minimal-subtraction coordinate $\lambda(\mu)$ is written directly as the positive coefficient in

$$g^\epsilon = \mu^\epsilon \left[\lambda(\mu) + \frac{3}{16\pi^2}\frac{\lambda(\mu)^2}{\epsilon} + \cdots\right].$$

Thus the momentum-subtraction and minimal-subtraction formulas use the same positive quartic-coordinate orientation; the displayed minus sign appears only when the coordinate is extracted from the 1PI vertex.

33.3 One-Loop Running in the Quartic Example

At one loop, the four-point bubbles change the quartic vertex, while the two-point tadpole is independent of k^2. In the self-energy convention

$$G_R(k) = \frac{1}{k^2 + m_R^2 - \Sigma_R(k)},$$

the amputated one-loop tadpole is

$$\Sigma^{(1)}_{\mathrm{tad}}(k) = -\frac{g_R}{2}\int^{\Lambda} \frac{\mathrm{d}^4\ell}{(2\pi)^4}\,\frac{1}{\ell^2 + m_R^2},$$

before the mass counterterm is chosen. The factor 1/2 is the tadpole symmetry factor. The loop momentum ℓ closes at the quartic vertex, so no external momentum flows through the loop and

$$\frac{\partial \Sigma^{(1)}_{\mathrm{tad}}}{\partial k^2} = 0.$$

The one-loop subtraction needed in the two-point function is therefore a mass subtraction, not a kinetic subtraction. Hence

$$Z_R = 1 + O(g_R^2), \qquad Z_{\mathrm{MOM}}(\mu) = 1 + O(g_R^2)$$

for the one-loop computation of $g(\mu)$.

Figure 33.3 displays the actual one-loop quartic coordinate calculation: tree vertex, three bubble channels, and the local counterterm fixed by the chosen subtraction condition.

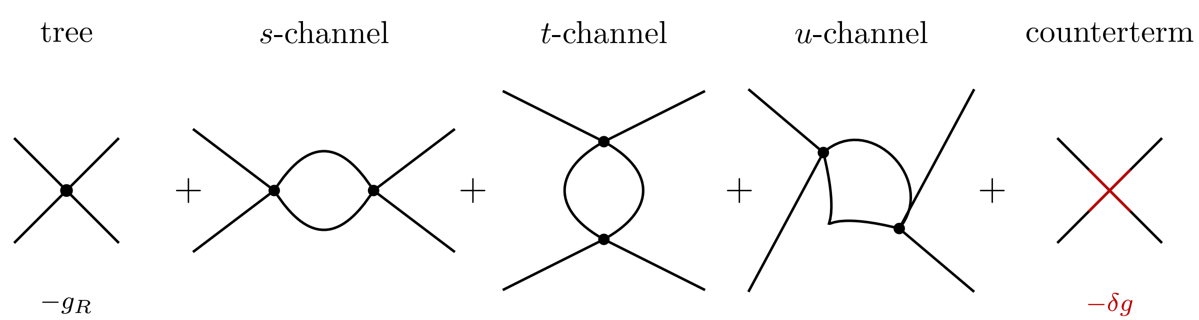

Figure 33.3: The one-loop scalar quartic coordinate receives the tree vertex, the three distinct bubble channels, and the local quartic counterterm fixed by the chosen subtraction condition.

With a momentum cutoff Λ, the one-loop relation at the symmetric subtraction point is

$$-g(\mu) = -g_R - \delta g + 3\frac{g_R^2}{32\pi^2}\int_0^1 \mathrm{d}x\,\left[\log\frac{\Lambda^2}{m_R^2 - sx(1-x)} - 1\right]_{s=-\frac{4}{3}\mu^2} + O(g_R^3).$$

Choose the finite convention

$$g_R = g(0).$$

This condition fixes δg. Subtracting the $\mu = 0$ equation from the equation at general μ removes the cutoff and gives

$$g(\mu) = g_R - \frac{3g_R^2}{32\pi^2} \int_0^1 \mathrm{d}x \, \log \frac{m_R^2}{m_R^2 + \frac{4}{3}\mu^2 x(1-x)} + O(g_R^3).$$

This is a finite relation between two renormalized quartic coordinates in the same theory. For $\mu \gg m_R$, the displayed correction contains a large logarithm. A comparison built from nearby scale coordinates is then better adapted to perturbation theory.

33.4 Nearby Scales and the Beta Function

Let μ' be close to μ. The same one-loop computation may be expressed as a relation between the two scale coordinates:

$$g(\mu') = g(\mu) - \frac{3}{32\pi^2} g(\mu)^2 \int_0^1 \mathrm{d}x \, \log \frac{m_R^2 + \frac{4}{3}\mu^2 x(1-x)}{m_R^2 + \frac{4}{3}\mu'^2 x(1-x)} + O(g(\mu)^3).$$

The expansion parameter is now $g(\mu)$, and the logarithm is small for μ' close to μ. Setting $\mu' = \mu + \mathrm{d}\mu$ gives

$$\frac{\mathrm{d}g(\mu)}{\mathrm{d}\log\mu} = \frac{3}{16\pi^2} g(\mu)^2 \int_0^1 \mathrm{d}x \, \frac{\frac{4}{3}\mu^2 x(1-x)}{m_R^2 + \frac{4}{3}\mu^2 x(1-x)} + O(g(\mu)^3).$$

The integral is a threshold factor. At scales much larger than the mass, $\mu \gg m_R$, it tends to 1, and

$$\frac{\mathrm{d}g}{\mathrm{d}\log\mu} = \frac{3}{16\pi^2} g^2 + O(g^3).$$

In this scheme and convention, the one-loop beta function is therefore

$$\beta(g) = \frac{3}{16\pi^2} g^2 + O(g^3) \qquad (\mu \gg m_R).$$

The one-loop differential equation can be integrated between two scales:

$$\frac{1}{g(\mu)} - \frac{1}{g(\mu')} = -\frac{3}{16\pi^2} \log \frac{\mu}{\mu'}.$$

Equivalently,

$$g(\mu) = \frac{g(\mu')}{1 - \frac{3}{16\pi^2} g(\mu') \log(\mu/\mu')}.$$

This expression contains powers of $g(\mu') \log(\mu/\mu')$ to all orders. Its perturbative domain is controlled by the running coordinate itself: $g(\widetilde{\mu})$ must remain small for the scales $\widetilde{\mu}$ used in the comparison.

33.5 The Landau Scale as a Perturbative Coordinate

The integrated one-loop equation may be written in terms of a scale μ_0 defined by

$$\mu_0 = \mu' \exp\left[\frac{16\pi^2}{3g(\mu')}\right].$$

Then

$$g(\mu) = \frac{1}{\frac{3}{16\pi^2}\log(\mu_0/\mu)}.$$

For $0 < \mu \ll \mu_0$, the denominator is large and the one-loop coordinate is small. As μ approaches μ_0, the perturbative coordinate becomes large and the one-loop approximation ceases to provide a controlled description. Within the one-loop equation, the pair $(\mu', g(\mu'))$ is equivalently represented by the single scale μ_0.

Figure 33.4 plots this one-loop coordinate flow and marks the scale μ_0 at which the perturbative coordinate leaves the controlled small-coupling region.

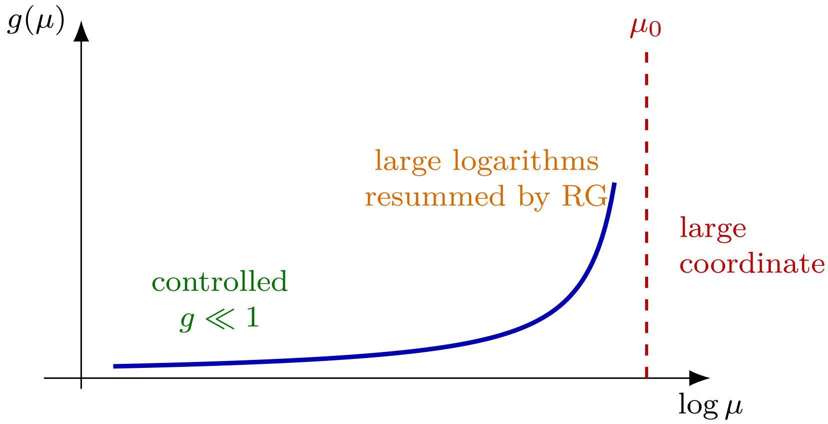

Figure 33.4: The one-loop scalar quartic flow grows with the Euclidean momentum scale. The scale μ_0 is where the one-loop coordinate diverges; the controlled perturbative domain is the region where the running coordinate remains small.

Remark 33.2 (Status of the Landau scale). The scale μ_0 is a statement about the one-loop perturbative coordinate. It gives a useful parametrization of the weak-coupling region and indicates where that coordinate loses perturbative control. A statement about the existence or nonexistence of a continuum scalar theory at arbitrarily short distances requires additional nonperturbative input.

Quoted Theorem 33.3 (Triviality of the standard scalar scaling limits)**.** *For nearest-neighbor ferromagnetic four-dimensional Ising-type spin systems at or near the critical point, and for four-dimensional $\lambda\phi^4$ fields with a lattice ultraviolet cutoff in the infinite-volume and vanishing-lattice spacing limit, the scaling limits covered by the Aizenman–Duminil-Copin theorem are Gaussian. Equivalently, after the continuum field normalization, the limiting Schwinger functions satisfy Wick's rule and the connected n-point functions with $n \geq 4$ vanish. Earlier results of Aizenman* *and Fröhlich establish complementary triviality, mean-field, and critical-approach statements in $d > 4$ and in related $d \geq 4$ scalar and Ising-type settings.* [1]

Proof mechanism and logical scope. The theorem concerns a concrete sequence of reflection-positive lattice models whose finite-cutoff observables are honest random variables. Let $a \downarrow 0$ be the lattice spacing along a critical or near-critical trajectory, let $\Phi_a(x)$ be the lattice spin or scalar field, and choose a field normalization Z_a such that the smeared variables

$$X_a(f) = Z_a\, a^4 \sum_{x \in a\mathbb{Z}^4} f(x)\Phi_a(x), \qquad f \in C_c^\infty(\mathbb{R}^4),$$

have nonzero finite two-point limits. Denote their joint cumulants by

$$\kappa_{a,n}(f_1, \ldots, f_n) = \operatorname{cum}\big(X_a(f_1), \ldots, X_a(f_n)\big).$$

Any subsequential scaling limit is Gaussian exactly when its covariance $\lim_{a\downarrow 0} \kappa_{a,2}$ exists and all limiting cumulants $\lim_{a\downarrow 0} \kappa_{a,n}$ with $n \geq 3$ vanish. This is the ordinary cumulant characterization of a Gaussian probability law: the logarithm of the characteristic function contains only its quadratic term.

For ferromagnetic even Ising and $\lambda\phi^4$ lattice measures, the $\Phi \mapsto -\Phi$ symmetry removes the odd cumulants. The load-bearing estimate is therefore the four-point truncated function

$$U_4(x_1, x_2, x_3, x_4) = \langle \Phi_{x_1}\Phi_{x_2}\Phi_{x_3}\Phi_{x_4}\rangle - \sum_{\text{pairings } P} \prod_{\{i,j\}\in P} \langle \Phi_{x_i}\Phi_{x_j}\rangle.$$

The random-current switching lemma rewrites U_4, up to a sign fixed by the ferromagnetic convention, as a two-current connection/intersection probability multiplied by two-point functions. A direct consequence is the tree-diagram comparison

$$|U_4(x_1, x_2, x_3, x_4)| \leq C \sum_{z\in\Lambda_a} \prod_{i=1}^{4} G_a(x_i, z), \qquad G_a(x,y) = \langle \Phi_x \Phi_y\rangle.$$

In dimensions $d > 4$ this bound already makes the normalized block-field fourth cumulant vanish, because the corresponding random walks are transient enough. In $d = 4$ the bound is scale-marginal. The theorem of Aizenman–Duminil-Copin supplies the missing logarithmic gain: for macroscopic boxes of lattice radius R,

$$\frac{\sum_{x_1,x_2,x_3,x_4\in B_R} |U_4(x_1,x_2,x_3,x_4)|}{\Big(\sum_{x,y\in B_R} G_a(x,y)\Big)^2} \leq \varepsilon(R), \qquad \varepsilon(R) \xrightarrow[R\to\infty]{} 0. \tag{33.1}$$

The proof of this estimate is the deep multiscale part: the random-current intersection event is decomposed by scales and is shown to carry an extra logarithmic smallness at the upper critical dimension.

[1] See M. Aizenman, "Proof of the triviality of ϕ^4_d field theory and some mean-field features of Ising models for $d > 4$," *Phys. Rev. Lett.* **47** (1981) 1–4, doi:10.1103/PhysRevLett.47.1; J. Fröhlich, "On the triviality of $\lambda\phi^4_d$ theories and the approach to the critical point in $d \geq 4$ dimensions," *Nucl. Phys. B* **200** (1982) 281–296, doi:10.1016/0550-3213(82)90088-8; M. Aizenman and H. Duminil-Copin, "Marginal triviality of the scaling limits of critical 4D Ising and ϕ^4_4 models," *Ann. of Math.* **194** (2021) 163–235, doi:10.4007/annals.2021.194.1.3, and the corrigendum in *Ann. of Math.* **199** (2024) 479, doi:10.4007/annals.2024.199.1.7.

Equation (33.1) implies, after replacing box indicators by smooth test functions and using standard approximation from above and below,

$$\kappa_{a,4}(f_1, f_2, f_3, f_4) \longrightarrow 0.$$

Ferromagnetic correlation inequalities and the random-current cumulant expansion then bound each higher even cumulant by finite sums in which at least one factor is a four-point current-intersection block and all remaining factors are two-point functions. The two-point factors have finite scaling limits by the chosen normalization, while the four-point block tends to zero by (33.1). Hence $\kappa_{a,n} \to 0$ for every $n \geq 4$. Uniform moment bounds supplied by the same current representation make the moment problem determinate for the smeared variables, so every subsequential scaling limit has characteristic function

$$\exp\left[-\frac{1}{2}\sum_{i,j} t_i t_j \lim_{a\downarrow 0} \kappa_{a,2}(f_i, f_j)\right].$$

This is precisely Wick factorization of the limiting Schwinger functions.

The theorem therefore separates two logically different statements. For the specified positive lattice scalar and nearest-neighbor ferromagnetic Ising-type scaling-limit problems, the continuum limits covered by the random-current estimates are Gaussian. The separate problem of constructing an exotic ultraviolet-complete four-dimensional local QFT whose small-coupling expansion agrees with formal ϕ_4^4 perturbation theory to all orders but differs by effects invisible to perturbation theory remains open.

33.6 General 1PI Coordinates

Definition 33.4 (Field-normalization factors)**.** Three field-normalization factors occur in this chapter, and they have different domains of definition.

symbol	meaning
Z_R	Cutoff-dependent factor used in the initial renormalization convention, for example $\phi_R = Z_R^{-1/2}\phi$ in the scalar quartic example.
$Z_{\mathrm{MOM}}(\mu)$	Finite momentum-subtraction rescaling between an already renormalized reference field and the scale-μ 1PI coordinate field: $[\phi]_\mu = Z_{\mathrm{MOM}}(\mu)^{-1/2}\phi_R^{\mathrm{ref}}$.
Z_ϕ	Total bare-to-renormalized field factor used in the Callan–Symanzik equation for the selected chart: $\phi_R^{\mathrm{chart}} = Z_\phi^{-1/2}\phi_0$.

Thus Z_R and $Z_{\mathrm{MOM}}(\mu)$ are not equal as written. If $\phi_R^{\mathrm{ref}} = (Z_\phi^{\mathrm{ref}})^{-1/2}\phi_0$, then the chart whose elementary field is $[\phi]_\mu$ has the total factor

$$Z_\phi^{\mathrm{chart}} = Z_\phi^{\mathrm{ref}}\, Z_{\mathrm{MOM}}(\mu).$$

If the reference field is itself defined by the same momentum-subtraction condition at $\mu = \mu_{\mathrm{ref}}$, then $Z_{\mathrm{MOM}}(\mu_{\mathrm{ref}}) = 1$; the cutoff dependence is in Z_ϕ^{ref}, not in the finite rescaling.

Let a regulated Euclidean action be written as

$$S_\Lambda[\phi] = S_{\mathrm{kin},\Lambda}[\phi] + \int \mathrm{d}^D x \sum_I g_I^{\mathrm{bare}}(\Lambda)\, \mathcal{O}_I(x).$$

For each label I, let $\mathcal{O}_I$ be a local operator with mass dimension d_I, field number n_I, and derivative tensor structure specified by a polynomial P_I in external momenta. The corresponding 1PI coordinate at scale μ is extracted from the n_I-point vertex by

$$g_I(\mu) = \Pi_I \left[Z_{\mathrm{MOM}}(\mu)^{n_I/2}\, \Gamma^{(n_I)}(k_1, \ldots, k_{n_I}) \right]_{\mathcal{S}_{I,\mu}}.$$

The projector Π_I includes the sign and tensor normalization conventions. In the scalar quartic example, Π_I is multiplication by -1 at the symmetric four-point configuration.

Two elementary coordinates fix the normalization conventions. First consider the two-derivative quadratic operator represented, up to total derivatives and normalization convention, by $\mathcal{O}_{2,2} = \phi\,\Box\phi$, in the same self-energy convention used above. Its 1PI Taylor coefficient at $k^2 = \mu^2$ is

$$\Gamma^{(2;2)}\big|_{k^2=\mu^2} = \left.\frac{\partial \Sigma}{\partial k^2}\right|_{k^2=\mu^2} = 1 - Z_{\mathrm{MOM}}(\mu)^{-1}.$$

With the minus sign included in the quadratic-coordinate projector, the corresponding renormalized coordinate is

$$g_{2,2}(\mu) = -Z_{\mathrm{MOM}}(\mu) \left(1 - Z_{\mathrm{MOM}}(\mu)^{-1}\right) = 1 - Z_{\mathrm{MOM}}(\mu).$$

This is the same field-normalization information expressed as a 1PI coordinate. Second, for the mass operator with bare coefficient $g_2^{\mathrm{bare}} = m_0^2$, the dimensionless coordinate may be written

$$\lambda_2(\mu) = \mu^{-2} Z_{\mathrm{MOM}}(\mu) \left[g_2^{\mathrm{bare}} - \Sigma(k)\big|_{k^2=\mu^2} \right],$$

again in the same self-energy and projector convention. These examples make explicit that the field normalization, relevant mass coordinate, and higher 1PI vertex coordinates are part of one coordinate chart.

Definition 33.5 (Mass data and mass coordinates)**.** Assume that the connected Euclidean two-point function under discussion satisfies the spectral representation of Chapter 14. If the spectral measure has an isolated atom

$$\mathrm{d}\rho_\Phi(s) = Z_\Phi\, \delta_{m_*^2} + \mathrm{d}\rho_{\Phi,\mathrm{c}}(s), \qquad Z_\Phi > 0,$$

where $\delta_{m_*^2}$ is the Dirac measure at $s = m_*^2$. If there is no support below m_*^2 in that channel, then m_* is the *spectral pole mass* seen by the interpolating operator Φ. If the corresponding state is a stable one-particle state and another local operator has nonzero overlap with the same state, it gives the same m_*; the residue changes with the operator, not the mass. In a gauge theory this statement is made for gauge-invariant operators or for physical BRST cohomology states. Pole positions of gauge-fixed elementary fields are not, by themselves, physical mass data.

By contrast, m_R is a finite 1PI subtraction coordinate, and $\lambda_2(\mu)$ is a dimensionless running coordinate for the relevant quadratic deformation. They are scheme-dependent coordinates on a family of regulated Green functions. The lattice parameter m_0^2, or its spin-model analogue such as $T - T_c$, is a regulator coordinate that must be tuned as the cutoff is removed. None of these three coordinates is a pole mass by definition.

Remark 33.6 (Relation of the mass notions). Suppose the exact renormalized two-point function in the finite 1PI chart has the form

$$G_R(k) = \frac{1}{k^2 + m_R^2 - \Sigma_R(k)}$$

in a neighborhood admitting analytic continuation to the isolated stable pole. Then the spectral pole mass satisfies

$$m_*^2 = m_R^2 - \Sigma_R(k^2 = -m_*^2), \tag{33.2}$$

with the same sign convention as the displayed Euclidean inverse propagator. An on-shell mass prescription imposes $m_R = m_*$ order by order, while a generic momentum-subtraction or minimal-subtraction prescription does not. In an MS chart, $\lambda_2(\mu)$ is related to m_* only after a finite matching condition and RG evolution have been specified. In a lattice regularization with lattice spacing a, the bare coordinate $m_0^2(a)$ is tuned to a critical surface $m_{0,c}^2(a)$ for a massless scaling limit, or away from it so that

$$m_{\text{gap}} = \lim_{a\to 0} \frac{1}{a\,\xi_{\text{lat}}(a)} \tag{33.3}$$

exists. When the lower edge of the reconstructed spectral support is an isolated one-particle atom, $m_{\text{gap}} = m_*$; otherwise m_{gap} is the threshold edge rather than a pole mass.

The first assertion is the definition of an isolated Källen–Lehmann atom: near $s = m_*^2$,

$$G_E(k) = \frac{Z_\Phi}{k^2 + m_*^2} + \text{term analytic at } k^2 = -m_*^2.$$

Thus the inverse two-point function vanishes at $k^2 = -m_*^2$. Substituting that value into the chosen 1PI inverse-propagator convention gives (33.2). A finite change of renormalization prescription changes the coordinate m_R and the finite part of Σ_R, but not the spectral singularity of the completed Green function.

Minimal subtraction fixes a coordinate by pole subtraction in dimensional regularization. It contains no condition at the physical pole, so determining m_* requires first expressing the finite Green function in that coordinate and then solving the pole equation. For the lattice statement, exponential decay of Euclidean two-point functions gives ξ_{lat}^{-1} as the lowest transfer-matrix energy in lattice units in the selected channel. Multiplication by a^{-1} converts it to continuum units. Osterwalder–Schrader reconstruction identifies the limiting transfer-matrix spectrum with the reconstructed Hamiltonian spectrum under the usual reflection-positivity and scaling-limit hypotheses. An isolated lowest eigenvalue gives the spectral atom and hence m_*; continuous spectral support beginning at the same energy gives only a gap edge.

The finite comparison of nearby scales gives

$$\frac{\mathrm{d}g_I(\mu)}{\mathrm{d}\log\mu} = \beta_I(\{g_J(\mu)\};\mu).$$

Since g_I has engineering dimension $D - d_I$, define the dimensionless coordinate

$$\lambda_I(\mu) = \mu^{d_I - D} g_I(\mu).$$

When the coordinate list contains all dimensionless ratios relevant to the chosen family of theories, the equations may be written as

$$\frac{\mathrm{d}\lambda_I}{\mathrm{d}\log\mu} = \beta_I(\{\lambda_J\}).$$

This autonomous form is a coordinate statement: the beta functions depend on the selected operator basis, subtraction configurations, field normalization, and finite part conventions.

The practical value of the 1PI RG is logarithmic organization. A fixed-order comparison between two widely separated scales can contain powers of $\log(\mu/\mu')$. The differential equation breaks that comparison into small steps and then integrates the result, thereby summing the logarithmic terms determined by the computed beta function.

33.7 Callan–Symanzik Equation from Bare-Scale Independence

The beta function is a vector field on the renormalized coordinate space. Its action on correlation functions follows from the same construction of renormalized coordinates.

There are two logically distinct field factors in the preceding discussion, after the reference renormalization convention has been chosen. The factor $Z_{\mathrm{MOM}}(\mu)$ is finite after renormalization; it relates an already renormalized reference field ϕ_R^{ref} to the momentum-subtraction field used in the scale-μ coordinate chart,

$$[\phi]_\mu = Z_{\mathrm{MOM}}(\mu)^{-1/2}\phi_R^{\mathrm{ref}}.$$

The factor denoted Z_ϕ in the Callan–Symanzik equation is instead the cutoff-dependent total factor that relates the regulated bare field to the renormalized field chosen for the chart. If

$$\phi_R^{\mathrm{ref}} = \big(Z_\phi^{\mathrm{ref}}(\lambda,\mu_{\mathrm{ref}},\Lambda)\big)^{-1/2}\phi_0,$$

then the momentum-subtraction chart whose elementary field is $[\phi]_\mu$ has

$$[\phi]_\mu = \big(Z_\phi^{\mathrm{ref}}(\lambda,\mu_{\mathrm{ref}},\Lambda)\, Z_{\mathrm{MOM}}(\mu)\big)^{-1/2}\phi_0.$$

Thus, in that chart,

$$Z_\phi^{\mathrm{chart}}(\lambda(\mu),\mu,\Lambda) = Z_\phi^{\mathrm{ref}}(\lambda,\mu_{\mathrm{ref}},\Lambda)\, Z_{\mathrm{MOM}}(\mu).$$

Below the superscript "chart" is suppressed: Z_ϕ always denotes the total bare-to-renormalized field factor for the correlation functions being studied, while $Z_{\mathrm{MOM}}(\mu)$ denotes the finite momentum-subtraction rescaling appearing in the 1PI vertex coordinates.

Let ϕ_0 be the regulated bare scalar field. Let ϕ_R now denote the elementary field of the selected chart, for instance $[\phi]_\mu$ in the momentum-subtraction chart above, and choose Z_ϕ by

$$\phi_R = Z_\phi(\lambda(\mu),\mu,\Lambda)^{-1/2}\phi_0.$$

For a connected noncoincident n-point function, write

$$G_{0,\Lambda}^{(n)}(x_1,\ldots,x_n;g_0,\Lambda) = \langle\phi_0(x_1)\cdots\phi_0(x_n)\rangle_{\mathrm{conn},\Lambda,g_0}$$

for the regulated bare function. A renormalization chart consists of functions

$$g_0^a = F^a(\lambda(\mu),\mu,\Lambda)$$

and a field factor Z_ϕ such that

$$G_R^{(n)}(x_1,\ldots,x_n;\lambda,\mu) = \lim_{\Lambda\to\infty} Z_\phi^{-n/2} G_{0,\Lambda}^{(n)}\big(x_1,\ldots,x_n;F(\lambda,\mu,\Lambda),\Lambda\big)$$

exists as a distribution away from coincident points. The finite coordinates λ_I are dimensionless coordinates; dimensionful parameters are either included as additional dimensionless ratios or are displayed separately below.

Let $t = \log \mu$. The RG vector field in this chart is

$$\beta_I(\lambda) = \left.\frac{\mathrm{d}\lambda_I}{\mathrm{d}t}\right|_{g_0,\Lambda}.$$

The anomalous dimension of the elementary field in the same chart is

$$\gamma_\phi(\lambda) = \frac{1}{2}\left.\frac{\mathrm{d}\log Z_\phi}{\mathrm{d}t}\right|_{g_0,\Lambda}.$$

The convention agrees with the normalization used earlier: $\phi_R = Z_\phi^{-1/2}\phi_0$.

Callan–Symanzik equation. With the definitions above, the renormalized connected noncoincident n-point function satisfies

$$\left(\mu\frac{\partial}{\partial\mu} + \sum_I \beta_I(\lambda)\frac{\partial}{\partial\lambda_I} + n\gamma_\phi(\lambda)\right) G_R^{(n)} = 0. \tag{33.4}$$

The derivative $\mu\partial_\mu$ is taken at fixed x_i and fixed renormalized coordinates λ_I.

The regulated bare function contains no independent dependence on the auxiliary scale μ. Therefore

$$0 = \left.\frac{\mathrm{d}}{\mathrm{d}t} G_{0,\Lambda}^{(n)}(x_1,\ldots,x_n; g_0,\Lambda)\right|_{g_0,\Lambda}.$$

Using

$$G_{0,\Lambda}^{(n)} = Z_\phi^{n/2} G_R^{(n)}$$

inside the renormalization chart and differentiating at fixed bare data gives

$$0 = Z_\phi^{n/2}\left[\left(\frac{\partial}{\partial t} + \sum_I \beta_I \frac{\partial}{\partial\lambda_I}\right) G_R^{(n)} + \frac{n}{2}\frac{\mathrm{d}\log Z_\phi}{\mathrm{d}t} G_R^{(n)}\right].$$

The cutoff limit exists by the definition of the chart, and the displayed identity becomes (33.4).

Contact terms are not part of the displayed noncoincident equation. When insertion points collide, the omitted terms are local distributions supported on the collision diagonals. Their organization requires a renormalized local operator basis and is developed in the next chapter.

33.8 Canonical Scaling and Fixed Points

The Callan–Symanzik equation records dependence on the auxiliary renormalization scale. Dimensional homogeneity is a separate statement. Suppose the elementary scalar has engineering dimension

$$d_\phi^{\mathrm{eng}} = \frac{D-2}{2}$$

and let u_A denote displayed dimensionful renormalized parameters with engineering dimensions y_A. Away from coincident points, dimensional homogeneity gives

$$\left(\sum_{i=1}^{n} x_i^\nu \frac{\partial}{\partial x_i^\nu} - \mu\frac{\partial}{\partial \mu} - \sum_A y_A u_A \frac{\partial}{\partial u_A} + n d_\phi^{\text{eng}}\right) G_R^{(n)} = 0.$$

If the u_A are displayed rather than converted into dimensionless ratios, the Callan–Symanzik equation includes the additional term $\sum_A \beta_{u_A}\partial/\partial u_A$, where

$$\beta_{u_A} = \left.\frac{\mathrm{d}u_A}{\mathrm{d}\log\mu}\right|_{g_0,\Lambda}.$$

Combining that equation with dimensional homogeneity gives

$$\left(\sum_{i=1}^{n} x_i^\nu \frac{\partial}{\partial x_i^\nu} + \sum_I \beta_I \frac{\partial}{\partial \lambda_I} + \sum_A (\beta_{u_A} - y_A u_A)\frac{\partial}{\partial u_A} + n(d_\phi^{\text{eng}} + \gamma_\phi)\right) G_R^{(n)} = 0.$$

Equivalently, one may replace u_A by dimensionless ratios u_A/μ^{y_A}; then the canonical terms are included in the beta functions of those ratios.

At a fixed point with no displayed dimensionful deformation, $\beta_I(\lambda_*) = 0$ and $\gamma_\phi(\lambda_*) = \gamma_{\phi,*}$. The noncoincident correlator then obeys

$$\left(\sum_{i=1}^{n} x_i^\nu \frac{\partial}{\partial x_i^\nu} + n\Delta_\phi\right) G_R^{(n)}(x_1,\ldots,x_n;\lambda_*) = 0, \qquad \Delta_\phi = d_\phi^{\text{eng}} + \gamma_{\phi,*}.$$

Thus the field scaling dimension at the fixed point is the engineering dimension plus the anomalous dimension defined by the field normalization in the renormalization chart. Scaling dimensions of composite operators require the mixing analysis of local operator insertions.

33.9 Logarithmic Consistency

The existence of finite beta functions imposes relations among logarithms in cutoff perturbation theory. Let

$$L = \log\frac{\Lambda}{\mu},$$

and suppose a one-coupling coordinate has the bare expansion

$$g(\mu) = g_0 - b_1 g_0^2 L - b_2 g_0^3 L - c_1 g_0^3 L^2 + O(g_0^4).$$

Since $\mathrm{d}L/\mathrm{d}\log\mu = -1$,

$$\frac{\mathrm{d}g(\mu)}{\mathrm{d}\log\mu} = b_1 g_0^2 + b_2 g_0^3 + 2c_1 g_0^3 L + O(g_0^4).$$

Inverting the first displayed relation to the order needed gives

$$g_0 = g(\mu) + b_1 g(\mu)^2 L + O(g(\mu)^3).$$

Therefore

$$\frac{\mathrm{d}g(\mu)}{\mathrm{d}\log\mu} = b_1 g(\mu)^2 + b_2 g(\mu)^3 + 2\big(c_1 + b_1^2\big) g(\mu)^3 L + O(g(\mu)^4).$$

A beta function expressed in terms of the renormalized coordinate must be finite as the cutoff is removed. Hence the explicit L-term at this order vanishes:

$$c_1 = -b_1^2.$$

Figure 33.5 shows why the nested one-loop double logarithm is constrained by the one-loop beta function: the explicit cutoff logarithm cancels only for $c_1 = -b_1^2$.

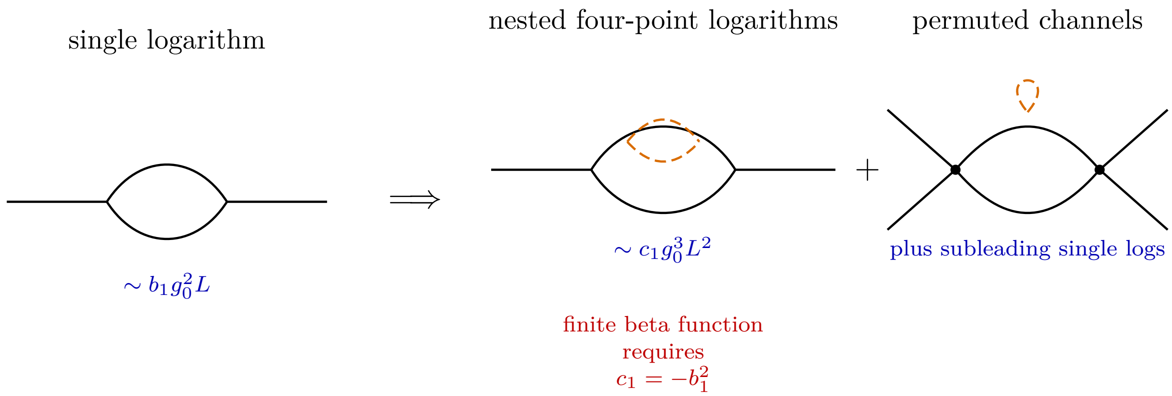

Figure 33.5: The double logarithm associated with nested one-loop subgraphs is constrained by the one-loop beta function. Dashed inner loops mark the nested subgraph whose one-loop logarithm is reused. Its coefficient is fixed by the requirement that the beta function, expressed in the renormalized coordinate, have a finite cutoff-removal limit.

This calculation is the scale-differential form of the locality statements from the previous chapters. The logarithm associated with a subgraph can be reused inside a larger graph, and the coefficient of the resulting double logarithm is determined by the lower-order beta function rather than by an independent input.

33.10 Scheme Changes

A renormalization scheme is a coordinate system on the renormalized family of theories. Let λ and $\widetilde{\lambda}$ be two coordinates related by a finite redefinition

$$\widetilde{\lambda} = f(\lambda), \qquad f(0) = 0, \qquad f'(0) = 1,$$

where the last condition fixes the leading normalization of the coordinate. If

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = \beta(\lambda), \qquad \frac{\mathrm{d}\widetilde{\lambda}}{\mathrm{d}\log\mu} = \widetilde{\beta}(\widetilde{\lambda}),$$

then the chain rule gives

$$\widetilde{\beta}(f(\lambda)) = f'(\lambda)\beta(\lambda), \qquad \beta(\lambda) = \frac{\widetilde{\beta}(f(\lambda))}{f'(\lambda)}.$$

If only the first nonlinear coefficient is displayed,

$$f(\lambda) = \lambda + \alpha\lambda^2 + O(\lambda^3),$$

then, to first order in α and without fixing the omitted cubic coefficient,

$$\beta(\lambda) = \widetilde{\beta}(\lambda) + \alpha\lambda\left(\lambda\frac{\partial}{\partial\lambda} - 2\right)\widetilde{\beta}(\lambda) + O(\alpha^2).$$

For one classically marginal coordinate,

$$\beta(\lambda) = b_1\lambda^2 + b_2\lambda^3 + b_3\lambda^4 + \cdots, \qquad \widetilde{\beta}(\lambda) = \widetilde{b}_1\lambda^2 + \widetilde{b}_2\lambda^3 + \widetilde{b}_3\lambda^4 + \cdots.$$

The relation above already implies

$$b_1 = \widetilde{b}_1, \qquad b_2 = \widetilde{b}_2.$$

To see the first scheme-dependent coefficient without hiding the role of the next finite redefinition, write

$$\widetilde{\lambda} = \lambda + \alpha\lambda^2 + \rho\lambda^3 + O(\lambda^4).$$

Using

$$\widetilde{\beta}(\widetilde{\lambda}) = f'(\lambda)\,\beta(\lambda), \qquad \widetilde{\lambda} = f(\lambda),$$

and re-expanding in powers of $\widetilde{\lambda}$ gives

$$\widetilde{b}_1 = b_1, \qquad \widetilde{b}_2 = b_2, \qquad \widetilde{b}_3 = b_3 - \alpha b_2 + (\rho - \alpha^2)b_1.$$

Thus, for a single marginal coupling and with the leading normalization fixed, the first two perturbative coefficients are invariant under finite analytic reparametrizations, while later coefficients are coordinate dependent.

For several couplings the corresponding statement is a statement about jets of a vector field, not about a list of scalar coefficients. Let a finite renormalized coordinate chart have coordinates λ^I centered at the point under discussion, and expand

$$\beta^I(\lambda) = M^I{}_J\lambda^J + \frac{1}{2}B^I{}_{JK}\lambda^J\lambda^K + O(\lambda^3), \qquad B^I{}_{JK} = B^I{}_{KJ}. \tag{33.5}$$

Let another scheme be related by the finite analytic coordinate change

$$\widetilde{\lambda}^A = R^A{}_I\lambda^I + \frac{1}{2}C^A{}_{IJ}\lambda^I\lambda^J + O(\lambda^3), \qquad C^A{}_{IJ} = C^A{}_{JI}, \tag{33.6}$$

where R is invertible. Write $S = R^{-1}$, and write $\widetilde{M} = RMS$. Then the quadratic coefficient of $\widetilde{\beta}$ is

$$\begin{aligned}\widetilde{B}^A{}_{BC} &= R^A{}_I B^I{}_{JK} S^J{}_B S^K{}_C \\ &\quad + C^A{}_{IJ}\left(S^I{}_B M^J{}_K S^K{}_C + S^I{}_C M^J{}_K S^K{}_B\right) - \widetilde{M}^A{}_D C^D{}_{IJ} S^I{}_B S^J{}_C.\end{aligned} \tag{33.7}$$

Thus the quadratic beta-function jet is not, in general, a tensorial invariant of the renormalization scheme. It is changed by the second derivative of the coordinate map whenever the linear term M is present. The invariant linear data at a fixed point are the similarity class of M, and hence its eigenvalues. The coordinate calculation is the following. The beta function transforms as a vector field:

$$\widetilde{\beta}^A(\widetilde{\lambda}) = \frac{\partial \widetilde{\lambda}^A}{\partial \lambda^I}\,\beta^I(\lambda).$$

The inverse coordinate map has the expansion

$$\lambda^I = S^I{}_A \widetilde{\lambda}^A - \frac{1}{2} S^I{}_A C^A{}_{JK} S^J{}_B S^K{}_C \widetilde{\lambda}^B \widetilde{\lambda}^C + O(\widetilde{\lambda}^3).$$

Substituting this inverse expansion and

$$\frac{\partial \widetilde{\lambda}^A}{\partial \lambda^I} = R^A{}_I + C^A{}_{IJ}\lambda^J + O(\lambda^2)$$

into the vector-field transformation law and collecting the terms quadratic in $\widetilde{\lambda}$ gives (33.7).

There is an important special case. If all displayed couplings are classically marginal at the reference point and the coordinate origin is the Gaussian fixed point, then $M = 0$. In that case (33.7) reduces to

$$\widetilde{B}^A{}_{BC} = R^A{}_I B^I{}_{JK} S^J{}_B S^K{}_C.$$

After the leading linear normalization R has been fixed, the one-loop quadratic tensor B is scheme independent. Without fixing R, the same geometric object is represented by different components in different linear bases. If $M \neq 0$, for example when relevant, irrelevant, or explicitly dimensionful coordinates are included, the quadratic coefficients are already coordinate dependent. At cubic order, even in the purely marginal case, the quadratic coordinate redefinition C combines with B; hence the single-coupling statement $b_2 = \widetilde{b}_2$ has no componentwise multi-coupling analogue without additional structure.

Remark 33.7 (Scheme coordinates for matched physical observables). Let $S_{\Lambda_0}(\theta)$ be the local action used in the regulated path integral, including all regulator-dependent local terms required by the chosen regularization procedure. Here Λ_0 denotes the ultraviolet regulator and θ denotes the full list of regulated action parameters. Let R and $\widetilde{R}$ be two renormalization schemes on the same perturbative domain. Assume the following data.

1. Each scheme assigns a finite renormalized coordinate to the same regulated action parameter θ:

   $$\lambda_\Lambda = \lambda_R(\theta, \Lambda_0), \qquad \widetilde{\lambda}_\Lambda = \lambda_{\widetilde{R}}(\theta, \Lambda_0),$$

   and the cutoff-removal limits are related by a finite analytic matching map

   $$\widetilde{\lambda} = f(\lambda), \qquad f(0) = 0, \qquad Df(0) \text{ invertible.}$$

   The same statement includes the finite field normalizations and local source coordinate maps needed to define inserted operators.

2. The observable A_Λ is defined at the regulated level before a renormalization scheme is chosen. Examples are an on-shell transition probability between normalized Haag–Ruelle particle states, a perturbative LSZ matrix element after the pole positions and residues have been matched, or an infrared-safe inclusive observable with the measurement function held fixed.

3. The ultraviolet and infrared limits required to define A exist order by order in the perturbative domain under the matching above. In massless theories this includes the infrared prescription, such as nonexceptional Euclidean momenta for Green functions or an inclusive measurement for scattering.

Let $A_R(\lambda)$ and $A_{\widetilde{R}}(\widetilde{\lambda})$ be the perturbative expansions obtained by computing the same regulated observable in the two schemes and then taking the common limit. Then, as formal perturbative series,

$$A_R(\lambda) = A_{\widetilde{R}}(f(\lambda)). \tag{33.8}$$

At finite Λ_0, A_Λ is a number, distribution, or transition probability computed in the regulated theory with action parameter θ. It does not know which finite coordinates will later be used to label the same regulated action. Thus

$$A_\Lambda(\theta) = A_{\Lambda,R}(\lambda_R(\theta, \Lambda_0)) = A_{\Lambda,\widetilde{R}}(\lambda_{\widetilde{R}}(\theta, \Lambda_0))$$

after including the field and source normalizations that belong to the two coordinate charts. The matching map is defined by eliminating the regulated action parameters between the two coordinate assignments and then taking $\Lambda_0 \to \infty$:

$$\lambda_{\widetilde{R}}(\theta, \Lambda_0) = f_{\Lambda_0}(\lambda_R(\theta, \Lambda_0)), \qquad f_{\Lambda_0} \to f.$$

If the observable has the stated perturbative limit, the finite-regulator identity passes to the limit order by order and gives (33.8).

For an LSZ amplitude, the finite field rescaling between schemes changes off-shell Green functions and amputated kernels, but the residue and one-particle-state normalizations used in the LSZ construction change by the inverse factors. The matched on-shell matrix element is therefore the same observable. For a local source insertion, a finite local source-coordinate redefinition can change the coincident-point extension of the source functional. This does not change a separated-point observable. If the observable itself probes coincident support, then its definition includes that source-response convention and the convention must be matched as part of the observable data.

Remark 33.8 (What is not scheme invariant). Equation (33.8) is a statement with a matching map. It does not say that $A_R(\lambda) = A_{\widetilde{R}}(\lambda)$ after the same coordinate values are inserted in two different schemes. It also does not make off-shell Green functions, beta-function components, anomalous-dimension matrices, or contact terms coordinate independent. Those quantities are useful precisely because they are chart-dependent representatives from which matched physical observables, fixed-point eigenvalues, anomaly classes, and other invariant data are extracted.

33.11 Perturbative Series as Asymptotic Data

The beta functions, anomalous dimensions, fixed-point coordinates, and critical exponents computed in the preceding and following chapters are usually obtained as formal expansions. The meaning of such an expansion must be specified separately from the rules used to compute its coefficients.

Definition 33.9 (Asymptotic expansion)**.** Let $A(g)$ be defined for g in a sector $S \subset \mathbb{C}$ whose closure contains $g = 0$, and let $\sum_{n\geq 0} a_n g^n$ be a formal power series. The series is an asymptotic expansion of A in S if, for every $N \geq 0$,

$$A(g) - \sum_{n=0}^{N} a_n g^n = o(g^N) \qquad (g \to 0,\ g \in S')$$

on every closed subsector S' strictly contained in S. A stronger version replaces $o(g^N)$ by $O(g^{N+1})$ with constants depending on N and S'.

An asymptotic expansion need not converge. Even when it determines every coefficient a_n, it does not by itself determine the function A: functions differing by terms such as $\exp(-c/g)$, with $c > 0$ in the sector under consideration, have the same power-series asymptotic expansion at the origin. Such nonperturbative terms are invisible to all orders in ordinary perturbation theory.

The common mechanism behind divergence is factorial growth of coefficients. In finite-dimensional integrals and in many field-theoretic expansions, the number of diagrams grows factorially. In examples where the saddle analysis of the analytically continued action is under control, the large-order coefficients have the form

$$a_n \sim C\,(-A)^{-n}\,\Gamma(n+b)$$

for constants A, C, b depending on the observable and on the expansion coordinate. Dyson's instability argument for QED is the simplest physical warning: if a perturbative series in e^2 had a nonzero radius of convergence around $e^2 = 0$, it would analytically continue to negative e^2, where like charges attract and the vacuum is not stable in the same way.[2] This argument is not a theorem about every renormalized quantity in every QFT; it is a reason not to identify perturbation theory with a convergent definition unless convergence or summability has actually been proved.

One possible reconstruction mechanism is Borel–Laplace summation. It is a theorem about a formal series together with analytic continuation and growth data for its Borel transform. The hypotheses are part of the statement.

Definition 33.10 (Gevrey-one series and directional Borel sum)**.** Let

$$\widehat{A}(g) = \sum_{n\geq 0} a_n g^n$$

be a formal power series. It is *Gevrey-one* if there are constants $C, M > 0$ such that

$$|a_n| \leq C\,M^n n! \qquad (n \geq 0).$$

Its formal Borel transform is

$$\mathcal{B}\widehat{A}(\xi) = \sum_{n\geq 0} \frac{a_n}{n!}\xi^n. \tag{33.9}$$

Fix a direction $\theta \in \mathbb{R}/2\pi\mathbb{Z}$. The direction is admissible for $\widehat{A}$ if the series $\mathcal{B}\widehat{A}$ converges near $\xi = 0$, continues holomorphically to a sector

$$\Sigma_{\theta,\eta} = \{\xi \neq 0 : \ |\arg\xi - \theta| < \eta\}$$

for some $\eta > 0$, and obeys an exponential bound

$$|\mathcal{B}\widehat{A}(\xi)| \leq C_\eta \exp(|\xi|/R_\eta) \qquad (\xi \in \Sigma_{\theta,\eta}) \tag{33.10}$$

[2]See F. J. Dyson, "Divergence of perturbation theory in quantum electrodynamics," *Phys. Rev.* **85** (1952) 631–632, doi:10.1103/PhysRev.85.631. For explicit large-order analysis in closely related settings, see C. M. Bender and T. T. Wu, "Anharmonic oscillator," *Phys. Rev.* **184** (1969) 1231–1260, doi:10.1103/PhysRev.184.1231, and L. N. Lipatov, "Divergence of the perturbation-theory series and the quasiclassical theory," *Sov. Phys. JETP* **45** (1977) 216–223.

for some $C_\eta, R_\eta > 0$. For g satisfying

$$|\arg g - \theta| < \frac{\pi}{2} - \delta, \qquad |g| < R_\eta \cos\delta$$

with $0 < \delta < \pi/2$, the directional Borel sum is

$$\mathcal{S}_\theta \widehat{A}(g) = \frac{1}{g}\int_0^{e^{i\theta}\infty} e^{-\xi/g}\, \mathcal{B}\widehat{A}(\xi)\, d\xi, \tag{33.11}$$

where the ray is oriented from 0 to infinity.

Theorem 33.11 (Watson lemma for the Borel–Laplace transform). *Under the hypotheses of Definition 33.10, $\mathcal{S}_\theta\widehat{A}(g)$ is holomorphic in the indicated sector of the g-plane and has $\widehat{A}(g)$ as its asymptotic expansion there: for every $N \geq 0$ and every closed subsector strictly inside the domain,*

$$\mathcal{S}_\theta\widehat{A}(g) - \sum_{n=0}^{N} a_n g^n = O(g^{N+1}). \tag{33.12}$$

Proof. Rotate the integration variable so that the Borel ray is the positive real axis; the general case is the same after replacing g by $e^{-i\theta}g$. The exponential bound (33.10) gives absolute convergence of (33.11) on each closed subsector with $\Re(1/g) > 1/R_\eta + \epsilon$. Holomorphy follows by dominated convergence applied to compact subsets of that domain.

Choose $\rho > 0$ inside the convergence disk of the Borel transform. For $|\xi| \leq \rho$,

$$\mathcal{B}\widehat{A}(\xi) = \sum_{n=0}^{N} \frac{a_n}{n!}\xi^n + \xi^{N+1}R_N(\xi)$$

with R_N bounded on $|\xi| \leq \rho$. The polynomial terms give exactly

$$\frac{1}{g}\int_0^\infty e^{-\xi/g}\frac{\xi^n}{n!}\, d\xi = g^n$$

when $\Re g > 0$, and by the same rotated-ray computation in a sector. The small-ξ remainder is bounded by a constant times

$$\frac{1}{|g|}\int_0^\rho e^{-c\xi/|g|}\xi^{N+1}\, d\xi = O(|g|^{N+1})$$

on each closed subsector, where $c > 0$ is the lower bound for $\Re(\xi/g)/(|\xi|/|g|)$. The tail integral from ρ to infinity is bounded by $C\exp(-c'\rho/|g|)$ for some $c' > 0$, hence is $O(|g|^{N+1})$ for every fixed N. This proves (33.12). □

Definition 33.12 (Lateral Borel sums and Stokes discontinuity). Let $\widehat{A}(g)$ be Gevrey-one, and suppose that its Borel transform is holomorphic in a punctured sector around the ray $\arg\xi = \theta$, except for a locally finite set of singular points on the ray. If the deformed rays $\arg\xi = \theta \pm \epsilon$ have Borel–Laplace sums and these sums have limits as $\epsilon \downarrow 0$, the limits are the lateral sums

$$\mathcal{S}_{\theta^+}\widehat{A}(g), \qquad \mathcal{S}_{\theta^-}\widehat{A}(g).$$

Their difference

$$\mathrm{Disc}_\theta\, \widehat{A}(g) = \mathcal{S}_{\theta^+}\widehat{A}(g) - \mathcal{S}_{\theta^-}\widehat{A}(g) \tag{33.13}$$

is the Stokes discontinuity across the ray. This definition is a statement about boundary values of a named Borel transform; it is not a prescription unless the analytic continuation, growth bounds, and lateral limits have been established.

Simple-pole Stokes jump. Let $A > 0$, and suppose that in a neighborhood of $\xi = A$ the Borel transform has the form

$$\mathcal{B}\widehat{A}(\xi) = \frac{r}{\xi - A} + H(\xi), \tag{33.14}$$

where H is holomorphic. Assume that away from this singularity the lateral Borel integrals along the positive ray satisfy the hypotheses of Definition 33.12. Then the contribution of this pole to the upper-minus-lower discontinuity is

$$\mathrm{Disc}_0\,\widehat{A}(g) = \frac{2\pi \mathrm{i} r}{g}\,\mathrm{e}^{-A/g} + \mathrm{Disc}_0^{\mathrm{other}}\,\widehat{A}(g), \tag{33.15}$$

where the last term denotes contributions from other singularities on the same ray.

Subtract the holomorphic part H, whose upper and lower deformations across a small disk around A have the same limit. The difference between the two lateral contours for the pole term is a positively oriented small circle around A. Hence

$$\frac{1}{g}\oint_{|\xi - A| = \epsilon} \mathrm{e}^{-\xi/g}\frac{r}{\xi - A}\,\mathrm{d}\xi = \frac{2\pi \mathrm{i} r}{g}\,\mathrm{e}^{-A/g}.$$

The remaining parts of the contour cancel by deformation in the common holomorphic domain. Summing over singularities on the ray gives the stated local contribution.

Definition 33.13 (One-parameter transseries system)**.** Fix $A > 0$, $\beta \in \mathbb{C}$, and a sector in the g-plane. A one-parameter transseries system at the first exponential scale is a formal object

$$\widehat{F}(g;\sigma) = \widehat{\Phi}_0(g) + \sigma\,\mathrm{e}^{-A/g} g^{\beta}\widehat{\Phi}_1(g), \tag{33.16}$$

where $\widehat{\Phi}_0$ and $\widehat{\Phi}_1$ are formal power series and $\sigma \in \mathbb{C}$ is a parameter. A summation of (33.16) requires summation data for both formal series and a rule for how σ changes when the summation direction crosses a Stokes ray.

Remark 33.14 (Algebra of the first Stokes cancellation). Assume that the lateral sums of $\widehat{\Phi}_0$ and $\widehat{\Phi}_1$ exist on a ray and satisfy

$$\mathcal{S}_+\widehat{\Phi}_0 - \mathcal{S}_-\widehat{\Phi}_0 = C\,\mathrm{e}^{-A/g} g^{\beta}\,\mathcal{S}_-\widehat{\Phi}_1, \qquad \mathcal{S}_+\widehat{\Phi}_1 = \mathcal{S}_-\widehat{\Phi}_1, \tag{33.17}$$

for a constant C. Then the two lateral sums of $\widehat{F}(g;\sigma)$ agree if and only if

$$\sigma_- = \sigma_+ + C. \tag{33.18}$$

If the data are real on the two sides of a real Stokes ray and C is purely imaginary, the median choice

$$\sigma_+ = \sigma_{\mathrm{R}} - \frac{C}{2}, \qquad \sigma_- = \sigma_{\mathrm{R}} + \frac{C}{2}, \qquad \sigma_{\mathrm{R}} \in \mathbb{R}, \tag{33.19}$$

gives a common real value whenever the two lateral boundary values are complex conjugates.

Using (33.17),

$$\begin{aligned} \mathcal{S}_+\widehat{F}(g;\sigma_+) &= \mathcal{S}_-\widehat{\Phi}_0 + (C + \sigma_+)\mathrm{e}^{-A/g} g^{\beta}\mathcal{S}_-\widehat{\Phi}_1, \\ \mathcal{S}_-\widehat{F}(g;\sigma_-) &= \mathcal{S}_-\widehat{\Phi}_0 + \sigma_-\mathrm{e}^{-A/g} g^{\beta}\mathcal{S}_-\widehat{\Phi}_1. \end{aligned}$$

Equality is therefore equivalent to (33.18) unless the displayed one-instanton lateral sum vanishes identically, in which case the same equation is the natural continuous extension. The median choice is the symmetric solution of this affine relation. Under the stated reality hypothesis the two lateral values are conjugate, so their common symmetric value is real.

Example 33.15 (Zero-dimensional stable quartic integral)**.** The normalized integral

$$I(g) = \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} \exp\left(-\frac{x^2}{2} - \frac{gx^4}{4!}\right) \mathrm{d}x \qquad (\Re g > 0) \tag{33.20}$$

is a finite-dimensional model of the distinction between coefficientwise perturbation theory and analytic reconstruction. Termwise expansion at $g = 0$ gives

$$I(g) \sim \sum_{n\geq 0} a_n g^n, \qquad a_n = (-1)^n \frac{(4n)!}{n!\,96^n (2n)!}. \tag{33.21}$$

Indeed

$$\frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} x^{4n} \mathrm{e}^{-x^2/2}\, \mathrm{d}x = (4n-1)!! = \frac{(4n)!}{2^{2n}(2n)!},$$

and the extra factor is $(-1)^n/(n!(4!)^n)$. Stirling's formula gives

$$\frac{a_{n+1}}{(n+1)a_n} \longrightarrow -\frac{2}{3}, \tag{33.22}$$

so the perturbative series has zero radius of convergence. Dividing by $n!$ gives the Borel series

$$\mathcal{B}I(\xi) = \sum_{n\geq 0} \frac{a_n}{n!} \xi^n = {}_2F_1\left(\frac{1}{4}, \frac{3}{4}; 1; -\frac{2\xi}{3}\right) \tag{33.23}$$

near the origin. The hypergeometric function has its first finite singularity at argument 1, hence at $\xi = -3/2$ in this normalization. Along the positive g-axis the integral is nevertheless well-defined and its perturbative series is a candidate for ordinary Borel summation. The opposite sign of g makes the integral unstable on the real contour; the same analytic formula must then be understood only after choosing a complex cycle.

Let $A > 0$, and suppose a Borel transform $B(\xi)$ is holomorphic on the cut plane $\mathbb{C} \setminus (-\infty, -A]$. The map

$$w(\xi) = \frac{\sqrt{1+\xi/A} - 1}{\sqrt{1+\xi/A} + 1}, \qquad \xi(w) = \frac{4Aw}{(1-w)^2}, \tag{33.24}$$

with the square root chosen positive at $\xi = 0$, maps the cut plane biholomorphically to the unit disk. It sends $\xi = 0$ to $w = 0$, the first branch point $\xi = -A$ to $w = -1$, and the positive real ξ-axis to $0 \leq w < 1$. Set $y = \sqrt{1+\xi/A}$. The cut plane is mapped by y to the right half plane $\Re y > 0$. The Cayley transform $w = (y-1)/(y+1)$ maps the right half plane to $|w| < 1$. Solving $y = (1+w)/(1-w)$ gives

$$1 + \frac{\xi}{A} = \left(\frac{1+w}{1-w}\right)^2, \qquad \xi = \frac{4Aw}{(1-w)^2}.$$

The stated images of 0, $-A$, and the positive real ray are immediate.

Remark 33.16 (Status of conformal-Borel numerics). The conformal map in (33.24) is a rigorous acceleration device only when the analytic domain of the Borel transform is known. In many applications to critical exponents one assumes, from finite-dimensional saddle analysis or from additional field-theoretic input, that the nearest Borel singularity is on the negative real axis and that no positive-ray singularity obstructs the Laplace integral. A conformal-Borel or Borel–Pade computation made under those assumptions is a controlled numerical procedure conditional on the stated singularity hypothesis; it is not a proof that the regulated QFT exists or that the perturbative expansion by itself defines it.

Definition 33.17 (Borel–Leroy and conformal-Borel approximants)**.** Let $\widehat{A}(g) = \sum_{n\geq 0} a_n g^n$ be a formal series and let $b > -1$. The Borel–Leroy transform with parameter b is

$$\mathcal{B}_b\widehat{A}(\xi) = \sum_{n\geq 0} \frac{a_n}{\Gamma(n+b+1)}\xi^n. \tag{33.25}$$

If $\mathcal{B}_b\widehat{A}$ satisfies the same analytic-continuation and growth hypotheses as in Definition 33.10, with the branch of ξ^b fixed on the chosen ray, the corresponding Borel–Leroy sum is

$$\mathcal{S}_{\theta,b}\widehat{A}(g) = \frac{1}{g^{b+1}}\int_0^{\mathrm{e}^{i\theta}\infty} \mathrm{e}^{-\xi/g}\xi^b\mathcal{B}_b\widehat{A}(\xi)\,\mathrm{d}\xi. \tag{33.26}$$

For the one-cut hypothesis of (33.24), write

$$\mathcal{B}_b\widehat{A}(\xi(w)) = \sum_{m\geq 0} c_m w^m$$

near $w = 0$, and let

$$\mathcal{B}^{\mathrm{conf}}_{b,N}(\xi) = \sum_{m=0}^{N} c_m w(\xi)^m. \tag{33.27}$$

The N-th conformal-Borel–Leroy approximant on the positive ray is

$$\mathcal{S}^{(A,b)}_N\widehat{A}(g) = \frac{1}{g^{b+1}}\int_0^{\infty} \mathrm{e}^{-\xi/g}\xi^b\mathcal{B}^{\mathrm{conf}}_{b,N}(\xi)\,\mathrm{d}\xi, \qquad g > 0, \tag{33.28}$$

when the integral converges. The data (A, b, N) are part of the approximation, not hidden conventions.

Coefficient preservation by the truncated conformal map. Assume the notation of Definition 33.17. Suppose $\mathcal{B}_b\widehat{A}$ is holomorphic at the origin, and $w(\xi)$ is the map (33.24). Then

$$\mathcal{B}^{\mathrm{conf}}_{b,N}(\xi) - \mathcal{B}_b\widehat{A}(\xi) = O(\xi^{N+1}) \qquad (\xi \to 0). \tag{33.29}$$

Consequently the formal small-g expansion of $\mathcal{S}^{(A,b)}_N\widehat{A}(g)$ reproduces the coefficients $a_0, \ldots, a_N$:

$$\mathcal{S}^{(A,b)}_N\widehat{A}(g) \sim \sum_{n=0}^{N} a_n g^n + O(g^{N+1}) \tag{33.30}$$

in the same Watson-lemma sense as Theorem 33.11, provided the positive-ray integral has a uniform exponential-growth bound. The map $w(\xi)$ is holomorphic near $\xi = 0$, satisfies $w(0) = 0$, and has nonzero derivative there:

$$w(\xi) = \frac{\xi}{4A} + O(\xi^2).$$

It therefore defines an invertible holomorphic coordinate near the origin. Truncating the Taylor expansion of $\mathcal{B}_b\widehat{A}(\xi(w))$ at order N in w changes the function by $O(w^{N+1})$, hence by $O(\xi^{N+1})$. This proves (33.29).

For each $0 \leq n \leq N$, the coefficient of ξ^n in $\mathcal{B}^{\mathrm{conf}}_{b,N}$ is therefore $a_n/\Gamma(n+b+1)$. Termwise integration of the polynomial part gives

$$\frac{1}{g^{b+1}}\int_0^{\infty} \mathrm{e}^{-\xi/g}\xi^{n+b}\,\mathrm{d}\xi = g^n\Gamma(n+b+1), \qquad b > -1, \tag{33.31}$$

and hence recovers $a_n g^n$. The remainder estimate is the same small-ray and tail estimate used in Theorem 33.11, with ξ^{N+1+b} replacing ξ^{N+1}. The hypothesis $b > -1$ is exactly the integrability condition at $\xi = 0$.

Remark 33.18 (How this applies to critical exponents). In the Wilson–Fisher ε-expansion and in fixed-dimension renormalized perturbation theory, one often applies (33.28) to a critical exponent, an anomalous dimension, or a fixed-point coordinate. The theorem-level input is the list of loop coefficients together with the renormalized chart, the Borel–Leroy parameter b, the assumed first singularity distance A, the analytic domain in the Borel plane, and a rule for estimating the truncation and parameter sensitivity. When these analytic data are not proved, the resulting number is a controlled extrapolation under declared hypotheses; it is not a proof of the existence or uniqueness of the critical QFT.

The preceding example is the finite-dimensional form of Dyson's warning: analytic continuation in a coupling can change the convergence of the integration cycle and the physical stability of the problem. The correct mathematical object is therefore not only a formal series but a pair consisting of a formal expansion and a choice of analytic sector or integration cycle. This is the point of the Lefschetz-thimble formulation.

Definition 33.19 (Holomorphic oscillatory integral and thimbles)**.** Let X be a complex n-manifold with holomorphic volume form Ω, let $S : X \to \mathbb{C}$ be a holomorphic Morse function, and let Γ be a real n-cycle on which

$$I_\Gamma(g) = \int_\Gamma \mathrm{e}^{-S(z)/g} a(z)\,\Omega \tag{33.32}$$

converges for $g = |g|\mathrm{e}^{i\theta}$. Here a is holomorphic, or more generally has controlled analytic growth compatible with the convergence of the integral. Set

$$h_\theta(z) = \mathrm{Re}\big(\mathrm{e}^{-i\theta} S(z)\big), \qquad \varphi_\theta(z) = \mathrm{Im}\big(\mathrm{e}^{-i\theta} S(z)\big).$$

For a critical point p_σ, its upward thimble $\mathcal{J}_\sigma^\theta$ is the real n-manifold obtained by flowing out of p_σ along the gradient flow of h_θ, so that $h_\theta \to +\infty$ at the ends. Its dual downward thimble $\mathcal{K}_\sigma^\theta$ is defined with the opposite flow. Along either flow,

$$\frac{\mathrm{d}h_\theta}{\mathrm{d}t} = \|\partial(\mathrm{e}^{-i\theta} S)\|^2, \qquad \frac{\mathrm{d}\varphi_\theta}{\mathrm{d}t} = 0 \tag{33.33}$$

for the upward convention. Thus the phase of the exponential is constant on each thimble.

Theorem 33.20 (Finite-dimensional thimble decomposition)**.** *Assume that h_θ is proper on the relative cycle problem defined by (33.32), that all critical values $\mathrm{e}^{-i\theta} S(p_\sigma)$ have distinct imaginary parts, and that the flows have no escape at finite flow time. Then the relative homology class of Γ decomposes as*

$$[\Gamma] = \sum_\sigma n_\sigma(\theta)[\mathcal{J}_\sigma^\theta], \qquad n_\sigma(\theta) = \langle \Gamma, \mathcal{K}_\sigma^\theta \rangle \in \mathbb{Z}, \tag{33.34}$$

and

$$I_\Gamma(g) = \sum_\sigma n_\sigma(\theta) I_\sigma(g), \qquad I_\sigma(g) = \int_{\mathcal{J}_\sigma^\theta} \mathrm{e}^{-S(z)/g} a(z)\,\Omega. \tag{33.35}$$

Near $g = 0$, each $I_\sigma(g)$ has a saddle expansion

$$I_\sigma(g) \sim \mathrm{e}^{-S(p_\sigma)/g}(2\pi g)^{n/2}\frac{a(p_\sigma)}{\sqrt{\det H_\sigma}}\left(1 + \sum_{m\geq 1} c_{\sigma,m}g^m\right), \tag{33.36}$$

after choosing the square-root phase determined by the oriented thimble; here H_σ is the Hessian of S at p_σ in holomorphic local coordinates. When two critical values have the same φ_θ, the integer basis $[\mathcal{J}_\sigma^\theta]$ can jump by a Stokes transformation. The homology class $[\Gamma]$ and the integral $I_\Gamma(g)$ are unchanged; only their expression in the thimble basis changes.

Proof. The gradient equation in Definition 33.19 gives

$$\frac{\mathrm{d}}{\mathrm{d}t}h_\theta(z(t)) = \sum_i \left|\frac{\partial}{\partial z^i}\left(\mathrm{e}^{-i\theta}S\right)\right|^2$$

in local holomorphic coordinates, while the Cauchy–Riemann equations give $\mathrm{d}\varphi_\theta/\mathrm{d}t = 0$. Thus each thimble is a constant-phase steepest-descent cycle and the exponential decays at its ends by properness of h_θ. Standard finite-dimensional Morse theory for the pair $\{h_\theta \leq H\} \subset X$, followed by $H \to +\infty$, identifies the middle-dimensional relative homology group with the free abelian group generated by the upward thimbles. The dual downward thimbles intersect them with pairing $\delta_{\sigma\tau}$, so the coefficient of $\mathcal{J}_\sigma^\theta$ in any relative cycle is $\langle \Gamma, \mathcal{K}_\sigma^\theta\rangle$. This proves (33.34), and integration of the same holomorphic form over homologous relative cycles gives (33.35).

For the expansion, apply the holomorphic Morse lemma near p_σ:

$$S(z) = S(p_\sigma) + \frac{1}{2}\sum_{i=1}^n \lambda_i w_i^2$$

in local coordinates. On the thimble the quadratic form has positive real part after multiplication by $\mathrm{e}^{-i\theta}$. Rescale $w_i = g^{1/2}y_i$, expand $a(w)$ and the higher-coordinate corrections of the volume form, and integrate term by term against the convergent Gaussian. Odd monomials vanish in the diagonal Gaussian coordinates and even monomials produce the powers in (33.36). The square-root of $\det H_\sigma$ is the Gaussian determinant with the orientation and phase chosen by the thimble.

A Stokes wall occurs precisely when two critical points can lie on a common gradient trajectory, which requires equality of the constant phase φ_θ. Crossing such a wall changes the thimble basis by adding integer multiples of thimbles connected by the flow. Since this is a change of basis in relative homology, the original cycle and integral are unchanged. □

Remark 33.21 (Resurgence as a regulated statement). In finite dimensions the Borel singularities of the saddle expansion around p_σ are controlled, under the usual analyticity and nondegeneracy hypotheses, by action differences $S(p_\tau) - S(p_\sigma)$. Lateral Borel sums across a Stokes ray differ by the contribution of thimbles whose critical values become phase-aligned with p_σ. In a QFT path integral this sentence becomes a theorem only after a regulator has turned the functional integral into a finite-dimensional or otherwise rigorously controlled analytic object, and after the regulator-removal limit has been proved in the sector of interest. Without those data, words such as "instanton resurgence" or "renormalon resurgence" name a proposed analytic mechanism, not a completed definition of the theory.

Renormalons and Borel-plane obstructions. The term *renormalon* refers to a class of large-order effects in renormalized perturbation theory whose diagnostic is a Borel singularity associated with an integration over a momentum region. It is not a theorem that every perturbative series in a QFT has a renormalon of a specified type, and it is not a replacement for a nonperturbative definition of the observable. Nor should it be stated as a property of the beta function alone. The statement must always name the observable or coefficient function, the expansion coordinate, the renormalization scheme, and the factorization prescription.

Factorial moment in a running-coupling model. For $p > 0$ and $n \geq 0$,

$$\int_0^1 x^{p-1}\big(-\log x\big)^n \,\mathrm{d}x = \frac{n!}{p^{n+1}}. \tag{33.37}$$

Consequently, if a controlled approximation to an observable contains

$$R(\alpha) = \alpha \int_0^1 \frac{x^{p-1}\,\mathrm{d}x}{1-\beta_0\alpha(-\log x)} \tag{33.38}$$

and the geometric expansion is used before the integral is performed, then

$$R(\alpha) \sim \alpha \sum_{n\geq 0} \frac{\beta_0^n n!}{p^{n+1}}\alpha^n, \qquad \mathcal{B}_R(u) = \frac{1}{p-\beta_0 u} \tag{33.39}$$

for the Borel transform of $R(\alpha)/\alpha$. The model therefore has a positive-axis Borel pole at $u = p/\beta_0$ when $\beta_0 > 0$.

Set $x = \mathrm{e}^{-t}$. Then $x^{p-1}\mathrm{d}x = \mathrm{e}^{-pt}\mathrm{d}t$ with $t \in [0,\infty)$, and

$$\int_0^1 x^{p-1}(-\log x)^n \,\mathrm{d}x = \int_0^\infty \mathrm{e}^{-pt}t^n \,\mathrm{d}t = \frac{\Gamma(n+1)}{p^{n+1}} = \frac{n!}{p^{n+1}}.$$

Expanding the denominator in (33.38) as $\sum_{n\geq 0}[\beta_0\alpha(-\log x)]^n$ gives the displayed asymptotic coefficients. Dividing the coefficient of α^{n+1} by $n!$ gives the geometric Borel series

$$\sum_{n\geq 0} \frac{\beta_0^n}{p^{n+1}} u^n = \frac{1}{p-\beta_0 u}.$$

A controlled field-theoretic model calculation has the same algebraic core. Suppose a Euclidean short-distance quantity contains, after a specified set of approximations such as insertion of a chain of one-loop self-energy bubbles, an integral over a momentum k of the form

$$\int \frac{\mathrm{d}k}{k}\, F(k/Q)\,\alpha(k),$$

where Q is the external scale, F restricts the relevant region, and $\alpha(k)$ is expanded around $\alpha(Q)$ using one-loop running. If

$$\alpha(k) = \frac{\alpha(Q)}{1+\beta_0\alpha(Q)\log(k/Q)} = \alpha(Q)\sum_{n\geq 0}\big[-\beta_0\alpha(Q)\log(k/Q)\big]^n$$

is inserted before the k-integral is performed, then integrals of powers of $\log(k/Q)$ can give $n!$-growth. In the Borel transform this factorial growth is represented, in this approximation, by singularities at finite Borel parameter.

The name of the renormalon records the momentum region. An infrared renormalon is produced by the small-k region of such an integral; in an asymptotically free theory such a singularity can lie on the positive Borel ray for particular Euclidean short-distance quantities and obstruct an unambiguous Borel sum of the perturbative coefficient function. The associated lateral-summation ambiguity then has the size of a power correction,

$$\exp[-c/\alpha(Q)] = \left(\frac{\Lambda_{\mathrm{RG}}}{Q}\right)^p$$

for suitable constants $c, p > 0$, where Λ_{RG} is the renormalization-group invariant scale. In QCD this is why infrared renormalon analysis is tied to the operator product expansion: perturbation theory for a Wilson coefficient and the definition of the corresponding long-distance matrix element are not separately physical, and their scheme/factorization ambiguities must cancel in the full observable.

Remark 33.22 (Algebraic form of OPE ambiguity cancellation). Let $Q \gg \mu$, and suppose a dimensionless Euclidean observable is represented in a specified factorization scheme by the truncated operator product expansion

$$\mathcal{X}_\pm(Q) = C_{0,\pm}(Q,\mu) + \frac{1}{Q^p} C_p(Q,\mu) M_{p,\pm}(\mu) + O(Q^{-p-\delta}) \tag{33.40}$$

with $p, \delta > 0$. Here $C_{0,\pm}$ are the two lateral Borel sums of the perturbative coefficient function for the identity operator, $M_{p,\pm}$ are the correspondingly defined matrix elements of an operator of mass dimension p, and C_p is assumed to have no lateral ambiguity at this order. If

$$C_{0,+}(Q,\mu) - C_{0,-}(Q,\mu) = -\frac{1}{Q^p} C_p(Q,\mu)\big(M_{p,+}(\mu) - M_{p,-}(\mu)\big), \tag{33.41}$$

then

$$\mathcal{X}_+(Q) - \mathcal{X}_-(Q) = O(Q^{-p-\delta}). \tag{33.42}$$

If the identity-coefficient ambiguity has the form

$$C_{0,+} - C_{0,-} = K(\mu)\left(\frac{\Lambda_{\mathrm{RG}}}{Q}\right)^p, \tag{33.43}$$

then cancellation at this order requires

$$M_{p,+} - M_{p,-} = -\frac{K(\mu)\Lambda_{\mathrm{RG}}^p}{C_p(Q,\mu)} \tag{33.44}$$

in the normalization used in (33.40).

Subtract the two lateral definitions of $\mathcal{X}$ in (33.40). The remainder contributes only $O(Q^{-p-\delta})$, and the displayed leading difference is

$$C_{0,+} - C_{0,-} + \frac{1}{Q^p} C_p(M_{p,+} - M_{p,-}).$$

This vanishes by (33.41), proving (33.42). Substituting (33.43) into (33.41) gives (33.44). The cancellation is algebraic; a QFT application still has to construct the factorization scheme, the operator M_p, and the lateral sums.

An ultraviolet renormalon is associated with the large-k region of the corresponding expansion. In theories whose perturbative coordinate grows toward the ultraviolet, such as an IR-free scalar or Abelian gauge theory, this large-momentum sensitivity is tied to the same short-distance loss of perturbative control indicated by the Landau scale. The precise location of a renormalon singularity, and whether it lies on the integration ray relevant for Borel summation, depends on the observable, the expansion variable, and the renormalization scheme. The invariant lesson is not that renormalons by themselves define the theory, but that a perturbative representation can carry ambiguities of order $\exp[-c/\alpha]$, or $\exp[-c/g^2]$ when g is the gauge coupling. Such terms are invisible to all orders in the perturbative expansion and must be fixed, canceled, or interpreted by additional nonperturbative or effective-field-theory data. [3]

Application status. The preceding definitions are analytic objects, not decorative language. A QFT application of Borel summation, transseries, or Lefschetz thimbles must name the regulated observable, the expansion coordinate, the analytic domain, and the limiting statement being asserted. The following structured input is the minimal specification used in this monograph.

Definition 33.23 (Regulated asymptotic-analysis specification for a QFT observable)**.** Let R label a regulator, let g be the perturbative expansion coordinate, and let $\mathcal{X}_R(g;\lambda)$ be a regulated observable, where λ denotes all other named parameters, including masses, subtraction scales, background sources, finite volume, and boundary conditions. A *regulated asymptotic-analysis specification* consists of:

1. a complex domain D_R in the g-plane on which $\mathcal{X}_R(g;\lambda)$ is defined as a function or distributional matrix element;
2. a formal perturbative series
$$\widehat{\mathcal{X}}_R(g;\lambda) = \sum_{n\geq 0} a_{R,n}(\lambda) g^n$$
with the coefficient-extraction operation specified;
3. a Borel transform or Borel–Leroy transform, together with its proved or hypothesized analytic continuation domain and growth bounds;
4. , when nonperturbative sectors are present, a sector set S_R, action differences $A_{R,\sigma}(\lambda)$, powers $\beta_{R,\sigma}$, and formal fluctuation series
$$\mathrm{e}^{-A_{R,\sigma}(\lambda)/g} g^{\beta_{R,\sigma}} \widehat{\Phi}_{R,\sigma}(g;\lambda);$$
5. a statement of what happens as R is removed: coefficientwise limit, Borel-plane limit, distributional limit, correlation-function limit, or no continuum-limit claim.

Remark 33.24 (Scope of a regulated asymptotic analysis). A specification in Definition 33.23 proves a Borel–Laplace reconstruction of $\mathcal{X}_R$ in a direction θ only if the transform in item 3 satisfies the hypotheses of Definition 33.10 and the resulting Borel–Laplace function is identified with $\mathcal{X}_R$ on a nonempty open subdomain of D_R. It proves a QFT statement only after the asserted regulator-removal limit in item 5 is established. Without item 5, the result is a theorem or approximation for the regulated problem, not for the continuum QFT.

[3] For a systematic review, see M. Beneke, "Renormalons," *Phys. Rept.* **317** (1999) 1–142, doi:10.1016/S0370-1573(98)00130-6, arXiv:hep-ph/9807443.

The first clause is exactly the content of the Borel–Laplace definition: Gevrey growth supplies a locally convergent Borel transform, analytic continuation and exponential bounds make the Laplace integral convergent, and Theorem 33.11 supplies the asymptotic expansion of the resulting function. The equality with the originally regulated observable is an additional identity of analytic functions or distributions. It follows from equality on a nonempty open set inside the common connected domain by the identity theorem, or by equality of distributional boundary values when the observable is defined distributionally. Removing the regulator is a separate limiting operation. Thus a statement at fixed R cannot imply a continuum-QFT statement unless item 5 is supplied.

For the zero-dimensional quartic integral of Example 33.15, the Borel transform

$$B(\xi) = {}_2F_1\left(\frac{1}{4}, \frac{3}{4}; 1; -\frac{2\xi}{3}\right)$$

has no singularity for $\xi \geq 0$ and is bounded on the positive real ξ-axis. Therefore

$$\frac{1}{g}\int_0^\infty \mathrm{e}^{-\xi/g} B(\xi)\,\mathrm{d}\xi$$

exists for every $g > 0$ and has the formal series $\sum_{n\geq 0} a_n g^n$ of (33.21) as its asymptotic expansion. This is a useful model calculation rather than a theorem about a continuum QFT. Euler's hypergeometric integral with

$$a = \frac{1}{4}, \qquad b = \frac{3}{4}, \qquad c = 1, \qquad z = -\frac{2\xi}{3}.$$

Since $\operatorname{Re} c > \operatorname{Re} b > 0$,

$$B(\xi) = \frac{1}{\Gamma(3/4)\Gamma(1/4)}\int_0^1 t^{-1/4}(1-t)^{-3/4}\left(1 + \frac{2\xi t}{3}\right)^{-1/4} \mathrm{d}t. \tag{33.45}$$

For $\xi \geq 0$ the last factor is real, positive, and bounded above by 1. The remaining beta integral is finite. Thus B is bounded on the positive ray and has no positive-ray singularity. The Borel–Laplace integral therefore converges for $g > 0$, and Theorem 33.11 gives the displayed asymptotic expansion because the Taylor coefficients of B are $a_n/n!$, as computed in Example 33.15.

Definition 33.25 (Quartic-oscillator spectral Borel problem)**.** Let $g \geq 0$, and let $H(g)$ be the Friedrichs realization on $L^2(\mathbb{R}, \mathrm{d}x)$ of

$$H(g) = -\frac{1}{2}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + \frac{1}{2}x^2 + gx^4. \tag{33.46}$$

The domain is determined by the closed quadratic form

$$q_g[\psi] = \frac{1}{2}\|\psi'\|_{L^2}^2 + \frac{1}{2}\|x\psi\|_{L^2}^2 + g\|x^2\psi\|_{L^2}^2.$$

Its spectrum is discrete and simple; write $E_n(g)$, $n = 0, 1, \ldots$, for the increasing eigenvalues. The Rayleigh–Schrödinger perturbative series at the n-th harmonic-oscillator level is

$$\widehat{E}_n(g) = \sum_{r\geq 0} E_{n,r} g^r. \tag{33.47}$$

A Borel-summability statement for (33.47) means that this particular spectral branch $E_n(g)$ is recovered by a Borel–Laplace transform satisfying Definition 33.10.

Quoted Theorem 33.26 (Quartic-oscillator Borel summability)**.** *For each fixed n, the series* (33.47) *is Borel summable on the positive real g-axis to the eigenvalue $E_n(g)$ of* (33.46)*. More precisely, the perturbative coefficients are Gevrey-one, the Borel transform has analytic continuation and growth in a sector containing the positive Borel ray, and the Borel–Laplace integral in that direction equals $E_n(g)$ for $g > 0$.*

Status of the quoted theorem. This is a theorem of Graffi–Grecchi–Simon for even polynomial anharmonic oscillators.[4] The local mechanism has three layers. First, for complex g near the positive axis one treats $H(g)$ as an analytic family of sectorial closed forms. Equivalently, after the complex dilation $x = \mathrm{e}^{\mathrm{i}\theta} y$, the quadratic form becomes

$$q_{g,\theta}[\psi] = \frac{1}{2}\mathrm{e}^{-2\mathrm{i}\theta}\|\psi'\|^2 + \frac{1}{2}\mathrm{e}^{2\mathrm{i}\theta}\|y\psi\|^2 + g\,\mathrm{e}^{4\mathrm{i}\theta}\|y^2\psi\|^2.$$

For g in a sector around the positive real axis one chooses θ so that the numerical range of this form lies in a fixed acute sector and the real part controls $\|\psi'\|^2 + \|y\psi\|^2 + |g|\|y^2\psi\|^2$. The associated operators are m-sectorial with compact resolvent, and isolated eigenvalue branches are defined by the Riesz projection

$$P_n(g) = -\frac{1}{2\pi\mathrm{i}}\oint_{\Gamma_n} (H(g) - z)^{-1}\,\mathrm{d}z,$$

where Γ_n surrounds the n-th harmonic-oscillator eigenvalue and no other one when g is small in the chosen sector. The eigenvalue

$$E_n(g) = \operatorname{tr}\big(H(g)P_n(g)\big)$$

is therefore an analytic function on this sectorial perturbation domain.

Second, the resolvent expansion around $H(0)$, combined with oscillator matrix-element estimates for x^4, gives a strong Gevrey-one remainder: for each closed subsector of the positive direction there are $C_n, A_n < \infty$ such that

$$\left| E_n(g) - \sum_{r=0}^{N-1} E_{n,r} g^r \right| \le C_n A_n^N N! |g|^N, \qquad N \ge 1. \tag{33.48}$$

The factorial comes from the repeated unbounded perturbation x^4 and the energy-denominator combinatorics; the estimate is a bound on the spectral branch $E_n(g)$ itself and therefore ties the formal Rayleigh–Schrödinger coefficients to an analytic eigenvalue function.

Third, the analytic sector together with (33.48) is a Nevanlinna–Watson Borel datum. It implies that the formal Borel transform

$$\mathcal{B}\widehat{E}_n(\xi) = \sum_{r\ge 0} \frac{E_{n,r}}{r!}\xi^r$$

continues through a sector containing $\xi \ge 0$, obeys the exponential growth needed for the Laplace integral, and satisfies

$$E_n(g) = \frac{1}{g}\int_0^\infty \mathrm{e}^{-\xi/g}\mathcal{B}\widehat{E}_n(\xi)\,\mathrm{d}\xi, \qquad g > 0.$$

[4] S. Graffi, V. Grecchi, and B. Simon, "Borel summability: Application to the anharmonic oscillator," *Phys. Lett. B* **32** (1970) 631–634, doi:10.1016/0370-2693(70)90564-2; see also B. Simon, "Coupling constant analyticity for the anharmonic oscillator," *Ann. Phys.* **58** (1970) 76–136, doi:10.1016/0003-4916(70)90240-X.

The monograph uses this theorem as a controlled comparison example: in QFT the same kind of analytic-domain, factorial-remainder, Borel-growth, and regulator-removal data must be supplied for the named regulated observable.

Remark 33.27 (Local Borel convergence from Gevrey-one growth). Suppose $\sum_{r\geq 0} a_r g^r$ satisfies $|a_r| \leq CM^r r!$. Then the formal Borel transform converges near $\xi = 0$. This local convergence is weaker than Borel summability of a specified observable.

$$\left|\frac{a_r}{r!}\xi^r\right| \leq C(M|\xi|)^r,$$

so the Borel series converges for $|\xi| < M^{-1}$. Definition 33.10 requires more: analytic continuation of the Borel transform to a sector containing the summation ray, an exponential-growth bound there, existence of the Laplace integral, and an identity between that Laplace integral and the observable on a nonempty domain. None of these follows from the local coefficient bound. Thus large-order estimates are evidence for a possible summation mechanism, but not the mechanism itself.

Definition 33.28 (Instanton-sector transseries)**.** Consider a regulated Euclidean gauge-theory path integral whose configuration space has connected components indexed by an integer topological charge $k \in \mathbb{Z}$. Assume the Euclidean action in sector k has the form

$$S_{E,R}[A,\Psi] = \frac{1}{4g^2}\int \mathrm{tr}_\Delta(F \wedge *F) - \mathrm{i}\theta k + S_{R,\mathrm{matter}}[A,\Psi], \tag{33.49}$$

where tr_Δ is the trace normalization fixed in the gauge-theory convention dictionary of this monograph. An instanton-sector transseries for a regulated observable is a formal expansion

$$\widehat{\mathcal{X}}_R(g,\theta) = \sum_{k\in\mathbb{Z}} \sum_{\alpha\in\mathcal{S}_{R,k}} \mathrm{e}^{-A_{R,k,\alpha}/g^2}\, \mathrm{e}^{\mathrm{i}k\theta}\, g^{\beta_{R,k,\alpha}}\, \widehat{\Phi}_{R,k,\alpha}(g), \tag{33.50}$$

where α labels the regulated saddle or quasi-saddle data inside the charge-k sector. The notation includes the fluctuation determinant, collective-coordinate measure, zero-mode insertions, and boundary contributions only if these have been specified by the regulator.

Algebraic constraints on an instanton-sector transseries. For a transseries of the form (33.50), the θ-dependence is 2π-periodic. If the regulated observable is real at $\theta = 0$ and the sector data obey the conjugation rule

$$A_{R,-k,\bar{\alpha}} = A_{R,k,\alpha}, \qquad \beta_{R,-k,\bar{\alpha}} = \beta_{R,k,\alpha}, \qquad \widehat{\Phi}_{R,-k,\bar{\alpha}}(g) = \overline{\widehat{\Phi}_{R,k,\alpha}(g)}$$

for $g > 0$, then the paired k and $-k$ contribution at real θ is real and equals

$$2\ \mathrm{Re}\left[\mathrm{e}^{-A_{R,k,\alpha}/g^2}\mathrm{e}^{\mathrm{i}k\theta}g^{\beta_{R,k,\alpha}}\widehat{\Phi}_{R,k,\alpha}(g)\right]. \tag{33.51}$$

Since $k \in \mathbb{Z}$,

$$\mathrm{e}^{\mathrm{i}k(\theta+2\pi)} = \mathrm{e}^{\mathrm{i}k\theta}.$$

This proves the periodicity. The stated conjugation rule makes the $-k$-sector term the complex conjugate of the k-sector term for real θ and $g > 0$. Adding the two terms gives twice the real part, which is (33.51).

BPST sector in the trace-delta convention. In the trace-delta Yang–Mills convention of this monograph,

$$S_{\mathrm{YM,E}} = \frac{1}{4g_{\mathrm{YM}}^2}\int_{\mathbb{R}^4} \mathrm{tr}_\Delta(F_{\mu\nu}F_{\mu\nu})\,\mathrm{d}^4x - \mathrm{i}\theta Q[A], \tag{33.52}$$

the $SU(2)$ BPST one-instanton sector contributes the exponential sector factor

$$\exp\left(-\frac{4\pi^2}{g_{\mathrm{YM}}^2} + \mathrm{i}\theta\right) \tag{33.53}$$

to any regulated observable whose insertions have nonzero projection onto that sector. In the common half-trace convention $\mathrm{tr}(T_aT_b) = \delta_{ab}/2$, this same factor is written $\exp[-8\pi^2/g_{\mathrm{ht}}^2 + \mathrm{i}\theta]$, with

$$g_{\mathrm{ht}} = \sqrt{2}\,g_{\mathrm{YM}}. \tag{33.54}$$

The explicit BPST calculation in Lemma 51.23 gives $Q[A] = 1$ and, in the active trace-delta convention,

$$\frac{1}{4g_{\mathrm{YM}}^2}\int_{\mathbb{R}^4} \mathrm{tr}_\Delta(F_{\mu\nu}F_{\mu\nu})\,\mathrm{d}^4x = \frac{4\pi^2}{g_{\mathrm{YM}}^2}.$$

Substitution in (33.52) gives (33.53). The half-trace basis used in much of the instanton literature differs from the trace-delta basis by $t_a = \sqrt{2}\,T_a$. Therefore the same connection is represented with $g_{\mathrm{ht}}^2 = 2g_{\mathrm{YM}}^2$, and

$$\frac{8\pi^2}{g_{\mathrm{ht}}^2} = \frac{4\pi^2}{g_{\mathrm{YM}}^2}.$$

The equality is only a convention change; it does not alter the topological charge or the physical semiclassical weight.

Controlled Approximation 33.29 (Semiclassical instanton expansion)**.** The factor (33.53) is not yet an instanton calculus formula for a continuum QFT observable. A semiclassical one-instanton approximation additionally requires a regulator, a gauge slice or BV treatment of the zero modes, the determinant ratio, the collective coordinate density on the instanton moduli space, insertion zero-mode saturation, and a prescription for boundary strata such as small instantons. Only after those data are defined and their regulator-removal behavior is proved does the sector expansion become a theorem about the observable rather than a semiclassical sector label.

Remark 33.30 (Status of instanton and renormalon applications)*.* Definition 33.28 is a bookkeeping standard, not an assertion that the instanton expansion has been justified. For a gauge theory it remains necessary to define the path integral regulator, the topological sectors, the treatment of gauge zero modes and collective coordinates, the determinant normalization, the behavior near small-size instantons or other boundary strata, and the continuum limit. Renormalon ambiguities are different objects: they arise from momentum-region singularities in perturbative coefficient functions and are tied to factorization and operator definitions. Instanton saddles and renormalon singularities can coexist in the same observable, but neither one is a substitute for the other.

In this monograph a displayed perturbative beta function or critical exponent has the following default meaning unless a stronger statement is stated: it is a coefficientwise construction in a specified regularized and renormalized chart, giving an asymptotic small-coupling expansion or an effective finite-order approximation in its stated domain. A finite truncation can be useful and sharply predictive when the running coupling and logarithms are controlled. A nonperturbative definition of the QFT, or a convergence theorem for the infinite formal series, requires additional data beyond the finite truncation.

33.12 Invariant Data at Fixed Points

The preceding one-coordinate computation is a special case of the tensorial transformation law for a vector field. Let $\mathcal{T}$ be a finite dimensional coordinate patch in the renormalized theory family, with local coordinates λ^I. The beta function is the vector field

$$\beta = \beta^I(\lambda)\frac{\partial}{\partial \lambda^I}.$$

A finite scheme change is a local diffeomorphism

$$\widetilde{\lambda}^A = f^A(\lambda), \qquad J^A{}_I(\lambda) = \frac{\partial f^A}{\partial \lambda^I}.$$

The components of the same vector field in the new coordinates are

$$\widetilde{\beta}^A(\widetilde{\lambda}) = J^A{}_I(\lambda)\, \beta^I(\lambda), \qquad \widetilde{\lambda} = f(\lambda).$$

Thus a beta function is not a coordinate-independent list of functions; the coordinate-independent object is the flow it defines on $\mathcal{T}$.

A fixed point is a zero of this vector field:

$$\beta^I(\lambda_*) = 0.$$

This statement is invariant under changes of coordinates. Let

$$M^I{}_J = \left.\frac{\partial \beta^I}{\partial \lambda^J}\right|_{\lambda_*}$$

be the linearization of the RG vector field at the fixed point. Since the extra term obtained by differentiating $J^A{}_I(\lambda)\beta^I(\lambda)$ is proportional to $\beta(\lambda_*)$, it vanishes at the fixed point. Therefore

$$\widetilde{M}^A{}_B = J^A{}_I(\lambda_*)\, M^I{}_J\, (J^{-1})^J{}_B(\lambda_*).$$

The linearized matrices in two schemes are similar. Their eigenvalues are therefore invariant, although their eigenvectors are represented by different coordinate components. These eigenvalues are the critical exponents of the linearized flow in the chosen normalization of RG time.

If M has zero eigenvalues, the linearized analysis identifies tangent directions that require higher-order study. A zero eigenvalue is the condition for linearized marginality; exact marginality is the stronger statement that the RG vector field vanishes along an actual submanifold of theory space. In local QFT this statement must also be made after quotienting redundant directions generated by field redefinitions and after imposing the symmetries used to define the coordinate patch.

Figure 33.6 illustrates this local geometry near a fixed point. The red integral curves are subsets of the same theory space; the gray and blue grids are two coordinate systems on that space. A finite scheme change alters component functions and arrow components, while preserving the fixed point, the integral curves as point sets, and the similarity class of the linearized vector field.

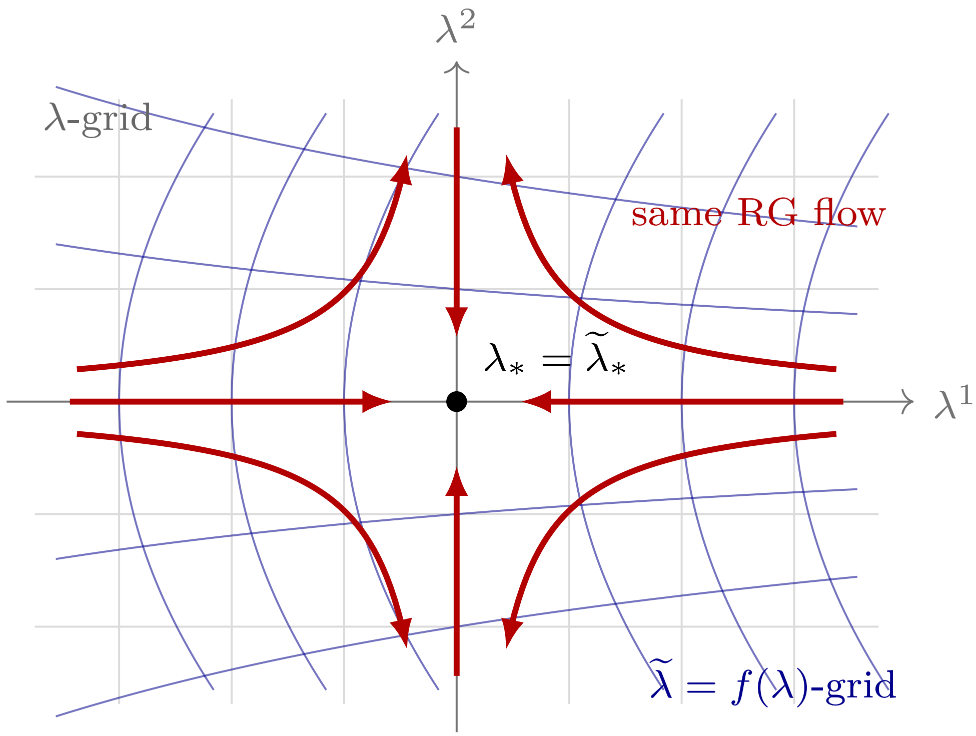

Figure 33.6: A finite scheme change is a change of local coordinates on the renormalized theory family. The gray and blue coordinate grids give different component descriptions of the same red RG vector field. The fixed point and the similarity class of the linearized flow at the fixed point are invariant geometric data.

The next chapter applies the same scale-dependent logic to local operator insertions. Infinitesimal deformations of the action define renormalized operators, and their scale dependence is governed by the linearization of the beta-function vector field.

Chapter 34

Renormalized Operators and Minimal Subtraction

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

34.1 Operators from Infinitesimal Deformations

The 1PI renormalization group compares scale-dependent coordinates $g_I(\mu)$ on a renormalized family of theories. Local operators enter the same structure through infinitesimal deformations of the action. Fix a finite or graded local operator basis $\{O_I\}_{I\in\mathcal{I}}$, chosen so that operators with the same spacetime and internal quantum numbers are included together whenever perturbation theory can mix them. To define insertions as distributions, first allow smooth compactly supported source functions $\eta_0^I(x)$ and write

$$\delta S_\eta = \int \mathrm{d}^D x \, \eta_0^I(x) \, O_I(x).$$

Constant sources $\eta_0^I(x) = \delta g_I$ give the deformation

$$\delta S = \int \mathrm{d}^D x \sum_I \delta g_I \, O_I(x).$$

Here δg_I are bare deformation coefficients. At scale μ, the same deformation can be described by renormalized source functions $\eta_\mu^J(x)$. Linearity in the infinitesimal source gives a matrix $N_{JI}(\mu)$

such that

$$\eta_0^I(x) = \sum_J \eta_\mu^J(x)\, N_{JI}(\mu).$$

For constant sources this becomes

$$\delta g_I = \sum_J \delta g_J(\mu)\, N_{JI}(\mu).$$

Substituting this into δS gives

$$\delta S = \int \mathrm{d}^D x \sum_J \delta g_J(\mu) \left(\sum_I N_{JI}(\mu)\, O_I(x) \right).$$

Definition 34.1 (Renormalized local operator)**.** In the deformation chart above, the renormalized operator associated with the source coordinate η_μ^I, or equivalently with the coupling coordinate $g_I(\mu)$ for constant sources, is

$$[O_I]_\mu = \sum_J N_{IJ}(\mu)\, O_J.$$

Equivalently,

$$\delta S = \int \mathrm{d}^D x \sum_I \delta g_I(\mu)\, [O_I]_\mu(x).$$

The matrix $N_{IJ}(\mu)$ is part of the renormalization scheme. Its rows label renormalized deformation coordinates, and its columns label the chosen bare operator basis. As an insertion in correlation functions, the equality is an equality of distributions away from coincident points; different renormalization prescriptions for contact terms differ by local terms supported on collision diagonals, in the sense of Definition 1.12.

34.2 Operators as Cotangent Data

Warning 34.2 (γ-indices). Throughout this chapter the anomalous-dimension matrix for deformation operators is indexed in the cotangent convention

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu}[O_I]_\mu = -\gamma_{IK}[O_K]_\mu, \qquad \gamma_{IK} = \frac{\partial \beta_K}{\partial g_I}.$$

Thus the first index labels the source or coupling coordinate dual to the operator being differentiated, and the second index labels the operator appearing after the cotangent action. Many column-vector conventions in the physics literature denote the same Jacobian component by

$$\gamma_{KI}^{\mathrm{col}} = \frac{\partial \beta_K}{\partial g_I} = \gamma_{IK}.$$

Comparisons of formulae must therefore transpose this pair of labels.

The preceding definition has a geometric interpretation. The infinitesimal coupling displacement

$$\delta g = \delta g_I \,\frac{\partial}{\partial g_I}$$

is a tangent vector to the renormalized family of theories. The corresponding local operator insertion is the dual object specified by the pairing

$$\langle \delta g, O\rangle = \int \mathrm{d}^D x\, \delta g_I\, [O_I]_\mu(x).$$

The deformation δS is this pairing. Therefore a change of renormalized coordinates

$$\widetilde{g}_A = f_A(g)$$

must transform the operator representatives by the inverse Jacobian:

$$[\widetilde{O}_A]_\mu = \frac{\partial g_I}{\partial \widetilde{g}_A}\, [O_I]_\mu.$$

This is the cotangent transformation law, with the Jacobian evaluated at the theory point under consideration. It is the local-operator version of the statement that beta functions are components of a vector field. The statement applies to the deformation operators dual to the selected coordinate chart; additional local operators may require enlarging the chart before their mixing can be described by the same matrix.

Definition 34.3 (Deformation-operator bundle)**.** Let U be a coordinate neighborhood in the finite-dimensional renormalized theory space with coordinates g_I. The *deformation-operator bundle* over U is the vector bundle $\mathcal{E}_{\mathrm{def}} \to U$ whose local representative column over the chart g is the ordered family of source-normalized insertion distributions

$$e_I(g, \mu) = [O_I]_\mu.$$

Its fiber at g is the span of the deformation operators dual to tangent vectors $\partial/\partial g_I$, with equality of insertions understood on noncoincident test configurations and with a separately specified contact-term extension. On an overlap with coordinates $\widetilde{g}_A = f_A(g)$, the transition functions are specified in the convention that local representative columns transform by $v_{\widetilde{g}} = M_{g\to\widetilde{g}} v_g$. The operator column therefore obeys

$$\widetilde{e}_A = M_{AI}(g)\, e_I, \qquad M_{AI}(g) = \frac{\partial g_I}{\partial \widetilde{g}_A}. \tag{34.1}$$

Thus, for deformation operators, $\mathcal{E}_{\mathrm{def}}$ is the source-defined realization of T^*U. If one includes local operators not dual to coupling coordinates, the same construction gives a larger operator bundle only after a finite-rank source-coordinate system and its transition functions have been specified.

Let $t = \log \mu$. The tangent vector δg_K evolves by the linearized RG equation

$$\frac{\mathrm{d}}{\mathrm{d}t}\delta g_K = \frac{\partial \beta_K}{\partial g_I}\, \delta g_I.$$

Scale independence of the bare deformation means that the pairing $\langle \delta g, O\rangle$ is independent of t. Hence the dual operator basis evolves with the negative transpose action:

$$\frac{\mathrm{d}}{\mathrm{d}t}[O_I]_\mu = -\frac{\partial \beta_K}{\partial g_I}\, [O_K]_\mu.$$

The index placement in the anomalous-dimension matrix below is chosen to encode precisely this cotangent action.

The scale dependence of N_{IJ} follows from the scale independence of the bare deformation. Let

$$\frac{\mathrm{d}g_I(\mu)}{\mathrm{d}\log\mu} = \beta_I(g(\mu))$$

be the beta functions of the underlying finite-dimensional coordinate system. For an infinitesimal displacement $g_I(\mu) \mapsto g_I(\mu) + \delta g_I(\mu)$, the beta function changes by

$$\delta\beta_K = \sum_I \frac{\partial \beta_K}{\partial g_I}\, \delta g_I(\mu).$$

Define the anomalous-dimension matrix in this deformation convention by

$$\gamma_{IK}(g) = \frac{\partial \beta_K}{\partial g_I}(g).$$

Differentiating $\delta g_I = \sum_J \delta g_J(\mu) N_{JI}(\mu)$ with respect to $\log\mu$ and using the preceding linearized flow gives

$$\begin{aligned}
0 &= \frac{\mathrm{d}\,\delta g_I}{\mathrm{d}\log\mu} \\
&= \sum_J \left[\delta\beta_J(g(\mu))\, N_{JI}(\mu) + \delta g_J(\mu)\frac{\mathrm{d}N_{JI}(\mu)}{\mathrm{d}\log\mu}\right] \\
&= \sum_{J,K} \delta g_K(\mu)\, \frac{\partial \beta_J}{\partial g_K}(g(\mu))\, N_{JI}(\mu) + \sum_J \delta g_J(\mu)\, \frac{\mathrm{d}N_{JI}(\mu)}{\mathrm{d}\log\mu}.
\end{aligned}$$

Since the infinitesimal renormalized displacement $\delta g_J(\mu)$ is arbitrary, this is equivalent to

$$\frac{\mathrm{d}N_{IJ}}{\mathrm{d}\log\mu} = -\sum_K \gamma_{IK}(g(\mu))\, N_{KJ}(\mu).$$

Consequently the renormalized operators satisfy

$$\frac{\mathrm{d}}{\mathrm{d}\log\mu}[O_I]_\mu = -\sum_K \gamma_{IK}(g(\mu))\, [O_K]_\mu.$$

Figure 34.1 records the two pieces of data entering this equation: operator mixing among the chosen local basis and field renormalization on the external legs of insertion kernels.

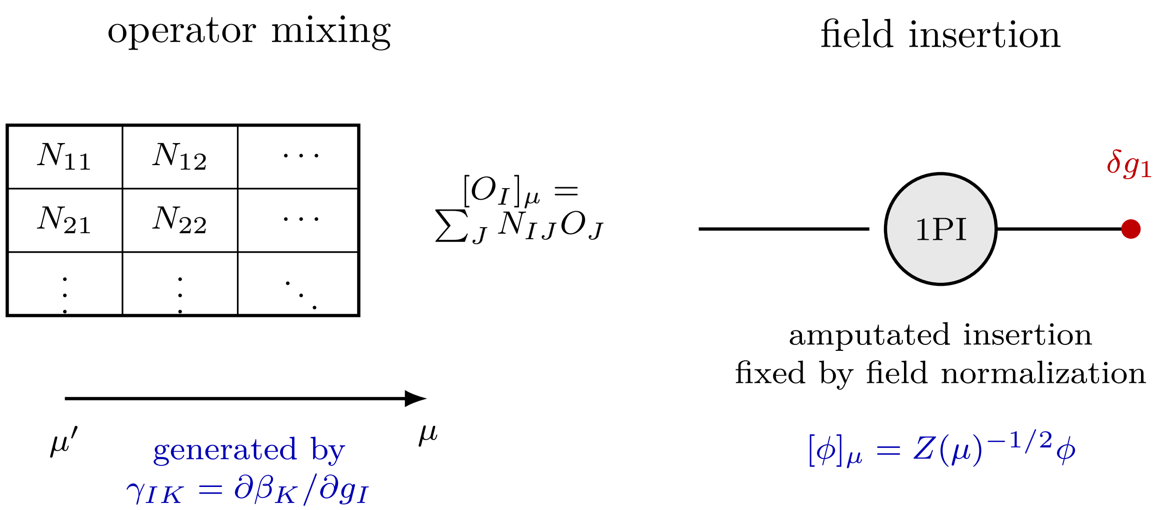

Figure 34.1: Renormalized local operators are rows of the mixing matrix N_{IJ}. The matrix evolves with the linearized beta-function vector field. For the elementary field insertion, the running is the same wavefunction normalization used in the 1PI coordinate system.

34.3 Source-Extended Wilsonian Representatives

The preceding discussion used local sources to define renormalized operators as cotangent vectors to a space of couplings. The same source coordinates also have a Wilsonian representative. The complete construction consists of three linked objects: a Wilsonian insertion functional, its connected low-field expectation, and its 1PI Legendre-transform representative.

Work at a finite ultraviolet regulator Λ_0, and let $\Lambda < \Lambda_0$ be a smooth Wilsonian cutoff. The regulated field is decomposed as a sum of an independent low field ϕ with covariance C_Λ and a shell field $\phi_{\rm sh}$ with positive covariance $\widehat{C}_{\Lambda_0,\Lambda} = C_{\Lambda_0} - C_\Lambda$, or with any equivalent smooth positive covariance decomposition. The shell kinetic term $\widehat{S}_{\rm kin}$ is the quadratic form inverse to $\widehat{C}_{\Lambda_0,\Lambda}$ on the regulated vector space. Choose a local bare operator basis $O_I(x)$ and source functions $\eta_0^I(x)$. In the Euclidean sign convention used in this volume,

$$Z_{\Lambda_0}[J,\eta_0] = \int D^{\rm ref}_{\Lambda_0}\phi \, \exp\left[-S_{\Lambda_0}[\phi] - \int \mathrm{d}^D x\, J(x)\phi(x) - \int \mathrm{d}^D x\, \eta_0^I(x) O_I(x)\right].$$

Here $D^{\rm ref}_{\Lambda_0}\phi$ is the reference density of Definition 11.3; the full quadratic kinetic term is included in S_{Λ_0}. In the Gaussian form used for the Wilsonian pushforward below, the same finite-regulator integral is expressed by placing the quadratic form in a centered Gaussian measure and retaining only the interaction/source functional in the exponential. Thus

$$-\frac{\delta W_{\Lambda_0}[J,\eta_0]}{\delta \eta_0^I(x)}\bigg|_{\eta_0=0} = \big\langle O_I(x)\big\rangle_{J,\Lambda_0}, \qquad W_{\Lambda_0} = \log Z_{\Lambda_0},$$

where the expectation value is computed with the source J still present. Higher derivatives with respect to η_0 give connected insertions, with the corresponding signs determined by the same convention.

The Wilsonian source coordinates at scale Λ are denoted $\eta_\Lambda^A(x)$. Locality permits a source-coordinate change by a local linear differential operator,

$$\eta_0^I(x) = \big(\mathcal{Z}_\Lambda\big)^I{}_A(\partial_x)\,\eta_\Lambda^A(x), \tag{34.2}$$

where

$$\big(\mathcal{Z}_\Lambda\big)^I{}_A(\partial) = \sum_{|\alpha|\geq 0} \big(\mathcal{Z}_\Lambda\big)^I{}_{A,\alpha}\,\partial^\alpha$$

as a formal derivative expansion, restricted by the spacetime and internal quantum numbers of the sources. For constant sources only the $\alpha = 0$ term contributes. The finite matrix $N_{AI}(\mu)$ introduced above is the corresponding zero-momentum source-renormalization matrix in a chosen 1PI coordinate chart.

Define the source-extended Wilsonian interaction $L_\Lambda[\phi;\eta_\Lambda]$ by the Gaussian pushforward

$$\exp\big[-L_\Lambda[\phi;\eta_\Lambda]\big] = \int \mathrm{d}\mu_{\widehat{C}_{\Lambda_0,\Lambda}}(\phi_{\mathrm{sh}})\,\exp\left[-L_{\Lambda_0}[\phi+\phi_{\mathrm{sh}};\eta_0(\eta_\Lambda)]\right], \tag{34.3}$$

where $\mathrm{d}\mu_{\widehat{C}_{\Lambda_0,\Lambda}}$ is the centered Gaussian measure whose covariance is the shell covariance between Λ_0 and Λ. Equation (34.3) is first an identity in the finite-dimensional regulated system; the continuum derivative expansion is then studied after the regulator is removed.

Definition 34.4 (Wilsonian composite insertion)**.** The Wilsonian representative of the source coordinate η_Λ^A is the local functional

$$\mathcal{O}^{\mathrm{W}}_{\Lambda,A}(x;\phi) = \left.\frac{\delta L_\Lambda[\phi;\eta_\Lambda]}{\delta\eta_\Lambda^A(x)}\right|_{\eta_\Lambda=0}.$$

It is a functional of the remaining low field ϕ. Its connected and 1PI images are obtained from the subsequent low-field integration and Legendre transform.

Let

$$W_\Lambda^{\mathrm{low}}[J,\eta_\Lambda] = \log\int \mathrm{d}\mu_{C_\Lambda}(\phi)\,\exp\left[-L_\Lambda[\phi;\eta_\Lambda] - \int J\phi\right].$$

For source functions J and η_Λ whose Fourier transforms are supported in the low-momentum region where the cutoff profile is unchanged, the Gaussian convolution identity gives

$$W_\Lambda^{\mathrm{low}}[J,\eta_\Lambda] = W_{\Lambda_0}[J,\eta_0(\eta_\Lambda)] \tag{34.4}$$

at the finite regulator. Differentiating at $\eta_\Lambda = 0$ gives

$$-\left.\frac{\delta W_\Lambda^{\mathrm{low}}[J,\eta_\Lambda]}{\delta\eta_\Lambda^A(x)}\right|_{\eta_\Lambda=0} = \big\langle\mathcal{O}^{\mathrm{W}}_{\Lambda,A}(x;\phi)\big\rangle^{\mathrm{low}}_{J,\Lambda}.$$

The equality (34.4) therefore identifies connected operator insertions computed from the bare and Wilsonian descriptions, after the source-coordinate map (34.2) has been applied.

The 1PI insertion is obtained by performing the remaining low-field integral and then taking the Legendre transform. If

$$\varphi(x) = \frac{\delta W_\Lambda^{\mathrm{low}}[J,\eta_\Lambda]}{\delta J(x)}$$

and

$$\Gamma_\Lambda[\varphi,\eta_\Lambda] = W_\Lambda^{\text{low}}[J,\eta_\Lambda] - \int \mathrm{d}^D x\, J(x)\varphi(x), \qquad J = J[\varphi,\eta_\Lambda],$$

then the cancellation of the J-variation in the Legendre transform gives

$$\left.\frac{\delta\Gamma_\Lambda[\varphi,\eta_\Lambda]}{\delta\eta_\Lambda^A(x)}\right|_\varphi = \left.\frac{\delta W_\Lambda^{\text{low}}[J,\eta_\Lambda]}{\delta\eta_\Lambda^A(x)}\right|_{J=J[\varphi,\eta_\Lambda]}.$$

Consequently the 1PI representative of the insertion is

$$\mathcal{O}^\Gamma_{\Lambda,A}(x;\varphi) = -\left.\frac{\delta\Gamma_\Lambda[\varphi,\eta_\Lambda]}{\delta\eta_\Lambda^A(x)}\right|_{\eta_\Lambda=0}.$$

Its field derivatives at $\varphi = 0$ are the amputated 1PI kernels with one operator insertion. These kernels agree with the projected 1PI insertion kernels in another subtraction scheme after the corresponding finite source-coordinate map and field normalization have been specified.

Figure 34.2 shows the nontrivial part of the source-extended comparison at two external low-field legs: differentiating the connected insertion with respect to ordinary field sources gives an insertion with exact external propagators; the 1PI representative is the amputated kernel obtained after the Legendre transform.

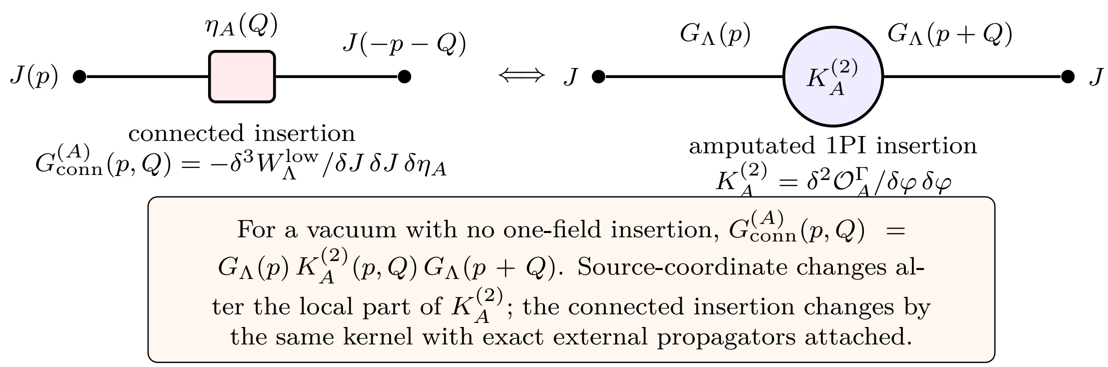

Figure 34.2: The Legendre transform changes a connected low-field insertion into an amputated 1PI insertion kernel. In the two-point sector, and when one-field insertion terms vanish by the vacuum quantum numbers, the connected insertion is obtained by attaching exact low-field propagators to the amputated kernel.

34.4 A Worked Insertion: The Mass Operator in ϕ^4

The abstract source bridge becomes concrete in the scalar quartic theory. Work at finite regulator in four Euclidean dimensions, and introduce a source η for the local operator

$$O_m(x) = \frac{1}{2}\phi(x)^2.$$

The source-dependent part of the regulated action, in the cutoff-dependent source coordinate η_0, is

$$\int \mathrm{d}^4 x\, \eta_0(x) O_m(x).$$

Let Q denote the momentum carried by the source insertion, and let

$$C_{\Lambda_0} = C_\Lambda + C_>$$

be the same covariance split used for the Wilsonian action. For covariances A, B, define the one-insertion bubble

$$\mathcal{I}_{A,B}(Q) = \int \frac{\mathrm{d}^4 q}{(2\pi)^4} A(q)\, B(q+Q).$$

Then

$$\mathcal{I}_{C_{\Lambda_0},C_{\Lambda_0}}(Q) = \mathcal{I}_{<,<}(Q) + \mathcal{I}_{>,>}(Q) + \mathcal{I}_\times(Q), \tag{34.5}$$

where

$$\mathcal{I}_{<,<} = \mathcal{I}_{C_\Lambda,C_\Lambda}, \qquad \mathcal{I}_{>,>} = \mathcal{I}_{C_>,C_>},$$

and

$$\mathcal{I}_\times = \mathcal{I}_{C_\Lambda,C_>} + \mathcal{I}_{C_>,C_\Lambda}.$$

The Wilsonian insertion functional is the source derivative of $L_\Lambda[\phi;\eta_\Lambda]$. At zeroth order in the quartic coupling, the Gaussian pushforward gives

$$\mathcal{O}^{\mathrm{W}}_{m,\Lambda}(x;\phi) = \frac{1}{2}\phi(x)^2 + \frac{1}{2}C_>(x,x) + \cdots,$$

where the second term is an identity-operator contribution. It affects the vacuum response to η, but not the two-field amputated insertion kernel. At first order in the quartic coupling g, the coefficient of $\frac{1}{2}\phi^2$ in the Wilsonian insertion receives the high-high bubble:

$$\mathcal{O}^{\mathrm{W}}_{m,\Lambda}(Q;\phi) = \left[1 - \frac{g}{2}\mathcal{I}_{>,>}(Q) + Z^{\mathrm{loc}}_{m,\Lambda}(Q)\right]\frac{1}{2}(\phi\phi)(Q) + \text{identity and higher local terms} + O(g^2). \tag{34.6}$$

Here $(\phi\phi)(Q)$ denotes the Fourier transform of $\phi(x)^2$, and $Z^{\mathrm{loc}}_{m,\Lambda}(Q)$ is the local source-coordinate counterterm and finite convention. The factor $1/2$ is the one-loop symmetry factor in the normalization $g\phi^4/4!$ and $O_m = \phi^2/2$.

Now compare with the BPHZ normal-product definition. Let $\mathcal{Q}_\mu$ be the nonexceptional source-momentum subtraction configuration used to define the two-field 1PI insertion kernel, and let

$$K^{(2)}_m(Q) = \frac{\delta^2}{\delta\varphi\,\delta\varphi}\mathcal{O}^\Gamma_m(Q;\varphi)\bigg|_{\varphi=0}$$

in the field normalization of the chosen 1PI coordinate chart. The renormalization condition

$$K^{(2)}_m(\mathcal{Q}_\mu) = 1$$

fixes the finite normalization of the renormalized operator. At one loop, the BPHZ-subtracted insertion kernel is

$$K^{(2)}_{m,\mathrm{BPHZ}}(Q) = 1 - \frac{g}{2}\left[\mathcal{I}_{C_{\Lambda_0},C_{\Lambda_0}}(Q) - \mathcal{I}_{C_{\Lambda_0},C_{\Lambda_0}}(\mathcal{Q}_\mu)\right] + O(g^2), \tag{34.7}$$

with the ultraviolet limit taken after the subtraction. The subtraction is a local normal-product convention for the operator O_m. The controlled comparison in Controlled Approximation 36.16 treats this finite normal-product choice as part of the local source-coordinate system: changing a Zimmermann normal product changes the finite local operator coordinates and therefore the source coordinate map.

Figure 34.3 displays the actual covariance assignment on the one-loop insertion graph. The loop has two internal propagator slots; inserting $C_{\Lambda_0} = C_\Lambda + C_>$ in each slot gives the low–low, high–high, and two mixed contributions in (34.5).

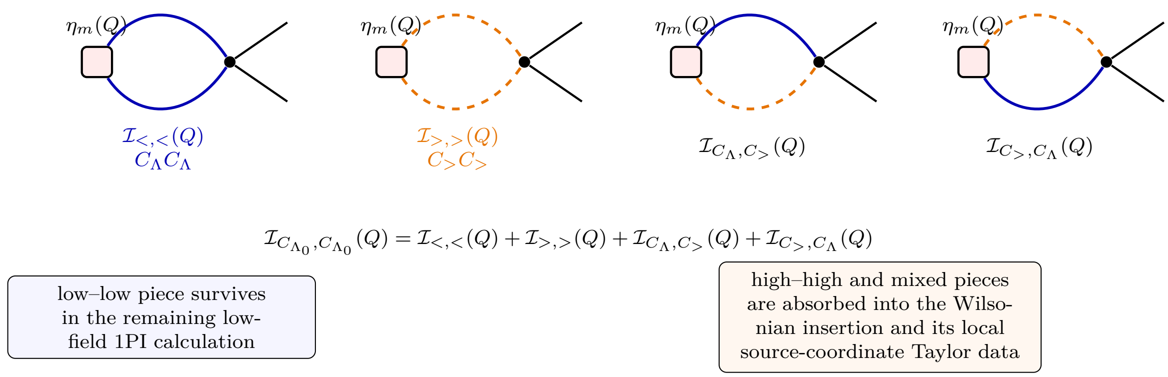

Figure 34.3: The one-loop mass-operator kernel is a single insertion graph with two internal covariance slots. Expanding $C_{\Lambda_0} = C_\Lambda + C_>$ on those slots gives the four displayed assignments; the two mixed assignments form $\mathcal{I}_\times$. This is the graph-level content behind the local Wilsonian source-coordinate matching.

The 1PI insertion computed from the Wilsonian description has the form

$$K^{(2)}_{m,\Lambda}(Q) = Z_{m,\Lambda}(Q) - \frac{g}{2}\mathcal{I}_{<,<}(Q) - \frac{g}{2}\mathcal{I}^{\text{loc}}_\times(Q) + O(g^2), \tag{34.8}$$

where $Z_{m,\Lambda}(Q)$ is the local coefficient multiplying $\frac{1}{2}\phi^2$ in the Wilsonian insertion, and $\mathcal{I}^{\text{loc}}_\times$ denotes the Taylor expansion of the mixed assignment in the chosen low-momentum source-coordinate system. Projecting at $\mathcal{Q}_\mu$ fixes the source-coordinate normalization:

$$1 = Z_{m,\Lambda}(\mathcal{Q}_\mu) - \frac{g}{2}\mathcal{I}_{<,<}(\mathcal{Q}_\mu) - \frac{g}{2}\mathcal{I}^{\text{loc}}_\times(\mathcal{Q}_\mu) + O(g^2). \tag{34.9}$$

Subtracting this condition from (34.8) gives the finite insertion kernel in the 1PI chart:

$$K^{(2)}_{m,\Lambda}(Q) = 1 - \frac{g}{2}\left[\mathcal{I}_{<,<}(Q) - \mathcal{I}_{<,<}(\mathcal{Q}_\mu)\right] + \mathcal{T}^{\text{loc}}_{\text{high+mix}}(Q;\mathcal{Q}_\mu) + O(g^2).$$

Here $\mathcal{T}^{\text{loc}}_{\text{high+mix}}(Q;\mathcal{Q}_\mu)$ is the finite local Taylor polynomial produced by the high-high and mixed assignments after the same subtraction condition has been imposed. Adding this Taylor data reconstructs the low-momentum expansion of (34.7). Thus the normal product, the Wilsonian insertion functional, and the 1PI insertion kernel are distinct representatives of the same source derivative after the finite-regulator pushforward, low-field integration, Legendre transform, and source-coordinate projection have been specified.

This construction also clarifies the transformation law of anomalous dimensions. Let $t = \log\mu$, and suppose a scale-dependent finite source-coordinate change relates two renormalized operator bases by

$$[\widetilde{O}_A]_\mu = M_{AI}(\mu)\,[O_I]_\mu.$$

If

$$\frac{\mathrm{d}}{\mathrm{d}t}[O_I]_\mu = -\gamma_{IK}[O_K]_\mu,$$

then

$$\frac{\mathrm{d}}{\mathrm{d}t}[\widetilde{O}_A]_\mu = -\widetilde{\gamma}_{AB}[\widetilde{O}_B]_\mu$$

with

$$\widetilde{\gamma} = M\gamma M^{-1} - \frac{\mathrm{d}M}{\mathrm{d}t}M^{-1}. \tag{34.10}$$

Theorem 34.5 (Anomalous dimensions as an RG connection)**.** *Let $\mathcal{E} \to U$ be a finite-rank renormalized operator bundle on a coordinate neighborhood U in theory space. Assume that the beta-function vector field $\beta = \beta_I(g)\partial/\partial g_I$ and the transition matrices $M_{\alpha\beta}(g,t)$ between source-coordinate systems are C^1 along the RG trajectories under consideration, or are formal power series for which the following differentiations are performed coefficientwise. In a local source chart, let e denote the local representative column $e_I = [O_I]_\mu$, and suppose the RG variation is*

$$\frac{\mathrm{d}}{\mathrm{d}t}e_I = -\gamma_{IK}(g(t),t)e_K. \tag{34.11}$$

Then the matrices γ define a connection on $\mathcal{E}$ along the RG vector field by

$$(D_t v)_\alpha = \frac{\mathrm{d}v_\alpha}{\mathrm{d}t} + \gamma_\alpha v_\alpha \tag{34.12}$$

for local representative columns v_α in a source-coordinate system α. Under a finite scale-dependent change of source-coordinate system with $\widetilde{e} = Me$ and $v_{\widetilde{\alpha}} = Mv_\alpha$, the connection coefficients transform as

$$\widetilde{\gamma} = M\gamma M^{-1} - \frac{\mathrm{d}M}{\mathrm{d}t}M^{-1}. \tag{34.13}$$

Conversely, any family of matrices obeying (34.13) on overlaps is precisely the local expression of a connection along the RG vector field. For the deformation-operator bundle of Definition 34.3, the connection induced by the linearized beta-function flow has

$$\gamma_{IK} = \frac{\partial \beta_K}{\partial g_I} \tag{34.14}$$

in the coordinate frame dual to g_I.

Proof. The operator frame equation (34.11) is the statement that the chosen renormalized source-representative column is parallel along the RG trajectory: $D_t e = 0$ in the local convention of (34.12). Let $\widetilde{e} = Me$. Differentiating gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\widetilde{e} = \left(\frac{\mathrm{d}M}{\mathrm{d}t}M^{-1} - M\gamma M^{-1}\right)\widetilde{e}.$$

Writing the same equation in the new chart as $\mathrm{d}\widetilde{e}/\mathrm{d}t = -\widetilde{\gamma}\,\widetilde{e}$ gives (34.13). The same computation is the patching criterion for a connection along a one-dimensional direction: if local matrices obey this law, the formula $D_t v = \mathrm{d}v/\mathrm{d}t + \gamma v$ is independent of the frame because

$$\left(\frac{\mathrm{d}}{\mathrm{d}t} + \widetilde{\gamma}\right)\widetilde{v} = M\left(\frac{\mathrm{d}}{\mathrm{d}t} + \gamma\right)v \qquad (\widetilde{v} = Mv).$$

Hence the local operators D_t glue to a well-defined connection along the RG vector field.

For deformation operators, an infinitesimal tangent vector $\delta g_K \partial/\partial g_K$ obeys the variational equation obtained by linearizing the RG flow:

$$\frac{\mathrm{d}}{\mathrm{d}t}\delta g_K = \frac{\partial \beta_K}{\partial g_I}\,\delta g_I.$$

The deformation insertion is the pairing $\int \delta g_I e_I$. Bare scale independence of this pairing gives

$$0 = \frac{\mathrm{d}}{\mathrm{d}t}\big(\delta g_I e_I\big) = \frac{\partial \beta_I}{\partial g_K}\delta g_K e_I + \delta g_I \frac{\mathrm{d}e_I}{\mathrm{d}t}.$$

Renaming dummy indices and using the arbitrariness of δg_I yields

$$\frac{\mathrm{d}e_I}{\mathrm{d}t} = -\frac{\partial \beta_K}{\partial g_I} e_K,$$

which is (34.11) with $\gamma_{IK} = \partial\beta_K/\partial g_I$. □

Thus the anomalous-dimension matrix transforms by conjugation only for scale-independent changes of operator coordinates. For scale-dependent renormalized source coordinates, (34.10) is the connection transformation law of Theorem 34.5.

34.5 Multiple Insertions and Contact-Term Coordinates

The linear source map in (34.2) is the part of the source coordinate change seen by a single insertion. Multiple insertions require the full Taylor expansion of the source-coordinate system. At finite regulator let $\mathcal{S}_\Lambda$ denote the space of regulated source functions $\eta^A_\Lambda(x)$. A local source-coordinate transformation is a smooth map

$$\mathcal{Z}_\Lambda : \mathcal{S}_\Lambda \longrightarrow \mathcal{S}_0, \qquad \eta_0 = \mathcal{Z}_\Lambda(\eta_\Lambda),$$

whose Taylor coefficients at the origin are local distributions. Explicitly,

$$\eta^I_0(z) = \sum_{r\geq 1} \frac{1}{r!} \int \prod_{a=1}^{r} \mathrm{d}^D x_a \, \mathcal{Z}^I{}_{A_1\cdots A_r}(z; x_1, \ldots, x_r)\eta^{A_1}_\Lambda(x_1)\cdots\eta^{A_r}_\Lambda(x_r). \tag{34.15}$$

The $r = 1$ coefficient is the linear differential operator in (34.2). For $r \geq 2$, locality means that $\mathcal{Z}^I{}_{A_1\cdots A_r}(z; x_1, \ldots, x_r)$ is supported on the small diagonal $z = x_1 = \cdots = x_r$ and is a finite sum of derivatives of delta functions, with coefficients depending on the chosen regulator scale and subtraction convention. These higher Taylor coefficients do not contribute for separated insertion points, but they determine the extension of inserted correlators as distributions across collision diagonals.

Let

$$G^0_{I_1\cdots I_s}(z_1, \ldots, z_s; J) = (-1)^s \frac{\delta^s W_{\Lambda_0}[J, \eta_0]}{\delta\eta_0^{I_1}(z_1)\cdots\delta\eta_0^{I_s}(z_s)}\bigg|_{\eta_0=0}$$

be the connected bare distribution with s operator insertions and arbitrary external source J. The renormalized distribution in the source coordinate η_Λ is

$$G^{\Lambda}_{A_1\cdots A_r}(x_1,\dots,x_r;J) = (-1)^r \frac{\delta^r W_{\Lambda_0}[J,\mathcal{Z}_\Lambda(\eta_\Lambda)]}{\delta\eta_\Lambda^{A_1}(x_1)\cdots\delta\eta_\Lambda^{A_r}(x_r)}\bigg|_{\eta_\Lambda=0}.$$

Set

$$H[\eta_\Lambda] = W_{\Lambda_0}[J,\mathcal{Z}_\Lambda(\eta_\Lambda)].$$

The functional Faà di Bruno formula for this composite map gives, before rewriting functional derivatives as insertion distributions,

$$\frac{\delta^r H}{\delta\eta_\Lambda^{A_1}(x_1)\cdots\delta\eta_\Lambda^{A_r}(x_r)}\bigg|_{\eta_\Lambda=0} = \sum_{\pi\in\mathrm{Part}(r)}\int\prod_{B\in\pi}\mathrm{d}^D z_B\ \frac{\delta^{|\pi|}W_{\Lambda_0}[J,\eta_0]}{\prod_{B\in\pi}\delta\eta_0^{I_B}(z_B)}\bigg|_{\eta_0=0}\prod_{B\in\pi}\mathcal{Z}^{I_B}{}_{A_B}(z_B;x_B).$$

The partition records which of the r renormalized source derivatives hit the same Taylor coefficient of the nonlinear source map $\mathcal{Z}_\Lambda$. The signs in the final partition formula are not additional signs attached to the Taylor coefficients of $\mathcal{Z}_\Lambda$. They come from rewriting the ordinary Faà di Bruno identity for the connected functional $W = \log Z$ in terms of connected insertion derivatives. Define

$$D^\Lambda_A := -\frac{\delta}{\delta\eta^A_\Lambda}, \qquad D^0_I := -\frac{\delta}{\delta\eta^I_0}.$$

Then $G^\Lambda_{A_1\cdots A_r} = D^\Lambda_{A_1}\cdots D^\Lambda_{A_r}H|_{\eta_\Lambda=0}$, while $G^0_{I_1\cdots I_s} = D^0_{I_1}\cdots D^0_{I_s}W_{\Lambda_0}|_{\eta_0=0}$. Because the displayed Faà di Bruno formula was written with ordinary derivatives $\delta/\delta\eta$, the left side obeys

$$G^{\Lambda}_{A_1\cdots A_r}(x_1,\dots,x_r;J) = (-1)^r\ \frac{\delta^r H}{\delta\eta_\Lambda^{A_1}(x_1)\cdots\delta\eta_\Lambda^{A_r}(x_r)}\bigg|_{\eta_\Lambda=0}.$$

For the bare connected cumulant attached to a partition π,

$$\frac{\delta^{|\pi|}W_{\Lambda_0}[J,\eta_0]}{\prod_{B\in\pi}\delta\eta_0^{I_B}(z_B)}\bigg|_{\eta_0=0} = (-1)^{|\pi|}G^0_{I_B\,:\,B\in\pi}(z_B\ :\ B\in\pi;J).$$

Thus a term indexed by π carries the chain-rule cumulant factor

$$(-1)^r(-1)^{|\pi|} = (-1)^{r-|\pi|}.$$

Equivalently, a block B of size $|B|$ collapses $|B|$ renormalized insertion derivatives into one bare connected cumulant and contributes the relative sign $(-1)^{|B|-1}$; multiplying over the blocks gives $(-1)^{\sum_B(|B|-1)} = (-1)^{r-|\pi|}$. The finite-regulator partition formula is therefore

$$\begin{aligned}G^{\Lambda}_{A_1\cdots A_r}(x_1,\dots,x_r;J) = \sum_{\pi\in\mathrm{Part}(r)}(-1)^{r-|\pi|}\int\prod_{B\in\pi}\mathrm{d}^D z_B\, G^0_{I_B\,:\,B\in\pi}(z_B\ :\ B\in\pi;J)\\ \times\prod_{B\in\pi}\mathcal{Z}^{I_B}{}_{A_B}(z_B;x_B).\end{aligned} \tag{34.16}$$

Here $\mathrm{Part}(r)$ is the set of partitions of $\{1,\dots,r\}$. If $B = \{b_1,\dots,b_s\}$, then

$$\mathcal{Z}^{I_B}{}_{A_B}(z_B;x_B) = \mathcal{Z}^{I_B}{}_{A_{b_1}\cdots A_{b_s}}(z_B;x_{b_1},\dots,x_{b_s}).$$

For two insertions the formula reads

$$\begin{aligned} G^{\Lambda}_{AB}(x,y;J) &= \int \mathrm{d}^D z\, \mathrm{d}^D w\, \mathcal{Z}^I{}_A(z;x)\mathcal{Z}^J{}_B(w;y) G^0_{IJ}(z,w;J) \\ &\quad - \int \mathrm{d}^D z\, \mathcal{Z}^I{}_{AB}(z;x,y) G^0_I(z;J). \end{aligned} \tag{34.17}$$

The first term is the product of the single-insertion linear maps. The second term is supported at $x = y$ and is therefore a contact term.

On the configuration space

$$\mathrm{Conf}_r = \{(x_1, \ldots, x_r) \mid x_a \neq x_b \text{ for } a \neq b\},$$

only the partition of $\{1, \ldots, r\}$ into singletons contributes to (34.16). All other partitions are local distributions supported on collision diagonals. If a block B has more than one element, the corresponding Taylor coefficient

$$\mathcal{Z}^{I_B}{}_{A_B}(z_B; x_B)$$

is supported on the diagonal where all points x_b, $b \in B$, coincide with z_B. This support does not intersect Conf_r. The only surviving term away from the collision diagonals is therefore the singleton partition, for which every Taylor coefficient is the linear source map.

The same structure appears directly in the Wilsonian representation. Define higher Wilsonian source derivatives by

$$\mathcal{O}^{\mathrm{W}}_{A_1 \cdots A_r}(x_1, \ldots, x_r; \phi) = \left. \frac{\delta^r L_\Lambda[\phi; \eta_\Lambda]}{\delta \eta_\Lambda^{A_1}(x_1) \cdots \delta \eta_\Lambda^{A_r}(x_r)} \right|_{\eta_\Lambda = 0}.$$

For two insertions, differentiating the low-field functional integral gives

$$G^{\Lambda}_{AB}(x,y;J) = \left\langle \mathcal{O}^{\mathrm{W}}_A(x) \mathcal{O}^{\mathrm{W}}_B(y) \right\rangle^{\mathrm{low}}_{\mathrm{conn},J,\Lambda} - \left\langle \mathcal{O}^{\mathrm{W}}_{AB}(x,y) \right\rangle^{\mathrm{low}}_{J,\Lambda}. \tag{34.18}$$

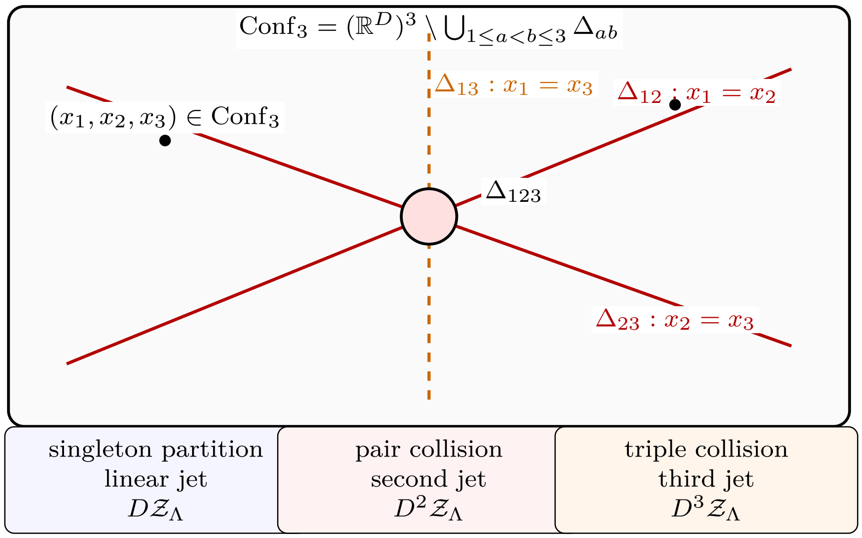
Thus the contact term is the second source derivative of the source-extended Wilsonian action in the chosen source-coordinate system.

For 1PI coordinates one must also distinguish the source Hessian of the Legendre transform from the connected two-insertion distribution. In condensed notation, with field indices i, j integrated or summed,

$$\left. \frac{\delta^2 \Gamma_\Lambda}{\delta \eta_\Lambda^A \delta \eta_\Lambda^B} \right|_{\varphi} = \left. \frac{\delta^2 W_\Lambda^{\mathrm{low}}}{\delta \eta_\Lambda^A \delta \eta_\Lambda^B} \right|_J - \frac{\delta^2 W_\Lambda^{\mathrm{low}}}{\delta \eta_\Lambda^A \delta J_i} \left(\frac{\delta^2 W_\Lambda^{\mathrm{low}}}{\delta J_i \delta J_j} \right)^{-1} \frac{\delta^2 W_\Lambda^{\mathrm{low}}}{\delta J_j \delta \eta_\Lambda^B}.$$

This is the finite-dimensional Legendre-transform identity applied to the regulated theory. The second term subtracts the part connected by one low-field two-point function. Consequently projected 1PI multi-insertion kernels have a contact-term convention inherited from both the nonlinear source-coordinate system and the Legendre-transform projection.

Figure 34.4 records the geometric support statement behind contact terms. The linear jet acts on the open configuration space of separated points. Higher source jets are local distributions supported on pairwise and higher collision diagonals, and the Legendre transform adds the separate one-low-field-reducible subtraction displayed above.



${\mathcal{Z}^I}_{AB}(z; x, y)$ is supported on $z = x = y$; ${\mathcal{Z}^I}_{ABC}(z; x, y, w)$ is supported on $z = x = y = w$.

Figure 34.4: Contact terms are support statements on configuration space. The singleton part of the source Taylor expansion acts on separated insertion points; higher Taylor coefficients are local distributions on collision strata, such as the pairwise diagonals Δ_{ab} and the triple diagonal Δ_{123} for three insertions.

34.6 Anomalous Dimensions and Scaling Operators

If a basis can be chosen along the flow in which

$$\gamma_{IK}(g(\mu)) = \delta_{IK}\gamma_I(g(\mu)),$$

then the operator equation integrates to

$$[O_I]_\mu = \exp\left[-\int_{\mu'}^{\mu} \frac{\mathrm{d}\widetilde{\mu}}{\widetilde{\mu}}\, \gamma_I(g(\widetilde{\mu}))\right] [O_I]_{\mu'}.$$

At an RG fixed point, $g(\mu) = g_*$, the entries $\gamma_I(g_*)$ are constant. The anomalous part of the scaling is then

$$[O_I]_\mu = \left(\frac{\mu}{\mu'}\right)^{-\gamma_I} [O_I]_{\mu'}.$$

An operator basis that diagonalizes γ at the fixed point is a basis of scaling operators for the anomalous part of dilatations. The full scaling dimension also includes the engineering dimension assigned before renormalization.

The elementary field is the simplest special case. Consider the deformation

$$\delta S = \int \mathrm{d}^D x\, \delta g_1\, \phi(x).$$

The amputated 1PI insertion is the external field insertion with the same normalization already used in the propagator. Hence

$$\delta g_1(\mu) = Z(\mu)^{1/2}\delta g_1, \qquad [\phi]_\mu = Z(\mu)^{-1/2}\phi.$$

The field anomalous dimension in this convention is

$$\gamma_\phi = -\frac{\mathrm{d}\log Z(\mu)^{-1/2}}{\mathrm{d}\log\mu} = \frac{1}{2}\frac{\mathrm{d}\log Z(\mu)}{\mathrm{d}\log\mu}.$$

At a fixed point, constant γ_ϕ gives

$$Z(\mu) \propto \mu^{2\gamma_\phi}.$$

34.7 Callan–Symanzik Equations With Operator Insertions

The operator mixing equation gives the insertion version of the Callan–Symanzik equation. Let

$$G^{(n)}_{0,J,\Lambda}(x;x_1,\dots,x_n;g_0,\Lambda) = \langle O_J(x)\,\phi_0(x_1)\cdots\phi_0(x_n)\rangle_{\mathrm{conn},\Lambda,g_0}$$

be the regulated bare connected correlator with one bare operator insertion. Let $G^{(n)}_I$ denote the corresponding renormalized correlator with one insertion of $[O_I]_\mu$ and n elementary renormalized fields:

$$G^{(n)}_I = \langle [O_I]_\mu(x)\,\phi_R(x_1)\cdots\phi_R(x_n)\rangle_{\mathrm{conn}}\,.$$

Away from coincident points, the renormalization chart gives

$$G^{(n)}_I = Z_\phi^{-n/2}\,N_{IJ}\,G^{(n)}_{0,J,\Lambda}$$

after the cutoff-removal limit. Repeated bare-operator labels are summed.

Insertion Callan–Symanzik equation. For noncoincident points $x, x_1, \dots, x_n$, the renormalized insertion correlators satisfy

$$\left(\mu\frac{\partial}{\partial\mu} + \beta_A(g)\frac{\partial}{\partial g_A} + n\gamma_\phi(g)\right)G^{(n)}_I + \gamma_{IK}(g)G^{(n)}_K = 0. \tag{34.19}$$

Let $t = \log\mu$. The bare correlator $G^{(n)}_{0,J,\Lambda}$ has no independent dependence on t at fixed bare couplings and cutoff. Differentiating

$$G^{(n)}_I = Z_\phi^{-n/2}N_{IJ}G^{(n)}_{0,J,\Lambda}$$

at fixed bare data gives

$$\left(\frac{\partial}{\partial t} + \beta_A\frac{\partial}{\partial g_A}\right)G^{(n)}_I = -n\gamma_\phi\,G^{(n)}_I + \frac{\mathrm{d}N_{IJ}}{\mathrm{d}t}\,Z_\phi^{-n/2}G^{(n)}_{0,J,\Lambda}.$$

Using

$$\frac{\mathrm{d}N_{IJ}}{\mathrm{d}t} = -\gamma_{IK}N_{KJ}$$

turns the last term into $-\gamma_{IK}G^{(n)}_K$. Moving both renormalization-factor contributions to the left gives (34.19).

Contact terms must be added when x collides with one of the other insertion points, or when several inserted operators are present and collide with one another. Those terms are local distributions supported on collision diagonals, as described by the source-coordinate Taylor expansion in Section 34.5. Their coefficients are governed by the same renormalized local operator basis, but they depend on the contact-term convention chosen for the source-renormalized generating functional.

At a fixed point, diagonalizing $\gamma_{IK}(g_*)$ gives scaling operators. If $[O_A]$ is an eigenoperator with anomalous dimension γ_A, then its full scaling dimension is

$$\Delta_A = d_A + \gamma_A,$$

where d_A is the engineering dimension in the fixed-point convention. Equation (34.19) is then the differential form of homogeneous scaling of correlation functions with an O_A insertion.

34.8 Dimensional Regularization and MS Coordinates

Now formulate the same 1PI RG in dimensional regularization. Let

$$D = d - \epsilon$$

and write the Euclidean action as

$$S[\phi] = S_{\mathrm{kin}}[\phi] + \int \mathrm{d}^{d-\epsilon}x \sum_I g_I^\epsilon \, O_I(x).$$

The superscript on g_I^ϵ records dependence on the regulator ϵ. The engineering dimensions are assigned as

$$[\phi] = \frac{d-\epsilon-2}{2}, \qquad [O_I] = d - \epsilon + \delta_I(\epsilon), \qquad [g_I^\epsilon] = -\delta_I(\epsilon),$$

where

$$\delta_I(\epsilon) = \delta_I^{(0)} + \epsilon\, \delta_I^{(1)}.$$

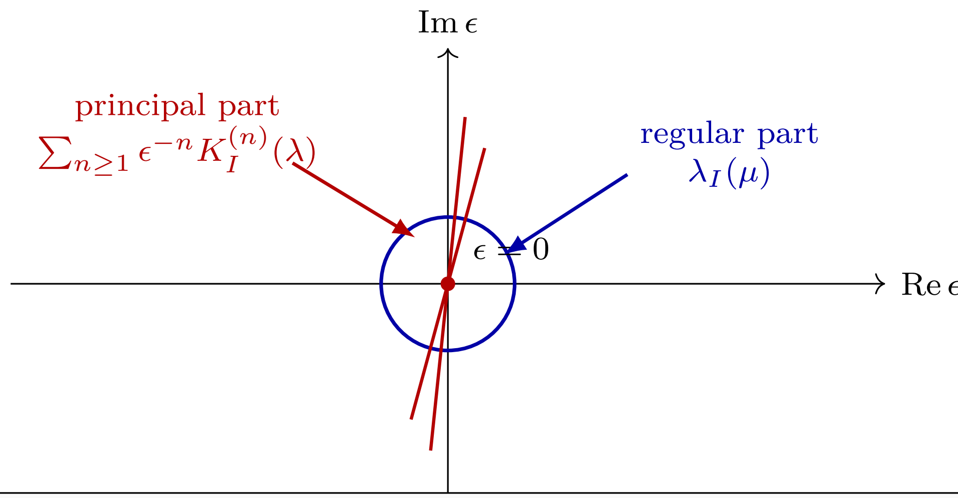
Definition 34.6 (Minimal subtraction coordinates)**.** The minimal-subtraction coordinate $\lambda_I(\mu)$ is defined by the requirement that the bare coupling have the form

$$g_I^\epsilon = \mu^{-\delta_I(\epsilon)} \left[\lambda_I(\mu) + \sum_{n\geq 1} \frac{1}{\epsilon^n} K_I^{(n)}(\lambda(\mu)) \right].$$

The functions $K_I^{(n)}$ are formal power series in the dimensionless coordinates λ_J. The bracket contains the finite coordinate λ_I and pole terms in ϵ; finite terms in the counterterm part are set to zero by the MS coordinate convention.

The MS convention fixes the finite redefinition freedom present in a general subtraction coordinate. It is especially convenient because the beta functions and anomalous dimensions are encoded in the pole coefficients.

Figure 34.5 depicts the MS coordinate as a Laurent-principal-part prescription at $\epsilon = 0$. The finite coordinate λ_I is the regular part selected after the pole part has been subtracted; the pole coefficients $K_I^{(n)}$ are the residues of the principal part in this formal meromorphic coordinate.



$$g_I^\epsilon = \mu^{-\delta_I(\epsilon)} \left[\lambda_I(\mu) + \underbrace{\sum_{n\geq 1} \epsilon^{-n} K_I^{(n)}(\lambda(\mu))}_{P_- \text{ principal part}} \right], \quad P_{\text{fin}}\big(\mu^{\delta_I(\epsilon)} g_I^\epsilon\big) = \lambda_I.$$

Figure 34.5: Minimal subtraction is a Laurent projection at the regulator point $\epsilon = 0$. The dimensionless running coordinate is the finite part after the principal pole part has been subtracted. The coefficients $K_I^{(n)}$ are then constrained by the condition $\mathrm{d}g_I^\epsilon / \mathrm{d}\log\mu = 0$.

34.9 The Scalar Quartic Pole at One Loop

For $d = 4$, consider the scalar quartic operator with dimensional regularization $D = 4 - \epsilon$. The quartic coupling g^ϵ has engineering dimension ϵ, and the interaction term is

$$\mathcal{L}_E \supset \frac{1}{4!} g^\epsilon \phi^4.$$

A general momentum-subtraction coordinate $\widetilde{\lambda}(\mu)$ can be defined at Euclidean momenta of size μ:

$$\mu^\epsilon \widetilde{\lambda}(\mu) = -Z(\mu)^2\, \Gamma^{(4)} \Big|_{k_i^2 = O(\mu^2),\, s=-\mu^2 a_s,\, t=-\mu^2 a_t,\, u=-\mu^2 a_u},$$

where $a_s, a_t, a_u > 0$ are fixed constants specifying the subtraction configuration.

At one loop,

$$\mu^\epsilon \widetilde{\lambda}(\mu) = g^\epsilon - \frac{(g^\epsilon)^2}{2} \int \frac{\mathrm{d}^{4-\epsilon} k}{(2\pi)^{4-\epsilon}} \int_0^1 \mathrm{d}x$$
$$\times \left[\frac{1}{(k^2 + \mu^2 a_s x(1-x))^2} + (a_s \to a_t) + (a_s \to a_u) \right] + O((g^\epsilon)^3).$$

Using

$$\int \frac{d^{4-\epsilon}k}{(2\pi)^{4-\epsilon}} \frac{1}{(k^2+\Delta)^2} = (4\pi)^{-2+\epsilon/2}\Gamma\left(\frac{\epsilon}{2}\right)\Delta^{-\epsilon/2},$$

and then integrating over x, this becomes

$$\mu^\epsilon \widetilde{\lambda}(\mu) = g^\epsilon - \frac{(g^\epsilon)^2}{2}\,\mu^{-\epsilon}(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)} \\ \times\left(a_s^{-\epsilon/2} + a_t^{-\epsilon/2} + a_u^{-\epsilon/2}\right) + O((g^\epsilon)^3).$$

Inverting the relation gives

$$g^\epsilon = \mu^\epsilon\left[\widetilde{\lambda}(\mu) + \widetilde{\lambda}(\mu)^2\left(\frac{3}{16\pi^2}\frac{1}{\epsilon} + O(\epsilon^0)\right) + O(\widetilde{\lambda}^3)\right].$$

The $O(\epsilon^0)$ term depends on the finite subtraction constants a_s, a_t, a_u. The MS coordinate $\lambda(\mu)$ is defined by retaining the pole coefficient and setting the finite counterterm convention to zero:

$$g^\epsilon = \mu^\epsilon\left[\lambda(\mu) + \frac{3}{16\pi^2}\frac{\lambda(\mu)^2}{\epsilon} + O(\lambda^3)\right].$$

This equation fixes the notation used later. For the Wilson–Fisher calculation, the bare quartic coefficient g_0 is this g^ϵ, and the dimensionful running quartic coefficient is

$$g_R(\mu) = \mu^\epsilon \lambda(\mu).$$

For Yang–Mills theory the coupling is placed in the inverse kinetic coefficient, so the analogous dimensionless coordinate is written

$$\lambda^2_{\mathrm{YM}}(\mu) = \mu^\epsilon g^2_{\mathrm{YM}}(\mu), \qquad \frac{1}{g^2_{\mathrm{YM}}(\mu)} = \mu^\epsilon \frac{1}{\lambda^2_{\mathrm{YM}}(\mu)}.$$

Thus the power of μ is the same engineering-dimension conversion; only the choice of coupling coordinate differs between a polynomial scalar vertex and an inverse gauge kinetic term.

Figure 34.6 displays the one-loop quartic MS structure in this convention: the logarithmic scalar bubble supplies the pole subtraction, and the engineering power of μ converts the coordinate in $4-\epsilon$ dimensions.

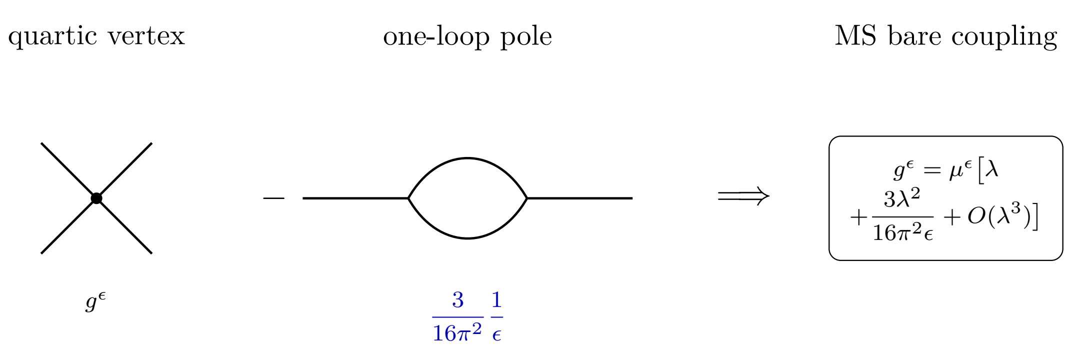


Figure 34.6: In four-dimensional scalar quartic theory, the one-loop bubble produces the pole coefficient $3/(16\pi^2\epsilon)$. The MS coordinate keeps this pole coefficient in the bare coupling and fixes the finite part by convention.

34.10 Beta Functions Away from the Target Dimension

In MS coordinates define

$$\beta_I^{\epsilon}(\lambda) = \frac{\mathrm{d}\lambda_I(\mu)}{\mathrm{d}\log\mu}.$$

The bare coupling g_I^{ϵ} is independent of μ. Differentiating the MS definition gives

$$\begin{aligned} 0 &= \frac{\mathrm{d}g_I^{\epsilon}}{\mathrm{d}\log\mu} \\ &= -\delta_I(\epsilon)\left[\lambda_I + \sum_{n\geq 1}\epsilon^{-n}K_I^{(n)}\right] + \beta_I^{\epsilon} + \sum_{n\geq 1}\epsilon^{-n}\frac{\partial K_I^{(n)}}{\partial\lambda_J}\beta_J^{\epsilon}. \end{aligned}$$

Here and below repeated J-indices are summed. Expand the $(d-\epsilon)$-dimensional beta function as

$$\beta_I^{\epsilon}(\lambda) = \sum_{m=0}^{\infty}\epsilon^m\beta_I^{(m)}(\lambda).$$

The positive powers of ϵ are constrained by the displayed equation. For example, the coefficient of ϵ^1 has the form

$$-\delta_I^{(1)}\lambda_I + \beta_I^{(1)} + \sum_{n\geq 1}\frac{\partial K_I^{(n)}}{\partial\lambda_J}\beta_J^{(n+1)} = 0,$$

and the coefficient of ϵ^2 has the form

$$\beta_I^{(2)} + \sum_{n\geq 1}\frac{\partial K_I^{(n)}}{\partial\lambda_J}\beta_J^{(n+2)} = 0.$$

The pole $K_I^{(n)}$ begins at increasingly high perturbative order as n grows. More precisely, grade the formal power series by perturbative degree and assume $K_I^{(n)} \in F^{n+1}$, where F^L denotes terms of degree at least L in the interaction coordinates. Then $\partial K_I^{(n)}/\partial\lambda_J \in F^n$. For the coefficient of ϵ^r with $r \geq 2$, the homogeneous degree-L part of

$$\beta_I^{(r)} + \sum_{n\geq 1}\frac{\partial K_I^{(n)}}{\partial\lambda_J}\beta_J^{(n+r)} = 0$$

contains $\beta_J^{(n+r)}$ only in degrees strictly smaller than L. Writing $\beta_{I,L}^{(r)}$ for the degree-L component, the lowest perturbative degree therefore gives $\beta_{I,L}^{(r)} = 0$, and induction on L gives $\beta_I^{(r)} = 0$ for every $r \geq 2$. Returning to the coefficient of ϵ^1, the remaining summation involves only $\beta_J^{(n+1)}$ with $n+1 \geq 2$, hence vanishes by the preceding induction, leaving $\beta_I^{(1)} = \delta_I^{(1)}\lambda_I$. Consequently

$$\beta_I^{(m)} = 0 \quad (m \geq 2), \qquad \beta_I^{(1)} = \delta_I^{(1)}\lambda_I.$$

Thus

$$\beta_I^{\epsilon}(\lambda) = \beta_I(\lambda) + \epsilon\,\delta_I^{(1)}\lambda_I, \qquad \beta_I(\lambda) = \beta_I^{(0)}(\lambda).$$

The function $\beta_I(\lambda)$ is the beta function of the target d-dimensional theory in the MS coordinate system.

34.11 Recursive Pole Equations

The nonpositive powers of ϵ determine the pole coefficients $K_I^{(n)}$ from $\beta_I(\lambda)$. Introduce the differential operators

$$D_\beta = \beta_J(\lambda)\frac{\partial}{\partial\lambda_J}, \qquad D_\epsilon = \delta_J^{(1)}\lambda_J\frac{\partial}{\partial\lambda_J}.$$

The coefficient of ϵ^0 gives

$$\beta_I(\lambda) - \delta_I^{(0)}\lambda_I = \big(\delta_I^{(1)} - D_\epsilon\big)K_I^{(1)}(\lambda).$$

For $n \geq 1$, the coefficient of ϵ^{-n} gives

$$\big(D_\beta - \delta_I^{(0)}\big)K_I^{(n)}(\lambda) = \big(\delta_I^{(1)} - D_\epsilon\big)K_I^{(n+1)}(\lambda).$$

The word "recursive" here has a precise algebraic meaning. Choose a perturbative filtration of the formal power-series ring in the couplings, for example by loop order or by the usual interaction degree in a finite renormalizable chart. Let $\mathcal{P}_{I,L}$ denote the finite-dimensional space of homogeneous monomials of filtration degree L that can contribute to the pole coefficient of g_I^ϵ. The operator

$$A_I := \delta_I^{(1)} - D_\epsilon$$

acts diagonally on monomials:

$$A_I(\lambda^\alpha) = \left(\delta_I^{(1)} - \sum_J \alpha_J\delta_J^{(1)}\right)\lambda^\alpha, \qquad \lambda^\alpha = \prod_J \lambda_J^{\alpha_J}.$$

Thus the only possible obstruction to solving the pole equation in a given monomial sector is a resonance

$$\delta_I^{(1)} = \sum_J \alpha_J\delta_J^{(1)}.$$

Lemma 34.7 (Existence and uniqueness of the MS pole recursion)**.** *Assume the following data.*

(i) The chosen MS coordinate chart has a finite perturbative filtration: for each I and each filtration degree L, only finitely many monomials occur in $\mathcal{P}_{I,L}$.

(ii) The pole order is bounded at fixed perturbative order: the component $K_{I,L}^{(n)}$ of $K_I^{(n)}$ in $\mathcal{P}_{I,L}$ vanishes for n larger than a finite bound depending on L.

(iii) For every sector in which a new coefficient $K_{I,L}^{(n+1)}$ is to be solved, the linear map $A_I = \delta_I^{(1)} - D_\epsilon : \mathcal{P}_{I,L} \to \mathcal{P}_{I,L}$ is invertible.

Then a formal target-dimension beta-function vector field $\beta_I(\lambda)$ determines at most one family of pole coefficients $\{K_I^{(n)}\}_{n\geq 1}$ satisfying the MS pole equations and the MS condition that no finite counterterm part is added. If the right-hand sides produced by the recursion lie in the corresponding sectors $\mathcal{P}_{I,L}$, the solution exists and is given degree by degree by

$$K_{I,L}^{(1)} = A_I^{-1}\left[\beta_I - \delta_I^{(0)}\lambda_I\right]_L,$$

and, for $n \geq 1$,

$$K_{I,L}^{(n+1)} = A_I^{-1}\left[\big(D_\beta - \delta_I^{(0)}\big)K_I^{(n)}\right]_L.$$

Here $[\cdots]_L$ denotes projection to filtration degree L.

Proof. At fixed (I, L), the sector $\mathcal{P}_{I,L}$ is finite-dimensional by hypothesis. The coefficient of ϵ^0 is the linear equation

$$A_I K^{(1)}_{I,L} = [\beta_I - \delta^{(0)}_I \lambda_I]_L.$$

Invertibility of A_I on $\mathcal{P}_{I,L}$ gives a unique solution whenever the displayed right-hand side belongs to that sector. Suppose inductively that $K^{(n)}_I$ has already been determined through the filtration degree under consideration. The coefficient of ϵ^{-n} is

$$A_I K^{(n+1)}_{I,L} = \Big[\big(D_\beta - \delta^{(0)}_I\big) K^{(n)}_I\Big]_L,$$

which is again a finite-dimensional linear equation with the same invertible left-hand side. This gives existence, when the right-hand side is in the chosen local sector, and uniqueness. The pole-order bound ensures that at a fixed perturbative degree only finitely many such equations must be solved. If two solutions existed, their difference in the first sector where they differ would lie in $\ker A_I$, contradicting the invertibility hypothesis. ☐

In ordinary renormalizable MS computations these hypotheses are supplied by the graph expansion: at fixed loop order there are finitely many local counterterm monomials in the selected chart, locality bounds the pole order, and nonresonance of A_I is checked on the monomials that actually occur. If a resonant monomial is present, the pole equations do not by themselves give a unique coefficient in that sector; one must add a normalization condition, enlarge the coordinate chart, or treat the resonance as a consistency condition rather than an automatic recursion.

In a homogeneous sector in which every coupling entering the pole coefficient for g^ϵ_I has the same ϵ-slope $\delta^{(1)}_J = \delta^{(1)}_I$, the operator D_ϵ reduces on that sector to

$$D_\epsilon = \delta^{(1)}_I \lambda_J \frac{\partial}{\partial \lambda_J}.$$

The pole equations then take the simpler form

$$\beta_I(\lambda) - \delta^{(0)}_I \lambda_I = \delta^{(1)}_I \left(1 - \lambda_J \frac{\partial}{\partial \lambda_J}\right) K^{(1)}_I(\lambda),$$

and, for $n \geq 1$,

$$\left(\beta_J \frac{\partial}{\partial \lambda_J} - \delta^{(0)}_I\right) K^{(n)}_I(\lambda) = \delta^{(1)}_I \left(1 - \lambda_J \frac{\partial}{\partial \lambda_J}\right) K^{(n+1)}_I(\lambda).$$

The single-coupling scalar quartic example belongs to this homogeneous case.

For a single marginal coupling with $\delta^{(0)} = 0$ and $\delta^{(1)} = -1$, as in $d = 4$ scalar quartic theory, the one-loop MS relation

$$g^\epsilon = \mu^\epsilon \left[\lambda + \frac{3}{16\pi^2} \frac{\lambda^2}{\epsilon} + O(\lambda^3)\right]$$

implies

$$\beta^\epsilon(\lambda) = \beta(\lambda) - \epsilon\lambda,$$

with

$$\beta(\lambda) = \frac{3}{16\pi^2} \lambda^2 + O(\lambda^3).$$

The $-\epsilon\lambda$ term is the engineering contribution in $4 - \epsilon$ dimensions; the ϵ^0 term is the four-dimensional perturbative beta function.

Figure 34.7 records the coefficient equations in the Laurent expansion. The positive powers of ϵ fix the allowed ϵ-dependence of the $d-\epsilon$ beta function, while the nonpositive powers give the displayed linear recursion for the pole coefficients.

coefficient equations in $\mathrm{d}g_I^\epsilon/\mathrm{d}\log\mu = 0$

$\epsilon^{m\geq 2}$: $\beta_I^{(m)} = 0, \qquad \epsilon^1$: $\beta_I^{(1)} = \delta_I^{(1)}\lambda_I.$

ϵ^0: $A_I K_I^{(1)} = \beta_I - \delta_I^{(0)}\lambda_I, \qquad A_I = \delta_I^{(1)} - D_\epsilon.$

$\downarrow K^{(1)} \mapsto K^{(2)}$

ϵ^{-1}: $A_I K_I^{(2)} = (D_\beta - \delta_I^{(0)})K_I^{(1)}.$

$\downarrow$ iterate

ϵ^{-n}: $A_I K_I^{(n+1)} = (D_\beta - \delta_I^{(0)})K_I^{(n)}, \quad n \geq 1.$

When A_I is invertible on the selected local monomial sector, each pole coefficient is fixed by lower data: $K_I^{(n+1)} = A_I^{-1}(D_\beta - \delta_I^{(0)})K_I^{(n)}.$

Figure 34.7: The scale independence of the regulated coupling is a Laurent identity in ϵ. Matching coefficients first fixes the positive powers in β^ϵ, then determines the pole coefficients recursively by the linear equations shown here.

The next chapter translates this scale dependence into a local spacetime statement involving the stress tensor trace. The beta-function vector field will become the coefficient of renormalized operator insertions in $T^\mu{}_\mu$.

Stress Tensor Trace and Conformal Currents

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

35.1 The Stress Tensor from Local Translations

Work in flat D-dimensional Euclidean spacetime, with coordinates x^μ and metric $\delta_{\mu\nu}$. A constant translation by a vector δa^μ acts on a scalar field by

$$\phi'(x') = \phi(x), \qquad x'^\mu = x^\mu + \delta a^\mu.$$

The corresponding active variation at the same coordinate x is

$$\delta\phi(x) = \phi'(x) - \phi(x) = -\delta a^\mu\, \partial_\mu \phi(x).$$

The stress tensor is obtained by promoting δa^μ to a smooth compactly supported function $\delta a^\mu(x)$. For a multiplet of fields one is free to add to the local variation a term proportional to $\partial_\mu \delta a_\nu$:

$$\delta\phi(x) = -\delta a^\mu(x)\, \partial_\mu \phi(x) + \partial_\mu \delta a_\nu(x)\, \mathcal{D}^{\mu\nu}\phi(x).$$

Here $\mathcal{D}^{\mu\nu}$ is a fixed linear differential operator on the fields. Different choices of $\mathcal{D}^{\mu\nu}$ change the stress tensor by equation-of-motion terms and improvement terms. Once the convention is chosen, define $T^{\mu\nu}$ by

$$S[\phi+\delta\phi] = S[\phi] - \int \mathrm{d}^D x\, \partial_\mu \delta a_\nu(x)\, T^{\mu\nu}(x),$$

for compactly supported $\delta a^\mu(x)$, up to terms proportional to the equations of motion. If δa^μ is constant, the derivative vanishes, which is the Noether statement of translation invariance.

Figure 35.1 contrasts constant translations with local translations and fixes the convention that the stress tensor is the coefficient of $\partial_\mu \delta a_\nu$.

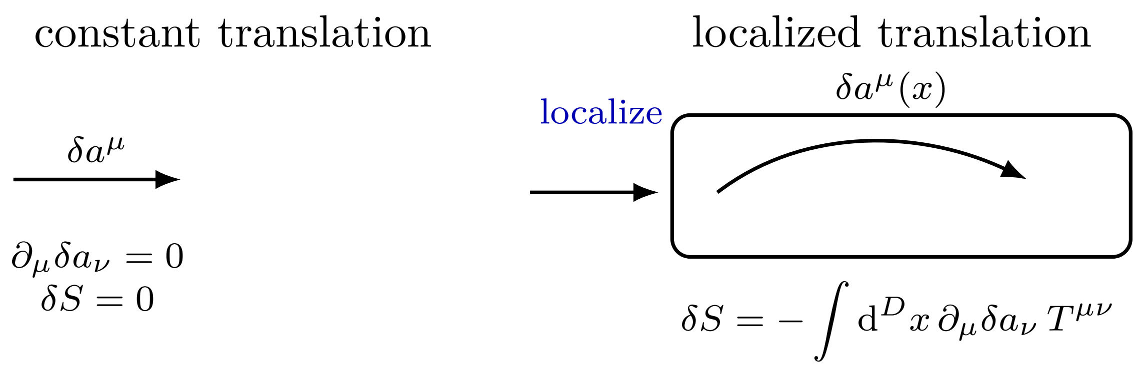

Figure 35.1: The stress tensor is the coefficient of the derivative of a local translation parameter. Constant translations are recovered by setting $\partial_\mu \delta a_\nu = 0$.

35.2 Background Metric Sources

The flat-space stress tensor above is the specialization of a source derivative with respect to a background metric. This construction requires its own data. Let $g_{\mu\nu}$ be a smooth Euclidean metric that equals $\delta_{\mu\nu}$ outside a compact set, and let $\eta^I(x)$ be smooth compactly supported sources for a chosen finite set of renormalized local operators O_I. At a regulator Λ, assume a metric-dependent regulated functional integral

$$Z_\Lambda[g,\eta] = \int \mathcal{D}^g_\Lambda \phi \, \exp\left[-S_\Lambda[g;\phi] - \int \mathrm{d}^D x\, \sqrt{g}\, \eta^I(x) O_{I,\Lambda}(x;g,\phi)\right].$$

The dependence of the cutoff, measure, and composite operators on g is part of the regulator convention. Metric-dependent local terms generated by the measure or by short-distance subtractions are absorbed into a local functional $P_\Lambda[g,\eta]$. In this chapter the source functional is the renormalized Euclidean free energy; the logarithm of the partition function is denoted K when it is needed:

$$\mathcal{W}[g,\eta] = \lim_{\Lambda\to\infty} \big(-\log Z_\Lambda[g,\eta] + P_\Lambda[g,\eta]\big).$$

If $K_\Lambda[g,\eta] = \log Z_\Lambda[g,\eta]$, then $\mathcal{W} = -K$ after the same choice of local subtraction chart. The opposite convention $K = \log Z$ is often useful for displaying connected insertions directly, but every first-derivative formula below changes sign when one replaces $\mathcal{W}$ by K. The limit is taken in the topology of distributions obtained by differentiating with respect to smooth test sources near $\eta = 0$ and $g = \delta$. It is a definition of the source-coordinate system; its existence must be established from the regulator and renormalization construction.

The stress tensor and operator insertions in this source-coordinate system are defined by

$$\langle T^{\mu\nu}(x)\rangle_{g,\eta} = -\frac{2}{\sqrt{g}(x)}\frac{\delta\mathcal{W}[g,\eta]}{\delta g_{\mu\nu}(x)}, \qquad \langle O_I(x)\rangle_{g,\eta} = \frac{1}{\sqrt{g}(x)}\frac{\delta\mathcal{W}[g,\eta]}{\delta\eta^I(x)}. \tag{35.1}$$

The stress-tensor sign follows from the metric response convention

$$\delta S[g;\phi] = -\frac{1}{2}\int \mathrm{d}^D x\,\sqrt{g}\,T^{\mu\nu}(x)\delta g_{\mu\nu}(x).$$

The operator-insertion sign follows from the Euclidean source coupling

$$S_{\mathrm{source}}[g,\eta;\phi] = \int \mathrm{d}^D x\,\sqrt{g}\,\eta^I O_I.$$

In $Z_\Lambda[g,\eta]$ this term appears in the exponential with sign $-S_{\mathrm{source}}$. The metric derivative is taken with respect to $g_{\mu\nu}$; by the chain-rule identity (58.2), this is the same stress-tensor convention as the contravariant-metric variation used in Chapter 58. At $\eta = 0$ and $g = \delta$, this metric derivative agrees with the flat-space Noether stress tensor up to contact terms, equation-of-motion operators, and improvement terms fixed by the source-coordinate system.

Assumption 35.1 (Covariant source regulator)**.** The regulated functional $Z_\Lambda[g,\eta]$, the local subtraction functional $P_\Lambda[g,\eta]$, and the limiting source-coordinate system $\mathcal{W}[g,\eta]$ are invariant under compactly supported diffeomorphisms. The metric and scalar sources transform by

$$\delta_\xi g_{\mu\nu} = \nabla_\mu\xi_\nu + \nabla_\nu\xi_\mu, \qquad \delta_\xi\eta^I = \xi^\mu\nabla_\mu\eta^I$$

for every smooth compactly supported vector field ξ. This regulator and subtraction-scheme hypothesis requires covariance of the cutoff and counterterm prescription in addition to locality. It is available for regulator constructions and counterterm prescriptions that are covariant with respect to the background metric. A cutoff tied to a fixed coordinate lattice, a fixed momentum frame, or a noncovariant smoothing kernel requires additional improvement terms before the hypothesis can hold. Dimensional regularization on a curved background also requires a covariant continuation of the tensor algebra and a covariant subtraction prescription. In a chiral theory with a gravitational anomaly, no local counterterm choice makes $\mathcal{W}$ invariant under all such diffeomorphisms; the right-hand side of the Ward identity below is then the anomaly functional rather than zero. The derivation in this section assumes the anomaly-free case.

Under Assumption 35.1, substituting the variations above into $\delta_\xi\mathcal{W} = 0$, using (35.1), and integrating the metric term by parts gives the source Ward identity

$$\nabla_\mu\langle T^{\mu\nu}(x)\rangle_{g,\eta} = -\langle O_I(x)\rangle_{g,\eta}\nabla^\nu\eta^I(x). \tag{35.2}$$

The sign in this Ward identity is tied to the source term $-\int\sqrt{g}\,\eta^I O_I$ in $Z_\Lambda[g,\eta]$. A source term with the opposite sign gives the corresponding opposite source term in the diffeomorphism Ward identity. Spinor, vector, and tensor sources add the corresponding representation terms to $\delta_\xi\eta$.

At an RG fixed point, a source-coordinate system whose beta functions vanish and whose stress tensor has been improved as below gives a fixed-point functional

$$\mathcal{W}_*[g,\eta].$$

This is the antecedent for the fixed-point and conformal source functionals used later. The conformal chapters denote the same free-energy convention by W_* and restate the sign of the source term there. The symbol $W_*[g,\eta]$ in those chapters refers to this same renormalized metric and operator source limit, specialized to a fixed point.

35.3 Dilatations and Engineering Dimensions

A constant infinitesimal scale transformation is the special local translation

$$\delta a^\mu(x) = \sigma x^\mu,$$

where σ is a constant. The stress-tensor definition gives

$$\delta S = -\sigma \int \mathrm{d}^D x \, T^\mu{}_\mu(x).$$

Thus the trace is the local operator that measures the response to an infinitesimal dilatation in the chosen stress-tensor convention.

For a free massless scalar,

$$S_{\text{kin}}[\phi] = \frac{1}{2} \int \mathrm{d}^D x \, \partial_\mu \phi \, \partial^\mu \phi,$$

scale invariance of the kinetic term fixes the engineering field dimension to

$$\Delta_\phi^{\text{eng}} = \frac{D-2}{2}.$$

Equivalently, with $x'^\mu = (1+\sigma)x^\mu$,

$$\phi'(x') = (1+\sigma)^{-(D-2)/2} \phi(x),$$

or, at fixed x,

$$\delta\phi(x) = -\sigma x^\mu \partial_\mu \phi(x) - \sigma \frac{D-2}{2} \phi(x).$$

In the local-translation notation this means that, for the scalar field, the trace of the chosen differential operator satisfies

$$\mathcal{D}^\mu{}_\mu \phi = -\frac{D-2}{2} \phi.$$

The invariance of the kinetic term can be checked directly. Put $\Delta_\phi = (D-2)/2$. For compactly supported variations,

$$\begin{aligned}
\delta S_{\text{kin}} &= -\sigma \int \mathrm{d}^D x \, \partial_\mu \phi \, \partial^\mu \big(x^\nu \partial_\nu \phi + \Delta_\phi \phi \big) \\
&= -\sigma \int \mathrm{d}^D x \, \left[(1+\Delta_\phi) \, \partial_\mu \phi \, \partial^\mu \phi + \frac{1}{2} x^\nu \partial_\nu \big(\partial_\mu \phi \, \partial^\mu \phi \big) \right] \\
&= -\sigma \left[1 + \Delta_\phi - \frac{D}{2} \right] \int \mathrm{d}^D x \, \partial_\mu \phi \, \partial^\mu \phi = 0.
\end{aligned} \tag{35.3}$$

Let now $D = d - \epsilon$, and let O_I be a local monomial or polynomial in fields and derivatives with engineering dimension

$$d_I(\epsilon) = d - \epsilon + \delta_I(\epsilon) = D + \delta_I(\epsilon).$$

Under the same scale transformation,

$$O_I'(x') = (1+\sigma)^{-d_I(\epsilon)} O_I(x).$$

For an action of the form

$$S[\phi] = S_{\text{kin}}[\phi] + \int \mathrm{d}^D x \sum_I g_I^\epsilon \, O_I(x),$$

the interaction part transforms as

$$\int \mathrm{d}^D x' \sum_I g_I^\epsilon O_I'(x') = \int \mathrm{d}^D x \sum_I g_I^\epsilon (1+\sigma)^{-\delta_I(\epsilon)} O_I(x).$$

The total variation is the sum of the kinetic and interaction variations. Equation (35.3) shows that the kinetic contribution vanishes in this engineering convention, for compactly supported versions of the dilatation variation. Thus the nonderivative trace term comes only from the interaction coordinates. To first order in σ,

$$\delta S = -\sigma \int \mathrm{d}^D x \sum_I \delta_I(\epsilon) g_I^\epsilon O_I(x).$$

Comparing this with the stress-tensor definition gives the bare trace identity

$$T^\mu{}_\mu = \sum_I \delta_I(\epsilon) \, g_I^\epsilon \, O_I,$$

modulo total derivatives and equation-of-motion operators.

Figure 35.2 records the scaling bookkeeping used in the derivation. The kinetic term has three factors: the Jacobian of the measure, the two derivatives, and the two fields. The interaction term has only the measure factor and the engineering dimension of the local operator. Comparing the resulting first-order variation with $\delta S = -\sigma \int T^\mu{}_\mu$ fixes the sign in the bare trace identity.

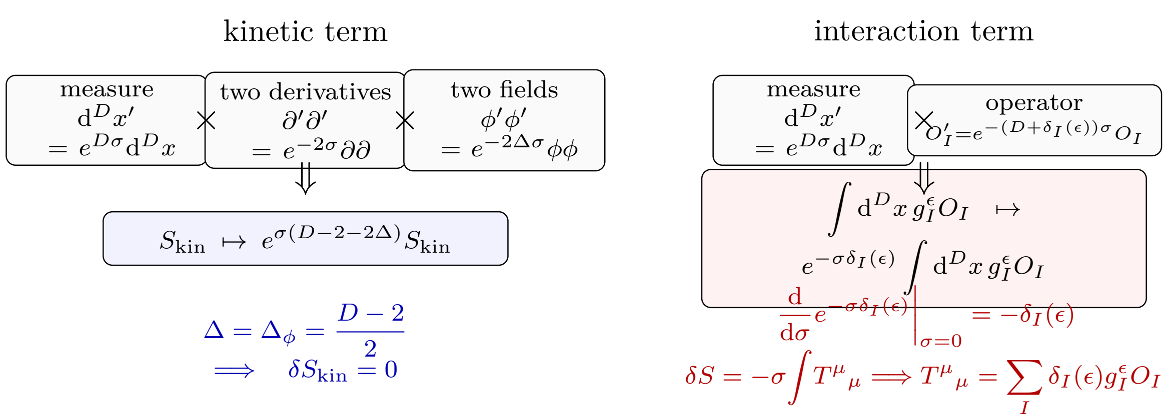

Figure 35.2: The bare trace identity follows from factor bookkeeping under a constant scale transformation. The kinetic term contributes the factor $e^{\sigma(D-2-2\Delta)}$ and is invariant at $\Delta_\phi = (D-2)/2$. An interaction operator of engineering dimension $D + \delta_I(\epsilon)$ leaves the residual factor $e^{-\sigma\delta_I(\epsilon)}$; comparison with $\delta S = -\sigma \int T^\mu{}_\mu$ gives $T^\mu{}_\mu = \sum_I \delta_I(\epsilon) g_I^\epsilon O_I$ modulo total derivatives and equation-of-motion operators.

35.4 The Renormalized Trace Identity

The preceding identity is a bare operator statement in the regulated theory. To convert it to a renormalized statement, use the same MS chart and source-renormalized operator convention as in the previous chapter. Minimal subtraction expresses each bare coupling as

$$g_I^\epsilon = \mu^{-\delta_I(\epsilon)} \left[\lambda_I(\mu) + \sum_{n \geq 1} \epsilon^{-n} K_I^{(n)}(\lambda(\mu)) \right],$$

where

$$\delta_I(\epsilon) = \delta_I^{(0)} + \epsilon \delta_I^{(1)}.$$

At finite ϵ, define the MS insertion associated with the coordinate λ_J by

$$\mathcal{O}_{J,\epsilon}^{\mathrm{MS}} = \frac{\partial}{\partial \lambda_J} \left(\sum_I g_I^\epsilon O_I \right),$$

where the derivative is taken at fixed bare operator basis O_I and fixed μ. The renormalized insertion is the finite limit

$$[O_J]_\mu = \lim_{\epsilon \to 0} \mathcal{O}_{J,\epsilon}^{\mathrm{MS}}$$

as a distribution away from coincident insertion points. Contact-term extensions of this distribution are additional scheme data.

Bare couplings are independent of μ. If

$$\beta_I^\epsilon(\lambda) = \frac{\mathrm{d}\lambda_I}{\mathrm{d}\log\mu} = \beta_I(\lambda) + \epsilon \delta_I^{(1)} \lambda_I$$

is the $D = d - \epsilon$ beta function in MS coordinates, then

$$0 = \frac{\mathrm{d}g_I^\epsilon}{\mathrm{d}\log\mu} = -\delta_I(\epsilon) g_I^\epsilon + \sum_J \beta_J^\epsilon \frac{\partial g_I^\epsilon}{\partial \lambda_J}.$$

Hence

$$\delta_I(\epsilon) g_I^\epsilon = \sum_J \big(\beta_J + \epsilon \delta_J^{(1)} \lambda_J \big) \frac{\partial g_I^\epsilon}{\partial \lambda_J}.$$

Substituting this relation into the bare trace identity gives

$$T^\mu{}_\mu = \sum_J \big(\beta_J + \epsilon \delta_J^{(1)} \lambda_J \big) \mathcal{O}_{J,\epsilon}^{\mathrm{MS}}.$$

Lemma 35.2 (Flat-space renormalized trace identity)**.** *In the MS coordinate chart above, and for separated insertions in flat space, the finite stress-tensor trace satisfies*

$$T^\mu{}_\mu = \sum_J \beta_J(\lambda) \, [O_J]_\mu. \tag{35.4}$$

Proof. Let f be a test density for the trace insertion whose support is separated from all other operator insertions. In the MS source-coordinate system the regulated operator insertion has a Laurent expansion of the form

$$\mathcal{O}^{\mathrm{MS}}_{J,\epsilon}(f) = \sum_{r\geq 1} \epsilon^{-r} C_{J,r}(f) + A_{J,0}(f) + O(\epsilon),$$

where $A_{J,0}(f) = [O_J]_\mu(f)$ and every $C_{J,r}$ is supported on a collision diagonal. For the separated test density under consideration $C_{J,r}(f) = 0$, hence

$$\operatorname*{FP}_{\epsilon=0}\Big[\big(\beta_J + \epsilon\delta^{(1)}_J\lambda_J\big)\mathcal{O}^{\mathrm{MS}}_{J,\epsilon}(f)\Big] = \beta_J [O_J]_\mu(f),$$

where $\mathrm{FP}_{\epsilon=0}$ denotes the coefficient of ϵ^0 in the Laurent expansion. Taking this finite part in the bare trace equation gives (35.4).

The order of operations in the preceding paragraph matters. For an unrestricted test density, multiplication by $\epsilon\delta^{(1)}_J\lambda_J$ sends the simple-pole contact residue $\epsilon^{-1}C_{J,1}$ to the finite local distribution $\delta^{(1)}_J\lambda_J C_{J,1}$, and it shifts the higher pole residues by one pole order. The pole equations coming from $\mathrm{d}g^\epsilon_I/\mathrm{d}\log\mu = 0$ are precisely the algebraic cancellation conditions that make the finite part of $\sum_J \beta^\epsilon_J \mathcal{O}^{\mathrm{MS}}_{J,\epsilon}$ well defined after the source counterterms have been included. Thus the separated identity above is obtained by first forming the MS-renormalized finite part of the product and then restricting away from collision diagonals. The local finite remnants for general test densities are the contact terms described after the proposition. □

At coincident insertion points the preceding proof has a narrower scope. The insertion $\mathcal{O}^{\mathrm{MS}}_{J,\epsilon}$ may have pole parts supported on collision diagonals, and multiplication by ϵ can leave a finite local distribution. Those finite remnants are the Weyl-anomaly and Ward-identity contact terms. The contact-distribution identity is formulated through the renormalized source functional of Section 35.2, together with its local source-coordinate system.

Let $\eta^A(x)$ denote all local sources in a chosen chart, including the constant coupling coordinates λ^I as the special case $\eta^I(x) = \lambda^I$. A local Weyl/RG source vector field is a first-order differential operator on source space,

$$\mathfrak{B}_\sigma = \int \mathrm{d}^d x\, \mathcal{B}^A_\sigma(x; g, \eta)\, \frac{\delta}{\delta\eta^A(x)},$$

where $\mathcal{B}^A_\sigma$ is a local polynomial in the sources, the metric, σ, and finitely many of their derivatives. Its zeroth-order part in the coupling-source directions is

$$\begin{aligned}\mathcal{B}^I_\sigma(x; g, \eta)\big|_{\eta=\lambda} = \sigma(x)\,\beta^I(\lambda)&\\ &+ \text{terms with derivatives of } \sigma\\ &+ \text{terms with positive powers of nonconstant sources.}\end{aligned}$$

The derivative-of-σ terms encode improvement and scheme-dependent local source choices; they vanish in the constant flat separated-point calculation above but contribute to contact distributions.

Proposition 35.3 (Trace identity as a contact distribution)**.** *Assume that the renormalized source functional $\mathcal{W}[g,\eta]$ exists in the sense of Section 35.2 and satisfies the local RG identity*

$$\left[\int \mathrm{d}^d x\, 2\sigma(x) g_{\mu\nu}(x)\frac{\delta}{\delta g_{\mu\nu}(x)} + \mathfrak{B}_\sigma\right]\mathcal{W}[g,\eta] = -\mathcal{A}_\sigma[g,\eta]. \tag{35.5}$$

Here σ is a compactly supported smooth Weyl parameter and $\mathcal{A}_\sigma[g,\eta]$ is a local functional, linear in σ and its derivatives. For

$$X = O_{A_1}(x_1)\cdots O_{A_n}(x_n),$$

define the full contact distribution by differentiating (35.5) with respect to the corresponding sources and then setting $g=\delta$ and $\eta=\lambda$. In insertion notation this gives

$$\int \mathrm{d}^d x\,\sigma(x)\left\langle\left(T^\mu{}_\mu - \beta^I[O_I]_\mu\right)(x)\,X\right\rangle_c = \mathcal{A}_\sigma[X] + \mathcal{C}^{\mathfrak{B}}_\sigma[X]. \tag{35.6}$$

The term $\mathcal{A}_\sigma[X]$ is the source derivative of $\mathcal{A}_\sigma[g,\eta]$. The term $\mathcal{C}^{\mathfrak{B}}_\sigma[X]$ is the finite sum obtained when one or more source derivatives hit the coefficients $\mathcal{B}^A_\sigma(x;g,\eta)$ rather than $\mathcal{W}$. Both terms are local: after differentiating with respect to sources, their kernels are supported on collision diagonals, and the remaining terms contain derivatives of the Weyl parameter associated with improvement or source-scheme choices. For constant σ and mutually distinct flat-space insertion points, these local terms vanish, and (35.6) reduces to (35.4).

Proof. The metric derivative convention (35.1) gives

$$\int \mathrm{d}^d x\,2\sigma g_{\mu\nu}\frac{\delta\mathcal{W}}{\delta g_{\mu\nu}} = -\int \mathrm{d}^d x\,\sqrt{g}\,\sigma\,\langle T^\mu{}_\mu(x)\rangle_{g,\eta}\,.$$

The zeroth-order coupling-source part of $\mathfrak{B}_\sigma$ gives

$$\int \mathrm{d}^d x\,\sigma(x)\beta^I(\lambda)\frac{\delta\mathcal{W}}{\delta\eta^I(x)} = \int \mathrm{d}^d x\,\sqrt{g}\,\sigma(x)\beta^I(\lambda)\,\langle[O_I]_\mu(x)\rangle_{g,\eta}$$

in the source-sign convention of this chapter. Substituting these two identities into (35.5) gives the one-insertion form of (35.6). Apply the functional derivative operator

$$\frac{\delta}{\delta\eta^{A_1}(x_1)}\cdots\frac{\delta}{\delta\eta^{A_n}(x_n)}$$

to (35.5). When all derivatives hit $\mathcal{W}$, the result is the connected distribution with the insertion $T^\mu{}_\mu - \beta^I[O_I]_\mu$, with the standard alternating connected-sign convention inherited from $\mathcal{W} = -\log Z$. When at least one derivative hits a coefficient $\mathcal{B}^A_\sigma$, locality of $\mathcal{B}^A_\sigma$ forces the resulting kernel to be supported where the corresponding source points collide with one another or with the point x. Those terms are, by definition, $\mathcal{C}^{\mathfrak{B}}_\sigma[X]$. The derivatives of the local functional $\mathcal{A}_\sigma[g,\eta]$ give $\mathcal{A}_\sigma[X]$, also supported on the same local loci after specializing to flat space. On the configuration space $x_i \neq x_j$ and $x \neq x_i$, these local distributions vanish, leaving the separated-point proposition. □

Because infinitesimal Weyl transformations commute, the anomaly in (35.5) must satisfy the Wess–Zumino consistency condition

$$\Delta_{\sigma_1}\mathcal{A}_{\sigma_2} - \Delta_{\sigma_2}\mathcal{A}_{\sigma_1} = 0, \qquad \Delta_\sigma = \int \mathrm{d}^d x\,2\sigma g_{\mu\nu}\frac{\delta}{\delta g_{\mu\nu}} + \mathfrak{B}_\sigma. \tag{35.7}$$

This equation is a condition on local functionals of sources and background fields. In even dimensions, curvature terms in $\mathcal{A}_\sigma[g,0]$ may produce flat-space stress-tensor contact distributions after differentiating with respect to the metric even though they vanish at separated flat points.

Thus a conformal fixed point is not specified by separated-point correlators alone; it also requires a source-coordinate system, an anomaly functional satisfying (35.7), and a stress-tensor improvement convention.

Figure 35.3 separates the two support regimes in the local RG identity. On the open configuration space of noncoincident insertions one obtains the beta-function trace identity; on the collision strata the same source-functional equation contains contact distributions and anomaly derivatives that must be retained as part of the renormalized QFT data.

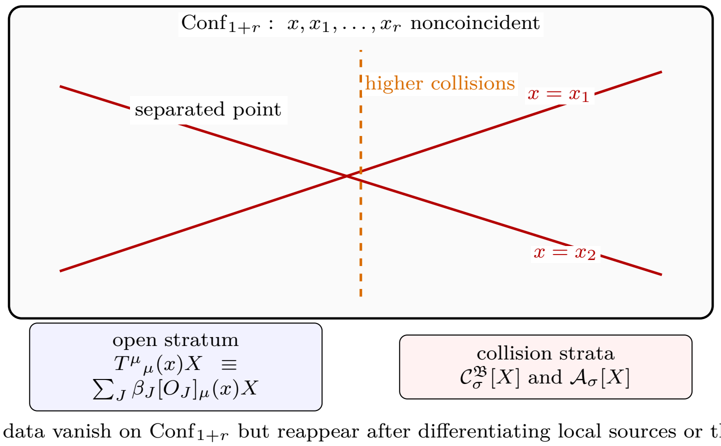

Figure 35.3: The renormalized trace identity has a separated-point part and a local contact part. Away from the collision diagonals the flat-space trace is the beta-function insertion. On the diagonals one must also keep the local distributions produced by source beta functions and by the anomaly functional; these data are invisible in ordinary separated correlators.

35.5 Fixed Points and Conformal Currents

An RG fixed point in the MS coordinate system is a point λ_* at which

$$\beta_J(\lambda_*) = 0 \qquad \text{for all } J.$$

At such a point the beta-function contribution to the trace vanishes. The remaining trace terms, if any, are total derivatives, contact terms, equation-of-motion operators, or improvement-dependent terms. Suppose that the stress tensor has been chosen symmetric, conserved, and traceless as a flat-space renormalized operator:

$$T^{\mu\nu} = T^{\nu\mu}, \qquad \partial_\mu T^{\mu\nu} = 0, \qquad T^{\mu}{}_{\mu} = 0.$$

Let $\xi^\mu(x)$ be a conformal Killing vector field in d dimensions, meaning

$$\partial_\mu \xi_\nu + \partial_\nu \xi_\mu - \frac{2}{d}\delta_{\mu\nu}\,\partial_\rho \xi^\rho = 0.$$

Define the current

$$j^\mu_\xi(x) = T^{\mu\nu}(x)\xi_\nu(x).$$

Its divergence is

$$\partial_\mu j^\mu_\xi = T^{\mu\nu}\partial_\mu \xi_\nu = \frac{1}{2}T^{\mu\nu}\big(\partial_\mu \xi_\nu + \partial_\nu \xi_\mu\big) = \frac{1}{d}T^\mu{}_\mu\, \partial_\rho \xi^\rho = 0.$$

Thus each conformal Killing vector gives a conserved Noether current.

The elementary conformal Killing vector fields are

$$\xi^\mu(x) = \begin{cases} a^\mu, & \text{translations,} \\ \omega^\mu{}_\nu x^\nu, \quad \omega_{\mu\nu} = -\omega_{\nu\mu}, & \text{rotations,} \\ c\, x^\mu, & \text{dilatations,} \\ b_\rho(2x^\rho x^\mu - x^2\delta^{\rho\mu}), & \text{special conformal transformations.} \end{cases}$$

Figure 35.4 shows the elementary Euclidean conformal Killing fields as vector-field flows in two dimensions. The algebraic conservation law $j^\mu_\xi = T^{\mu\nu}\xi_\nu$ uses the same CKV equation, and the figure places that conservation law in the geometric context of the four generating families.

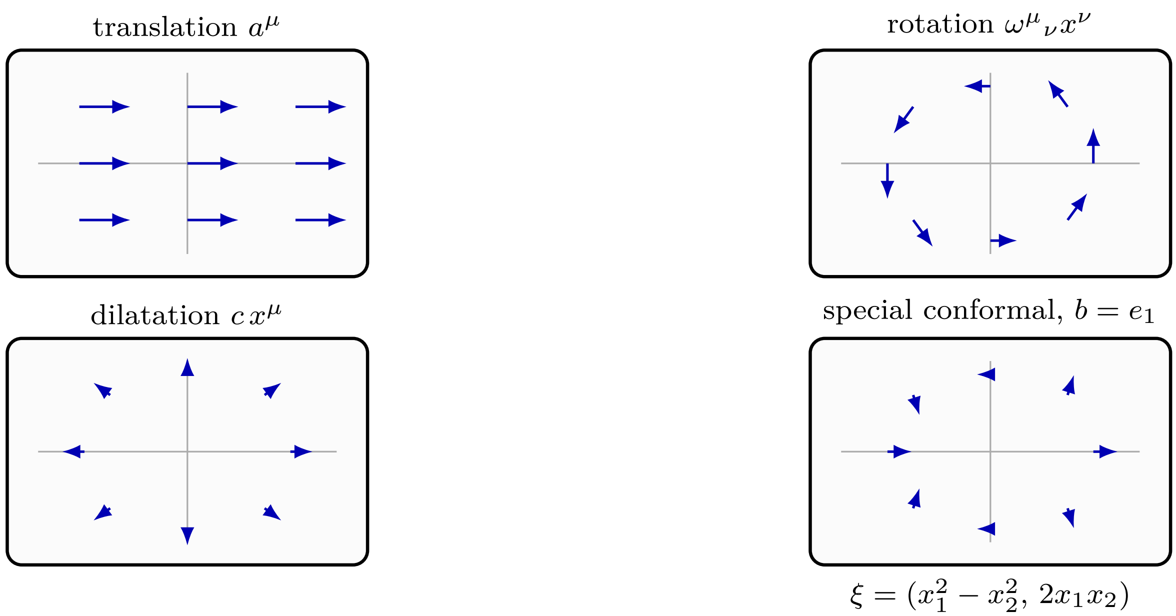

Figure 35.4: The four elementary conformal Killing vector fields. Translation, rotation, dilatation, and special conformal generators are different vector-field geometries even though the conservation proof for $j^\mu_\xi = T^{\mu\nu}\xi_\nu$ uses the same symmetric, conserved, traceless stress tensor and the same conformal Killing equation.

35.6 Virial Currents and Improvement

The fixed-point trace identity determines only the beta-function contribution to $T^\mu{}_\mu$. The stress tensor may still have a total-derivative trace

$$T^\mu{}_\mu = \partial_\mu V^\mu$$

for a local vector operator V^μ, called a virial current. In this case the dilatation current

$$D^\mu = x_\nu T^{\mu\nu} - V^\mu$$

is conserved:

$$\partial_\mu D^\mu = T^\mu{}_\mu - \partial_\mu V^\mu = 0.$$

This establishes scale invariance generated by D^μ, but it does not by itself give conserved special conformal currents of the form $T^{\mu\nu}\xi_\nu$.

If the virial current can be removed by an improvement of the stress tensor, then the same fixed point admits a traceless stress tensor and the conformal currents above. For example, if

$$V_\mu = (d-1)\partial_\mu L$$

for a local scalar operator L, then the improvement

$$T'_{\mu\nu} = T_{\mu\nu} + \big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L$$

changes the trace by

$$T'^\mu{}_\mu = T^\mu{}_\mu - (d-1)\partial^2 L,$$

and removes this virial trace.

For the free massless scalar this improvement has a definite coefficient. Keep the spacetime dimension in this paragraph denoted by D, with $D > 1$. The flat canonical stress tensor for

$$S_{\mathrm{kin}}[\phi] = \frac{1}{2}\int \mathrm{d}^D x\, \partial_\rho\phi\, \partial^\rho\phi$$

is

$$T^{\mathrm{can}}_{\mu\nu} = \partial_\mu\phi\, \partial_\nu\phi - \frac{1}{2}\delta_{\mu\nu}\partial_\rho\phi\, \partial^\rho\phi.$$

Its trace is

$$\begin{aligned} T^{\mathrm{can}\,\mu}{}_\mu &= -\frac{D-2}{2}\,\partial_\rho\phi\,\partial^\rho\phi \\ &= -\frac{D-2}{4}\,\partial^2(\phi^2) + \frac{D-2}{2}\,\phi\,\partial^2\phi. \end{aligned}$$

The second term is an equation-of-motion operator for the free action. Thus, modulo the free equation of motion and separated-insertion contact conventions, the canonical trace is the total derivative

$$T^{\mathrm{can}\,\mu}{}_\mu \equiv -\frac{D-2}{4}\,\partial^2(\phi^2).$$

Define the conformal-coupling coefficient

$$\xi_D^{\mathrm{conf}} = \frac{D-2}{4(D-1)}.$$

With the improvement convention used above,

$$L_{\mathrm{scalar}} = -\xi_D^{\mathrm{conf}}\phi^2,$$

so that

$$\begin{aligned} T^{\mathrm{conf}}_{\mu\nu} &= T^{\mathrm{can}}_{\mu\nu} + \big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L_{\mathrm{scalar}} \\ &= T^{\mathrm{can}}_{\mu\nu} + \xi_D^{\mathrm{conf}}\big(\delta_{\mu\nu}\partial^2 - \partial_\mu\partial_\nu\big)\phi^2. \end{aligned}$$

Its trace is

$$T^{\mathrm{conf}\,\mu}{}_{\mu} = \frac{D-2}{2}\,\phi\,\partial^2\phi,$$

which vanishes as an operator modulo the free equation of motion. The same ξ_D^{conf} is the coefficient of the curved source term $\frac{1}{2}\int \mathrm{d}^D x\,\sqrt{g}\,\xi_D^{\mathrm{conf}} R\phi^2$; the sign difference above is only the translation between that curvature-source coefficient and the scalar L in the flat-space convention $(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2)L$.

Stress-tensor criterion for conformal currents. Let a flat-space local QFT in dimension $d \geq 2$ have a symmetric conserved stress tensor $T_{\mu\nu}$. Suppose that scale invariance is implemented by a conserved current

$$D^\mu = x_\nu T^{\mu\nu} - V^\mu, \qquad \partial_\mu D^\mu = 0,$$

so that $T^\mu{}_\mu = \partial_\mu V^\mu$ as an operator identity, modulo equations of motion and contact terms with other insertions. If the virial current has the form

$$V_\mu = (d-1)\partial_\mu L + J_\mu, \qquad \partial_\mu J^\mu = 0,$$

for a local scalar operator L and a conserved local current J_μ, then the improved stress tensor

$$T'_{\mu\nu} = T_{\mu\nu} + \big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L$$

is symmetric, conserved, and traceless. Consequently each conformal Killing vector ξ^μ gives a conserved current

$$j_\xi^\mu = T'^{\mu\nu}\xi_\nu.$$

The improvement term is symmetric, and its divergence vanishes identically:

$$\partial^\mu\big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L = \partial_\nu\partial^2 L - \partial_\nu\partial^2 L = 0.$$

Its trace is

$$\delta^{\mu\nu}\big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L = -(d-1)\partial^2 L.$$

Using

$$T^\mu{}_\mu = \partial_\mu V^\mu = (d-1)\partial^2 L + \partial_\mu J^\mu = (d-1)\partial^2 L$$

gives $T'^\mu{}_\mu = 0$. For a conformal Killing field ξ,

$$\partial_\mu\xi_\nu + \partial_\nu\xi_\mu = \frac{2}{d}(\partial\cdot\xi)\delta_{\mu\nu}.$$

Using symmetry and conservation of T',

$$\begin{aligned}
\partial_\mu(T'^{\mu\nu}\xi_\nu) &= T'^{\mu\nu}\partial_\mu\xi_\nu \\
&= \frac{1}{2}T'^{\mu\nu}(\partial_\mu\xi_\nu + \partial_\nu\xi_\mu) \\
&= \frac{1}{d}(\partial\cdot\xi)T'^\mu{}_\mu = 0.
\end{aligned}$$

Thus every conformal Killing vector defines a conserved current.

Definition 35.4 (Virial-improvement quotient)**.** Fix the source-coordinate system, stress-tensor convention, and contact-term convention. Let $\mathfrak{V}$ be the vector space of local vector operators that are admissible as virial currents in the identity

$$T^{\mu}{}_{\mu} = \partial_\mu V^\mu,$$

and let $\mathfrak{S}$ be the vector space of local scalar operators L for which the flat-space improvement

$$T_{\mu\nu} \longmapsto T_{\mu\nu} + \big(\partial_\mu\partial_\nu - \delta_{\mu\nu}\partial^2\big)L$$

is an allowed change of stress-tensor representative. These vector spaces are already quotiented by equation-of-motion operators and by the contact distributions that vanish in separated insertions in the chosen source-coordinate system. Derivatives are the induced maps on these quotients. Let

$$\mathfrak{J} = \{\, J_\mu \in \mathfrak{V} : \partial_\mu J^\mu = 0 \,\}$$

be the subspace of conserved local currents. The scalar virial obstruction is the class

$$\mathrm{obs}^{\mathrm{scal}}_{\mathrm{vir}}(V) = [V] \in \mathcal{H}^{\mathrm{scal}}_{\mathrm{vir}} := \mathfrak{V}\Big/\big(\mathfrak{J} + (d-1)\partial\mathfrak{S}\big), \qquad (d-1)\partial\mathfrak{S} = \{(d-1)\partial_\mu L : L \in \mathfrak{S}\}.$$

Remark 35.5 (Scalar-improvement criterion)*.* Under the hypotheses of the stress-tensor criterion above, and restricting to the scalar improvement displayed there, the scale current can be promoted to conformal Killing currents by improving the stress tensor if and only if

$$\mathrm{obs}^{\mathrm{scal}}_{\mathrm{vir}}(V) = 0 \quad \text{in} \quad \mathcal{H}^{\mathrm{scal}}_{\mathrm{vir}}.$$

If the obstruction class vanishes, then by definition there exist $L \in \mathfrak{S}$ and $J_\mu \in \mathfrak{J}$ such that

$$V_\mu = (d-1)\partial_\mu L + J_\mu$$

in the local-operator quotient. The criterion then gives a symmetric conserved traceless improved stress tensor, hence conserved conformal Killing currents.

Conversely, suppose a scalar improvement by $L \in \mathfrak{S}$ makes the trace vanish. The improved trace is

$$0 = T^{\mu}{}_{\mu} - (d-1)\partial^2 L = \partial_\mu\big(V^\mu - (d-1)\partial^\mu L\big)$$

in the same local-operator quotient. Therefore $J_\mu := V_\mu - (d-1)\partial_\mu L$ lies in $\mathfrak{J}$, and the class of V in $\mathfrak{V}/(\mathfrak{J} + (d-1)\partial\mathfrak{S})$ is zero.

Remark 35.6 (General improvements)*.* Definition 35.4 isolates the scalar improvement used in this chapter and in the free-scalar example. If a broader stress-tensor source-coordinate system allows additional identically conserved improvement tensors, the quotient must be enlarged by the image of the corresponding trace-changing map. The precise statement is always the same: the obstruction to conformal currents is the class of the virial current in the quotient of local virial currents by conserved currents and by virial currents generated by allowed improvements.

Remark 35.7 (Scale invariance and conformal invariance: status)*.* The algebraic criterion above reduces the implication from scale invariance to conformal invariance to a concrete local-operator statement: one must prove that the virial obstruction class vanishes. The following are the status boundaries used in this monograph.

(a) In $d = 2$, the Zamolodchikov–Polchinski implication admits theorem formulations only after a definite analytic framework is specified. In the common formulation one assumes a unitary local relativistic QFT with a normalizable vacuum, a local conserved stress tensor, a conserved scale current, reflection positivity or Hilbert-space positivity, and spectral/discreteness conditions strong enough for the stress-tensor two-point functions and the c-function argument to be meaningful. Under such hypotheses one proves $\mathrm{obs}^{\mathrm{scal}}_{\mathrm{vir}}(V) = 0$, or the corresponding vanishing in the allowed improvement quotient, so Remark 35.5 applies. This is a theorem about the formulated implication under those hypotheses, not a statement about every object called a two-dimensional scale-invariant theory in the literature.

(b) In $d = 4$, the implication is not used here as an unconditional theorem. There are important perturbative checks and nonperturbative arguments based on four-dimensional anomaly monotonicity, dilaton scattering, and stress-tensor correlator constraints, but the conclusion is the same local cohomological statement: the virial class must vanish in the quotient determined by the allowed improvements. The necessary spectral, regularity, and contact-term assumptions must be stated separately. Some claims in the physics literature are better understood as conditional arguments or conjectural criteria rather than fully formulated mathematical theorems.

(c) In $d = 3$ and $d > 4$, no general theorem of the form "scale invariance implies conformal invariance" is assumed. Whenever later chapters use conformal symmetry in these dimensions, the existence of a traceless improved stress tensor, the vanishing of the virial obstruction class, or equivalent conformal Ward identities, must be part of the stated data.

[1]

Figure 35.5 displays the quotient as the actual improvement test used in the proof. A scalar improvement L changes the stress tensor and simultaneously changes the virial representative by $(d-1)\partial_\mu L$. Conserved currents do not change the trace. The class of V_μ after these two identifications is therefore precisely the remaining obstruction to a traceless representative.

[1] For theorem formulations in two dimensions and their relation to Zamolodchikov's c-function argument, see A. B. Zamolodchikov, "Irreversibility of the flux of the renormalization group in a 2D field theory," *JETP Lett.* **43** (1986) 730–732, and J. Polchinski, "Scale and conformal invariance in quantum field theory," *Nucl. Phys. B* **303** (1988) 226–236. For four-dimensional conditional arguments and limitations, see M. A. Luty, J. Polchinski, and R. Rattazzi, "The a-theorem and the asymptotics of 4D quantum field theory," *JHEP* **01** (2013) 152, arXiv:1204.5221, and A. Dymarsky, Z. Komargodski, A. Schwimmer, and S. Theisen, "On scale and conformal invariance in four dimensions," *JHEP* **10** (2015) 171, arXiv:1309.2921. See also D. Dorigoni and S. Rychkov, "Scale invariance + unitarity ⇒ conformal invariance?," arXiv:0910.1087, for perturbative checks and a discussion of why the two-dimensional proof does not directly extend to higher dimensions.

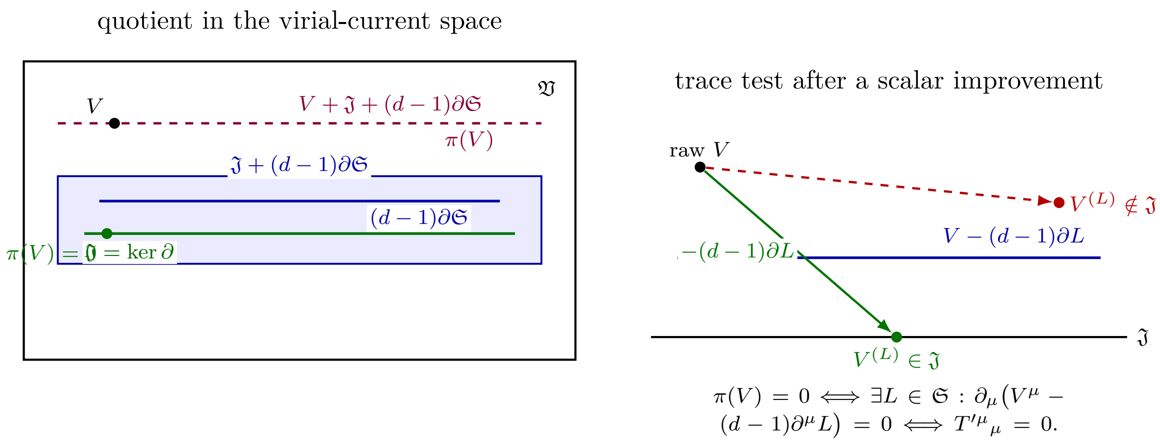

Figure 35.5: The virial obstruction as a concrete quotient test. Scalar improvements generate the subspace $(d-1)\partial\mathfrak{S} \subset \mathfrak{V}$, while conserved currents $\mathfrak{J}$ have zero divergence and hence do not affect the trace. The class $\pi(V)$ vanishes exactly when the improved virial representative is conserved, so that the improved trace is zero.

Before applying these criteria to scalar critical phenomena, we separate two renormalization constructions that will both be used below. The location of a nonzero fixed point and the anomalous dimensions of its scaling operators are computed from 1PI or minimal-subtraction coordinates. The finite-cutoff statement that irrelevant microscopic coordinates are suppressed after the relevant coordinates have been tuned is Wilsonian. The next chapter develops the Wilsonian construction and its cutoff-removal estimate; the subsequent chapters then compute the Wilson-Fisher fixed point in $4-\epsilon$ dimensions and apply the resulting data to Ising universality.

Chapter 36

Wilsonian Effective Actions and Exact Cutoff Flow

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

36.1 Smooth Cutoffs and Effective Actions

We work in Euclidean signature on $\mathbb{R}^D$, first for one real scalar field. Fourier transforms are normalized by

$$\phi(x) = \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, \mathrm{e}^{\mathrm{i}k\cdot x}\widetilde{\phi}(k), \qquad \widetilde{\phi}(k) = \int \mathrm{d}^D x\, \mathrm{e}^{-\mathrm{i}k\cdot x}\phi(x).$$

For compactness, write

$$\int_k F(k) := \int \frac{\mathrm{d}^D k}{(2\pi)^D}\, F(k), \qquad \frac{\delta\widetilde{\phi}(p)}{\delta\widetilde{\phi}(k)} = (2\pi)^D \delta^{(D)}(p-k).$$

Gauge theories require extra finite-cutoff data. A Wilsonian construction for ordinary scalar or matter variables may be written as a covariance split and a Gaussian pushforward. For gauge variables, the corresponding construction is made inside one of two gauge-compatible frameworks: a finite lattice formulation with group-valued link variables and gauge-invariant blocking maps, or a finite-cutoff BV formulation whose action, half-density, bracket, Laplacian, integration cycle, and coarse-graining map satisfy the quantum master equation. The scalar formulas in this chapter supply the ordinary field model. Their gauge-theory use is routed through the lattice chapter and the BV master-formalism chapter, where the gauge quotient, ghosts, antifields, and Ward identities are part of the finite-cutoff data.

Let $\chi : [0,\infty) \to [0,1]$ be a smooth nonincreasing cutoff profile with $\chi(0) = 1$ and rapid decay as $t \to \infty$. The generic Wilson-Polchinski algebra below only needs the covariance difference $C_\Lambda - C_{\Lambda'}$ to be a positive covariance. Exact preservation of a nonzero low-source sector by a source-independent Wilsonian action requires an additional plateau condition, stated later in (36.38); without such a plateau one must keep source-dependent Wilsonian vertices or prove an explicit leakage estimate. At cutoff scale $\Lambda > 0$, define

$$\chi_\Lambda(k) := \chi(k^2/\Lambda^2), \qquad C_\Lambda(k) := \frac{\chi_\Lambda(k)}{k^2 + m^2}.$$

Here $m^2 \geq 0$ is the mass parameter in the quadratic kernel. The Wilsonian action at scale Λ is written

$$S_\Lambda[\phi] = S_{\mathrm{kin},\Lambda}[\phi] + L_\Lambda[\phi], \tag{36.1}$$

where

$$S_{\mathrm{kin},\Lambda}[\phi] = \frac{1}{2}\int_k \widetilde{\phi}(-k)\, \frac{k^2 + m^2}{\chi_\Lambda(k)}\, \widetilde{\phi}(k). \tag{36.2}$$

Perturbation theory around this Gaussian measure uses $C_\Lambda(k)$ as propagator. The cutoff is therefore part of the definition of the covariance, so every propagator in the Gaussian expansion carries the same regulated kernel.

Figure 36.1 fixes the cutoff convention used in this chapter: the smooth profile $\chi_\Lambda(k)$ is built into the Gaussian covariance, hence every perturbative propagator carries the same ultraviolet profile.

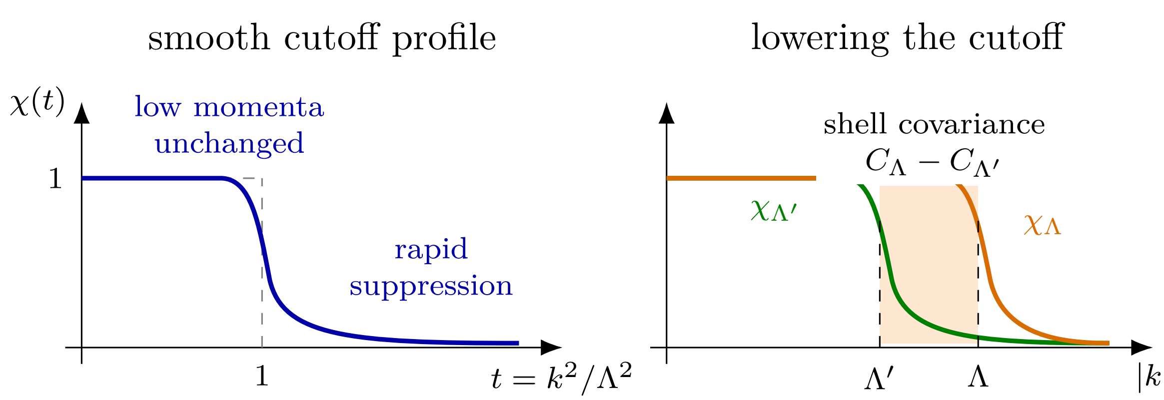

Figure 36.1: The plateau cutoff profile drawn here equals one for sufficiently small momentum and suppresses modes above Λ. When the cutoff is lowered to Λ', the difference of covariances is concentrated near the momentum shell between the two scales. Non-plateau smooth profiles do not give an exact low-source identity without adding source-dependent Wilsonian vertices.

The interaction functional L_Λ is an arbitrary translation-invariant functional compatible with the imposed symmetries. In a finite spatial volume with a finite momentum cutoff, L_Λ is an ordinary smooth or polynomial function of finitely many Fourier modes. Its vertex expansion is

$$L_\Lambda[\phi] = \sum_{n\geq 0} \frac{1}{n!} \int \prod_{i=1}^{n-1} \frac{\mathrm{d}^D k_i}{(2\pi)^D} L_\Lambda^{(n)}(k_1, \dots, k_{n-1}) \\ \times \widetilde{\phi}(k_1) \cdots \widetilde{\phi}(k_{n-1}) \widetilde{\phi}(-k_1 - \cdots - k_{n-1}). \tag{36.3}$$

The coefficient functions $L_\Lambda^{(n)}$ are symmetric in their n external momenta after the momentum-conserving argument is restored. Locality of the Wilsonian action means that, for momenta small compared with Λ, these coefficient functions admit an expansion in polynomials of the external momenta, with the nonpolynomial dependence controlled at the cutoff scale. The derivative expansion supplies an infinite set of local coordinates organized by powers of momentum over Λ.

The source-dependent generating functional at cutoff Λ is

$$Z_\Lambda[J] = \int \mathrm{d}\mu_{C_\Lambda}(\phi) \exp\left[-L_\Lambda[\phi] - \int \mathrm{d}^D x\, J(x)\phi(x)\right]. \tag{36.4}$$

The Gaussian measure $\mathrm{d}\mu_{C_\Lambda}$ carries $S_{\mathrm{kin},\Lambda}$ as in (11.1); with the reference density convention the same expression is

$$Z_{0,\Lambda}^{-1} \int D_\Lambda^{\mathrm{ref}}\phi \exp\left[-S_{\mathrm{kin},\Lambda}[\phi] - L_\Lambda[\phi] - \int \mathrm{d}^D x\, J(x)\phi(x)\right].$$

The normalization $Z_{0,\Lambda}^{-1}$ is immaterial for connected correlators with at least one source derivative. The source-independent Wilsonian condition for lowering Λ to $\Lambda' < \Lambda$ is the equality

$$Z_{\Lambda'}[J] = Z_\Lambda[J] \tag{36.5}$$

for sources J that annihilate the shell covariance, $\widehat{C}_{\Lambda,\Lambda'}J = 0$. For an orthogonal finite-mode split this means J belongs to the dual of the retained low-mode space. For a smooth profile it is an exact nonzero condition only when the profile has a plateau and the source support lies strictly inside that plateau. If the profile is non-plateau, such as a Gaussian profile, the equality in (36.5) is not an exact statement about the source-independent $L_{\Lambda'}$; one must either add source-dependent vertices to the pushforward or state and prove a profile-dependent leakage estimate. Under the annihilator condition, the scale label on S_Λ is a label on a description of the same selected source functional.

36.2 Lowering the Cutoff

The exact Wilsonian step is most transparent with a finite regulator. Let E_Λ be the finite-dimensional real vector space of Fourier modes retained by the ultraviolet regulator, and let $\mathrm{d}\mu_{C_\Lambda}$ be the centered Gaussian measure with covariance C_Λ on this space. In the notation of Definition 11.3, this chapter has absorbed the quadratic kinetic term into $\mathrm{d}\mu_{C_\Lambda}$; equivalently,

$$\mathrm{d}\mu_{C_\Lambda}(\phi) = Z_{0,\Lambda}^{-1} \exp\{-S_{\mathrm{kin},\Lambda}[\phi]\}\, D_\Lambda^{\mathrm{ref}}\phi.$$

The interaction L_Λ is integrated against this Gaussian reference measure. If

$$C_\Lambda = C_{\Lambda'} + \widehat{C}_{\Lambda,\Lambda'}$$

with both summands positive covariances on the regulated vector space, then the Gaussian convolution identity says

$$\int_{E_\Lambda} F(\phi)\,\mathrm{d}\mu_{C_\Lambda}(\phi) = \int_{E_{\Lambda'}} \int_{\widehat{E}_{\Lambda,\Lambda'}} F(\phi' + \phi_{\mathrm{sh}})\,\mathrm{d}\mu_{\widehat{C}_{\Lambda,\Lambda'}}(\phi_{\mathrm{sh}})\,\mathrm{d}\mu_{C_{\Lambda'}}(\phi') \tag{36.6}$$

for every integrable regulated function F. Equation (36.6) is a theorem about Gaussian measures on finite-dimensional vector spaces. Its proof and its continuum status are logically separate.

Finite-regulator Gaussian pushforward. Assume $E_\Lambda = E_{\Lambda'} \oplus \widehat{E}_{\Lambda,\Lambda'}$ and that $C_{\Lambda'}$ and $\widehat{C}_{\Lambda,\Lambda'}$ are positive covariance operators on the two summands. Let $C_\Lambda = C_{\Lambda'} \oplus \widehat{C}_{\Lambda,\Lambda'}$. If F is integrable with respect to the centered Gaussian measure μ_{C_Λ}, then (36.6) holds.

Let X' and X_{sh} be independent centered Gaussian random variables with values in $E_{\Lambda'}$ and $\widehat{E}_{\Lambda,\Lambda'}$ and covariances $C_{\Lambda'}$ and $\widehat{C}_{\Lambda,\Lambda'}$. For every linear functional $\ell \in E_\Lambda^*$,

$$\mathbb{E}\,\mathrm{e}^{\mathrm{i}\ell(X'+X_{\mathrm{sh}})} = \exp\Big\{-\frac{1}{2}\ell(C_{\Lambda'}\ell)\Big\}\exp\Big\{-\frac{1}{2}\ell(\widehat{C}_{\Lambda,\Lambda'}\ell)\Big\} = \exp\Big\{-\frac{1}{2}\ell(C_\Lambda\ell)\Big\}.$$

Thus $X' + X_{\mathrm{sh}}$ has the centered Gaussian law with covariance C_Λ. Equality of expectations of every integrable F gives (36.6).

Hypothesis 36.1 (Continuum interpretation of Wilsonian pushforward)**.** Choose a sequence of finite regulators $N \to \infty$, source spaces $\mathcal{S}_<$ for momenta below a fixed physical scale, and a topology $\mathcal{T}$ on Schwinger functionals or on local Wilsonian kernels. A nonperturbative continuum interpretation of the Wilsonian pushforward requires the following additional assertions.

First, the interacting finite-regulator source functionals

$$Z_{\Lambda,N}[J] = \int_{E_{\Lambda,N}} \exp\{-L_{\Lambda,N}[\phi] - \langle J,\phi\rangle\}\,\mathrm{d}\mu_{C_{\Lambda,N}}(\phi)$$

must converge in $\mathcal{T}$, after the chosen renormalization conditions are imposed, for $J \in \mathcal{S}_<$. This is an existence statement for the interacting integral, logically independent of the Gaussian convolution identity.

Second, for each pair $\Lambda' < \Lambda$, the finite-regulator pushforwards defined by (36.6) must converge in the same topology to a limiting map that preserves the limiting low-source functional. If the infinitesimal Wilson-Polchinski equation is used, the finite-regulator vector fields and their solutions must also converge in the chosen function-space topology.

The finite-regulator proposition is the theorem used in the algebra below. Hypothesis 36.1 is a separate regulator-removal problem. In a model where this hypothesis remains unproved, the continuum Wilsonian flow is a controlled formal or perturbative construction, while a nonperturbative use requires the convergence asserted in Hypothesis 36.1.

The algebraic step behind Wilsonian RG is the covariance identity

$$C_\Lambda(k) = C_{\Lambda'}(k) + \widehat{C}_{\Lambda,\Lambda'}(k), \qquad \widehat{C}_{\Lambda,\Lambda'}(k) := \frac{\chi_\Lambda(k) - \chi_{\Lambda'}(k)}{k^2+m^2}. \tag{36.7}$$

The first covariance belongs to a low field ϕ'. The second covariance belongs to an independent shell field $\phi_{\rm sh}$, with kinetic term

$$\widehat{S}_{\rm kin}[\phi_{\rm sh}] = \frac{1}{2}\int_k \widetilde{\phi}_{\rm sh}(-k)\,\frac{k^2+m^2}{\chi_\Lambda(k)-\chi_{\Lambda'}(k)}\,\widetilde{\phi}_{\rm sh}(k). \tag{36.8}$$

The shell field is denoted $\phi_{\rm sh}$. A tilde denotes Fourier transformation; thus $\widetilde{\phi}_{\rm sh}(k)$ is the shell field's Fourier mode, while $\widetilde{\phi}(k)$ elsewhere is the Fourier mode of the active field variable ϕ. The hat in $\widehat{C}_{\Lambda,\Lambda'}$ labels the covariance difference; it is not a field notation, and the shell field will not be denoted by a hatted ϕ.

Figure 36.2 records the exact propagator split used in the Wilsonian pushforward: active low modes retain $C_{\Lambda'}$, and the shell field is integrated with covariance $\widehat{C}_{\Lambda,\Lambda'}$.

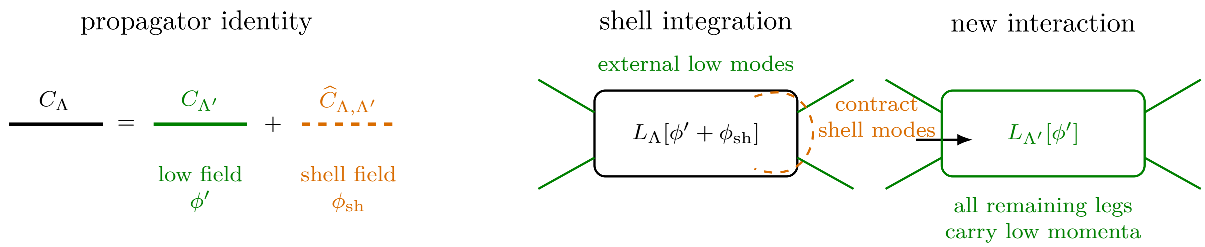

Figure 36.2: The old Gaussian covariance can be realized as the covariance of two independent fields. Integrating the shell field contracts the dashed propagators and produces a new interaction for the low field.

Before the support of the source is used, the covariance split rewrites the cutoff-Λ functional as

$$\begin{aligned} Z_\Lambda[J] = \int [D\phi']\,\exp\left[-S_{{\rm kin},\Lambda'}[\phi']\right] \int [D\phi_{\rm sh}]\,\exp\left[-\widehat{S}_{\rm kin}[\phi_{\rm sh}] - L_\Lambda[\phi'+\phi_{\rm sh}]\right] \\ \times \exp\left[-\int {\rm d}^D x\, J(x)\big(\phi'(x)+\phi_{\rm sh}(x)\big)\right]. \end{aligned} \tag{36.9}$$

The condition on J is now used in its precise regulated meaning: the source belongs to the annihilator of the shell covariance, so that the Gaussian random variable $\langle J, \phi_{\rm sh}\rangle$ has zero variance. Equivalently, for an orthogonal mode split the source belongs to the dual of the low subspace. For a smooth momentum cutoff this exact condition is available for a nonzero open low-momentum support only when the profile has a plateau; a non-plateau profile requires the source-dependent construction introduced in (36.36). Under the exact annihilator condition, the source term in (36.9) couples only to ϕ'. The shell field may then be integrated out by the defining identity

$$\exp\{-L_{\Lambda'}[\phi']\} = \int [D\phi_{\rm sh}]\,\exp\left[-\widehat{S}_{\rm kin}[\phi_{\rm sh}] - L_\Lambda[\phi'+\phi_{\rm sh}]\right], \tag{36.10}$$

up to a ϕ'-independent normalization. Combining (36.8) and (36.10) with the Gaussian measure for ϕ' gives (36.5). The definition is exact for each finite regulator by the Gaussian pushforward calculation above. Perturbation theory expands the logarithm of the shell expectation in connected shell contractions. The continuum claim is the additional Hypothesis 36.1: after the renormalization conditions are imposed, both the interacting source functional and the Wilsonian pushforward or its infinitesimal flow must have the stated regulator-removal limit.

36.3 The Wilson-Polchinski Equation

Let Λ' approach Λ. The shell covariance becomes infinitesimal, and the definition of $L_{\Lambda'}$ becomes a differential equation. With $C_\Lambda(k) = \chi_\Lambda(k)/(k^2+m^2)$ and with the functional-derivative convention already stated, the interaction functional satisfies

$$\Lambda\partial_\Lambda L_\Lambda[\phi] = \frac{1}{2}\int_k \Lambda\partial_\Lambda C_\Lambda(k)\left[\frac{\delta L_\Lambda}{\delta\widetilde{\phi}(k)}\frac{\delta L_\Lambda}{\delta\widetilde{\phi}(-k)} - \frac{\delta^2 L_\Lambda}{\delta\widetilde{\phi}(k)\delta\widetilde{\phi}(-k)}\right]. \tag{36.11}$$

In (36.11), $\widetilde{\phi}(k)$ denotes the Fourier mode of the remaining field. The notation matches the functional derivative convention; after the infinitesimal shell has been integrated, there is again only one field argument of L_Λ.

The analytic meaning of (36.11) is fixed by the following status convention.

Definition 36.2 (Function spaces for the Wilson-Polchinski equation)**.** The Wilson-Polchinski equation will be used in three nested settings.

Finite regulator. Put the theory in finite volume and impose a finite ultraviolet mode cutoff Λ_{UV}. All fields then belong to a fixed finite-dimensional real vector space $E_{\Lambda_{\mathrm{UV}}}$. In this setting L_Λ is a C^2 function on $E_{\Lambda_{\mathrm{UV}}}$, the functional derivatives in (36.11) are ordinary derivatives, and $\Lambda\partial_\Lambda L_\Lambda$ is the derivative of a C^1 curve in the topology of uniform convergence on bounded subsets, with two field derivatives continuous in the same sense. This is the status of the Gaussian convolution derivation.

Formal local expansion. Write L_Λ by the vertex expansion (36.3). For each n, each number q of momentum derivatives, and each compact set K in the momentum-conserving external-momentum domain, define the seminorm

$$p_{n,q,K}(L_\Lambda) = \max_{|\alpha|\le q}\sup_{(k_1,\ldots,k_{n-1})\in K}\left|\partial^\alpha L_\Lambda^{(n)}(k_1,\ldots,k_{n-1})\right|.$$

The Fréchet topology generated by these seminorms is the coefficientwise smooth topology on vertex kernels. A formal perturbative solution is a curve whose vertex kernels satisfy the coefficient equations obtained from (36.11) order by order in the chosen coupling, field-number, loop, and derivative expansion.

Banach RG chart. For theorem-level estimates one must choose a norm. One convenient local model fixes integers $m \ge 0$, a weight $a > 0$, and a constant $c > 1$, and takes $\mathcal{B}_\Lambda^{m,a}$ to be the space of symmetric momentum-conserving kernels for which

$$\|L_\Lambda\|_{\Lambda,m,a} = \sum_{n\ge 0} a^n \max_{|\alpha|\le m}\sup_{|k_i|\le c\Lambda}\Lambda^{d_n+|\alpha|}\left|\partial^\alpha L_\Lambda^{(n)}(k_1,\ldots,k_{n-1})\right|$$

is finite. The constants d_n encode the chosen engineering dimensions of the n-point vertices, and may be changed by a finite reparametrization of coordinates. A Banach-space solution on a scale interval I is a C^1 curve $\Lambda \mapsto L_\Lambda \in \mathcal{B}_\Lambda^{m,a}$ after identifying nearby $\mathcal{B}_\Lambda^{m,a}$ by dimensionless momenta $p_i = k_i/\Lambda$, with (36.11) holding in the Banach norm. Existence, uniqueness, and cutoff-uniform bounds are analytic assertions about this chosen normed space.

Since

$$\Lambda\partial_\Lambda C_\Lambda(k) = \frac{\Lambda\partial_\Lambda\chi(k^2/\Lambda^2)}{k^2+m^2},$$

the integration kernel is supported where the cutoff profile changes, namely near $|k| \simeq \Lambda$ for a rapidly decreasing smooth cutoff. The two terms in (36.11) have a direct graphical meaning: the product of first derivatives joins two vertices by one shell propagator, whereas the second derivative contracts two legs of a single vertex.

Figure 36.3 is the graphical form of (36.11): one term joins two Wilsonian vertices by a shell line, and the other closes two legs on one vertex.

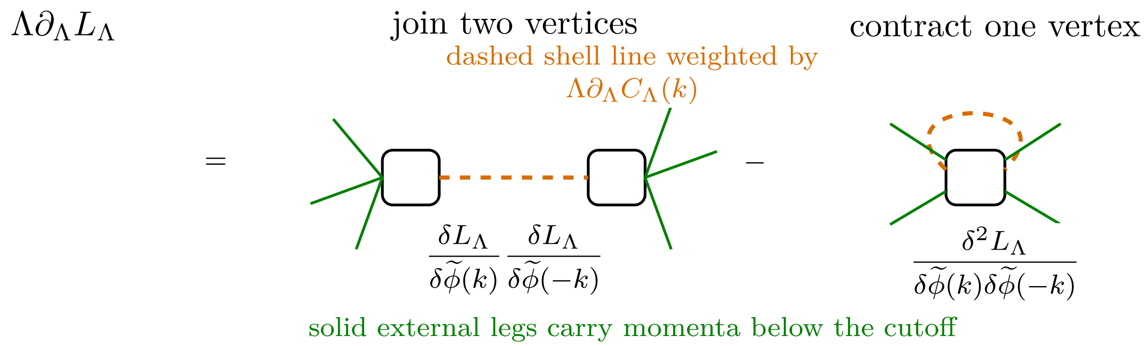

Figure 36.3: The exact cutoff flow has two local operations. The first term connects two interaction vertices with an infinitesimal shell propagator. The second term contracts two legs belonging to the same interaction vertex.

In the finite-regulator setting, equation (36.11) is a closed ordinary differential equation on L_Λ. In the formal local expansion it becomes an infinite coupled system of equations for the coefficient kernels and their derivative expansion. In a Banach RG chart it becomes a vector-field equation only after one verifies that the right-hand side maps the chosen open subset of $\mathcal{B}_\Lambda^{m,a}$ into the appropriate tangent space and satisfies the estimates needed for the claimed solution class. The use of a smooth cutoff is important: it keeps the infinitesimal shell operation compatible with a derivative expansion at external momenta small compared with Λ.

The sign in (36.11) is fixed by the direction of the cutoff derivative. For $\Lambda' = \Lambda - \delta\Lambda$, the shell covariance is

$$\delta C(k) = C_\Lambda(k) - C_{\Lambda'}(k) = \delta\Lambda\,\partial_\Lambda C_\Lambda(k) + O(\delta\Lambda^2).$$

The Gaussian convolution formula gives, to first order in $\delta\Lambda$,

$$\mathrm{e}^{-L_{\Lambda-\delta\Lambda}[\phi]} = \left[1 + \frac{1}{2}\int_k \delta\Lambda\,\partial_\Lambda C_\Lambda(k)\frac{\delta^2}{\delta\widetilde{\phi}(k)\delta\widetilde{\phi}(-k)}\right]\mathrm{e}^{-L_\Lambda[\phi]}.$$

Since

$$\frac{\delta^2 \mathrm{e}^{-L_\Lambda}}{\delta\widetilde{\phi}(k)\delta\widetilde{\phi}(-k)} = \left[\frac{\delta L_\Lambda}{\delta\widetilde{\phi}(k)}\frac{\delta L_\Lambda}{\delta\widetilde{\phi}(-k)} - \frac{\delta^2 L_\Lambda}{\delta\widetilde{\phi}(k)\delta\widetilde{\phi}(-k)}\right]\mathrm{e}^{-L_\Lambda},$$

and

$$L_{\Lambda-\delta\Lambda} = L_\Lambda - \delta\Lambda\,\partial_\Lambda L_\Lambda + O(\delta\Lambda^2),$$

the displayed Wilson-Polchinski equation follows. This derivation is an identity for the regulated finite-dimensional Gaussian integral; the continuum notation suppresses the regulator that makes the functional derivatives ordinary derivatives on a finite vector space. The ϕ-independent normalization omitted in (36.10) is the vacuum-energy coordinate. If it is retained, it replaces $L_\Lambda[\phi]$ by $L_\Lambda[\phi] + c_\Lambda$ and contributes only $\Lambda\partial_\Lambda c_\Lambda$ to the left-hand side of the flow. The functional derivatives in the right-hand side annihilate c_Λ. The displayed equation is therefore the Wilsonian interaction flow modulo this field-independent normalization, whose value may be fixed separately without changing any non-vacuum vertex or connected normalized correlator.

36.4 Effective Average Action and the Wetterich Equation

The Wilsonian interaction L_Λ is obtained by integrating a momentum shell and leaving an action for the remaining field variable. There is a second exact cutoff construction, logically different but derived from the same regulated integral, in which all modes are integrated at once while an infrared quadratic term suppresses low-momentum fluctuations. The resulting object is a cutoff-dependent 1PI functional. This section uses the name *effective average action* for that modified Legendre transform.

Because the earlier source convention in (36.4) used $-\langle J, \phi\rangle$, introduce in this section the source coordinate

$$\mathcal{J} := -J, \qquad \langle \mathcal{J}, \phi\rangle := \int \mathrm{d}^D x\, \mathcal{J}(x)\phi(x) = \int_p \widetilde{\mathcal{J}}(-p)\widetilde{\phi}(p),$$

where $\int_p$ has the same Fourier normalization as $\int_k$. This is a change of source coordinate only; no physics is attached to the sign.

Definition 36.3 (Infrared regulator and effective average action)**.** Work first at finite volume and with a finite ultraviolet mode cutoff, so the real field space is a finite-dimensional vector space E_N. Let $S_N[\phi]$ be the full regulated Euclidean action on E_N, including the quadratic part and all interaction terms allowed by the chosen regulator, and let $D_N\phi$ denote the chosen finite-dimensional reference density. An infrared regulator at scale $\kappa > 0$ is a C^1 family of symmetric nonnegative bilinear forms $R_{\kappa,N} : E_N \to E_N^*$. In a translation-invariant scalar regulator one writes

$$\Delta S_{\kappa,N}[\phi] = \frac{1}{2}\int_p \widetilde{\phi}(-p)R_\kappa(p)\widetilde{\phi}(p), \qquad R_\kappa(p) = Z_\kappa \kappa^2 r(p^2/\kappa^2), \tag{36.12}$$

with $r(s) > 0$ for s near 0 and $r(s) \to 0$ rapidly as $s \to \infty$. The displayed profile is a standard scalar model of the definition; the finite-regulator derivation below only needs a symmetric C^1 nonnegative family $R_{\kappa,N}$.

Define

$$\begin{aligned} Z_{\kappa,N}[\mathcal{J}] &:= \int_{E_N} D_N\phi\, \exp\{-S_N[\phi] - \Delta S_{\kappa,N}[\phi] + \langle \mathcal{J}, \phi\rangle\}, \\ W_{\kappa,N}[\mathcal{J}] &:= \log Z_{\kappa,N}[\mathcal{J}], \qquad \varphi_{\mathcal{J}} := \frac{\delta W_{\kappa,N}}{\delta \mathcal{J}}. \end{aligned} \tag{36.13}$$

On a source neighborhood where $\mathcal{J} \mapsto \varphi_{\mathcal{J}}$ is locally invertible, let $\mathcal{J}_{\kappa,N}[\varphi]$ denote the inverse map. The effective average action is the modified Legendre transform

$$\Gamma_{\kappa,N}[\varphi] = \langle \mathcal{J}_{\kappa,N}[\varphi], \varphi\rangle - W_{\kappa,N}[\mathcal{J}_{\kappa,N}[\varphi]] - \Delta S_{\kappa,N}[\varphi]. \tag{36.14}$$

Equivalently, $\Gamma_{\kappa,N} + \Delta S_{\kappa,N}$ is the ordinary Legendre transform of $W_{\kappa,N}$. If the integral is defined by a positive measure, $W_{\kappa,N}$ is convex in $\mathcal{J}$, and $\Gamma_{\kappa,N} + \Delta S_{\kappa,N}$ is convex in φ. The subtracted functional $\Gamma_{\kappa,N}$ need not itself be convex at positive κ.

The cutoff κ in this section is an infrared scale. It should not be identified with the Wilsonian ultraviolet cutoff Λ unless a separate matching map has been specified. At large κ, the extra quadratic term suppresses fluctuations with $p^2 \lesssim \kappa^2$. At $\kappa = 0$, if $R_\kappa \to 0$ and the limit exists, the modified Legendre transform becomes the ordinary 1PI effective action of the regulated theory.

Legendre Hessian identity. In the finite-regulator setting of Definition 36.3, assume that the source-field map is locally invertible at $\mathcal{J}$. Then

$$\frac{\delta\Gamma_{\kappa,N}}{\delta\varphi} = \mathcal{J}_{\kappa,N}[\varphi] - R_{\kappa,N}\varphi, \qquad \Gamma^{(2)}_{\kappa,N}[\varphi] + R_{\kappa,N} = \left(W^{(2)}_{\kappa,N}[\mathcal{J}]\right)^{-1}, \tag{36.15}$$

where $W^{(2)}_{\kappa,N}$ is the connected two-point covariance in the presence of the source and the inverse is the inverse linear map $E_N^* \to E_N$ on the chosen source neighborhood.

Differentiate

$$\Gamma_{\kappa,N}[\varphi] + \Delta S_{\kappa,N}[\varphi] = \langle \mathcal{J}, \varphi\rangle - W_{\kappa,N}[\mathcal{J}], \qquad \varphi = \frac{\delta W_{\kappa,N}}{\delta \mathcal{J}}.$$

The terms containing $\delta\mathcal{J}$ cancel because $\delta W_{\kappa,N} = \langle \varphi, \delta\mathcal{J}\rangle$. Hence $\delta(\Gamma_{\kappa,N} + \Delta S_{\kappa,N})/\delta\varphi = \mathcal{J}$, which gives the first identity after subtracting $\delta\Delta S_{\kappa,N}/\delta\varphi = R_{\kappa,N}\varphi$. A second variation gives

$$\Gamma^{(2)}_{\kappa,N} + R_{\kappa,N} = \frac{\delta\mathcal{J}}{\delta\varphi}.$$

On the other hand $\delta\varphi/\delta\mathcal{J} = W^{(2)}_{\kappa,N}$. Local invertibility of the source-field map says precisely that these two derivatives are inverse finite-dimensional matrices.

Finite-regulator Wetterich equation. Let $t = \log\kappa$. Suppose that $R_{\kappa,N}$ is C^1 in t, the regulated integral in (36.13) is differentiable in t, and the source-field map is locally invertible along the curve under consideration. Then, at fixed average field φ,

$$\partial_t \Gamma_{\kappa,N}[\varphi] = \frac{1}{2}\, \mathrm{Tr}_{E_N}\left[\left(\Gamma^{(2)}_{\kappa,N}[\varphi] + R_{\kappa,N}\right)^{-1} \partial_t R_{\kappa,N}\right]. \tag{36.16}$$

Differentiate the modified Legendre transform (36.14) with respect to t while holding φ fixed. As in the preceding lemma, the terms containing $\partial_t \mathcal{J}_{\kappa,N}[\varphi]$ cancel. Thus

$$\partial_t \Gamma_{\kappa,N}[\varphi] = -\partial_t W_{\kappa,N}[\mathcal{J}]\big|_{\mathcal{J}} - \partial_t \Delta S_{\kappa,N}[\varphi]. \tag{36.17}$$

The only explicit t-dependence in $Z_{\kappa,N}[\mathcal{J}]$ is the regulator, so

$$\partial_t W_{\kappa,N}[\mathcal{J}]\big|_{\mathcal{J}} = -\frac{1}{2}\,\langle \phi\,(\partial_t R_{\kappa,N})\,\phi\rangle^{\mathrm{full}}_{\mathcal{J},\kappa}.$$

Here the bracket denotes the full source-dependent expectation in the regulated integral. Decomposing the full second moment into its connected and mean parts gives

$$\langle \phi\,(\partial_t R_{\kappa,N})\,\phi\rangle^{\mathrm{full}}_{\mathcal{J},\kappa} = \langle \varphi, (\partial_t R_{\kappa,N})\varphi\rangle + \mathrm{Tr}_{E_N}\left[W^{(2)}_{\kappa,N}[\mathcal{J}]\,\partial_t R_{\kappa,N}\right].$$

Since

$$\partial_t \Delta S_{\kappa,N}[\varphi] = \frac{1}{2}\langle \varphi, (\partial_t R_{\kappa,N})\varphi\rangle,$$

the mean-field terms cancel in (36.17). The result is

$$\partial_t \Gamma_{\kappa,N}[\varphi] = \frac{1}{2}\,\mathrm{Tr}_{E_N}\left[W^{(2)}_{\kappa,N}[\mathcal{J}]\,\partial_t R_{\kappa,N}\right].$$

Substituting the Hessian identity (36.15) proves (36.16).

After suppressing the finite regulator from the notation, the formal continuum version is

$$\partial_t \Gamma_\kappa[\varphi] = \frac{1}{2}\,\mathrm{Tr}\left[\left(\Gamma^{(2)}_\kappa[\varphi] + R_\kappa\right)^{-1}\partial_t R_\kappa\right], \qquad t = \log\kappa. \tag{36.18}$$

The trace in (36.18) means the trace over spacetime, internal indices, and statistics, with a minus sign for fermionic variables when the derivation is repeated in the superalgebraic setting. For the scalar translation-invariant regulator (36.12), the factor $\partial_t R_\kappa(p)$ is concentrated at momenta $p^2 \simeq \kappa^2$ for a smooth profile. This makes the right-hand side formally both infrared and ultraviolet regulated. A theorem-level continuum use still requires more than this formal observation: one must specify the regulator-removal topology, prove convergence of $W_{\kappa,N}$ or $\Gamma_{\kappa,N}$, and prove that the finite-regulator traces converge uniformly on the field neighborhood being used.

Figure 36.4 compares the cutoff kernels rather than the names of the constructions. The Wilsonian covariance multiplies the propagator by a profile that keeps low modes and suppresses high modes. The effective-average-action regulator adds a masslike kernel to low modes and vanishes for high modes; the flow is localized by $\partial_t R_\kappa$. This is the concrete sense in which the two cutoff-dependent objects are different.

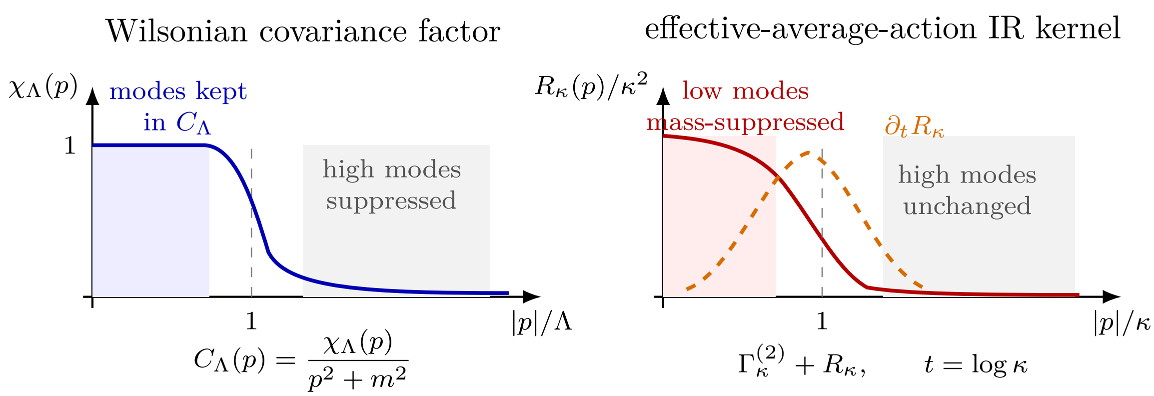

Figure 36.4: The Wilsonian and effective-average-action cutoffs act in opposite ways on momentum modes. The Wilsonian covariance keeps the low-mode propagator and removes high modes as Λ is lowered. The effective-average-action regulator adds a large quadratic penalty to modes with $|p| \lesssim \kappa$ and vanishes at high momentum; the flow kernel $\partial_t R_\kappa$ is concentrated near $|p| \simeq \kappa$. Matching the two descriptions is therefore a statement about compatible kernels and coordinates, not an identity of the cutoff-dependent functionals.

Example 36.4 (Constant-field projection and the local potential flow)**.** Assume a single scalar field and project the effective average action to the derivative expansion

$$\Gamma_\kappa[\varphi] = \int \mathrm{d}^D x\,\left\{\frac{1}{2} Z_\kappa\,\partial_\mu\varphi\,\partial_\mu\varphi + U_\kappa(\varphi)\right\} + \text{terms with more derivatives or more fields.} \tag{36.19}$$

For a constant field $\varphi(x) = v$, the Hessian in momentum space is

$$\Gamma_\kappa^{(2)}(p, q; v) = (2\pi)^D \delta^{(D)}(p + q)\big(Z_\kappa p^2 + U_\kappa''(v)\big)$$

inside this projection. Dividing (36.18) by the spacetime volume gives

$$\partial_t U_\kappa(v) = \frac{1}{2}\int_p \frac{\partial_t R_\kappa(p)}{Z_\kappa p^2 + R_\kappa(p) + U_\kappa''(v)} \tag{36.20}$$

before any expansion in powers of U_κ''. This is an exact identity only after projection to the ansatz (36.19); the omitted derivative and field operators feed back into the exact flow through $\Gamma_\kappa^{(2)}[\varphi]$.

For the illustrative limiting profile

$$R_\kappa(p) = Z_\kappa(\kappa^2 - p^2)\theta(\kappa^2 - p^2)$$

and with $\eta_\kappa := -\partial_t \log Z_\kappa$ set to zero, one obtains

$$\partial_t U_\kappa(v) = \frac{v_D\,\kappa^D}{1 + U_\kappa''(v)/(Z_\kappa \kappa^2)}, \qquad v_D := \frac{1}{D\,2^{D-1}\pi^{D/2}\Gamma(D/2)}. \tag{36.21}$$

The step-function regulator is not smooth. In a proof-oriented treatment it should be replaced by a smooth family approaching it, or else treated in a function space where the distributional boundary term is controlled. Formula (36.21) is therefore best read as an efficient projection formula, not as a substitute for the smooth-regulator finite-dimensional derivation.

Remark 36.5 (Relation to the Wilson-Polchinski equation). Both (36.11) and (36.18) are exact cutoff identities at finite regulator, but they differentiate different objects. The Wilson-Polchinski equation acts on a Wilsonian interaction before the remaining low fields have been integrated. The Wetterich equation acts on an infrared-regulated Legendre transform after the regulated integral has been performed. Therefore the vertices $L_\Lambda^{(n)}$ and $\Gamma_\kappa^{(n)}$ are not the same coordinate functions, and equality of beta functions is meaningful only after a finite matching map has been chosen.

For compatible cutoff kernels, the formal exact-RG literature constructs a Legendre-type relation between Polchinski and effective-average-action flows; one convenient account is in Rosten's review, following the earlier work of Morris and Wetterich.[1] In this monograph that relation is used only with its hypotheses displayed: a fixed finite regulator, compatible quadratic kernels, invertible Legendre map, and specified continuum or perturbative limit. It is not a license to identify arbitrary Wilsonian truncations with arbitrary effective-average-action truncations.

Remark 36.6 (Gauge theories). The scalar derivation uses an ordinary positive quadratic infrared regulator. For gauge theories, such a regulator generally breaks the gauge symmetry of the gauge-fixed functional integral unless it is embedded into a background field construction or a BV/BRST formulation with the corresponding modified Ward or Slavnov–Taylor identity. Thus a gauge-theory use of (36.18) requires extra data: the gauge fixing, ghost and antifield conventions, the regulator's transformation law, and the identity that replaces gauge invariance along the flow. These conditions are part of the definition of the regulated gauge-theory problem, not optional checks after a scalar-like flow has been written down.

36.5 Linearized Flow and Scaling Coordinates

A fixed point of the Wilsonian flow is a scale-invariant interaction L_* after all quantities have been written in dimensionless coordinates. Let $t = \log \Lambda$. Near a fixed point write

$$L_\Lambda = L_* + \sum_I g_I(\Lambda)\, \mathcal{O}_I,$$

where $\mathcal{O}_I$ are local coordinates on theory space. The linearized flow has the form

$$\frac{\mathrm{d}g_I}{\mathrm{d}t} = \sum_J M_I{}^J g_J + O(g^2).$$

Choosing eigenvectors of M gives scaling coordinates u_α:

$$\frac{\mathrm{d}u_\alpha}{\mathrm{d}t} = -y_\alpha u_\alpha + O(u^2). \tag{36.22}$$

The number y_α is the relevance exponent.[2] In the convention $t = \log \Lambda$, decreasing the cutoff moves toward the infrared, so (36.22) implies

$$u_\alpha(\Lambda) = u_\alpha(\Lambda_0) \left(\frac{\Lambda}{\Lambda_0}\right)^{-y_\alpha} + O(u^2).$$

A coordinate with $y_\alpha > 0$ grows when Λ is lowered. It is a relevant coordinate and must be fixed by a renormalization condition, or tuned to zero when one asks for an infrared trajectory ending at the fixed point. A coordinate with $y_\alpha < 0$ is irrelevant: its value at a fixed physical scale is attracted to a function of the relevant and marginal coordinates along a renormalized trajectory, provided the nonlinear cutoff-removal estimates stated below hold.

A theorem-level codimension statement about a critical surface requires a smooth local model of theory space and a differentiable RG endpoint map. The eigenvalue calculation supplies the candidate relevant tuning directions; the local smoothness and codimension assertion used in this volume is the following.

Definition 36.7 (Banach RG chart)**.** Fix an integer $k \geq 1$. A C^k Banach RG chart near a fixed point is a triple $(\mathfrak{U}, \psi, \Phi_s)$ with the following data. The set $\mathfrak{U}$ is an open neighborhood of the fixed point in a C^k Banach manifold $\mathfrak{T}$ of regulated Wilsonian actions, modulo the redundant field redefinitions and symmetry identifications already fixed in the chart. The chart map

$$\psi : \mathfrak{U} \longrightarrow X$$

takes values in a Banach space X, and

$$X = X_{\mathrm{rel}} \oplus X_{\mathrm{rest}}$$

[2] This sign convention matches the 1PI thermal-coordinate convention used in the Wilson–Fisher fixed-point calculation. There the dimensionless temperature coordinate obeys $\mathrm{d}\tau/\mathrm{d}\log\mu = -y_t\tau + \cdots$, with $y_t = D - \Delta_{\phi^2} > 0$. Both displayed differential equations are written with respect to an increasing scale variable. The infrared-oriented variables $s_{\mathrm{W}} = \log(\Lambda_0/\Lambda)$ and $s_{1\mathrm{PI}} = \log(\mu_0/\mu)$ reverse the sign and give $\mathrm{d}u_\alpha/\mathrm{d}s_{\mathrm{W}} = y_\alpha u_\alpha + \cdots$ and $\mathrm{d}\tau/\mathrm{d}s_{1\mathrm{PI}} = y_t\tau + \cdots$. The Wilsonian cutoff flow and the 1PI subtraction-scale flow are still different vector fields until the finite matching map between Wilsonian and 1PI coordinates is specified.

is a topological direct sum with finite-dimensional relevant block $X_{\mathrm{rel}} \cong \mathbb{R}^r$. The maps Φ_s, $s \geq 0$, are the local RG maps from the ultraviolet scale to a lower scale, with $s = \log(\Lambda_0/\Lambda)$, and are C^k wherever the trajectory stays inside $\mathfrak{U}$. In coordinates write

$$\varphi_s = \psi \circ \Phi_s \circ \psi^{-1}, \qquad \pi_{\mathrm{rel}} : X_{\mathrm{rel}} \oplus X_{\mathrm{rest}} \to X_{\mathrm{rel}}$$

for the coordinate RG map and relevant projection.

Finite-reference critical surface from an implicit-function chart. Let $(\mathfrak{U}, \psi, \Phi_s)$ be a C^k Banach RG chart and fix a finite RG time $s_R = \log(\Lambda_0/\Lambda_R) > 0$. Let

$$E_{s_R}(z) = \pi_{\mathrm{rel}}\big(\varphi_{s_R}(z)\big), \qquad z = (u, w) \in X_{\mathrm{rel}} \oplus X_{\mathrm{rest}},$$

be the endpoint map that extracts the relevant coordinates at the reference scale Λ_R. Suppose E_{s_R} is defined and C^k on an open neighborhood of a point z_*, that $E_{s_R}(z_*) = 0$, and that the partial derivative

$$D_u E_{s_R}(z_*) : X_{\mathrm{rel}} \longrightarrow X_{\mathrm{rel}}$$

is an isomorphism. Then, after possibly shrinking the neighborhood of z_*, the set

$$\mathcal{C}_{s_R} = \{z : E_{s_R}(z) = 0\}$$

is a C^k embedded Banach submanifold of codimension r. In the chosen coordinates it is the graph

$$u = G_{s_R}(w)$$

for a C^k map G_{s_R} defined on an open subset of X_{rest}. This is the Banach-space implicit function theorem applied to the endpoint map E_{s_R}: the hypotheses make $E_{s_R}(u, w) = 0$ an equation in the finite-dimensional relevant block X_{rel}, with C^k dependence on the remaining Banach variable w, and the invertibility of $D_u E_{s_R}(z_*)$ supplies a unique C^k graph satisfying

$$E_{s_R}(u, w) = 0 \quad \Longleftrightarrow \quad u = G_{s_R}(w)$$

inside that neighborhood. A graph over the closed complemented subspace X_{rest} is an embedded C^k Banach submanifold, and its codimension is $\dim X_{\mathrm{rel}} = r$. The nontrivial QFT burden in any application is the construction of the chart, the differentiability of the RG endpoint map in the chosen norm, and the invertibility of the relevant block derivative; once those have been established, the graph statement is ordinary functional analysis.

The construction above is a finite-reference statement. The infinite-time critical surface consisting of trajectories that remain in the fixed-point neighborhood and converge to the fixed point as $\Lambda \to 0$ requires a stable- or center-stable-manifold theorem for the chosen Banach RG flow, with the corresponding spectral-gap, smoothness, and existence hypotheses. The monograph will not use the phrase “codimension r critical surface” as a theorem-level assertion unless the local chart, endpoint map, and invertibility or stable-manifold hypotheses have been stated.

The scaling dimension of the local operator conjugate to u_α is

$$\Delta_\alpha = D - y_\alpha$$

when the fixed point is conformal and the coupling multiplies $\int \mathrm{d}^D x \, \mathcal{O}_\alpha(x)$. Thus the Wilsonian eigenvalue problem and the conformal scaling-operator problem are the same local question seen from two sides: flow in theory space and dilation on local operators.

36.6 Redundant Directions and Field Coordinates

Theory space is coordinatized by actions, but different coordinates can describe the same correlation functions. A local change of field variable

$$\phi(x) \longmapsto \phi(x) + \epsilon F[\phi](x)$$

changes the action, to first order in ϵ, by

$$S[\phi] \longmapsto S[\phi] + \epsilon \int \mathrm{d}^D x \, \frac{\delta S}{\delta\phi(x)} F[\phi](x) - \epsilon \,\operatorname{Tr} \frac{\delta F}{\delta \phi} + O(\epsilon^2).$$

The trace term is the local Jacobian contribution in a regulated functional integral. Operators of the form

$$\int \mathrm{d}^D x \, \frac{\delta S}{\delta\phi(x)} F[\phi](x) \quad \text{together with the associated Jacobian}$$

generate redundant directions. They change the coordinate representative of the Wilsonian action and the representatives of local composite operators, but they leave separated-point correlation functions invariant after the corresponding field redefinition is applied.

The quotient by redundant directions is important in the linearized RG problem. An eigenvector of the flow that is tangent to a field redefinition is a change of local coordinates on theory space. Relevant, marginal, and irrelevant directions that classify continuum limits are therefore physical directions modulo these redundant tangent vectors, with symmetries and operator normalizations fixed as part of the coordinate choice.

36.7 Renormalized Trajectories and Universality

Let u_r denote the relevant coordinates and u_i the irrelevant coordinates near a fixed point. In a Banach RG chart where the necessary graph estimates have been proved, a renormalized trajectory is represented by a submanifold of theory space on which the irrelevant coordinates are functions of the relevant ones:

$$u_i = F_i(u_r).$$

The functions F_i are determined by the requirement that the trajectory can be extended toward the ultraviolet while remaining in the basin where the fixed-point expansion is valid. Perturbatively, they are found by solving the irrelevant beta-function equations order by order in the relevant and marginal coordinates.

Universality is the statement that many different microscopic actions flow to the same renormalized trajectory at a fixed physical scale. Suppose two bare actions at cutoff Λ_0 have the same relevant coordinates after tuning, but differ by an irrelevant coordinate $u_i(\Lambda_0)$. Linearized flow gives

$$u_i(\Lambda_R) = \left(\frac{\Lambda_R}{\Lambda_0}\right)^{-y_i} u_i(\Lambda_0) + \text{nonlinear terms}, \qquad y_i < 0,$$

for a fixed reference scale $\Lambda_R \ll \Lambda_0$. Thus the difference in any low-momentum coordinate or correlator projector whose linearization is bounded in this chart is

$$O\left(\|u_i(\Lambda_0)\| \left(\frac{\Lambda_R}{\Lambda_0}\right)^{-y_i}\right),$$

after the relevant coordinates and field normalizations have been matched. The suppression exponent is $-y_i = \Delta_i - D > 0$ for the first omitted irrelevant operator. Nonlinear versions of this statement require the Banach-norm estimates used in Controlled Approximation 36.16 and in the finite-coordinate continuum-limit theorem below.

This gives a precise meaning to effective field theory. A finite list of relevant and marginal coordinates must be measured or tuned. Irrelevant operators are still present, and their coefficients encode real short-distance physics, but their effect on low-energy observables is organized by powers of the ratio of scales and by the symmetries that determine which operators may appear.

36.8 A Quartic-Sextic Toy Flow

Consider the massless scalar theory in $D = 4$ and keep only two local coordinates in the interaction,

$$L_\Lambda[\phi] = \int \mathrm{d}^4x \left(g_4(\Lambda)\phi(x)^4 + g_6(\Lambda)\phi(x)^6\right). \tag{36.23}$$

This is a two-dimensional projection of the full Wilsonian flow. Numerical normalizations of g_4 and g_6 are included in the constants a and b below. The corresponding dimensionless coordinates are

$$\lambda_4(\Lambda) := g_4(\Lambda), \qquad \lambda_6(\Lambda) := \Lambda^2 g_6(\Lambda). \tag{36.24}$$

The canonical term in the second equation is $2\lambda_6$, because ϕ^6 has coefficient of mass dimension -2 in four dimensions. A projected Wilsonian beta function is, by definition,

$$\beta_A(\lambda) := \Lambda \frac{\mathrm{d}\lambda_A}{\mathrm{d}\Lambda}.$$

The variables λ_A are coordinates on a chosen cutoff scheme, not observables by themselves. To isolate this two-coordinate mechanism, choose local coordinates in which the small-coupling flow begins as

$$\Lambda \frac{\mathrm{d}\lambda_4}{\mathrm{d}\Lambda} = -a\lambda_6 + \cdots, \qquad \Lambda \frac{\mathrm{d}\lambda_6}{\mathrm{d}\Lambda} = 2\lambda_6 + b\lambda_4^2 + \cdots, \tag{36.25}$$

where a and b depend on the cutoff profile and on the normalization of the two operators. The ellipses denote terms of higher order in the retained local coordinates and terms involving the omitted coordinates. The coefficient 2 is the canonical irrelevant eigenvalue in the convention $t = \log \Lambda$: at fixed dimensionful g_6, the dimensionless $\lambda_6 = \Lambda^2 g_6$ decreases when the cutoff is lowered.

Assume $\lambda_6 = O(\lambda_4^2)$ along the trajectory and work to the first nontrivial order. Let

$$h(\Lambda) := \lambda_6(\Lambda) + \frac{b}{2}\lambda_4(\Lambda)^2.$$

Using (36.25),

$$\Lambda \frac{\mathrm{d}}{\mathrm{d}\Lambda}\left(\lambda_6 + \frac{b}{2}\lambda_4^2\right) = 2\left(\lambda_6 + \frac{b}{2}\lambda_4^2\right) + O(\lambda_4 h) + O(\lambda_4^3). \tag{36.26}$$

Thus, over a perturbative range in which the variation of λ_4 only affects this equation at higher order,

$$h(\Lambda) = h(\Lambda_*)\left(\frac{\Lambda}{\Lambda_*}\right)^2 + O(\lambda_4^3).$$

Along the flow toward the infrared, $\Lambda \downarrow 0$, the transverse combination h is suppressed by the canonical irrelevant power. The attracting curve is therefore

$$\lambda_6(\Lambda) = -\frac{b}{2}\lambda_4(\Lambda)^2 + O(\lambda_4^3) \tag{36.27}$$

on the attracting curve. Substitution into the λ_4 equation gives

$$\Lambda\frac{\mathrm{d}\lambda_4}{\mathrm{d}\Lambda} = \frac{ab}{2}\lambda_4^2 + O(\lambda_4^3). \tag{36.28}$$

This equation is the induced beta function for the retained marginal coordinate in the reduced coordinate system. Comparison with a 1PI renormalization convention requires an explicitly chosen finite reparametrization between Wilsonian coordinates and the renormalized coupling used to label Green functions; in the displayed coordinate system the irrelevant coordinate has been eliminated by solving its own flow equation.

Figure 36.5 displays the reduced two-coordinate flow used in the example: the irrelevant sextic coordinate is slaved to the quartic coordinate along the renormalized trajectory.

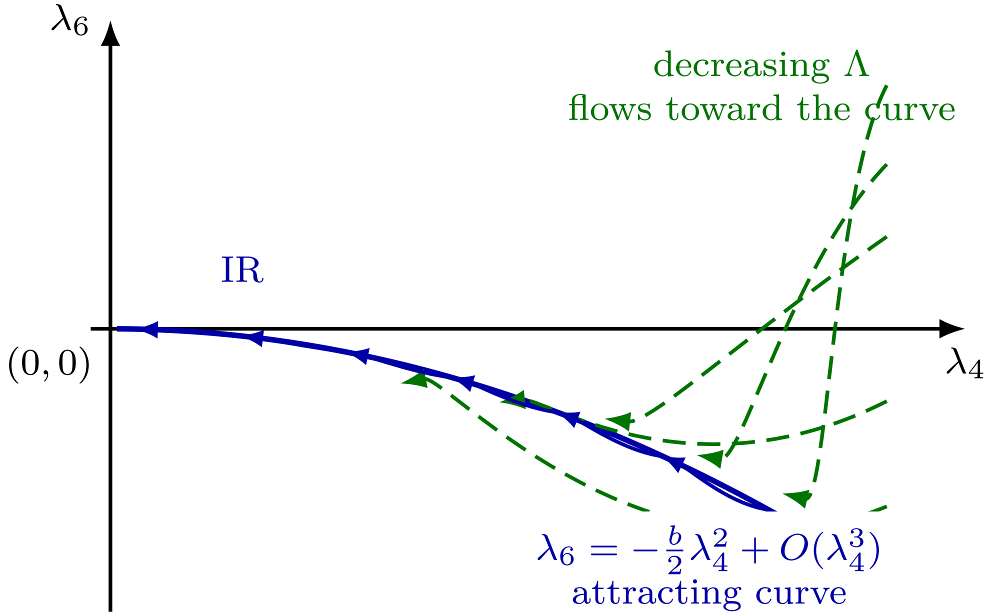

Figure 36.5: In the two-coordinate projection, the irrelevant coordinate λ_6 rapidly approaches a curve determined by λ_4. The arrows indicate the direction of decreasing cutoff. Dashed trajectories approach distinct neighborhoods of the solid attracting curve; the projection is not meant to show finite-time merging of RG characteristics. The curve is drawn in a normalization with $b > 0$; changing the sign convention for the ϕ^6 coordinate reflects the vertical axis but not the attraction statement.

This example is deliberately modest. It shows one concrete feature of the full equation: irrelevant local coordinates are generally generated even if they are absent in the chosen ultraviolet-regulated action, and near a controlled trajectory they are determined, order by order, by the coordinates that remain to be fixed at a reference scale.

36.9 Renormalizability as a Continuum Limit

The Wilsonian flow is a downward flow in cutoff. If an action S_{Λ_0} is given at a finite ultraviolet cutoff Λ_0, then (36.10) or (36.11) constructs S_Λ for $\Lambda < \Lambda_0$. The finite-cutoff construction therefore supplies a trajectory below Λ_0; a description extending to arbitrarily large Λ is a continuum-limit input.

Take a regulated path integral at cutoff Λ_0, with interaction

$$L_{\Lambda_0}[\phi] = \sum_I g_I^{\text{bare}}(\Lambda_0)\, O_I[\phi], \tag{36.29}$$

where O_I are local operators compatible with the symmetries. After flowing down to a fixed reference scale Λ_R, low-momentum Green functions can be expressed in terms of the Wilsonian coordinates $g_I(\Lambda_R)$. A continuum limit is a limit $\Lambda_0 \to \infty$ in which the bare coordinates are chosen as functions of Λ_0 so that selected physical coordinates at Λ_R are held fixed and the remaining Wilsonian coordinates at Λ_R approach limits. The finite-coordinate estimate below makes precise what is meant in a local projection. Its inputs are the endpoint tuning problem, the irrelevant semigroup estimate, a uniform bound on the retained irrelevant bare coordinates, and convergence of the generated integral. The Wilsonian mechanism is the estimate showing how these inputs produce a cutoff-independent reference-scale point.

In the quartic-sextic projection, impose the ultraviolet boundary condition

$$\lambda_4(\Lambda_0) = \lambda_4^{\text{bare}}(\Lambda_0), \qquad \lambda_6(\Lambda_0) = 0,$$

and choose $\lambda_4^{\text{bare}}(\Lambda_0)$ so that

$$\lambda_4(\Lambda_R) = \lambda_4^R$$

is fixed at the reference scale. The Wilsonian renormalizability question in this projection is whether

$$\lim_{\Lambda_0 \to \infty} \lambda_6(\Lambda_R)\,\Big|_{\lambda_4(\Lambda_R) = \lambda_4^R} \tag{36.30}$$

exists. Under perturbative control, with small couplings along the trajectory and sufficiently mild dependence of the beta functions on the irrelevant coordinate, the limit can be seen directly from the transverse coordinate h. The boundary condition $\lambda_6(\Lambda_0) = 0$ gives

$$h(\Lambda_0) = \frac{b}{2}\lambda_4(\Lambda_0)^2.$$

After tuning $\lambda_4(\Lambda_R) = \lambda_4^R$, the homogeneous memory of this ultraviolet boundary condition is

$$h(\Lambda_R) = h(\Lambda_0)\left(\frac{\Lambda_R}{\Lambda_0}\right)^2 + O\big((\lambda_4^R)^3\big)$$

within the perturbative domain. Therefore

$$\lambda_6(\Lambda_R) = -\frac{b}{2}(\lambda_4^R)^2 + O\big((\lambda_4^R)^3\big) + O\left(\left(\frac{\Lambda_R}{\Lambda_0}\right)^2\right),$$

where the coefficient of the last term is bounded by the assumed control of the bare trajectory. This displays the continuum-limit mechanism: the irrelevant coordinate at the fixed physical scale is selected by the renormalized trajectory, while the memory of the microscopic boundary condition is power-suppressed.

Figure 36.6 shows the continuum-limit mechanism in the same two-coordinate model: different microscopic boundary conditions approach the same finite-scale renormalized trajectory up to $(\Lambda_R/\Lambda_0)^2$ corrections.

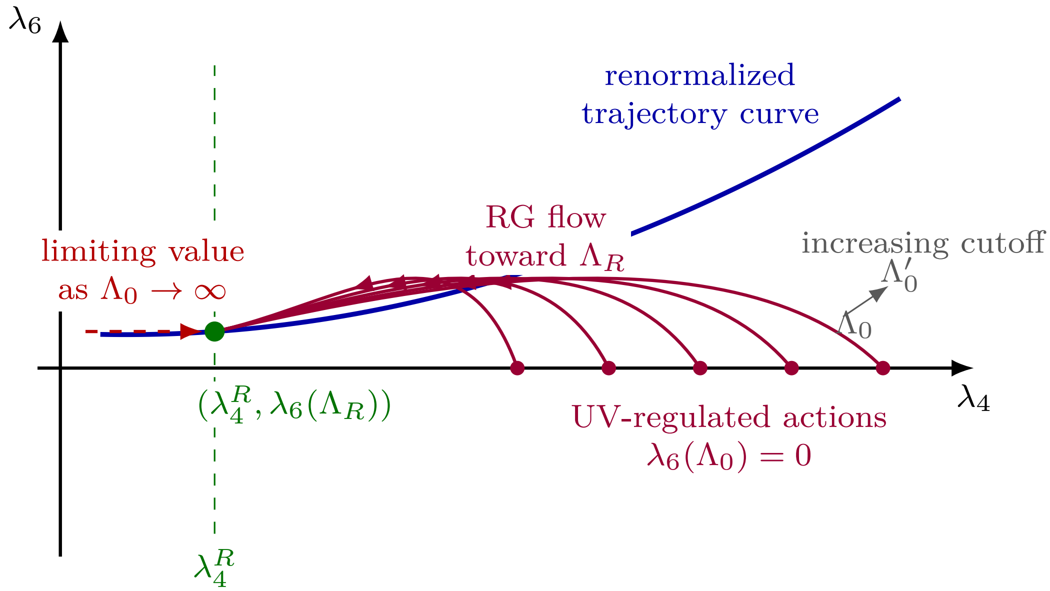

Figure 36.6: For each ultraviolet cutoff Λ_0, the bare quartic coupling is tuned so that $\lambda_4(\Lambda_R) = \lambda_4^R$. The continuum-limit statement asks whether the induced value of $\lambda_6(\Lambda_R)$ approaches a limit as Λ_0 is removed.

The same analysis allows a finite nonzero value of the dimensionless irrelevant coordinate at the ultraviolet cutoff. In the example,

$$g_6^{\mathrm{bare}}(\Lambda_0) = \Lambda_0^{-2}\lambda_6(\Lambda_0).$$

Thus a finite $\lambda_6(\Lambda_0)$ corresponds to a dimensionful bare coefficient suppressed by the cutoff. This is the form produced by lattice regularizations with lattice spacing $a = \Lambda_0^{-1}$: many local operators are present at the cutoff scale, but after tuning the relevant and marginal coordinates, irrelevant coordinates approach their continuum trajectory values at fixed physical scale. For a hypercubic lattice, the edge of the Brillouin zone is $\Lambda_{\mathrm{BZ}} = \pi/a = \pi\Lambda_0$. The estimates in this chapter use $\Lambda_0 = a^{-1}$ as the inverse-spacing cutoff convention; using Λ_{BZ} instead only rescales the constants multiplying cutoff-suppressed powers.

The perturbative Wilsonian statement has explicit hypotheses. Along the trajectory under consideration, the couplings must remain small enough for the local-coordinate expansion and the omitted-operator estimates to be valid; the derivatives such as $\partial\beta_6/\partial\lambda_6$ and $\partial\beta_4/\partial\lambda_4$ must remain controlled; and the beta function for the retained marginal coordinate must vary slowly enough along the trajectory that the irrelevant directions are genuinely suppressed. In this regime, the linearized irrelevant eigenvalues and the generated-integral estimate give the power-counting organization of local operators in perturbative renormalization.

This finite-coordinate estimate should not be mistaken for a constructive existence theorem for a non-Gaussian four-dimensional scalar continuum limit. Quoted Theorem 33.3 states that, for the positive lattice $\lambda\phi_4^4$ and nearest-neighbor ferromagnetic Ising-type scaling-limit problems covered by the rigorous triviality results cited there, the critical or near-critical continuum limits are Gaussian. The Wilsonian estimate above is a local perturbative mechanism: it explains how irrelevant coordinates lose memory of their finite-cutoff boundary values when a controlled trajectory with fixed renormalized coordinates is assumed. It does not prove that such a controlled trajectory exists to arbitrarily high cutoff at nonzero renormalized quartic coupling. For the specified standard families and covered critical regimes, the triviality result says that the limiting connected correlations beyond the two-point function vanish.

36.10 A Local Estimate for Cutoff Removal

The quartic-sextic example is the one-dimensional irrelevant-coordinate version of a general local estimate. This estimate is a finite-coordinate statement: choose a projection of the Wilsonian action onto local coordinates

$$z = (u, v) \in U \times V,$$

where $u = (u^1, \dots, u^r)$ are the coordinates fixed by renormalization conditions at the reference scale Λ_R, and $v = (v^1, \dots, v^s)$ are irrelevant coordinates retained in the projection. Let

$$t = \log \Lambda, \qquad t_R = \log \Lambda_R, \qquad t_0 = \log \Lambda_0.$$

In the coordinate neighborhood under consideration, write the projected flow as

$$\frac{\mathrm{d}u^a}{\mathrm{d}t} = B^a(u, v), \qquad \frac{\mathrm{d}v^\rho}{\mathrm{d}t} = A^\rho{}_\sigma v^\sigma + F^\rho(u, v). \tag{36.31}$$

The matrix A is the linear irrelevant block. In the convention $t = \log \Lambda$, an irrelevant coordinate has a positive eigenvalue in A; the flow is therefore contracting in that coordinate when the cutoff is lowered from t_0 to $t_R < t_0$. We assume a norm on V and constants $K_A, \omega > 0$ such that

$$\|e^{A\tau}\| \le K_A e^{\omega\tau}, \qquad \tau \le 0. \tag{36.32}$$

Thus $e^{A(t_R - t_0)}$ is bounded by

$$K_A \left(\frac{\Lambda_R}{\Lambda_0}\right)^\omega.$$

For a solution of (36.31) on $[t_R, t_0]$, variation of constants gives

$$v(t_R) = e^{A(t_R - t_0)} v(t_0) - \int_{t_R}^{t_0} e^{A(t_R - s)} F(u(s), v(s))\, \mathrm{d}s. \tag{36.33}$$

The first term is the direct memory of the irrelevant bare coordinate. The second term is generated by the flow along the trajectory. These two terms have different logical roles: suppression of the first term follows from the irrelevant eigenvalues, while existence of the cutoff-removal limit requires control of the generated integral and of the tuning used to hold $u(t_R)$ fixed.

The direct boundary-memory estimate follows by applying (36.32) with $\tau = t_R - t_0 \le 0$. If the irrelevant bare coordinate satisfies $\|v(t_0)\| \le M$ uniformly in t_0, then the direct boundary contribution to $v(t_R)$ obeys

$$\|e^{A(t_R-t_0)}v(t_0)\| \le K_A M \left(\frac{\Lambda_R}{\Lambda_0}\right)^{\omega}.$$

If the first omitted irrelevant coordinate has exponent $\omega_{\min}$, the same computation begins with the power $(\Lambda_R/\Lambda_0)^{\omega_{\min}}$. This estimate controls the homogeneous boundary-memory term in (36.33); the generated inhomogeneous term remains the analytic part of the continuum-limit problem.

The generated term in (36.33) is the part that selects the continuum graph. The precise finite-coordinate hypothesis is the existence, after tuning the retained bare coordinates, of a limit

$$V_R^{\rho}(u_R) = \lim_{\Lambda_0\to\infty}\left[-\int_{t_R}^{t_0}\left(e^{A(t_R-s)}F(u(s),v(s))\right)^{\rho}\mathrm{d}s\right], \tag{36.34}$$

where the trajectory is constrained by

$$u(t_R) = u_R.$$

When this limit exists uniformly for u_R in a small coordinate neighborhood, the finite projection of the renormalized trajectory at Λ_R is the graph

$$v^{\rho} = V_R^{\rho}(u_R).$$

For finite Λ_0, define the generated-integral remainder

$$R_F(t_0;u_R) = -\int_{t_R}^{t_0} e^{A(t_R-s)}F(u(s),v(s))\,\mathrm{d}s - V_R(u_R).$$

Finite-coordinate cutoff-removal estimate. Fix u_R and suppose that, for every sufficiently large t_0, the retained bare coordinates can be tuned so that $u(t_R) = u_R$. Assume:

(i) the solution remains in a coordinate neighborhood where (36.31) is valid;

(ii) the irrelevant semigroup satisfies (36.32);

(iii) the irrelevant bare coordinates are uniformly bounded;

(iv) the generated integral in (36.34) converges uniformly with

$$\|R_F(t_0;u_R)\| \le K_F\left(\frac{\Lambda_R}{\Lambda_0}\right)^{\omega_F}$$

for some $K_F, \omega_F > 0$.

For the tuned finite-cutoff trajectory, write

$$z_R(t_0;u_R) := \big(u(t_R;t_0,u_R),\ v(t_R;t_0,u_R)\big).$$

Then the reference-scale Wilsonian coordinates have the limit

$$\lim_{\Lambda_0\to\infty} z_R(t_0;u_R) = \big(u_R, V_R(u_R)\big) \tag{36.35}$$

in the retained coordinate space $U \times V$, and the irrelevant coordinates at the reference scale obey

$$v(t_R) = V_R(u_R) + O\left[\left(\frac{\Lambda_R}{\Lambda_0}\right)^{\min(\omega,\omega_F)}\right], \qquad \Lambda_0 \to \infty,$$

with the exponent replaced by the smallest retained irrelevant exponent when several irrelevant coordinates are present. Consequently, if Q is any continuous finite-coordinate observable, projected vertex, or low-momentum kernel functional defined in a neighborhood of $(u_R, V_R(u_R))$, then

$$\lim_{\Lambda_0 \to \infty} Q\big(z_R(t_0; u_R)\big) = Q\big(u_R, V_R(u_R)\big).$$

If Q is Lipschitz in the chosen coordinate norm, the same power gives an error bound for this convergence, with a constant multiplied by the Lipschitz constant of Q.

Indeed, equation (36.33) writes $v(t_R)$ as the sum of the boundary contribution and the generated contribution. The semigroup bound and the uniform bound on $v(t_0)$ give

$$\|e^{A(t_R - t_0)} v(t_0)\| \le K_A M \left(\frac{\Lambda_R}{\Lambda_0}\right)^{\omega}.$$

The generated contribution is $V_R(u_R) + R_F(t_0; u_R)$, with R_F bounded by the fourth hypothesis. Combining the two estimates gives the displayed asymptotic form. The relevant coordinate is fixed by the tuning condition $u(t_R; t_0, u_R) = u_R$, so the full retained coordinate vector converges to $(u_R, V_R(u_R))$. The assertion for Q follows from continuity; the quantitative version follows from applying the Lipschitz bound of Q to the coordinate difference.

The four hypotheses above are the mathematical content of a Wilsonian continuum-limit argument in a chosen local projection. The tuning condition $u(t_R) = u_R$ is a statement about the endpoint map from bare coordinates at Λ_0 to renormalized coordinates at Λ_R. In perturbation theory this endpoint map is usually solved order by order. When the linearized endpoint map in the retained coordinates is invertible, the implicit function theorem gives the local tuning functions at finite Λ_0. The remaining analytic task is to prove estimates, uniform in Λ_0, that keep the trajectory in the assumed coordinate neighborhood and make the generated integral converge.

Remark 36.8 (Status of the cutoff-removal hypotheses). The finite-coordinate estimate derives the displayed reference-scale convergence from the four listed hypotheses. Hypothesis (ii) is a backward semigroup estimate for the irrelevant part of the linearized projected RG equation in a chosen norm. It is immediate in a diagonal finite-dimensional toy model with strictly negative irrelevant exponents; in an actual Wilsonian space it is an analytic estimate about the chosen Banach or Fréchet space of functionals and the linearized cutoff-flow operator. Hypothesis (iv) is the uniform convergence, after the retained coordinates are tuned, of the generated irrelevant coordinate. This is one form of the cutoff-removal problem itself.

Several rigorous results prove analogues of these estimates only after adding substantial structure. Polchinski's smooth-cutoff argument proves perturbative renormalizability order by order for renormalizable Euclidean Lagrangians by deriving inductive bounds on cutoff-dependent vertices after the relevant parts are fixed.[3] Salmhofer's rigorous RG framework proves perturbative flow estimates, especially for fermionic systems, in specified norms and small-coupling regimes.[4]

[3]J. Polchinski, *Nucl. Phys. B* **231** (1984) 269–295.
[4]M. Salmhofer, *Renormalization: An Introduction*, Springer, 1999.

The Brydges–Kennedy tree and Mayer expansion technology supplies iterative bounds used in constructive RG, but every application still verifies its own covariance estimates, norms, tuning equations, and convergence criteria.[5]

The nonperturbative status is model-dependent. Constructive scalar field theory gives non-Gaussian ϕ_2^4 and ϕ_3^4 continuum theories under its own ultraviolet, infrared, and stability hypotheses.[6] By contrast, the standard positive four-dimensional scalar and nearest-neighbor Ising-type families covered by Quoted Theorem 33.3 have Gaussian scaling limits. Therefore later use of a Wilsonian continuum-limit estimate must identify which semigroup, tuning, and convergence estimates are available in the chosen framework.

Remark 36.9 (Renormalons and Wilsonian data). Assumption (iv) is a continuum-limit hypothesis on the Wilsonian generated integral. It is stronger than the existence of a formal perturbative expansion for the projected coordinates. A renormalon analysis is one way in which perturbation theory can diagnose the failure of a naive coefficientwise description to determine the full generated integral. In a running-coupling expansion, integration over very small or very large intermediate momenta can produce factorially growing coefficients and Borel-plane singularities. When the corresponding ambiguity has the size of a power correction, the Wilsonian description must supply the missing input through retained nonperturbative coordinates, through an operator-product-expansion matrix element, or through another matched effective description. Thus renormalons do not replace the cutoff-removal hypothesis; they identify particular ways in which that hypothesis contains information beyond formal perturbation theory.

Figure 36.7 draws the quantitative estimate used in this discussion. Increasing the ultraviolet separation $T = t_0 - t_R = \log(\Lambda_0/\Lambda_R)$ suppresses direct memory of the irrelevant boundary coordinate by $e^{-\omega T}$. After the relevant coordinates are tuned at t_R, endpoints obtained from different bounded irrelevant boundary values therefore approach the same continuum graph value up to the convergence rate of the generated integral.

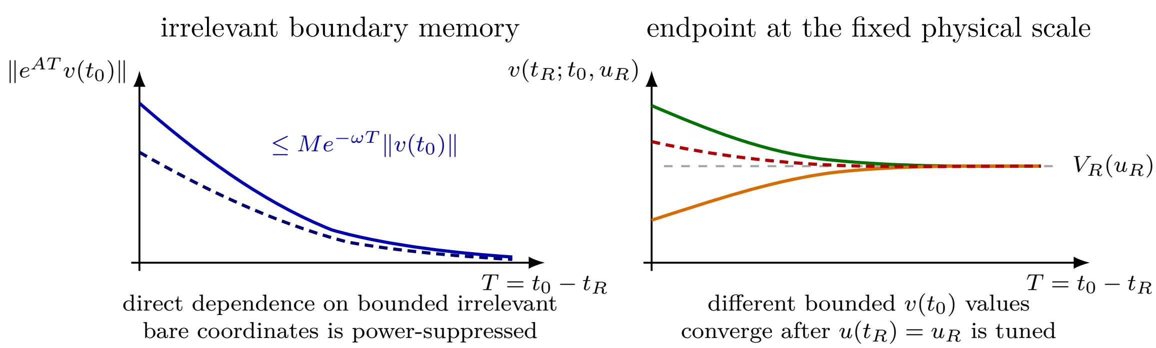

Figure 36.7: The two quantitative pieces in the finite-coordinate cutoff-removal estimate. If the irrelevant semigroup satisfies $\|e^{A(t_R-t_0)}\| \leq Me^{-\omega(t_0-t_R)}$, direct memory of a bounded irrelevant boundary coordinate is suppressed by $(\Lambda_R/\Lambda_0)^\omega$. The estimate uses uniform convergence of the generated integral; with that input, all tuned endpoints with bounded irrelevant bare coordinates converge to the same graph $v = V_R(u_R)$ at the physical scale.

[5] D. C. Brydges and T. Kennedy, *J. Stat. Phys.* **48** (1987) 19–49.

[6] See J. Glimm and A. Jaffe, *Quantum Physics: A Functional Integral Point of View*, second edition, Springer, 1987, for the constructive scalar-field framework and references to the original constructions.

For a lattice regulator with lattice spacing $a = \Lambda_0^{-1}$, a bounded dimensionless irrelevant bare coordinate $v^\rho(t_0)$ corresponds to a dimensionful coefficient multiplied by the appropriate positive power of a. The finite-coordinate cutoff-removal estimate explains the resulting universality statement in this local projection: after the retained coordinates are tuned at Λ_R, bounded changes of microscopic irrelevant lattice couplings alter $v(t_R)$ only by powers of Λ_R/Λ_0, while the limiting value belongs to the continuum graph selected by the flow.

36.11 The Bridge to BPHZ and 1PI Coordinates

The preceding sections define the Wilsonian action S_Λ by Gaussian pushforward. Exact preservation of a source-independent low-source functional requires the annihilator condition explained above, and for the smooth source-independent theorem below this will be implemented by an admissible plateau cutoff. Earlier chapters defined BPHZ subtractions and 1PI renormalized coordinates. These are different constructions, so their relation must be stated with the maps that connect them.

Fix a finite ultraviolet regulator Λ_0, a smooth intermediate cutoff Λ, and a Euclidean subtraction scale μ satisfying

$$\mu \ll \Lambda \ll \Lambda_0.$$

Keep distinct names for the two RG times:

$$t_{\mathrm{W}} := \log \Lambda, \qquad t_{1\mathrm{PI}} := \log \mu.$$

They parameterize different vector fields. The Wilsonian time t_{W} acts on the cutoff action before the remaining low field is integrated, while $t_{1\mathrm{PI}}$ acts on projected 1PI vertices after the connected functional has been Legendre transformed. To compare the two flows, choose a fixed matching ratio

$$\zeta := \frac{\Lambda}{\mu} \gg 1.$$

Along such a matched comparison,

$$t_{\mathrm{W}} = t_{1\mathrm{PI}} + \log \zeta, \qquad \left.\frac{\mathrm{d}}{\mathrm{d}t_{1\mathrm{PI}}}\right|_\zeta = \left.\frac{\mathrm{d}}{\mathrm{d}t_{\mathrm{W}}}\right|_\zeta.$$

If $u_A(\Lambda)$ are Wilsonian coordinates and $g_I(\mu)$ are 1PI coordinates, the bridge is a finite matching map at fixed ζ,

$$g_I(\mu) = M_I(u(\Lambda), \zeta) + O(\zeta^{-\Delta_{\mathrm{irr}}}),$$

where $\Delta_{\mathrm{irr}} > 0$ is the smallest suppression exponent among the omitted irrelevant coordinates in the chosen local expansion. Differentiating at fixed ζ gives the corresponding relation between beta functions,

$$\beta_I^{1\mathrm{PI}} = \frac{\partial M_I}{\partial u_A}\,\beta_A^{\mathrm{W}} + O(\zeta^{-\Delta_{\mathrm{irr}}}),$$

with summation over A. Thus the two uses of t in the preceding chapters have the same orientation only after this matching convention is chosen; without the matching map they refer to different mathematical constructions.

The external momenta used in the 1PI projectors are assumed to have size $O(\mu)$ and to be nonexceptional. Let

$$W_{\Lambda_0}[J] = \log Z_{\Lambda_0}[J]$$

be the connected generating functional of the theory regulated at ultraviolet scale Λ_0, with the cutoff-dependent local terms in the path-integral Lagrangian chosen so that the selected 1PI coordinates have finite limits. Let $L_\Lambda = L^{\mathrm{src}}_{\Lambda,0}$ be the source-independent Wilsonian interaction obtained from (36.10) by integrating modes between Λ_0 and Λ. For a non-plateau smooth cutoff and a nonzero open low-momentum source sector, exact source preservation requires enlarging the Wilsonian data to include source-dependent vertices. The corresponding finite-regulator object is

$$\exp[-L^{\mathrm{src}}_{\Lambda,J}[\phi_<]] := \int \mathrm{d}\mu_{C_>}(\phi_>) \, \exp\left[-L_{\Lambda_0}[\phi_< + \phi_>] - \langle J, \phi_> \rangle\right], \tag{36.36}$$

where $C_{\Lambda_0} = C_\Lambda + C_>$ and $\langle J, \phi\rangle = \int J\phi$. With

$$W^{\mathrm{src,low}}_\Lambda[J] := \log \int \mathrm{d}\mu_{C_\Lambda}(\phi_<) \, \exp\left[-L^{\mathrm{src}}_{\Lambda,J}[\phi_<] - \langle J, \phi_< \rangle\right],$$

this gives the exact identity

$$W^{\mathrm{src,low}}_\Lambda[J] = W_{\Lambda_0}[J] \tag{36.37}$$

after the remaining field is integrated. However, differentiating (36.37) with respect to J also differentiates $L^{\mathrm{src}}_{\Lambda,J}$. Therefore an exact matching implication based on this formulation must include source-vertices as part of the coordinate data. The controlled comparison below instead uses an *admissible plateau cutoff*: choose a smooth profile satisfying

$$\chi(s) = 1 \quad (0 \le s \le c_\chi^2) \tag{36.38}$$

for some $c_\chi > 0$. Let $\mathcal{E}_<$ denote the finite-dimensional low source test space chosen with

$$\operatorname{supp} \widehat{J} \subset \{|k| < c_< \Lambda\}, \qquad 0 < c_< < c_\chi. \tag{36.39}$$

Since $\Lambda < \Lambda_0$, this implies $C_>(k)\widehat{J}(k) = 0$ on the low test space. Thus the source-independent Wilsonian action L_Λ has an exact low-source identity. The connected functional computed from it is denoted

$$W^{\mathrm{low}}_\Lambda[J] = \log \int \mathrm{d}\mu_{C_\Lambda}(\phi) \, \exp\left[-L_\Lambda[\phi] - \int J\phi\right].$$

The finite-dimensional Gaussian convolution identity and (36.39) give the exact equality

$$W^{\mathrm{low}}_\Lambda[J] = W_{\Lambda_0}[J] \tag{36.40}$$

at the finite regulator. No exact source-independent statement of this form is asserted below for non-plateau profiles such as a Gaussian cutoff. Such a profile may be treated either by keeping the source-dependent vertices in (36.36), or by proving a separate profile-dependent leakage estimate; that is a different comparison problem.

Exact low-source identity for a plateau split. Assume (36.38) and (36.39). At finite regulator, (36.40) holds for every source $J \in \mathcal{E}_<$.

By Gaussian convolution,

$$\int \mathrm{d}\mu_{C_{\Lambda_0}}(\phi)\, \mathrm{e}^{-L_{\Lambda_0}[\phi]-\langle J,\phi\rangle} = \int \mathrm{d}\mu_{C_\Lambda}(\phi_<) \int \mathrm{d}\mu_{C_>}(\phi_>)\, \mathrm{e}^{-L_{\Lambda_0}[\phi_<+\phi_>]-\langle J,\phi_<+\phi_>\rangle}.$$

For $J \in \mathcal{E}_<$, the covariance of the scalar Gaussian random variable $\langle J, \phi_>\rangle$ is

$$\langle J, C_> J\rangle = \int_k |\widehat{J}(k)|^2 \frac{\chi(k^2/\Lambda_0^2) - \chi(k^2/\Lambda^2)}{k^2+m^2}.$$

On $\operatorname{supp}\widehat{J}$, both cutoff profiles equal one by (36.38) and (36.39); hence the integrand vanishes and $\langle J, \phi_>\rangle = 0$ almost surely. The previous display becomes

$$\int \mathrm{d}\mu_{C_\Lambda}(\phi_<)\, \mathrm{e}^{-\langle J,\phi_<\rangle} \int \mathrm{d}\mu_{C_>}(\phi_>)\, \mathrm{e}^{-L_{\Lambda_0}[\phi_<+\phi_>]}.$$

The inner integral is, by definition, $\exp[-L_\Lambda[\phi_<]]$ when the field-independent normalization is included as the vacuum-energy coordinate of L_Λ. With that convention this is exactly $Z_\Lambda^{\mathrm{low}}[J]$, and taking logarithms gives (36.40). If one fixes the vacuum-energy coordinate separately, the two logarithms differ only by the chosen source-independent constant and all positive source derivatives agree.

The 1PI effective action at the same finite regulator is the Legendre transform of the connected functional. If

$$\varphi(x) = \frac{\delta W[J]}{\delta J(x)},$$

then, in the Euclidean sign convention of this volume,

$$\Gamma[\varphi] = W[J] - \int \mathrm{d}^D x\, J(x)\varphi(x), \qquad J = J[\varphi].$$

Equation (36.40) therefore implies equality of the low-momentum 1PI kernels obtained from the source-independent plateau-cutoff Wilsonian description and from the original regulated description, after the same Legendre transform and the same field normalization convention are used. Here “low 1PI” means the Legendre transform of the connected functional after restriction to the finite source space $\mathcal{E}_<$. It is not being identified with the restriction of a Legendre transform already taken on the full source space; that different operation would require an additional Schur-complement statement. The Wilsonian vertices $L_\Lambda^{(n)}$ and the 1PI vertices $\Gamma^{(n)}$ are distinct vertices; their general relation includes all tree and loop diagrams built from the Wilsonian vertices and the remaining cutoff covariance C_Λ.

Figure 36.8 shows the nontrivial point in the Legendre-transform bridge. A Legendre transform performed only on the low source space inverts the low-source Hessian $W^{(2)}_{<<}$. A full Legendre transform followed by restriction to low fields instead inverts the Schur complement $W^{(2)}_{<<} - W^{(2)}_{<>}(W^{(2)}_{>>})^{-1}W^{(2)}_{><}$. The chapter uses the first operation; the second requires extra hypotheses and is not silently identified with it.

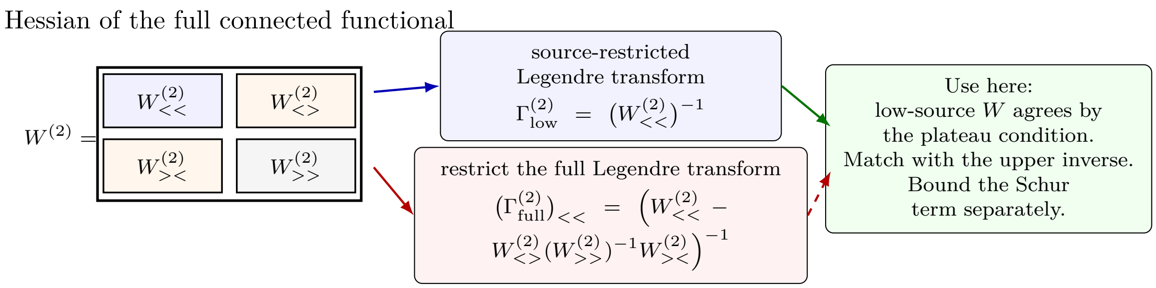

Figure 36.8: The low-source Legendre transform is not the same operation as restricting a full Legendre transform. In Hessian language, the former inverts $W^{(2)}_{<<}$, while the latter inverts the Schur complement that subtracts high-source feedback through $W^{(2)}_{<>}(W^{(2)}_{>>})^{-1}W^{(2)}_{><}$. The Wilsonian–BPHZ comparison in this section uses the source-restricted transform; identifying it with the restricted full transform would require an additional estimate.

Definition 36.10 (BPHZ–Wilsonian comparison setup)**.** A comparison setup consists of the following finite choices. First choose a BPHZ scheme $\mathfrak{b}$: a Taylor subtraction point and subtraction degree $\delta(\gamma)$ for every superficially divergent 1PI subgraph type γ, including the oversubtraction degrees used for normal products. The corresponding forest operation is

$$R^{\mathfrak{b}}_{\Gamma} I_{\Gamma} = \sum_{F\in\mathfrak{F}(\Gamma)} (-1)^{|F|} \left(\prod_{\gamma\in F} t_{\gamma}^{\delta(\gamma),\mathfrak{b}}\right) I_{\Gamma},$$

with nested products ordered from smaller subgraphs to larger ones. Second choose the Wilsonian covariance split

$$C_{\Lambda_0} = C_{\Lambda} + C_{>},$$

with an admissible plateau profile satisfying (36.38) and a low test space satisfying (36.39), the Banach chart $\mathcal{B}^{m,a}_{\Lambda}$ in which Wilsonian kernels are estimated, the finite local coordinate projectors $\rho_A(L_\Lambda) = u_A$, and the finite 1PI projectors Π_I at nonexceptional Euclidean momenta of size $O(\mu)$. Third choose a matching ratio $\zeta = \Lambda/\mu$ in a compact subinterval of $(1,\infty)$. All statements below are statements relative to this setup. A non-plateau smooth cutoff is a different setup: either source-dependent vertices must be included, or an explicit leakage estimate must be proved before the comparison theorem is invoked.

Proposition 36.11 (BPHZ local parts as Wilsonian local coordinates)**.** *Consider a power-counting finite scalar theory in a massive Euclidean momentum-subtraction setting. For every superficially divergent subgraph γ with E_γ external scalar legs, the BPHZ local part*

$$t_{\gamma}^{\delta(\gamma),\mathfrak{b}}\,\overline{R}_{\gamma} I_{\gamma}$$

is a finite sum of external-momentum monomials

$$\sum_{|\alpha|\le\delta(\gamma)} c^{\mathfrak{b}}_{\gamma,\alpha}\, p_{\gamma}^{\alpha}.$$

After Fourier transform, each term is a local vertex of the form

$$c^{\mathfrak{b}}_{\gamma,\alpha} \int \mathrm{d}^D x\, P_\alpha(\partial_1,\ldots,\partial_{E_\gamma})\phi(x_1)\cdots\phi(x_{E_\gamma})\big|_{x_i=x}.$$

For the minimal BPHZ degree $\delta(\gamma) = \omega(\gamma)$, these vertices are precisely among the relevant or marginal local Wilsonian coordinates determined by power counting. Oversubtractions add a finite list of higher-derivative local coordinates, and Zimmermann identities are the corresponding finite changes of local operator coordinates.

Proof. The prepared integrand $\overline{R}_\gamma I_\gamma$ has all proper subdivergences subtracted. The operation $t_\gamma^{\delta,\mathfrak{b}}$ is the Taylor polynomial in the independent external momenta of γ at the specified subtraction configuration, hence it has the displayed monomial form. Multiplication by p^α in momentum space is the Fourier transform of a derivative acting on the fields incident to the contracted vertex, so insertion of this Taylor polynomial into the contracted graph is the insertion of a local interaction vertex with E_γ fields and $|\alpha|$ derivatives.

For a scalar field with engineering dimension $[\phi] = (D-2)/2$, the dimension of such a local monomial in the derivative-free scalar examples of this chapter is

$$\Delta_{\gamma,\alpha} = E_\gamma \frac{D-2}{2} + |\alpha|.$$

The superficial degree $\omega(\gamma)$ is precisely the largest derivative order for which the local counterterm has scaling dimension at most D, in the power-counting convention used to define the BPHZ subtraction degree. Thus $|\alpha| \leq \omega(\gamma)$ is equivalent to $\Delta_{\gamma,\alpha} \leq D$ in this scalar setting. These are the relevant or marginal local coordinates in the Wilsonian linearized scaling convention $y_A = D - \Delta_A$. If $\delta(\gamma) > \omega(\gamma)$, the additional Taylor coefficients have $\Delta_A > D$; they are irrelevant Wilsonian coordinates retained by the chosen oversubtracted local chart. The difference between two choices of subtraction degree or finite Taylor part is therefore a finite change of coefficients multiplying local vertices, which is the Wilsonian coordinate form of the Zimmermann identity described in Chapter 32. □

Lemma 36.12 (Low-momentum Taylor remainder from a Wilsonian norm)**.** *Fix a finite loop order ℓ, a finite list of low-momentum 1PI projectors Π_I, and a comparison interval*

$$1 < \zeta_- \leq \Lambda/\mu \leq \zeta_+ < \infty.$$

Work in a Wilsonian Banach chart $\mathcal{B}_\Lambda^{m,a}$ of the form defined above, with m larger than the largest Taylor order extracted by the projectors Π_I. Let $v_{\perp,N}$ be the omitted part of L_Λ, and assume:

(i) $\|v_{\perp,N}\|_{\Lambda,m,a} \leq K_N$*;*

(ii) every Taylor monomial in $v_{\perp,N}$ that can enter one of the projectors Π_I has excess scaling exponent at least $p_N > 0$ relative to the retained projection;

(iii) the retained Wilsonian coordinates and the covariance $C_\Lambda(k)$ stay in a bounded subset of the same chart on the comparison interval.

Then, for every graph contributing through loop order ℓ to one of the projectors Π_I and containing at least one insertion of $v_{\perp,N}$, its contribution is bounded by

$$C_{I,\ell,N} K_N \left(\frac{\mu}{\Lambda}\right)^{p_N},$$

with $C_{I,\ell,N}$ depending on the bounded retained-coordinate set, on the cutoff profile, on the projectors, and polynomially on $\log(\Lambda/\mu)$ on the comparison interval.

Proof. Consider first a single omitted vertex kernel with external momenta of size $O(\mu)$. Write those momenta as $k_i = \mu\kappa_i$, where the κ_i range over a compact set fixed by the projectors. The norm $\|\cdot\|_{\Lambda,m,a}$ bounds all derivatives of the dimensionless kernel in the variables k_i/Λ up to order m. Since the Taylor monomials of excess smaller than p_N have been retained and subtracted into $L_\Lambda^{(N)}$, Taylor's theorem with integral remainder gives

$$|\Pi_I v_{\perp,N}| \le C_{I,N} K_N \left(\frac{\mu}{\Lambda}\right)^{p_N}$$

for each projected vertex contribution.

For a fixed loop order ℓ and a fixed finite family of projectors, only finitely many graph topologies and Taylor derivatives are involved. Rescale each remaining low loop momentum by $q = \Lambda x$. The smooth cutoff gives uniform bounds on the rescaled covariance and its derivatives away from the mass singularities excluded by the massive, nonexceptional hypothesis. The bounded retained vertices supply constants in the chosen chart. The Taylor-remainder factor from at least one omitted vertex is therefore carried through the whole graph. Logarithms arise only from scale integrations over the finite interval between μ and Λ, and on the fixed comparison interval they are bounded by a polynomial in $\log(\Lambda/\mu)$. Summing the finite set of graph and derivative contributions gives the stated constant $C_{I,\ell,N}$. □

Lemma 36.13 (Forest operation and the Wilsonian vertex split)**.** *Fix a graph* Γ *whose vertices are labeled by kernels appearing in the additive decomposition*

$$L_\Lambda = L_\Lambda^{(N)} + v_{\perp,N}.$$

The BPHZ forest operation is linear in every vertex kernel and depends on the graph only through its topology, momentum routing, subtraction degrees, and subtraction points. Consequently,

$$R_\Gamma^{\mathfrak{b}} I_\Gamma[L_\Lambda] = \sum_{\sigma: V(\Gamma)\to\{N,\perp\}} R_\Gamma^{\mathfrak{b}} I_{\Gamma,\sigma}[L_\Lambda^{(N)}, v_{\perp,N}], \tag{36.41}$$

where σ *records which vertices of* Γ *use retained kernels and which use* $v_{\perp,N}$*. The summands with at least one* $\perp$*-vertex are exactly the subtracted graphs to which Lemma 36.12 applies, provided the lemma's Banach norm bounds are imposed on the subtracted integrands.*

Proof. Before subtraction, the Feynman integrand is multilinear in the vertex kernels. Expanding each vertex label according to $L_\Lambda^{(N)} + v_{\perp,N}$ gives the finite sum over maps $\sigma : V(\Gamma) \to \{N, \perp\}$. For a fixed forest F, the operator

$$\prod_{\gamma\in F} t_\gamma^{\delta(\gamma),\mathfrak{b}}$$

acts by Taylor expansion in the external variables assigned to the subgraphs γ. It does not inspect whether a vertex kernel in the integrand is retained or omitted; it is a linear differential operator with coefficients fixed by the graph topology and by $\mathfrak{b}$. Therefore this Taylor operator commutes with the finite additive expansion over vertex labels. Summing over forests gives (36.41).

If a summand contains a $\perp$-vertex, every forest subtraction of that summand still contains the same $\perp$-vertex unless the Taylor contraction has replaced the whole subgraph containing it by its local Taylor polynomial. In that case the resulting local polynomial is a Taylor coefficient of a graph with a $v_{\perp,N}$-insertion. The Wilsonian Banach norm in Lemma 36.12 was imposed on the finite set of kernels and derivatives entering these Taylor coefficients, so the same $(\mu/\Lambda)^{p_N}$ bound applies to the subtracted summand. □

Definition 36.14 (Admissible finite-order BPHZ–Wilsonian matching context)**.** Consider a massive Euclidean scalar theory with local polynomial interactions, finite ultraviolet regulator Λ_0, an intermediate admissible plateau smooth cutoff Λ in the sense of (36.38), and nonexceptional external momenta of size $O(\mu)$, with $\mu < \Lambda$. Fix:

(i) a BPHZ subtraction scheme $\mathfrak{b}$ consisting of the forest formula of Chapter 32 with specified Taylor subtraction points and oversubtraction degrees;

(ii) a finite-dimensional low test space $\mathcal{E}_<$ of sources and classical fields whose Fourier transforms are supported in $|k| < c_<\Lambda$, where $0 < c_< < c_\chi$ and c_χ is the plateau constant in (36.38); this test space contains the momenta used by the selected 1PI projectors and satisfies $C_> J = 0$;

(iii) a finite list of 1PI projectors Π_I at scale μ, each extracting a Taylor coefficient of a low-momentum 1PI kernel at a prescribed nonexceptional subtraction configuration $\mathcal{S}_I$;

(iv) a finite list of Wilsonian local-coordinate projectors ρ_A at scale Λ, extracting the coefficients $u_A = \rho_A(L_\Lambda)$ of local vertex tensors P_A.

Let $L_\Lambda^{(N)}(u)$ be the local Wilsonian action reconstructed from the retained coordinates u_A, and let

$$v_{\perp,N} := L_\Lambda - L_\Lambda^{(N)}(u)$$

be the omitted part. For a fixed loop order ℓ, define the matching map

$$M_I^{(\ell,N)}(u;\Lambda,\mu,\mathfrak{b}) := \Pi_I\,\Gamma^{<,(\leq\ell)}_{\Lambda,N}[u], \tag{36.42}$$

where $\Gamma^{<,(\leq\ell)}_{\Lambda,N}[u]$ is the low-mode 1PI effective action defined as follows: compute the connected functional by integrating the full finite-regulator remaining field with covariance C_Λ and vertices $L_\Lambda^{(N)}(u)$, restrict its source argument to $\mathcal{E}_<$, then take the local Legendre transform on that finite source space with the same finite local normalization convention as $\mathfrak{b}$. The resulting formal 1PI functional is truncated after loop order ℓ.

Hypothesis 36.15 (Finite-order BPHZ–Wilsonian matching estimates)**.** In the context of Definition 36.14, assume the following estimates hold on the coordinate neighborhood under consideration:

(a) the BPHZ forest theorem applies to all graphs through loop order ℓ that contribute to the projectors Π_I;

(b) the Hessian of W_Λ^{low} on the low source space is invertible on the source neighborhood used for the Legendre transform;

(c) in a chosen Wilsonian Banach norm, $\|v_{\perp,N}\|_{\Lambda,m,a} \leq K_N$, and the first omitted local tensor that can contribute to the projectors Π_I has excess scaling exponent at least $p_N > 0$, with the retained coordinates and covariance bounded as in Lemma 36.12; the same bounds hold for the finite set of Taylor-subtracted kernels obtained by applying $R_\Gamma^{\mathfrak{b}}$ to graphs with at least one $v_{\perp,N}$-insertion. This bounded-chart hypothesis is an order-by-order perturbative hypothesis in the renormalized coupling, or a genuine nonperturbative hypothesis only for trajectories for which the stated norm remains bounded;

(d) the limit $\Lambda_0 \to \infty$, when it is taken, is taken along a Polchinski-flow counterterm trajectory: the relevant and marginal UV-cutoff coordinates in the regulated path-integral Lagrangian at

Λ_0 are tuned as functions of Λ_0 so that the selected renormalized boundary coordinates at a fixed reference scale stay fixed and the Wilsonian kernels at the intermediate scale Λ have the perturbative limits supplied by Polchinski/Salmhofer/Kopper–Müller-type cutoff estimates in the chosen norm.

Controlled Approximation 36.16 (Finite-order BPHZ–Wilsonian comparison)**.** In an admissible matching context as in Definition 36.14, and under Hypothesis 36.15, the BPHZ-renormalized 1PI coordinates through loop order ℓ obey

$$g_I^{\mathfrak{b},(\le\ell)}(\mu) = M_I^{(\ell,N)}(u(\Lambda);\Lambda,\mu,\mathfrak{b}) + R_I^{(\ell,N)}(\Lambda,\mu), \qquad |R_I^{(\ell,N)}| \le C_{I,\ell,N} K_N \left(\frac{\mu}{\Lambda}\right)^{p_N}. \tag{36.43}$$

If a sublist A_0 of Wilsonian coordinates has the same cardinality as the chosen 1PI coordinates and the Jacobian

$$J_{IA} = \frac{\partial M_I^{(\ell,N)}}{\partial u_A}\bigg|_{u=u_*}, \qquad I \in \mathcal{I},\ A \in A_0,$$

is invertible at a reference point u_*, then the finite-dimensional implicit function theorem gives a local finite change of coordinates

$$u_A = G_A\big(g^{\mathfrak{b}}, u_{\bar{A}}; \Lambda/\mu, \mathfrak{b}\big), \qquad A \in A_0,$$

with the same $O((\mu/\Lambda)^{p_N})$ truncation error.

Derivation of the comparison. The displayed comparison is an implication from the four estimates in Hypothesis 36.15; those estimates are the analytic input. The derivation records what the finite matching map becomes once they are available.

The plateau low-source identity above gives (36.40) for all sources in $\mathcal{E}_<$. This equality is an equality of functions on the same finite-dimensional source space. By Hypothesis 36.15(b), the maps

$$J \longmapsto \varphi = \frac{\delta W[J]}{\delta J}$$

are locally invertible for both sides of (36.40). Since the functions W agree, their first derivatives and local inverse maps agree. Therefore the Legendre transforms on $\mathcal{E}_<$,

$$\Gamma^<[\varphi] = W[J(\varphi)] - \langle J(\varphi), \varphi\rangle,$$

agree on the corresponding low classical-field neighborhood. This proves equality of low-mode 1PI kernels at finite regulator. The object just constructed is the 1PI functional for the low test space; it is the object used by the projectors Π_I.

Theorem 32.6 proves, by the Hepp-sector Taylor-remainder estimates in Chapter 32, that at the fixed loop order ℓ every ultraviolet subtraction in the chosen massive BPHZ scheme $\mathfrak{b}$ is a Taylor polynomial in the external variables of the subgraph and that the subtracted graph has a finite $\Lambda_0 \to \infty$ limit. Thus, after the selected subtraction points, field normalization, and oversubtraction degrees are fixed, the projected BPHZ coordinates $g_I^{\mathfrak{b},(\le\ell)}(\mu)$ are finite Taylor coefficients of the same low-mode 1PI kernels obtained from the Wilsonian action. The $\Lambda_0 \to \infty$ limit here is not taken at fixed UV-cutoff Lagrangian coordinates: by Hypothesis 36.15(d), it is taken along the Polchinski-flow counterterm trajectory that holds the chosen renormalized boundary data fixed and has a limit for the Wilsonian kernels at the intermediate scale Λ. At fixed loop order this is precisely the perturbative renormalized trajectory constructed by the Wilsonian estimates, not a nonperturbative assertion about a cutoff coupling held fixed.

Computing the projected low kernels with the retained local action $L_\Lambda^{(N)}(u)$ is exactly the definition (36.42) of $M_I^{(\ell,N)}$.

It remains only to compare the exact Wilsonian action with its finite local projection. The graph expansion is first decomposed according to $L_\Lambda = L_\Lambda^{(N)} + v_{\perp,N}$. By Lemma 36.13, the BPHZ forest operation commutes with this finite additive vertex decomposition, and the subtracted graphs with at least one $v_{\perp,N}$-insertion are still graphs to which the Wilsonian Taylor-remainder norm estimate applies. Hypothesis 36.15(c) puts those subtracted graphs in the situation of Lemma 36.12. The lemma gives the displayed power bound for their contribution to the selected Taylor coefficients of low 1PI kernels. Substituting this estimate into the equality of finite-regulator low 1PI kernels, and then taking the tuned BPHZ/Polchinski $\Lambda_0 \to \infty$ limit at fixed Λ and μ, gives (36.43).

The final assertion is finite-dimensional. If J_{IA} is invertible, the map from the selected Wilsonian coordinates u_A, $A \in A_0$, to the selected 1PI coordinates has an invertible derivative at u_*. The implicit function theorem therefore gives the displayed local coordinate map G_A, with the same remainder estimate because the previous paragraph already controls the omitted Wilsonian coordinates.

The finite change of coordinates in Controlled Approximation 36.16 can be constructed recursively in the loop expansion. Write

$$M_I^{(\ell,N)}(u) = \sum_{r=0}^{\ell} \hbar^r M_{I,r}(u), \qquad u_A = \sum_{r=0}^{\ell} \hbar^r U_{A,r}, \qquad g_I = \sum_{r=0}^{\ell} \hbar^r g_{I,r}.$$

Choose the sublist A_0 with invertible tree-level Jacobian

$$J_{IA} = \left.\frac{\partial M_{I,0}}{\partial u_A}\right|_{u=U_0}, \qquad A \in A_0.$$

At order zero, solve $g_{I,0} = M_{I,0}(U_0)$. Suppose that $U_{A,s}$ has been determined for $s < r$. The coefficient of $\hbar^r$ in $M_I(u)$ has the form

$$[\hbar^r]\, M_I(u) = J_{IA} U_{A,r} + \mathcal{F}_{I,r}(U_0, \ldots, U_{r-1}; u_{\bar{A}}),$$

where $\mathcal{F}_{I,r}$ is computed from lower-order coordinate coefficients, the explicit r-loop low-mode 1PI graphs, and the retained coordinates $u_{\bar{A}}$ outside A_0. Therefore

$$U_{A,r} = (J^{-1})_{AI} \left[g_{I,r} - \mathcal{F}_{I,r}(U_0, \ldots, U_{r-1}; u_{\bar{A}}) \right].$$

This recursion is the perturbative coordinate map

$$u_A = G_A(g, u_{\bar{A}}; \Lambda/\mu, \mathfrak{b})$$

order by order. The coefficients $\mathcal{F}_{I,r}$ are finite because BPHZ supplies finite 1PI projectors at the chosen loop order, and the Wilsonian Taylor-remainder lemma controls the omitted local coordinates by the displayed power of μ/Λ.

Remark 36.17 (Scope of the matching implication). Controlled Approximation 36.16 is a fixed-loop perturbative consequence of a specified subtraction scheme, a specified Wilsonian norm, and the admissible plateau cutoff (36.38). The plateau is load-bearing: it makes $C_{>}J = 0$ on the low test space and hence makes (36.40) exact for the source-independent Wilsonian action used in the matching map. Non-plateau smooth profiles such as Gaussian cutoffs require either the source-dependent Wilsonian action (36.36) together with source-vertex coordinates, or a separate leakage theorem; they are not covered by Controlled Approximation 36.16 as stated.

The massive BPHZ scheme used here is the forest-formula scheme of Chapter 32. Massless theories require BPHZL or another infrared-safe subtraction scheme, and dimensional regularization with minimal subtraction is a different coordinate system whose relation to the present one is another finite matching map. Since BPHZ is a perturbative forest-formula construction, there is no separate "nonperturbative BPHZ construction" being compared here. The nonperturbative question is instead whether a Wilsonian or constructive continuum theory exists and whether its correlation functions have, in the chosen local coordinates, the BPHZ-renormalized series as their perturbative asymptotic expansion. That question requires existence of the relevant measures or functionals, Legendre transforms, and cutoff-uniform Banach estimates for the model under study.

The bounded-chart hypothesis specifies the class of trajectories being compared. For scalar quartic theory in four dimensions, for example, the nonperturbative continuum limit at fixed positive bare family is obstructed in the standard reflection-positive lattice universality classes discussed earlier. The Polchinski theorem used here is an order-by-order theorem in the renormalized coupling after the counterterms have been tuned; in that perturbative coefficientwise sense the retained coordinates remain in the required neighborhood at every fixed loop order.

Remark 36.18 (Status of the comparison). The exact finite-regulator input is (36.40), valid here because the cutoff has a low-momentum plateau and the source support is strictly inside it. The Legendre-transform step is a finite-dimensional local theorem under Hessian invertibility on the chosen low test space. The BPHZ input is the order-by-order massive forest-formula theorem proved in Chapter 32, with BPHZL or another infrared prescription required for massless exceptional regions. The Wilsonian input is an estimate in the chosen normed RG chart and along the tuned Polchinski-flow counterterm trajectory. Minimal subtraction, momentum subtraction, and Wilsonian coordinates are different coordinate systems; their comparison is the finite matching problem just constructed. A theorem connecting this perturbative comparison to an actual continuum QFT requires additional existence and uniform-estimate theorems for the model under study.

Remark 36.19 (Fixed-loop comparison of renormalizability criteria). In the massive, nonexceptional, finite-projector, plateau-cutoff, and tuned Polchinski-trajectory setting of Controlled Approximation 36.16, the following two renormalizability criteria are equivalent through the fixed loop order ℓ, up to the displayed $(\mu/\Lambda)^{p_N}$ error from omitted irrelevant Wilsonian coordinates.

(i) BPHZ renormalizability: after applying the forest formula in the chosen scheme $\mathfrak{b}$, all projected 1PI coordinates $g_I^{\mathfrak{b},(\leq\ell)}(\mu)$ have finite $\Lambda_0 \to \infty$ limits, and the required subtraction freedom is a finite list of local Taylor coefficients.

(ii) Polchinski-Wilsonian renormalizability: the Wilsonian trajectory is specified at scale Λ by a finite list of relevant or marginal local coordinates u_A, together with an irrelevant remainder whose norm obeys Lemma 36.12; the selected low 1PI coordinates are then finite functions of u_A after low-mode integration.

First, BPHZ subtraction data determine Wilsonian local coordinates by Proposition 36.11. The selected 1PI coordinates are then obtained by the finite matching map $M_I^{(\ell,N)}$. Conversely, Wilsonian data satisfying the stated norm bound determines finite BPHZ projected coordinates: apply the same projectors Π_I to the low-mode 1PI functional, and assign the resulting local Taylor parts to the BPHZ subtraction coordinates. A change of BPHZ subtraction point, oversubtraction degree, or finite Taylor part changes the Wilsonian description by a finite local coordinate transformation in the retained chart.

The two directions are obtained as follows. Assume first the BPHZ criterion. Proposition 36.11 identifies every forest Taylor subtraction through the selected loop order with a local vertex in the Wilsonian chart. Minimal subtractions occupy relevant and marginal coordinates, while oversubtractions occupy the explicitly retained higher-derivative local coordinates. After these local coordinates are fixed, Controlled Approximation 36.16 gives

$$g_I^{\mathfrak{b},(\leq\ell)}(\mu) = M_I^{(\ell,N)}(u(\Lambda);\Lambda,\mu,\mathfrak{b}) + R_I^{(\ell,N)}$$

with the stated bound on $R_I^{(\ell,N)}$. Thus the BPHZ finite local subtraction freedom is represented by the finite Wilsonian coordinate list, and the omitted Wilsonian coordinates affect the selected projectors only by the Taylor-remainder estimate.

Conversely, assume the Wilsonian criterion. The finite-regulator Gaussian identity constructs the same low-source connected functional as the original regulated theory, and the Hessian hypothesis in Controlled Approximation 36.16 constructs the low-mode Legendre transform. Applying the projectors Π_I to this low-mode 1PI functional gives finite numbers through loop order ℓ. For every superficially divergent graph contributing to these projectors, its local Taylor part is one of the finitely many local monomials in the retained Wilsonian chart, again by Proposition 36.11. Assigning those Taylor coefficients as BPHZ subtraction coordinates gives a BPHZ scheme whose projected coordinates agree with the Wilsonian values up to the same remainder estimate. The construction is recursive in loop order because the forest formula subtracts proper divergent subgraphs before the overall graph, whereas the Wilsonian matching recursion displayed above solves the local coordinate map at order r using only lower-order coordinate data and the explicit r-loop low-mode graphs.

Finally, the difference between two BPHZ subtraction choices is a finite sum of Taylor polynomials in external momenta. Fourier transforming these polynomials gives a finite sum of local vertices, hence a finite change of the retained Wilsonian coordinates. Where the Jacobian in Controlled Approximation 36.16 is invertible, this finite change is a local coordinate transformation by the implicit function theorem.

Remark 36.20 (Perturbative and continuum scopes). The preceding fixed-loop comparison is a two-way implication only after the finite-loop, massive, nonexceptional, and finite-projector hypotheses, together with the plateau-cutoff and tuned counterterm-trajectory hypotheses, of Controlled Approximation 36.16 have been imposed. In that setting, BPHZ forest-formula local Taylor parts construct the Wilsonian local coordinates, and controlled Wilsonian local coordinates construct BPHZ subtraction coordinates by projecting the low-mode 1PI functional. The result is an equivalence of finite coordinate descriptions of selected perturbative 1PI data, with the omitted irrelevant coordinates contributing the stated $(\mu/\Lambda)^{p_N}$ remainder.

The corresponding continuum-QFT problem has additional objects. For the model in question one must construct the regulated and limiting functionals, choose a topology on the full Wilsonian coordinate space, prove cutoff-uniform estimates in that topology, construct the Legendre transform on the required source domain, and then prove that the BPHZ-renormalized series is the perturbative asymptotic expansion of those continuum objects. BPHZ itself supplies the perturbative forest-formula side of this comparison; the existence-and-asymptotics problem belongs to the constructive or nonperturbative Wilsonian analysis of the model.

36.12 One-Loop Matching in the Quartic Scalar Theory

The matching map in Controlled Approximation 36.16 can be displayed directly in the four-point function of the massive scalar theory in four Euclidean dimensions. Work with

$$S_{\mathrm{int}}[\phi] = \frac{g_0}{4!} \int \mathrm{d}^4x\, \phi(x)^4$$

and a finite covariance $C_{\Lambda_0}(k)$. Let

$$C_{\Lambda_0}(k) = C_\Lambda(k) + C_>(k), \qquad C_>(k) = C_{\Lambda_0}(k) - C_\Lambda(k),$$

where C_Λ is the covariance of the remaining low field and $C_>$ is the covariance integrated out in the Wilsonian step from Λ_0 to Λ. For a four-point external configuration

$$\mathcal{P} = (p_1, p_2, p_3, p_4), \qquad \sum_{i=1}^{4} p_i = 0,$$

define the channel momenta

$$P_s = p_1 + p_2, \qquad P_t = p_1 + p_3, \qquad P_u = p_1 + p_4.$$

For any two covariances A, B, define the one-loop bubble functional

$$\mathcal{B}_{A,B}(\mathcal{P}) = \sum_{c=s,t,u} \int \frac{\mathrm{d}^4q}{(2\pi)^4}\, A(q)\, B(q + P_c).$$

Thus $\mathcal{B}_{C_{\Lambda_0},C_{\Lambda_0}}$ is the regulated full one-loop bubble sum, while

$$\mathcal{B}_{<,<} := \mathcal{B}_{C_\Lambda,C_\Lambda}, \qquad \mathcal{B}_{>,>} := \mathcal{B}_{C_>,C_>}$$

record the low-low and high-high parts of the loop. The remaining mixed piece is

$$\mathcal{B}_\times = \mathcal{B}_{C_\Lambda,C_>} + \mathcal{B}_{C_>,C_\Lambda}.$$

The exact finite-regulator identity is

$$\mathcal{B}_{C_{\Lambda_0},C_{\Lambda_0}} = \mathcal{B}_{<,<} + \mathcal{B}_{>,>} + \mathcal{B}_\times. \tag{36.44}$$

In the Wilsonian action, the high-high part appears directly in the quartic vertex. Let $u_4(\Lambda;\mathcal{P})$ be the coefficient whose contribution to L_Λ has four-field kernel u_4, so that the corresponding tree 1PI vertex is $-u_4$. To second order in g_0,

$$u_4(\Lambda;\mathcal{P}) = g_0 - \frac{g_0^2}{2}\, \mathcal{B}_{>,>}(\mathcal{P}) + u_{4,\mathrm{ct}}^{\mathrm{loc}}(\Lambda;\mathcal{P}) + O(g_0^3), \tag{36.45}$$

where $u_{4,\mathrm{ct}}^{\mathrm{loc}}$ denotes the local quartic counterterm and finite local convention chosen at the ultraviolet regulator. The factor $1/2$ is the symmetry factor of the bubble in the normalization $(g_0/4!)\phi^4$.

Figure 36.9 displays the actual one-loop partition used by the matching formula: the same bubble graph is evaluated with the four possible covariance assignments on its two internal lines. This is the graph-level content behind the algebraic identity (36.44).

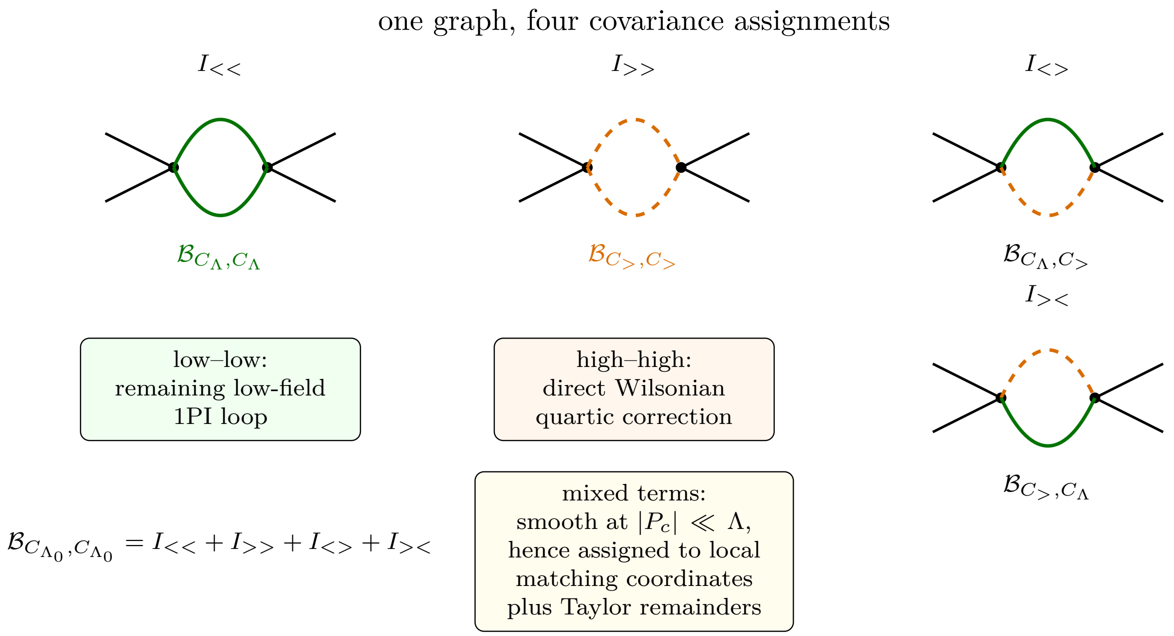

Figure 36.9: The covariance decomposition of the one-loop four-point bubble. Each panel is the same bubble graph with a different assignment of the two internal propagators to the low covariance C_Λ or the integrated covariance $C_>$. The $I_{>>}$ term is the high-momentum correction to the Wilsonian quartic vertex, $I_{<<}$ is generated by the later low-field 1PI loop, and the mixed assignments are smooth for external momenta $|P_c| \ll \Lambda$ and therefore enter the finite local matching map up to Taylor-remainder estimates.

The mixed term in (36.44) must be accounted for explicitly. In the exact Wilsonian functional it is not absent: it is produced by lower Wilsonian vertices generated by one high contraction and then used in the remaining low-field integration. If the external momenta are $O(\mu)$ with $\mu \ll \Lambda$, this contribution is smooth in the external invariants and has a Taylor expansion in powers of μ/Λ. In a finite derivative projection it is therefore part of the local matching map and of the first omitted irrelevant coordinates.

Let $\mathcal{S}_\mu$ be the symmetric Euclidean subtraction configuration used to define the 1PI quartic coordinate

$$g(\mu) = -\Gamma^{(4)}(\mathcal{S}_\mu).$$

For the logarithmically divergent one-loop four-point graph, the BPHZ overall subtraction is subtraction of the zeroth Taylor coefficient at $\mathcal{S}_\mu$. Thus, after the coupling counterterm has been fixed by the displayed condition,

$$\Gamma^{(4)}_{\mathrm{BPHZ}}(\mathcal{P}) = -g(\mu) + \frac{g(\mu)^2}{2}\left[\mathcal{B}_{C_{\Lambda_0},C_{\Lambda_0}}(\mathcal{P}) - \mathcal{B}_{C_{\Lambda_0},C_{\Lambda_0}}(\mathcal{S}_\mu)\right] + O(g^3), \tag{36.46}$$

with the limit $\Lambda_0 \to \infty$ taken after the subtraction. The difference in brackets has a finite limit at nonexceptional momenta.

The same finite-regulator 1PI kernel computed from the Wilsonian action is

$$\begin{aligned}\Gamma^{(4)}_{\Lambda,\mathrm{low}}(\mathcal{P}) = -u_4(\Lambda;\mathcal{P}) + \frac{u_4(\Lambda;\mathcal{S}_\mu)^2}{2}\mathcal{B}_{<,<}(\mathcal{P})\\ + \mathcal{M}_\times(\Lambda;\mathcal{P}) + O(u_4^3).\end{aligned} \tag{36.47}$$

Here $\mathcal{M}_\times$ is the contribution generated by the mixed covariance assignments, expressed in the low-field description. Its Taylor polynomial at $\mathcal{S}_\mu$ is local. Projecting (36.47) at $\mathcal{S}_\mu$ gives the one-loop matching map

$$g(\mu) = u_4(\Lambda;\mathcal{S}_\mu) - \frac{u_4(\Lambda;\mathcal{S}_\mu)^2}{2}\mathcal{B}_{<,<}(\mathcal{S}_\mu) - \Pi_{\mathcal{S}_\mu}\mathcal{M}_\times(\Lambda) + O(u_4^3), \tag{36.48}$$

where $\Pi_{\mathcal{S}_\mu}$ denotes evaluation of the four-point 1PI projector defining the coupling. If the Wilsonian derivative expansion is truncated after the local quartic coordinate, the finite matching map (36.42) shifts the retained coordinate by

$$-\Pi_{\mathcal{S}_\mu}\mathcal{M}_\times(\Lambda) + O(u_4^3).$$

If the first discarded Taylor coefficient in the four-point kernel has excess exponent p_N, the Taylor-remainder estimate of Lemma 36.12 gives the bound

$$C_N\|v_{\perp,N}\|_{\Lambda,m,a}\left(\frac{\mu}{\Lambda}\right)^{p_N}.$$

Subtracting the value at $\mathcal{S}_\mu$ from (36.47) and using the matching map removes the local coordinate ambiguity. The nonlocal low-momentum dependence is

$$\Gamma^{(4)}_{\Lambda,\mathrm{low}}(\mathcal{P}) - \Gamma^{(4)}_{\Lambda,\mathrm{low}}(\mathcal{S}_\mu) = \frac{g(\mu)^2}{2}\left[\mathcal{B}_{<,<}(\mathcal{P}) - \mathcal{B}_{<,<}(\mathcal{S}_\mu)\right] + \text{local Taylor terms} + O(g^3).$$

Adding the local high and mixed Taylor data reconstructs the low-momentum expansion of the BPHZ expression (36.46). This calculation displays the three roles separately: BPHZ removes the ultraviolet part of the full bubble by a local subtraction; the Wilsonian vertex stores the high-momentum part of the same graph; the 1PI coordinate is obtained only after the remaining low-field Legendre transform and the projector at $\mathcal{S}_\mu$.

The comparison proposition and the one-loop calculation also fix the role of beta functions. The BPHZ construction proves locality and finiteness of the subtracted 1PI kernels. The 1PI renormalization group differentiates finite coordinates $g_I(\mu)$ with respect to the subtraction scale μ. The Wilsonian flow differentiates the cutoff-dependent action L_Λ with respect to Λ. These two vector fields live on different coordinate spaces. They become comparable only after the matching map from L_Λ to the 1PI coordinates $g_I(\mu)$ has been specified. Under a finite change of coordinates, their components transform by the chain rule, as in the 1PI scheme-change discussion. Equality of physical low-momentum correlators is therefore a weaker statement than equality of the displayed beta-function components in two unmatched coordinate systems.

For gauge theories the same diagram of constructions must be lifted to the BRST/BV setting. The Wilsonian pushforward must preserve the quantum master equation, and the 1PI Legendre transform must satisfy the corresponding Slavnov–Taylor or BV master identity. That gauge-theoretic refinement is developed in the BV chapter; the present scalar discussion supplies the renormalization-theoretic comparison without adding gauge constraints.

Chapter 37

The Wilson-Fisher Fixed Point and Scaling Operators

Conventions in this chapter.

- **Signature.** Euclidean $\mathbb{R}^D$.
- **Metric sign.** positive metric $\delta_{\mu\nu}$.
- $\hbar$. 1, unless explicitly displayed.
- **Vacuum symbol.** $\Omega = \Omega$ only after Hilbert-space reconstruction; otherwise brackets denote the stated functional expectation.
- **Generator convention.** Lorentzian generators introduced by continuation use $U(a) = \exp(\mathrm{i}a^\mu P_\mu)$.
- **Global guide.** Recurrent symbols, overload warnings, and standing sign conventions are collected in the Notation and Convention Guide; the local definitions in this chapter fix the operative meaning.

37.1 Scalar Quartic Theory Below Four Dimensions

The trace identity makes fixed points structurally important. The next task is to construct the perturbative data of a non-Gaussian fixed point in a controlled small-ϵ calculation. Consider a single real scalar field in

$$D = 4 - \epsilon$$

Euclidean dimensions.

Definition 37.1 (Dimensional-regularized perturbative status)**.** The calculation in this chapter is a dimensionally regularized perturbative calculation. At each fixed loop order and for each fixed graph, the symbol

$$\int \frac{\mathrm{d}^{4-\epsilon}\ell}{(2\pi)^{4-\epsilon}}\, F(\ell, p, m)$$

denotes the meromorphic continuation in the complex variable $D = 4 - \epsilon$ of the corresponding rotationally invariant Euclidean loop-momentum integral, defined first in a domain where the graph integral or its Feynman-parameter representation converges. Subtractions are then applied coefficient by coefficient in the loop expansion. Thus the graph rules use analytic continuation of finite-dimensional momentum integrals; no field-configuration-space measure in noninteger dimension is being constructed.

The quantities $\beta^\epsilon(\lambda)$, $\gamma_\phi(\lambda)$, $\gamma_2(\lambda)$, $\lambda_*(\epsilon)$, and the scaling dimensions extracted from them are formal perturbative objects in a specified subtraction scheme. Before solving for the fixed point, the beta function and anomalous dimensions are formal power series in the dimensionless coupling λ, with coefficients meromorphic, and after subtraction regular, as $\epsilon \to 0$ in the displayed orders. The Wilson–Fisher fixed-point coordinate is obtained as a formal small-ϵ branch $\lambda_*(\epsilon) \in \epsilon\,\mathbb{R}[[\epsilon]]$. Substituting this branch into anomalous dimensions gives formal ϵ-expansions for Δ_ϕ, Δ_{ϕ^2}, and other scaling data. Convergence or summability of these formal series is an additional analytic question.

The local action density used to generate the perturbative graph rules is

$$\mathcal{L}_E = \frac{1}{2}\partial_\mu\phi\,\partial^\mu\phi + \frac{1}{2}m_0^2\phi^2 + \frac{1}{4!}g_0\phi^4.$$

This action is invariant under the $\mathbb{Z}_2$ transformation $\phi \mapsto -\phi$. Unless an odd source is explicitly introduced, the renormalization-group chart used in this chapter is the $\mathbb{Z}_2$-even one. This convention matters for the count of relevant tuning conditions: inside the even chart the mass perturbation is the relevant deformation that must be tuned, while in the full local theory space an odd source for ϕ is also a relevant coordinate. The quartic coupling g_0 has mass dimension ϵ. The mass parameter m_0^2 must be tuned so that the infrared two-point function has no mass gap. This tuning is an infrared condition: it is not guaranteed by the algebra of counterterms, and it is meaningful only when the flow reaches a massless long-distance theory. The symbol m_0^2 here denotes the bare quadratic coordinate in the cutoff action, not the spectral pole mass of Definition 33.5. The massless Wilson–Fisher point is obtained by tuning this coordinate to the critical surface; massive departures from the fixed point are measured by a renormalized relevant coordinate, and only after reconstruction and spectral analysis can that coordinate be related to a physical pole or gap. The dimensionless quartic coordinate used below is therefore not the dimensionful coefficient g_0. In the notation of the minimal-subtraction chapter, g_0 is the bare $D = 4 - \epsilon$ coupling g^ϵ, and a renormalized quartic coordinate is obtained by factoring out the engineering dimension:

$$g_0 = \mu^\epsilon\left[\lambda(\mu) + \Delta_\lambda(\lambda(\mu),\epsilon)\right], \qquad g_R(\mu) := \mu^\epsilon\lambda(\mu), \qquad \Delta_\lambda = O(\lambda^2).$$

The symbol $\lambda(\mu)$ in the momentum-subtraction calculation immediately below denotes the dimensionless coordinate. The term $-\epsilon\lambda$ in the beta function is precisely the derivative of the factor $\mu^{-\epsilon}g_0$ at fixed bare coupling.

Definition 37.2 (Symmetric MOM quartic chart)**.** In the one-component $\mathbb{Z}_2$-even scalar theory, the symmetric Euclidean momentum-subtraction chart at scale $\mu > 0$ is the local renormalized coordinate system defined as follows. The dimensionless quartic coordinate is the 1PI coefficient

$$\lambda(\mu) = -\mu^{-\epsilon}Z(\mu)^2\,\Gamma^{(4)}\Big|_{k_i^2=\mu^2,\; s=t=u=-\frac{4}{3}\mu^2},$$

where

$$Z(\mu) = \left(1 - \frac{\partial\Sigma}{\partial k^2}\right)^{-1}_{k^2=\mu^2}.$$

The subtraction point is nonexceptional: no nonempty proper subset of the external momenta has vanishing total momentum. The mass coordinate of this chart is fixed separately by the endpoint condition that the infrared two-point function be massless. Thus the displayed $\lambda(\mu)$ is a coordinate on the massless endpoint slice; the mass tuning is the separate condition that places the trajectory on that slice.

If several schemes are present, the coordinates of this chart will be denoted $\lambda_{\mathrm{MOM}}(\mu)$ and $Z_{\mathrm{MOM}}(\mu)$; the lighter notation $\lambda(\mu)$ and $Z(\mu)$ is used here only while no pole-subtraction field factor is being discussed. In particular, $Z_{\mathrm{MOM}}(\mu)$ is a finite residue normalization at the subtraction momentum, whereas the minimal-subtraction field factor introduced below contains only pole counterterms in ϵ.

Lemma 37.3 (One-loop quartic vector field)**.** *In the chart of Definition 37.2, the one-loop dimensionally regularized quartic RG vector field is*

$$\beta^{\epsilon}(\lambda) = \frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = -\epsilon\lambda + \left(\frac{3}{16\pi^2} + O(\epsilon)\right)\lambda^2 + O(\lambda^3).$$

Consequently the nonzero perturbative zero in the one-coupling massless chart has the formal small-ϵ expansion

$$\lambda_*(\epsilon) = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2).$$

Proof. At one loop $Z(\mu) = 1$, and the bubble graph gives

$$\lambda(\mu) = \mu^{-\epsilon}\left[g_0 - \frac{3}{2}g_0^2(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)}\left(\frac{4}{3}\mu^2\right)^{-\epsilon/2} + O(g_0^3)\right].$$

Let

$$A_0(\epsilon) = -\frac{3}{2}(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)}\left(\frac{4}{3}\right)^{-\epsilon/2}.$$

Then the preceding equation has the form

$$\lambda(\mu) = \mu^{-\epsilon}g_0 + A_0(\epsilon)\,\mu^{-2\epsilon}g_0^2 + O(g_0^3).$$

Differentiating at fixed bare coupling gives

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = -\epsilon\,\mu^{-\epsilon}g_0 - 2\epsilon\,A_0(\epsilon)\,\mu^{-2\epsilon}g_0^2 + O(g_0^3).$$

To express the right-hand side in terms of $\lambda(\mu)$, use

$$\mu^{-\epsilon}g_0 = \lambda(\mu) - A_0(\epsilon)\lambda(\mu)^2 + O(\lambda^3), \qquad \mu^{-2\epsilon}g_0^2 = \lambda(\mu)^2 + O(\lambda^3).$$

Thus

$$\frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = -\epsilon\lambda - \epsilon\lambda^2\left[-\frac{3}{2}(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)}\left(\frac{4}{3}\right)^{-\epsilon/2}\right] + O(\lambda^3).$$

The pole in the bracket is multiplied by the engineering factor ϵ; the result is finite order by order in the small but nonzero parameter ϵ. Since

$$-\frac{3}{2}(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)}\left(\frac{4}{3}\right)^{-\epsilon/2} = -\frac{3}{16\pi^2}\frac{1}{\epsilon} + O(\epsilon^0),$$

the $D = 4 - \epsilon$ beta function is denoted β^ϵ:

$$\beta^\epsilon(\lambda) = \frac{\mathrm{d}\lambda}{\mathrm{d}\log\mu} = -\epsilon\lambda + \left(\frac{3}{16\pi^2} + O(\epsilon)\right)\lambda^2 + O(\lambda^3).$$

This notation distinguishes the $4-\epsilon$-dimensional vector field from the strictly four-dimensional quartic beta function discussed in the 1PI RG chapter, which is obtained by setting the engineering term to zero. The zero of β^ϵ is

$$\lambda_* = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2).$$

For sufficiently small ϵ, the formal fixed-point coordinate lies in the perturbative domain in the following precise sense. The calculation constructs a formal power series

$$\lambda_*(\epsilon) = \sum_{r\geq 1} a_r\epsilon^r, \qquad a_1 = \frac{16\pi^2}{3},$$

whose coefficients are determined recursively from the beta function expanded as a formal series in λ and ϵ. At any finite loop order, one obtains a truncated polynomial vector field and a zero whose residual in the next omitted order is of higher order in ϵ. An exact RG flow or a nonperturbative continuum QFT with a fixed point at fixed positive ϵ requires additional input: for example a constructive Wilsonian or lattice continuum-limit theorem, or a summability theorem for the perturbative data together with a proof that the summed correlators satisfy the required locality, positivity, and regularity properties. In this chapter, unless a separate nonperturbative construction is explicitly stated, "the Wilson–Fisher fixed point" means this formal perturbative fixed-point data. The mass perturbation is a separate relevant direction and will be identified below from the ϕ^2 scaling operator. □

Remark 37.4 (Local uniqueness of the perturbative branch). The uniqueness statement supplied by this calculation is local and chart-dependent. Restrict to the one-component $\mathbb{Z}_2$-even scalar chart in which the mass has been tuned and the only displayed dimensionless interaction coordinate is λ. Put

$$\beta^\epsilon(\lambda) = -\epsilon\lambda + b\lambda^2 + O(\epsilon\lambda^2, \lambda^3), \qquad b = \frac{3}{16\pi^2}.$$

For a nonzero perturbative zero write $\lambda = \epsilon u$. Then

$$\epsilon^{-2}\beta^\epsilon(\epsilon u) = -u + bu^2 + O(\epsilon).$$

At $\epsilon = 0$ the nonzero root is

$$u_0 = b^{-1} = \frac{16\pi^2}{3},$$

and

$$\frac{\partial}{\partial u}(-u + bu^2)\bigg|_{u=u_0} = 1 \neq 0.$$

Equivalently, solving order by order in ϵ determines a unique formal branch $u(\epsilon) = u_0 + O(\epsilon)$ in a neighborhood of u_0. Together with the Gaussian branch $\lambda = 0$, this exhausts the small one-coupling branches visible in this local chart.

The scope is local uniqueness in the one-component $\mathbb{Z}_2$-even small-coupling scalar chart. Other perturbative fixed-point constructions belong to different charts or field contents: $O(N)$-vector

Wilson–Fisher fixed points, multicritical scalar fixed points such as the tricritical ϕ^6 branch near $D = 3 - \epsilon$, multi-coupling gauge or gauge–Yukawa fixed points of Banks–Zaks type, and decoupled product fixed points. Nonperturbative fixed points outside the small-coupling neighborhood require separate construction.

Figure 37.1 displays the local one-coordinate Wilson–Fisher construction: the symmetric Euclidean 1PI quartic vertex defines the coordinate, the beta function has the perturbative fixed point, and the critical trajectory is obtained after imposing the mass endpoint condition.

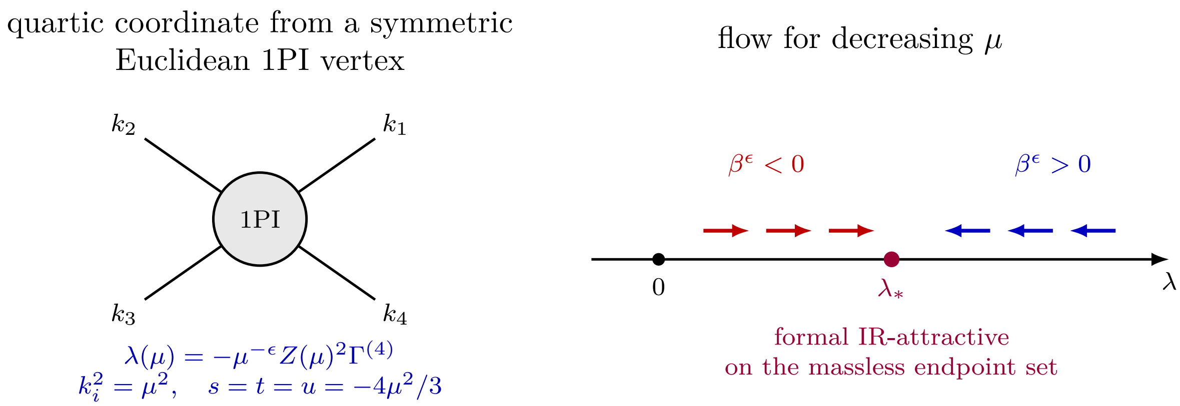

Figure 37.1: The dimensionless quartic coordinate is defined by a symmetric 1PI subtraction. In the formal $4-\epsilon$ perturbative vector field the classical term $-\epsilon\lambda$ and the one-loop term $3\lambda^2/(16\pi^2)$ balance at the nonzero zero λ_*. The displayed one-dimensional flow is the perturbative flow after the mass endpoint condition has been imposed.

The bare coupling and the renormalized coupling have different infrared behavior. The dimensionless bare coordinate $\mu^{-\epsilon}g_0$ diverges as $\mu \to 0$. In the formal perturbative RG equation, the renormalized coupling $\lambda(\mu)$, after the fluctuation correction in the 1PI coordinate definition is included, has the endpoint value $\lambda_*(\epsilon)$ along the massless critical trajectory.

Figure 37.2 separates these two coordinate behaviors: the dimensionless bare coordinate diverges under the infrared rescaling, while the renormalized coordinate approaches the Wilson–Fisher fixed-point value.

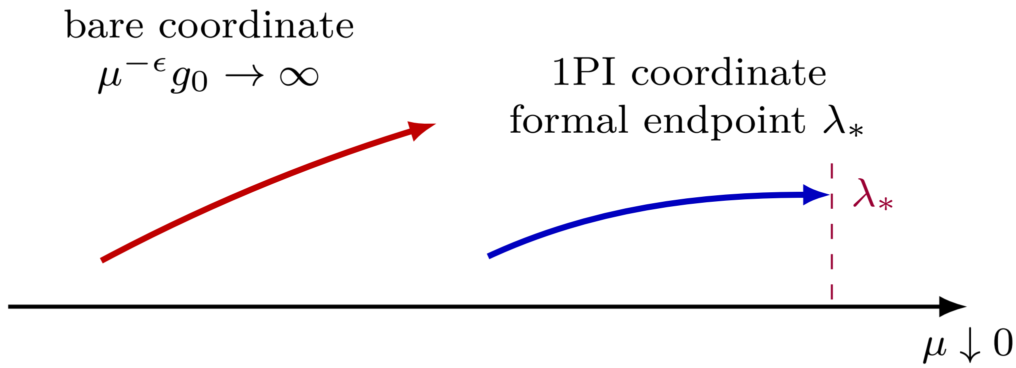

Figure 37.2: The finite infrared coupling in the formal perturbative flow is defined by the renormalized 1PI coordinate. The dimensionless bare coordinate grows without approaching a finite fixed-point value.

37.2 The First Scaling Operators

Definition 37.5 (Scaling operators in a local source-coordinate system)**.** Fix a renormalized local source-coordinate system near a fixed point. Thus one has a finite set of renormalized local fields O_A, with total derivatives, equation-of-motion fields, and the identity source either removed or placed in separate blocks, and a source deformation

$$\delta S = \sum_A \int \mathrm{d}^D x \, g^A(x) \, O_A(x).$$

For constant sources, let g^A denote the corresponding dimensionless coordinates and suppose that their RG equation has a linearization

$$\frac{\mathrm{d}g^A}{\mathrm{d}\log\mu} = -M^A{}_B \, g^B + O(g^2)$$

at the fixed point. A scaling source is an eigen-coordinate u^r of M. If

$$\frac{\mathrm{d}u^r}{\mathrm{d}\log\mu} = -y_r u^r + O(g^2),$$

then the dual scaling operator has dimension

$$\Delta_r = D - y_r.$$

Equivalently, under a change of physical scale $\mu \mapsto s\mu$ at the linearized fixed point, u^r scales as $s^{-y_r} u^r$. Relevant, marginal, and irrelevant directions are respectively those with $y_r > 0$, $y_r = 0$, and $y_r < 0$. This definition is local in the chosen source-coordinate system; if several fields with the same quantum numbers mix, the operators themselves are the eigenvectors of the mixing matrix, not the individual basis representatives.

The elementary field $O_1 = \phi$ has a fixed-point scaling dimension independent of finite analytic changes of the local field coordinate, but the anomalous-dimension function away from the fixed point depends on the renormalization chart. We compute it below in the minimal-subtraction pole chart. Let λ_{MS} be the dimensionless quartic coordinate in this chart, and let

$$\phi_0 = \left(Z_\phi^{\mathrm{MS}}\right)^{1/2} \phi_{\mathrm{MS}}, \qquad Z_\phi^{\mathrm{MS}}(\lambda_{\mathrm{MS}}, \epsilon) = 1 + \sum_{r\geq 1} \frac{Z_{\phi,r}(\lambda_{\mathrm{MS}})}{\epsilon^r},$$

where ϕ_0 is the regulated field appearing in the bare graph expansion and Z_ϕ^{MS} contains no finite part. The field anomalous dimension in this chart is

$$\gamma_\phi^{\mathrm{MS}}(\lambda_{\mathrm{MS}}) = \frac{1}{2}\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\log Z_\phi^{\mathrm{MS}}\bigg|_{g_0,\epsilon}.$$

Since $Z_\phi^{\mathrm{MS}} = 1 + O(\lambda_{\mathrm{MS}}^2)$ in scalar quartic theory, the field anomalous dimension starts only at order $\lambda_{\mathrm{MS},*}^2 = O(\epsilon^2)$. Thus

$$\Delta_\phi = \frac{D-2}{2} + \gamma_{\phi *}^{\mathrm{MS}} = 1 - \frac{\epsilon}{2} + O(\epsilon^2).$$

The conventional critical exponent η is defined by the long-distance two-point decay

$$\langle \phi(x)\phi(0)\rangle \sim |x|^{-D+2-\eta}.$$

Since a scalar primary of dimension Δ_ϕ has two-point exponent $2\Delta_\phi$, this convention gives

$$\eta = 2\Delta_\phi - (D-2) = 2\gamma_{\phi *}^{\mathrm{MS}}.$$

The first nonzero field anomalous dimension comes from the momentum-dependent part of the two-loop sunset self-energy. In the following pole computation write λ for λ_{MS}. With the interaction normalized as $\lambda\phi^4/4!$, the sunset graph has symmetry factor $1/6$, hence

$$\Sigma_{\mathrm{sun}}^{(2)}(k) = \frac{\lambda^2}{6}\,\mu^{2\epsilon} I(k), \qquad I(k) = \int_{p,q} \frac{1}{p^2 q^2 (p+q+k)^2}, \qquad \int_p := \int \frac{\mathrm{d}^{4-\epsilon}p}{(2\pi)^{4-\epsilon}}.$$

First integrate over q:

$$\int_q \frac{1}{q^2(q+p+k)^2} = \frac{1}{(4\pi)^{D/2}} \frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)} \left((p+k)^2\right)^{-\epsilon/2}, \qquad D = 4-\epsilon.$$

The remaining massless two-point integral gives

$$\begin{aligned} I(k) &= \frac{(k^2)^{1-\epsilon}}{(4\pi)^D} \frac{\Gamma(1-\epsilon/2)^3\Gamma(-1+\epsilon)}{\Gamma(3-3\epsilon/2)} \\ &= -\frac{k^2}{2(4\pi)^4}\frac{1}{\epsilon} + \text{finite and higher-order terms in } \epsilon. \end{aligned}$$

The factor $1/2$ is the $\Gamma(3)^{-1}$ value in this last two-point integral, equivalently the corresponding Feynman-parameter normalization. Multiplying it by the sunset symmetry factor $1/6$ gives the coefficient $1/12$. Therefore the divergent part of the derivative is

$$\frac{\partial \Sigma^{(2)}(k)}{\partial k^2}\bigg|_{\mathrm{div}} = -\frac{\lambda^2}{12(16\pi^2)^2}\frac{1}{\epsilon},$$

where the self-energy sign convention is the same as in the momentum-subtraction chart, but the subtraction now retains only the pole part. Write

$$a(\lambda) = \frac{\lambda^2}{12(16\pi^2)^2}.$$

The pole part of the minimal-subtraction field factor is determined by the same residue condition:

$$Z_\phi^{\mathrm{MS}} = \Big[(1-\partial_{k^2}\Sigma)^{-1}\Big]_{\mathrm{pole}} = 1 - \frac{a(\lambda)}{\epsilon} + O(\lambda^3, \epsilon^0)$$

where $[\cdot]_{\mathrm{pole}}$ means that all finite terms are discarded. The sign in the anomalous dimension is then fixed by differentiating at fixed regulator definition. To the order needed here $\beta_{\mathrm{MS}}(\lambda) = -\epsilon\lambda + O(\lambda^2)$, so

$$\frac{1}{2}\mu\frac{\mathrm{d}}{\mathrm{d}\mu}\log Z_\phi^{\mathrm{MS}} = \frac{1}{2}\beta_{\mathrm{MS}}(\lambda)\frac{\partial}{\partial\lambda}\left(-\frac{a(\lambda)}{\epsilon}\right) = a(\lambda) + O(\lambda^3).$$

Therefore

$$\gamma_\phi^{\mathrm{MS}}(\lambda) = \frac{\lambda^2}{12(16\pi^2)^2} + O(\lambda^3).$$

Substituting $\lambda_{\mathrm{MS},*} = (16\pi^2/3)\epsilon + O(\epsilon^2)$ gives

$$\eta = \frac{\epsilon^2}{54} + O(\epsilon^3)$$

in the interaction normalization $\lambda\phi^4/4!$. This value is not an artifact of the pole chart. If a second chart is obtained by a finite analytic coupling redefinition $\lambda' = \lambda + c_2\lambda^2 + O(\lambda^3)$ and the finite field-coordinate change $\phi' = F(\lambda)^{-1}\phi$, $F(0) = 1$, then

$$\gamma'_\phi(\lambda') = \gamma_\phi(\lambda) + \beta(\lambda)\frac{\partial \log F(\lambda)}{\partial\lambda}.$$

At an exact fixed point the second term vanishes. In the present ϵ-expansion, replacing λ_* by $\lambda'_* = \lambda_* + O(\lambda_*^2)$ changes $\gamma_\phi = A\lambda_*^2 + O(\lambda_*^3)$ only at order $O(\epsilon^3)$.

The operator $O_2 = \phi^2$ is more delicate. The constant source deformation

$$\delta S = \int \mathrm{d}^D x\, \delta g_2\, \phi^2(x)$$

corresponds to a zero-momentum insertion. In the massless theory, the one-loop graph then contains an infrared-divergent integral of the form

$$\int \frac{\mathrm{d}^D\ell}{(2\pi)^D}\frac{1}{(\ell^2)^2}.$$

The divergence is caused by the subtraction kinematics, not by the local UV definition of the operator. Equivalently, the scaling-degree extension of the coincident insertion controls the local counterterm ambiguity only after the massless infrared prescription has supplied a separated-point distribution to extend.

Use instead a spacetime-dependent source:

$$\delta S = \int \mathrm{d}^D x\, \delta g_2(x)\, O_2(x) = \int \frac{\mathrm{d}^D p}{(2\pi)^D}\, \delta\widetilde{g}_2(p)\, \widetilde{O}_2(-p).$$

Define the renormalized source by a nonzero-momentum 1PI insertion,

$$\delta\widetilde{g}_2(p;\mu) = -Z(\mu)\,(\text{amputated 1PI insertion of } O_2)\Big|_{k^2=(p+k)^2=\mu^2}.$$

The renormalized operator is determined by preserving the deformation:

$$\delta\widetilde{g}_2(p)\,\widetilde{O}_2(-p) = \delta\widetilde{g}_2(p;\mu)\,[\widetilde{O}_2(-p)]_\mu.$$

At $p^2 = \mu^2$, define

$$\gamma_2(\mu) = \frac{\mathrm{d}}{\mathrm{d}\log\mu}\log\left(\frac{\delta\widetilde{g}_2(p;\mu)}{\delta\widetilde{g}_2(p)}\right).$$

Figure 37.3 identifies the two insertion normalizations entering γ_2: the zero-momentum composite insertion and the fixed-momentum subtraction used to define the renormalized ϕ^2 coordinate.

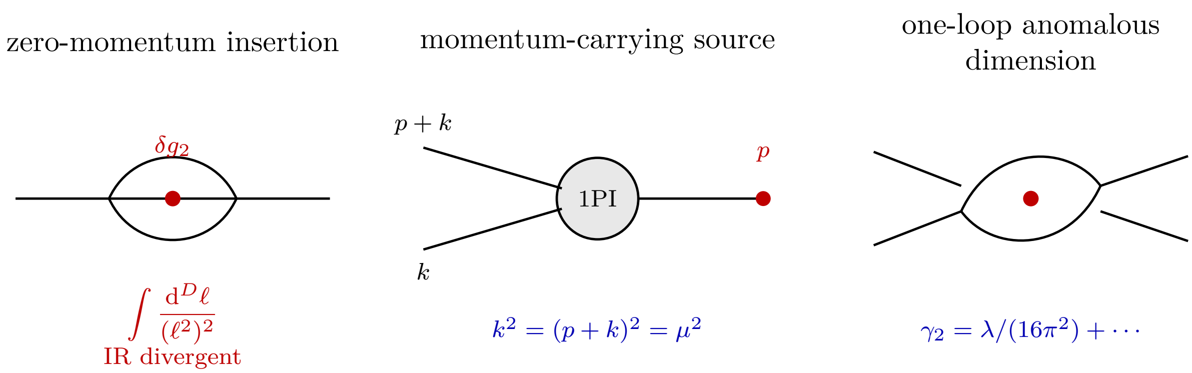

Figure 37.3: The ϕ^2 operator is renormalized by coupling it to a source with nonzero momentum. This avoids the infrared singularity of the zero-momentum subtraction and gives a finite definition of the anomalous dimension.

The one-loop source relation is

$$\delta\widetilde{g}_2(p;\mu) = \delta\widetilde{g}_2(p)\left[1 - \frac{g_4}{2}\int \frac{\mathrm{d}^{4-\epsilon}\ell}{(2\pi)^{4-\epsilon}}\frac{1}{\ell^2(p+\ell)^2} + O(g_4^2)\right],$$

or

$$\delta\widetilde{g}_2(p;\mu) = \delta\widetilde{g}_2(p)\left[1 - \frac{g_4}{2}(4\pi)^{-2+\epsilon/2}\frac{\Gamma(\epsilon/2)\Gamma(1-\epsilon/2)^2}{\Gamma(2-\epsilon)}|p|^{-\epsilon} + O(g_4^2)\right].$$

It follows that

$$\gamma_2(\mu) = \lambda(\mu)\left(\frac{1}{16\pi^2} + O(\epsilon)\right) + O(\lambda(\mu)^2).$$

At the Wilson-Fisher fixed point,

$$\gamma_{2*} = \frac{\epsilon}{3} + O(\epsilon^2), \qquad \Delta_{\phi^2} = (2-\epsilon) + \gamma_{2*} = 2 - \frac{2}{3}\epsilon + O(\epsilon^2).$$

Leading $N = 1$ scaling data. In the one-component scalar theory with interaction normalized as $\lambda\phi^4/4!$, the minimal-subtraction pole chart gives

$$\gamma_\phi(\lambda) = \frac{\lambda^2}{12(16\pi^2)^2} + O(\lambda^3), \qquad \gamma_2(\lambda) = \frac{\lambda}{16\pi^2} + O(\epsilon\lambda, \lambda^2).$$

On the nonzero small-ϵ fixed-point branch

$$\lambda_{\mathrm{MS},*} = \frac{16\pi^2}{3}\epsilon + O(\epsilon^2),$$

the elementary field and the even quadratic scalar have dimensions

$$\Delta_\phi = 1 - \frac{\epsilon}{2} + \frac{\epsilon^2}{108} + O(\epsilon^3), \qquad \Delta_{\phi^2} = 2 - \frac{2}{3}\epsilon + O(\epsilon^2).$$

Equivalently,

$$\eta = 2\gamma_{\phi*} = \frac{\epsilon^2}{54} + O(\epsilon^3), \qquad y_t = D - \Delta_{\phi^2} = 2 - \frac{\epsilon}{3} + O(\epsilon^2).$$

These are the direct scaling consequences of the pole data already computed. The field statement follows from the pole part of the sunset self-energy:

$$\log Z_\phi^{\mathrm{MS}} = -\frac{\lambda^2}{12(16\pi^2)^2}\frac{1}{\epsilon} + O(\lambda^3).$$

Since the engineering part of the beta function is $-\epsilon\lambda + O(\lambda^2)$, differentiating $\frac{1}{2}\log Z_\phi^{\mathrm{MS}}$ at fixed regulated theory gives

$$\gamma_\phi(\lambda) = \frac{1}{2}\left(-\epsilon\lambda\right)\frac{\partial}{\partial\lambda}\left[-\frac{\lambda^2}{12(16\pi^2)^2}\frac{1}{\epsilon}\right] + O(\lambda^3) = \frac{\lambda^2}{12(16\pi^2)^2} + O(\lambda^3).$$

The quadratic-source statement follows from the nonexceptional insertion calculation: the factor 1/2 in the one-loop graph and the pole of the massless two-point integral give

$$\log Z_{2,\mathrm{src}}^{\mathrm{MS}} = -\frac{\lambda}{16\pi^2}\frac{1}{\epsilon} + O(\lambda\epsilon^0, \lambda^2),$$

and the same fixed-regulator differentiation gives $\gamma_2(\lambda) = \lambda/(16\pi^2) + O(\epsilon\lambda, \lambda^2)$. The one-loop fixed point is obtained by solving

$$-\epsilon\lambda + \frac{3\lambda^2}{16\pi^2} + O(\lambda^3) = 0$$

on the nonzero formal branch. Substitution into

$$\Delta_\phi = \frac{D-2}{2} + \gamma_{\phi*}, \qquad \Delta_{\phi^2} = D - 2 + \gamma_{2*}$$

then gives the displayed dimensions. The formula for η is the definition of the two-point exponent $2\Delta_\phi = D - 2 + \eta$, and $y_t = D - \Delta_{\phi^2}$ is Definition 37.5 applied to the source dual to $[\phi^2]$.

37.3 Two-Loop Pole Data and NLO Epsilon Expansion

The preceding calculation gives the fixed-point branch and the thermal exponent to leading order. The next coefficient of ν, and the next coefficient of the quartic irrelevant exponent, require the two-loop minimal-subtraction pole data. This section stays in the one-component $\mathbb{Z}_2$-even scalar theory. The $O(N)$ generalization is a different tensor combinatorics problem and is not folded into the notation here.

Set

$$x := \frac{\lambda_{\rm MS}}{16\pi^2}.$$

With the action normalized by $\lambda\phi^4/4!$, the local pole part of the two-loop four-point calculation is

$$\frac{g_0}{16\pi^2} = \mu^\epsilon \left[x + \frac{3x^2}{\epsilon} + x^3\left(\frac{9}{\epsilon^2} - \frac{17}{6\epsilon}\right) + O(x^4)\right]. \tag{37.1}$$

The coefficient 3 is the sum of the s, t, u one-loop bubble channels in the $1/4!$ vertex normalization. The double pole $9/\epsilon^2$ is not a new primitive datum: it is fixed by inserting the one-loop local counterterm into the one-loop four-point graph and by the forest consistency condition that the cutoff coupling be independent of μ. The new two-loop four-point information is the simple pole $-17x^3/(6\epsilon)$. In a forest subtraction this number is the sum of the primitive two-loop four-point pole and the local remnants of its subgraph subtractions, evaluated at any nonexceptional Euclidean subtraction configuration; locality of the pole part makes it independent of the chosen configuration.

For the momentum-carrying ϕ^2 source used above, let $Z_{2,\rm src}^{\rm MS}$ denote the minimal-subtraction source factor

$$Z_{2,\rm src}^{\rm MS} := \frac{\delta\widetilde{g}_2(p;\mu)}{\delta\widetilde{g}_2(p)}. \tag{37.2}$$

Its logarithm has the simple-pole coefficient

$$\log Z_{2,\rm src}^{\rm MS} = \frac{-x + \frac{5}{12}x^2}{\epsilon} + \text{double poles} + O(x^3). \tag{37.3}$$

The $-x/\epsilon$ term is the one-loop nonzero-momentum insertion computed above. The $5x^2/(12\epsilon)$ term is the forest-subtracted two-loop simple pole of the same insertion: the one-loop source counterterm removes the nested subdivergence, and the remaining local part is proportional to the same source operator. The double poles in (37.3) are determined by lower-order subdivergences and cancel out of the finite anomalous dimension after the pole equations are imposed.

For the elementary field, the two-loop sunset computation already gave

$$\log Z_\phi^{\rm MS} = -\frac{x^2}{12\epsilon} + O(x^3). \tag{37.4}$$

Only this two-loop field pole is needed for η through order ϵ^2. The next coefficient of η would require the three-loop simple pole in $Z_\phi^{\rm MS}$, so it is not part of a two-loop calculation.

Two-loop $N = 1$ Wilson–Fisher epsilon data. In the minimal-subtraction chart with $x = \lambda_{\rm MS}/(16\pi^2)$, the two-loop beta function and anomalous dimensions determined by (37.1)–(37.4) are

$$\beta_x^\epsilon(x) := \frac{\mathrm{d}x}{\mathrm{d}\log\mu} = -\epsilon x + 3x^2 - \frac{17}{3}x^3 + O(x^4), \tag{37.5}$$

$$\gamma_2(x) = x - \frac{5}{6}x^2 + O(x^3), \tag{37.6}$$

$$\gamma_\phi(x) = \frac{x^2}{12} + O(x^3). \tag{37.7}$$

The nonzero small-ϵ zero is

$$x_* = \frac{\epsilon}{3} + \frac{17}{81}\epsilon^2 + O(\epsilon^3). \tag{37.8}$$

Consequently

$$\eta = \frac{\epsilon^2}{54} + O(\epsilon^3), \tag{37.9}$$

$$\Delta_\phi = 1 - \frac{\epsilon}{2} + \frac{\epsilon^2}{108} + O(\epsilon^3), \tag{37.10}$$

$$\gamma_{2*} = \frac{\epsilon}{3} + \frac{19}{162}\epsilon^2 + O(\epsilon^3), \tag{37.11}$$

$$\Delta_{\phi^2} = 2 - \frac{2}{3}\epsilon + \frac{19}{162}\epsilon^2 + O(\epsilon^3), \tag{37.12}$$

$$y_t := D - \Delta_{\phi^2} = 2 - \frac{\epsilon}{3} - \frac{19}{162}\epsilon^2 + O(\epsilon^3), \tag{37.13}$$

$$\nu := \frac{1}{y_t} = \frac{1}{2} + \frac{\epsilon}{12} + \frac{7}{162}\epsilon^2 + O(\epsilon^3), \tag{37.14}$$

$$\omega := \left.\frac{\partial\beta_x^\epsilon}{\partial x}\right|_{x=x_*} = \epsilon - \frac{17}{27}\epsilon^2 + O(\epsilon^3). \tag{37.15}$$

The derivation is the finite algebra of minimal-subtraction pole equations and fixed-point substitution. If

$$\frac{g_0}{16\pi^2} = \mu^\epsilon\left[x + \frac{Ax^2}{\epsilon} + x^3\left(\frac{A^2}{\epsilon^2} + \frac{C}{\epsilon}\right) + O(x^4)\right],$$

then differentiating at fixed g_0 gives

$$0 = \epsilon F(x,\epsilon) + \beta_x^\epsilon(x)\,\partial_x F(x,\epsilon), \qquad F(x,\epsilon) = x + \frac{Ax^2}{\epsilon} + x^3\left(\frac{A^2}{\epsilon^2} + \frac{C}{\epsilon}\right).$$

Writing $\beta_x^\epsilon = -\epsilon x + \beta_1 x^2 + \beta_2 x^3 + O(x^4)$ and comparing powers of x, the x^2 term gives $\beta_1 = A$. The $1/\epsilon$ part of the x^3 equation cancels because the double pole is A^2, and the finite part gives $\beta_2 = 2C$. In (37.1), $A = 3$ and $C = -17/6$, proving (37.5).

For a source factor whose logarithm is

$$\log Z(x,\epsilon) = \frac{\ell_1(x)}{\epsilon} + \text{higher poles},$$

the finite anomalous dimension is obtained from $\beta_x^\epsilon \partial_x \log Z$. The pole equations make the higher-pole contribution cancel the divergent pieces; the finite part is

$$-x\,\ell_1'(x)$$

for a source renormalization and

$$-\frac{1}{2}x\,\ell_1'(x)$$

for the field factor, because $\phi_0 = (Z_\phi^{\mathrm{MS}})^{1/2}\phi_{\mathrm{MS}}$. Applying this to $\ell_1^{(2)}(x) = -x + 5x^2/12$ gives (37.6), while $\ell_1^{\phi}(x) = -x^2/12$ gives (37.7).

To solve for the fixed point, put

$$x_* = a\epsilon + b\epsilon^2 + O(\epsilon^3).$$

Substitution into (37.5) gives

$$0 = (-a + 3a^2)\epsilon^2 + \left(-b + 6ab - \frac{17}{3}a^3\right)\epsilon^3 + O(\epsilon^4).$$

The nonzero branch has $a = 1/3$, and then the ϵ^3 equation gives $b = 17/81$, proving (37.8).

Equations (37.9)–(37.12) are direct substitutions of x_* into (37.7) and (37.6). The thermal exponent is

$$y_t = (4-\epsilon) - \Delta_{\phi^2},$$

and the expansion of its reciprocal gives

$$\frac{1}{2 - \epsilon/3 - 19\epsilon^2/162} = \frac{1}{2} + \frac{\epsilon}{12} + \frac{7\epsilon^2}{162} + O(\epsilon^3).$$

Finally,

$$\partial_x\beta_x^{\epsilon} = -\epsilon + 6x - 17x^2 + O(x^3),$$

and substituting x_* gives

$$-\epsilon + 6\left(\frac{\epsilon}{3} + \frac{17}{81}\epsilon^2\right) - 17\left(\frac{\epsilon}{3}\right)^2 = \epsilon - \frac{17}{27}\epsilon^2 + O(\epsilon^3).$$

37.4 Critical Surface and the Mass Exponent

The mass perturbation is the deformation generated by the renormalized operator $[O_2]_\mu$. Let t be a renormalized coefficient for this deformation, so that near the fixed point

$$\delta S_t = \int \mathrm{d}^D x\, t\,[O_2]_\mu(x).$$

The dimension of t at the fixed point is

$$y_t = D - \Delta_{\phi^2}.$$

Using the result above,

$$y_t = (4-\epsilon) - \left(2 - \frac{2}{3}\epsilon + \frac{19}{162}\epsilon^2\right) + O(\epsilon^3) = 2 - \frac{\epsilon}{3} - \frac{19}{162}\epsilon^2 + O(\epsilon^3).$$

This identification uses the fact that the thermal source is already a linearized scaling coordinate in the $\mathbb{Z}_2$-even scalar sector at the order being computed. More explicitly, let g^A denote source coordinates for a finite list of even scalar local operators O_A, with the identity operator and equation-of-motion or total-derivative redundant directions removed. The linearized source RG at the fixed point has the form

$$\frac{\mathrm{d}g^A}{\mathrm{d}\log\mu} = -M^A{}_B\, g^B + O(g^2),$$

and the relevant exponents are the eigenvalues of $M^A{}_B$, after diagonalizing possible operator mixing. In the one-component scalar theory at this order, the even scalar sector containing the mass deformation has a single relevant nontrivial basis element, represented by $[O_2]_\mu = [\phi^2]_\mu$. The identity source is the vacuum-energy coordinate and ϕ^4 is the quartic direction, whose fixed-point eigenvalue is the positive irrelevant exponent $\omega = \epsilon - \frac{17}{27}\epsilon^2 + O(\epsilon^3)$. Hence the thermal block is one-dimensional and its eigenvalue is $D - \Delta_{\phi^2}$. In a theory with another even scalar of the same quantum numbers and degenerate dimension, t would have to be replaced by the corresponding eigen-coordinate of $M^A{}_B$, and the formula above would refer to that eigenvalue rather than to a chosen basis operator. The corresponding dimensionless coordinate

$$\tau(\mu) = \mu^{-y_t} t$$

obeys, to linear order at the fixed point,

$$\frac{\mathrm{d}\tau}{\mathrm{d}\log\mu} = -y_t\,\tau + O(\tau^2, \tau(\lambda - \lambda_*)).$$

Thus τ grows when μ is lowered. In the $\mathbb{Z}_2$-even finite chart and to linear order at the fixed point, the condition $\tau = 0$ is the codimension-one relevant-coordinate condition, with the quartic coordinate flowing to λ_* along it. The corresponding nonlinear statement that the tuned set is a C^k codimension-one submanifold is the finite-reference implicit-function construction of Chapter 36 applied to the $\mathbb{Z}_2$-even RG chart, after the endpoint map and its nondegeneracy have been established. Choosing m_0^2 so that the long-distance theory is massless is the microscopic way of imposing this endpoint condition.

If the $\mathbb{Z}_2$ symmetry is not imposed, an odd deformation

$$\delta S_h = \int \mathrm{d}^D x\, h\, [\phi]_\mu(x)$$

is present. Its fixed-point eigenvalue is

$$y_h = D - \Delta_\phi = 3 - \frac{\epsilon}{2} - \frac{\epsilon^2}{108} + O(\epsilon^3),$$

so h is also relevant. The statement that the massless critical surface has one relevant tuning condition is therefore a statement about the $\mathbb{Z}_2$-even subspace; in the local chart including h, both h and t must be set to zero to reach the symmetric Wilson-Fisher fixed point. A codimension statement again uses the Banach-chart hypotheses of the finite-reference implicit-function construction.

Let a trajectory start at a reference scale μ_0 with small nonzero $\tau_0 = \tau(\mu_0)$. Linearized running gives

$$\tau(\mu) = \tau_0 \left(\frac{\mu}{\mu_0}\right)^{-y_t}.$$

The scale at which $|\tau(\mu)|$ becomes order one sets the inverse correlation length:

$$\xi^{-1} \propto \mu_0 \, |\tau_0|^{1/y_t}.$$

Therefore the correlation-length exponent in this perturbative calculation is

$$\nu = \frac{1}{y_t} = \frac{1}{2} + \frac{\epsilon}{12} + \frac{7}{162}\epsilon^2 + O(\epsilon^3).$$

The proportionality constant in ξ^{-1} depends on the normalization of the thermal scaling field τ; the exponent does not.

Figure 37.4 records the $\mathbb{Z}_2$-even critical surface in the local coordinates used here: the thermal direction is relevant, while the critical trajectory flows into the interacting fixed point.

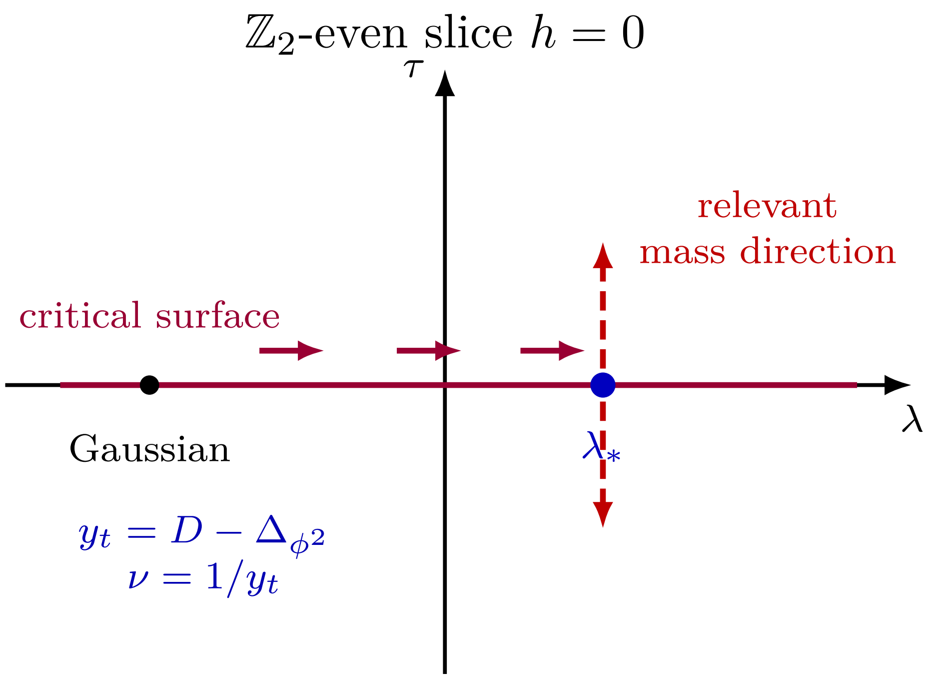

Figure 37.4: In the $\mathbb{Z}_2$-even finite chart, the massless endpoint condition removes the relevant thermal direction. The dashed transverse arrows show the mass perturbation, the direction dual to $[O_2]$, with eigenvalue $y_t = D - \Delta_{\phi^2}$.

37.5 Correlators and Local Composite Fields

At the fixed point, the running of the renormalized momentum-space operator is

$$[\widetilde{O}_2(p)]_{\mu=|p|} = \left(\frac{|p|}{\mu_0}\right)^{-\gamma_{2*}} \widetilde{O}_2(p),$$

where μ_0 is a fixed reference scale. The correlator of renormalized operators is finite and, by dimensional analysis,

$$\left\langle [\widetilde{O}_2(p)]_{\mu=|p|} [\widetilde{O}_2(q)]_{\mu=|q|} \right\rangle \propto \delta^{(4-\epsilon)}(p+q)\, |p|^{-\epsilon}.$$

Consequently

$$\mu_0^{2\gamma_{2*}} \left\langle \widetilde{O}_2(p)\widetilde{O}_2(q) \right\rangle \propto \delta^{(4-\epsilon)}(p+q)\, |p|^{-\epsilon+2\gamma_{2*}}.$$

Fourier transformation gives the position-space scaling law

$$\mu_0^{2\gamma_{2*}} \langle O_2(x)O_2(0)\rangle \propto \frac{1}{|x|^{2\Delta_{\phi^2}}}, \qquad \Delta_{\phi^2} = 2-\epsilon+\gamma_{2*}.$$

Figure 37.5 displays the invariant content of this calculation. Once a common normalization is chosen at $\mu_0|x| = 1$, the scaling dimension is the slope of the correlator on logarithmic axes. The anomalous dimension γ_{2*} changes that slope by $2\gamma_{2*}$, not by introducing a new scale.

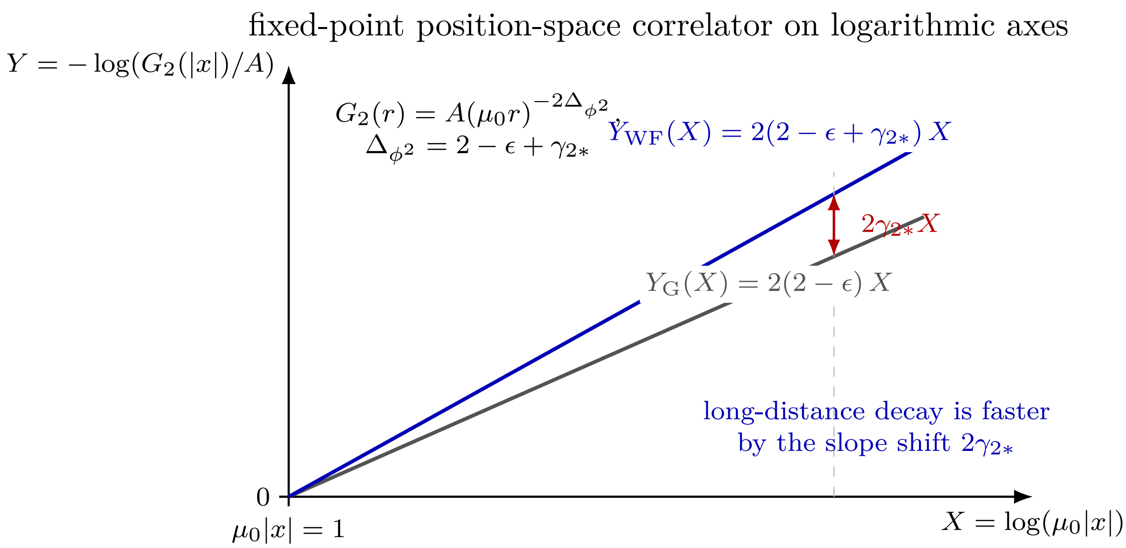

Figure 37.5: Logarithmic plot of the ϕ^2 two-point function at a fixed point, with $G_2(r) = \mu_0^{2\gamma_{2*}}\langle O_2(x)O_2(0)\rangle$, $r = |x|$, and a common normalization $G_2(1/\mu_0) = A$. The Gaussian scalar composite has slope $2(2-\epsilon)$. The Wilson–Fisher scaling operator has slope $2\Delta_{\phi^2} = 2(2-\epsilon+\gamma_{2*})$. Thus the anomalous dimension appears as a slope shift $2\gamma_{2*}$ in the log-log correlator.

There is a related locality point. The object obtained by choosing the subtraction scale separately for each Fourier mode,

$$[O_2(x)]_{\mathrm{mode}} = \int \frac{\mathrm{d}^{4-\epsilon}p}{(2\pi)^{4-\epsilon}}\, e^{ip\cdot x}\, [\widetilde{O}_2(p)]_{\mu=|p|},$$

is not a local field. By the running formula it equals

$$\int \frac{\mathrm{d}^{4-\epsilon}p}{(2\pi)^{4-\epsilon}}\, e^{ip\cdot x} \left(\frac{|p|}{\mu_0}\right)^{-\gamma_{2*}} \widetilde{O}_2(p),$$

and multiplication by the non-polynomial function $|p|^{-\gamma_{2*}}$ is nonlocal in position space. The local scaling field is obtained by fixing the reference normalization once and for all.

The notation $O_2 = \phi^2$ is a label for the renormalized local field in this operator family; it is not a definition by an unregulated product at coincident points. A point-splitting representative has the form

$$\mu_0^{\gamma_{2*}} O_2(x) \propto \lim_{x'\to x} |x'-x|^{2\gamma_{\phi*}-\gamma_{2*}} \left[\hat{\phi}(x')\hat{\phi}(x) - \left\langle \hat{\phi}(x')\hat{\phi}(x) \right\rangle\right],$$

where the subtraction removes the singular two-point function before the coincident-point limit is taken.

37.6 Descendants and Irrelevant Directions

The cubic operator is not independent at the interacting fixed point. In the renormalized operator algebra, the equation of motion gives a descendant relation with a coupling-dependent normalization. If the renormalized dimensionful quartic coupling is written as

$$g_R(\mu) = \mu^\epsilon \lambda(\mu),$$

then, away from contact terms and up to the overall sign convention for $\Box$, the renormalized equation of motion gives

$$\Box\phi(x) = \frac{g_R(\mu)}{3!}\,[\phi^3(x)]_\mu.$$

At the fixed point this is equivalently

$$[\phi^3(x)]_\mu = \frac{3!}{\mu^\epsilon \lambda_*}\,\Box\phi(x),$$

again modulo contact terms and finite normalizations of the chosen composite operator. If the proportionality coefficient is denoted by $\kappa_*(\mu)$,

$$[\phi^3(x)]_\mu = \kappa_*(\mu)\,\Box\phi(x),$$

then the action normalization above gives, at the classical level,

$$\kappa_{\rm cl}(\mu) = \frac{3!}{g_R(\mu)} = \frac{6}{g_R(\mu)}.$$

A perturbative finite normalization of the composite operator replaces this by

$$\kappa_*(\mu) = \frac{6}{g_R(\mu)}\big(1 + O(g_R(\mu))\big) = \frac{6}{g_R(\mu)} + O(1),$$

with the $O(1)$ term depending on the composite-operator convention. The statement invariant under such choices is that O_3 is an equation-of-motion descendant of $O_1 = \phi$. Its dimension is

$$\Delta_{\phi^3} = \Delta_\phi + 2.$$

The quartic operator $O_4 = \phi^4$ is instead the operator associated with motion in the quartic-coupling direction. As for O_2, one may first use a momentum-dependent source,

$$\delta S_4 = \int \mathrm{d}^D x\, \delta g_4(x)\, \phi^4(x) = \int \frac{\mathrm{d}^D p}{(2\pi)^D}\, \delta\widetilde{g}_4(p)\, \widetilde{O}_4(-p).$$

The renormalized source is extracted from a four-point 1PI insertion with external momenta of order μ and source momentum $p = O(\mu)$. In this case one may set $p = 0$: the massless infrared singularity that obstructed the zero-momentum O_2 subtraction is absent for this insertion. The momentum-dependent source definition therefore agrees with the earlier x-independent coupling-deformation definition. A small source perturbation obeys the linearized RG equation

$$\frac{\mathrm{d}\,\delta g_4(\mu)}{\mathrm{d}\log\mu} = \frac{\partial\beta^\epsilon(\lambda(\mu))}{\partial\lambda(\mu)}\,\delta g_4(\mu).$$

Therefore

$$\omega = \frac{\partial\beta^\epsilon(\lambda)}{\partial\lambda}\bigg|_{\lambda=\lambda_*} = \left(-\epsilon + \frac{3\lambda}{8\pi^2} - \frac{17\lambda^2}{(16\pi^2)^2} + O(\lambda^3)\right)\bigg|_{\lambda=16\pi^2\left(\frac{\epsilon}{3}+\frac{17}{81}\epsilon^2\right)+O(\epsilon^3)} = \epsilon - \frac{17}{27}\epsilon^2 + O(\epsilon^3),$$

which is positive. This positivity is the same statement as infrared attractiveness of the quartic direction when the flow is followed toward smaller μ. The scaling dimension is therefore

$$\Delta_{\phi^4} = D + \omega = 4 - \frac{17}{27}\epsilon^2 + O(\epsilon^3) > D.$$

Thus ϕ^4 is irrelevant at the interacting fixed point. This statement is about perturbations around the fixed point; it is compatible with the fact that the quartic interaction was needed to produce that fixed point.

Figure 37.6 summarizes the local operator-spectrum conclusion of this perturbative calculation: descendants, relevant primaries, and the quartic perturbation's irrelevant fixed-point eigenvalue occupy distinct roles.

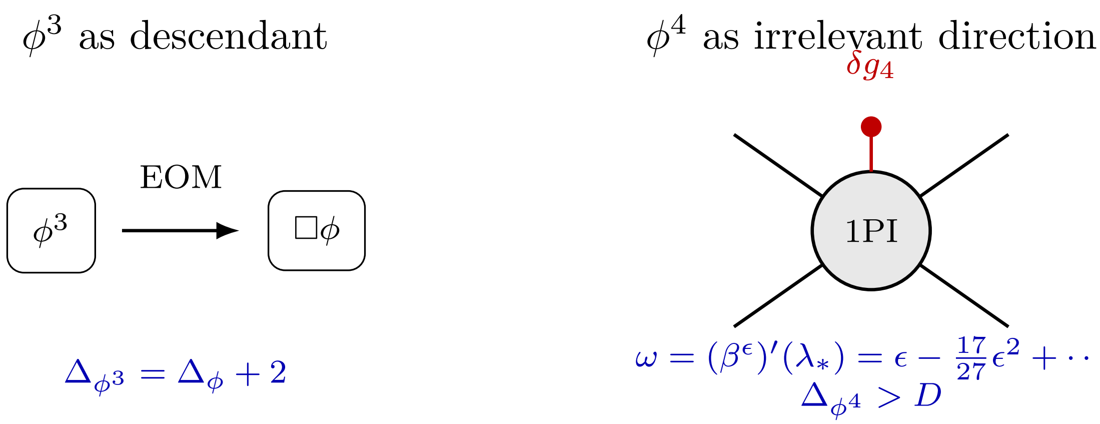

Figure 37.6: The cubic operator is an equation-of-motion descendant. The quartic operator is independent, but its dimension is larger than D at the interacting fixed point, so changing its coefficient is an irrelevant deformation.

The low-lying scalar dimensions are summarized as follows. In the third column, O_{irr} denotes the leading nonredundant $\mathbb{Z}_2$-even scalar irrelevant deformation after the identity and the energy operator have been removed. In the $4-\epsilon$ perturbative chart this direction is represented by ϕ^4; in lower-dimensional fixed-point CFTs the notation O_{irr} refers to the corresponding scaling operator, not to an unrenormalized fourth power of the spin field.

	Δ_ϕ	Δ_{ϕ^2}	$\Delta_{O_{\mathrm{irr}}}$
$d=4-\epsilon$	$1-\frac{\epsilon}{2}+\frac{\epsilon^2}{108}+O(\epsilon^3)$	$2-\frac{2}{3}\epsilon+\frac{19}{162}\epsilon^2+O(\epsilon^3)$	$4-\frac{17}{27}\epsilon^2+O(\epsilon^3)$
$d=3$	0.518148806(24)	1.41262528(29)	3.82951(61)
$d=2$	$\frac{1}{8}$	1	4

The first row is the perturbative epsilon expansion. The $d = 3$ and $d = 2$ rows are data about the corresponding fixed points themselves; they are not deduced by substituting $\epsilon = 1$ or $\epsilon = 2$ into the finite truncation displayed in the first row. In the $d = 3$ row the fixed-point fields are conventionally denoted $\sigma, \varepsilon, \varepsilon'$: ϕ, ϕ^2, ϕ^4 are the Landau representatives of the corresponding scaling directions, not definitions by unrenormalized powers at the fixed point. The displayed numerical values are conformal-bootstrap data for the three-dimensional Ising CFT. The quoted Δ_σ and Δ_ε are the mixed-correlator values reported in Chang, Dommes, Erramilli, Homrich, Kravchuk, Liu, Mitchell, Poland, and Simmons-Duffin, *Bootstrapping the 3d Ising Stress Tensor*, arXiv:2411.15300; earlier precision islands for these two dimensions were obtained by El-Showk, Paulos, Poland, Rychkov, Simmons-Duffin, and Vichi, *Phys. Rev. D* **86** (2012) 025022, arXiv:1203.6064; *J. Stat. Phys.* **157** (2014) 869–914, arXiv:1403.4545; and by Kos, Poland, Simmons-Duffin, and Vichi, *JHEP* **08** (2016) 036, arXiv:1603.04436. The value in the third column is the dimension of the leading $\mathbb{Z}_2$-even scalar irrelevant primary ε', whose Landau representative is the quartic direction; the number displayed here is the spectral estimate quoted in Simmons-Duffin, *JHEP* **03** (2017) 086, arXiv:1612.08471. The mixed-correlator crossing and positivity system underlying the $\Delta_\sigma, \Delta_\varepsilon$ island is derived from the higher-dimensional conformal-block conventions in Section 64.10; the numerical island itself remains external high-precision input rather than a theorem proved in this perturbative Wilson–Fisher chapter.

The $d = 2$ row is exact CFT data. The critical Ising CFT is the unitary minimal model $\mathcal{M}(3, 4)$ with Virasoro primaries σ and ε of weights

$$(h_\sigma, \bar{h}_\sigma) = \left(\frac{1}{16}, \frac{1}{16}\right), \qquad (h_\varepsilon, \bar{h}_\varepsilon) = \left(\frac{1}{2}, \frac{1}{2}\right),$$

so $\Delta_\sigma = h_\sigma + \bar{h}_\sigma = 1/8$ and $\Delta_\varepsilon = 1$. The scalar irrelevant entry of dimension 4 is the $T\bar{T}$ Virasoro descendant of the identity, the two-dimensional continuation of the leading even irrelevant lattice-scalar direction recorded in the third column. It is not the dimension of an unrenormalized σ^4 operator. These exact statements are the conformal-field-theoretic form of the Onsager critical Ising solution, and follow from the minimal-model classification of Belavin, Polyakov, and Zamolodchikov.

37.7 The $O(N)$ Wilson–Fisher Family

Definition 37.6 ($O(N)$ quartic scalar chart)**.** For a positive integer N, let $\phi = (\phi^1, \ldots, \phi^N)$ be an $O(N)$-vector scalar. Indices are raised and lowered with δ_{ij}, repeated $O(N)$ indices are summed, and

$$\phi^2 := \delta_{ij}\phi^i\phi^j.$$

The $O(N)$-invariant quartic theory in $D = 4 - \epsilon$ is

$$S_E[\phi] = \int \mathrm{d}^D x \left[\frac{1}{2}\partial_\mu\phi^i\partial_\mu\phi^i + \frac{1}{2}r_0\,\phi^i\phi^i + \frac{g_0}{4!}\,(\phi^i\phi^i)^2\right]. \tag{37.16}$$

The quartic vertex tensor associated with the normalization in (37.16) is

$$V_{ij;kl} = \frac{g_0}{3}\left(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}\right). \tag{37.17}$$

For $N = 1$ the tensor in parentheses equals 3, so this is the same $g_0\phi^4/4!$ normalization used above. The singlet quadratic source is coupled to

$$S(x) := \frac{1}{2}\phi^i(x)\phi^i(x).$$

The factor $1/2$ is a source convention; it does not affect the scaling dimension.

Set again

$$x := \frac{\lambda_{\mathrm{MS}}}{16\pi^2}.$$

The one-component theory is the $N = 1$ member of this family. In the minimal-subtraction chart determined by the singlet quartic vertex (37.17), the two-loop local pole map is

$$\frac{g_0}{16\pi^2} = \mu^\epsilon\left[x + \frac{N+8}{3}\frac{x^2}{\epsilon} + x^3\left\{\frac{(N+8)^2}{9\epsilon^2} - \frac{3N+14}{6\epsilon}\right\} + O(x^4)\right]. \tag{37.18}$$

The coefficient $N + 8$ has a concrete origin. In a one-loop four-point graph, the closed internal index loop gives the N term, while the exchange contractions among the three tensor structures in (37.17) give the 8 term. The double pole in (37.18) is fixed by this one-loop tensor contraction and the forest equations. The new two-loop tensor datum is the simple-pole coefficient $-(3N+14)/6$.

The singlet source and field pole factors are

$$\log Z^{\mathrm{MS}}_{S,\mathrm{src}} = \frac{-\frac{N+2}{3}x + \frac{5(N+2)}{18}x^2}{\epsilon} + \text{double poles} + O(x^3), \tag{37.19}$$

$$\log Z^{\mathrm{MS}}_{\phi} = -\frac{N+2}{36}\frac{x^2}{\epsilon} + O(x^3). \tag{37.20}$$

The factor $N + 2$ is the index contraction of a singlet ϕ^2 insertion with the quartic tensor. The same pole-equation argument used in the one-component calculation gives the finite anomalous dimensions.

$O(N)$ **Wilson–Fisher data through two loops.** In the MS coordinate $x = \lambda_{\mathrm{MS}}/(16\pi^2)$, the singlet $O(N)$-invariant quartic chart has

$$\beta^\epsilon_x = -\epsilon x + \frac{N+8}{3}x^2 - \frac{3N+14}{3}x^3 + O(x^4), \tag{37.21}$$

$$\gamma_S(x) = \frac{N+2}{3}x - \frac{5(N+2)}{18}x^2 + O(x^3), \tag{37.22}$$

$$\gamma_\phi(x) = \frac{N+2}{36}x^2 + O(x^3). \tag{37.23}$$

The nonzero perturbative fixed-point coordinate is

$$x_* = \frac{3}{N+8}\epsilon + \frac{9(3N+14)}{(N+8)^3}\epsilon^2 + O(\epsilon^3). \tag{37.24}$$

The singlet thermal exponent, field anomalous dimension, and leading quartic irrelevant exponent are

$$\eta = \frac{N+2}{2(N+8)^2}\epsilon^2 + O(\epsilon^3), \tag{37.25}$$

$$\Delta_\phi = 1 - \frac{\epsilon}{2} + \frac{N+2}{4(N+8)^2}\epsilon^2 + O(\epsilon^3), \tag{37.26}$$

$$\Delta_S = 2 - \frac{6}{N+8}\epsilon + \frac{(N+2)(13N+44)}{2(N+8)^3}\epsilon^2 + O(\epsilon^3), \tag{37.27}$$

$$y_t := D - \Delta_S = 2 - \frac{N+2}{N+8}\epsilon - \frac{(N+2)(13N+44)}{2(N+8)^3}\epsilon^2 + O(\epsilon^3), \tag{37.28}$$

$$\nu := \frac{1}{y_t} = \frac{1}{2} + \frac{N+2}{4(N+8)}\epsilon + \frac{(N+2)(N^2+23N+60)}{8(N+8)^3}\epsilon^2 + O(\epsilon^3), \tag{37.29}$$

$$\omega := \partial_x \beta_x^\epsilon|_{x=x_*} = \epsilon - \frac{3(3N+14)}{(N+8)^2}\epsilon^2 + O(\epsilon^3). \tag{37.30}$$

This is the $O(N)$ tensor-combinatoric analogue of the previous minimal-subtraction calculation. Let

$$A = \frac{N+8}{3}, \qquad C = -\frac{3N+14}{6}.$$

Equation (37.18) has the same algebraic form as the one-component pole map:

$$\frac{g_0}{16\pi^2} = \mu^\epsilon \left[x + \frac{Ax^2}{\epsilon} + x^3\left(\frac{A^2}{\epsilon^2} + \frac{C}{\epsilon}\right) + O(x^4) \right].$$

Differentiation at fixed g_0 gives $\beta_x^\epsilon = -\epsilon x + Ax^2 + 2Cx^3 + O(x^4)$, which is (37.21). The simple-pole coefficient in (37.19) is

$$\ell_1^S(x) = -\frac{N+2}{3}x + \frac{5(N+2)}{18}x^2.$$

The finite source anomalous dimension is $-x(\ell_1^S)'(x)$, up to terms beyond two loops, giving (37.22). Similarly the field simple-pole coefficient $\ell_1^\phi(x) = -(N+2)x^2/36$ gives $-\frac{1}{2}x(\ell_1^\phi)'(x)$, namely (37.23).

Solving $\beta_x^\epsilon(x_*) = 0$ with $x_* = a\epsilon + b\epsilon^2 + O(\epsilon^3)$ gives

$$a = \frac{1}{A} = \frac{3}{N+8}, \qquad b = -\frac{2C}{A^3} = \frac{9(3N+14)}{(N+8)^3},$$

which proves (37.24). Substituting (37.24) into (37.23) gives $\eta = 2\gamma_\phi(x_*)$, hence (37.25) and (37.26). Substitution into (37.22) gives

$$\gamma_S(x_*) = \frac{N+2}{N+8}\epsilon + \frac{(N+2)(13N+44)}{2(N+8)^3}\epsilon^2 + O(\epsilon^3).$$

Since the singlet S has engineering dimension $D-2 = 2-\epsilon$, $\Delta_S = 2 - \epsilon + \gamma_S(x_*)$. Equations (37.27)–(37.29) follow by expanding $y_t = D - \Delta_S = 2 - \gamma_S(x_*)$ and then its reciprocal. Finally,

$$\partial_x \beta_x^\epsilon = -\epsilon + \frac{2(N+8)}{3}x - (3N+14)x^2 + O(x^3),$$

and substituting (37.24) gives (37.30).

For $N = 1$, the $O(N)$ two-loop data reduce to the one-component formulas above. For $N > 1$ there are additional non-singlet operator sectors. The symmetric traceless tensor

$$T^{ij} := \phi^i \phi^j - \frac{\delta^{ij}}{N} \phi^k \phi^k$$

and the vector ϕ^i have their own source-RG blocks. The formulas above concern the singlet thermal direction and the elementary vector field. A complete operator-spectrum analysis must diagonalize each $O(N)$ representation sector separately.

37.7.1 Large N, the Spherical Model, and the Sigma-Model Chart

The limit $N \to \infty$ is not obtained by holding x fixed. The fixed point in (37.24) has $x_* = O(1/N)$, while the collective coordinate

$$u := Nx$$

has a finite limit. Multiplying (37.21) by N and putting $x = u/N$ gives

$$\beta_u^{\epsilon} = -\epsilon u + \frac{1}{3} u^2 + O\left(\frac{1}{N}\right), \qquad u_* = 3\epsilon + O\left(\frac{1}{N}\right). \tag{37.31}$$

Thus the quartic coordinate of each finite-N fixed point tends to zero, but the singlet collective interaction stays finite.

The nonperturbative large-N limit is best derived before expanding around four dimensions. Work with a finite ultraviolet cutoff and an $O(N)$-invariant potential of the form

$$S[\phi] = \int \mathrm{d}^D x \left[\frac{1}{2} \partial_\mu \phi^i \partial_\mu \phi^i + N\, U(\rho)\right], \qquad \rho := \frac{\phi^i \phi^i}{N}. \tag{37.32}$$

At finite cutoff, introduce fields $\rho(x)$ and $\sigma(x)$ by a Fourier representation of the constraint $\rho(x) = \phi^i(x)\phi^i(x)/N$. The contour of σ is chosen so that the finite-dimensional regulated integral is convergent and may be deformed to the steepest-descent contour. After integrating over the N vector components, the effective action per component is

$$\frac{1}{N} S_{\text{eff}}[\rho, \sigma] = \int \mathrm{d}^D x \left[U(\rho) - \frac{1}{2} \sigma \rho\right] + \frac{1}{2} \operatorname{Tr}_\Lambda \log(-\partial^2 + \sigma). \tag{37.33}$$

For constant saddle fields, write $\sigma = m^2$. The saddle equations are

$$U'(\rho) = \frac{1}{2} m^2, \qquad \rho = \Omega_D(m), \qquad \Omega_D(m) := \int^\Lambda \frac{\mathrm{d}^D p}{(2\pi)^D} \frac{1}{p^2 + m^2}, \tag{37.34}$$

in the symmetric phase. If an ordered component $\langle \phi^1 \rangle = M$ is allowed, the second equation becomes

$$\rho = \frac{M^2}{N} + \Omega_D(m), \qquad m^2 M = 0.$$

The critical point is obtained by tuning the relevant parameter in U so that $m = 0$ is a saddle:

$$\rho_c = \Omega_D(0), \qquad U'(\rho_c) = 0.$$

For $2 < D < 4$, the small-m expansion of the regulated integral has a universal nonanalytic term

$$\Omega_D(m) - \Omega_D(0) = -K_D\, m^{D-2} + O(m^2\Lambda^{D-4}), \qquad K_D := -\frac{\Gamma(1-D/2)}{(4\pi)^{D/2}} > 0. \tag{37.35}$$

The sign is fixed by the fact that $\Omega_D(m)$ decreases with m. If τ is the linear thermal displacement from the critical saddle, then

$$\tau \propto m^{D-2}, \qquad \xi = m^{-1},$$

and therefore

$$\nu_{N=\infty} = \frac{1}{D-2}. \tag{37.36}$$

This agrees with the $N \to \infty$ limit of (37.29) after setting $D = 4 - \epsilon$:

$$\frac{1}{D-2} = \frac{1}{2-\epsilon} = \frac{1}{2} + \frac{\epsilon}{4} + \frac{\epsilon^2}{8} + O(\epsilon^3).$$

At the critical saddle the vector two-point function is $1/p^2$, so

$$\Delta_\phi = \frac{D-2}{2}, \qquad \eta_{N=\infty} = 0.$$

The singlet thermal operator is represented at large N by the auxiliary field σ, not by an unrenormalized pointwise product. Its quadratic kernel contains the bubble

$$B_D(p) := \int \frac{\mathrm{d}^D q}{(2\pi)^D}\frac{1}{q^2(q+p)^2} = b_D\,|p|^{D-4}, \qquad b_D = \frac{\Gamma(2-D/2)\Gamma(D/2-1)^2}{(4\pi)^{D/2}\Gamma(D-2)}. \tag{37.37}$$

For $2 < D < 4$, this term dominates over the local $U''(\rho_c)$ term at small momentum. Hence the σ propagator scales as

$$\langle \sigma(p)\sigma(-p)\rangle \propto |p|^{4-D}.$$

A scalar operator of dimension Δ has momentum-space two-point scaling $|p|^{2\Delta-D}$. Thus

$$\Delta_\sigma = 2, \qquad y_t = D - \Delta_\sigma = D - 2, \tag{37.38}$$

which is the same content as (37.36).

Example 37.7 (Large-N critical saddle)**.** Consider the finite-cutoff $O(N)$-invariant scalar model (37.32), with U tuned so that the translation-invariant large-N saddle has $m = 0$. Assume $2 < D < 4$, the cutoff is removed only after the saddle equations have been expressed in terms of a fixed finite critical displacement τ, and the saddle remains on a steepest-descent contour obtained from the regulated finite-dimensional integral. Then at $N = \infty$

$$\Delta_\phi = \frac{D-2}{2}, \qquad \eta = 0, \qquad \Delta_\sigma = 2, \qquad \nu = \frac{1}{D-2}.$$

At the critical saddle the inverse vector propagator is p^2, hence the vector two-point function scales as p^{-2}. Comparing with the momentum-space scaling law $|p|^{2\Delta_\phi - D}$ gives $2\Delta_\phi - D = -2$, or $\Delta_\phi = (D-2)/2$, and therefore $\eta = 0$.

The thermal displacement is measured by the saddle mass m. For $2 < D < 4$, the cutoff integral has the nonanalytic small-m expansion

$$\Omega_D(m) - \Omega_D(0) = -K_D m^{D-2} + O(m^2\Lambda^{D-4}), \qquad K_D > 0,$$

so a finite critical displacement satisfies $\tau \propto m^{D-2}$. Since the correlation length of the vector propagator is $\xi = m^{-1}$, this gives $\xi \propto |\tau|^{-1/(D-2)}$, hence $\nu = 1/(D-2)$.

Finally, the quadratic kernel of the collective field σ is dominated in the infrared by the bubble

$$B_D(p) = b_D |p|^{D-4}$$

rather than by the local term. Its propagator therefore scales as $|p|^{4-D}$. Comparing $|p|^{4-D}$ with $|p|^{2\Delta_\sigma - D}$ gives $\Delta_\sigma = 2$. The source dual to σ is the thermal source, so $y_t = D - \Delta_\sigma = D - 2$, consistently reproducing the value of ν just derived.

The first nonzero field anomalous dimension is an $O(1/N)$ effect from exchange of the collective σ field; the present saddle calculation establishes the exact $N = \infty$ dimensions and gives the expansion point for the systematic $1/N$ diagrammatics.

Equations (37.34) are the continuum field-theory form of the spherical model: the fluctuating N-component spin length is replaced, at $N = \infty$, by a saddle constraint on $\rho = \phi^2/N$. This is a statement about the regulated large-N limit and its continuum critical saddle, not an independent postulate about universality.

There is also a lower-critical-dimension chart. The $O(N)$ nonlinear sigma model with field $n^i(x)$ constrained by $n^i n^i = N$ has regulated action

$$S_\sigma[n, \alpha] = \frac{1}{2T} \int \mathrm{d}^D x \, \left[\partial_\mu n^i \partial_\mu n^i + \alpha(n^i n^i - N)\right]. \tag{37.39}$$

At $N = \infty$, integrating over $N - 1$ components gives the same saddle equations as above, with

$$T_c = \Omega_D(0)^{-1}, \qquad \Omega_D(0) - \Omega_D(m) = K_D m^{D-2} + \cdots .$$

Consequently the sigma model has the same large-N critical exponent $\nu = 1/(D-2)$ for $2 < D < 4$. Near $D = 2 + \widetilde{\epsilon}$, the usual dimensionless sigma-model coupling $\mathfrak{g}$ obeys, for $N > 2$,

$$\beta_{\mathfrak{g}} = \widetilde{\epsilon}\,\mathfrak{g} - \frac{N-2}{2\pi}\mathfrak{g}^2 + O(\mathfrak{g}^3), \qquad \mathfrak{g}_* = \frac{2\pi}{N-2}\widetilde{\epsilon} + O(\widetilde{\epsilon}^2). \tag{37.40}$$

This fixed point is the $2+\widetilde{\epsilon}$ perturbative chart for the same $O(N)$ critical family. The $N = 2$ model is exceptional: the coefficient $N-2$ vanishes, and the Berezinskii–Kosterlitz–Thouless mechanism is not captured by (37.40).

More generally, the Wilson–Fisher epsilon expansion is an asymptotic small-ϵ expansion unless an additional summability theorem is specified. Large-order analyses of related perturbative ϕ^4 series exhibit factorial coefficient growth, and no summability theorem is being assumed here for the displayed epsilon series. Consequently a finite number of terms should be read as asymptotic information about the fixed point near four dimensions. Extracting accurate $d = 3$ numbers from the epsilon series requires an extra resummation prescription, for example a Borel or conformal-Borel method together with assumptions about singularities of the Borel transform; it is not the same operation as evaluating a convergent Taylor series at $\epsilon = 1$.

37.8 Scaling Coordinates as a Local RG Chart

The preceding computations identify individual scaling operators. For the universality discussion, the corresponding coordinate statement is needed. Fix a finite projection of the local action space near a fixed point, after quotienting by total derivatives and equation-of-motion redundancies in the chosen renormalized-operator scheme. Let $g^\alpha(\mu)$ be dimensionless coordinates in this projection, with $g^\alpha = 0$ at the fixed point, and let

$$\frac{\mathrm{d}g^\alpha}{\mathrm{d}\log\mu} = \beta^\alpha(g)$$

be the projected RG vector field. The linearized matrix is

$$M^\alpha{}_\beta = \left.\frac{\partial\beta^\alpha}{\partial g^\beta}\right|_{g=0}.$$

Assume, in the finite projection under consideration, that M is diagonalizable in a basis represented by scaling operators. A relevant coordinate u^A is one whose operator has dimension $\Delta_A < D$; write

$$y_A = D - \Delta_A > 0.$$

An irrelevant coordinate v^ρ is one whose operator has dimension $\Delta_\rho > D$; write

$$\omega_\rho = \Delta_\rho - D > 0.$$

With the convention that μ is the running physical momentum scale, the linearized equations are

$$\frac{\mathrm{d}u^A}{\mathrm{d}\log\mu} = -y_A u^A + O(g^2), \qquad \frac{\mathrm{d}v^\rho}{\mathrm{d}\log\mu} = \omega_\rho v^\rho + O(g^2). \tag{37.41}$$

Thus a relevant coordinate grows toward the infrared unless it is tuned, while an irrelevant coordinate decays toward the infrared at the linearized level. This is a statement about the endpoint map of the RG flow, not about a microscopic equality of actions.

37.8.1 Dangerously Irrelevant Coordinates

Irrelevance is a statement about the RG endpoint in a specified coordinate chart. Setting the corresponding coordinate to zero inside an observable is a separate limiting operation whose validity depends on the physical limit and on the observable topology. The precise distinction is as follows.

Definition 37.8 (Dangerously irrelevant coordinate for an observable)**.** Fix a finite RG chart near a fixed point, with relevant coordinates u^A and irrelevant coordinates v^ρ as in (37.41). Let $\mathcal{O}$ be an observable whose scaling limit is represented in the same chart by an observable map

$$F_{\mathcal{O}}(u, v)$$

after the required source normalization and subtraction conventions have been specified. An irrelevant coordinate v^ρ is called dangerously irrelevant for $\mathcal{O}$, in a sector S of the relevant-coordinate space, if the following three conditions hold.

First, v^ρ is RG-irrelevant at the fixed point: $\omega_\rho = \Delta_\rho - D > 0$. Second, for flows approaching the fixed point through the sector S, the reduced map obtained by first setting $v^\rho = 0$ is not asymptotic to the full observable map. Equivalently, after choosing an infrared rescaling factor b,

$$F_{\mathcal{O}}(u, v) = b^{-\Delta_{\mathcal{O}}}\, \mathcal{F}_{\mathcal{O}}\big(b^{y_A} u^A, b^{-\omega_\rho} v^\rho, \ldots\big), \tag{37.42}$$

and the scaling function in the sector under consideration has no finite limit, or has the wrong limiting branch, as $w = b^{-\omega_\rho} v^\rho \to 0$. Third, this singular dependence changes an exponent or a leading amplitude of $\mathcal{O}$.

Thus "dangerous" is a property of a coordinate together with an observable and a sector of its scaling variables. The same coordinate remains irrelevant for the stability of the fixed point and for observables whose scaling functions have regular $w \to 0$ limits.

The canonical example is the scalar/Ising equation of state above four Euclidean dimensions. At the Gaussian fixed point in $D > 4$, the field has dimension

$$\Delta_\phi = \frac{D-2}{2}.$$

Let M denote the uniform order parameter, t the thermal coordinate, h the magnetic source, and $g > 0$ the quartic coordinate in the Landau functional

$$f_{\mathrm{L}}(M; t, h, g) = \frac{1}{2} t M^2 + \frac{g}{4!} M^4 - hM. \tag{37.43}$$

The Gaussian engineering dimensions are

$$y_t = 2, \qquad y_h = D - \Delta_\phi = \frac{D+2}{2}, \qquad y_g = 4 - D < 0.$$

The quartic coordinate is therefore irrelevant at the Gaussian fixed point. Nevertheless it is load-bearing in the ordered equation of state. Stationarity of (37.43) gives

$$h = tM + \frac{g}{6} M^3. \tag{37.44}$$

For $h = 0$ and $t < 0$,

$$M^2 = -\frac{6t}{g}. \tag{37.45}$$

Setting $g = 0$ before minimizing removes the stabilizing term and destroys the ordered saddle. The singular dependence on g is not a contradiction of RG irrelevance; it says that the ordered order-parameter observable uses a singular branch of the scaling function.

To see the exponent directly, apply the Gaussian scaling form

$$M(t, h, g) = b^{-(D-2)/2} \mathcal{M}\left(b^2 t,\ b^{(D+2)/2} h,\ b^{4-D} g\right). \tag{37.46}$$

Choose $b = |t|^{-1/2}$. In the ordered sector $t < 0$, $h = 0$, the third argument is

$$w = b^{4-D} g = g\,|t|^{(D-4)/2} \to 0^+.$$

Equation (37.45) implies

$$\mathcal{M}(-1,0,w) \sim \left(\frac{6}{w}\right)^{1/2} \qquad (w \to 0^+).$$

Substitution into (37.46) gives

$$M(t,0,g) \sim \sqrt{\frac{6}{g}}\,|t|^{1/2}, \qquad D > 4, \quad t \to 0^-. \tag{37.47}$$

The magnetic critical exponent is therefore the mean-field value $\beta_{\text{mag}} = 1/2$, not the value $(D-2)/4$ obtained by incorrectly assuming a regular $w \to 0$ limit of $\mathcal{M}(-1,0,w)$. At the critical isotherm $t = 0$, (37.44) gives

$$M(0,h,g) \sim \left(\frac{6h}{g}\right)^{1/3},$$

so $\delta = 3$. The minimized free-energy density in the ordered phase is

$$f_{\text{L,min}}(t<0, h=0, g) = -\frac{3t^2}{2g}.$$

Equivalently, the free-energy scaling function behaves as w^{-1}. This is the elementary mechanism behind the failure of naive hyperscaling above the upper critical dimension: the Gaussian value $\nu = 1/2$ and the free-energy exponent $2-\alpha = 2$ do not satisfy $2-\alpha = D\nu$ when $D > 4$.

At the upper critical dimension $D = 4$, the same coordinate is marginally irrelevant. In the one-component normalization $x = \lambda/(16\pi^2)$ used in (37.5), put

$$L = \log\frac{\mu_0}{\mu}.$$

The four-dimensional quartic flow satisfies

$$\frac{\mathrm{d}x}{\mathrm{d}L} = -3x^2 + O(x^3), \qquad x(L) = \frac{x_0}{1+3x_0L} + O(L^{-2}) \sim \frac{1}{3L}. \tag{37.48}$$

The thermal coordinate obeys, to the leading logarithmic order needed here,

$$\frac{\mathrm{d}t}{\mathrm{d}L} = \big(2 - x(L) + O(x(L)^2)\big)t. \tag{37.49}$$

Therefore

$$t(L) = t_0 e^{2L}\big(1+3x_0L\big)^{-1/3}(1+o(1)).$$

The correlation-length scale L_ξ is determined by $|t(L_\xi)| = O(1)$, and hence

$$\xi \asymp |t_0|^{-1/2}\left(\log\frac{1}{|t_0|}\right)^{1/6} \tag{37.50}$$

up to a nonuniversal multiplicative constant and lower logarithms. At that scale the ordered saddle gives $M_{\text{scaled}} \asymp x(L_\xi)^{-1/2}$, while the field rescaling contributes e^{-L_ξ} at leading logarithmic order. Thus

$$M(t_0,0,x_0) \asymp |t_0|^{1/2}\left(\log\frac{1}{|t_0|}\right)^{1/3}, \qquad t_0 \to 0^-. \tag{37.51}$$

The logarithm is the marginal version of the singular $g^{-1/2}$ dependence in (37.47). The power exponents are mean-field exponents, while the leading logarithmic corrections remember the slow RG decay of the quartic coordinate.

Definition 37.9 (Critical surface in a finite RG chart)**.** Let $u = (u^1, \ldots, u^r)$ be the relevant coordinates in a finite local RG chart at a fixed point. At a reference scale μ_R, the critical surface in that chart is the set of ultraviolet coordinates whose RG trajectory exists down to μ_R and satisfies

$$u(\mu_R) = 0.$$

If the theory is restricted by a symmetry, only relevant coordinates compatible with that symmetry are included in u.

This definition is set-theoretic. Its promotion to a C^k submanifold statement requires the finite-reference implicit-function construction: one must specify a Banach or finite-dimensional RG chart, prove that the endpoint map is C^k, and prove that its derivative in the relevant directions is invertible. The linearized eigenvalue calculation identifies the candidate relevant coordinates; it does not by itself prove smoothness or codimension of the nonlinear tuned set.

At linear order between a microscopic cutoff Λ_0 and a reference scale $\mu_R < \Lambda_0$, equation (37.41) gives

$$u^A(\mu_R) = \left(\frac{\Lambda_0}{\mu_R}\right)^{y_A} u^A(\Lambda_0), \qquad v^\rho(\mu_R) = \left(\frac{\mu_R}{\Lambda_0}\right)^{\omega_\rho} v^\rho(\Lambda_0).$$

Therefore holding $u^A(\mu_R)$ fixed as $\Lambda_0 \to \infty$ requires the ultraviolet coordinate $u^A(\Lambda_0)$ to be tuned with precision of order $(\mu_R/\Lambda_0)^{y_A}$. A bounded ultraviolet irrelevant coordinate contributes to $v^\rho(\mu_R)$ only at order $(\mu_R/\Lambda_0)^{\omega_\rho}$, apart from the generated contribution along the tuned trajectory. The Wilsonian cutoff-removal estimate of Chapter 36 gives the nonlinear finite-coordinate form of this statement.

For the Wilson-Fisher fixed point in the $\mathbb{Z}_2$-even scalar chart, the leading relevant coordinate is the thermal coordinate dual to $[O_2]$, with $y_t = D - \Delta_{\phi^2}$. In the full scalar chart the odd coordinate dual to ϕ is also relevant, with $y_h = D - \Delta_\phi$. The phrase "codimension-one critical surface" will therefore mean the $\mathbb{Z}_2$-even chart and the finite-reference submanifold theorem above, unless the magnetic coordinate has been included and separately tuned.

Chapter 38 applies this fixed-point data to the statistical Ising model. The coarse-grained Ising variables determine which local scalar deformations are compatible with spin-flip symmetry, and the Wilson-Fisher eigenvalues y_t, y_h, and ω_ρ, together with the exponents η and ν, determine the scaling of the corresponding thermal, magnetic, and irrelevant directions near criticality.

38.1 The Finite Lattice Ensemble

Fix a spatial dimension $D \geq 1$. A finite Ising system is specified by a finite subset $\Lambda \subset \mathbb{Z}^D$, a set $E(\Lambda)$ of nearest-neighbor unordered pairs, and spin variables

$$s_x \in \{-1, +1\}, \qquad x \in \Lambda.$$

The set $E(\Lambda)$ encodes the boundary convention. For example, it may come from free boundary conditions on a box, or from periodic boundary conditions after identifying opposite faces. Bulk thermodynamic quantities are defined by taking $\Lambda \nearrow \mathbb{Z}^D$ along a specified family and then checking which limits are independent of this boundary convention. For ferromagnetic coupling $J > 0$, external magnetic field h, and inverse temperature $\beta = T^{-1}$ in units with Boltzmann's constant equal to one, the energy of a spin configuration $s = \{s_x\}_{x\in\Lambda}$ is

$$H_\Lambda(s) = -J \sum_{\langle xy\rangle \in E(\Lambda)} s_x s_y - h \sum_{x\in\Lambda} s_x.$$

The finite-volume partition function and thermal expectation of an observable $F : \{-1,+1\}^\Lambda \to \mathbb{C}$ are

$$Z_\Lambda(\beta,h) = \sum_{s_x=\pm 1} \exp[-\beta H_\Lambda(s)], \qquad \langle F\rangle_{\Lambda,\beta,h} = Z_\Lambda(\beta,h)^{-1} \sum_{s_x=\pm 1} F(s)\,\mathrm{e}^{-\beta H_\Lambda(s)}.$$

This is the finite-lattice row of Table 11.1: at fixed Λ the object is an ordinary finite probability measure on a finite set of configurations. Its use as a regulator for a continuum Euclidean QFT requires thermodynamic and scaling limits with their own positivity, locality, and tightness or convergence hypotheses. At $h = 0$ the model has the global $\mathbb{Z}_2$ symmetry $s_x \mapsto -s_x$ for all x. The Wilson–Fisher chapter used the $\mathbb{Z}_2$-even RG chart unless an odd source was added. The present chapter includes that odd sector by the magnetic source: in continuum variables it is the deformation $\int h(x)\phi(x)$, and on the lattice it is represented by the $-h\sum_x s_x$ term in H_Λ. Setting $h = 0$ gives the symmetric critical theory, while differentiating with respect to h at $h = 0$ inserts the $\mathbb{Z}_2$-odd spin field σ.

The same finite probability space can be written in diagonal operator notation. Let

$$V_x = \mathrm{span}\{|+\rangle_x, |-\rangle_x\}, \qquad \mathcal{H}_\Lambda = \bigotimes_{x\in\Lambda} V_x,$$

and define commuting spin operators by $\hat{S}_x|s\rangle_\Lambda = s_x|s\rangle_\Lambda$, where $|s\rangle_\Lambda = \bigotimes_x |s_x\rangle_x$. Then

$$\hat{H}_\Lambda = -J\sum_{\langle xy\rangle} \hat{S}_x\hat{S}_y - h\sum_x \hat{S}_x, \qquad Z_\Lambda(\beta,h) = \mathrm{Tr}_{\mathcal{H}_\Lambda}\,\mathrm{e}^{-\beta\hat{H}_\Lambda}.$$

The space $\mathcal{H}_\Lambda$ in this display is a finite-dimensional representation of a classical statistical ensemble. A continuum Hilbert space, when constructed from the scaling limit of Euclidean correlators, is a further object obtained after the limit.

Figure 38.1 keeps the finite Ising ensemble data separate from the reconstructed continuum Hilbert space: spins are summed in a finite-dimensional trace before any scaling limit is taken.

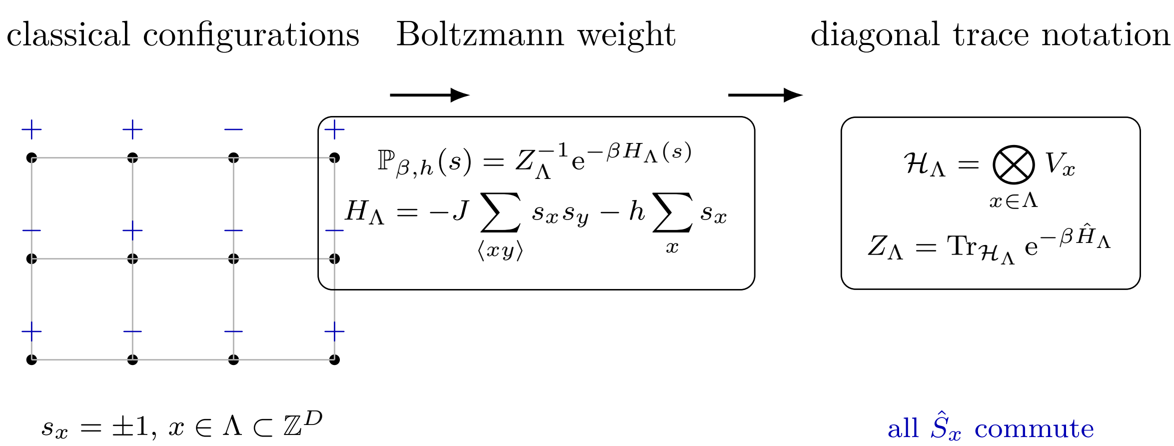

Figure 38.1: The statistical Ising model is a probability measure on lattice spin configurations. Diagonal operators provide an exact finite-volume trace notation for the same measure.

For a finite set of energy eigenstates n with energies E_n, the canonical weights

$$p_n = \frac{1}{Z}\mathrm{e}^{-\beta E_n}, \qquad Z = \sum_n \mathrm{e}^{-\beta E_n},$$

are obtained by extremizing the Shannon entropy

$$S[p] = -\sum_n p_n \log p_n$$

subject to $\sum_n p_n = 1$ and $\sum_n p_n E_n = U$. Indeed, the stationary point of

$$S[p] + \alpha\Big(\sum_n p_n - 1\Big) + \beta\Big(U - \sum_n p_n E_n\Big)$$

has $\log p_n = \alpha - 1 - \beta E_n$, hence the displayed Boltzmann form.

The entropy also has a simple monotonicity statement for symmetric probability evolution. If a finite distribution $p_n(t)$ obeys

$$\dot{p}_n = \sum_m v_{nm}(p_m - p_n), \qquad v_{nm} = v_{mn} \geq 0,$$

then $\sum_n \dot{p}_n = 0$ and

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \frac{1}{2}\sum_{m,n} v_{mn}(p_m - p_n)(\log p_m - \log p_n) \geq 0.$$

This is the finite-state entropy-increase mechanism underlying thermal equilibration in the idealized symmetric-rate case.

38.2 Spin Correlators and Phases

Quoted Theorem 38.1 (Ferromagnetic thermodynamic limits and phase selection)**.** *Consider the finite-volume Ising model on boxes $\Lambda \nearrow \mathbb{Z}^D$ with finite-range couplings $J_{xy} = J_{yx} \geq 0$, inverse temperature $\beta \geq 0$, and external fields h_x. Let $s_A := \prod_{x\in A} s_x$ for finite $A \subset \mathbb{Z}^D$. In finite volume the ferromagnetic measure satisfies the following correlation inequalities.*

(i) FKG positive association: if F and G are increasing functions of the spin configuration, then

$$\langle FG\rangle_{\Lambda,\beta,h} \geq \langle F\rangle_{\Lambda,\beta,h}\langle G\rangle_{\Lambda,\beta,h}.$$

(ii) The GKS inequalities, for nonnegative fields: for finite A, B,

$$\langle s_A\rangle_{\Lambda,\beta,h} \geq 0, \qquad \langle s_A s_B\rangle_{\Lambda,\beta,h} - \langle s_A\rangle_{\Lambda,\beta,h}\langle s_B\rangle_{\Lambda,\beta,h} \geq 0.$$

Equivalently, spin correlations are monotone nondecreasing under increasing ferromagnetic couplings and nonnegative external fields.

(iii) The GHS inequality, for nonnegative fields:

$$\frac{\partial^3 \log Z_\Lambda}{\partial h_x\,\partial h_y\,\partial h_z} \leq 0.$$

In particular, the finite-volume magnetization is concave as a function of a uniform positive field.

Consequently the plus and minus boundary-condition Gibbs states

$$\langle F\rangle^{\pm}_{\beta,h} := \lim_{\Lambda\nearrow\mathbb{Z}^D}\langle F\rangle^{\pm}_{\Lambda,\beta,h}$$

exist for every local observable F whenever the boxes increase through a cofinal rectangular sequence. At $h=0$, the one-sided states

$$\langle F\rangle^{\pm}_{\beta,0} = \lim_{h\downarrow 0}\langle F\rangle^{\pm}_{\beta,\pm h}$$

exist by monotonicity. If $\langle\cdot\rangle^{+}_{\beta,0} = \langle\cdot\rangle^{-}_{\beta,0}$, the thermodynamic limit is independent of the usual plus/minus/free boundary choices. If the two differ, the plus and minus limits are distinct translation-invariant Gibbs states. They are pure phases whenever they satisfy the clustering condition

$$\lim_{|a|\to\infty}\Big(\langle F\,\tau_a G\rangle^{\pm}_{\beta,0} - \langle F\rangle^{\pm}_{\beta,0}\langle G\rangle^{\pm}_{\beta,0}\Big) = 0$$

for all local F,G, where τ_a translates G. Clustering is the condition that makes the limiting Gibbs state extremal, hence pure.

Here is the finite-volume mechanism behind Quoted Theorem 38.1. Write $K_{xy} := \beta J_{xy} \geq 0$ and $H_x := \beta h_x \geq 0$. Boundary fields can be incorporated into the H_x's after adding the fixed exterior spins, so it is enough to work on a finite graph $G = (\Lambda, E)$ with weight

$$w(s) = \exp\left(\sum_{\{x,y\}\in E} K_{xy}s_xs_y + \sum_{x\in\Lambda} H_xs_x\right).$$

Order configurations by $s \leq t$ when $s_x \leq t_x$ for every x. For the coordinatewise join and meet, $s\vee t$ and $s\wedge t$, the one-edge factor obeys

$$\mathrm{e}^{K_{xy}(s\vee t)_x(s\vee t)_y}\mathrm{e}^{K_{xy}(s\wedge t)_x(s\wedge t)_y} \geq \mathrm{e}^{K_{xy}s_xs_y}\mathrm{e}^{K_{xy}t_xt_y}.$$

The single-site factors give equality in the same inequality. Hence

$$w(s\vee t)w(s\wedge t) \geq w(s)w(t), \tag{38.1}$$

which is log-supermodularity on the finite distributive lattice $\{-1,+1\}^{\Lambda}$. Positive association follows by induction over sites: conditioning on all spins except one gives a one-site measure whose conditional probability of $+1$ is increasing in the conditioned configuration by (38.1); the covariance decomposition

$$\mathrm{Cov}(F,G) = \mathbb{E}[\mathrm{Cov}(F,G\mid\mathcal{F})] + \mathrm{Cov}(\mathbb{E}[F\mid\mathcal{F}],\mathbb{E}[G\mid\mathcal{F}])$$

then propagates the one-site Chebyshev inequality to all sites. This is the finite FKG proof in the present Ising setting.

The GKS inequalities admit an equally concrete current expansion. Add a ghost vertex g and edges $\{x,g\}$ with coupling H_x; set $K_{xg} = H_x$. A current is a function $n : \bar{E} \to \mathbb{Z}_{\geq 0}$ on $\bar{E} = E \cup \{\{x,g\} : x\in\Lambda\}$, with weight

$$W(n) = \prod_{e\in\bar{E}}\frac{K_e^{n_e}}{n_e!}.$$

Let ∂n be the set of vertices incident to an odd total current. Since the ghost spin is fixed to $+1$, for $A \subset \Lambda$

$$\langle s_A \rangle_{\Lambda,K,H} = \frac{\sum_{\partial n \cap \Lambda = A} W(n)}{\sum_{\partial n \cap \Lambda = \emptyset} W(n)}. \tag{38.2}$$

Every summand is nonnegative, which gives the first GKS inequality. For the second one, the switching identity says that, for any function depending only on the sum $n_1 + n_2$,

$$\sum_{\substack{\partial n_1 \cap \Lambda = A \\ \partial n_2 \cap \Lambda = B}} W(n_1) W(n_2)\, \Phi(n_1{+}n_2) = \sum_{\substack{\partial m_1 \cap \Lambda = A \triangle B \\ \partial m_2 \cap \Lambda = \emptyset}} W(m_1) W(m_2)\, \Phi(m_1{+}m_2)\, \mathbf{1}_{\mathcal{F}_B}(m_1{+}m_2), \tag{38.3}$$

where $\mathcal{F}_B(N)$ is the event that every connected component of the support graph of N contains an even number of vertices of B. Applying (38.3) with $\Phi = 1$ gives

$$\langle s_A s_B \rangle - \langle s_A \rangle \langle s_B \rangle = \frac{\sum_{\substack{\partial m_1 \cap \Lambda = A \triangle B \\ \partial m_2 \cap \Lambda = \emptyset}} W(m_1) W(m_2) \big(1 - \mathbf{1}_{\mathcal{F}_B}(m_1 + m_2)\big)}{\big(\sum_{\partial n \cap \Lambda = \emptyset} W(n)\big)^2} \geq 0. \tag{38.4}$$

Differentiating $\langle s_A \rangle$ with respect to H_x or K_{xy} inserts respectively s_x or $s_x s_y$ and subtracts the disconnected product, so (38.4) is also the monotonicity statement in field and ferromagnetic coupling.

The GHS inequality has a finite-dimensional Gaussian proof. The third derivative

$$U_3(x,y,z) := \frac{\partial^3 \log Z_\Lambda}{\partial H_x\, \partial H_y\, \partial H_z}$$

is the third Ursell function

$$\langle s_x s_y s_z \rangle - \langle s_x \rangle \langle s_y s_z \rangle - \langle s_y \rangle \langle s_x s_z \rangle - \langle s_z \rangle \langle s_x s_y \rangle + 2 \langle s_x \rangle \langle s_y \rangle \langle s_z \rangle.$$

Choose a diagonal constant J_0 large enough that the matrix

$$V_{ij} = K_{ij} + J_0 \delta_{ij}$$

is positive definite; adding $J_0 \sum_i s_i^2/2$ changes the Hamiltonian by a constant. Since the off-diagonal entries of V are nonnegative and the diagonal entries can be chosen positive, the centered Gaussian vector X with covariance V satisfies

$$\mathbb{E} \exp\left(\sum_i X_i s_i \right) = \exp\left(\frac{1}{2} \sum_{i,j} V_{ij} s_i s_j \right).$$

Thus the finite Ising partition function is, up to a positive constant,

$$Z_\Lambda(H) = 2^{|\Lambda|} \mathbb{E}_X \prod_i \cosh(X_i + H_i). \tag{38.5}$$

To compute the third Ursell function, introduce four independent Gaussian vectors X, Y, Z, W with the same covariance and combine the five terms in U_3 into one differential expression acting on

$$G(X,Y,Z,W) = \prod_i \cosh(X_i + H_i) \cosh(Y_i + H_i) \cosh(Z_i + H_i) \cosh(W_i + H_i).$$

The orthogonal change of variables

$$\alpha = \frac{X+Y+Z+W}{2}, \qquad \beta = \frac{-X+Y-Z+W}{2},$$
$$\gamma = \frac{-X-Y+Z+W}{2}, \quad \delta = \frac{X-Y-Z+W}{2}$$

preserves the product Gaussian law and gives independent Gaussian vectors $\alpha, \beta, \gamma, \delta$, each with covariance V. In these variables the Ursell combination takes the form

$$U_3(x,y,z) = -C_{\Lambda,H}\,\mathbb{E}\left[\frac{\partial^3}{\partial\beta_x\,\partial\gamma_y\,\partial\delta_z}\prod_i Q_i(\alpha_i,\beta_i,\gamma_i,\delta_i)\right], \tag{38.6}$$

with $C_{\Lambda,H} > 0$. The single-site factor Q_i is the transformed product of the four cosh factors. Its Taylor expansion is a sum of monomials in $\alpha_i + 2H_i, \beta_i, \gamma_i, \delta_i$ with the following parity property: after differentiating once in each of $\beta_x, \gamma_y, \delta_z$, every monomial that survives the Gaussian expectation has a nonnegative coefficient and even total power in each of the four independent Gaussian families. Because V has nonnegative entries, every such Gaussian moment is nonnegative. The minus sign in (38.6) therefore gives

$$U_3(x,y,z) \le 0.$$

For a uniform field H,

$$\frac{\mathrm{d}^2}{\mathrm{d}H^2}\langle s_0\rangle = \sum_{x,y\in\Lambda}\frac{\partial^3 \log Z_\Lambda}{\partial H_0\,\partial H_x\,\partial H_y} \le 0,$$

which is the stated concavity of the finite-volume magnetization.

These finite-volume inequalities imply stochastic monotonicity in boundary condition, coupling, and field. If $\Lambda_1 \subset \Lambda_2$, the plus-boundary measure on Λ_2, restricted to Λ_1, stochastically dominates the plus-boundary measure on Λ_1; the minus-boundary expectations have the opposite monotonicity. Thus the expectations of every spin monomial form bounded monotone nets along cofinal rectangular boxes, and every local observable is a finite linear combination of spin monomials. The thermodynamic limits in the quoted theorem follow.

The one-sided $h \downarrow 0$ limits are bounded monotone limits in the field coordinate. Equality of the plus and minus limits forces every Gibbs limit squeezed between them by stochastic domination to agree with the common state, which is boundary-condition independence in the ferromagnetic class. If the limits differ, they are distinct Gibbs states selected by plus and minus boundaries, or equivalently by the sign of a symmetry-breaking field before the field is taken to zero. Finally, clustering implies extremality: if a translation-invariant Gibbs state decomposed into a nontrivial convex combination, correlations of distant translates would retain the variance of the conditional expectation onto the translation-invariant tail sigma-algebra. A clustering plus or minus state is therefore pure.

The basic observables are spin correlation functions. At $h = 0$, for translation-invariant infinite-volume limits supplied by Quoted Theorem 38.1, write

$$C_\beta(x_1,\ldots,x_n) = \langle s_{x_1}\cdots s_{x_n}\rangle_\beta.$$

The two-point function at large separation is often summarized by

$$f_\beta(r) \simeq \langle s_0 s_x\rangle_\beta, \qquad r = |x|.$$

For $D = 2, 3$ and ferromagnetic nearest-neighbor coupling, there is a critical temperature T_c. In the ordered region $T < T_c$, when the plus and minus limits are clustering and therefore pure in the sense of Quoted Theorem 38.1, boundary conditions or the one-sided field limits $h \to 0^\pm$ select states with nonzero magnetization

$$m_\pm(T) = \lim_{h\to 0^\pm} \lim_{\Lambda \nearrow \mathbb{Z}^D} \langle s_0 \rangle_{\Lambda,\beta,h}, \qquad m_+(T) = -m_-(T) \neq 0.$$

The full two-point function tends to $m_\pm(T)^2$ at large distance in such a phase. The connected correlator

$$G_\beta(x) = \langle s_0 s_x \rangle_\beta - \langle s_0 \rangle_\beta \langle s_x \rangle_\beta$$

decays at large $|x|$ away from criticality. In the disordered region $T > T_c$,

$$G_\beta(x) \sim A(T)\, \mathrm{e}^{-|x|/\xi(T)}$$

up to powers of $|x|$, where $\xi(T)$ is the correlation length. One precise definition, when the limit exists along a coordinate direction, is

$$\xi(T)^{-1} = -\lim_{r\to\infty} \frac{1}{r} \log |G_\beta(re_1)|.$$

At $T = T_c$, the correlation length diverges and the spin two-point function has power-law asymptotics

$$\langle s_0 s_x \rangle_{\beta_c} \sim \frac{A_\sigma}{|x|^{2\Delta_\sigma}}.$$

The exponent Δ_σ is the scaling dimension of the continuum spin field.

Figure 38.2 displays the three large-distance regimes encoded by the two-point function: exponential decay away from criticality, power-law behavior at criticality, and the associated divergence of the correlation length.

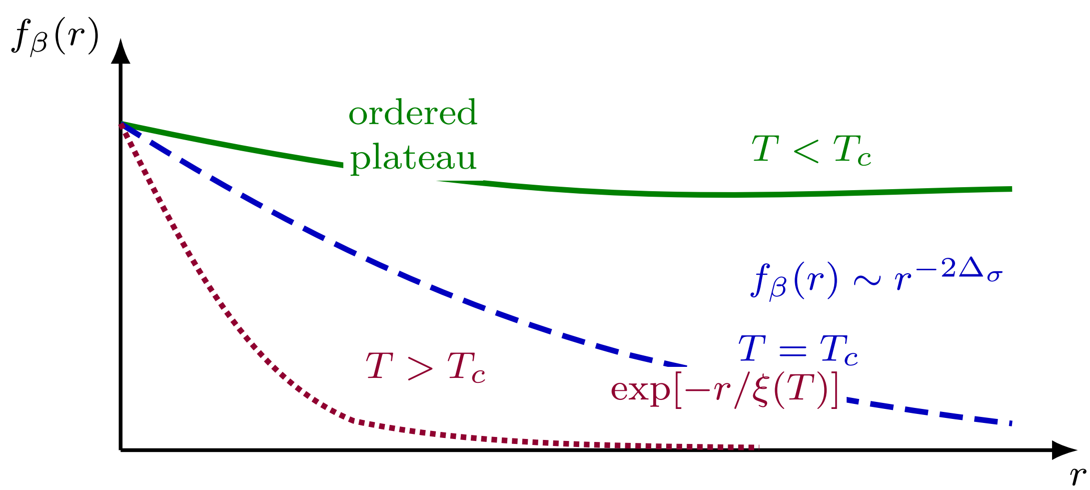

Figure 38.2: Long-distance spin correlations distinguish the ordered, critical, and disordered regimes. The ordered, critical, and disordered curves are drawn solid, dashed, and dotted respectively. In the ordered phase the full two-point function approaches the square of the magnetization; the connected correlator still decays away from the critical point.

The values relevant for the first Ising universality classes are

D	Δ_σ	ν
2	$\frac{1}{8}$	1
3	$0.518\ldots$	$0.62998\ldots$

where ν is defined by the divergence

$$\xi(T) \sim \xi_0\, |T - T_c|^{-\nu} \qquad (T \to T_c).$$

38.3 The Scaling Limit

The continuum Ising field theory is defined, when the limit exists, from large-distance lattice correlators near criticality. Let $a = L^{-1}$ be the lattice spacing in continuum units. A fixed point $x \in \mathbb{R}^D$ corresponds to a nearest lattice point $[x/a] = [Lx]$. In this subsection set the magnetic field to zero, so the $\mathbb{Z}_2$ symmetry is preserved and the thermal coordinate is the relevant coordinate being varied.

Dimension	Ising scaling-limit status	Scalar ϕ^4 comparison	Use in this chapter
$D = 2$	Critical planar Ising spin correlations and fermionic observables have rigorously constructed conformally covariant scaling limits in standard planar domains.	$P(\phi)_2$, including ϕ_2^4, is a constructive scalar QFT class after Wick ordering and the required local renormalizations.	Two-dimensional Ising may be cited as a theorem-level example of a nontrivial lattice-to-continuum critical limit, while keeping distinct the exact Ising lattice construction and the $P(\phi)_2$ constructive family.
$D = 3$	The nontrivial nearest-neighbor Ising critical scaling limit and its identification with the three-dimensional Ising CFT are not presently available as a complete theorem with OS/Wightman reconstruction data and universal correlators.	Massive ϕ_3^4 with positive quartic interaction is a constructed Glimm–Jaffe superrenormalizable scalar QFT: its Euclidean Schwinger functions satisfy the OS hypotheses, hence give a Wightman QFT by reconstruction.	Statements about the three-dimensional Ising continuum theory are therefore conditional on scaling-limit and universality hypotheses, even when supported by RG, bootstrap, Monte Carlo, and perturbative evidence. The proved massive ϕ_3^4 Wightman construction is not, by itself, a construction of the critical Wilson–Fisher/Ising fixed point.
$D = 4$	For the standard reflection-positive critical nearest-neighbor Ising scaling problem covered by the marginal triviality theorem, scaling limits are Gaussian.	The same Aizenman–Duminil-Copin theorem covers the corresponding lattice ϕ_4^4 scaling problem with positive quartic interaction.	There is no interacting four-dimensional Ising/ϕ_4^4 continuum fixed point from this standard lattice construction. This theorem is distinct from the separate logical question of nonstandard UV completions with identical formal perturbation theory.
$D > 4$	Standard critical Ising scaling limits in the theorem classes governed by mean-field/triviality results are Gaussian.	Scalar ϕ_D^4 with positive quartic coupling is trivial in the corresponding reflection-positive scaling-limit regimes.	The Ising fixed point used below is not a nontrivial $D > 4$ continuum QFT; the Wilson–Fisher deformation is meaningful below four dimensions.

Table 38.1: Dimension-dependent theorem status of Ising and scalar ϕ^4 continuum-limit claims. The table separates actual construction/triviality theorems from the conditional three-dimensional scaling-limit assertions used in the RG discussion.

References for Table 38.1. For the planar Ising entries, see Smirnov's discrete-holomorphic fermion construction for the critical random-cluster Ising model and the Chelkak–Hongler–Izyurov proof of conformal invariance of critical spin correlations. For the constructive scalar entries, see the Nelson, Simon, and Glimm–Jaffe constructions of $P(\phi)_2$ and ϕ_3^4. For the four-dimensional marginal theorem, see Aizenman–Duminil-Copin, "Marginal triviality of the scaling limits of critical 4D Ising and ϕ_4^4 models," *Ann. of Math.* **194** (2021) 163–235, together with its corrigendum. Earlier Aizenman and Fröhlich triviality theorems cover complementary above-four-dimensional scalar/Ising regimes.

The $D \geq 4$ Gaussian entries in Table 38.1 concern separated critical scaling limits and the endpoint of the tuned RG trajectory. They do not mean that the quartic coordinate may be deleted from every finite-regulator observable before the scaling limit is taken. In the terminology of Section 37.8.1, the quartic coordinate above four dimensions is dangerously irrelevant for the ordered equation of state: it flows to zero at the Gaussian fixed point, but it stabilizes the ordered saddle and appears singularly in the magnetization and free-energy amplitudes. At $D = 4$ the same coordinate is marginally irrelevant and produces the leading logarithmic corrections derived in (37.50) and (37.51). This separates the Gaussian character of the critical separated-point continuum limit from the singular quartic dependence of ordered thermodynamic observables.

Let $\xi_{\mathrm{lat}}(T)$ be the correlation length measured in lattice units, using connected correlators in a chosen pure phase when $T < T_c$. Choose a sequence of temperatures $T(L) \to T_c$ such that the signed thermal scale

$$\mathfrak{m} = \lim_{L\to\infty} \operatorname{sgn}(T(L) - T_c)\, \frac{L}{\xi_{\mathrm{lat}}(T(L))}$$

exists. The physical inverse correlation length is $|\mathfrak{m}|$. The sign records which side of the critical point is approached. More general scaling limits with a magnetic deformation require a second scaling coordinate to be held fixed. If u_h is the coefficient of the spin field, this coordinate has the form $L^{D-\Delta_\sigma} u_h$. It is set to zero here. The quantity $|\mathfrak{m}|$ is the continuum mass gap extracted from the lattice transfer-matrix or correlation-length scale. It is a spectral pole mass only under the additional condition that the reconstructed two-point spectral measure in the relevant channel has an isolated lowest one-particle atom, as in Definition 33.5; otherwise it is the lower edge of the spectrum in that channel.

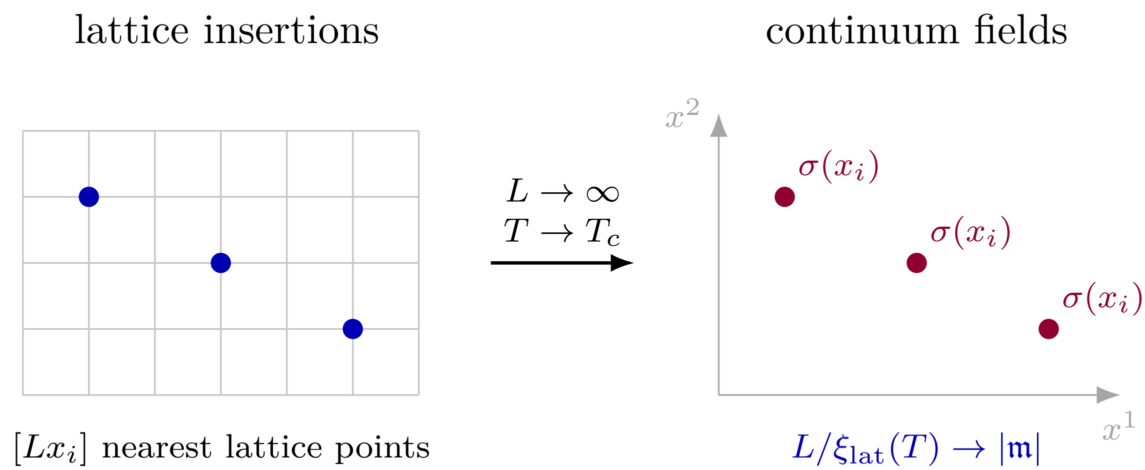
Hypothesis 38.2 (Separated spin scaling limit)**.** For the temperature trajectory above, assume that there is a spin-field renormalization factor $Z_\sigma(L,T) > 0$ such that, for every n and every configuration of pairwise distinct continuum points $x_1, \ldots, x_n$, the limit

$$\lim_{\substack{T\to T_c,\ L\to\infty \\ \operatorname{sgn}(T-T_c)L/\xi_{\mathrm{lat}}(T)\to\mathfrak{m}}} Z_\sigma(L,T)^{-n/2} \langle s_{[Lx_1]} \cdots s_{[Lx_n]} \rangle_{\beta(T)} = \langle \sigma(x_1) \cdots \sigma(x_n) \rangle_{\mathrm{Ising},\mathfrak{m}}$$

exists. The convergence is meant after the thermodynamic limit specified for the lattice model, and with the boundary/pure-phase convention fixed when $\mathfrak{m} < 0$.

When Hypothesis 38.2 holds, its right side defines the separated-point spin Schwinger functions of the continuum Ising scaling theory at thermal scale $\mathfrak{m}$. At $\mathfrak{m} = 0$, equivalently at $\xi_{\mathrm{lat}}(T)/L \to \infty$, the limiting fixed point is called the critical Ising fixed point. If this fixed point admits a local stress tensor that is conserved, symmetric, and improvable to a traceless tensor whose charges generate the conformal transformations of the separated-point Schwinger functions, then the fixed point is the Ising conformal field theory. At criticality $Z_\sigma(L, T_c)$ may be chosen proportional to $L^{-2\Delta_\sigma}$, so the rescaled spin insertions have finite correlators. The limiting objects in this display are Euclidean separated-point Schwinger functions. Reflection positivity of these limiting distributions is not a consequence of the scaling formula alone. It is a property that must either be proved from a reflection-positive regulated lattice model and a sufficiently strong mode of convergence, or imposed as a separate reconstruction hypothesis. When this positivity and the remaining reconstruction hypotheses hold, the Schwinger functions determine a Lorentzian QFT Hilbert space by the Osterwalder–Schrader reconstruction of Chapter 12. That reconstructed Hilbert space is not the finite-dimensional spin-trace space $\mathcal{H}_\Lambda$ used to define the classical thermal ensemble.

Figure 38.3 records the scaling-limit map: renormalized lattice insertions converge to separated-point Schwinger functions, and OS reconstruction is an additional step after reflection positivity and the remaining hypotheses are established.



$$\boxed{Z_\sigma^{-n/2}\,\langle s_{[Lx_1]}\cdots s_{[Lx_n]}\rangle \longrightarrow \langle \sigma(x_1)\cdots\sigma(x_n)\rangle_{\mathrm{Ising},\mathfrak{m}}}$$

Figure 38.3: The Ising field theory is the continuum scaling limit of long-distance spin correlators. The absolute value of $\mathfrak{m}$ is the inverse correlation length in the limiting continuum units, while its sign records the high- or low-temperature side.

38.4 Reflection Positivity Along the Scaling Limit

Choose one lattice coordinate and call it Euclidean time. Let θ be reflection across the hyperplane midway between the time slices $n^0 = 0$ and $n^0 = 1$:

$$\theta(n^0, n^1, \ldots, n^{D-1}) = (1 - n^0, n^1, \ldots, n^{D-1}).$$

For a finite reflection-invariant lattice region Λ, write $\Lambda_+ = \{n \in \Lambda : n^0 \geq 1\}$, and let $\mathcal{A}_+$ be the algebra of complex functions of the lattice variables with support in Λ_+. If $F \in \mathcal{A}_+$, define the anti-linear reflection

$$(\Theta F)(q) = \overline{F(q \circ \theta)},$$

where q denotes the complete lattice configuration.

Definition 38.3 (Finite-lattice reflection positivity)**.** A finite lattice probability measure μ_Λ is reflection positive with respect to the time reflection θ if

$$\int (\Theta F)(q)\, F(q)\, \mathrm{d}\mu_\Lambda(q) \geq 0 \tag{38.7}$$

for every $F \in \mathcal{A}_+$. Equivalently, the sesquilinear form $(F, G) \mapsto \int (\Theta F) G\, \mathrm{d}\mu_\Lambda$ is positive semidefinite on $\mathcal{A}_+$.

This is the finite-cutoff precursor of the Osterwalder–Schrader positivity condition. It is stronger than pointwise positivity of the Boltzmann weight: it constrains how the action couples fields on opposite sides of every reflection plane used in reconstruction.

Proposition 38.4 (Ferromagnetic nearest-neighbor models are reflection positive)**.** *Consider a reflection-invariant finite box with free boundary conditions, or a periodic torus with the reflection plane chosen so that the action decomposes into reflected halves and bonds crossing the plane. The source-free nearest-neighbor Ising measure with coupling $J \geq 0$ is reflection positive. The real scalar lattice measure*

$$\mathrm{d}\mu_\Lambda(s) = Z_\Lambda^{-1} \prod_{x\in\Lambda} \rho(\mathrm{d}s_x)\, \exp\left[\sum_{\langle xy\rangle} K\, s_x s_y\right], \qquad K \geq 0, \tag{38.8}$$

is also reflection positive whenever ρ is a positive one-site measure for which the finite-volume partition function exists. Thus the nearest-neighbor generalized Ising model with $\rho(\mathrm{d}s) = \exp[-P(s)]\mathrm{d}s$, P bounded below with sufficient growth, and $K = \beta \geq 0$, preserves reflection positivity. Convexity of P is not required; a double-well one-site potential does not by itself violate reflection positivity.

Proof. The Ising model is the special case $\rho = \frac{1}{2}(\delta_{-1} + \delta_{+1})$ and $K = \beta J$. It is therefore enough to prove the scalar statement. Decompose the action into terms strictly on the positive side, their reflected copies, and the bonds crossing the reflection plane:

$$\exp[-S_\Lambda(s)] = \exp[-S_+(s_+)]\, \exp[-S_+(\theta s_-)] \prod_{y\in\Sigma_+} \exp[K_y s_{\theta y} s_y]\,,$$

where y runs over the positive-side endpoints of the crossing bonds and $K_y \geq 0$. Expanding every crossing factor gives

$$\prod_{y\in\Sigma_+} \exp[K_y s_{\theta y} s_y] = \sum_{m:\Sigma_+\to\mathbb{Z}_{\geq 0}} \prod_{y\in\Sigma_+} \frac{K_y^{m_y}}{m_y!} \prod_{y\in\Sigma_+} s_{\theta y}^{m_y} \prod_{y\in\Sigma_+} s_y^{m_y}.$$

Substitution into the quadratic form $\int(\Theta F)F\,\mathrm{d}\mu_\Lambda$ factorizes the positive and negative half-lattice integrals. For each multi-index m the contribution is

$$\frac{1}{Z_\Lambda} \prod_{y\in\Sigma_+} \frac{K_y^{m_y}}{m_y!} \left| \int F(s_+) \prod_{y\in\Sigma_+} s_y^{m_y}\, \exp[-S_+(s_+)] \prod_{x\in\Lambda_+} \rho(\mathrm{d}s_x) \right|^2 .$$

The coefficients are nonnegative because $K_y \geq 0$. The sum of these nonnegative terms is the desired quadratic form, proving (38.7). □

The proposition identifies a sufficient condition, not a definition of the universality class. Adding next-nearest-neighbor, anisotropic, or higher-derivative lattice couplings preserves reflection positivity only when the interaction crossing each reflection plane is a positive kernel in the above sense. Negative cross-reflection couplings, or derivative discretizations whose cross-plane kernel has negative directions, generally destroy the factorization into sums of squares. Such models may still have the same formal RG relevant coordinates, but they do not automatically supply Osterwalder–Schrader positivity for a Lorentzian reconstruction.

Remark 38.5 (Closedness of reflection positivity under scaling limits). Let $a \downarrow 0$ label reflection-positive lattice measures μ_a. Let $A_a^I(f)$ be renormalized smeared lattice observables whose linear normalizations are real and whose test functions are supported in the positive Euclidean half-space. Suppose that for every finite collection of polynomial functionals $F_\alpha(A_a)$ supported in that half-space and every set of complex coefficients c_α, the reflected quadratic forms

$$Q_a(c) = \sum_{\alpha,\beta} \overline{c_\alpha} c_\beta \, \langle \Theta F_\alpha(A_a) \, F_\beta(A_a) \rangle_{\mu_a}$$

converge to the corresponding continuum quadratic form $Q_*(c)$. Then $Q_*(c) \geq 0$ for all such c_α; the limiting Schwinger distributions are reflection positive on this test-function domain. For a fixed finite list of observables and coefficients, this is simply the closedness of the cone $[0, \infty) \subset \mathbb{R}$: finite-lattice reflection positivity gives $Q_a(c) \geq 0$, and the convergence hypothesis gives $Q_*(c) = \lim_{a \downarrow 0} Q_a(c)$. The finite list and vector c are arbitrary, so every reflected finite Gram matrix built from the continuum smeared observables is positive semidefinite on the stated test domain.

The hypothesis in this remark concerns reflected quadratic forms and separated-point correlators together. Source-local subtractions used to define a distributional generating functional must either arise from genuine lattice observables whose reflected quadratic forms converge, or be separately checked to preserve the Osterwalder–Schrader quadratic inequalities. Coordinate universality and critical exponent matching do not imply this positivity statement.

Microscopic lattice observables become continuum operators through their leading terms in the scaling-field expansion. Let

$$e_x = -\sum_{\mu=1}^{D} s_x s_{x+\hat{\mu}}$$

be a local energy-density observable on the hypercubic lattice. At separated continuum points and at criticality,

$$s_{[x/a]} = C_\sigma \, a^{\Delta_\sigma} \sigma(x) + \sum_j C_j \, a^{\Delta_j} O_j(x), \qquad \Delta_j > \Delta_\sigma,$$

and

$$e_{[x/a]} - \langle e \rangle_c = C_\varepsilon \, a^{\Delta_\varepsilon} \varepsilon(x) + \sum_k C'_k \, a^{\Delta'_k} O'_k(x), \qquad \Delta'_k > \Delta_\varepsilon.$$

The constants C_σ and C_ε depend on the microscopic normalization of the lattice observables. The dimensions and operator-product coefficients of the scaling fields are fixed-point data.

In scalar continuum coordinates, the leading $\mathbb{Z}_2$-odd scalar field ϕ represents the Ising spin field σ, while the leading $\mathbb{Z}_2$-even mass operator, denoted ϕ^2 after identity mixing is subtracted, represents the energy field ε:

$$\phi \longrightarrow \sigma, \qquad [\phi^2] \longrightarrow \varepsilon.$$

If u_t denotes the thermal scaling coordinate, then

$$\Delta S_t = \int \mathrm{d}^D x \, u_t \, \varepsilon(x), \qquad [u_t] = D - \Delta_\varepsilon.$$

Since $\xi^{-1} \propto |u_t|^{1/(D-\Delta_\varepsilon)}$, comparison with $\xi \propto |T - T_c|^{-\nu}$ gives

$$\Delta_\varepsilon = D - \frac{1}{\nu}.$$

38.5 Observable Limits as Source-Dependent Distributions

The separated-point scaling formula is the restriction of a stronger distributional statement. Let a be the lattice spacing and let $\mathcal{D}(\mathbb{R}^D)$ be the space of smooth compactly supported test functions. For $f, g \in \mathcal{D}(\mathbb{R}^D)$, define the renormalized smeared lattice observables

$$\Sigma_a(f) = a^D \sum_{n\in\mathbb{Z}^D} f(an)\, C_\sigma^{-1} a^{-\Delta_\sigma} s_n,$$

and

$$E_a(g) = a^D \sum_{n\in\mathbb{Z}^D} g(an)\, C_\varepsilon^{-1} a^{-\Delta_\varepsilon} \big(e_n - \langle e\rangle_c\big),$$

where the sums are restricted to the finite lattice region before the thermodynamic limit is taken. The constants C_σ and C_ε are the same nonuniversal normalization constants appearing in the leading scaling-field expansion. The point fields $\sigma(x)$ and $\varepsilon(x)$ are the distributional kernels whose smeared limits are $\Sigma(f) = \int \mathrm{d}^D x\, f(x)\sigma(x)$ and $E(g) = \int \mathrm{d}^D x\, g(x)\varepsilon(x)$.

Definition 38.6 (Source-dependent scaling limit)**.** Fix the thermal scaling trajectory used above. A source-dependent scaling limit for a chosen collection of microscopic local observables A_a^I consists of a continuum source coordinate $\eta^A(x)$, a lattice source coordinate $\eta_a^I(n)$, and local source maps

$$\eta_a = \mathcal{Z}_a(\eta),$$

such that, after subtraction of source-local vacuum terms,

$$W_a[\mathcal{Z}_a(\eta)] - W_a[0] - P_a(\eta) \longrightarrow W_*[\eta] \tag{38.9}$$

as a functional of test sources near $\eta = 0$. Here

$$\exp W_a[\eta_a] = \left\langle \exp\left[-a^D \sum_n \eta_a^I(n) A_a^I(n)\right]\right\rangle_a,$$
